garding extraglandular symptomatology. Upregulation of the type I IFN/BAFF axis may account for that. So far, rituximab has only provided modest therapeutic benefit, but it appears to be more efficacious in clinical manifestations in which vasculitis is thought to be the main mechanism of action (e.g., purpura, vasculitic neuropathy, cryoglobulinemia) as well as in LPD in the context of SS.

Belimumab, a monoclonal antibody against BAFF, was tested in a phase 2 RCT, showing improvement in disease activity, fatigue, and mucosal dryness symptomatology but no effect on objective measures of oral and ocular dryness. Belimumab response was found to associate with the number of natural killer cells in the blood and in the salivary glands as well as with type I IFN activity.

In phase 2 RCTs, abatacept has been shown to benefit SS patients in terms of improving disease activity scores, histopathology, and salivary flow. Two phase 3 placebo-controlled RCTs (NCT02915159, NCT02067910) are underway to test efficacy and safety of subcutaneous abatacept in SS. Lanalumab, a monoclonal antibody targeting B cells through BAFF receptor blockade and antibody-dependent cellular cytotoxicity, showed some beneficial effects in a recent study. In addition, molecules targeting the CD40/CD40L pathway are in the pipeline. In fact, a monoclonal antibody against CD40 (iscalimab) had favorable results, significantly improving disease activity and fatigue indices. Finally, RSLV-132, which is a RNase1 fused to the Fc region of IgG1, has been tested in a phase 2 RCT, with favorable results in disease activity and fatigue indices in pilot analysis.[29] A phase 3 RCT (NCT03247686) has finished recruitment, and results are awaited.

It is anticipated that in the next few years, data derived from ongoing RCTs will enhance our therapeutic armamentarium and the new knowledge acquired through multi-effort collaborations will allow the design of novel tailored treatment approaches.

ON THE HORIZON

1. Completion of ongoing randomized trials with biologic agents in Sjögren syndrome will hopefully expand our therapeutic armamentarium.
2. Multi-effort harmonization of clinical information along with implementation of high-throughput techniques will allow the identification of distinct pathogenetic mechanisms in different disease phenotypes.
3. Novel biomarkers for early diagnosis, prognostic classification, and response to different treatment modalities will be hopefully available.
4. Design of novel therapeutic trials targeting newly identified pathogenetic pathways will be feasible.

Scleroderma–Systemic Sclerosis

John Varga and Fredrick M. Wigley

Systemic sclerosis (SSc) is an acquired chronic multisystem disease characterized by autoimmunity and inflammation, widespread functional and structural abnormalities in small blood vessels, and progressive fibrosis of the skin and visceral organs. Multiple cell types and their products interact to mediate the pathogenic processes that underlie the diverse clinical manifestations of SSc.

PREVALENCE AND EPIDEMIOLOGY

SSc is a sporadic disease with worldwide distribution. Incidence estimates in the United States range from 9 to 19 cases per million per year, and prevalence rates range from 28 to 253 cases per million. Applying the revised American College of Rheumatology classification criteria, which are more sensitive for identifying early stage of SSc, the prevalence estimates are expected to be considerably higher.[1] Age, gender, and ancestry are important factors that determine disease susceptibility as well as outcomes.[2] Like other connective tissue diseases, SSc is more prevalent in women, with the most common age of onset in the range of 40 to 60 years. Disease onset tends to occur at a younger age among patients of African ancestry than among whites. Furthermore, African ancestry patients are more likely to have diffuse skin involvement, digital ulcers, pulmonary hypertension (PH), cardiac involvement, and pulmonary fibrosis, and have a worse prognosis.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of SSc involves dynamic interplay among inherited genetic risk factors, environmental exposures, and stable epigenetic modifications. SSc is a polygenic disease and is not inherited in a Mendelian fashion. Disease concordance rates among both monozygotic and dizygotic twins are relatively low (<5%). Nonetheless, family studies show that 1.6% of patients with SSc have a first-degree relative with the disease (relative risk of 13), indicating an important role for genetic background in SSc disease susceptibility. Indeed, certain human leukocyte antigen (HLA) haplotypes show striking associations with distinct SSc-specific autoantibody responses. Candidate genes shown to be associated with SSc include those implicated in interferon (IFN) signaling, T- and B-cell activation, DNA clearance, and innate immunity (Table 56.1). It is remarkable that a majority of these genes are involved in immune regulation, highlighting the potential importance of immune dysregulation in the pathogenesis of SSc.[3]

Environmental Factors

Although the etiology of SSc is unknown, microbial exposures and exposure to environmental and occupational agents, dietary factors, and drugs have been implicated as potential triggering factors. Evidence for a potentially pathogenic role for cytomegalovirus (CMV), Epstein-Barr virus (EBV), and parvovirus B19 infection or reactivation, as well as *Helicobacter pylori* infection, has been presented. Gut-microbial dysbiosis is prominent in SSc patients but its role in pathogenesis is uncertain. Several epidemic outbreaks of apparently novel multisystem illnesses with SSc-like features have been linked to environmental exposures, such as contaminated rapeseed cooking oils in Spain (the toxic oil syndrome) and gadolinium-associated nephrogenic fibrosis and L-tryptophan dietary supplements (eosinophilia–myalgia syndrome) in the United States.[4] The incidence of SSc is increased in males with occupational exposure to silica. Additional occupational exposures linked to increased risk of SSc include polyvinyl chloride, trichloroethylene, organic solvents, and heavy metals. Drugs linked to SSc-like illnesses include bleomycin, taxane, pentazocine, cocaine, and anorexigens associated with pulmonary artery hypertension. The apparent association of SSc with silicone breast implants initially raised alarm, but epidemiological investigations failed to substantiate an increased risk.[5]

Pathology

The hallmark pathological features of SSc are a noninflammatory obliterative microangiopathy in multiple vascular beds associated with fibrosis of the skin and internal organs. In early-stage disease, inflammatory cellular infiltrates may be prominent in many organs. Vascular injury is the earliest and possibly primary event in the pathogenesis of SSc. Patients show widespread vascular lesions characterized by bland intimal proliferation in the small and medium-sized arteries (Fig. 56.1). In late stages, a combination of perivascular adventitial fibrosis and generalized capillary rarefaction are prominent.

Fibrotic changes are widely distributed, but most prominent in skin, lungs, gastrointestinal (GI) tract, heart, tendon sheath, and perifascicular tissue surrounding skeletal muscle. Accumulation of collagen-rich connective tissue composed of fibulins; elastin; proteoglycans; matricellular proteins, such as tenascin-C and alternatively spliced fibronectin (EDA isoform); and other structural macromolecules in these organs causes distortion of tissue architecture, resulting in progressive functional impairment. Fibrosis of the skin causes dermal expansion with obliteration of hair follicles and sweat and sebaceous glands. Lungs show patchy infiltration with lymphocytes, plasma cells,

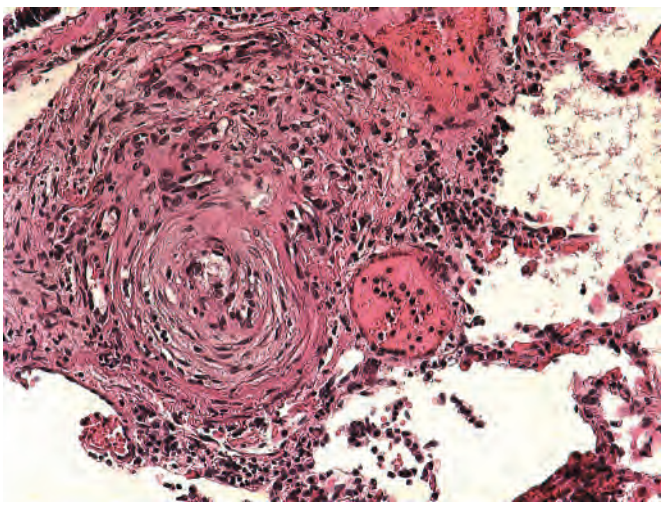

FIG. 56.1 Pulmonary Arterial Involvement. Significant intimal layer hyperplasia is seen, leading to narrowing of the vascular lumen. (Courtesy Dr. Anjana Yeldandi.)

macrophages, and eosinophils in early disease. In later stages, fibrosis and vascular damage predominate in the lungs, often coexisting in the same lesions. Intimal thickening of the pulmonary arteries, best seen with elastin stain, is a pathological hallmark of PH and at autopsy is often associated with multiple pulmonary emboli. Progressive thickening of the alveolar septae results in obliteration of the air spaces with a characteristic nonspecific interstitial pneumonia (NSIP) pattern and, less commonly, honeycombing (usual interstitial pneumonia, UIP), as well as loss of the pulmonary blood vessels. Pathological changes in the GI tract can occur at any level, from the mouth to the rectum. The esophagus shows atrophy of the lamina propria, submucosa, and muscular layers, with variable fibrosis. Replacement of the normal intestinal architecture results in disordered peristaltic activity, resulting in gastroesophageal reflux, small bowel dysmotility, and bacterial overgrowth. Chronic gastroesophageal reflux leads to esophageal inflammation, ulcerations, and stricture formation, and, in some cases, premalignant Barrett metaplasia.

The heart is frequently affected, with prominent myocardial contraction band necrosis, which reflects ischemia–reperfusion injury, and patchy areas of myocardial fibrosis. In the kidneys, vascular lesions predominate, and glomerulonephritis is rare. Scleroderma renal crisis (SRC) is an uncommon but often fulminant event associated with reduplication of elastic lamina, marked intimal proliferation, and narrowing of the lumen (onion skinning). Microangiopathic hemolysis may be accompanied by thrombocytopenia, making the differentiation from thrombotic thrombocytopenic purpura (TTP) challenging.

Pathogenesis

A comprehensive view of SSc pathogenesis must be capable of integrating the vasculopathy, immune dysregulation, and fibrosis of multiple organs, which are the hallmarks of the disease. As illustrated in Fig. 56.2, complex and dynamic interplay among these distinct pathomechanistic processes initiates, amplifies, and sustains tissue damage in SSc.[6] Animal models (Table 56.2) can be informative for delineating cell types, molecular mechanisms, and pathways contributing to SSc pathogenesis and for evaluating potential therapies.

Microangiopathy

Evidence of vascular involvement is an early, possibly initial, and widespread feature of SSc, and vascular damage in small and medium-sized vessels has major impact on the course of the disease. Vascular endothelial cell injury is initially associated with largely functional and potentially reversible alterations. Raynaud's phenomenon is characterized by abnormal blood flow response to vasomotor or cold challenge and altered production of, and responsiveness to, factors mediating vasodilatation (nitric oxide and prostacyclins) and vasoconstriction (endothelins). Microvessels show loss of pericyte coverage, increased permeability, enhanced transendothelial leukocyte migration, activation of fibrinolytic cascades, and platelet aggregation culminating in thrombosis. Endothelial–mesenchymal transition contributes to intimal and medial hypertrophy, which is coupled to fibrosis of the adventitial layers, resulting in vessel stiffening and luminal narrowing. Combined with endothelial cell apoptosis, the process culminates in the characteristically striking absence of small blood vessels seen on angiograms of the hands and kidneys in late-stage disease. Paradoxically, despite elevated circulating levels of angiogenic signals, including vascular endothelial growth factor (VEGF), reflecting pervasive tissue hypoxia, the process of revascularization appears to be defective in SSc.[7] Vascular injury in SSc is particularly prominent in the kidneys of patients with SRC, with evidence of endothelin-1 deposition and complement activation in the damaged small vessels.

Cellular and Humoral Immune Responses

In the early stages of SSc, activated T cells and monocytes/macrophages within lesional skin and the lungs secrete proinflammatory and profibrotic mediators, including transforming growth factor-β (TGF-β), cytokines, and chemokines. Because

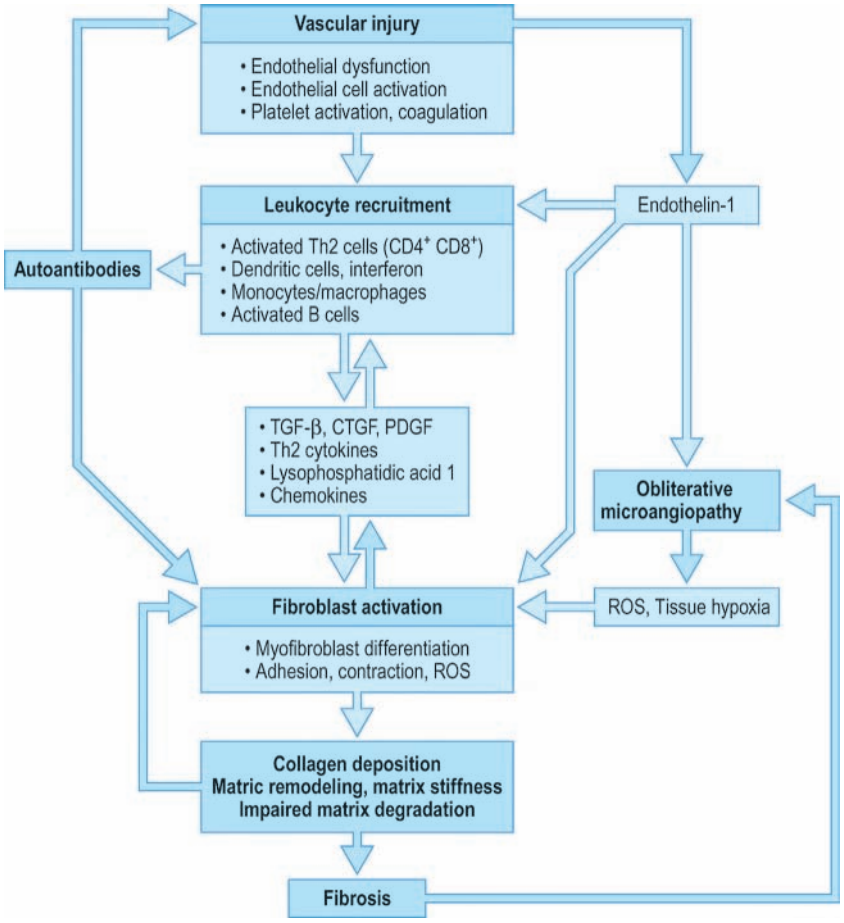

FIG. 56.2 **Pathogenesis of Systemic Sclerosis.** Interactions of cellular and molecular events triggered by injury that underlie the pathogenesis of vascular and immune dysfunction, culminating in fibrosis. *CTGF*, Connective tissue growth factor; *PDGF*, platelet-derived growth factor; *ROS*, reactive oxygen species; *TGF-β*, transforming growth factor-β.

TABLE 56.2 Selected Animal Models of Systemic Sclerosis

Animal Model	Fibrosis	Inflammation	Vascular	Affected Organ	Comment
Bleomycin (subcutaneous)	+	+	±	Skin, lungs	Fibrosis self-limited; localized
Graft-versus-host disease (GvHD)	+	+	–	Skin, lung, kidney	Complex procedure; radiation
Ang2-induced	+	+	+	Skin, lung	Skin localized
Fra2 tg	+	+	+	Skin, lung	Pulmonary hypertension (PH); early mortality
PDGFR tg	+	–	–	Multiorgan	
Wnt10b tg	+	–	–	Skin	Loss of dermal white adipose tissue (dWAT)
TSK1	+	–	–	Hypodermal lungs—emphysema	Fibrillin-1 mutation
TSK2	+	+	–	Skin	Collagen III mutation
Stiff skin syndrome	+	+	–	Skin	Fibrillin-1 mutation
Fli1-deleted	+	–	RVH	Skin, heart	
ROS	+	+	+	Skin, lung, kidney	Not widely used
Topo 1 immunization	+	+	–	Skin	Not well established
Chronic GvHD	+	+	±	Skin	Immune-driven

TGF-β, in particular, can induce its own production as well as that of other profibrotic paracrine mediators, such as connective tissue growth factor (CTGF) and platelet-derived growth factor (PDGF), an initial cytokine burst could result in amplified cytokine production and sustained autocrine and paracrine signaling. Additionally, as the extracellular matrix (ECM) of affected tissues undergoes fibrotic remodeling, it loses compliance and increases its stiffness. The mechanically altered microenvironment triggers biomechanical activation of resident stromal cells, both directly via the process of mechanotransduction and also by liberating latent matrix-bound TGF-β which then further amplifies the process. Alterations in the relative proportions and function of regulatory T cells (Treg) and T-helper 17 (Th17) cells, and innate lymphoid cells (ILCs) have been documented and may play important roles in pathogenesis. Single-cell RNA sequencing is generating a wealth of novel insights.

Virtually all patients with SSc have antinuclear and other autoantibodies in serum. Many of these autoantibodies are highly specific for SSc, associate with individual disease endophenotypes, and tend to be mutually exclusive (see below). Multiple mechanisms have been proposed to account for autoantibody generation in SSc.[8] A remarkable link between antibodies against RNA polymerase III and contemporaneous cancer has been noted, suggesting that some forms of SSc might represent a paraneoplastic syndrome. Although SSc-associated autoantibodies have well-documented clinical utility as diagnostic and prognostic disease markers, their direct pathogenic role in SSc remains uncertain.[9] Many patients with SSc have functional autoantibodies directed against fibroblasts and endothelial cells; the PDGF receptor; vascular cell receptors, such as endothelin-1 and angiotensin II receptors; and matrix metalloproteinases (MMPs). The pathogenic contribution of these potentially damaging autoantibodies is an area of intense investigation.

Fibrosis: Cellular and Molecular Components

Interstitial and vascular fibrosis, the hallmarks of SSc, are characterized by replacement of normal tissue architecture with dense and noncompliant connective tissue. Although restricted organ fibrosis is a very common sequel to any form of chronic or recurrent tissue injury, fibrosis synchronously affecting multiple organs is unique to SSc. Fibroblasts and related stromal cells of mesenchymal origin are key effector cells responsible for the development of fibrosis. Under physiological conditions, the fibroblast repair program is tightly regulated to enable optimal tissue regeneration, whereas under pathological conditions, fibroblast activation is sustained and amplified, resulting in exaggerated matrix deposition, disruption of tissue architecture, and failure of affected organs. Fibroblasts explanted from lesional SSc tissues display a variably abnormal phenotype when propagated ex vivo, with enhanced synthesis of collagen and other ECM molecules, expression of α smooth muscle actin and stress fiber formation, and spontaneous generation of reactive oxygen species (ROS). The persistent activated scleroderma phenotype reflects epigenetic modifications caused by chromatin remodeling, DNA methylation, or altered expression of noncoding regulatory microRNA and long RNAs.

The pleiotropic cytokine TGF-β is a pivotal regulator of both tissue repair and fibrosis (Chapter 9). Multiple abnormalities in TGF-β pathways have been identified in SSc, indicating a key role in pathogenesis.[10] Therapies that selectively or nonselectively block growth factor signaling triggered by growth factors, chemokines, PDGF, Wnt, and CTGF have shown some efficacy in both preclinical models and in human trials, and others are currently in clinical development.

CLINICAL FEATURES

Overview

The term *scleroderma* refers to systemic sclerosis, while *morphea*, also called *localized scleroderma*, denotes a disorder generally limited to skin or underlying tissue. SSc is highly variable in its clinical expression with subsets of patients that have unique clinical features and distinct clinical outcomes. Patients present with a seemingly common pathological disease process that can target skin, blood vessels, and the lungs, heart, GI tract, kidneys, and musculoskeletal system. Raynaud phenomenon is virtually universal in SSc, suggesting that perturbation of the terminal arteries of the circulation is a fundamental process that is common to the different subsets of the disease. Thickening of the skin distinguishes SSc from other rheumatic diseases (Table 56.3); scleroderma (hard skin) is the most specific and prominent physical finding. A small number of patients develop systemic features of SSc without appreciable skin involvement, a phenotype that is termed *systemic sclerosis sine scleroderma*. While traditionally patients are classified by the degree of clinically involved skin into two major subtypes (diffuse [dcSSc] or limited [lcSSc]), it is now recognized that the disease course and the ultimate specific organ outcome can be better predicted by a classification using a composite score encompassing the degree of skin involvement, autoantibodies, and the degree of presenting organ disease. Predictors of elevated mortality rates among patients with SSc include diffuse skin disease with a rapid rate of skin progression and internal organ involvement (especially the lungs or the kidneys, resulting in an SRC), male gender, black race, presence of malignancy, and later age of disease onset.[11,12] In some patients with SSc who have "overlap" features, SSc coexists with clinical and laboratory evidence of another autoimmune disease, such as polymyositis, autoimmune thyroid disease, Sjögren syndrome, polyarthritis, autoimmune liver disease, or systemic lupus erythematosus (SLE) (Table 56.4).

TABLE 56.3 Classification of Systemic Sclerosis

Diffuse cutaneous scleroderma—skin thickening on the trunk in addition to the face, proximal and distal extremities
Limited cutaneous scleroderma—skin thickening limited distal to the elbow and knee; may also involve the face and neck
CREST syndrome—subcutaneous *c*alcinosis; *R*aynaud phenomenon; *e*sophageal dysmotility; *s*clerodactyly; *t*elangiectasia (term no longer used)
Sine scleroderma—systemic sclerosis with no apparent skin thickening but characteristic visceral organ involvement, vascular and serological features
Overlap syndrome—criteria for systemic sclerosis (SSc), coexisting with features of systemic lupus erythematosus, rheumatoid arthritis, or inflammatory muscle disease
Mixed connective tissue disease—overlap syndrome with anti-U1 ribonucleoprotein (RNP) antibodies
Early disease—Raynaud phenomenon (RP) with puffy fingers and other clinical and/or laboratory features of SSc; specific autoantibodies, abnormal nailfold capillaroscopy, finger edema, and ischemic injury (also called very early diagnosis of systemic sclerosis, VEDOSS)

Morphea

Morphea (localized scleroderma) is now properly used to describe a group of patients with disease generally limited to fibrosing skin disorders that occurs with similar frequency in both children and adults (Table 56.5). Unlike scleroderma, in morphea internal organ involvement is unusual. Subtypes of morphea exist including circumscribed or plaques that can occur as solitary or multiple lesions (generalized morphea), linear lesions, pansclerotic, or mixed forms. Linear morphea can occur on the head, leaving severe facial deformity. When this occurs in the upper forehead, it is called *en coup de sabre*. This should be distinguished from *Parry-Romberg syndrome*, or *facial hemiatrophy*, which also affects the face, usually unilaterally, with atrophy of skin rather than fibrosis. Both en coup de sabre and Parry-Romberg syndrome can be associated with central nervous system (CNS) involvement, presenting as headaches, visual disturbance, or a seizure disorder.

TABLE 56.4 Frequency and Clinical Correlations of Systemic Sclerosis Autoantibodies

	% Frequency in SSc	Disease Subtype	Clinical Associations	Prognosis
Anticentromere	20–38	lcSSc	Pulmonary arterial hypertension	Better prognosis
Anti-topoisomerase I	15–42	dcSSc	Pulmonary fibrosis Heart involvement	Worse prognosis
Anti-RNA polymerase III	5–31	dcSSc	Renal crisis Tendon friction rubs, synovitis, myositis, joint contractures. Increased risk of cancer	Increased mortality
Anti-U3 RNP (fibrillarin)	4–10	dcSSc	Renal crisis and cardiac involvement	Poor prognosis, especially in African Americans
Anti-Th/To	1–13	lcSSc	Pulmonary fibrosis and renal crisis	Poor prognosis
Anti-U11/U12 RNP	3.2	—	RP Gastrointestinal involvement Lung fibrosis	Increased mortality
Anti-U1 RNP	2–14	lcSSc	RP, puffy fingers, arthritis, myositis, overlap syndrome (*i.e.*, MCTD)	Better prognosis
Anti-PM-Scl	4–11	Overlap with polymyositis lcSSc	RP, arthritis, myositis pulmonary involvement, calcinosis, and sicca symptoms	Better prognosis
Anti-Ku	2–4	—	Myositis, arthritis, and joint contractures	—
Anti-hUBF (NOR 90)	<5	lcSSc	Mild internal organ involvement	Better prognosis
Anti-Ro52/TRIM21	15–20	Association with other autoimmune diseases	Older age onset, pulmonary fibrosis	—

KEY CONCEPTS

Clinical Patterns of Systemic Sclerosis

Limited Cutaneous Scleroderma (lcSSc)
- Skin thickening limited to distal limbs or fingers alone (sclerodactyly)
- Increase matted telangiectasia and subcutaneous calcinosis
- Severe Raynaud phenomenon with digital ischemia
- Risk of pulmonary arterial hypertension
- Other autoimmune diseases (hypothyroid, primary biliary cholangitis, Sjögren syndrome)

Diffuse Cutaneous Scleroderma (dcSSc)
- Even skin thickening proximal limbs (upper arms, chest, abdomen)
- Increased risk of internal organ disease (ILD, SRC, heart, GI)
- Rapid disease onset
- Intense fatigue, weight loss, pruritus, arthritis, contractures
- Tendon friction rubs
- Myopathy

Systemic Sclerosis Sine Scleroderma
- No skin thickening
- Raynaud phenomenon or typical peripheral vascular disease
- One or more typical scleroderma visceral disease
- Autoantibodies

Morphea
- Localized scleroderma
- Lack of systemic disease

GI, gastrointestinal; *ILD*, interstitial lung disease; *SRC*, scleroderma renal crisis.

TABLE 56.5 Classification of Localized Scleroderma

- Plaque types of (morphea)
- Circumscribed plaques
- Guttate
- Keloid/nodular
- Bullous
- Generalized morphea
- Three or more locations
- Pansclerotic morphea
- Linear scleroderma
- Frontoparietal linear morphea (*en coup de sabre*)
- Parry-Romberg syndrome (progressive hemifacial atrophy)
- Linear streaks on limbs or trunk
- Deep morphea

Symptoms

Characteristically, the earliest symptoms of SSc are nonspecific and include fatigue, musculoskeletal distress (stiffness or pain), and feeling ill. Cold sensitivity with associated Raynaud's phenomenon is often the only early clinical clue to the presence of disease. Symptoms of esophageal dysfunction with dysphagia, heartburn, and periodic GI reflux, along with Raynaud's phenomenon, can precede other manifestations of SSc by years. In general, patients with dcSSc have a short interval between the onset of Raynaud's phenomenon and other signs and symptoms. Soft tissue swelling, intense pruritus and burning, and pitting edema on the limbs are signs of the early inflammatory or "edematous" phase of the diffuse cutaneous form of the disease. The skin of the fingers, hands, distal limbs, and face are usually affected first and more severely compared with other body areas (Fig. 56.3). Patients may note skin hyperpigmentation (patches or generalized tanning). Other early skin changes include vitiligo-like hypopigmentation ("salt and pepper" appearance), often along the scalp, dorsum of the hand, on the chest, or the back (Fig. 56.4). Escalating musculoskeletal symptoms are common and are associated with muscle weakness and decreased joint mobility.

CLINICAL PEARLS

Clinical Features of Early Systemic Sclerosis

- Definite Raynaud phenomenon
- Gastroesophageal reflux with heartburn
- Swelling of the fingers and hands
- Musculoskeletal pain and stiffness
- Dilated nailfold capillaries
- Hyper- or hypopigmentary changes of skin

FIG. 56.3 Skin Fibrosis in Systemic Sclerosis. Severe fibrosis of the skin of the hands and forearms causing joint contractures and skin ulcerations in a woman with diffuse cutaneous systemic sclerosis.

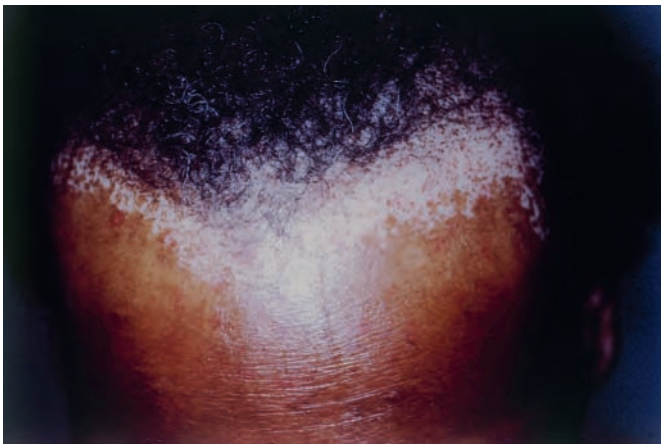

FIG. 56.4 Pigmentation Changes in the Skin. Vitiligo (salt-and-pepper) appearance of the involved skin in a patient of African descent with diffuse cutaneous systemic sclerosis.

Clinical Course

The early edematous phase of dcSSc has prominent inflammatory features, with significant skin edema and erythema, and is associated with inflammatory cell infiltration in the dermis. After a period of weeks to months, the inflammatory phase fades and the "fibrotic" phase dominates with increased collagen and extracellular material deposited causing thickening of the skin and loss of flexibility. The fibrotic process starts in the dermis and is associated with loss of body hair, reduced production of skin oils, and a decline in sweating capacity as these cutaneous structures atrophy. Gradually, the subcutaneous tissue becomes affected, with atrophy of subcutaneous fat and fibrosis extending to the underlying fascia, muscle, and other soft tissue structures. Progressive flexion contractures of the finger and other joints ensue (Fig. 56.5). Tendon friction rub is a prominent crepitation that can be felt or even heard over tendons of the lower and upper extremities. Tendon friction rubs are caused by fibrosis in the tissues surrounding the affected joints; they are associated with rapidly progressive skin disease and are linked to an overall poor prognosis.

While the degree of skin involvement is highly variable, the natural history of skin disease in dcSSc tends to be monophasic,

FIG. 56.5 Traumatic Digital Ulcer. Ulceration of atrophic skin over the metacarpal joint of patient with diffuse scleroderma.

and relapse is uncommon after the edematous and active fibrotic phase.[13] The duration of active skin disease from the first signs of skin involvement to its maximal extent is characteristically about 18 months; cutaneous inflammation and progressive fibrosis gradually subside, and regression of skin involvement begins. In the late stages of dcSSc, skin remodeling can be dramatic, with return to normal-appearing skin in those areas spared from severe end-stage fibrosis. Skin ulcerations or dystrophic calcification often are late disease complications of the fibrotic, atrophic, and avascular skin (see Fig. 56.5). Although the skin involvement is generally the most dramatic and visible manifestation of dcSSc, internal organ involvement occurs during the early active stage of advancing skin disease. Patients with dcSSc have a significant risk for interstitial lung disease (ILD), severe GI dysfunction, SRC, progressive heart disease, and recurrent digital ulcers during the initial active inflammatory and fibrotic phases of the skin disease. In practical terms, this means that in dcSSc, the initial 3 to 4 years is the period that the systemic process is most active; if organ failure does not occur during this period, the systemic process may stabilize without further progression.

In contrast to dcSSc, the disease course in the limited cutaneous (lcSSc) variant of SSc is more indolent and often relatively benign. After the onset of Raynaud phenomenon, several years may pass before additional symptoms or signs are recognized. The most common non-Raynaud's symptoms in patients with lcSSc are those of upper GI disease with dysphagia and gastroesophageal reflux. Dilated venules form visible erythematous vascular lesions *(telangiectasia)* early in the disease, seen most commonly on the fingertips, palms, face, lips, and inside the oral cavity (Fig. 56.6). Subcutaneous calcinosis caused by deposition of calcium hydroxyapatite crystals occurs commonly at sites of tissue ischemia and recurrent trauma, such as the fingertips, forearm, or elbow. Severe Raynaud's phenomenon with macrovascular occlusive involvement occurs more frequently in lcSSc than in dcSSc and can be associated with critical digital ischemia, ischemic ulcerations, gangrene, and amputation.

In both dcSSc and lcSSc, visible capillary abnormalities easily seen at the nailfold (dilatation and loss or dropout of capillaries) are near universal. An individual presenting with Raynaud's phenomenon, abnormal nailfold capillaries, puffy fingers, and the presence of an SSc-specific autoantibody can be suspected of having SSc even before other more obvious manifestations are noted.[14]

FIG. 56.6 Telangiectasia. Characteristic telangiectasia on the lip in a woman with limited cutaneous systemic sclerosis.

Raynaud's Phenomenon

Raynaud's phenomenon (RP) is clinically defined as well-demarcated color changes of the digits induced by cold or emotional stress.[15] Vascular constriction of arterio-venous anastomoses (AVAs), arterioles, and small arteries in the skin and tissues of the digits causes the pallor of the digits, the phase of complete loss of blood flow. The initial vasospasm and pallor is followed by cyanosis of the skin caused by venous pooling and low flow with deoxygenated blood. Finally, after rewarming, the recovery phase occurs with vasodilation manifested by hyperemia with blushed reddened skin as blood flow rebounds. Raynaud's phenomenon is common, affecting 3% to 5% of the general population and about 10% to 15% of selected populations (e.g., cold geographic environments). Raynaud's phenomenon is considered to be *primary RP* when there is no other associated disease state. In these cases, it is thought to represent a genetic trait with young age of onset of cold sensitivity as a result of abnormal cutaneous vessel reactivity to environmental temperatures. The underlying defect in primary RP is generally considered to be a *local fault* in the thermoregulatory vessels with a change in functional activity of the vasculature without evidence of structural alteration or injury to vessels. There is evidence that this local fault is due to enhanced sympathetic responses via increased α_2-adrenergic receptor activity on the smooth muscle cells of the involved AVAs in patients with Raynaud's phenomenon.[16]

In contrast, *secondary RP* are a variety of acquired conditions including those that cause vascular injury and can be associated with structural deterioration and/or loss of the cutaneous vessels including the nutritional microvasculature. In SSc, the disease process targets the peripheral vasculature, including AVAs or thermoregulatory blood vessels. This leads to not only the abnormal reactivity to ambient temperatures typical of Raynaud's phenomenon but also significant structural disease of blood vessels, which causes tissue ischemia as a result of compromise to blood flow within capillaries or nutritional vessels. As a consequence of both an exaggerated response to cold and structural vascular disease, patients with SSc have severe Raynaud's phenomenon with multiple, and often prolonged, daily episodes. The severe vascular disease can lead to critical ischemia with digital ulcerations or deep tissue infarction and gangrene. The vascular disease in SSc is not limited to skin but is systemic. There is evidence that abnormal vascular reactivity resulting in tissue injury occurs in the pulmonary, renal, GI, and coronary circulations.

Treatment of Raynaud's phenomenon must be individualized and adjusted according to its severity. Initial therapy should include avoidance of cold exposure and use of methods of reducing sympathetic tone such as reducing emotional stress. Many patients with primary RP do well with non-drug therapy alone. The best studied medications to treat Raynaud's phenomenon are the calcium channel blockers and they are the recommended first choice of therapy. Currently, phosphodiesterase inhibitors such as sildenafil are considered a second-line option with or without a calcium channel blocker. Evidence for use of other agents is weak.

Gastrointestinal Involvement

GI disease is a major cause of morbidity and mortality and accounts for one of the most frequent initial symptoms of scleroderma.[17] Every part of the GI tract can be involved, including the oral pharynx, esophagus, stomach, and the small and large bowels. Almost all patients with SSc demonstrate evidence of distal esophageal dysfunction. Clinically, this presents with dysphagia, heartburn, and regurgitation typical of gastroesophageal reflux disease (GERD). These symptoms are caused by peristaltic dysfunction of the distal esophagus, decreased lower esophageal sphincter (LES) pressure, and delayed gastric emptying, which is thought to be secondary to autonomic dysfunction. Pathological studies of the esophagus show that the smooth muscle (circular greater than longitudinal) of the bowel atrophies without significant fibrosis, vascular injury, or obvious inflammation. Functional and pharmacological studies have shown that a neurogenic process precedes smooth muscle dysfunction. Autoantibodies directed against enteric neurons and anti-muscarinic antibodies are found, suggesting that the initial insult is an immune process targeting neurological mechanisms of normal GI motility.

Early satiety, bloating, nausea, periodic vomiting, and decreased appetite with weight loss can occur secondary to poor gastric emptying (gastroparesis). Gastroparesis is commonly associated with retention of food and liquids in the stomach and esophageal dysfunction thus aggravating GERD. Mild to severe intestinal dysmotility can involve either or both the small and large bowels. Patients may note a change in bowel habits with episodes of either diarrhea from small disease or periods of constipation due to decreased transit in the large bowel. Persistent diarrhea with bloating and pain may be a manifestation of malabsorption of fats as an atonic and small intestinal bacterial overgrowth (SIBO); untreated this can be associated with dramatic weight loss and malnutrition. In severe cases bowel dysmotility episodes of pseudo-obstruction involving either the small or large bowel presents with severe abdominal pain, bloating, abdominal distension, and vomiting.

Treatment of the scleroderma bowel involvement is focused on conventional methods of managing GI dysmotility in that there is no solid evidence that disease-modifying therapy such as immunosuppression alters the GI disease process. GERD can be managed with careful eating habits, attention to body position after eating, blocking acid production with an H_2 blocker or a proton pump inhibitor, and in some cases the use of a pro-kinetic drug to help esophageal emptying (e.g., metoclopramide, domperidone). Constipation is treated with appropriate fiber intake, a stool softener, or agents to assist bowel movement (e.g., polyethylene glycol, linaclotide, or prucalopride), while SIBO

and diarrhea respond to dietary changes (e.g., FODMAP diet) and intermittent antibiotic therapy. Severe disease with pseudo-obstruction requires periods of bowel rest and total parenteral nutrition (TPN).

Pulmonary Involvement

Lung disease accounts for significant lifetime morbidity and is now the leading cause of death in patients with SSc. A survey of all-cause mortality reported that 35% of all SSc-related deaths were directly attributable to interstitial lung disease SSc-related ILD (SSc-ILD), and 26% of deaths resulted from pulmonary arterial hypertension (PAH) or PH with secondary heart disease. Another survey reported a high risk of mortality from ILD (hazard ratio [HR] 3.70); PAH identified on transthoracic echocardiography (TTE) (HR 7.49), and a diffusing capacity for carbon monoxide (DLCO) of less than 60% of the predicted value (HR 3.17).[18] Emerging pulmonary vascular disease leads to PAH in about 10–15% of patients with scleroderma.

Interstitial Lung Disease

While ILD is the leading cause of mortality, the clinical course is highly variable without progressive disease in the majority. NSIP is the most common histopathological pattern in patients with SSc-ILD. Inflammatory alveolitis and subsequent tissue fibrosis causes a functional restrictive ventilatory defect and an abnormal gas exchange. In early disease, SSc-ILD is often asymptomatic, detected in over 40% by either lung function or high-resolution CT scan imaging (HRCT). The presence of fibrosis and ground-glass opacities on HRCT is an indication of the activity of the disease process and correlates with subsequent decline in forced vital capacity (FVC). Aggressive life-threatening disease occurs in a subgroup of patients (10% to 20%) and is measured by a progressive fall in FVC usually within 4 years of the onset of scleroderma. It is a good prognosis if there is only minor impairment in FVC on lung function on first encounter, but a FVC of less than 70% of predicted is associated with a poor prognosis. Likewise, when the extent of disease defined by HRCT is less than 20%, the 10-year survival is reported to be 67%, whereas in the group with HRCT-defined disease extent of greater than 20%, 10-year survival is considerably poorer at 43%.[26] There are clinical features and biological biomarkers that can predict the course of ILD. The prevalence of SSc-ILD is found in 50% of those with dcSSc compared with 35% in those with lcSSc. The presence of topoisomerase-I, U3RNP, or Th/To autoantibodies are strongly linked to risk of developing SSc-ILD, and the worst outcome is often seen in African Americans and Native Americans.[27] Two multicenter clinical trials give evidence that immunosuppressive therapy can control active SSc-ILD; one compared cyclophosphamide to placebo, and the other compared cyclophosphamide to mycophenolate. Both studies demonstrated statistically significant stabilization or improvement of lung function with equivalent benefit for both agents. Nintedanib (a tyrosine kinase inhibitor) with antifibrotic properties is now FDA approved for treatment of early active SSc-ILD. Other agents are being tested in SSc-ILD, including rituximab (monoclonal antibody [mAb] to CD20 on B lymphocytes) and pirfenidone (an antifibrotic/anti-inflammatory agent used in idiopathic pulmonary fibrosis).

Pulmonary Hypertension

PH can occur in scleroderma secondary to isolated pulmonary vascular disease (PAH), in association with SSc-ILD and hypoxia or secondary to cardiac disease. Therefore, patients need to undergo a right heart cauterization (RHC) to confirm the presence of PAH or PH and to characterize its severity. PAH is now defined by RHC showing a mean pulmonary artery pressure (mPAP) greater than 20 mm Hg and a pulmonary capillary wedge pressure ≤15 mm Hg with pulmonary vascular resistance (PVR) ≥3 Wood without evidence of significant pulmonary parenchymal disease. PAH is detected by RHC in 8% to 15% of patients. The natural history of PAH is highly variable; in the majority it is clinically silent for years (9 to 12 years after the onset of disease) before it presents with exertional dyspnea and hypoxia secondary to altered gas exchange and right heart failure. PAH can also occur within 5 years from the disease onset, particularly in patients with anti-U3 RNP (fibrillarin) antibodies. Risk factors for developing SSc-PAH include disease onset at a later age, history of severe RP, numerous skin telangiectasias, abnormal nailfold capillaries, and the presence of anti-centromere, anti-U1 ribonucleoprotein (RNP), anti–U3 RNP, or anti-B23 antibodies. Early detection and intervention with combination therapy has improved survival with now a 3-year survival reported to be 56% to 75%. Current therapy for SSc-associated PAH is focused on supportive care, reduction of cardiac workload, and vasoactive drugs.[19] Treatment regimens include four classes of medications which are prostacyclin analogs, endothelin-receptor antagonists, phosphodiesterase-5 inhibitors, and guanylate cyclase stimulators. In relatively short-term clinical trials, each of these treatments has been shown to improve exercise tolerance and hemodynamics, with variable benefit on disease progression. Early intervention and combination therapy help to achieve improved survival outcomes. Lung transplantation remains an option for carefully selected patients with SSc, with survival following lung transplantation being similar to that of non-SSc patients with other lung diseases.

Cardiac Involvement

Cardiac involvement is common, but often there are no signs or symptoms until the heart has been severely affected. Clinical criteria are insensitive, but modern sensitive tools, such as echocardiography, tissue Doppler imaging, Holter monitoring, speckle-tracking echocardiography, cardiac magnetic resonance imaging, or thallium scanning, can detect disease early and suggest that 40% to 60% of patients have heart disease. When heart disease is symptomatic, the prognosis is poor with primary heart disease accounting for 15% to 30% of all SSc deaths. SSc can affect virtually any cardiac structure, including the myocardium with fibrosis or inflammatory myocarditis, the myocardial microvasculature, or the pericardium with asymptomatic small effusions or large effusions leading to cardiac tamponade. As a consequence of cardiac tissue injury, left ventricular (LV) systolic dysfunction and/or LV diastolic dysfunction and/or right ventricular (RV) failure can occur and conduction abnormalities with arrhythmias are common, but valvular heart disease is unusual. Myocardial fibrosis is thought a consequence of vasospasm of coronary arterial microcirculation, cardiomyocyte injury, and fibroblast proliferation. Involvement of a larger vessel causing coronary artery disease is not established. Cardiac disease occurs in both the limited and the diffuse subtypes but is more common in the patients with rapidly progressive diffuse skin disease, in those with anti-SCL70, anti-U3 RNP, anti-KU, or anti-Th/To antibodies, and in association with peripheral muscle disease. The ideal therapy is defined by the underlying situation (e.g., vasodilator therapy to improve heart perfusion

or anti-arrhythmia therapy for a complex arrhythmia). A disease-modifying drug that specifically targets scleroderma heart disease has not yet been discovered.

Renal Involvement

Renal disease is an important clinical problem with both direct involvement and compromise to kidney function secondary to other organ dysfunction. The most dreaded renal complication is a SRC, which affects approximately 11% of dcSSc and 4% of lcSSc subjects. A SRC classically presents with the new onset of accelerated arterial hypertension and rapidly progressive oliguric renal insufficiency, but more modest elevations in blood pressure and normotensive events can occur due to the same underlying pathology. Other causes of renal disease can occur in SSc, including interstitial nephritis, glomerulonephritis, and anti-neutrophil cytoplasmic antibody (ANCA)–associated vasculitis, which can be confused with an SRC. The exact mechanism triggering acute SRC is not known, but an autoimmune insult to the underlying SSc microvascular disease is thought to initiate a self-perpetuating process leading to intimal thickening and vascular occlusion, glomerular hypoperfusion, and a high renin state. SRC generally develops relatively early (<3 to 4 years) in the disease; in patients with rapid progression of diffuse skin disease who have anti-RNA polymerase III antibodies (about 30%) or anti-topoisomerase (about 10%); the risk is low in patients with anti-centromere antibodies. Patients with SRC who present with a creatinine greater than 3 mg/dL have a poor outcome, with increased likelihood of permanent hemodialysis, need for renal transplantation, and/or high mortality. Prompt and aggressive intervention with angiotensin-converting enzyme (ACE) inhibitors to achieve blood pressure control before evidence of renal dysfunction significantly improves the prognosis; since the introduction of ACE inhibitors survival from SRC has dramatically improved from a 1-year survival rate of 10% to a 5-year survival rate of 60%.[20] About 30% to 45% of patients whose blood pressure is normalized do not require dialysis, but despite ideal therapy, approximately 40% of patients with SSc still need long-term kidney support or have a poor survival. In a subset of patients, reasonable kidney function can resume months after renal failure and they no longer need dialysis support. Renal transplantation is still an option, with a long-term outcome similar to that of other causes of renal failure.

Musculoskeletal Complications

Musculoskeletal impairment is a leading cause of disability and poor quality of life among patients with SSc. It is seen in the majority of patients, occurs early in the disease, and commonly has a dominant effect on hand function. There is a variety of associated clinical symptoms, including arthralgias, myalgias, stiffness, pain and loss of function as a result of joint contractures, inflammatory arthritis, myopathy, nerve entrapment (e.g., carpal tunnel syndrome), fibrosis of tendons, and deconditioning from disuse. Loss of joint function is less likely to be secondary to synovitis but is usually caused by fibrosis of the overlying skin, the supporting joint structures, and the joint capsule itself. Flexion contractures associated with "friction rubs" most prominently felt over the ankles, knees, shoulders, and wrist are typical of advanced dcSSc. Muscle weakness is a common comorbid condition caused by deconditioning, muscle disuse, or malnutrition associated with weight loss. Most patients with skeletal myopathy have proximal muscle weakness on examination, and about 40% have one of the scleroderma/myopathy–associated autoantibodies (*i.e.*, anti-PM/Scl-75, anti-PM/Scl-100, anti-CD1 or anti-Ku). While the predominant features on muscle biopsies of the weak scleroderma patient are necrosis and inflammation, there is a wide range of histopathological features consistent with overlap polymyositis, dermatomyositis, necrotizing myopathy, and fibrosis alone. The small subset of SSc patients with a fibrosing myopathy alone tends to be of the diffuse skin subtype, African American race, have lower FVC, and have shorter disease duration.[21,22] When inflammation and/or necrosis are seen, immunosuppressive therapy has the potential to control the muscle disease.

Emotional Aspects

Scleroderma is a chronic disfiguring disease that can affect every aspect of a patient's life including employment, performance in the family, social interactions, and sexually. Fear, anxiety, and depression are coupled with functional disability, chronic pain, sleep disturbance, fatigue, and a poor view of appearance and body image. A major depressive disorder is a common consequence that may fluctuate in severity and have an unrecognized major negative impact on quality of life. The emotional aspects of the disease need to be addressed by both medical intervention and management of the psychological aspects of living with the disease.

Approach to Treatment

CLINICAL PEARLS

Recommended Approach to Systemic Sclerosis

- Determine scleroderma skin score to define clinical subtype
- Frequent clinical reassessment to define disease activity and emotional impact
- Careful clinical history to evaluate for gastrointestinal dysmotility
- Monitor for new-onset hypertension: prevent renal crisis
- Pulmonary function test: early detection of interstitial lung disease
- Doppler echocardiography: screen for pulmonary arterial hypertension
- Obtain serology profile to help predict clinical outcome

The clinical and biological evidence support the concept that SSc occurs in a genetically susceptible host, and that the disease process is initiated by a yet unidentified factor (e.g., cancer or environmental factor) that provokes autoimmunity with secondary inflammation, vascular injury, and, unlike other autoimmune diseases, progressive tissue fibrosis. The spectrum of the disease is highly variable with distinct clinical phenotypes ranging from rapid diffuse skin disease with serious internal organ involvement to a mild course with minimal skin fibrosis and overall good outcome. The natural course of the disease also varies in an individual patient. Inflammation occurs early in the acute phase, with signs of vascular perturbation (e.g., RP), followed by rapid tissue fibrosis and then later an indolent phase with skin remodeling with or without progressive internal organ disease. The management must target the specific situation, level of disease activity, and specific organ dysfunction. Most success occurs in treating specific organ involvement (e.g., ACE inhibitor for SRC) as outlined in the above text. Intervention with currently available drugs should be initiated early, ideally during the edematous active inflammatory phase of the disease. It is during the early stage of the disease that any disease modifying agent has the greatest potential to control disease-progression. The primary outcome measure in most clinical

trials has focused on aggressive skin disease as measured by the modified Rodnan skin score; in current studies, however, composite scores that tally the burden of disease (activity and severity) as well as patient-reported distress are included. While no disease-modifying agent is fully established, attempts to control the scleroderma disease process can be divided into immunotherapy, treatment of fibrosis, and medications directed at the vascular disease process.[6,23]

Immunotherapy

Nonselective immunotherapy is the most popular approach (methotrexate, cyclophosphamide, azathioprine, mycophenolate, intravenous immunoglobulin) used to control active skin disease, ILD, inflammatory muscle or joint disease, while few studies have supported the use of selective immunotherapy (anti-thymocyte globulin, cyclosporin A, sirolimus). Biological agents have been used to target inflammatory cytokines (anti-TNF, Il-6, IL-1) or T-cell activation (abatacept) or B-cell populations (rituximab). For patients with severe disease or who are failing low-dose immunotherapy, cell-based immunotherapy using autologous hematopoietic stem cell transplantation following myeloablation or non-myeloablative therapy has shown promise.[24,25]

Treatment of Fibrosis

While there are several agents under investigation, there is no clear evidence of an agent that directly suppresses activated tissue fibroblasts. Strategy to alter fibroblast to myofibroblast or epithelial–mesenchymal transition, shortening fibroblast survival or affecting fibroblast interactions with ECM via blocking cellular integrins are all under investigation. Antagonists of the bioactive phospholipid lysophosphatidic acid (LPA), agonist for the cannabinoid receptor (CB2) and small molecules that inhibit tyrosine kinase (imatinib) and downstream growth factors are being studied. Nintedanib has shown promise in a clinical trial demonstrating a reduction in the rate of decline of lung function in patients with SSc-ILD.[18] Pirfenidone, another antifibrotic agent, is being tested in a clinical trial for treating SSc-ILD.

Treatment of Vascular Disease

Although nonspecific vasodilation therapy (see Reynaud Phenomenon and Pulmonary Hypertension sections) is the main approach to the vascular disease, it is recognized that vascular injury is a major process that needs attention. Targeting the vascular disease process is attempted by the use of endothelin receptor antagonists, prostaglandin therapy, inhibiting platelet activation, statins, enhancing nitric oxide (phosphodiesterase inhibitors), and immunotherapy.

Treatment

It is important to carefully characterize the patient's clinical phenotype, specific organ involvement, and level of disease activity before deciding on therapy. It is also important to distinguish disease activity from disease severity or advanced cumulative organ damage. For example, a patient with late-stage dcSSc with irreversible organ damage is unlikely to benefit from aggressive immunosuppressive or antiinflammatory therapy. It is during the early edematous stage of the disease that immunosuppression and antiinflammatory and antifibrotic agents have the greatest potential to control disease progression. Clinical experience teaches that once the edematous phase of the disease shifts to the more indolent fibrotic phase, current treatments are less likely to control the progression of disease and tissue damage. Few well-designed controlled studies have been carried out for the treatment of early active disease; most reports are of anecdotal, uncontrolled experiences, complicated by investigator bias and the highly variable natural course of SSc.

Scleroderma is a multifaceted disease that includes active autoimmunity, vascular injury, and fibrosis and/or epithelial damage. Thus, the major targets for therapy include regulating the immune system, controlling tissue fibrosis, and protection or prevention of progressive vascular disease. Drugs currently used for dcSSc include methotrexate, cyclophosphamide, and mycophenolate mofetil. Targeting specific immune cells is now a novel strategy that includes eliminating B cells with rituximab and suppressing activation of T cells with abatacept. Inhibiting proinflammatory and/or profibrotic cytokines or signaling pathways that may block tissue injury and fibrosis are being explored. These include anti-chemokines (CCR2) or inhibitors of CTGFs, recombinant humanized mAb to block TGF-β_1 activity, modulation of interleukin-6 (IL-6) signaling, antagonists of the bioactive phospholipid LPA, and small-molecule inhibitors, such as tyrosine kinase inhibitors or pirfenidone. It is recognized that vascular disease also plays a fundamental role in the morbidity and mortality seen in scleroderma. Novel drugs targeting vascular disease, including endothelin receptor antagonists, agents that enhance nitric oxide production, prostacyclin analogs, antiplatelet agents, and statins, are currently being used.

THERAPEUTIC PRINCIPLES

Treatment of Systemic Sclerosis

Organ-Specific Therapy

- Vasodilator therapy for Raynaud's phenomenon
- Proton pump inhibitor for gastroesophageal reflux
- Angiotensin-converting enzyme inhibitor for scleroderma renal crisis
- Vasodilator therapy for pulmonary arterial hypertension
- Antiinflammatory therapy for arthritis
- Immunosuppressive therapy for interstitial lung disease

Disease-Modifying Agents

- Nintedanib, an orally active small-molecule multiple kinase inhibitor, is currently approved for the treatment of SSc-associated ILD
- Several immunomodulatory, antiinflammatory, vasoactive, and antifibrotic agents, as well as autologous hematopoietic stem cell transplantation, are used and/or currently under investigation.

ON THE HORIZON

Novel Therapeutic Approaches to Systemic Sclerosis Management in Clinical Trials

- Targeted individualized therapies employing precision medicine approaches to optimize therapeutic efficacy while minimizing drug-associated toxicity
- Development of antifibrotic agents, including new approaches to block fibrogenic pathways
- Use of biological agents, including anti-cytokines, anti-chemokines, and growth factor inhibitors

Other Fibrosing Diseases

Several disorders can cause skin fibrosis and mimic SSc. SSc can be distinguished from these SSc-like fibrosing conditions by characteristic clinical, pathological, and laboratory features. The

TABLE 56.6 Differential Diagnosis of Systemic Sclerosis and Scleroderma

Disorders Characterized by Similar Clinical Presentations
- Systemic lupus erythematosus
- Sjögren syndrome
- Rheumatoid arthritis
- Polymyositis/dermatomyositis
- Primary Raynaud's phenomenon

Disorders Characterized by Similar Visceral Features
- Primary pulmonary hypertension
- Primary biliary cirrhosis
- Idiopathic intestinal hypomotility
- Idiopathic pulmonary fibrosis
- Malignant hypertension

Disorders Characterized by Skin Thickening
- Scleromyxedema
- Scleredema (of Buschke), diabetic scleredema
- Nephrogenic fibrosing dermatopathy
- Eosinophilic fasciitis/diffuse fasciitis with eosinophilia
- Eosinophilia–myalgia syndrome
- Generalized morphea
- Chronic graft-versus-host disease
- POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes)
- Amyloidosis
- Carcinoid syndrome
- Pentazocine-induced scleroderma
- Diabetic digital sclerosis
- Vinyl chloride disease
- Toxic oil syndrome
- Bleomycin exposure
- Werner syndrome
- Phenylketonuria
- Porphyria cutanea tarda
- Vibration white finger syndrome
- Chronic reflex sympathetic dystrophy

most distinguishing clinical features of SSc include the presence of RP, nailfold capillary changes, the characteristic distribution, and characteristic skin changes. The skin pattern in SSc is noted for severe finger, hand, and distal limb involvement and sparing of the skin of the back of the trunk. SSc-specific serum autoantibodies also help define the presence of the SSc disease process. Conditions that mimic SSc include localized forms of scleroderma (see Table 56.5), eosinophilic fasciitis, nephrogenic systemic fibrosis, scleromyxedema (papular mucinosis), scleredema, graft-versus-host disease (GvHD), toxic oil syndrome, and eosinophilia–myalgia syndrome (Table 56.6).

Inflammatory Muscle Diseases

Arash H. Lahouti and Lisa Christopher-Stine

The idiopathic inflammatory myopathies (IIMs) are a group of rare systemic diseases. They consist of polymyositis (PM), dermatomyositis (DM), inclusion body myositis (IBM), and more recently described immune-mediated necrotizing myopathy. Traditionally, they are believed to be autoimmune diseases, although recent studies suggest that there is a close resemblance between IBM and other neurodegenerative diseases. Similar to other autoimmune diseases, patients with IIM often have autoantibodies in their serum. Some of these antibodies are specific for myositis and are not seen in other rheumatic disorders. Our knowledge of the myositis-specific antibodies is not comprehensive but new antibodies are being discovered constantly. Each myositis-specific antibody is closely linked to a unique clinical phenotype. Thus, these antibodies have value in classifying patients with IIMs. They can forewarn physicians of particular extramuscular manifestations and guide them toward initiating appropriate treatments.

The IIMs present with muscle weakness and elevated muscle enzymes. In patients with DM, skin manifestations may be the initial presentation. The differential diagnosis of the IIMs is broad and includes drug-induced myopathies, neuromuscular disorders, muscular dystrophies, and metabolic and endocrine myopathies. To add to the complexity of the classification, some DM patients do not develop muscle weakness, referred to as clinically amyopathic DM. The age and gender of the patient, the pattern of the weakness, the severity of the manifestations, and the associated symptoms usually aid in suspecting the correct diagnosis. For example, IBM is distinguished from other IIMs by a characteristic involvement of the finger flexor and knee extensor muscles, which is often asymmetrical. IBM is more common in older men, whereas PM and DM are commonly seen in young to middle-aged women and children. Dermatomyositis is often associated with characteristic skin findings, which are not a feature of PM and IBM. However, differentiation between the IIMs cannot be made on clinical grounds in a substantial number of patients, and further diagnostic testing is required. For example, both PM and immune-mediated necrotizing myopathy present in a same fashion with a predominant symmetrical proximal muscle weakness and elevated muscle enzymes. They can be distinguished only by pathological examination. On muscle biopsy, immune-mediated necrotizing myopathy is associated with necrosis and regeneration of muscle fibers and a characteristic sparse inflammatory infiltrate. In contrast, PM is associated with the presence of cytotoxic inflammatory cells surrounding and invading muscle fibers. Electromyography is a valuable tool for differentiating between weakness originating from muscle rather than peripheral nerves. Magnetic resonance imaging (MRI) can be extremely helpful to identify inflammatory changes in patients with subtle clinical muscle involvement. Moreover, MRI can help to better estimate the burden of the disease and differentiate acute changes (edema) from chronic changes (atrophy). The role of new imaging modalities such as whole-body MRI needs to be further investigated.

Interstitial lung disease, gastrointestinal involvement, and arthritis are among the most common extramuscular manifestations of the IIMs. Interstitial lung disease commonly occurs as part of the antisynthetase syndrome in a subset of patients who have antisynthetase autoantibodies. Gastrointestinal manifestations include dysphagia and aspiration pneumonia. Dysphagia is particularly common and can be seen in all forms of the IIM. In addition, certain forms of the IIMs, particularly DM, can be a paraneoplastic phenomenon. The most common cancers associated with myositis include gynecological (ovarian), pulmonary, gastrointestinal (pancreatic, stomach, and colorectal), and non-Hodgkin lymphoma. Also, the IIMs may be associated with other autoimmune diseases such as systemic lupus erythematosus, Sjögren syndrome, and systemic sclerosis.

Muscle biopsy is critical for the diagnosis of IIMs. The presence of perifascicular atrophy is strongly suggestive of DM, whereas the finding of rimmed vacuoles in the appropriate context suggests IBM. Muscle biopsy may also help differentiate between the IIMs and other forms of myopathy presenting as myositis clinical mimics such as drug-induced myopathies and muscular dystrophies.

Treatment of the IIMs is based largely on experience. Corticosteroids remain the mainstay of treatment. Steroid-sparing agents such as azathioprine, methotrexate, mycophenolate mofetil, and hydroxychloroquine are frequently initiated at presentation while a steroid taper is attempted. In patients with refractory disease, rituximab, intravenous immunoglobulin, and biological medications may be tried. Inclusion body myositis is the most resistant subset of the IIMs.

Finally, an iatrogenic form of myositis has recently been described, precipitated by treatment with immune checkpoint inhibitors (ICS). ICS are novel immunotherapy antineoplastic agents that take advantage of blocking negative T-cell co-stimulation to unleash potent anti-tumor immune responses. Unfortunately, removing such immunologic checkpoints can also precipitate a de novo myositis as well as the exacerbation or relapse of pre-existing myositis.

CLINICAL FEATURES

The clinical hallmark of PM, DM, and IMNM is the gradual onset of symmetrical proximal muscle weakness over weeks to months. In some cases, myalgia may be the presenting or most bothersome symptom, but more often the patient is evaluated for the physical limitations imposed by weakness: difficulty arising from a low chair or bed or combing and brushing hair. Rash is the first feature in a considerable proportion of patients who have DM, but muscle weakness usually follows within a few months. A subset of patients with DM, clinically amyopathic dermatomyositis (C-ADM), may present only with rash in the absence of muscle weakness throughout the course of their illness. These patients are also at risk for pulmonary involvement, as are those with classic DM. The prevalence of interstitial pneumonitis in C-ADM can approach 5% to 10%, compared with 40% of patients with classic DM.[1] Arthritis, Raynaud phenomenon, fever, or lung disease presenting as cough or dyspnea may dominate the clinical picture. Cardiac and gastrointestinal symptoms, other than dysphagia in severe cases, are rarely early manifestations. Renal and central nervous system (CNS) involvement are almost never a part of the IIMs.

KEY CONCEPTS

Definition and Incidence of Idiopathic Inflammatory Myopathies

- Polymyositis (PM), dermatomyositis (DM), and related inflammatory muscle diseases are called IIM.
- Indistinguishable muscle inflammation may accompany other autoimmune connective tissue diseases or limb-girdle muscular dystrophies.
- The annual incidence in the US is 5–10 cases per million. DM and PM are more common in women than in men in all age groups; inclusion body myositis (IBM) is more common in men.

Some of the rashes of DM are virtually pathognomonic; others are not disease-specific (Fig. 57.1). The heliotrope rash, a violaceous discoloration of the eyelids, is sometimes no more than a line along the margin of the upper lid, but it may also affect both upper and lower lids completely and can be associated with edema mimicking thyroid disease. A reddish, sometimes raised and/or scaly, eruption over the metacarpophalangeal joints is known as Gottron papules. In some cases, the metatarsophalangeal joints, elbows, knees, and malleoli show a similar rash. Both heliotrope and Gottron rashes can occur rarely in cases of frank systemic lupus erythematosus (SLE) without muscle involvement. Other common rashes include a flat, red blanching eruption of the upper chest (often in a V distribution), the upper back (where a shawl would touch), and sometimes the extensor surfaces of the upper arms and thighs. Another rash that mimics the malar rash of lupus on the face may be present; however, in contrast to lupus, it does not spare the nasolabial folds. Although found on sun-exposed parts of the body, these rashes are often not photosensitive in nature. As in other connective tissue diseases, nailfold capillary dilatation, infarcts, and cuticular overgrowth occur. Mechanic's hands, a roughening and cracking of the radial sides of the fingers and the palm, resembling a condition found in people who labor with their hands, is characteristic of a subset of myositis patients with the "antisynthetase syndrome" and can also be seen in patients with PM-Scl and U1-RNP autoantibodies.

CLASSIFICATION

In the past 40 years, several investigators have proposed diagnostic classification criteria for IIM. The criteria proposed by Bohan and Peter four decades ago remain the most familiar and clearest definitions of PM and DM (Table 57.1).[2,3] They combine clinical, laboratory, electrodiagnostic, and pathological features. These criteria, however, are limited by their poor specificity in distinguishing PM from other entities, including late-onset muscular dystrophies. The resultant misclassification limits the homogeneity of the patients included in previous observational and interventional studies. Additionally, the Bohan and Peter criteria completely omit the diagnosis of IBM, the most frequent type of IIM in patients over 50 years of age.

In 2004, more comprehensive criteria of IIM were proposed and approved by a group of international experts (Table 57.2). Unlike the previous criteria, these new criteria offer the advantage of classifying two rare forms of autoimmune myositis, *i.e.*, IMNM and DM *sine* dermatitis, as separate categories (see Table 57.2).[4] Separate classification criteria systems for IBM have been devised. According to most of the previous IBM criteria, characteristic muscle biopsy changes were necessary for a definite diagnosis of IBM. However, because selective involve-

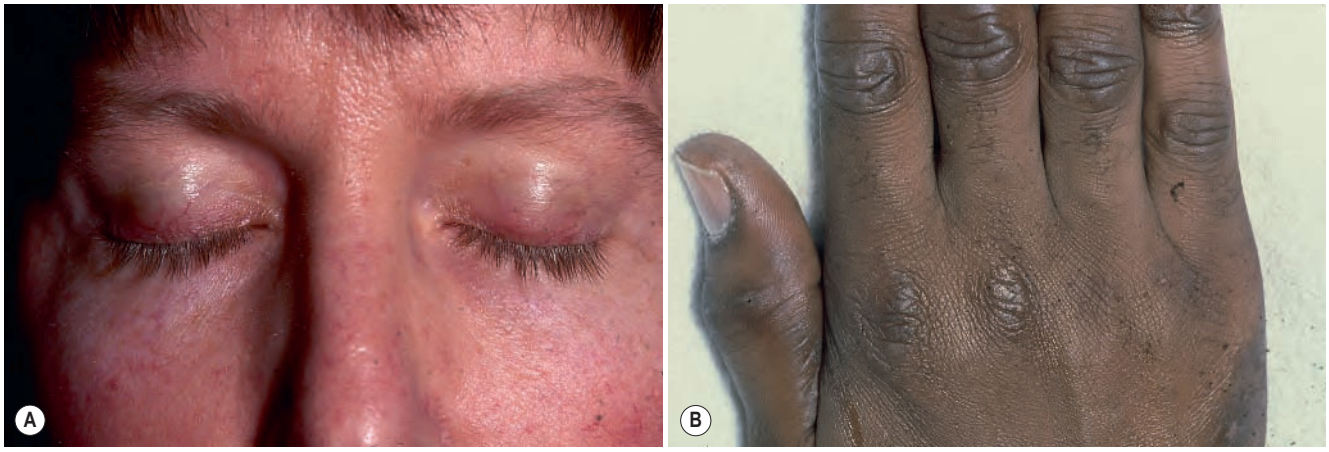

FIG. 57.1 Dermatomyositis Rash. (A) In addition to the heliotrope rash on the eyelids of this patient with dermatomyositis, there is a flat, red rash on the nose and cheeks. (B) A raised, shiny-red rash—Gottron papules—is apparent on the interphalangeal and the second and third metacarpophalangeal joints of this man with dermatomyositis.

TABLE 57.1 Idiopathic Inflammatory Myopathy: Diagnostic Criteria

Bohan and Peter Criteria

1. Symmetrical proximal muscle weakness
2. Skeletal muscle enzyme elevation
3. Abnormal EMG[a]
4. Muscle biopsy abnormalities
5. Typical skin rash of DM[b]

[a]Polyphasic, short, small motor-unit potentials; fibrillation, positive sharp waves, increased insertional irritability; bizarre, high-frequency, repetitive discharges.
[b]Gottron sign, heliotrope rash.
Possible PM = any two of the first four criteria; possible DM = criterion 5 (rash) + any two criteria.
Probable PM = any three of the first four criteria; probable DM = criterion 5 (rash) + any three criteria.
Definite PM = all four of the first four criteria; definite DM = criterion 5 (rash) + all four other criteria.
DM, Dermatomyositis; *EMG*, electromyography; *PM*, polymyositis.

ment of finger flexors and knee extensors is almost exclusive to IBM among other forms of myopathy, the newly proposed *ENMC IBM Research Diagnostic Criteria 2011* entails a separate category for clinically defined IBM (Table 57.3).[5]

It has been useful for some purposes to divide cases into groups: PM, DM, juvenile myositis, myositis associated with another connective tissue disease (usually systemic sclerosis, SLE, or Sjögren syndrome), cancer-associated myositis (usually cases in which the diagnoses are made within 6 to 12 months of one another), IBM, and a miscellaneous group that includes such rare entities as eosinophilic myositis (Table 57.4). This classification has allowed recognition of unique clinical and pathogenetic features and response to therapy. In the case of cancer-associated myositis, a more rational approach to workup based on recognition of groups at risk is now possible.

In 2017 the European League Against Rheumatism and American College of Rheumatology (EULAR ACR) Diagnostics Classification Criteria were published, becoming the acceptable gold standard criteria for classification for clinical trial purposes.[6] These criteria utilized data from 976 IIM patients (74% adults; 26% children) and 624 non-IIM patients with mimicking conditions (82% adults; 18% children). Each item was assigned a weighted score. The total score corresponds to a probability of having IIM. Subclassification is then performed using a classification tree. These new criteria addressed the addition of IBM, juvenile myositis, and amyopathic dermatomyositis. However, it had too few cases included for adjudication to add immune-mediated necrotizing myopathy (IMNM) as a separate diagnostic category from polymyositis. In addition, anti-Jo-1 is the only included myositis-specific autoantibody (MSA), and interstitial lung disease is not included among the clinically weighted items, effectively eliminating any patient with the antisynthetase syndrome in the absence of muscle or skin disease. Thus, more sophisticated big data modeling is likely to lead to more robust myositis classification criteria in the future.

KEY CONCEPTS

Characteristic Hallmarks of Inflammatory Myositis

- The clinical hallmark is proximal limb and neck weakness, rarely associated with muscle pain.
- The laboratory hallmarks are elevated serum levels of creatine kinase (CK), aldolase, lactic dehydrogenase, and the transaminases; a characteristic pattern ("irritable myopathy") is seen on electromyography (EMG). Elevated serum levels of autoantibodies are common.
- The pathological hallmarks are focal muscle necrosis, degeneration, regeneration, and inflammation.

TABLE 57.2 Proposed Diagnostic Criteria for Polymyositis and Dermatomyositis

The European Neuromuscular Centre (ENMC) criteria for the idiopathic inflammatory myopathies[4]

1. Clinical criteria
   a. Subacute onset
   b. Age >18 years (onset may be in childhood in DM and nonspecific myositis)
   c. Symmetrical proximal weakness
   d. Typical DM rash (including heliotrope, Gottron papules, Gottron sign, V sign, and shawl sign)
   e. Lack of features suggestive of IBM (asymmetry, finger flexor ≥ deltoid weakness, and knee extensors/ankle dorsiflexors ≥ hip flexors weakness), toxic myopathies, endocrine myopathies, amyloidosis, family history of muscular dystrophy or proximal motor neuropathies (*e.g.*, SMA)
2. Elevated serum creatine kinase level
3. Other laboratory criteria
   a. Abnormal electromyography
      Inclusion criteria
      I. Increased insertional and spontaneous activity in the form of fibrillation potentials, positive sharp waves, or complex repetitive discharges
      II. Morphometric analysis reveals the presence of short duration, small amplitude, polyphasic motor-unit action potentials (MUAPs)
      Exclusion criteria
      I. Myotonic discharges that would suggest proximal myotonic dystrophy or other channelopathy
      II. Morphometric analysis reveals predominantly long duration, large-amplitude MUAPs
      III. Decreased recruitment pattern of MUAPs
   b. MRI: diffuse or patchy increased signal (edema) within muscle tissue on Short T1 Inversion Recovery (STIR) images
   c. Myositis-specific antibodies detected in serum
4. Abnormal muscle biopsy
   a. Endomysial inflammatory cell infiltrate surrounding and invading nonnecrotic muscle fibers
   b. Endomysial CD8 T cells surrounding, but not definitely invading, nonnecrotic muscle fibers; or ubiquitous MHC-1 expression
   c. Perifascicular atrophy
   d. Membrane attack complex (MAC) depositions on small blood vessels, or reduced capillary density, or tubuloreticular inclusions in endothelial cells on EM, or MHC-1 expression of perifascicular fibers
   e. Perivascular, perimysial inflammatory cell infiltrate
   f. Scattered endomysial CD8 T-cell infiltrate that does not clearly surround or invade muscle fibers
   g. Many necrotic muscle fibers as the predominant abnormal histological feature. Inflammatory cells are sparse or only slight perivascular; perimysial infiltrate is not evident
   h. Rimmed vacuoles, ragged red fibers, cytochrome oxidase–negative fibers that would suggest IBM
   i. MAC deposition on the sarcolemma of nonnecrotic fibers and other indications of muscular dystrophies with immunopathology

Polymyositis—*Definite polymyositis:* (1) All clinical criteria with the exception of rash, (2) elevated serum creatine kinase (CK), (3) muscle biopsy criteria include (a) and exclude (c, d, h, and i); *probable polymyositis:* (1) All clinical criteria with the exception of rash, (2) elevated serum CK, (3) other laboratory criteria (1 of 3), (4) muscle biopsy criteria include (b) and exclude (c, d, g, h, and i). **Dermatomyositis**—*Definite dermatomyositis:* (1) All clinical criteria, (2) muscle biopsy criteria include (c); *probable dermatomyositis:* (1) All clinical criteria, (2) muscle biopsy criteria include (d) or (e), or elevated serum CK, or other laboratory criteria (1 of 3). **Amyopathic dermatomyositis**—(1) Rash typical of DM: heliotrope, periorbital edema, Gottron papules/sign, V sign, shawl sign, holster sign, (2) skin biopsy demonstrates a reduced capillary density, deposition of MAC on small blood vessels along the dermal-epidermal junction, and variable keratinocyte decoration for MAC, (3) no objective weakness, (4) normal serum CK, (5) normal electromyogram, (6) muscle biopsy, if done, does not reveal features compatible with definite or probable DM. **Possible dermatomyositis sine dermatitis**—(1) All clinical criteria with the exception of rash, (2) elevated serum CK, (3) other laboratory criteria (1 of 3), (4) muscle biopsy criteria include (c) or (d). **Nonspecific myositis**—(1) All clinical criteria with the exception of rash, (2) elevated serum CK, (3) other laboratory criteria (1 of 3), (4) muscle biopsy criteria include (e) or (f) and exclude all others. **Immune-mediated necrotizing myopathy**—(1) All clinical criteria with the exception of rash, (2) elevated serum CK, (3) other laboratory criteria (1 of 3), (4) muscle biopsy criteria include (g) and exclude all others.

TABLE 57.3 ENMC IBM Research Diagnostic Criteria 2011[5]

Clinical and Laboratory Features	Pathological Features
a. Duration >12 months	I. Endomysial inflammatory infiltrate
b. Age at onset >45 years	II. Rimmed vacuoles
c. CK no greater than 15 × ULN	III. Protein accumulation* or 15–18-nm filaments
d1. Knee extension weakness > hip flexion weakness	IV. Upregulation of MHC class I
d2. Finger flexion weakness > shoulder abduction weakness	

*Demonstration of amyloid or other protein accumulation by established methods (*e.g.*, for amyloid Congo red, crystal violet, thioflavin T/S, for other proteins p62, SMI-31, TDP-43). Current evidence favors p62 in terms of sensitivity and specificity, but the literature is limited, and further work is required.
Clinicopathologically defined IBM: Clinical criteria include (a–c) and at least one of the (d) criteria plus the first three pathological features. **Clinically defined IBM:** All clinical criteria plus one or more pathological features. **Probable IBM:** Clinical criteria include (a–c) and at least one of the (d) criteria plus one or more pathological features.
CK, Creatine kinase; *IBM*, inclusion body myositis; *ULN*, upper limit of normal.

TABLE 57.4 Traditional Classification of Idiopathic Inflammatory Myopathies

Type I	Primary idiopathic polymyositis
Type II	Primary idiopathic dermatomyositis
Type III	Dermatomyositis or polymyositis associated with malignancy
Type IV	Childhood dermatomyositis or polymyositis
Type V	Myositis associated with another connective tissue disease
Type VI	Inclusion body myositis
Type VII	Miscellaneous: eosinophilic myositis, localized nodular myositis, etc.

Several autoantibodies, called "myositis-specific autoantibodies," are unique to myositis. These have allowed a useful alternative classification (Table 57.5). For example, patients with antibodies to the aminoacyl-tRNA (transfer RNA) synthetases, of which Jo-1 is the best known, have a characteristic syndrome called antisynthetase syndrome, which usually includes interstitial lung disease, nondeforming inflammatory arthritis, fevers, mechanic's hands, and Raynaud phenomenon, in addition to myositis. Those with antibodies to the signal recognition particle (anti-SRP) have an IMNM manifested by severe disease of abrupt onset, often in the autumn. According to some studies, cardiac involvement is less common and survival is better in patients with anti-SRP than has previously been reported.[7] Those with antibodies to the nuclear antigen Mi-2 almost always have the V and shawl rashes and cuticular overgrowth in addition to myositis. A recently discovered antibody, anti-3-hydroxy-3-methylglutaryl-coenzyme A reductase (anti-HMGCR), is tightly linked to IMNM.[8,9] Interestingly, the HMGCR is the pharmacological target of statin drugs, such as atorvastatin, and a subset of patients with anti-HMGCR antibodies develop this antibody in the context of previous statin exposure, although it is also seen in statin-naïve individuals, albeit to a lesser extent. Patients with anti-HMGCR antibodies present with profound proximal muscle weakness and a marked creatine kinase (CK) elevation. Further, compared with statin-exposed individuals, statin-naïve anti-HMGCR positive patients tend to be younger, have higher CK levels, and have a blunted response to immunosuppressive medications (see Table 57.5).[2,9]

TABLE 57.5 Clinical Features Associated with Myositis-Specific Autoantibodies

Autoantibodies	Association	Characteristic Clinical Features
Anti-Jo-1 and other antisynthetases	PM, DM, IMNM	Relatively acute onset of myositis, frequent interstitial lung disease, fever, Raynaud phenomenon, arthritis, mechanic's hands, moderate response to therapy, persistent disease. Patients sometimes meet criteria for SLE or RA, but muscle disease or lung disease dominate the clinical picture and prognosis.
Anti-SRP	IMNM	Very acute onset of myositis, often in autumn, severe weakness, no rash, palpitations, females predominate, poor response to therapy
Anti-Mi-2	DM	Relatively acute onset of myositis, classic dermatomyositis rashes with V sign and shawl sign, cuticular overgrowth, good response to therapy
Anti-HMGCR	IMNM	Necrotizing myopathy, may be preceded by statin therapy, very high CK levels, minimal muscle wasting
Anti-MDA5	DM, clinically amyopathic DM	Clinically amyopathic dermatomyositis with rapidly progressive interstitial lung disease; characteristic skin findings include cutaneous ulcers and palmar papules
Anti-TIF1-γ (p155/140)	DM	Juvenile dermatomyositis and cancer-associated dermatomyositis
Anti-SAE	DM	Severe skin manifestations and dysphagia
Anti-NXP-2	DM	Associated with calcinosis and muscle contractures in children

DM, Dermatomyositis; *IMNM*, immune-mediated necrotizing myopathy; *MDA5*, melanoma differentiation–associated protein 5; *NXP-2*, nuclear matrix protein; *PM*, polymyositis; *RA*, rheumatoid arthritis; *SAE*, small ubiquitin-like modifier activating enzyme; *SLE*, systemic lupus erythematosus; *SRP*, signal recognition particle; *TIF1-γ*, transcription intermediary factor 1-γ.

IBM is different from other inflammatory myopathies. Patients with IBM rarely improve in strength with immunosuppressive therapy. They tend to be older, and in contrast to patients with PM and DM, who are predominantly women, patients with IBM are more commonly men. They have gradual, painless, asymmetrical, progressive weakness and focal atrophy that develop over years, and they may complain of frequent falls. Two decades after onset, they are frequently wheelchair-bound. The forearms of these patients exhibit a scalloped appearance, attributed to muscle atrophy. Difficulty with swallowing can occur with any inflammatory myopathy and is frequently a major problem in patients with IBM. The CK and other skeletal muscle–associated serum enzymes are normal in about one-quarter of patients with IBM and only moderately elevated in the remainder. The electromyogram in IBM frequently demonstrates both myogenic and neurogenic

features secondary to the effective denervation of some muscle cells by inflammation and necrosis.

Proposed criteria for the diagnosis of IBM rely on both pathological and clinical features. In the clinical setting of an inflammatory myopathy, the presence of the characteristic inclusions or rimmed vacuoles is diagnostic. Among the inflammatory myopathies, IBM is distinguished by substantial numbers of rimmed cytoplasmic vacuoles with tubulofilamentous material within myofibers. A variety of proteins have been found by immunohistochemistry in the muscle cells in IBM, including ubiquitin, β-amyloid precursor protein, and the transcription factor nuclear factor kappa B (NF-κB). Many of the proteins accumulating in the IBM muscle are also involved in other neurodegenerative diseases. For example, aggregation of p62, an autophagy-related protein, has been shown in IBM muscle, in Lewy bodies in Parkinson disease, and in neurofibrillary tangles in Alzheimer disease, suggesting the possibility of a degenerative process in IBM. More recently, an autoantibody to cytosolic 5′-nucleotidase 1a (c5N1A) was discovered. Although this antibody has a good specificity to distinguish IBM against other forms of autoimmune myopathy, it is positive in only 60% of IBM patients.[10] In addition, anti-c5N1A can be detected in other connective tissue diseases (such as lupus, DM, and Sjögren syndrome), as well as in healthy subjects.[11]

IBM must be distinguished from other chronic myopathies. These include acquired myopathies, such as those caused by toxins, and genetically determined myopathies, such as some muscular dystrophies and the metabolic myopathies. There are several important differences between IBM and these other myopathies. The distinction, however, is not as well defined as might be expected. Although some of the familial forms of IBM have a distinctive clinical presentation, often early in life, there have been several families with the typical late onset and inflammatory picture of the presumed sporadic cases. Several genetic loci have been identified in familial IBM, so it will be important to assess any identified mutations in familial IBM–associated genes in sporadic cases.[12]

ETIOLOGY

Immunological Clues to Origin

The implications of myositis-specific autoantibodies that bind to and inhibit the function of native human enzymes involved in the formation of new proteins are tantalizing and probably significant. These autoantibodies appear to develop before symptomatic weakness or serum CK elevation, suggesting a close link to an initiating factor. Some of the clinical features, such as fever, arthritis, and lung disease, and the apparent seasonality in onset of disease in patients with anti-SRP, are reminiscent of some viral infections. In patients with autoantibodies against one of the aminoacyl-tRNA synthetases, such as Jo-1 (histidyl-tRNA synthetase), the possible connection to a viral inciting agent appeared compelling, as certain picornaviruses, which are closely related to viruses long suspected of causing myositis, such as coxsackie viruses, can mimic tRNA in acting as a substrate for an aminoacyl-tRNA synthetase.[13] Direct proof connecting picornaviruses to human myositis, however, has not been obtained.

In individuals infected with HIV or human T-cell lymphotropic virus (HTLV)-1, the development of IBM has been reported. However, it is not always the first manifestation in these cases. There is no evidence of viral replication within the muscles, but instead the chronic infection triggers an inflammatory response.[14]

Drugs and Toxins

A large number of environmental agents have been associated with myopathies. Drug-induced myopathy should be considered particularly in cases where no other cause has been identified. Sometimes the illness strikingly resembles the spontaneous disease. D-penicillamine, for example, can induce a variety of autoimmune phenomena, including an inflammatory myopathy that closely resembles PM. A number of drugs can also produce myopathies that can be clinically confused with IIM but are histologically distinct. This large group includes 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-coA) reductase inhibitors, corticosteroids, colchicine, and zidovudine (AZT).

In corticosteroid-induced myopathy, type II muscle fiber atrophy is prominent on muscle biopsy, and weakness improves when the dose is lowered. Colchicine can cause myopathy and painful neuromyopathy. The CYP3A4 system metabolizes colchicine, and taking another drug metabolized by the same pathway can result in myopathy.[15] Muscle biopsy shows autophagic vacuoles that stain for acid phosphatase. Discontinuation of colchicine usually results in improvement. AZT produces a characteristic mitochondrial myopathy. The myopathy associated with HIV infection can be distinguished from that caused by AZT by muscle biopsy, as characteristic mitochondrial abnormalities are found in the latter. Amiodarone rarely causes proximal and distal muscle weakness, or the accompanying tremor or distal sensory loss. Muscle biopsy reveals autophagic vacuoles with myeloid inclusions and debris. This is seen more commonly in patients with chronic kidney disease. The antimalarial drugs chloroquine and hydroxychloroquine produce a vacuolar myopathy, possibly by raising the intralysosomal pH so that the acid cathepsins that digest waste products in the lysosome are inoperable, so waste products accumulate in vacuoles.

Immune-checkpoint inhibitors (ICIs) are a class of novel immunotherapeutic antineoplastic agents that halt inhibitory immune-checkpoint pathways. Best known are anti-programmed death-1 (PD-1) antibodies, anti-programmed death-ligand 1 (PD-L1) antibodies, and anti-cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) antibodies. While their ability to reactivate immune responses against cancer is novel and promising, inappropriate immune activation by ICIs can lead to adverse effects, termed immune-related adverse events (irAEs). The incidence of irAEs is reported to be between 17.1% and 72%, depending on the type and dose of the ICI, as well as the cancer phenotype.[16–18] While such irAEs can affect any organ, rheumatic disease complications are observed, probably a reflection of a pathogenic role of immune checkpoints in rheumatic diseases.[19,20] Because ICIs block negative T-cell co-stimulation, immunotherapy leads to an enhanced immune response, including autoimmune responses. Thus, many de novo rheumatologic manifestations as well as the exacerbation or relapse of pre-existing rheumatic diseases have been reported during and after ICI therapy.[21] A recent meta-analysis utilizing 5560 patients noted the incidence of myositis was rare at 0.22%.[22]

Bacterial and Parasitic Diseases

Certain parasitic diseases can produce an illness by direct invasion of muscle. Weakness, fever, and eosinophilia are usually present. Bacterial pyomyositis is uncommon in North America

but occurs more commonly in other parts of the world. It is attended by the signs of local infection and is often asymmetrical. A recent report, however, details two cases of pyomyositis initially diagnosed as PM. Patients presenting with disseminated pyomyositis may be difficult to distinguish clinically from those with IIM, especially in immunosuppressed individuals, who may not mount a systemic response.[23]

PATHOGENESIS

The precise mechanisms of cell damage and death in the IIMs are still unknown. T lymphocytes invading muscle fibers are predominantly lacking the costimulatory receptor CD28, indicative that they are chronically stimulated and end-differentiated. $CD28^{null}$ lymphocytes are found in both muscle tissue and peripheral blood. They produce proinflammatory cytokines and release perforin and granzyme into targeted muscle cells. B cells and plasma cells are also present in muscle-infiltrating infiltrates. The differentiation of B cells into antibody-producing plasma cells occurs within myositis muscle and is regulated by B cell–activating factor (BAFF). These antibodies are likely directed against autoantigens or cross-reacting viral antigens.

In addition to adaptive immune mechanisms, innate and nonimmune mechanisms also may be responsible for muscle cell damage and death. For example, Toll-like receptor (TLR)-3 and TLR-7 are expressed by infiltrating inflammatory cells and immature myoblasts in myositis muscle. TLR activation leads to production of inflammatory cytokines such as interleukin (IL)-6, thereby triggering or perpetuating inflammatory responses. Classic apoptosis is absent in IIM biopsies, but growing evidence suggests that autophagy could be responsible for myofiber death.

After damage, a muscle fiber, which is a syncytium, can regenerate. Initially, on light microscopy one can appreciate loss of striations leading to a homogeneous appearance, fiber size variation, atrophy, and centralization of the nuclei. In the inflammatory myopathies, cell-mediated cytotoxicity is a primary method of destruction. Macrophages and cytotoxic T cells invade the myofibers. The myocyte cytoplasm close to the invaginated cells appears vacuolated and swollen. Other regions of the same cell may show intense regeneration, as seen histologically by aggregates of nuclei with prominent nucleoli and fiber splitting. Thus degeneration and regeneration can coexist in the same fiber.

Cytokines and chemokines (Chapters 14 and 15), which form an integrated network regulating inflammation, are produced by muscle fibers, immune cells, and endothelial cells. As an example, IL-1 is consistently found in myositis muscle. IL-1 facilitates transmigration of leukocytes by increasing the expression of adhesion molecules on endothelial cells. Further, IL-1 can decrease the proliferation of myoblasts. In some myositis patients, treatment with anakinra, an IL-1 receptor antagonist, results in improvement. This finding further supports a pathogenic role of IL-1. IL-1 acts in synergy with the other proinflammatory cytokines, tumor necrosis factor (TNF) and IL-17, to induce the production of IL-6 and CCL20 by myoblasts. The chemokine CCL20 recruits Th17 lymphocytes and immature dendritic cells into the muscle. IL-6 perpetuates inflammation by suppressing $FOXP3^{+}$ regulatory T cells. More recently, IL-15 has been reported to have a pathogenic role. IL-15 is expressed in muscle cells and myoblasts derived from PM and DM patients. IL-15 regulates T-cell activation and proliferation, and a higher expression of this cytokine at baseline may be associated with a poor response to immunosuppressive therapy.[24]

The role of type I interferons (IFN-Is) in the pathogenesis of DM has been extensively studied. The IFN-Is are a family of highly related glycoproteins, including IFN-α and IFN-β, that act on the type 1 IFN receptor. In DM muscle, the IFN-Is are produced by plasmacytoid dendritic cells (pDCs).[25] After activation of the IFN receptor, a cluster of IFN-I–inducible genes is transcribed, resulting in upregulation of several proteins, also known as the IFN signature, in the muscle and peripheral blood of patients with DM. Well known is the myxovirus resistance protein A (MxA), which, similar to other IFN-I–inducible proteins, has antiviral properties. This protein is overexpressed in both the muscle and skin in DM but not in PM or IBM. Further, decreased expression of MxA mRNA in peripheral blood mononuclear cells may correlate with decreasing muscle symptoms in juvenile DM patients. Indeed, some of the IFN-induced proteins may sustain autoimmunity in DM. For example, retinoic acid-inducible gene 1 (RIG-I) and melanoma differentiation-associated gene 5 (MDA-5) are IFN-I–induced proteins that induce IFN-I production in a positive feedback fashion. Both proteins contribute to IFN induction in response to measles virus infection,[26] nurturing the suspicion for a role of viral infections in myositis. Engel and colleagues[27] have demonstrated several important pathological distinctions between DM and PM and have suggested that in DM, the capillaries are the initial point of injury. A model of disease has been proposed in which primarily capillaries are damaged and myocytes are secondarily involved. Complement and immunoglobulins may be found in the capillary walls even where the remainder of the muscle is normal. The membrane attack complex of complement deposits there, and endothelial cells are swollen and pale. Even in unaffected regions of muscle, special staining reveals a marked decrease in capillary numbers. More advanced changes include microtubular endothelial inclusions and microvacuoles. Evaluation of lymphocyte populations in DM shows a high percentage of B cells and macrophages in the perivascular regions and an increasing frequency of CD4 T cells and pDCs toward the perimysium and endomysium. In DM, especially the juvenile-onset form, inflammation and necrosis followed by atrophy appear in a perifascicular pattern. Perivascular lymphocytic infiltrates, typical of later disease, have not been described as an early change. Consistent with the importance of immune complexes, histological abnormalities in the DM skin are indistinguishable from the changes in lupus.

In contrast to DM, PM and IBM do not demonstrate marked capillary changes, the perivascular infiltrates are less pronounced, and T-cell infiltrates in the perimysial and endomysial regions are more pronounced. Nonnecrotic fibers may be surrounded by T cells and macrophages. T cells are enriched for the CD8 subset. There is negligible evidence of natural killer (NK) cell presence. Should cytotoxic T cells prove to be the major effector cells, cloned T cells could lead to relevant antigenic targets. CD8 T cells recognize their antigenic peptide in association with major histocompatibility complex (MHC) class I molecules. Although resting normal muscle has very low class I expression, it is upregulated in regenerating and degenerating fibers found in both inflammatory and noninflammatory myopathies. Interestingly, in DM, class I expression is upregulated predominantly in the perifascicular regions, around sites of atrophy, and near sites of cellular invasion. In contrast, in PM, class I expression may be diffusely upregulated even where

there is no cellular infiltrate. IBM shows a more focal class I distribution in regions of T-cell invasion. The presence of focal regions of MHC class I expression in nonnecrotic fibers at the site of activated CD8 T cells is compatible with cytotoxicity as a prime mechanism of myocyte necrosis in IBM and PM. A pivotal study using transgenic mice demonstrated that abnormal accumulation of MHC class I molecules in the endoplasmic reticulum (ER) of muscle may initiate the ER stress response.[28]

KEY CONCEPTS

Differential Histological Features of Myositis

- In dermatomyositis the earliest changes involve vessel walls, and B cells and CD4 T cells predominate in the muscle biopsy.
- In polymyositis and inclusion body myositis, the dominant pathological feature is targeting and invasion of muscle cells by CD8 cytotoxic T cells.

Proposed pathogenic mechanisms for the development of the sporadic forms of IBM are complex and include both autoimmunity and degeneration. Many proteins also found in other neurodegenerative diseases have been shown to accumulate in IBM muscle. In addition, IBM patients typically do not respond to immunosuppressive medications. These findings likely suggest that IBM is a degenerative disease. However, IBM is sometimes associated with other autoimmune diseases. In IBM biopsy specimens, inflammatory cells are predominantly composed of CD8 T cells, and a majority of patients express a circulating antibody to cytosolic 5′-nucleotidase 1 A, supporting the role of autoimmunity in the pathogenesis of IBM.

In necrotizing autoimmune myositis (also known as IMNM), there is necrosis of muscle fibers with myophagocytosis and regeneration and paucity of T-cell infiltration. Complement deposition on blood vessels has been reported. In muscle biopsies from patients with statin-associated necrotizing autoimmune myositis, MHC class-I upregulation is frequently seen.[14]

The pathogenic role of autoantibodies found in IIM patients remains uncertain. MSAs are found in 60% to 80% of patients and appear to delineate specific clinical entities; each group has a strong but not absolute human leukocyte antigen (HLA) association. In a patient with myositis and antihistidyl-tRNA synthetase (Jo-1) autoantibodies, sera available from long before the onset of symptoms or biochemical damage to muscle tissue contained the autoantibodies, suggesting that the autoantibodies were not merely a response to release of tissue antigens. The extraordinary specificity of MSAs for IIM and the lack of evidence for strong polyclonal stimulation in these diseases suggest that MSAs are related to the fundamental causative process in IIM.

The structures bound by MSAs are mostly intracellular ribonucleoproteins involved in protein synthesis, such as the aminoacyl-tRNA synthetases and the SRP. These autoantigens are found in every nucleated cell. In general, the antibodies bind to conformational epitopes and, at least in the case of the antisynthetases, block enzymatic activity. It is possible that a structural property of muscle allows these particular proteins to be presented to the immune system when the cells are damaged; alternatively, the capacity of muscle fibers to degenerate alongside intense regeneration within the same fiber may allow these proteins to be efficiently displayed.[29] Experiments have suggested that some aminoacyl-tRNA synthetases have a direct proinflammatory role through a subsidiary chemokine-like action.

A landmark study determined that cultured myoblasts express high levels of autoantigens, which are strikingly downregulated as cells differentiate into myotubes *in vitro*. These data strongly associate regenerating rather than mature muscle cells as the source of continuous autoantigen supply in autoimmune myositis.[29]

GENETICS

The IIMs do not exhibit a simple mode of inheritance, and the rare familial cases mostly reflect IBM of early onset. As noted above, there are HLA associations for particular MSAs. Specifically, HLA-DR52 has a strong association (90%) with antisynthetase-positive myositis in people of both European and African descent.[30] HLA DRB1*11:01 was recently shown to be associated with an increased risk of anti-HMGCR myopathy.[31]

NATURAL HISTORY

The prognosis for patients with IIM varies greatly with clinical type, autoantibodies, extraskeletal muscle involvement, and the interval between diagnosis and the start of treatment.

Patients with DM or myositis accompanying another connective tissue disease are likely to recover most of their strength with prompt and adequate therapy. Although recurrences are common, persistent profound weakness does not usually occur. Most patients with anti-Mi-2 autoantibodies also usually respond well to therapy. Strength usually recovers well in patients whose myositis is cancer related, but overall mortality due to the tumor is high. Indeed, an accompanying tumor remains one of the most frequent causes of death in patients with an IIM. Among the MSAs, anti-TIF-1γ and anti–NXP-2 antibodies are found with increased frequency in patients with cancer-associated DM.[32]

Patients with PM fare less well, even when those with IBM are rigorously excluded. A return to normal strength is very unusual, and each recurrence is likely to be followed by greater residual weakness, even if inflammation is fully controlled. IBM has a poorer prognosis, but it is possible that the gradual decline in strength can be halted for long periods by corticosteroid and/or cytotoxic therapy if continuing inflammation is present. Severe muscle weakness and atrophy and very high CK levels are prominent features in patients with anti-SRP autoantibodies. Patients with anti-MDA5 antibodies are at increased risk for developing progressive interstitial lung disease. Those with anti-Jo-1 autoantibodies or antibodies to another synthetase are likely to respond to therapy initially, but they typically require continuing immunosuppression to treat frequent recurrences. In this group morbidity and mortality are heavily influenced by the progression of lung involvement. Longitudinal outcome studies in DM and PM are few. Cardiac involvement, respiratory involvement, and cancer were the main causes of death in several cohort analyses. Disease course is monocyclic in approximately 20% of patients, polycyclic in 20%, and chronic in the remainder. Relapses have been noted in the initial years of therapy and after prolonged disease-free intervals; therefore, periodic surveillance is warranted for at least 2 years after remission.

PATIENT MANAGEMENT

The treatment of myositis is based on controlling skeletal muscle inflammation and damage. Immunosuppressive therapy is used

in the initial stages of the disease to reduce inflammation and muscle damage. There are very few randomized controlled trials of any of the immunosuppressive agents used; thus, therapeutic regimens and responses have remained largely anecdotal. After the initial inflammation is controlled, strengthening exercises are useful in improving functional capabilities.

Corticosteroids

Corticosteroids are the main immunosuppressive agents used in myositis treatment. An initial course of pulses of methylprednisolone may be helpful, particularly in disease of acute onset, and may also be helpful in managing disease flares. If active muscle inflammation persists or the side effects of corticosteroids are severe, other immunosuppressive treatments are employed.

Second-Line and Third-Line Immunosuppressive Therapies

The most frequently used second-line agents in the treatment of myositis are azathioprine and methotrexate. Azathioprine reduces long-term disability. Methotrexate is useful in patients with little or no response to corticosteroid therapy. Combination therapies, such as methotrexate with azathioprine, are useful even if patients have failed to respond to one of the agents alone. High-dose intravenous immunoglobulin (IVIG) is of proven benefit in DM.[33] Whereas patients with statin-associated anti-HMGCR myopathy may be particularly responsive to IVIG,[34] its usefulness in PM is less predictable. Apheresis proved ineffective in a controlled blinded study.[35] Both cyclosporine and tacrolimus have been effective in some cases, as have cyclophosphamide and chlorambucil. The most recent therapeutic options include mycophenolate and rituximab. Recently a large, randomized placebo-phase clinical trial was conducted to elucidate the role of a 44-week course of rituximab therapy in adults and children with refractory PM and DM. In general, 83% of refractory myositis patients met the Definition of Improvement (DOI), and the presence of antisynthetase and anti–Mi-2 autoantibodies was associated with a shorter time to improvement.[36,37] In refractory patients who have not responded to the above-mentioned treatments, biological agents such as etanercept, adalimumab, anakinra, abatacept, and high-dose cyclophosphamide have been tried with variable success.[24,38–41] Thus far, there has been no effective therapeutic regimen for IBM. However, IVIG has been reported to provide a transient response.[14]

Monitoring Disease Activity

Improvement in strength and normalization of serum CK activity are the best indirect measures of disease activity. A decrease in serum CK activity may herald clinical improvement, but corticosteroid treatment alone can reduce CK activity without associated clinical improvement. A lack of improvement in strength in a corticosteroid-treated patient may be due to the resistance of the inflammatory process, the presence of a corticosteroid-induced myopathy, muscle atrophy, and/or misdiagnosis. A diagnostic and therapeutic taper of the corticosteroids may then be warranted. If inflammation is present concurrently, other immunosuppressive agents are useful as the dosage of corticosteroids is lowered. If the CK value begins to rise, even if it is still within the normal range, and the symptoms of myositis are worsening in a patient whose disease has previously been controlled with corticosteroids, an increase in the dose may be warranted.

Treatment-Resistant Myositis

Some treatment-resistant PM patients have another disease. In such cases IBM or a limb-girdle muscular dystrophy should be suspected. Unlike other myositis patients, those with IBM rarely, if ever, improve in strength with immunosuppressive therapy, but stabilization of strength can be achieved in some IBM patients with immunosuppressive agents.[42,43] Patients with limb-girdle muscular dystrophies may mimic PM clinically. They may have inflammation on muscle biopsy and may occasionally have associated autoantibodies. Thus, patients with a suspected IIM who do not respond to immunosuppressive therapy should undergo further evaluation, including genetic testing, to search for a limb-girdle muscular dystrophy.

Nonskeletal Muscle Involvement

Other organs frequently involved in myositis include the skin, lungs, and joints. Such organ involvement and the systemic features of myositis (fever and weight loss) usually improve with immunosuppressive therapy that controls inflammation in the skeletal muscle. Hydroxychloroquine and other antimalarials are useful in controlling the rashes associated with myositis.

DIAGNOSTIC TOOLS, EVALUATION, AND DIFFERENTIAL DIAGNOSIS

CLINICAL PEARLS

Clinical Features That Suggest a Non-Idiopathic Inflammatory Myopathy Diagnosis

- Family history of a similar illness
- Weakness related to exercise, eating, or fasting
- Sensory, reflex, or other neurological signs
- Cranial nerve involvement
- Fasciculations
- Muscle cramping (severe)
- Myasthenia (increasing weakness with repeated contractions)
- Myotonia (difficulty relaxing a contracted muscle)
- Significant atrophy or hypertrophy early in the illness
- Marked asymmetry
- Dyspnea due to diaphragmatic weakness with normal chest x-ray

Clinical, laboratory, pathological, and electrodiagnostic findings contribute to the proper diagnosis of IIM. Even in individuals with typical clinical features, it is essential to exclude other diseases that may have similar symptoms and signs (Table 57.6). Certain clinical features should suggest a different diagnosis. These include a family history of a similar illness; sensory, reflex, or other neurological changes; fasciculations; a relationship of the weakness to exercise, food intake, or fasting; major muscle cramping, myotonia (difficulty relaxing a contracted muscle), or myasthenia (increasing weakness with repeated contractions); significant early muscle atrophy or hypertrophy; marked asymmetry; weakness in the distribution of the cranial nerves; and dyspnea due to diaphragmatic weakness rather than lung fibrosis.

The single most useful laboratory feature of muscle destruction is elevation of the serum CK, although this is nonspecific, and a small proportion of patients—probably less than 5%—have a bonafide inflammatory muscle disease without ever having an elevated CK. Elevations of the serum levels of aldolase, serum glutamic-oxaloacetic transaminase (SGOT), serum glutamate pyruvate transaminase (SGPT), and lactate dehydroge-

TABLE 57.6 Differential Diagnosis of Idiopathic Inflammatory Myopathy

Neuromuscular Disorders
Genetic muscular dystrophies
Metabolic myopathies
Disorders of carbohydrate metabolism: McArdle disease, phosphofructokinase deficiency, adult acid maltase deficiency, and others
Disorders of lipid metabolism: carnitine deficiency, carnitine palmitoyl transferase deficiency
Disorders of purine metabolism: myoadenylate deaminase deficiency
Mitochondrial myopathies
Spinal muscular atrophies
Neuropathies: Guillain–Barré and other autoimmune polyneuropathies, diabetes mellitus, porphyria
Myasthenia gravis and Eaton–Lambert syndrome
Amyotrophic lateral sclerosis
Myotonic dystrophy and other myotonias
Familial periodic paralysis

Endocrine and Electrolyte Disorders
Hypokalemia, hypercalcemia, hypocalcemia, hypomagnesemia
Hypothyroidism, hyperthyroidism
Cushing syndrome, Addison disease

Toxic Myopathies (Partial List)
Alcohol
Amiodarone
Chloroquine and hydroxychloroquine
Cocaine
Colchicine
Corticosteroids
D-penicillamine
Ipecac
Statins and other lipid-lowering agents
Zidovudine (AZT)

Infections
Viral: HIV, human T-lymphotropic virus 1 (HTLV-1), influenza
Bacterial: *Staphylococcus, Streptococcus, Clostridia*
Parasitic: toxoplasmosis, trichinosis, schistosomiasis, cysticercosis

Miscellaneous
Polymyalgia rheumatica
Vasculitis
Eosinophilia myalgia syndrome
Paraneoplastic syndromes

nase (LDH) are as frequent but less specific for muscle disease. Unlike inflammatory markers for other autoimmune inflammatory diseases, those such as the erythrocyte sedimentation rate (ESR) and C-reactive protein are often not elevated. Although some studies have shown ESR to be elevated in 50% of patients, most experts find a substantially lower proportion of IIM patients to have an elevated ESR, even with active disease.[44] Likewise, hematological abnormalities, including anemia, are uncommon and rarely related to the underlying myopathy. If a significant abnormality is found, the physician should be alert to another cause for it.

Electromyographic (EMG) abnormalities are frequently present. Although the test is useful for excluding some neurological diseases that resemble IIM, it is painful for many patients and not useful for following the course of the illness.

MRI, especially a combination of the T1 and the fat-suppressed T2 (STIR) sequences, is remarkably useful in defining the extent of involvement and in planning a biopsy (Fig. 57.2). Whole-body MRI has been shown to facilitate the characterization of inflammatory myopathy, as certain patterns of muscle and subcutaneous tissue inflammation were predictive of the IIM subset (DM, PM, or IBM). In a recent study in juvenile DM, whole-body MRI was able to reveal inflammatory changes of subcutaneous and fascial tissue that was undetectable on clinical examination.[45] MRI can also help differentiate active disease from chronic disease, with active myositis being notable for changes consistent with muscle edema on T2-weighted images, and chronic myositis revealing a decrease in muscle bulk and replacement by adipose on T1-weighted images.[46] Although not specific, the changes of inflammatory myopathy on imaging can provide considerable assistance in confusing cases, as well as help in choosing a site to biopsy.

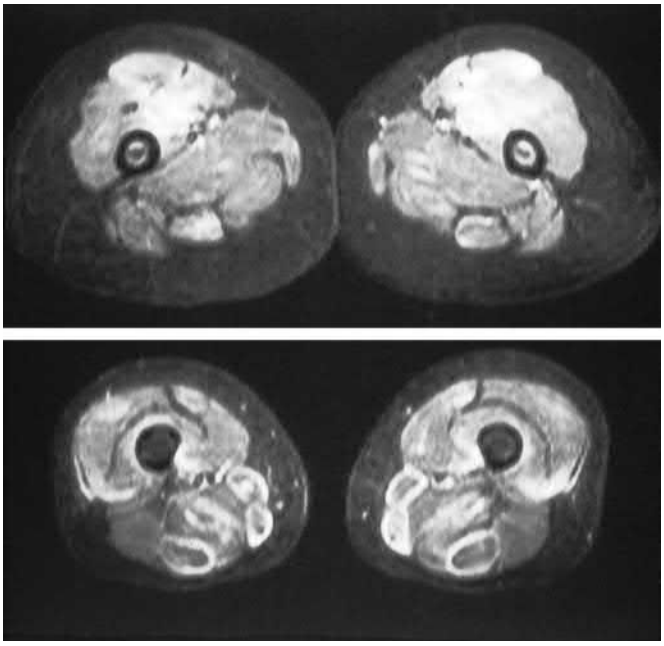

FIG. 57.2 Magnetic Resonance Images of the Upper and Lower Thighs of a Patient with Dermatomyositis Using the Fat-Suppressed T2 (STIR) Technique. With this technique inflammation appears as a bright signal; normal muscle is gray; bone, fat, fascia, and normal skin are dark. Blood vessels may appear as bright spots. Note the remarkable symmetry of the inflammation. In this patient most of the involvement is in the quadriceps in the upper thighs and around the periphery of the hamstring muscle group.

A muscle biopsy should be performed in every suspected case of myositis (Fig. 57.3). Although the patchy involvement means that the biopsy can occasionally miss inflammation, certain confounding diagnoses—for example amyloidosis, eosinophilic myositis, dystrophy, or some metabolic myopathies as well as the important variant IBM—can be diagnosed definitively only by biopsy. The identification of autoantibodies, particularly the myositis-specific autoantibodies, has distinct clinical and prognostic use.

ON THE HORIZON

- While there are newly revised and updated classification criteria for inflammatory myopathies, more precise criteria derived from big data as well as novel autoantibodies are likely in the future. Long-term studies are needed to better characterize the prognosis of idiopathic inflammatory myopathies, particularly in relation to recently discovered autoantibodies.

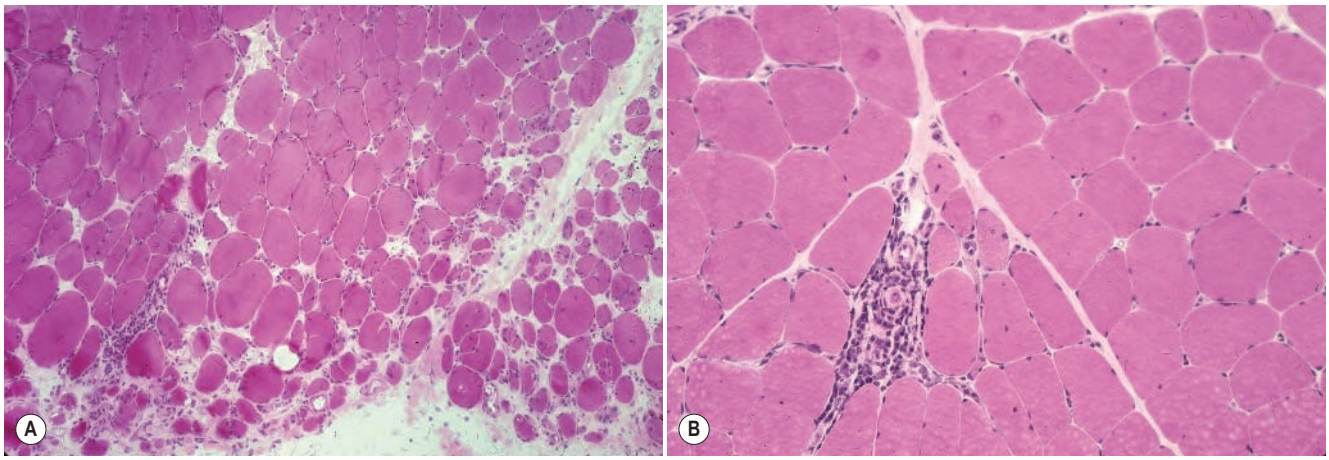

FIG. 57.3 Biopsy in Dermatomyositis. (A) Low-power (original magnification ×100) view of a muscle biopsy from a patient with dermatomyositis. Note the marked variation in fiber size and the large number of atrophic myocytes, particularly at the periphery of the fascicles. (B) High-power (original magnification ×200) view of inflammation around the vessels in the muscle biopsy of a patient with dermatomyositis. There are nearby atrophic cells and cells whose nuclei have moved away from the periphery of the cell (centralized nuclei).

PITFALLS

It is increasingly apparent that the boundary between IIM and some genetically determined myopathies cannot be cleanly drawn. Recently dystrophies with an extraordinary variety of clinical manifestations (with regard to age and distribution of weakness) have also been described.[47] Not only can inflammation be seen on biopsy in some patients, but a partial clinical response to corticosteroids also can occur. Furthermore, it is increasingly recognized that mitochondrial abnormalities can be limited to groups of skeletal muscles, leading to confusion with IIM. Toxic myopathies, of course, will continue to occur with the release of new drugs and thus will continue to be a possible source of diagnostic confusion.

Thus, not only must the history, physical examination, and biopsy be performed and interpreted with compulsiveness and care, but molecular diagnostic techniques also must be employed by clinicians in pursuit of an accurate diagnosis and appropriate therapy. The correct response to disease that persists in the face of powerful immunosuppressive therapy is a careful rethinking of the diagnosis, including, on occasion, rebiopsy and molecular consultation.

Spondyloarthritis

John D. Reveille and Lauren K. Ridley

The term *spondyloarthritis* (SpA) encompasses a heterogeneous group of inflammatory diseases characterized by spinal and peripheral joint arthritis, inflammation of the attachments of ligaments and tendons to bones (enthesitis), and, at times, mucocutaneous, ocular, and/or cardiac manifestations. These disorders show familial aggregation and are typically associated with genes of the major histocompatibility complex (MHC), particularly the human leukocyte antigen (HLA)-B27 (Chapter 5). The SpA spectrum includes (1) axial spondyloarthritis (AxSpA), including ankylosing spondylitis (AS) and non-radiographic axial spondyloarthritis (nr-AxSpA); (2) peripheral spondyloarthritis, which includes (a) reactive arthritis (ReA); (b) psoriatic arthritis (PsA) and/or spondylitis; (c) enteropathic arthritis and/or spondylitis associated with the inflammatory bowel diseases (IBD), ulcerative colitis (UC), or Crohn disease (CD), (d) juvenile-onset spondyloarthritis; and (e) undifferentiated SpA, which encompasses patients expressing elements of, but failing to fulfill, accepted criteria for one of the above diseases. In addition, isolated acute anterior uveitis (AAU)[1] and spondylitic heart disease (complete heart block and/or isolated aortic regurgitation)[2] associated with HLA-B27 may also be classified within the spectrum of SpA.

CLASSIFICATION OF SPONDYLOARTHRITIS

There are no diagnostic criteria for any of the SpA. Classification criteria have been developed to provide greater specificity in clinical studies. These include the Amor Criteria, proposed in 1988, the European Spondyloarthropathy Study Group (ESSG) criteria for SpA developed in 1991, and the modified New York criteria in 1984, which do not include advanced imaging techniques such as MRI (Table 58.1).[3] However, it may take up to 10 years to develop radiographic sacroiliitis after the onset of inflammatory back pain. In 2009, the Assessment of SpondyloArthritis International Society (ASAS) published new criteria that allowed (1) diagnosis of sacroiliitis based on MRI, and (2) classification of patients based solely on clinical features. This includes the use of HLA-B27 typing and C-reactive protein (CRP) determination and allows for the diagnosis of earlier disease found on MRI.[3] In recent years, more weight has been placed on the differentiation of non-radiographic axial spondyloarthritis (nr-AxSpA).

Criteria for peripheral spondyloarthritis based on the presence of peripheral arthritis, enthesitis, or dactylitis have also been developed utilizing the innovations of advanced imaging and HLA-B27 typing.[3] This resulted in a reclassification of all the various spondyloarthritides under the diagnoses of axial and peripheral SpA which aids in treatment since axial and peripheral disease respond differently.

For PsA, the Classification Criteria for Psoriatic ARthritis (CASPAR) have been established (see Table 58.1).[3] No criteria have been validated for enteropathic arthritis or for reactive arthritis.

The International League Against Rheumatism (ILAR) juvenile idiopathic arthritis (JIA) classification criteria do not recognize SpA as a distinct clinical entity. Instead, juvenile SpA patients tend to fall under three of seven subtypes of JIA in the ILAR classification: enthesitis-related arthritis (ERA), PsA, or undifferentiated arthritis. IBD-related arthritis, reactive arthritis, and juvenile AS are not addressed in the ILAR classification criteria. (ILAR; see Table 58.1).

EPIDEMIOLOGY

The frequency of SpA in general and AS in particular varies in different populations and parallels the frequency of HLA-B27. The prevalence of AS varies from 0.2% to 0.7% among people of European ancestry[4–6] and has been reported in similar frequencies in eastern Asia (Table 58.2). AS is much less frequent in persons of African and Japanese descent, in whom HLA-B27 is rare.

The prevalence of ReA has varied over time and in different regions, depending on endemic rates of sexually acquired and enteric infections that trigger it. The frequency of ReA has dramatically declined following the adoption of safer sexual practices and better sanitation, at least in economically advanced countries, in the wake of the human immunodeficiency virus (HIV) epidemic.

Psoriasis affects 1% to 3% of the general population.[5] Psoriatic arthritis occurs in about 20% to 30% of patients with psoriasis.[7] PsA incidence is similar between males and females, and it is uncommon in Asians and blacks.[8]

The prevalence of IBD is 100 to 200 per 100,000 among Caucasians, with an equal male-to-female ratio.[4,6] It is rare in people of African and Asian descent. The prevalence of extraintestinal manifestations, such as peripheral or axial disease, in IBD varies between Crohn disease and ulcerative colitis (Table 58.3).

In North American JIA patients, enthesitis-related arthritis is found in 10% to 11% of patients, psoriatic arthritis in 6% to 11%, and undifferentiated SpA in about 1% to 2% of patients.[9]

TABLE 58.1 CLASSIFICATION CRITERIA FOR SPONDYLOARTHRITIS

A. Amor Criteria for Spondyloarthropathy

Clinical symptoms or history	Points
a. Lumbar or dorsal morning stiffness or pain at night	1
b. Asymmetrical oligoarthritis	2
c. Buttock pain (1 point) or alternating buttock pain (2 points)	1 or 2
d. Dactylitis	2
e. Heel pain or other well-defined enthesopathy	2
f. Iritis or uveitis	1
g. Nongonococcal urethritis or cervicitis with 1 month before the onset of arthritis	1
h. Acute diarrhea within 1 month before the onset of arthritis	2
i. Psoriasis, balanitis, or inflammatory bowel disease (ulcerative colitis or Crohn disease)Radiographic findings	3
a. Sacroiliitis (bilateral grade 2 or unilateral grade 3)Genetic background	2
b. Presence of HLA-B27 and/or family history of ankylosing spondylitis, reactive arthritis, uveitis, psoriasis, or inflammatory bowel diseaseResponse to treatment	2
a. Clear-cut improvement within 48 h after NSAIDs intake or rapid relapse of the pain after NSAIDs discontinuation	2

If the sum is greater than or equal to 6, the patient is considered to have a spondyloarthritis.

B. European Spondyloarthropathy Study Group (ESSG) Criteria for Spondyloarthritis

1. Inflammatory back pain or synovitis (asymmetrical, lower extremity) plus one of the following:
   (a) Alternating buttock pain
   (b) Sacroiliitis
   (c) Heel pain (enthesitis)
   (d) Positive family history
   (e) Psoriasis
   (f) Crohn disease, ulcerative colitis
   (g) Urethritis or cervicitis or acute diarrhea in the preceding 4 weeks

C. The Modified New York Criteria for Ankylosing Spondylitis[4]

1. Clinical criteria:
   (a) Low-back pain and stiffness for more than 3 months which improves with exercise, but is not relieved by rest
   (b) Limitation of motion of the lumbar spine in both the sagittal and frontal planes
   (c) Limitation of chest expansion relative to normal values correlated for age and gender
2. Radiological criterion:
   (a) Sacroiliitis grade 2 bilaterally or grade 3–4 unilaterally
   (b) *Definite ankylosing spondylitis* if the radiological criterion is associated with at least one clinical criterion

D. The Classification Criteria for Psoriatic Arthritis (CASPAR) Criteria for Psoriatic Arthritis

1. Inflammatory joint disease plus at least three points from the following features:
   (a) Current psoriasis (assigned a score of 2; all others assigned a score of 1)
   (b) History of psoriasis
   (c) Family history of psoriasis
   (d) Dactylitis
   (e) Juxta-articular new bone formation
   (f) Rheumatoid factor seronegativity
   (g) Nail dystrophy

E. ASAS Criteria for Axial Spondyloarthritis in Patients With Chronic Low Back Pain for at Least 3 Months

1. Sacroiliitis on imaging (either MRI findings of inflammatory disease in the sacroiliac joints or sacroiliitis on standard pelvic X-rays by New York criteria) plus ONE of the following OR HLA-B27 positivity plus TWO of the following:
   (a) Inflammatory low back pain
   (b) Arthritis
   (c) Enthesitis
   (d) Dactylitis
   (e) Psoriasis
   (f) Crohn disease or ulcerative colitis
   (g) Good response to nonsteroidal anti-inflammatory agents
   (h) Positive family history of SpA
   (i) Presence of human leukocyte antigen (HLA)-B27
   (j) Elevated cross-reactive protein

F. ASAS Criteria for Peripheral Spondyloarthritis—Arthritis or Enthesitis or Dactylitis With At Least One of:

a. Uveitis
b. Psoriasis
c. Crohn disease or ulcerative colitis
d. Previous infection
e. Presence of HLA-B27
f. Sacroiliitis on imaging

OR

with at least two of:

a. Inflammatory low back pain
b. Arthritis
c. Enthesitis
d. Dactylitis
e. Positive family history of SpA

G. The International League Against Rheumatism (ILAR) Juvenile Idiopathic Arthritis Classification Criteria for Enthesitis-Related Arthritis (ERA)

Arthritis and enthesitis

OR

Arthritis or enthesitis with at least two of:

1. Sacroiliac joint tenderness and/or inflammatory spinal pain
2. Presence of HLA-B27
3. Family history in at least one first- or second-degree relative of medically confirmed HLA-B27-associated disease
4. Anterior uveitis that is usually associated with pain, redness, or photophobia
5. Onset of arthritis in a boy after 8 years of age

Exclusions

- Psoriasis confirmed by a dermatologist in at least one first- or second-degree relative
- Presence of systemic arthritis

H. The International League Against Rheumatism (ILAR) Juvenile Idiopathic Arthritis Classification Criteria for Psoriatic Arthritis

Arthritis and psoriasis

OR

Arthritis with at least two of the following:

1. Dactylitis
2. Nail pitting or onycholysis3.First-degree relative with psoriasis

Exclusions

- Arthritis in an HLA-B27-positive male patient that started after age 6
- Personal or family history of HLA-B27-associated disease
- RF positivity on two or more occasions at least three months apart

KEY CONCEPTS

The Genetic Basis of Spondyloarthritis

- Human leukocyte antigen (HLA)-B27 comprises over 80% of the overall genetic susceptibility to ankylosing spondylitis (AS) and contributes heavily to susceptibility for ReA, PsA, and enteropathic SpA.
- Additional risk comes from other major histocompatibility complex (MHC) genes, including *HLA- B*40*, among others, for AS and *C*06:02* for psoriasis.
- Genome-wide association studies (GWAS) utilizing dense single nucleotide polymorphism (SNP) mapping have located more than 130 additional genes or genetic regions in AS susceptibility.
- Over 60 genes have been identified thus far in psoriasis pathogenesis.
- GWAS utilizing dense SNP mapping examining larger sample sizes will likely continue to locate many of the remaining genes in AS susceptibility.

PATHOGENESIS

Genetics of Spondyloarthritis

Familial Aggregation

The sibling recurrence risk ratio in AS is as high as 82%, and twin-based studies estimate disease heritability exceed 90%.[10] The concordance rate for AS in identical twins has been reported to be as high as 63% compared with 23% in

nonidentical twins.[10] The concordance rate for psoriasis in monozygotic twins is 70% *versus* 15% to 30% in dizygotic twins. Recurrence risk for parents and siblings of patients with CD is 4.8% and 7%, respectively, and for UC 0.9% and 1.2%, respectively.[10]

HLA-B27 and Spondyloarthritis

HLA-B27 is found in 85% to 90% of AS patients of European ancestry, over 85% of AS patients of Hispanic ancestry, 56% to 84% of Middle Eastern or North African ancestry, and about 60% of AS patients of Asian and African American populations.[10–13] The estimated prevalence of HLA-B27 in the United States is 6.1% overall, is highest in younger individuals (7.5% before age 50 years), and falls rapidly over age 50 years (3.3%).[14]

Approximately 70% of patients with ReA have HLA-B27, except in Africa, where no association of HLA-B27 was seen in those with HIV-associated SpA.[12] HLA-B27 is found in 60% to 70% of patients with psoriatic spondylitis and in 25% of those with peripheral PsA.[11,12] Up to 70% of those with IBD-associated spondylitis have HLA-B27, although no HLA-B27 association is seen with asymptomatic sacroiliitis. Approximately 50% of patients with AAU alone are HLA-B27 positive.[11]

There are over 222 molecular subtypes of HLA-B27 that have been described as of March 2020 (http://www.ebi.ac.uk/ipd/imgt/hla/nomenclature/index.html). The most common subtypes (HLA-B*27:05, B*27:02, B*27:04, B*27:07) are clearly associated with SpA. Each subtype is found in specific populations. These subtypes evolved from the parent allele HLA-B*27:05 along five lines (Fig. 58.1) in three distinct geographical regions.

There are different hypotheses that have been extended how HLA-B27 impacts disease susceptibility. One theory suggests that SpA results from a unique set of antigenic peptides, either bacterial or self, that are bound and presented by HLA-B27 to CD8 T cells, resulting in a HLA-B27–restricted cytotoxic T-cell response found only in joints and other affected tissues (the so-called arthritogenic peptide hypothesis). However, such peptides have not been reproducibly identified to date. In fact, the data showing interaction between HLA-B27 and a gain-of-function (GOF) variant of endoplasmic reticulum (ER)–associated aminopeptidase I (ERAP1) suggest that *aberrant* antigen processing may play a central role in AS susceptibility.[15] The same has been described for HLA-C*06:02 and psoriasis.[18] An alternative concept focuses on self-association as a unique property of the HLA-B27 molecule. HLA-B27 heavy chains can form homodimers *in vitro* that are dependent on disulfide binding through their cysteine-67 residues in the extracellular α_1 domain (as well as other cysteine residues in other domains) (Fig. 58.2).[12,16] These B27 homodimers are detectable at the cell surface in patients with SpA, are capable of peptide binding, and are more abundantly expressed when the cell's antigen-presenting function is impaired. They are ligands for a number of natural killer (NK) and related cell surface receptors. Populations of synovial and peripheral blood monocytes, NK cells, and B and T lymphocytes both from patients with SpA and from controls carry receptors for HLA-B27 homodimers, including killer immunoglobulin-like receptor (KIR)3DL1 and KIR3DL2 and immunoglobulin (Ig)–like transcript 4 (ILT4).[12,15] These homodimers may act as a proinflammatory target or receptor for humoral or cell-mediated autoimmune responses. However, it is not known whether HLA-B27 homodimer formation is specific for, or even correlates with, the presence of SpA; in fact, disease does not develop in most HLA-B27–positive individuals. Alternatively, HLA-B27 misfolding and accumulation within the ER can result in a proinflammatory intracellular stress response through stimulating secretion of type 1 interferon (IFN).[16]

Other Major Histocompatibility Complex Genes and SpA Susceptibility

Other MHC genes have been implicated in AS in addition to HLA-B27 (Fig. 58.3), although their identification is complicated by the tight linkage disequilibrium found within the MHC, and many of the associations may reflect linkage to B27. These include the epithelial "stress" marker MICA, tumor necrosis factor (*TNF*), heat shock protein (*HSP*)*-70, LMP-2* and *LMP-7, HLA-DRB1*01*, and *DRB1*04* alleles.[12] However, other MHC genes have been shown to be SpA-associated independent of HLA-B27. These include *HLA-A*02:01* and *B*40* as well as negative associations with *HLA-B*07, B*15* and *B*35*, which have been described in whites, Han Chinese, and blacks with AS.[17] Also, in white Americans, *HLA-DPB1*03:01* is associated with AS.[13] *HLA-DRB1*15:01/DQB1*06:02* is negatively associated with AS but positively associated with uveitis.[13,17]

In psoriasis, the primary MHC association is with HLA-Cw6 (*HLA-C*06:02*) (though not with PsA). *HLA-B*38* has been associated with psoriatic arthritis.[17] The *HLA-B*27:05:02-C*06:02* haplotype is associated with enthesitis, dactylitis, and symmetric sacroiliitis, whereas *HLA-B*08:01-C*07:01* and its component alleles are positively associated with joint fusion and deformities, asymmetrical sacroiliitis, and dactylitis.[18] Both of these haplotypes are linked to more severe disease.[18] In contrast, *HLA-B*44* haplotypes are associated with milder disease.[18] *HLA-DRB1*01:03* has been strongly associated with enteropathic peripheral arthritis.[17]

Non–Major Histocompatibility Complex Genes in Susceptibility to Spondyloarthritis

Genome-wide association studies (GWAS) have implicated over 130 genes in AS susceptibility (see Fig. 58.3). These genes fall into different functional networks (Table 58.4). The most consistent (and best replicated) association is with *ERAP1*, which acts as a molecular ruler in the ER in trimming peptides processed in proteasomes to optimal length of nine amino acids for MHC class I binding and presentation. HLA-B27–negative patients with AS lack an association with *ERAP1*,[15] although an association with *ERAP2* is seen.

A number of genes whose products are operative in the Th17 pathway have also been associated with AS susceptibility: the IL-23 receptor (*IL23R*), which pairs with the *IL12RB1* gene product to confer IL-23 (but not IL-12) responsiveness on cells expressing both subunits; prostaglandin E receptor 4 (*PTGER4*), which stimulates dendritic cell (DC) production of IL-23 and, in turn, Th17 expansion and is overexpressed in SpA synovium; signal transducer and activator of transcription 3 (*STAT3*), a key regulatory factor in Th17 responses; and *Interleukin-12β* (*IL12B*), which encodes the IL12p40 protein, a component of both IL-12 and IL-23. *Jak2* plays a role in the downstream signaling pathway of IL-23R.[19]

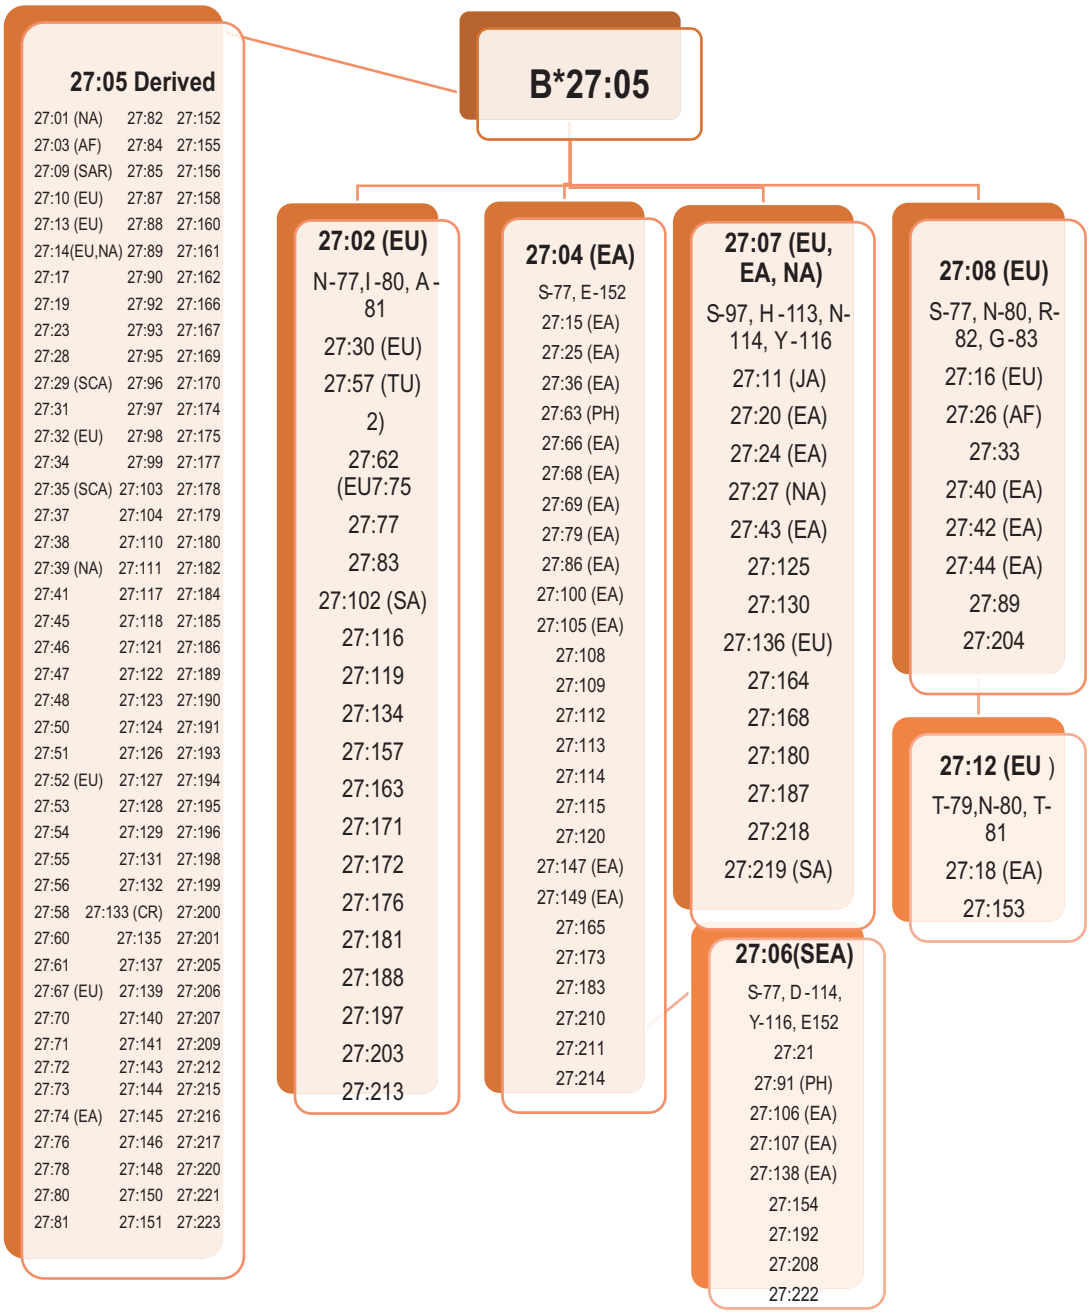

FIG. 58.1 The six major families of human leukocyte antigen (HLA)-B27 subtypes (HLA-B*27:59, B*27:64, B*27:65, and B*27:94 represent truncated genes with deletions of most of exons 2 and 3 and are not included above) are denoted in relationship to the "parent" subtype HLA-B*27:05. The ethnic or geographic origin of the subtypes is indicated in parentheses next to the allele: EU, European; NA, North American; SA, South American; EA, East Asian; SEA, Southeast Asian; NEA, Northeast Asian; ME, Middle East; Afr, African; UK, British Isles; Tur, Turkish; Mex, Mexican mestizo. Where no parentheses are given, the origin of the cell line from which the sequence came is unknown. Most B27 subtypes have evolved through five patterns of evolution along geographic lines. The first group, with HLA-B*27:02-B*27:23 (and B*27:30), appears to have evolved in Europe and the Middle East, entails anywhere from one to seven amino acid substitutions in the first (α_1) domain, and has the second (α_2) domain identical to B*27:05. The second group, including HLA-B*27:04 as the most common allele, evolved in Eastern Asia and includes a uniform amino acid substitution in the α_1 domain and anywhere from one to seven substitutions in the α_2 domain. The third and fourth groups seem to have evolved directly from HLA-B*27:05, from mutations in either exon 2 or 3, respectively. The fifth group, including HLA-B*27:07 as its leading member, evolved in southern and eastern Asia, the Middle East, and Sardinia with patterned amino acid substitutions in the α_2 domain. Finally, the sixth group, with HLA-B*27:08 as its common member evolved largely in East Europe, has different characteristic pattern of amino acid substitutions in the α_2 domain. Notable exceptions include HLA-B*27:13, B*27:109 and B*27:112-27:115, which have amino acid substitution outside α_1 and α_2 in the membrane proximal (α_3) domain. *AF*, African, *EU*, European, *EA*, Eastern Asian; *JA*, Japanese; *NA*, North American; *SEA*, Southeast Asian; *PH*, Philipino; *SA*, South American; *SCA*, Scandinavian; *TUR*, Turkic. (https://www.ebi.ac.uk/ipd/imgt/hla/allele.html).[13] (Data are derived from http://www.ebi.ac.uk/cgi-bin/imgt/hla/allele.cgi.)

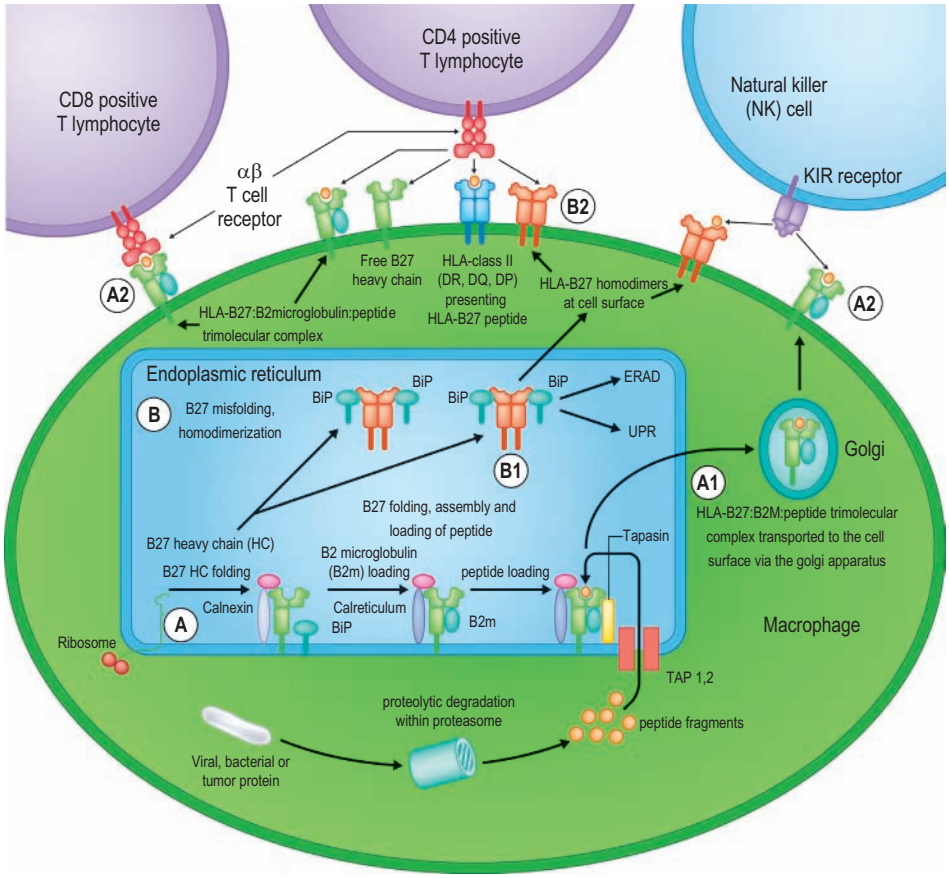

FIG. 58.2 After transcription of the human leukocyte antigen (HLA)-B27 heavy chain on ribosomes, it is inserted into the endoplasmic reticulum (ER), glycosylated, and two pathways ensue. (A) The B27 heavy chain is retained through binding with calnexin and ERp57, folded into its tertiary structure, and bound to β_2 microglobulin. After that calnexin releases the complex and it is associated with calreticulum, which, in turn, chaperones the formation of the peptide loading on to the complex of heavy chain, β_2 microglobulin and antigenic peptide, via the TAP proteins and tapasin. The antigenic peptide is derived from intracellular proteins from viruses, bacteria, tumors, and so on, that have been degraded in proteasomes, and then the peptides are trimmed for optimal length for peptide loading by endoplasmic reticulum-associated aminopeptidases (ERAP1 and ERAP2). Then the trimolecular peptide complex (HLA-B27 heavy chain, β_2 microglobulin and peptide) travels through the Golgi apparatus (A1) to the cell surface, where the antigenic peptide is presented either to the α: β T-cell receptor on CD8 T lymphocytes or to the killer immunoglobulin (KIR) receptor on natural killer (NK) cells (A2); or (B) the HLA-B27 heavy chain misfolds in the ER, forming B27 homodimers and other misfoldings which are bound to the ER chaperone BiP. Then, they either (B1) accumulate there, causing either ER-associated degradation (ERAD) or a proinflammatory ER unfolded protein response (UPR); or (B2) the B27 homodimers migrate to the cell surface, where they either become antigenic themselves or present peptide to receptors on T cells and NK cells.

GWAS in psoriasis and PsA have identified over 60 genes implicated in disease susceptibility outside the MHC.[20] These include genes in common with those for AS (*IL23R, IL12B, CDKAL1*, and *ERAP1*, the last showing interaction with HLA-Cw6 similar to that seen with HLA-B27) (see Fig. 58.3).

The first gene to be implicated in IBD susceptibility was *NOD2/CARD15*, which specifically leads to susceptibility to Crohn disease and whose protein product serves as a receptor for bacterial products in monocytes that transduces signals leading to NF-κB activation. A number of GWAS have implicated over 240 genes in IBD susceptibility.[21] The IL-23/IL-17 signaling pathway also appears involved with IBD pathophysiology with IL-23 shown to be important in development and maintenance of mucosal cells. Some of the genes implicated include *JAK2, IL23R*, and *TYK2*, among others. What is especially striking is the number of genes shared with the various types of SpA,[13] suggesting a common pathogenesis (see Fig. 58.3).

Genes and Severity of SpA

Disease severity in AS also has a hereditary component. By defining severity on the basis of radiographic involvement, two genes have been identified in a large candidate gene study.[22] One is the gene for cyclooxygenase I (COX-I)—the target of nonsteroidal anti-inflammatory drugs (NSAIDs)—the other for the receptor activator of NF-κB (RANK). No evidence was found for an MHC contribution to radiographic severity.

Infection

A role for triggering infections has been better documented in SpA than in most other rheumatic diseases. In developed countries, the most frequent type of ReA occurs following urogenital infections with *Chlamydia trachomatis* (endemic ReA). Postdysenteric ReA occurs after various *Shigella* and *Salmonella* (especially *S. typhimurium* and *S. enteriditis*), *Campylobacter jejuni* and *C. fetus*, and, in Europe, *Yersinia enterocolitica* species.

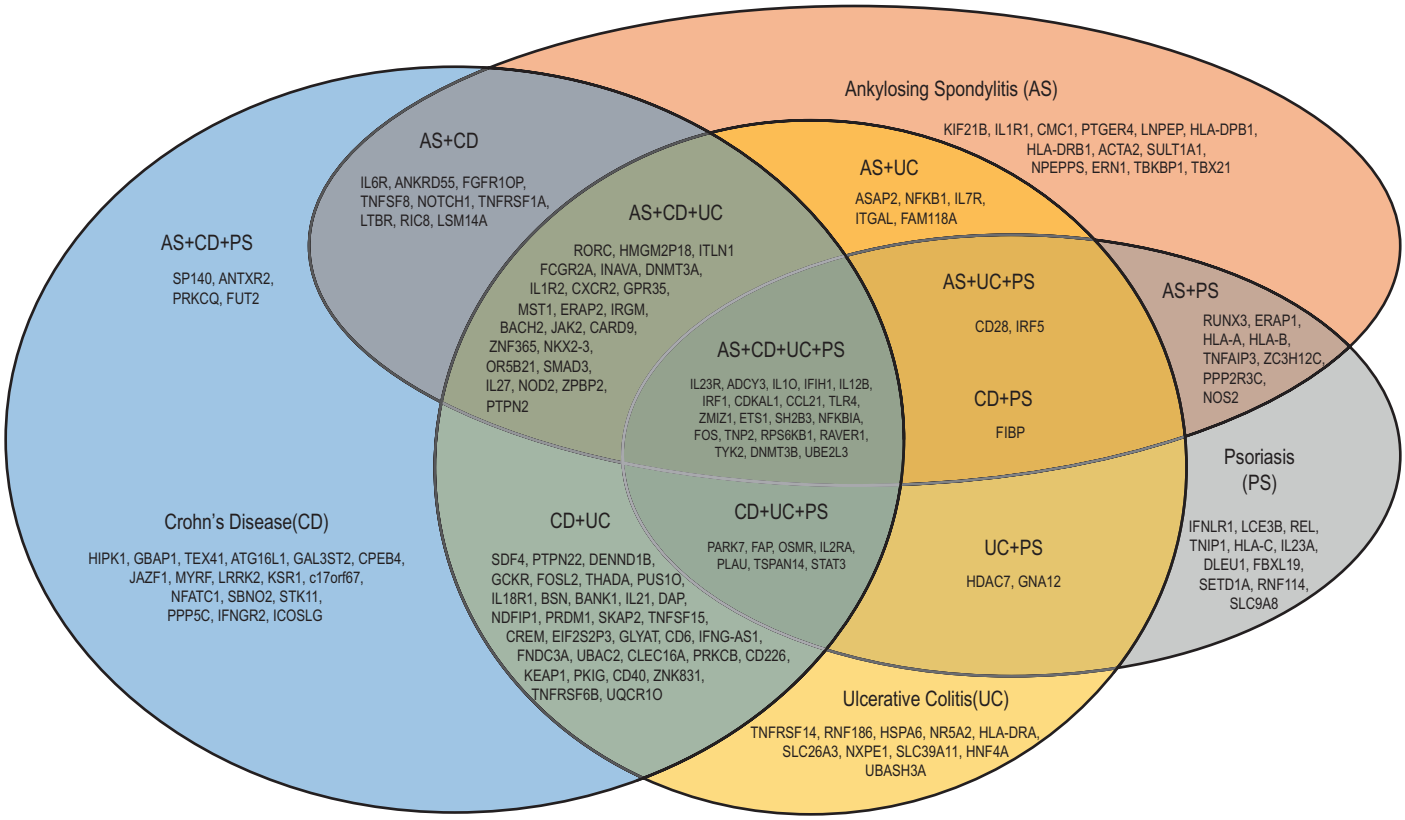

FIG. 58.3 Genetic factors implicated in spondyloarthritis. The Gut and Spondyloarthritis

Many studies have shown subclinical gut inflammation in SpA patients. Indeed, between 30% and 60% of patients with ReA, undifferentiated SpA and AS had evidence of histological gut inflammation.[23] These observations have raised the speculation that the inciting event in the SpA may be a breakdown of the gut–blood barrier to intestinal bacteria. Patients with AS and their relatives have increased intestinal permeability compared with healthy controls.

The bacterial population inhabiting human intestines, referred to as the gut microbiome (Chapter 23), is a vast microbial community. There is a beneficial relationship between the human system and the gut microbiome. The human gut provides the nutrients that the microbiome metabolizes to provide metabolites such as Vitamin K and short chain fatty acids, which have immunologic capacities and possibly affect the education of the adaptive immune system. The gut microbiome in patients with SpA is different compared to non-SpA populations. However, older studies implicating a role for gut *Klebsiella pneumonia* in the pathogenesis of SpA have been refuted.[13]

There does appear to be an interplay between host genetics (*e.g.*, HLA-B27) and intestinal bacterial composition. This suggests a link between dysbiosis and SpA, upsetting the homeostasis between the microbiome and the host immune systems.[24]

PATHOLOGY OF SPA

Few data exist from synovial or spinal tissues from early disease, and the difficulty with tissue access further complicates this.[25,26] The synovium in SpA has diminished lymphoid aggregates and displays a tortuous vascular morphology compared with the rheumatoid synovium. This may be caused by vascular endothelial growth factor (VEGF) and angiogenic growth factor Ang2, the messenger RNAs (mRNAs) of which have been observed at higher levels in the synovium in PsA compared with RA. VEGF is particularly interesting because it can synergize with RANK ligand (RANKL) to induce bone resorption and also synergize with bone morphogenetic proteins to trigger bone formation, both processes typical of the altered bone remodeling seen in PsA and SpA.[25,26]

Increased production of the scavenger receptor CD163 by macrophages in both the lining and sublining layers is seen in SpA compared with RA.[24] Local production of soluble CD163 inhibits synovial T-cell activation, and levels of synovial CD163 fall with effective treatment. Increased expression of Toll-like receptors 2 and 4 (TLR2, TLR4) has been shown in SpA on $CD163^+$ peripheral blood mononuclear cells in patients with synovitis, which decreases with TNF-α blockade. The interplay between the gut microbiome via the innate immune system appears to play a role in development of SpA. A number of mouse models have shown that SpA does not develop in germ-free environments. Bacteria invade the altered gut barrier, there is activation of TLRs and NF-κB, leading to release of cytokines such as IL-23, IL-1, and IL-6. This, in combination with CD4 T cells. appears to lead to pathogenic Th17 effector cells at sites of inflammation. Joint tissues in patients with SpA have shown lymphocytic infiltrates with IL-17A predominate expression.[27]

Pathological examination of enthesitis in AS demonstrates local inflammation, fibrosis, erosion, and ossification. Immunohistochemical staining for phosphorylated SMAD1/5 in entheseal biopsies of patients with SpA reveals active bone morphogenetic protein signaling.[25] Entheseal T cells are activated by systemic IL-23, leading again to increased IL-17 production.

The pathology of psoriasis consists of an inflammatory cell infiltration in the dermis, with localized increased cytokine production and hyperproliferation of keratinocytes (Chapter 65). CD4 cells are prominent in the dermis, CD8 in the epidermis; both mature T cells respond to peptides presented by antigen-presenting cells (APCs). Differentiation of type 1 (Th1) and type 17 helper T (Th17) cells is triggered in the dermis and multiple other sites, further triggering release of other chemokines. Th17 cells, osteoclast precursors (OCPs), and dendritic cells infiltrate joints from adjacent entheses or the bloodstream. These infiltrating cells express TNF, IL-17, and RANKL and in combination with the increased expression of RANKL by synoviocytes in the lining, leads to the differentiation of OCPs into osteoclasts. This leads to the pathological bone formation in PsA.[8] In addition, $CD14^+$ monocytes that are committed to becoming osteoclasts or osteoclast precursors are increased in the circulation of patients with PsA compared with healthy controls and decline rapidly following treatment with TNF antagonists.

Intracellular and extracellular signaling pathways are being discovered that are important in pathogenesis and therefore are targets for therapy. The Janus kinase (JAK) family of intracellular protein tyrosine kinases mediate signaling pathways of extracellular cytokines and growth factors involved in SpA (Fig. 58.4).

CLINICAL FEATURES

Ankylosing Spondylitis

Musculoskeletal Symptoms

KEY CONCEPTS

Clinical Features of Inflammatory Back Pain

- Low-back pain that is present every day for at least 3 months
- Age of onset <45 years
- Morning stiffness in the back lasting at least 30 min
- Pain that is relieved by exercise and worsened by rest
- Alternating buttock pain
- Relief with nonsteroidal anti-inflammatory drugs

The first symptoms of AS usually appear in adolescence or early adulthood. The hallmark of AS is the presence of inflammatory back pain.[3] Occasionally, the first symptom of AS comes from extraspinal sources, such as AAU, peripheral joint or hip arthritis, or enthesitis, especially in patients with disease onset in childhood.

In patients with AS, the most commonly affected joints outside the spine are the hips. Peripheral arthritis other than in the hips and shoulders is uncommonly seen in patients with AS but, when present, is typical of that seen in other types of SpA, with an asymmetric oligoarthritis presenting predominantly in the lower extremities.

Chest pain, often pleuritic, can be seen in patients with AS because of involvement of the costovertebral joints, with loss of chest expansion and a restrictive ventilatory defect.

Enthesitis is a classic feature of SpA (Fig. 58.5). The most common (and most disabling) sites for enthesitis are in the foot, at the insertion of the Achilles tendon, and of the plantar fascia onto the calcaneus.[28]

Physical measurements that have been validated and recommended by an ASAS Working Group as useful for evaluating patients with AS/AxSpA specifically and with inflammatory back pain in general include forward lumbar spinal flexion (the Schober test), lateral lumbar bending, chest wall expansion, and occiput-to-wall distance.

Extraarticular Manifestations

Uveitis. The anterior portion of the uvea consists of the *iris* and *ciliary body*, and the posterior portion is known as the *choroid*. Inflammation of the anterior uveal tract is known as *anterior uveitis* or *iritis* (Chapter 75). AAU represents the typical uveitis found in SpA, occurring in up to a third of SpA patients, depending on type of SpA and disease duration, most common in AS (20% to 30%).[29] Typically, AAU presents unilaterally with sudden onset, is self-limited, and tends to be recurrent. Symptoms may include redness, eye pain, blurred vision, increased lacrimation, photophobia, and miosis. The diagnosis is confirmed by slit-lamp examination, which is also useful in monitoring treatment responses.

Prognosis is favorable in AAU, with resolution of symptoms typically in 4 to 6 weeks. Although AAU is the most common uveitis associated with SpA, posterior uveitis has been reported, especially in those with coexistent IBD.[1]

Cardiac Manifestations. The characteristic cardiac abnormalities in AS are aortic regurgitation and conduction abnormalities. Less commonly associated cardiac conditions include pericarditis, ascending aortic aneurysm, aortitis, cardiomyopathy, and mitral valve disease. HLA-B27 is an important genetic risk factor for these cardiac conditions. Aortic insufficiency is estimated to occur in up to 34% of patients with AS, especially in greater disease duration.[30]

Cardiac conduction abnormalities, including atrioventricular and intraventricular blocks, are the most common cardiac complication in patients with AS, occurring in up to 9%.[30]

Pulmonary Manifestations. The prevalence of pulmonary involvement is highest (40% to 80%) with high-resolution computed tomography (CT) compared to x-ray or lung spirometry studies, and higher with longer disease duration,[30] although the patient may be asymptomatic. The most frequently recognized manifestations are upper-lobe fibrosis, mycetoma formation, and pleural thickening. The upper-lobe fibrosis may be progressive. Another common finding is the presence of bilateral symmetric apical

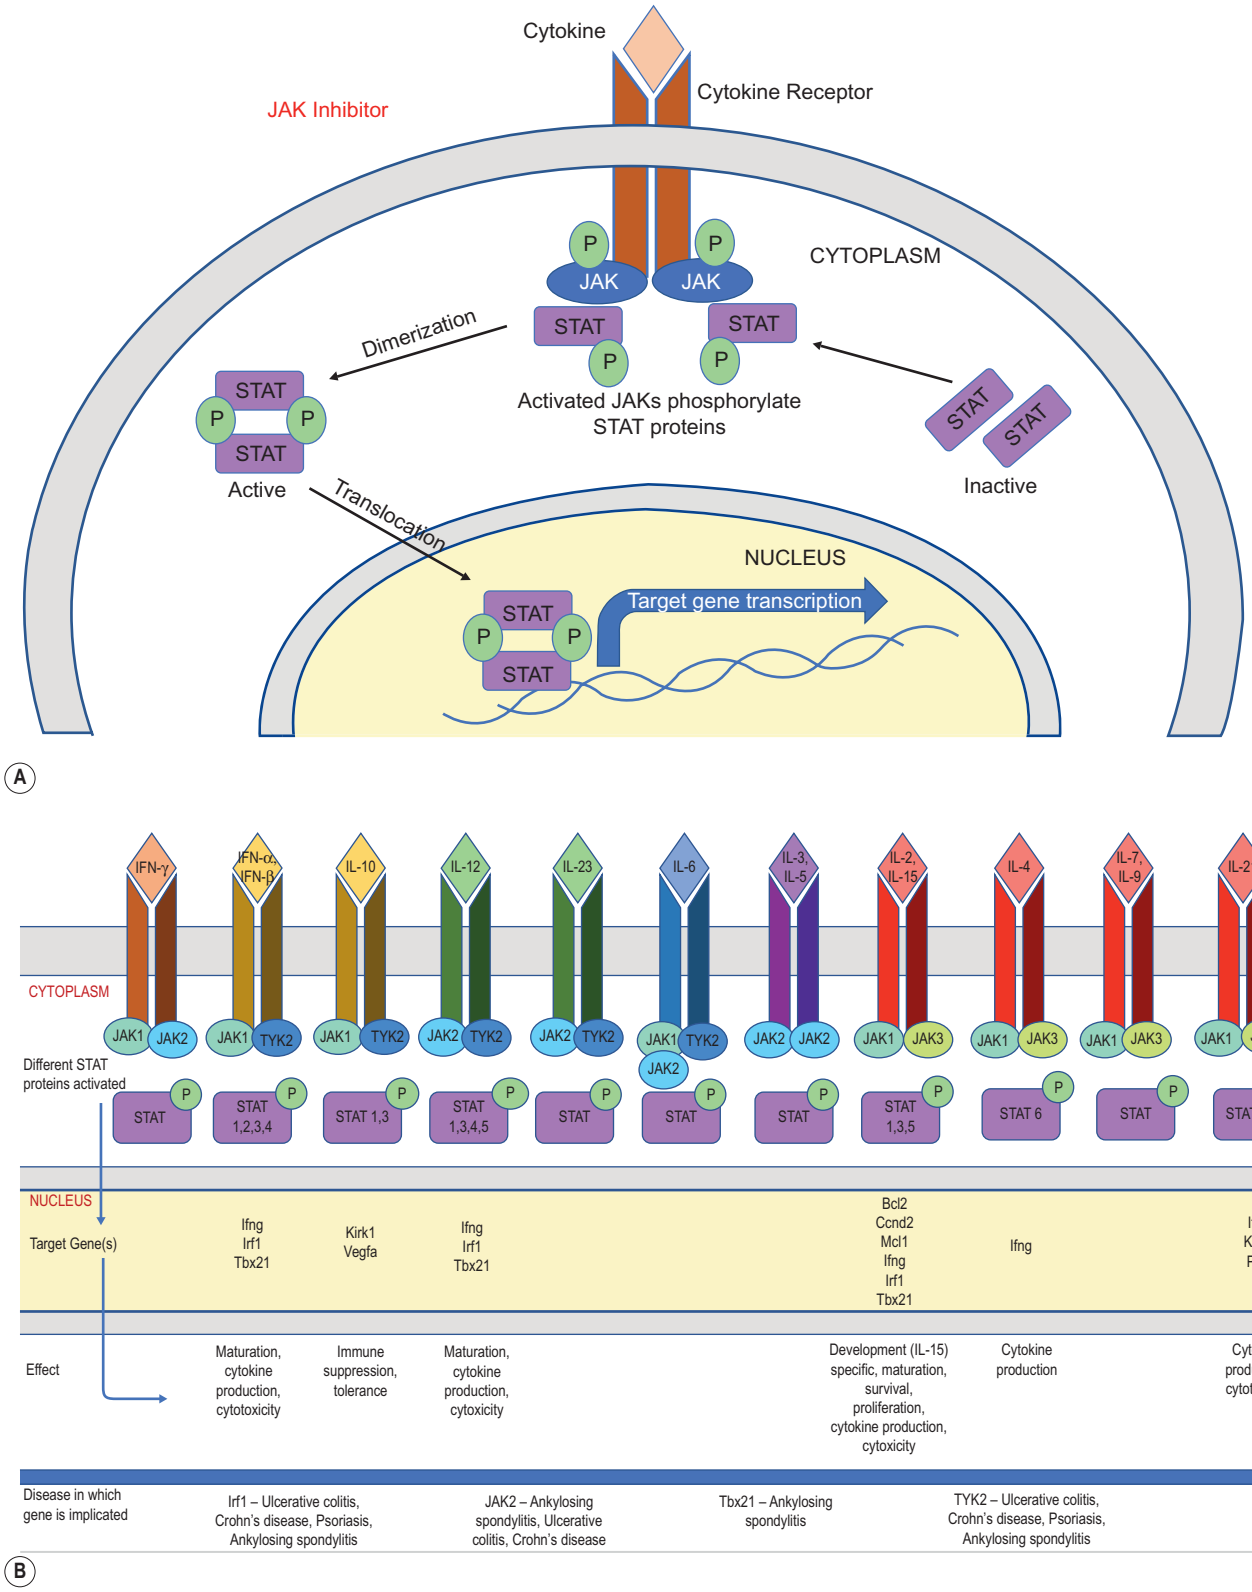

FIG. 58.4 JAK-STAT Pathway. (A) JAK-STAT signaling pathway: Receptor-associated JAKs that are activated by cytokines then autophosphorylate at the receptor subunit. This allows docking of STAT to the JAK, which is followed by phosphorylation of the STAT. The phosphorylated STATs then hetero- or homodimerize, translocate to the nucleus, bind promoter elements, and regulate transcription of target genes. (B) Cytokines signal through certain JAKs, then activating specific STATs. Genes are expressed depending on the JAK-STAT pathway, which then leads to effects. Some of the genes associated with SpAs are listed. (Adapted from Gotthardt D, Trifinopoulos J, Sexl V, et al. JAK/STAT cytokine signaling at the crossroad of NK cell development and maturation. *Front Immunol*. 2019.)

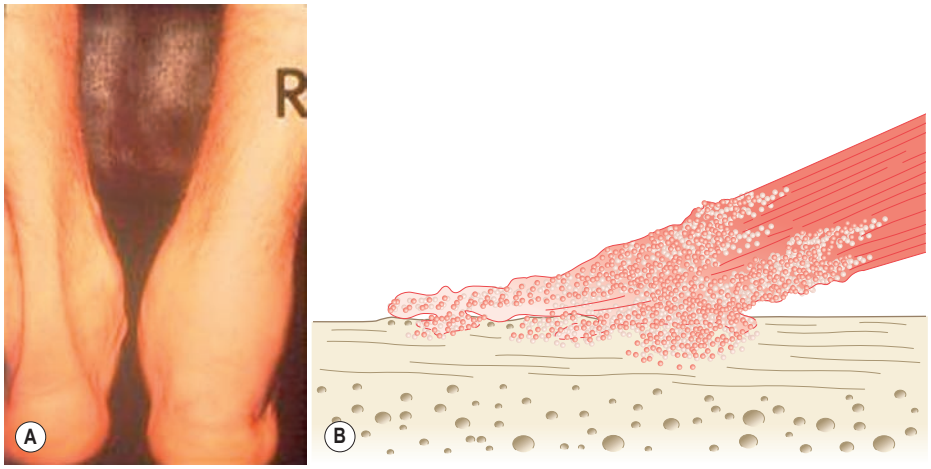

FIG. 58.5 (A) Achilles tendinitis/enthesitis in a patient with reactive arthritis. (B) Schematic drawing of enthesitis, showing periosteal new bone formation, and subchondral bone inflammation and resorption.

pleural thickening. Several recent studies have also shown an increased association with obstructive sleep apnea.[31]

Renal Manifestations. SpA patients have increased risk of renal complications. The most common is immunoglobulin A nephropathy, but other renal complications include secondary renal amyloidosis, NSAID nephropathy, nephrolithiasis, and glomerulonephritis.[32]

Osteoporosis. The prevalence of osteoporosis in AS varies between 11% and 34%.[33] Measuring bone mineral density in patients with spondylitis is complicated by false increases in spinal density from dense syndesmophyte formation, leading some to recommend quantitative CT over standard dual-energy x-ray absorptiometry (DEXA) for bone mineral density measurements, although the consensus is still to screen by DEXA.[46] Trabecular bone score (TBS) obtained from the spinal DEXA scan predicts major osteoporotic and spinal fractures in AS independent of Fracture Risk Assessment Tool (FRAX) score.[34] This has potential use for fracture prediction.[34]

Spondylodiscitis and Spinal Fractures. An uncommon but well-recognized complication of AS is spondylodiscitis, a destructive discovertebral lesion also called *Andersson lesion*. Typically, these lesions are confined to the thoracolumbar spine, sometimes with multiple-level involvement. Spondylodiscitis usually occurs at an advanced stage of AS under the form of an erosive condition related to both inflammatory, mechanical factors, and osteoporosis. The patient may or may not have a history of preceding trauma.

Even trivial falls can be catastrophic for AS patients, who are at risk for spinal fractures because of spinal rigidity and osteoporosis. The estimated prevalence of fractures in AS varies from 11% to 25%.[33] Fractures through the disk space, the weakest point in the ankylosed spine, are most common. The cervical spine is the most frequently affected region, followed by the thoracolumbar junction, and may or may not be complicated by spinal cord injury.

Neurological Manifestations. Neurological involvement in AS is most often related to spinal fracture or cauda equina syndrome. The cauda equina syndrome in AS is characterized by a slow insidious progression and a high incidence of dural ectasia, although a rapid onset secondary to a traumatic event has been reported. It tends to be a late manifestation of AS.[35] Patients with cauda equina syndrome present with a prodrome of sensory, motor, or reflex loss before progression to bowel or bladder incontinence. About half the patients have pain in the rectum or lower limbs that is presumably neurogenic in origin.

Fatigue and Psychosocial Manifestations. Fatigue and sleep disturbance are common in AS. Sleep disturbance is multifactorial, with age, anxiety, depression, nocturnal back pain, extra-spinal disease, and duration of delay in diagnosis all being important.[36] The prevalence of depression in AxSpA varies widely depending on the criteria used, ranging from 11% to 64%.[37] Depression is associated with worse disease activity, greater functional impairment, long-term smoking, and poor global health scores.[37]

AS in Women. There tends to be a greater delay in the diagnosis of AS in women. This may be in part due to higher incidence of nr-AxSpA in women,[13] with less radiographic damage and radiographic progression.[38] Women have a higher frequency of enthesitis, psoriasis, and IBD.[38] Studies have also shown higher disease activity but poorer response to TNFi treatment in women.[38] Women tend to have less severe involvement of the spine but more peripheral joint involvement. A large review of the impact of AS on reproductive events concluded that AS did not adversely affect the ability to conceive, pregnancy outcome, or neonatal health.[39]

Reactive Arthritis

The classic triad of arthritis, urethritis, and conjunctivitis, representing what was formerly known as *Reiter syndrome*, is a presenting feature of only a minority of patients with ReA (comprising only a third of the cases in some series). In ReA, the clinical features are viewed more as a spectrum ranging from the classic triad to undifferentiated SpA.

Typically, the features start 1 to 4 weeks after a triggering event, frequently an enteric or urogenital infection, but often the event passes unnoticed without any specific symptoms. The syndrome starts with constitutional symptoms, such as fatigue, malaise, and fever, followed by a sterile, asymmetrical, additive lower-extremity oligoarticular or monoarticular inflammatory arthritis. Upper-extremity involvement is less common. Dactylitis occurs in the toes or fingers, resulting in "sausage digits," which represent inflammation not only of the interphalangeal joints but also of the surrounding soft tissue structures, including tendons and subcutaneous tissue.

Sacroiliitis and spondylitis are less common than peripheral arthritis, although inflammatory back pain does occur.

Unilateral and bilateral sacroiliac involvement and even spondylitis occur, especially in those with chronic or long-standing disease. As with AxSpA, enthesitis is most common in the Achilles tendon and plantar fascia insertions, although tenderness over the symphysis pubis, iliac crest, ischial tuberosity, greater trochanters, and costochondral junctions may also occur.

Mucocutaneous lesions may be difficult to distinguish from psoriasis, especially circinate balanitis and keratoderma blennorrhagica. Circinate balanitis is an ulcerative mucosal lesion over the glans or shaft of the penis that is demarcated by a serpiginous erythematous border. Keratoderma blennorrhagica is a painless desquamative psoriatic-like papulosquamous eruption and is sometimes referred to as *pustulosis palmoplantaris* and occurs on the palms and soles of the feet. Oral lesions present as shallow, painless ulcers or patches on the palate and tongue or mucositis of the soft palate and uvula. Conjunctivitis and AAU also occur, as described in AS. Unilateral or bilateral conjunctivitis is usually an early feature manifesting with irritation, erythema, and lacrimation.

Juvenile Spondyloarthritis

JSpA usually manifests as enthesis and/or arthritis, otherwise known as seronegative enthesopathy and arthropathy (SEA) syndrome or enthesitis-related arthritis (ERA). Enthesitis is more common and can affect more sites than in adult SpA. Less commonly, JSpA can manifest as juvenile AS, psoriatic arthritis, reactive arthritis, and arthritis associated with IBD. Unlike adult SpA, spine or sacroilliac (SI) joint involvement is uncommon at presentation. Arthritis is typically more peripheral, apart from the hip, and the lower extremities tend to be more commonly affected. Tarsitis is unique to juvenile SpA and is inflammation of the intertarsal bones and overlying tissues, which causes midfoot pain and swelling. Involvement of the spine or SI joint can develop over 5 to 10 years.[40]

Psoriatic Arthritis

Skin involvement exhibits five clinical patterns (Table 58.5). Usually psoriatic arthritis occurs after onset of psoriasis, with a latency of 10 years on average,[7] although PsA can precede skin disease or occur simultaneously in 15% of patients.[8] The joint disease occurs in five different subtypes, as defined by the Moll and Wright classification (Fig. 58.6), including oligoarticular, polyarticular, distal interphalangeal (DIP)-predominant, axial or spondyloarthritis, and arthritis mutilans.[8] Oligoarticular PsA tends to be asymmetric, affecting four or fewer joints. Polyarticular PsA may be more symmetric and affects five or more joints. The distal subtype usually occurs with other subtypes but can occur alone in 5% of patients. Axial subtype affects the spine and SI joints. Arthritis mutilans is the deforming subtype with telescoping, flail digits, and marked bone resorption.[8] Enthesitis is encountered in 30% to 50% of patients. Acute or chronic dactylitis is reported in 40% to 50% of patients and is often associated with severe articular disease.[8] Extraarticular manifestations with nail disease including pitting or onycholysis is common, whereas uveitis is less common,[8] occurring in less than 10% of patients with PsA.[8]

TABLE 58.5 Skin Involvement in Psoriasis

Clinical Pattern of Skin Involvement	Description
Plaque	Most common type. Also called psoriasis vulgaris. Scaly erythematous plaques on the trunk and extensor surfaces
Inverse	Slightly erosive plaques in intertriginous locations
Guttate	Usually affects children or adolescents. Often triggered by group-A streptococcal tonsil infection
Pustular	Localized or generalized coalescing sterile pustules. Typically affects palms and soles
Erythrodermic	Most severe type, covering about 90% of the total body surface

From: Rendon A, Schäkel K. Psoriasis pathogenesis and treatment. *Int J Mol Sci.* 2019;20(6).

Enteropathic Arthritis

The arthritis associated with inflammatory bowel disease (IBD), called enteropathic arthritis, is most commonly nondestructive and reversible. Two patterns of peripheral arthritis have been recognized. Type 1 is pauciarticular, involving the knees and ankles more than the upper extremities. It tends to resolve in less than 10 weeks, may precede the diagnosis of IBD, runs parallel to intestinal disease, and is associated with HLA-B27, -B35, and -*DRB1*01:03*.[41,42] The second type has a polyarticular presentation, is more likely to involve the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints than the lower extremities, and is more likely to have a chronic course. It may run independent of intestinal disease and is associated with HLA-B44.[41,42] A third type has more recently been described, involving both peripheral and axial arthritis.[41] The symptoms of peripheral arthritis tend to coincide with activity of the bowel disease in ulcerative colitis (UC) but not Crohn disease (CD). Total colectomy is associated with remission of arthritis in half of patients. In contrast, axial involvement may precede the development of IBD, has no gender predilection, and resembles the development of AS. The axial symptoms do not parallel activity of IBD. In addition to spondylitis, an isolated sacroiliitis occurs that is often asymmetric and not associated with HLA-B27. Axial involvement is more common in patients with CD than those with UC.[41]

Mucocutaneous complications of IBD include erythema nodosum, which occurs in up to 15% of those with CD and up to 10% in those with UC, although other reports showed lower frequency[41]; pyoderma gangrenosum, more rare and severe, with a prevalence of less than 2% in IBD patients; and, rarely, erythema multiforme or Sweet syndrome.[41] Oral lesions, including painful aphthous ulcers, periodontitis, aphthous stomatitis, and pyostomatitis vegetans, can parallel underlying IBD.[42]

Episcleritis is the most common ocular manifestation associated with IBD and is more associated with intestinal disease activity than other ocular manifestations. Anterior uveitis in IBD patients is more often bilateral, insidious in onset, chronic, and does not parallel intestinal activity.[43]

Undifferentiated Spondyloarthritis

Patients who do not meet criteria or clinical features of the "classic" SpA are regarded as having undifferentiated SpA, accounting for about 40% of patients at presentation (Table 58.6).[44] Follow-up studies suggest that about one-third will go into remission over time and more than half will develop a "classic" SpA, usually AS.[44]

FIG. 58.6 Patterns of Psoriatic Arthritis. (A) Rheumatoid-like distribution; (B) sausage digits; (C) distal interphalangeal involvement; and (D) psoriatic arthritis mutilans.

CLINICAL RELEVANCE

Utility of Human Leukocyte Antigen (HLA)-B27 Testing in the Evaluation of Inflammatory Back Pain and Spondyloarthritis

- Not indicated where the diagnosis is unquestionable, as it has little value in prognosis.
- Although patients with SpA of African and Middle Eastern ancestry are often HLA-B27 negative, the finding of HLA-B27 in these patients has higher predictive value.
- Most useful in patients with either inflammatory back pain without radiographic changes or with other features of spondyloarthritis (unexplained lower extremity arthritis in a young adult, uveitis, etc.).

Measures of SpA Activity and Severity

In the past few years, outcome measures have been developed and validated to quantitate disease activity and severity; these are summarized in Table 58.7. These instruments are extensively validated and easy to administer in clinical practice and have been shown to perform well in clinical trials. There is no consensus on which are preferable to use.

Radiographic Imaging of Spondyloarthritis

Axial Spondyloarthritis

Radiographic AxSpA (AS) is the demonstration of sacroiliitis on plain radiographs (Fig. 58.7).[3] One problem with radiographic

TABLE 58.7 Measurements of Disease Outcome in Spondyloarthritis

Ankylosing Spondylitis

1) Disease activity
   (a) Bath Ankylosing Spondylitis Disease Activity Index (BASDAI)
   (b) Ankylosing Spondylitis Disease Activity Score (ASDAS)
   (c) Patient and Physician Global Assessments
2) Function
   (a) Bath Ankylosing Spondylitis Functional Index (BASFI)
   (b) Dougados Functional Index
3) Quality of Life
   (a) SF-36
   (b) Ankylosing Spondylitis Quality of Life Index (ASQOL)
   (c) ASAS Health Index
4) Metrometry
   (a) Schober test (lumbar flexion)
   (b) Chest expansion
   (c) Occiput-to-wall distance
   (d) Lateral bending
   (e) Bath Ankylosing Spondylitis Metrology Index (BASMI)
5) Imaging
   (a) Standard radiography, computed tomography, magnetic resonance imaging
   (b) Modified Stroke Ankylosing Spondylitis Spinal Score (mSASSS)
   (c) Bath Ankylosing Spondylitis Radiographic Index (BASRI)
6) Assessment in Ankylosing Spondylitis (ASAS) 20
   (a) An improvement of 20% and absolute improvement of 10 units on a 0–100 scale in three of the following four domains:
      i. Patient global assessment (by visual analogue scale [VAS] global assessment)
      ii. Pain assessment (the average of VAS total and nocturnal pain scores)
      iii. Function (represented by BASFI)
      iv. Inflammation (the average of the BASDAI's last two VAS concerning morning stiffness, intensity, and duration)
      v. Absence of deterioration in the potential remaining domain (deterioration is defined as 20% worsening)

Psoriatic Arthritis

1) Arthritis
   (a) ACR response criteria
   (b) Psoriatic Arthritis Response Criteria (PsARC)
2) Skin response
   (a) Psoriasis Area and Severity Index (PASI)
   (b) Target lesion score
   (c) Static global assessment
3) Quality of life (HAQ, SF-36, DLQI)
4) Radiographic
5) Composite measures
   (a) Psoriatic Arthritis Disease Activity Score
   (b) Composite Psoriatic Disease Activity Index
   (c) Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA) Composite Exercise (GRACE) instrument

imaging is that up to 10 years may elapse from the onset of inflammatory back pain to the appearance of radiographic sacroiliitis.[3] The introduction of MRI of the spine and entheses has allowed not only correct anatomical description of spinal structures but also differentiation of AS-related and unrelated inflammatory spinal lesions earlier than is possible with standard radiography.[45] MRI of the sacroiliac joints and spine is currently the only imaging tool to localize and quantify spinal inflammation accurately (Fig. 58.8) and is being developed as a measure of disease activity and treatment response.

Two outcome instruments have been introduced in the assessment of disease damage and progression in AS: the Bath Ankylosing Spondylitis Radiographic Index (BASRI) and the modified Stroke Ankylosing Spondylitis Scoring System (mSASSS) (see Table 58.7). As a rule, these instruments have a low sensitivity to change (7.5% over 2 years).

Psoriatic Arthritis

PsA has characteristic radiographic manifestations, including asymmetrical involvement, involvement of the DIP joints, and the classic "pencil-in-cup" deformities. Also seen are periostitis, bony ankylosis, and eccentric erosions with new bone formation. Radiographic severity is quantitated using different scoring methods: the modified Steinbrocker global scoring, the modified (from RA) Sharp/van der Heijde method, and PsA Ratingen score (PARS).[47]

There are a number of disease impact quantification methods used in assessing PsA (see Table 58.7).

DISEASE COURSE AND PROGNOSIS

Ankylosing Spondylitis

AS significantly impacts the lives of those affected. Patients with AS are more likely to be work-disabled, not participate in the labor force, and more likely to have never married or to be divorced. Women with AS were less likely to have had children.[49]

There has been some debate about whether non-radiographic-AxSpA is a self-limited form of AxSpA with a more favorable course, an early stage within the disease spectrum, or even a different disease.[48] Only about 5% of patients with early AxSpA change from nr-AxSpA to radiographic-AxSpA.[48] A recent study showed the incidence of peripheral and extra-articular manifestations of nr-AxSpA and r-AxSpA to be similar and with equivalent disease burden over 5 years of follow-up.[48]

Although AS is a chronic condition that can frequently have an unpredictable course, some studies suggest that those with higher levels of disease activity early in the course of the disease are more likely to have active disease in the future (Fig. 58.9).[49] Hip involvement is a predictive factor for severe disease.[45] Other factors that may suggest a worse outcome include ESR greater than 30 mm/h; unresponsiveness to NSAIDs; limitation of motion of the lumbar spine; dactylitis; oligoarthritis; or onset at less than 16 years.[49]

A growing body of data have shown that patients with AS are at risk for early mortality as a result of cardiovascular disease.[50] However, the impact of newer agents—such as anti-TNF and anti–IL-17 drugs—on the natural history of this disease remains to be seen.

Reactive Arthritis

Most cases tend to remit within 6 months of onset. For those that last longer than 6 months, this is considered a sign of development of chronic ReA.[51] An American study with 5 years of follow-up showed that one-third of patients fully recovered and two-thirds continued to have subjective complaints, with half of the total patients developing chronic arthritis.[51] In a Finnish study with 11 years of follow-up, 16% of patients had chronic arthritis. The majority of these patients were also HLA-B27 positive and some developed sacroiliitis.[51]

Psoriatic Arthritis

Deformities and joint damage occur in many PsA patients. Within the first 2 years of diagnosis, 47% of patients have bony erosions despite use of disease-modifying antirheumatic drugs (DMARDs). PsA is also associated with increased risk

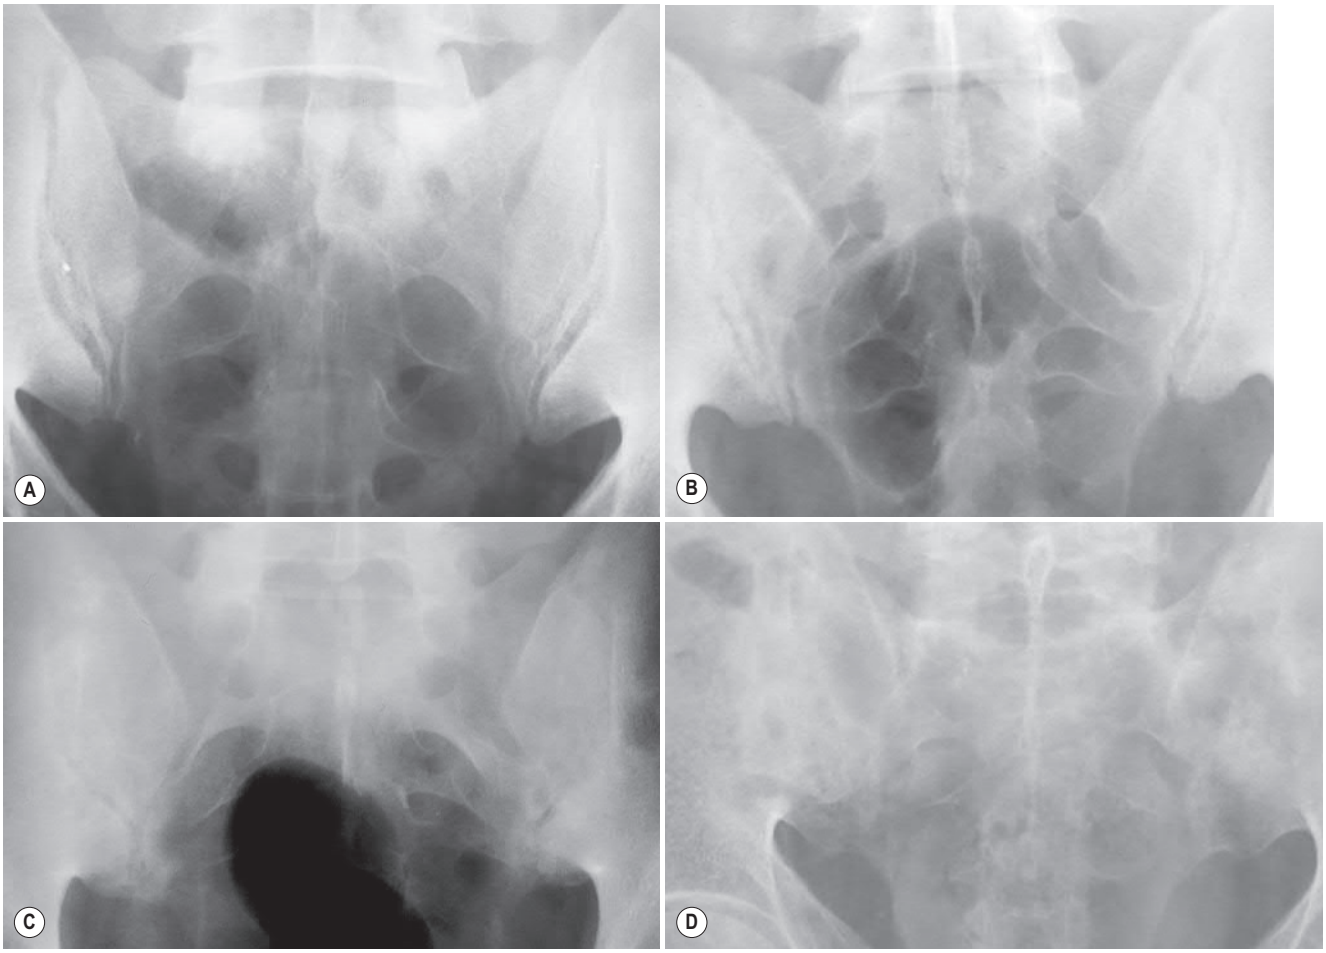

FIG. 58.7 Grading of Radiographic Sacroiliitis. (A) Grade 0–1 (normal); (B) grade 2–3, with sclerosis and small erosions; (C) advanced grade 3, with joint space narrowing and large erosions; and (D) grade 4 (total sacroiliac fusion).

of cardiovascular events, hypertension, diabetes, metabolic syndrome, and fatty liver. However, mortality rates have decreased and are now similar to the general population.[8]

Juvenile Spondyloarthritis

Although not extensively studied, the prognosis in JSpA is guarded.[40] Available data suggest that children with disease activity for greater than 5 years are more likely to be disabled. In fact, the probability of remission was only 17% after 5 years of disease. Nearly 60% of children with JSpA have moderate to severe limitation after 10 years of disease. What is not clear is the extent to which the outcome in juvenile-onset AS is different from that in adult-onset disease.

TREATMENT

Evidence-based recommendations have recently been updated for treatment of AS and nr-AxSpA by the American College of Rheumatology (Table 58.8).[46]

Patient Education and Physiotherapy

A great deal of educational information is available for patients (http://www.spondylitis.org and http://www.arthritis.org). Unsupervised recreational exercise improves pain and stiffness, and back exercise improves pain and function in patients with AS and other types of SpA, but these effects differ with disease duration. Health status is improved when patients perform recreational exercise at least 30 minutes/day and back exercises at least 5 days/week.

THERAPEUTIC PRINCIPLES

Treatment Principles for Medical Management of Spondyloarthritis

- Patient education, regular exercise, smoking cessation, and physiotherapy should be initiated early in the disease course.
- Nonsteroidal anti-inflammatory drugs (NSAIDs) remain the "first-line" treatment.
- Disease-modifying antirheumatic drugs (DMARDs: sulfasalazine) are used for peripheral arthritis.
- Intraarticular/intralesional corticosteroid injections are administered.
- Biological agents for axial disease refractory to NSAIDs, peripheral arthritis refractory to DMARDs, and entheseal lesions refractory to NSAIDs.
- It is important to remember to treat coexistent/complicating conditions (inflammatory bowel disease [IBD], psoriasis, osteoporosis, premature atherosclerosis).

Medical Treatment

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs remain the starting point of treatment, and many patients will attain satisfactory symptom control with these

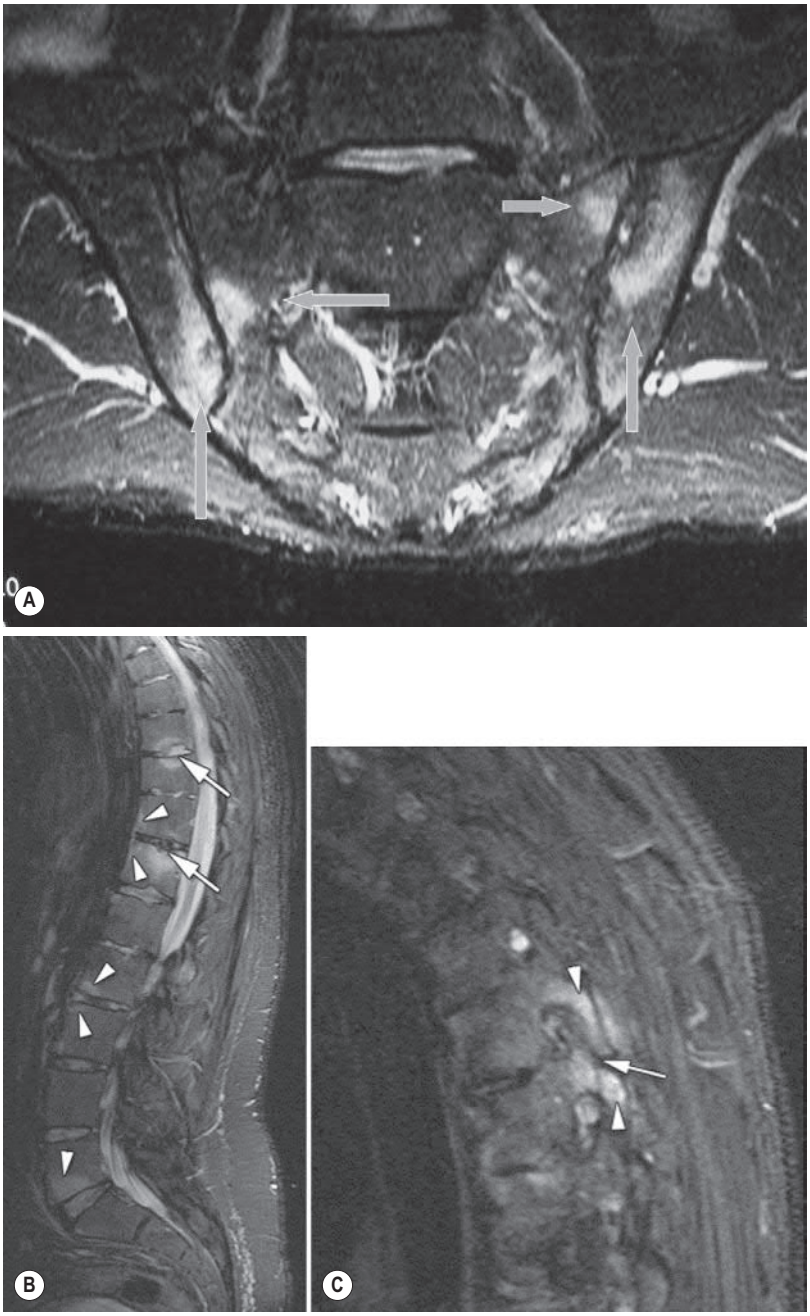

FIG. 58.8 (A) Magnetic resonance imaging (MRI) of the sacroiliac joints, showing areas of marrow edema (*indicated by arrows*) on STIR sequences. (B) Lateral spine, showing enhancement of the insertion of the annulus fibrosis on the disk (*arrowheads*) and subchondral bone (*arrows*). (C) Involvement of the subchondral bone of the apophyseal joints.

agents alone. There are no strong data to suggest the superiority of any specific NSAID in patients with SpA. There is inconsistent evidence that continuous NSAID use results in slower rates of radiographic progression over 2 years, compared to on-demand use of NSAIDs. As such, the new 2019 ACR/SAA/SPARTAN treatment guidelines conditionally recommend use of continuous treatment over on-demand treatment with NSAIDs for controlling disease activity in active AS.[46] COX-2 antagonists are recommended mainly for patients with proven peptic ulcer disease. Of concern is the association of the use of NSAIDs with flares of colitis, suggesting they should be used with care in this setting.

Disease-Modifying Anti-Inflammatory Drugs

DMARDs may be considered in patients whose peripheral arthritis is uncontrolled despite NSAIDs or when TNFi is not available.[46]

Sulfasalazine. The efficacy of sulfasalazine in the treatment of peripheral joint involvement in AS and other SpAs is well established. Coincident with improvement in peripheral arthritis is a fall in acute-phase reactants, such as the ESR and CRP. Most of the evidence to date shows there is little benefit for treatment of axial disease. Consideration may be given in patients with contraindications to or limited access to TNFi or biological agents or for those who decline treatment with biological agents.[46]

FIG. 58.9 The "Classic" Course of Ankylosing Spondylitis. Disease progression from shortly after disease onset in 1947 until just before the patient's death in 1973. The slight improvement between 1972 and 1973 was as a result of his having undergone total hip arthroplasties.

TABLE 58.8 Treatment of Spondyloarthritis

- Patient education
- Physiotherapy
- Medications
- Nonsteroidal anti-inflammatory drugs
- Disease-modifying antirheumatic drugs:
  - Sulfasalazine (especially for peripheral arthritis)
  - Methotrexate (especially for peripheral or psoriatic arthritis)
  - Apremilast (especially for psoriatic arthritis)
  - Abatacept (especially for psoriatic arthritis)
- Corticosteroids:
  - Systemic
  - Intraarticular, intralesional
- Biological agents:
  - Tumor necrosis factor blockers
  - Interleukin (IL)-17 blockers
  - Interleukin (IL)-12/23 and (IL)-23 blockers or (IL)-12/23 blockers
  - Janus kinase inhibitors
- Treatment of osteoporosis
- Surgery
- Hip replacement
- Corrective spinal surgery

Methotrexate. Although less well studied than sulfasalazine, methotrexate has been shown to be effective in some studies of peripheral arthritis and psoriasis in patients with AS and other SpA. Its efficacy in treating axial SpA has not been established.

Other DMARDs. For AS, leflunomide, apremilast, and thalidomide are not recommended.[46] Apremilast (an oral phosphodiesterase 4 inhibitor) and abatacept (selectively modulates T-cell activation) have been shown to be effective in psoriatic arthritis but not in AS.[52]

Corticosteroids. Although not well studied in patients with AS, many clinicians add low-dose glucocorticoids to the management of active SpA where NSAIDs or DMARDs fail to achieve a satisfactory response. On occasion, pulse steroids have also been utilized. Given the lack of controlled data as to their effectiveness, the side effects of long-term glucocorticoid therapy (including osteoporosis, a major cause of morbidity in AS patients, and possible worsening of psoriasis), and the emergence of more effective treatments, their use is not recommended unless more effective treatments are not available.

Intraarticular/Intralesional Corticosteroids

Intraarticular and peritendinous injections of depot steroid preparations are frequently employed by clinicians for symptomatic relief of local flare-ups, although they have not been extensively studied in controlled trials. Injecting around the Achilles or patellar tendons is generally not recommended because of the risk of tendon rupture.

Antibiotics

There is no convincing evidence that treatment of gastrointestinal infection alters the course of ReA, although antibiotic therapy may be warranted in severe bacterial GI infection. Benefits shown in one trial of antibiotics in *Chlamydia*-induced ReA have not yet been confirmed.[53] Overall, there is little evidence that antibiotics have a place in the management of ReA or other SpA.

Tumor Necrosis Factor-α Blockers

This category of medications has been shown to be effective in controlling inflammation and improving function in patients with AS (Table 58.9). Currently five TNFi agents have been approved for use by the Food and Drug Administration (FDA) for the treatment of AS in the United States: infliximab, an infusion of a chimeric mAb to TNF-α (infliximab) at 5 mg/kg of infliximab every 6 to 8 weeks; etanercept, given 50 mg subcutaneously weekly; adalimumab, which is used at a dose of 40 mg administered subcutaneously every other week; golimumab, at a dose of 50 mg administered subcutaneously monthly or 2 mg/kg intravenously every 8 weeks; and certolizumab, at either 200 mg administered subcutaneously every other week or 400 mg once a month. The onset of action is quite rapid, usually following the first infusion or injection. There is no evidence to support use of one TNFi over another for musculoskeletal disease, although adalimumab and infliximab are recommended over etanercept for the treatment of patients with AS with recurrent uveitis. Etanercept is also not approved for use in Crohn disease or ulcerative colitis, so the use of another TNFi would be a better choice for patients with AS and coexisting IBD.[46] These agents are effective also in PsA and nr-AxSpA.[46] Improvement was seen not only clinically but also radiographically, with improvement of lesions suggestive of disease activity on MRI, and, in studies extending greater

TABLE 58.9 2016 Update of the ASAS-EULAR Recommendations for Use of Biological Therapy in Axial Spondyloarthritis[a]

1. For the initiation of biological therapy:
   (a) A diagnosis of definitive AxSpA by a rheumatologist.
   (b) Elevated CRP, the presence of inflammation on MRI of the SI joints and/or spine, or the presence of radiographic sacroiliitis (according to modified New York criteria).
   (c) Presence of refractory disease defined by:
      (i) All patients: failure of at least 2 NSAIDS over 4 weeks in total.
      (ii) Patients with predominant peripheral manifestations: failure of one local steroid injection if appropriate or failure of therapeutic trial of sulfasalazine.
   (d) High disease activity with either ASDAS ≥ 2.1 or BASDAI ≥ 4.
   (e) Favorable opinion of the rheumatologist that benefit outweighs the risk, including considering potential contraindications to biological therapy.
2. For the monitoring of biological DMARD: both the BASDAI and the ASAS core set for clinical practice should be followed regularly
3. For the continuation of biological DMARD, consideration should be made after 12 weeks' treatment. Response is defined as improvement when:
   (a) ASDAS improvement ≥1.1 or BASDAI improvement ≥ 2 (0–10),[b] and
   (b) Rheumatologist opinion that treatment should be continued.

[a]van der Heijde D, Ramiro S, Landewe R, et al. 2016 update of the ASAS-EULAR management recommendations for axial spondyloarthritis. *Ann Rheum Dis.* 2017 Jun;76(6):978–991.
[b]Either ASDAS or BASDAI can be used but needs to be the same measure per patient.
ASDAS, Ankylosing Spondylitis Disease Activity Score; *AxSpA*, axial spondyloarthritis; *BASDAI*, Bath Ankylosing Spondylitis Disease Activity Index; *MRI*, magnetic resonance imaging; *SI*, sacroiliac; *NSAIDs*, nonsteroidal anti-inflammatory drugs.

than 4 years, slowing progression on standard radiographs, especially in those with shorter disease duration treated for an extended period.[54]

Interleukin-17 Blockers

Secukinumab and ixekizumab are anti–IL-17A monoclonal antibodies that have been shown to control the symptoms of active AS and PsA, and both have been approved by the FDA. The impact of these medications on other disease features, such as radiographic progression, remains to be determined. IL-17 blockers may be considered if TNF blockers are contraindicated such as in congestive heart failure (CHF) or demyelinating disease. Both medications have been associated with new onset or exacerbation of inflammatory bowel disease.[46]

Interleukin-12/23 Blockers

Ustekinumab is an IL-12/23 inhibitor that has been approved for treatment of psoriasis, PsA, and IBD. Tildrakizumab, risankizumab and guselkumab are IL-23 inhibitors which have shown benefit in PsA, although their efficacy in AxSpA has not been demonsrtated.[52]

Janus Kinase Inhibitors

Tofacitinib is an oral JAK inhibitor that may be another option in axial disease. Phase III study results are not available, but a phase II study showed benefit in clinical and radiographic changes in axial disease over 12 weeks.[46] Tofacitinib has been FDA approved for psoriatic arthritis and moderately to severely active ulcerative colitis. A number of other JAK inhibitors are being examined in the treatment of AxSpA.

Surgical Treatment of Ankylosing Spondylitis Complications

Because the hip is the joint most commonly involved in patients with AS, total hip arthroplasty is the most common surgical procedure.[55] Heterotopic new bone formation may be a potential problem.

Limited prevalence data suggest that patients with AS, even those with mild disease, are at increased risk for vertebral fracture, often resulting in neurological compromise.[56] Surgical options vary depending on acuity of fracture or dislocation and if there are neurological signs. In general, custom-fitted halo vest immobilization is recommended. Posterior fixation with or without laminectomy and anterior grafting if there is a severe bone gap may be necessary depending on the acuity and severity, but wedge osteotomies are typically considered first if possible. The fixed kyphotic deformities seen in patients with advanced AS are of considerable distress to patients and may result in substantial functional impairment. Indications for cervical extension osteotomy are the loss of horizontal gaze or the onset of breathing and eating difficulties due to stiff kyphosis.[57]

CONCLUSIONS AND RESEARCH OPPORTUNITIES

ON THE HORIZON

Research Opportunities in Spondyloarthritis

- Improved understanding of pathogenic mechanisms of spondyloarthritis (SpA)
- Elucidation of the roles of non–major histocompatibility complex (MHC) genes in SpA
- Definition of the link between gut microbiome and ankylosing spondylitis (AS)
- Improved measures of treatment outcomes
- Advances in biological therapies of SpA

Progress has been made in the classification and epidemiology of SpA, particularly in the elucidation of the factors involved in SpA pathogenesis. It has become clear that HLA-B27, followed by ERAP1 and IL-23R, are important genetic risk factors in SpA but are not sufficient alone to cause disease. GWAS and whole-genome sequencing continue to identify susceptibility genes for SpA, including those in the antigen processing and Th17 pathways, some of which are shared by some or all SpA and others that are specific for a given disease.

This continues to open doors for new treatment strategies, including IL-12/23 or JAK inhibition. However, why IL-12/23 or IL-23 inhibition is an ineffective target in AS is not understood and means further studies on the IL-23–IL-17 axis are needed. Further research may help to give a broader choice of therapies for SpA patients.

The link of gut inflammation to the triggering of AS is strongly suggested by data thus far, especially its possible link to the gut microbiome. How inflammation and the gut microbiome contribute to SpA pathogenesis is insufficiently understood.

Continued improvement in imaging techniques and specificity, early diagnosis of SpA, understanding pathological difference in nr-AxSpA and r-AxSpA, development of biomarkers, and understanding relationship between axial and peripheral disease are some of the many important unmet needs.[52] Understanding these in combination with the advances in treatment hold promise for a better future for patients with these diseases.

Small- and Medium-Vessel Primary Vasculitis

Raashid Ahmed Luqmani, Tamir Malley, Ana Águeda and Lorraine O'Neill

Small- and medium-vessel vasculitides are characterized by inflammation of the blood vessel wall, resulting in end organ failure or irreversible tissue damage and necrosis. In some cases, this is relatively trivial and may lead to minor inconvenience for the patient. However, in many forms of vasculitis, the consequences of rapid onset of ischemia and occlusion of blood vessels are devastating, leading to organ failure and death.

The distinction between small- and medium-vessel vasculitis entities is arbitrary, with three main patterns of vasculitis: small, medium, and large. Although there is merit in this classification, there are different patterns of involvement for patients with predominantly small-vessel involvement (characterized by capillaritis) compared with—but overlapping with—patients with medium-vessel involvement typified by small arteriolar inflammation. For example, in the kidney, small-vessel involvement leads to inflammation of glomeruli (glomerulonephritis); by contrast, medium-vessel inflammation of renal arterioles results in infarction of the kidney with tissue loss. Therefore, patterns of disease are well recognized, with typical dominance of kidney, lung, and upper airway involvement in patients with granulomatosis with polyangiitis (GPA), previously termed Wegener's granulomatosis. In microscopic polyangiitis (MPA), there is lack of upper airway involvement but significant renal and lung involvement. Finally, in eosinophilic glomerulonephritis with polyangiitis (EGPA), previously termed Churg-Strauss syndrome, the pattern of clinical involvement is dominated by upper and lower airway disease combined with neurological (peripheral nerve) features. These three entities are grouped together by their association with the presence of antineutrophil cytoplasmic antibody (ANCA) in most, but not all, cases.

In patients with polyarteritis nodosa (PAN), one of the main forms of medium-vessel vasculitis, the most characteristic findings are bowel ischemia or infarction and peripheral neuropathy. In a childhood onset form of medium-vessel vasculitis (Kawasaki disease [KD]), the clinical features are diverse and include mucocutaneous inflammation and systemic upset with fever, and in 2% to 4% of cases, there is coronary artery dilatation and/or aneurysm development, which can potentially rupture, leading to fatal consequences.[1]

The diversity of different forms of vasculitis with overlapping features suggests that the underlying mechanisms are varied, but some pathways are likely to be shared. This is reflected in treatment approaches, which—with some exceptions—are often very similar across diseases. Disease relapses can occur in up to 55% of patients within the first 3 years of achieving remission with on-going persistent risk of relapse. In addition, within the first 6 months of remission-induction therapy, many patients fail to achieve remission due to persistent or recurrent active ANCA-associated vasculitides (AAV).[2] This can lead to repeated high doses of immunosuppressive therapy, thus increasing the risk of adverse effects.[3]

EPIDEMIOLOGY

Despite improvement in our understanding of the epidemiology of the systemic vasculitides, patients are often not diagnosed as having vasculitis for extended periods. The discovery of ANCA and their association with small-vessel vasculitis has improved recognition.[4] Greater awareness of vasculitis may be a factor that explains an apparent increase in incidence from 1.5 to 6.1/million per year.[5] AAV have an incidence of 20 per million new cases per annum (GPA nine per million, MPA 9 per million, EGPA 2 per million), a prevalence of 200 per million and an average age of onset of 60 to 70 years.[6] In southern Europe, the number of cases of MPA is greater than those of GPA. MPA is also more common than GPA in Japan. ANCA directed against myeloperoxidase (MPO) is the predominant antibody detected in patients with AAV in Japan, whereas autoantibodies directed against proteinase 3 (PR3) are rarely seen in Japanese patients but are the most frequent ANCA antibody in patients in northern Europe.

The epidemiology of EPGA is less well understood compared with other forms of AAV. EGPA is characterized by an elevated eosinophil count in patients with late-onset asthma. Around 50% of cases have ANCA, usually directed against MPO. There is a potential overlap condition called *hypereosinophilic syndrome* (HES), and it is not clear whether some cases of HES are really cases of EGPA, or vice versa. Indeed, if patients are ANCA-negative, distinguishing the two conditions can be challenging.[7] Furthermore, because bronchospasm is a key feature of EGPA, it is possible that some cases of asthma, an extremely common condition, may, in fact, represent mild forms of EGPA. This has been brought more to light in cases of drug-induced EGPA, specifically in the setting of the use of montelukast, a leukotriene inhibitor, as a treatment for moderate to severe asthma. It has been suggested that these patients probably had underlying EGPA, which had previously been suppressed with systemic glucocorticoids, but when these were withdrawn, features of EGPA became more apparent.

AAV typically affects older individuals in their 60s or 70s, but can occur at any age. Most patients survive their initial illness as a result of effective immunotherapy, and therefore the prevalence of these diseases is growing. In southern Sweden, estimates of prevalence are 160 per million (95% confidence interval [CI] 114 to 206) for GPA, 94 (58 to 129) for MPA, 31 (11 to 52) for PAN, and 14 (0.3 to 27) for EGPA.[8] However, these are based on a relatively small population size and are higher than those reported from a Spanish series, where the prevalence of all forms of AAV was under 45 per million.

The two main forms of medium-vessel vasculitis are PAN and KD. PAN is extremely rare. There is very wide misconception among many physicians that PAN is the most common form of vasculitis, and this is partly encouraged by the older literature, which refers to all forms of vasculitis as PAN (initially called *periarteritis nodosa* and subsequently *polyarteritis nodosa*). In fact, most patients with so-called PAN probably did not have this disease but were more likely suffering from one of the forms of small-vessel vasculitis, particularly MPA and GPA. PAN has been associated with infection, especially hepatitis B and hepatitis C. The epidemiology of hepatitis B has been transformed by effective immunization; as a result of this, hepatitis B associated with PAN is now a rare disease. Recent figures suggest an incidence of PAN of 0.6 to 3.6 per million adults.[9]

KD is most common in children under the age of 5 years, but can occur in older children and young adults, in which case it is more difficult to diagnose because it is not suspected. In a recent Italian study of children under the age of 14 years, the incidence rate was 17.6/100,000 children under the age of 5 years, with a slight increase in reported cases during spring and winter compared with other times of the year. This is a slightly higher incidence rate than previously reported by other studies in Europe with a range of 3.6/100,000 to 15.2/100,000 children under the age of 5 years. Earlier figures from a large-scale study from the United States of over 6000 children admitted to the hospital because of KD suggested that the peak age of onset was 1 year, and children under the age of 2 years accounted for over a third of all cases. The under-5-year incidence was reported as 8.1/100,000 children in 1988, rising to 18.5/100,000 children in 1997, similar to the recent Italian experience. Males were more commonly affected than females (~60% males); there was no obvious seasonal variation. In a recent nationwide hospital survey in Japan, however, the incidence rates for KD during 2011 and 2012 were over 2400 cases per million children under the age of 5 years. The higher incidence of KD in patients of Japanese ethnicity appears to be independent of their geographical location. In fact, during 1996 to 2006, the average annual incidence of KD in Japanese American children in Hawaii was 210.5/100,000 children, in contrast to the rate for Caucasian children in Hawaii of 13.7/100,000, similar to the rate of 12.0/100,000 among Caucasian children in the continental United States.[10]

Leukocytoclastic skin vasculitis is one of the more common forms of small vessel vasculitis occurring with an annual incidence of about 45 per million (Table 59.1).[11] Less than a third is found in association with immunoglobulin A (IgA; Henoch-Schönlein purpura [HSP], or IgA vasculitis). IgA vasculitis is very common in children and is usually self-limiting; annual incidence is 100 to 200/million children ≤17 years of age or younger.[12] By contrast, this is a much less common disease in adults (around 13/million per year).

Cryoglobulinemic vasculitis is strongly associated with hepatitis C, and its epidemiology is likely to mirror the prevalence of the hepatitis C virus (HCV) infection. However, there are no published incidence and prevalence figures for cryoglobulinemic vasculitis itself.

TABLE 59.1 Diagnosis, Incidence and Prevalence in KD, PAN, AAV and Leukocytoclastic Vasculitis

Diagnosis	Incidence	Prevalence	References/ Reviews
KD	For children <5 years old: 2431/million (Japan) 1131/million (Korea) 690/million (Taiwan) 36–185/million (Italy)	Not applicable	Suka et al.[96]
PAN	3.6/million adults	2.6–14/million adults	Nesher et al.[5] Mohammad et al.[4]
AAV	9.5–16/million/year (Germany) 22.6/million (Japan) 21.8/million (UK)	149/million	Reinhold-Keller et al.[10] Herlyn et al.[11] Fujimoto et al.[94]
Leukocytoclastic vasculitis	45/million (equal male and female; increased incidence with age)	No data	Arora et al.[7]

AAV, ANCA-associated vasculitis; *ANCA*, antineutrophil cytoplasmic antibody; *KD*, Kawasaki disease; *PAN*, polyarteritis nodosa.

KEY CONCEPTS

Pathogenic Mechanisms in Antineutrophil Cytoplasmic Antibody-Associated Vasculitides

- The recognition of an association between some forms of vasculitis and the presence of ANCA has transformed understanding of the group of diseases considered to be associated with ANCA and in which ANCAs are suspected to have a pathogenic role.
  - GPA.
  - MPA.
  - EGPA.
- A genome-wide association study (GWAS) has demonstrated strong associations with specific alleles.
  - Anti-proteinase 3 ANCA with specific HLA-DP alleles and alleles encoded by genes for α_1-antitrypsin and proteinase 3.
  - Anti-myeloperoxidase ANCA with specific HLA-DQ alleles.
- Environmental factors.
  - Silica exposure.
  - Specific strains of *Staphylococcus aureus*.
- Immune dysregulation.
  - Defective regulation of T-cell immunity.
  - Neutrophil generation of extracellular traps (NETs) containing proteinase 3 and myeloperoxidase.
  - Activation of alternative complement pathway by ANCA-activated neutrophils.

PATHOGENESIS OF ANTINEUTROPHIL CYTOPLASMIC ANTIBODY-ASSOCIATED VASCULITIDES

The Pathogenic Role of ANCA in GPA and MPA

There is some evidence that ANCA play a role in the pathogenesis of GPA, MPA, and EGPA. Based on the immunofluorescence pattern, different forms of ANCA can be distinguished, but only

two are of direct clinical relevance: cytoplasmic c-ANCA (corresponding to antibodies directed against PR3 and perinuclear p-ANCA (predominantly corresponding to antibodies directed against MPO). p-ANCA can also be directed against other antigens, including bactericidal/permeability-increasing (BPI) protein, lactoferrin (LF), human neutrophil elastase (HNE), cathepsin G, and azurocidin, but their clinical significance is not well characterized. Although ANCAs are associated with vasculitis, titers are not reliable for monitoring disease status because there is no clear relationship with remission or relapse.

Transfer of MPO-ANCA in humans (maternal–fetal route) and animal models (necrotizing pauciimmune glomerulonephritis after passive transfer of purified antibody or splenocytes from MPO-deficient mice immunized with purified murine MPO) has resulted in features typical of MPA.[13] By contrast, the pathogenicity of antiPR3 antibodies is less well established. In one animal model of autoimmune-prone nonobese diabetic (NOD) mice, immunization with recombinant mouse PR3 (rmPR3) in complete Freund's adjuvant (CFA) had no clinical effect but resulted in high levels of circulating c-ANCA; transfer of splenocytes from these immunized animals into mice with severe combined immunodeficiency (SCID) resulted in vasculitis and severe segmental and necrotizing glomerulonephritis.[14] Transfer of splenocytes from the CFA-alone-immunized mice (controls) resulted in no disease, further suggesting that disease development depends on PR3-specific immune responses. In a second model of PR3-ANCA vasculitis, based on animals with a human–mouse chimeric immune system,[15] more than 70% of mice treated with IgG from patients with antiPR3 AAV (as compared with IgG from patients with non-vasculitic renal disease; or healthy controls) developed mild kidney disease with glomerular hypercellularity and focal pulmonary hemorrhage. Fifteen (83%) mice treated with antiPR3 IgG later showed mild kidney disease with glomerular hypercellularity, and 3 (17%) had severe glomerular injury. In the lungs, 13 (72%) showed areas of focal pulmonary hemorrhage, whereas lungs of the control group ($n = 8$) appeared normal ($P < .01$). There were no granulomatous lesions, but because granulomatous lesions are dependent on a robust T-cell–mediated response, the authors argued that a refinement of the model to include greater levels of chimerism and administration of interleukin-7 (IL-7)–Fc protein to augment T-cell development would be required to study this.[15]

Even though these studies strongly support a pathogenic role for ANCA, conventional serological assays fail to detect ANCA in some patients with classic clinical and pathological features of AAV, and titers do not correlate well with disease activity. Roth et al. examined MPO epitopes specificities,[16] reporting 25 different epitopes bound by anti-MPO antibodies; although some epitopes were associated with active disease, others were either not specific to active disease or not associated with disease at all. Igs purified from patients with ANCA-negative vasculitis could bind to a specific MPO epitope. Furthermore, the absence of ANCA in some patients could be explained by competitive binding to a fragment of ceruloplasmin (CP), the natural inhibitor of MPO. This CP fragment decreased anti-$MPO_{447–459}$ autoantibody reactivity by 30% to 50%, whereas full-length CP did not have any effect.[16] ANCAs are reported in small numbers of healthy individuals. How the pathogenic transformation of ANCA occurs is still unclear, but it is probably a multifactorial process requiring a complex interaction among genetics, the environment, and the immune system facilitating a break in immune tolerance.

GENETICS

There has been significant progress in the understanding of AAV genetics following the publication of two GWAS.[17] The strongest human leukocyte antigen (HLA) association is with the HLA-DPB1 haplotype, especially for the PR3-ANCA–positive subgroup, regardless of the clinical diagnosis.[18] Further analysis has revealed an association between MPO-ANCA and a single nucleotide polymorphism (SNP) in the HLA-DQ region, which had probably been masked previously as a result of the small number of MPO-ANCA–positive patients included in initial analyses. Other HLA associations are reported, such as HLA-DRB1*09:01 and HLA-DQB1*03:03 in Japanese patients with MPA. Less robust findings, not replicated in other studies, include a protective effect of HLA-DR13(6) and HLA-DR1, but an increased proportion of HLA-DR4 in Dutch patients with GPA compared with controls[18]; HLA-DRB1 in PR3-ANCA-positive (but not MPO-ANCA) patients[18]; HLA-B50, HLA-DR1, HLA-DR9, HLA-DQw7, and HLA-DR3 in GPA.[18] In EGPA, the most robust association is with HLA-DRB4. Overall, there is evidence for genetic susceptibility to AAV, related to specific SNPs in the HLA region. Other genetic associations with GPA include *PRTN3, SERPINA 1, PTPN22*, and *CTLA4*.

PR3 is either stored in neutrophil azurophilic granules or exposed on the cell membrane (where it can interact directly with ANCA). Although the proportion of neutrophils displaying membrane PR3 ($mPR3^+$) is stable over time, surface expression of PR3 may be enhanced. The percentage of $mPR3^+$ neutrophils is genetically determined. Schreiber et al. showed that among 125 healthy controls, 35 patients with GPA, 15 patients with other inflammatory diseases, and 27 pairs of monozygotic (MZ) and dizygotic (DZ) twins, the percentage of $mPR3^+$ neutrophils correlated significantly in MZ twins (but not in DZ twins) and the heritability percentage was estimated as 99%. Furthermore, the absolute number of PR3 molecules expressed on the cell membrane was correlated among MZ (but not DZ) twins, with a heritability estimate of 96.7%.[18] Following neutrophil activation and enzyme release, PR3 can mediate direct tissue damage. α_1-antitrypsin, encoded by the gene *SERPINA1* (found on chromosome 14), is the major inhibitor. Two α_1-antitrypsin alleles, Z and S, are associated with low enzymatic activity. A significant correlation with the Z allele (odds ratio [OR] 0.3; $P = 1.25 \times 10^{-5}$), but not the S allele, is reported in PR3-ANCA–positive patients with GPA.[18] *PRTN3* (the gene encoding PR3) is associated with GPA, especially among patients who are PR3-ANCA-positive.[18]

The 620WPTPN22 variant of *PTPN22* (encoding lymphoid tyrosine phosphatase) correlates with abnormal regulatory CD4 T regulatory cell (Treg) function, increased humoral activity, and enhanced neutrophil function in patients with GPA.[19] CTLA-4 (encoding cytotoxic T lymphocyte antigen-4) polymorphisms are associated with GPA.[19] CTLA-4 is a negative regulator of T-cell activation, which competes with the costimulatory molecule CD28 for binding of CD80 or CD86 on antigen-presenting cells (APCs). Abatacept, a monoclonal antibody (mAb), containing the binding domain of CTLA-4, reduces CD28–CD80/CD86 interaction and, therefore, T-cell stimulation—which could explain its potential benefit in a small trial of non–life-threatening GPA.[20] Haplotypes of IL-10 (a pleiotropic cytokine with complex and multiple effects in immune modulation) are associated with several immunological disorders, including systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), and giant cell

arteritis. IL-10 production is largely (50% to 70%) determined by genetic factors, and elevated plasma levels are reported in EGPA but not in GPA.[21] Wieczorek et al. evaluated the impact of functionally relevant IL-10 polymorphisms in 403 patients with GPA, 103 with EGPA (compared with 507 controls).[21] There was a significant association with the 3575/1082/592 TAC haplotype—part of the extended ancient haplotype of IL-10.2—in ANCA-negative EGPA but not in GPA.[21]

EPIGENETICS

Genetic factors alone are not enough to explain the range of phenotypic presentations in AAV. Epigenetic dysregulation is increasingly recognized as a contributor to immune-mediated diseases. Epigenetics relate to heritable changes in gene function, without altering the DNA sequence. Most prominent epigenetic changes are DNA methylation, histone alterations, and microRNAs (miRNAs). Epigenetic modifications can be stable over time or can respond to developmental and environmental triggers, leading to phenotypic aberrances. Central to the pathogenesis of AAV is a dysregulated immune response resulting in ANCA production and aberrant expression of their target autoantigens, MPO and PR3. The expression of MPO and PR3 occurs primarily during early neutrophil development to produce intragranular constituents and is silenced in mature cells. However, in AAV, expression remains active. One epigenetic change that helps explain this is the reduced levels of the H3K27me3 histone modification at both the MPO and PR3 gene loci. H3K27me3 histone is associated with transcriptional silencing in patients with AAV compared with healthy individuals.[22]

ENVIRONMENTAL AND INFECTIOUS TRIGGERS

Genetic and epigenetic modifications may render a patient susceptible to developing disease in the presence of an appropriate trigger. Several triggers have been associated with AAV, including toxins, viral and bacterial infections, and some licit and illicit drugs.

Silica dust exposure has been associated with the development of AAV and other autoimmune diseases, such as SLE, RA, and scleroderma, as demonstrated in a recent large epidemiological survey of almost three million individuals.[23] Silica is an abundant earth material found in sand, grain, grass, and wool. Processing these materials may expose workers to respirable crystalline silica. Silica-induced ANCA-positive disease is often associated with p-ANCA, targeting MPO, and the clinical presentation is usually MPA rather than GPA.[23] The mechanism by which silica exposure triggers the development of AAV is not fully understood. *In vitro*, silica can activate monocytes and macrophages, releasing cytokines, such as IL-1 and tumor necrosis factor (TNF), as well as releasing oxygen radicals and lysosomal enzymes, including PR3 and myeloperoxidase. Furthermore, silica can inactivate α_1-antitrypsin. Asbestos, another silicon-containing mineral, has been suggested as a trigger for AAV in a small case-control study of 31 patients (22 GPA, 8 MPA, 1 EGPA) and 30 healthy controls; three patients had prior exposure to asbestos versus none of the controls.[24] There are few published studies investigating the potential pathogenic role of asbestos in the development of AAV.

It is estimated that 63% of patients with GPA are chronic nasal carriers of *Staphylococcus aureus*, resulting in an increased risk of relapse. Maintenance treatment with trimethoprim-sulfamethoxazole (cotrimoxazole) has been shown to reduce the incidence of relapse in a double-blind, placebo-controlled study in patients with GPA, where a maintenance dose of 960 mg two times daily of trimethoprim-sulfamethoxazole resulted in a 60% reduction in relapse. However, this has not been replicated in other studies. The mechanism for the pathogenic role of *S. aureus* is still unclear. Potential pathways include stimulation of B and/or T cells by *S. aureus* superantigens (SAgs); polyclonal activation of B cells by cell wall components of the bacterium, resulting in persistence of ANCA; and neutrophil priming leading to surface expression of PR3.[25]

Although parvovirus B19 has been proposed as a trigger for AAV in a few case reports, a case-control study failed to demonstrate any association because IgG antibodies to parvovirus B19 were detected equally in the sera of patients with AAV and control subjects, and all 13 patients with AAV and 39 controls were negative for IgM antibodies and viral DNA.[26] Hepatitis B virus (HBV) is implicated in the pathogenesis of PAN,[27] but there is no evidence to support a role for HBV or HCV in AAV.

Lysosomal-associated membrane protein 2 (LAMP-2) is a heavily glycosylated type 1 membrane protein, abundant on neutrophil and endothelial cell surfaces, which shuttles between lysosomes and the cell membrane. LAMP-2 cross-reacts with FimH, a gram-negative adhesin, which facilitates bacterial entry to host tissues. Preliminary studies have suggested a role for LAMP-2 in small-vessel vasculitis. The LAMP-2 epitope P41 to 49 has been reported to have a 100% homology with amino acids 72 to 80 of mature FimH.[28] Antibodies to human LAMP-2 have been shown to injure human microvascular endothelium *in vitro* and induce focal necrotizing glomerulonephritis (FNGN) in rats; immunization with FimH-induced pauciimmune FNGN associated with antibodies that bound human and rat LAMP-2; furthermore, patients with pauciimmune FNGN were found to have an increased likelihood of infections with FimH-expressing bacteria shortly before presentation of their FNGN.[28] LAMP-2 antibodies were found in patients with active disease or relapse but not in those in remission.[28] More recently, LAMP2-ANCA have been reported in 35% of children with small vessel vasculitis but not associated with disease severity.[29] Although this a promising new explanation for some cases of small-vessel vasculitis, the lack of replication of these findings makes them hard to substantiate.

CpG-oligodeoxynucleotides (ODN) is a short synthetic DNA containing unmethylated CpG motifs, highly prevalent in bacterial DNA, and recognized by Toll-like receptor 9 (TLR9), which is expressed by a variety of cells in the immune system. TLR9 triggering results in proinflammatory IL production. It has been reported that CpG motifs and IL-2 exposure can induce B lymphocytes to proliferate, increase antigen presentation, produce a range of cytokines, and differentiate into Ig-producing cells, ultimately leading to ANCA production.[30]

DRUG INDUCED ANTINEUTROPHIL CYTOPLASMIC ANTIBODY-ASSOCIATED VASCULITIDES

The most commonly implicated drugs that can induce an AAV-like syndrome are propylthiouracil (PTU), hydralazine, levamisole-adulterated cocaine, TNF inhibitors, sulfasalazine, D-penicillamine, and minocycline (Fig. 59.1).

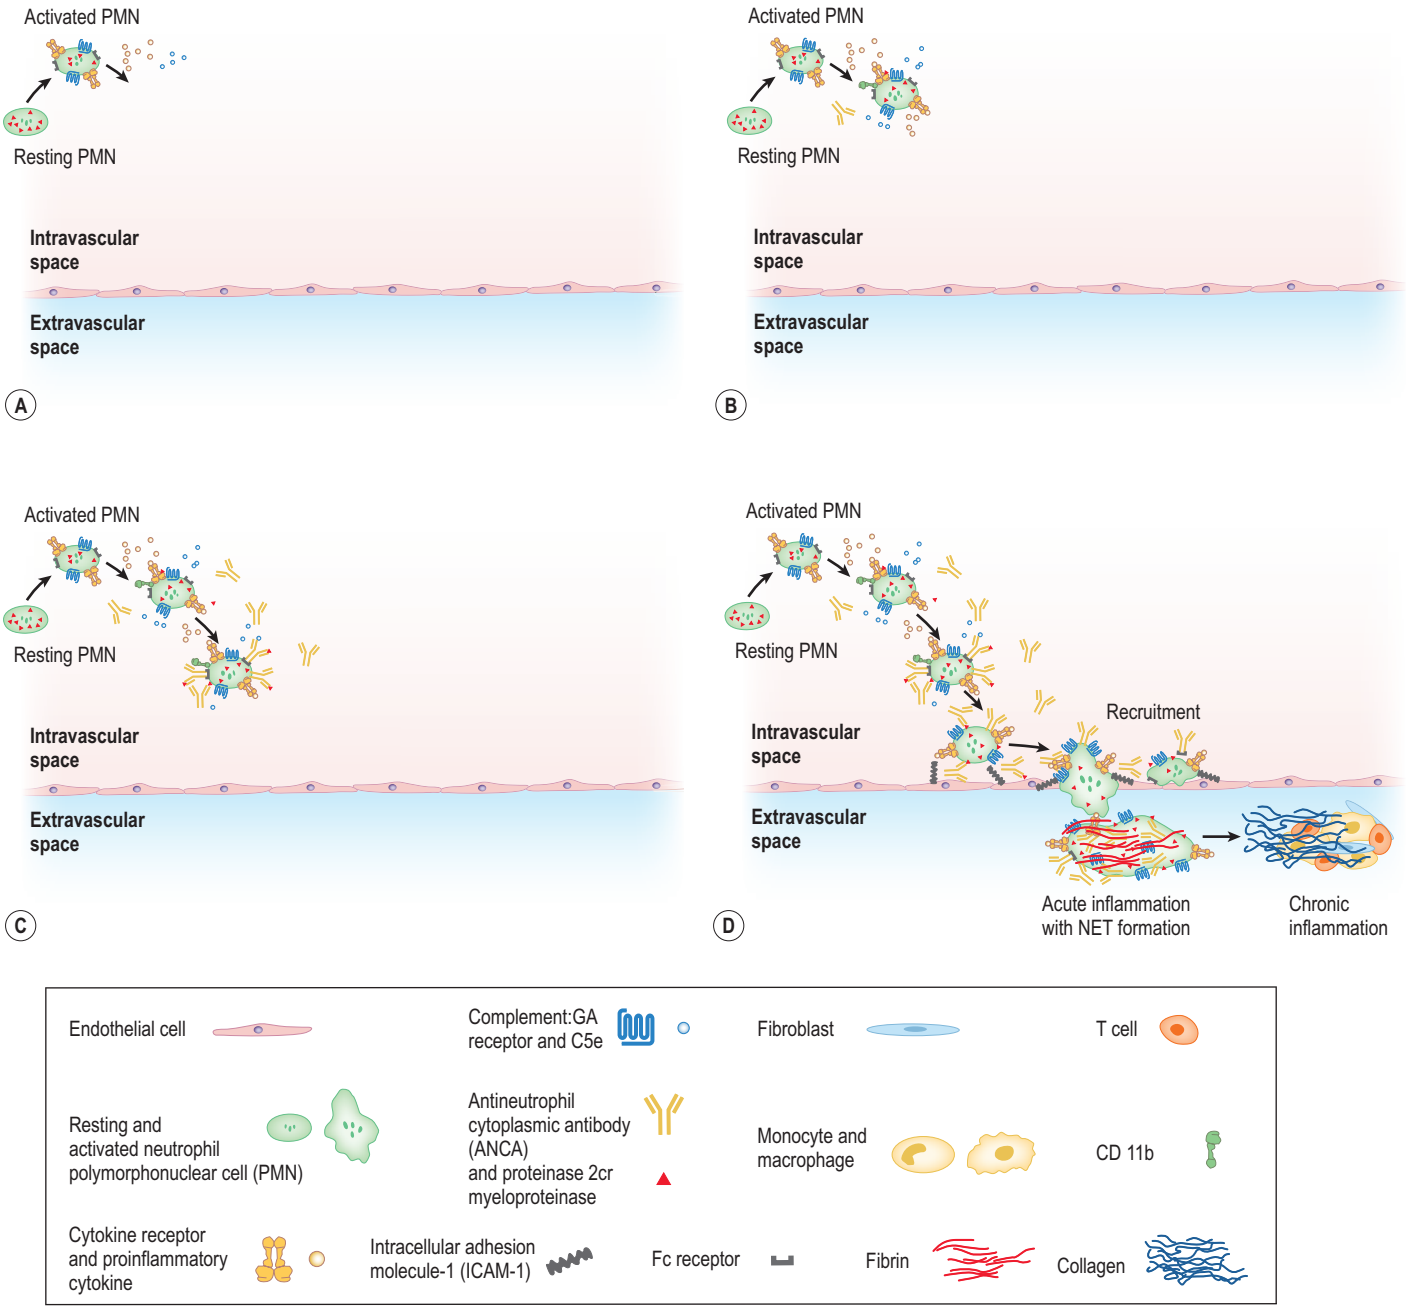

FIG. 59.1 Proposed pathogenic mechanisms in antineutrophil cytoplasmic antibody (ANCA) associated vasculitis. The interaction between activated neutrophils and ANCA is depicted in the figure, with resting neutrophils becoming activated (A), interacting with ANCA in the intravascular space (B), triggering a series of cascading events leading to vascular invasion (C) by inflammatory cells and the formation of neutrophil extracellular traps and eventually chronic inflammation in the extravascular space (D). *NET*, Neutrophil generation of extracellular trap.

Propylthiouracil

The most commonly described drug associated with the presence of ANCA is PTU. PTU is used to treat hyperthyroidism and was the first drug described to induce a condition mimicking AAV in the 1990s. Even though its use has declined over time, reports of PTU-induced AAV still emerge. Clinically, PTU-induced AAV may manifest as acute kidney injury caused by pauci-immune necrotizing and crescentic glomerulonephritis in addition to respiratory tract, joint, and skin diseases.

Reports of the proportion of patients who develop ANCA as a result of exposure to antithyroid medications varies widely from 4% to 46%; by contrast, the prevalence of antithyroid drug-induced AAV is much lower (0% to 1.4%). Although PTU is the most commonly reported antithyroid drug, methimazole and carbimazole have also been implicated. In a study by Noh et al,[31] the estimated annual incidence of antithyroid drug-induced vasculitis was 0.53 to 0.79 patients per 10,000 patients with Graves disease, especially for patients receiving PTU; the

ratio of the estimated incidence for methimazole and PTU was 1:39. Most patients with PTU-induced ANCA will not develop clinical features of vasculitis. Patients with PTU-induced AAV (usually MPO-positive) are younger, more commonly female compared with those with primary AAV, and usually have significantly higher anti-MPO ANCA titers compared with patients without vasculitis. Other ANCA subtypes may be found, including HNE-ANCA and LF-ANCA; however, when PTU-induced AAV develops, MPO-ANCA is usually present, regardless of the existence of other forms of ANCA. The pathogenesis of AAV related to antithyroid drugs is unclear. PTU is predominantly metabolized in the liver, but a proportion is modified by MPO in neutrophils.[32] Neutrophils are responsible for NET formation, and PTU can induce abnormal configured NETs *in vitro;* these abnormal NETs cannot easily be released into liquid phase and are not effectively digested by DNase I, therefore, remaining in the tissue.[33] Immunization of rats with abnormal NETs results in production of MPO-ANCA.[33]

Hydralazine

Hydralazine is widely used to treat hypertension, acting as a smooth muscle relaxant and causing arterial and arteriolar vasodilation. It has been implicated in the development of drug-induced SLE and AAV. High titers of MPO-ANCA, ANA, anti-double-stranded DNA (dsDNA), and anti-histone antibodies are found; hypocomplementemia is also frequent. The underlying mechanism of action for hydralazine-induced AAV is not clear. One potential pathway by which hydralazine acts is through reverse epigenetic silencing of tumor suppressors but also potentially of MPO and PR3.

Levamisole-Contaminated Cocaine

It is commonplace for illicit drugs, such as cocaine, to be combined with adulterants, such as levamisole, in an effort to increase profits. Levamisole is similar in physical appearance and has possible potentiating effects on levels of dopamine in the central nervous system. It is estimated that more than 75% of cocaine users in the United States are exposed to levamisole.

Clinical manifestations of AAV induced by levamisole-contaminated cocaine include constitutional features; arthralgia; retiform purpura involving the ears, face, and extremities; and, less commonly, renal and lung diseases. Laboratory abnormalities include leukopenia, neutropenia, and high-titer p-ANCA, directed against MPO-ANCA or against atypical p-ANCA–associated antigens, such as HNE, LF, and cathepsin G. PR3-ANCA, ANA, and antiphospholipid autoantibodies have also been described in these patients. This multiplicity of antibodies helps distinguish AAV induced by levamisole-contaminated cocaine from primary AAV, which usually targets just one antigen.

Levamisole has an estimated mean half-life of 5.6 hours; therefore, serum testing is likely to be negative if the most recent exposure occurred over 24 hours prior to sample collection. Urinary detection of levamisole is highly suggestive of drug-induced disease and is useful if exposure occurred less than 48 hours prior to testing.

The mechanism by which levamisole-contaminated cocaine induces AAV is unclear. Levamisole, like PTU, could serve as a substrate for MPO to form reactive metabolites that might induce autoimmunity. Levamisole can enhance NETosis through engagement of muscarinic (subtype 3) receptors; furthermore, NETs generated by levamisole can induce endothelial cell death and vascular dysfunction by disrupting normal endothelium-dependent vasorelaxation. Abusing cocaine without levamisole can also trigger a syndrome mimicking AAV. The clinical presentation can be identical to that of patients with GPA, although cerebral angiitis, urticarial vasculitis, and EGPA-like syndromes have also been described. In GPA-like vasculitis, patients typically present with cutaneous vasculitis, nasal septal destruction, and pauci-immune crescentic glomerulonephritis. The autoantibody profile usually includes c-ANCA with PR3 specificity, although there are reports of cases with negative ANCA or p-ANCA with PR3 specificity. In these cases, the target of p-ANCA may be atypical, such as HNE.[34]

Cocaine-induced midline destructive lesions (CIMDLs) in the upper respiratory tract mimic limited forms of GPA.[35] Patients with CIMDLs may present with or without ANCA, and when ANCA-positive, the pattern often varies. Some patients are positive for c-ANCA with PR3 specificity, but more often, patients with CIMDLs present p-ANCA with specificity for atypical ANCA, such as HNE. Wiesner et al. reported that 76% of the patients with CIMDLs were ANCA-positive (mostly p-ANCA): 57% had PR3-ANCA and 86% had HNE-ANCA; this compares with the absence of HNE-ANCA in GPA and MPA, suggesting that the presence of HNE-ANCAs may be helpful in distinguishing CIMDL from GPA.[36]

Table 59.2 provides a summary of the most significant associations between drugs and ANCA or AAV. The management of all forms of drug-induced AAV is withdrawal of the offending agent, supportive measures, and, in severe cases, immunosuppression, dialysis, and plasma exchange.

LOSS OF B- AND T-CELL TOLERANCE IN ANTINEUTROPHIL CYTOPLASMIC ANTIBODY-ASSOCIATED VASCULITIS

The imbalance of effector and Tregs underpins the autoimmune dysregulation seen in AAV with multiple alterations in the circulating T-cell population. Patients with AVV have a reduced number of circulating Tregs,[37] which are functionally impaired, and an expanded population of CD4 effector memory T cells with an increased number of activated T cells.[38] Persistence of CD4 T-cell activation in peripheral blood correlates with disease severity.[39]Aberrant T helper (Th) polarization, with an increase in proinflammatory Th17 responses, further contributes to vascular injury.[39] It has been suggested that these alterations to the peripheral T-cell compartment could be influenced by environmental factors, such as infection.

The discovery of B cells in the inflammatory lesions in AAV together with the success of B-cell depletion therapies suggests that B cells play a significant role in the pathogenesis of AAV; however, the exact mechanism of this involvement is still not known. Regulatory B cells are reduced in AAV, whereas B-lymphocyte stimulator (BLyS) levels are significantly increased, thereby promoting B-cell differentiation, proliferation, and survival.[40] B cells may play a number of roles in AAV: as precursors to antibody-producing plasma cells, as APCs, producing proinflammatory mediators, or in costimulation of T cells.

ROLE OF NEUTROPHILS

In addition to containing the antigens for ANCA, activated neutrophils release many mediators that modulate the inflammatory response and can directly contribute to tissue inflammation,

TABLE 59.2 Drug-Induced Vasculitis Associated With Antineutrophil Cytoplasmic Antibody Positivity—Implicated Drugs, Proposed Mechanisms of Action and Laboratory Findings

Drug/Class	Proposed Mechanism of Action	IF Pattern	ANCA Serotype	Other ANCA Autoantigens	Other Antibodies	Ref.
Allopurinol	Limited data	p-ANCA	MPO-ANCA	—	ANA	Jia et al.[50]
Anti–TNF (ADA, ETN, IFX)	TNF may induce the formation of immune complexes, activation of complement and mediate inflammation by switching from a cytokine response of T-helper type 1 to type 2, upregulating antibody production	p-ANCA c-ANCA	MPO-ANCA PR3-ANCA	—	ANA	Rowley et al.[51]
Benzylthiouracil	Limited data	p-ANCA	MPO-ANCA	HNE LF	—	Leung et al.[52]
Carbimazole	Limited data	p-ANCA c-ANCA	MPO-ANCA PR3-ANCA	—	—	
Cocaine	Enhanced formation of NETs enriched in neutrophil elastase and inflammatory mitochondrial DNA with enhanced release of B cell–activating factor belonging to the TNF family (BAFF)	c-ANCA p-ANCA	PR3-ANCA	HNE	—	Holden et al.[40] and Nakazawa et al.[41]
D-penicillamine	Limited data	p-ANCA	MPO-ANCA	HNE LF	ANA Anti-dsDNA abs	Schulte et al.[53]
Hydralazine	Hydralazine mediated reversal of epigenetic silencing of MPO and PR3, with subsequent increased expression of both autoantigens. Induction of cytotoxic products and neutrophil apoptosis mediated by hydralazine binding MPO	P-ANCA	MPO-ANCA PR3-ANCA	HNE LF	ANA Anti-dsDNA abs Antihistone abs Anticardiolipin abs	
Levamisole contaminated cocaine	Enhanced NETosis through engagement of muscarinic subtype 3 receptor Metabolism of levamisole by MPO with formation of reactive metabolites Genetic susceptibility to agranulocytosis in HLA B27+ patients	p-ANCA c-ANCA	MPO-ANCA PR3-ANCA (double + is very common)	HNE Cathepsin G LF	ANA Anticardiolipin abs	Holden [40] and Cid et al.[54]
Methimazole	Limited data	p-ANCA c-ANCA Atypical ANCA	MPO-ANCA PR3-ANCA	HNE	ANA	Yalcinkaya et al.[55] and Sansonno et al.[56]
Minocycline	Minocycline oxidation by MPO, with abnormal production of reactive metabolites and modification of enzymatic activity, triggering the induction of ANCA Cytotoxicity leading to premature apoptosis of neutrophils, with abnormal release of nucleosomes and drug-modified proteins (including myeloperoxidase, elastase, LL37, and HMGB1), which can be bound to NETs triggering lupus/vasculitis via type I IFN production	p-ANCA Atypical ANCA	MPO-ANCA PR3-ANCA	HNE Cathepsin G BPI	ANA Anti-dsDNA abs	Varricchi et al.[57]
PTU	Cross-reactivity between anti-thyroperoxidase (anti-TPO) antibody and MPO. Alteration of NET configuration PTU-induced structural change in MPO, which serves as a neoantigen Metabolism of PTU by MPO (in the presence of H_2O_2 and Cl^-) into strong toxic metabolites. Subsequent binding to neutrophils proteins and recognition by T cells with B cells activation, resulting in autoantibody production Competitive inhibition of MPO oxidation activity by PTU, in a dose dependent manner	p-ANCA atypical ANCA	MPO-ANCA PR3- ANCA	HNE LF BPI Azurocidin Cathepsin G	ANA Antihistone abs Anticardiolipin abs	Wang and Tsai[27], Yalcinkaya et al.[55], Craven et al.[58], and Walsh et al.[95]
Sulfasalazine	Sulfasalazine-induced neutrophil apoptosis, with subsequent membrane expression of PR3 and MPO	p-ANCA c-ANCA	MPO-ANCA PR3-ANCA	LF	ANA Anti-dsDNA abs	Jia et al.[50] and Luqmani and Ponte[59]

vascular injury, and damage in AAV via phagocytosis, degranulation, and cytokine production. Neutrophils release B cell–activating factors (BAFFs) that enhance B-cell proliferation and retard apoptosis. Neutrophils from patients with AAV are more prone to spontaneous release of NETs.[41] In the normal immune system, NETs consist of chromatin fibers released from dying neutrophils and are designed to trap and kill extracellular pathogens. NETs not only contain proinflammatory proteins that directly cause endothelial cell damage and complement activation, but also form a link between innate and adaptive immunity via providing access to MPO and PR3.

ROLE OF COMPLEMENT

Despite the apparent paucity of immune complexes in AAV, complement (and in particular, activation of the alternative complement pathway) plays a crucial role in the pathogenesis of AAV. When primed neutrophils are activated by ANCA, they produce complement pathway (C5a), which, in addition to recruitment, primes additional neutrophils for further activation by ANCA.[42] C3a, C5a, and soluble C5b-9 levels are elevated in active disease; plasma levels of complement factor H, a regulator of the alternative complement pathway, are significantly lower in patients with active AAV.[43] Low serum levels of C3 at diagnosis are associated with a worse prognosis.[44] There is also a suggestion that C5a may play a role in the hypercoagulability associated with active AAV.

PATHOGENESIS OF KAWASAKI DISEASE

The incidence of KD is highest in East Asian countries, such as Japan, Korea, and Taiwan. The incidence in Japanese children is 10-fold higher compared with that in the United States. Japanese data show a seasonal variation in incidence, with an increase seen in the winter; furthermore, siblings of patients with KD are at increased risk of disease compared with the general population,[45] and the risk of sibling patients is increased among patients whose parents previously had the disease.[46] KD shows geographical clustering, with shared clinical features between clusters of disease. These findings support a role for an infectious environmental trigger, together with genetic susceptibility. Several disease susceptibility genes have been identified, including genes that affect the function of molecules involved in the calcineurin-nuclear factor of activated T cells (NFATs) pathway; transforming growth factor-β (TGF-β) lipopolysaccharide-induced endothelial cell inflammation pathways; and genes encoding Fcγ receptors, such as *ITPKC, FAM167-BLK, CD40, FCGR2A, HLA, CASP3, TGFB2, TGFBR2, SMAD3*, and *PLCB4/PLCB1*.[47] *CD40* and *FCGR2A* have been associated with disease susceptibility in Europeans.

SNPs identified within the *ITPKC* and *PLCB4/PLCB1* genes are associated with the risk of coronary artery aneurysms.[47] *ITPKC* and *CASP3* SNPs are associated with lack of response to intravenous immunoglobulin (IVIG) treatment.[47] ITPKC is a negative regulator of T-cell activation via downregulation of the Ca^{2+}/NFAT signaling pathway. The SNP located in the intron of *ITPKC* regulates splicing, decreasing negative regulation of T cells and leading to increased T-cell activation and IL-2 production.[47]

TNF, nuclear factor-κB (NF-κB), IL-17, TGF-β, interferon-γ (IFN-γ), granulocyte–colony-stimulating factor (G-CSF), IL-1β, IL-6, follistatin-like protein 1, and TLR2 are reported to be elevated in patients with KD.[48,49] In the acute phase of disease, circulating IL-17 levels and IL-17–induced cytokinesis are increased, suggesting an imbalance between Th17 and Tregs. Th17 levels are higher in children with coronary lesions.[50] There is evidence for marked activation of cytotoxic and Th lymphocytes and dendritic cells, with upregulation of type I IFN responses, supporting a possible viral etiology of KD—based on a transcriptomic study of patients who died or who were undergoing heart transplantation.[51]

KD has been suspected to be triggered by bacterial or viral infections, but no single causative agent has been identified. It has been suggested that SAgs are implicated. Several microorganisms can produce SAgs, including bacteria (*e.g.*, staphylococci, streptococci, mycobacteria, *Mycoplasma, Yersinia, Lactobacillus)* and viruses (*e.g.*, Epstein-Barr virus). SAg-producing bacteria have been isolated from children with acute KD, including toxic shock syndrome toxin 1 (TSST-1) producing *S. aureus* and pyrogenic exotoxin–producing *Streptococcus*.[52] In a mouse model involving injections of intraperitoneal *Lactobacillus casei*, disease could not be induced in recombinase activating gene-1–deficient mice, implicating T cells as critical drivers of the disease process.[53]

Pathogenesis of Polyarteritis Nodosa

The pathogenesis of idiopathic PAN is unknown; clinical responses to immunosuppressive therapy strongly support an underlying immunological mechanism. Elevated levels of IL-2, IL-8, IFN-γ, TNF, and IL-1β have been reported in PAN, as well as elevated levels of circulating soluble adhesion molecules, such as intercellular adhesion molecule-1, vascular cell adhesion molecule-1, and E-selectin, suggesting that endothelial cell activation could perpetuate and potentiate the inflammatory milieu. IFN-γ and TNF increase the expression of class I major histocompatibility complex (MHC) antigens and induce MHC class II expression, resulting in antigen presentation to T cells. In one study of 24 patients with idiopathic PAN, macrophages and CD4 T lymphocytes were the predominant cell types found in lesions. T lymphocytes were more abundant in nerve biopsy specimens compared with muscle biopsy specimens (52% vs 35%; $P < .001$), while macrophages were predominant in muscle specimens (45% vs 33%; $P = .005$). Histologically, T lymphocytes were distributed throughout the vessel wall, whereas macrophages predominated in the periphery.[54]

In HBV-induced PAN, there is direct injury to the vessel wall as a result of viral replication[27] and deposition or *in situ* formation of immune complexes, which activate complement, thereby recruiting and activating neutrophils. The immunological process usually occurs within 6 months of HBV infection. During the active phase of disease, complement levels are low, consistent with complement consumption resulting from immune-complex deposition.

Alterations in the *MEFV* gene (encoding pyrin) may represent an important susceptibility factor for PAN. Pyrin is critically important in regulating IL-1β production; mutations of pyrin may be associated with loss of regulation of inflammatory pathways via apoptosis and IL-1β release, resulting in augmented inflammation, similar to patients with familial Mediterranean fever, who can be carriers of *MEFV* mutations.[55]

PATHOGENESIS OF CRYOGLOBULINEMIC VASCULITIS

The pathological hallmark of cryoglobulinemic vasculitis is deposition of cold-precipitating Igs in small vessels, resulting in vas-

cular inflammation and damage. In most patients, chronic HCV infection is the trigger, but cryoglobulinemic vasculitis can also occur in the context of other chronic infections and in some autoimmune rheumatic diseases and lymphoproliferative disorders.

HCV plays several important roles in the pathogenesis of cryoglobulinemic vasculitis. HCV glycoproteins interact directly with B-cell surface receptors, lowering the activation threshold and resulting in polyclonal activation and expansion of B cells.[56] Circulating, clonally expanded B cells produce monoclonal IgM rheumatoid factor (RF). Mixed cryoglobulins contain a monoclonal IgM RF directed against the Fc segment of IgG and polyclonal IgG. When IgM RF is exposed to cold conditions, it undergoes conformational changes, resulting in cryoprecipitation. Cold-insoluble immune complexes are formed predominantly by IgM RF linked to IgG (which, in turn, is bound to HCV core protein). Cryoglobulinemic vasculitis should be considered an antigen-driven disease, because HCV persistence ensures sustained lymphoid proliferation and continued cryoglobulin production.

C1q protein levels and C1q binding are significantly increased in cryoglobulinemic vasculitis. C1q is required for binding of immune complexes to endothelial cells. Although mixed cryoglobulins can be detected in up to 60% of patients with chronic hepatitis C, cryoglobulinemic vasculitis occurs only in a minority, suggesting that host factors must be equally important in the pathogenesis of the disease.

PATHOGENESIS OF EOSINOPHILIC GLOMERULONEPHRITIS WITH POLYANGIITIS

Despite the established role of ANCA in GPA and MPA, the pathogenic role of ANCA in EGPA is less clear. In EGPA, only 30% to 40% of patients are ANCA-positive; the presence or absence of ANCA in EGPA defines distinct clinical phenotypes. The pathological hallmark of EGPA is prominent tissue and peripheral blood eosinophilia, suggesting a central pathogenic role for the eosinophil. EGPA is considered to be Th2 mediated, given the striking early allergic manifestations, together with the marked increase in circulating Th2 cytokines, including IL-5, which plays a crucial role in eosinophil differentiation in bone marrow, as well as recruitment and activation of eosinophils at sites of inflammation. IL-5 could delay apoptosis of eosinophils and modulate the function of mast cells and basophils.[57] Elevated levels of IFN-γ (a potent Th1 cytokine involved in granuloma formation) provide evidence for the involvement of other Th responses. Th17 responses are upregulated, and B lymphocytes and humoral responses are likely to be important, given that B-cell depletion can induce remission and reduce circulating IL-5 and eosinophils.

The precise mechanisms of eosinophil-mediated inflammation in EPGA remain unclear. Eosinophils are granulocytic cells capable of releasing multiple proinflammatory cytokines, chemokines, and reactive oxygen species, which have direct effects on the vessel and perivascular tissues—including tissue fibrosis, thrombosis, and allergic inflammation. Indirect effects include recruitment and activation of other inflammatory cells to perpetuate the inflammatory response.

CLASSIFICATION OF VASCULITIDES

Several sets of classification criteria have been published, the most recent being one by the American College of Rheumatology (ACR) in 1990. These are primarily for the purposes of epidemiological studies or for defining patients for inclusion in clinical studies, rather than being used in clinical practice. However, as is often the case with classification criteria, they are misapplied as diagnostic criteria in daily practice and may fail to provide a clear-cut distinction between vasculitis and other conditions.[58] An international effort is currently underway to develop improved classification criteria as well as diagnostic criteria for patients with vasculitis or suspected vasculitis, and it is likely to lead to a new set of evidence-based criteria to improve diagnosis and classification of vasculitis in the future.[59] There is considerable overlap between different forms of vasculitis. The group of patients with diseases clustered around the presence of ANCA share many features in common, particularly the presence of glomerulonephritis and pulmonary infiltrates. In the case of EGPA, patients also experience rhinitis, nasal polyps, asthma, and rashes and may develop mononeuritis multiplex or sensory peripheral neuropathy. In addition to renal and lung inflammation, patients with GPA typically suffer from upper respiratory problems, such as nasal crusting or discharge; subglottic stenosis; or hearing loss. Patients with MPA do not usually develop significant upper airway disease; their disease tends to be more limited to the kidneys and/or lungs. All of these conditions can also affect any other organs, such as skin. Skin is the most commonly affected site in most forms of vasculitis. This can vary from small infarcts around nail edges to purpura, ulcers, nodules, and even gangrene.

The development of consensus criteria for diagnosis by the Chapel Hill group has provided a more rational approach to define disease entities. They are not true classification or diagnostic criteria because they are not evidence based (they are consensus of opinion from several experts), but they have advantages over the 1990 ACR criteria. They were developed after recognition of ANCAs, which are an important part of the 2013 definitions. One of the major flaws of the ACR criteria is the failure to recognize MPA as an entity separate from PAN.[59] This failure to separate PAN and MPA has probably prevented proper diagnosis, and it is a historical legacy from an assumption that almost all forms of vasculitis are, in fact, variations of PAN.

Furthermore, current classification criteria offer limited information about the severity, prognostication or relapse risk of AAV. Identifying and predicting organ involvement guides effective treatment of AAV. For example, while isolated orbital disease may be considered as limited disease, it is organ-threatening and may also evolve to affect new organs—through a continuum of disease severity—thereby raising the question of whether all forms of AAV should be regarded as severe and be treated as such. Alternative classifications—involving MPO and PR3 ANCA serological subtypes—have been proposed to allow the opportunity to add new organ involvement if they occur, in turn recognizing the dynamic nature of AAV.[60] This may help individualize cases and provide information about the severity and localization of lesions in order to guide more effective therapeutic decisions.

DIAGNOSIS

AAV are a group of three main entities: GPA, MPA, and EGPA. These three conditions overlap with many shared clinical features. Figs. 59.2 and 59.3 describe clinical patterns in patients with MPA and GPA and show that there are many similarities, with a dominance of kidney and lung involvement in both conditions. EGPA is characterized by eosinophilia, late-onset asthma, and neuropathic involvement, but cardiac involvement

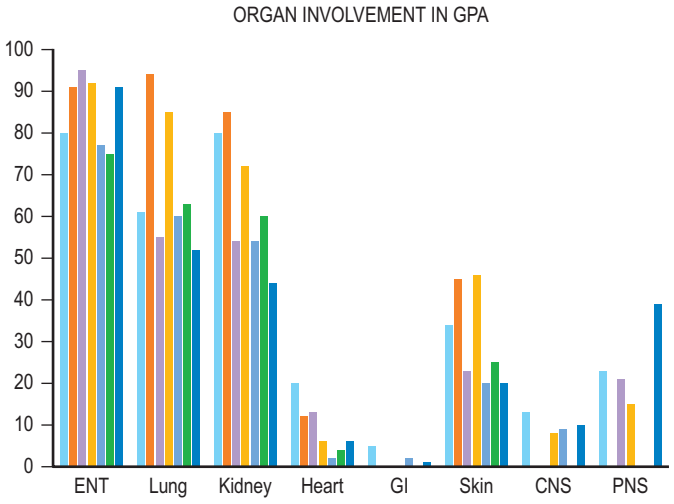

FIG. 59.2 Organ involvement in patients with granulomatosis with polyangiitis. *ENT*, Ear, nose, and throat; *GPA*, granulomatosis with polyangiitis. (Data compared across seven cohorts—reviewed by Luqmani R, Ponte C. Antineutrophil cytoplasmic antibody associated vasculitides and polyarteritis nodosa. In: Bijlsma JWJ, Hachulla E, eds. *EULAR Textbook on Rheumatic Diseases*. London, UK: BMJ Publishing Group Ltd; 2015:717-753, Chapter 27).[75]

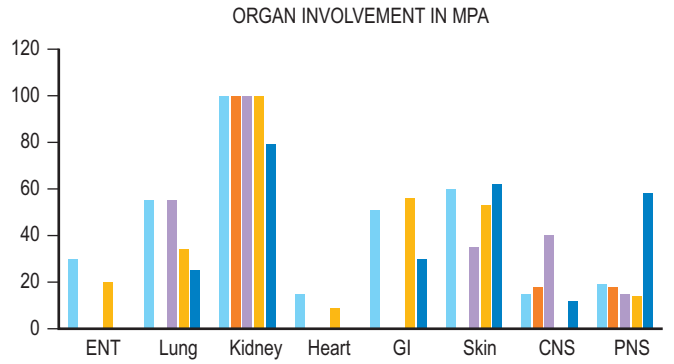

FIG. 59.3 Organ involvement in patients with microscopic polyangiitis. *ENT*, Ear, nose, and throat; *MPA*, microscopic polyangiitis. (Data compared across seven cohorts—reviewed by Luqmani R, Ponte C. ANCA associated vasculitides and polyarteritis nodosa. In: Bijlsma JWJ, Hachulla E, eds. *EULAR Textbook on Rheumatic Diseases*. London, UK: BMJ Publishing Group Ltd; 2015:717–753, Chapter 27.)[75]

may develop in a subset of patients with EGPA, particularly in association with hypereosinophilia. Systemic features, such as malaise, fever, weight loss, or myalgia, could be mistaken for a variety of other conditions, and it may delay recognition of disease. Patients with MPA can present just with isolated microscopic hematuria and hypertension, with nonspecific systemic features. In contrast, patients with GPA typically suffer from upper airway problems, with nasal crusting, blood-stained discharge, sinusitis, or hearing loss. In anti-glomerular basement membrane (anti-GBM) antibody disease, clinical features sometimes overlap with those of AAV, but the dominant features are pulmonary hemorrhage leading to hemoptysis and rapid deterioration in renal function. It is not entirely clear whether the anti-GBM disease should be regarded as vasculitis or vasculopathy, but it has been included in the current Chapel Hill Consensus definitions of a small-vessel vasculitis. Confusingly, some patients with anti-GBM antibodies also have ANCA.

The clinical course in MPA is typically acute, whereas GPA may remain undiagnosed for several months or even years before the upper airway and or lower airway symptoms are recognized as being related to vasculitis. For almost all forms of acute AAV, the differential diagnosis is infection, cancer, or drug toxicity. One of the drugs recently recognized to induce an AAV mimic is cocaine,[61] which can cause local tissue necrosis, especially in the palate, leading to palatal and nasal septal perforation. Interestingly, cocaine can induce ANCA production and therefore can be a true mimic of AAV. Typically, the ANCA is directed against elastase or is nonspecific. The use of cocaine continues to grow worldwide and is an increasing public health concern. Cocaine-induced vasculitis is an important differential diagnosis to consider. Two distinct vasculitic syndromes have been described due to cocaine: CIMDL and AAV. The former occurs as a result of direct vasoconstriction effect of cocaine causing ischemic necrosis of the septal cartilage and perforation of the nasal septum, mimicking GPA. The latter, which can present with high titers of p-ANCA and c-ANCA with MPO and/or PR3 positivity, is due to contamination of cocaine with levamisole; the main features being cutaneous involvement, arthralgia, otolaryngologic manifestations, agranulocytosis, and rarely renal involvement. Contamination of cocaine with levamisole is becoming a growing problem. Presumably, levamisole (a veterinary anthelmintic agent) is a cheap white powder that can be mixed readily with cocaine but can cause an acute necrotizing vasculitis of skin and the extremities. A high degree of suspicion and awareness is needed in order to properly diagnose and treat these patients. Careful history taking, sometimes with sensitive, confidential, repeated questioning, may be required to eventually identify this as a cause of a patient's condition. Cessation of cocaine and levamisole use is essential and may be the only step required to resolve this clinical condition.[62] However, once palatal or nasal perforation has developed, patients may require local surgical repair.

Cryoglobulinemic vasculitis typically presents with purpuric lesions on the legs, and the lesions may ulcerate. Patients often complain of joint pains and malaise. Neuropathies can occur with either mononeuritis multiplex or sensory neuropathy; membranous glomerulonephritis is a recognized complication. Most cases appear to be associated with hepatitis C (more than 90% in some series), and eradication of hepatitis C appears to be effective in reducing the manifestations of disease.

True PAN typically presents with neuropathies, systemic inflammation, and ischemic abdominal pain (difficulty eating because of medium-vessel supply to the gut and nerves). If it is associated with hepatitis B, the patient may or may not have obvious signs of liver disease.

Isolated cutaneous vasculitis typically presents as purpuric lesions, skin ulceration, or broken livedo, and biopsy of the skin will show typical changes of a necrotizing vasculitis.

KD usually presents in childhood as an acute illness, with relapsing high fevers, significant lymphadenopathy, and a systemic inflammatory syndrome. The child typically has mucosal inflammation with strawberry tongue; about 10 days after the onset, skin desquamation is a very typical feature. The most worrying feature of KD is the development of coronary artery aneurysms, which occur in around 2% to 4% of children and can be fatal, if untreated. This can be detected by using echocardiography.

Laboratory Investigations

The investigation of patients with suspected small- or medium-vessel vasculitis should follow a careful history and examination to determine the likely diagnosis and underlying illness. The differential diagnosis is very wide. It is important to be vigilant in looking for positive signs of vasculitis, but it is equally important not to forget to look for more common causes of the clinical presentation. Many of the studies performed can result in nonspecific findings, such as an elevated white blood cell count, platelet count, or the erythrocyte sedimentation rate. The C-reactive protein (CRP) level is typically raised. Patients may be anemic. Liver or, more importantly, renal function may be abnormal. The presence of hypereosinophilia can be suggestive of a diagnosis of EGPA, but there are other causes of hypereosinophilia, particularly drug reactions. It is important to test renal function in patients with suspected vasculitis in case there is nephritis, and it is always important to perform urinalysis for microscopic hematuria or proteinuria. Although these might be explained by the presence of a kidney infection or other causes, they raise a strong suspicion of glomerular inflammation. An abnormal urinary sediment in combination with hypertension should alert the physician to the possibility of kidney involvement by small-vessel vasculitis. Since the 1980s, the discovery of ANCA[4] has transformed the recognition of renal vasculitis, so that these patients can be managed more effectively.

Histology remains a critically important diagnostic test, not only to make a positive diagnosis but also to exclude other causes. Although histology from the airways can be nondiagnostic, this may still assist in ensuring that the patient does not have cancer, sarcoidosis, tuberculosis, or IgG4-related disease, all of which could present in a similar way with inflammation of the upper or lower airway. IgG4-related disease (IgG4-RD) is an important differential diagnosis due to its propensity to mimic AAV. For instance, nasal manifestations of IgG4-RD, causing chronic sinusitis and paranasal sinusitis, and orbital manifestations of IgG4-RD can be remarkably similar to limited GPA. The diagnosis of IgG4-RD is based on a combination of clinical presentation and histology. A histological diagnosis, the gold standard, requires demonstration of IgG4-positive plasma cells in tissue specimens and a ratio of IgG4-positive to total IgG-positive plasma cells greater than 40%. Accurate and swift diagnosis of IgG4-RD is important because potential irreversible tissue damage due to fibrosis may occur. Prolonged untreated inflammation due to IgG4-RD may also lead to amyloidosis, emphasizing the importance of timely recognition and treatment.[63]

Renal histology is still the gold standard to diagnose suspected glomerulonephritis and may be useful in predicting the prognosis.[64] Four categories of renal lesion have been proposed: focal, crescentic, mixed, and sclerotic. Follow-up of patients with different patterns has shown progressively worse renal outcome from focal (the best) through to sclerotic (the worst) over the subsequent 5 years.

ASSESSMENT

The outcome of small- and medium-vessel vasculitis has been completely transformed by immunosuppressive therapy. With treatment almost all patients with KD recover from their initial illness. In AAV, more than 70% survive at least 5 years from starting treatment. The majority of patients with PAN respond to initial therapy. However, the risk of recurrence of disease is high in small-vessel vasculitides. Relapse rates are likely to exceed 50% over time.[2] Patients experience comorbidities as a consequence of the disease or its treatment. A central issue is their immunocompromised state, rendering them susceptible to infections. In the long term, small-vessel vasculitides and their treatment can be associated with effects on the cardiovascular system with increased risk of hypertension, coronary heart disease, and stroke. Immunosuppressants given to patients can significantly improve disease control but may increase the risk of malignancy. The continued need for glucocorticoid therapy contributes to hypertension, diabetes, heart diseases, osteoporosis, and infection.

It is, therefore, obvious that careful evaluation of a patient's status is required throughout the course of disease. Constant vigilance is required to detect and manage any flare-up of disease because the consequences of untreated inflammation of vessels to vital organs can be severe. Although for most patients, initial therapy is very successful and improvements in disease status is obvious to the patient, the subsequent disease course can be much more complicated because of comorbidities, the evolution of disease-related damage, and morbidity caused by treatment as well as disease flare-ups. There are no suitable biomarkers that can be universally applied in small- and medium-vessel vasculitides to determine the patient's disease state to provide an evidence-based rationale for adjustment of therapy. ANCA titers fluctuate during the course of disease, and although ANCA remains a very useful diagnostic test, its value in managing variations in disease activity is very limited. Up to 40% of patients have an elevation of ANCA without any new deterioration in clinical state, but a recent study has shown that patients with renal involvement as part of their presentation are likely to have relapses associated with ANCA rises.[65] Among 166 patients with AAV, all were positive for ANCA and 104 had renal involvement (a mixture of PR3-ANCA and MPO-ANCA). The hazard ratio for ANCA rises predicting subsequent relapse was 11.09 (CI 5.01 to 24.55), suggesting that this test may be of value in detection of future relapse in this subset of patients. However, for most patients with systemic vasculitis, careful clinical evaluation remains a cornerstone of effective disease management as recommended by the EULAR guidelines on management of systemic vasculitis.[66]

In simple terms, at the onset of the condition, disease activity is the dominant problem, and treatment should be directed toward it; but over the course of time, with the development of consequences of vasculitis or its treatment, there is an increasing component of damage or scarring and also side effects of drug therapy. Similarly, different patients function at different levels with the same amount of disease, or damage, and therefore, the ability to perform normal tasks is an important component of their overall condition to consider (Table 59.3).

KEY CONCEPTS

Assessment of Disease Activity in Vasculitis

- For small- and medium-vessel vasculitis in adults, version 3 and a specific version of the Birmingham Vasculitis Activity Score (BVAS) for GPA are used.
- BVAS version 3 is the most generic and applicable across different forms of vasculitis; BVAS for GPA has been specifically designed for use in GPA and contains very specific items related to that condition.
- During sequential monitoring, a time frame of 3 months is recommended so that disease activity is considered to be of most relevance during this time. The time frame is based on pragmatic clinical experience that this is the usual time taken during which immunosuppressive therapy is likely to have a significant effect on active disease manifestations.

TABLE 59.3 Assessing Disease Activity in Vasculitis

System Assessed	BVAS	BVAS GPA	PVAS	Comments
General	Myalgia, arthralgia/arthritis, fever, weight loss	Arthritis, fever	Myalgia, arthralgia/arthritis, fever, weight loss	These are typical features in many forms of systemic vasculitis.
Skin	Infarct, purpura, skin ulcer, gangrene	Purpura, skin ulcer, gangrene	Polymorphous exanthema, livedo, panniculitis, purpura, skin nodules, infarct, ulcer, gangrene, other skin vasculitis	Skin is a common organ involved in most forms of small and medium vessel vasculitis. Skin manifestations in AAV tend to be less serious compared with manifestations in kidneys, lungs, and upper airways. For skin vasculitis in children, the manifestations are more diverse.
Mucous Membrane/eyes	Mouth ulcers, genital ulcers, adnexal inflammation, proptosis, red eye, (epi)scleritis, conjunctivitis, blepharitis, keratitis, blurred vision, visual loss, uveitis, retinal vasculitis	Mouth ulcer, conjunctivitis/episcleritis, retro-orbital mass, uveitis, scleritis, retinal exudates	Mouth ulcers, genital ulcers, adnexal inflammation, proptosis, red eye (epi)scleritis, conjunctivitis, blepharitis, keratitis, blurred vision, visual loss, uveitis, retinal vasculitis	Eye involvement is most common in GPA and less often seen in MPA or EGPA.
Ear, nose, and throat	Bloody nasal discharge, paranasal sinus involvement, subglottic stenosis, conductive hearing loss, sensorineural hearing loss	Blood nasal discharge, paranasal sinus involvement, swollen salivary glands, subglottic inflammation, conductive hearing loss, sensorineural hearing loss	Blood nasal discharge, paranasal sinus involvement, subglottic stenosis, conductive hearing loss, sensorineural hearing loss	ENT manifestations are most common in GPA and rarely seen in MPA or EGPA. However, EGPA is often characterized by the presence of nasal polyps, which are inflammatory in nature.
Chest	Wheezing, nodules or cavities, pleural effusion, infiltrates, endobronchial changes, massive hemoptysis, respiratory failure	Nodules or cavities, pleurisy, infiltrates, endobronchial changes, alveolar hemorrhage hemoptysis, respiratory failure	Wheezing, nodules or cavities, pleural effusion, infiltrates, endobronchial changes, massive hemoptysis, respiratory failure	The chest is commonly affected in all three forms of ANCA vasculitis. Wheezing is a common feature of EGPA as are infiltrates. In contrast, infiltrates, nodules, and endobronchial disease dominate in GPA. Massive hemoptysis can occur in patients with GPA or MPA and less frequently in patients with EGPA, but may also be a typical feature with GBM disease.
Cardiovascular system	Loss of pulses, ischemic cardiac pain, cardiomyopathy, congestive cardiac failure, valvular heart disease, pericarditis	Pericarditis	Loss of pulses, bruits, blood pressure discrepancy, claudication, ischemic cardiac pain, cardiomyopathy, congestive cardiac failure, valvular heart disease, pericarditis	Cardiovascular manifestations are most widely recognized in KD, which is not particularly well covered by PVAS. Although CVD manifestations do occur in small- and medium-vessel vasculitis, they are more typically seen in large vessel diseases, such as Takayasu arteritis.
Abdominal system	Ischemic abdominal pain, peritonitis, bloody diarrhea	Mesenteric ischemia	Abdominal pain, peritonitis, bloody diarrhea, bowel ischemia	Gut involvement is more typical in medium-vessel vasculitis, especially polyarteritis nodosa, but is well recognized in patients with GPA, especially with colitis giving rise to bloody diarrhea.
Renal system	Hypertension, proteinuria, hematuria, impaired renal function, deterioration in renal function	Hematuria, red cell casts, or glomerulonephritis, deterioration in renal function	Hypertension, proteinuria, hematuria, impaired renal function, deterioration in renal function	Renal involvement in small-vessel vasculitis is one of the major manifestations, leading to organ failure and death and should be carefully assessed. Renal involvement in medium-vessel vasculitis is much less common and takes the form of infarction of segments of the kidney, leading to hematuria and hypertension with consequent impairment of renal function.
Nervous system	Headache, meningitis, organic confusion, seizures, stroke, cord involvement, cranial nerve, lesion, sensory or motor neuropathies	Meningitis, stroke, cord involvement, cranial nerve lesion, sensory or motor neuropathies	Headache, meningitis, organic confusion, seizures, stroke, cord involvement, cranial nerve, lesion, sensory or motor neuropathies	Neurological involvement is a common feature in small- and medium-vessel vasculitis; often it does not lead to immediate loss of life. Strokes are less common, whereas peripheral neuropathies are more common and can cause long-term disability.

AAV, ANCA-associated vasculitides; *ANCA*, antibodies to neutrophil cytoplasm; *BVAS*, Birmingham vasculitis activity score; *CVD*, cardiovascular disease; *EGPA*, eosinophilic glomerulonephritis with polyangiitis; *GBM*, glomerular basement membrane; *GPA*, granulomatosis with polyangiitis; *KD*, Kawasaki disease; *MPA*, microscopic polyangiitis; *PVAS*, pediatric vasculitis activity score.

The primary tool used is the BVAS in adults and the Pediatric Vasculitis Activity Score (PVAS) in children (reviewed by Ponte et al.).[67] Training is recommended for assessment in the BVAS. BVAS provides a quantitative score based on individual items, providing an effective means to define the patient's status with regards to response to therapy. Many recent studies of different immunosuppressive agents have made use of the BVAS either to define improvement in terms of a fall in BVAS score or to define a cut-off representing active disease, or inactive disease, or flare-up, depending on the number of items present. Although it is subject to observer variability, it provides an effective means by which groups of patients can be compared against each other and allows individual patients to be followed up over the course of their condition. The score is weighted according to the organ system and the individual manifestation to reflect the severity of the disease. The range of scores for BVAS and PVAS are 0 to 63. For BVAS GPA, items are divided into major (scoring 3 points) and minor (scoring 1 point each); with 15 to 19 major items and 19 to 23 minor items, the range of sores is 0 to 76. The PVAS was developed as a pediatric version of the BVAS but validated in children with vasculitis and demonstrated to be effective at discriminating different disease states. It is increasingly used as a research tool in pediatric vasculitis.

Damage Assessment in Vasculitis

The concept of damage in patients with vasculitis is about the permanent consequences of having vasculitis. It is an attempt to measure disease burden regardless of cause. The Vasculitis Damage Index (VDI) is the most widely used and validated measure for assessment of damage in vasculitis (reviewed by Ponte et al.).[67] The VDI captures the long-term consequences of a diagnosis of vasculitis and its treatment and associated co-morbidities. Damage is defined as lasting at least 3 months or occurring at least 3 months ago for single time point events (*e.g.*, stroke or myocardial infarction) and should be recorded as a permanent change to the patient's damage status. A VDI of more than 5 points recorded within 6 months of disease carries a significant increased risk of subsequent mortality compared with a lower damage index at 6 months (reviewed by Ponte et al.).[67] VDI is a useful index of future harm. A further development of the damage index has been the combined damage assessment (CDA). In a comparative study with the VDI, CDA was shown to be inferior to it (reviewed by Ponte et al.).[67]

TREATMENT

Once a diagnosis of small- and medium-vessel vasculitis has been established, treatment should be focused on patients and their problems rather than the specific diagnosis. Treatment for different forms of vasculitis may look very different, but many aspects of different forms of vasculitis require the same therapeutic approach. Without a clear understanding of the underlying pathogenesis of disease, we are inevitably led by the need to suppress inflammation and reduce damage to prevent mortality and improve survival. However, as well as modifying immune dysregulation, it is important to consider other aspects of the patient's condition, such as comorbidities and the prevention of future comorbidities.

No Treatment/Symptom Relief

Small-vessel vasculitis, such as isolated cutaneous vasculitis resulting from infection or use of pharmaceutical agents, may respond to simple withdrawal of the offending agent or resolution of the infection without the need for specific treatment. However, for more recalcitrant disease, symptom relief may be required and occasionally systemic steroids. Symptom relief could be provided in the form of antipruritic agents or topical cream to reduce skin inflammation and/or topical steroids. NSAIDs can be helpful in relieving symptoms of joint pain or swelling. As monotherapy they are unlikely to resolve skin manifestations but could be tried in combination with other therapies. Colchicine has been used for skin vasculitis and occasionally can be effective, although the doses required should remain below 2 mg/day to avoid the predictable side effects of abdominal cramps and diarrhea.

Target-Directed Therapies

In diseases where there is a clearly defined provoking agent, as in hepatitis B–related PAN or hepatitis C-related cryoglobulinemic vasculitis, eradication of the virus is a key part of treatment of the disease. Effective antiviral agents play a vital role in the management of virus, associated with the need for immunosuppression. Hepatitis B-related PAN is treated with a combination of antiviral therapy plus plasma exchange to remove immune-complexes and other inflammatory mediators combined with a course of glucocorticoid therapy. For hepatitis C-related cryoglobulinemic vasculitis, recent reports of virus eradication may also be transforming the outcome of this disease. Unfortunately, the toxicity of these regimens can be considerable, with over 40% requiring erythropoietin, red blood cell transfusions, and/or G-CSF.

Specific Therapies

In KD, although the etiological factors have not yet been defined, it seems likely that this is related to some kind of infectious agent (see earlier section on pathogenesis). The most effective therapy is use of high doses of IVIG (0.4 g/kg per day for 5 days) combined with high doses of aspirin, which is usually curative. Whether or not this will prevent long-term harm to the cardiovascular system, particularly the coronary arteries, remains to be explored.

Glucocorticoids

Glucocorticoids (see Chapter 83) remain a cornerstone in the management of most forms of multisystem vasculitis. They are relatively contraindicated in KD because they may potentially worsen the development of coronary artery aneurysm, but they have been used in combination with IVIG and aspirin with beneficial outcomes. However, they are an integral part of almost all therapeutic regimens for management of vasculitis. In some instances, such as isolated skin vasculitis, they are the only treatment required, but more often they are insufficient on their own without causing significant morbidity from side effects. Typical doses of glucocorticoid therapy are 1 mg/kg per day over a period of 2 to 4 weeks, reducing to around 10 to 15 mg/day within 6 months, and then slowly withdrawing steroids in the next 6 to 12 months. The use of high-dose intravenous methylprednisolone is popular but lacks evidence. The only randomized trial of intravenous methylprednisolone compared it against plasma exchange in patients with severe AAV (reviewed by Ponte et al.).[67] This study demonstrated the superiority of plasmapheresis over IV prednisolone, both used as adjunct therapies (in combination with cyclophosphamide and high doses of oral prednisolone)

for treatment of severe AAV (mainly MPA plus some cases of GPA) with significant renal impairment (creatinine levels above 500 μmol/L [5.66 mg/dL]).

The role of glucocorticoid therapy has been increasingly challenged by more recent trials using smaller doses for shorter periods or even eliminating steroid use completely in some instances. While intensive immunosuppression using high doses of corticosteroids remains established as part of the initial management of AAV, close consideration needs to be given to the extensive side-effect profile associated with corticosteroids. There is significant morbidity associated with corticosteroid use in patients with AAV within just one year of treatment—8.2% developing new onset diabetes (50% of which occurred within 1.7 months), 29% gaining over 10 kg in weight, 2.6% developing peptic ulceration, 2.5% suffering insufficiency fractures, 2% developing cataracts and 0.4% developing avascular necrosis. These adverse effects become more pronounced with increasing length of corticosteroid exposure. After a median of 5 years, 41% of patients develop hypertension, 38% become osteoporotic, 28% develop diabetes mellitus and 25% develop cataracts.[68] The risk of osteoporosis is largely preventable with concurrent use of bisphosphonate therapy (unless there is significant renal dysfunction) with supplementary calcium and vitamin D replacement. The increased risk of cardiovascular disease (CVD) in AAV patients is not only associated with accelerated atherosclerosis due to inflammation, but also corticosteroid use causing multiple metabolic side effects including hypertension, hyperlipidemia, weight gain and diabetes, which are all significant cardiovascular risk factors.[68] Indeed, the challenge is balancing risk of AAV relapse with risk of corticosteroid-related morbidity. There are encouraging data from the PEXIVAS and CLEAR studies that indicate the possibility of effective treatment of AAV with reduced doses of corticosteroid.[2,69]

Other Immunosuppressive Therapies

Cyclophosphamide (see Chapter 84) has been available since the 1950s but was first used for the management of systemic vasculitis in the 1970s and remains the most effective agent we have for managing multiorgan systemic vasculitis. Initially it was used as a daily oral agent at 2 mg/day to 3 mg/day, and it transformed the outcome of patients with AAV from inevitable mortality to a high likelihood of survival. It is a cytotoxic agent and carries with it the risk associated with chemotherapy, including increased risk of malignancy, especially in the bladder because it is predominantly excreted through the kidneys and accumulates in the bladder. Initial protocols were associated with excessive risks of bladder cancer (~33-fold), but despite this, the daily oral cyclophosphamide dosing regimen was not effective in maintaining control of disease. Therefore, over the past 20 years or so, there have been a number of trials comparing reduced doses of cyclophosphamide, high-dose intermittent pulse therapy (reviewed by Yates et al.),[66] or with combination strategies of induction with short courses of cyclophosphamide followed by a switch to another drug for maintenance[66] or by replacing cyclophosphamide with another agent, such as methotrexate (MTX). All these studies[66] have demonstrated the equivalence of using shorter courses of daily oral cyclophosphamide and, more recently, of using of high-dose intermittent pulses of cyclophosphamide to reduce the total dose even further. The total cumulative dose from six cycles of cyclophosphamide over a period of 3 months would be 6 g (based on 15 mg/kg per treatment on six occasions). This compares with 9 g to 12 g of cyclophosphamide given as daily oral therapy over 4 to 6 months.[66]

Although the relapse rate for patients given high-dose intermittent cyclophosphamide was higher during the subsequent 5 years compared with that for patients who were not given daily oral cyclophosphamide, relapse was always effectively managed with reintroduction of therapy and never led to mortality.[66] The consequences of exposure to cyclophosphamide are likely to be a risk of cancer (more recent studies suggest that this risk is relatively modest now that the regimens include much lower total doses), infertility, hair loss, nausea, vomiting, diarrhea, cytopenia, and increased risk of infection. Less common complications of cyclophosphamide include hyponatremia. The introduction of rituximab for AAV has had a significant impact on the use of cyclophosphamide, with increasing numbers of patients being managed with rituximab in place of cyclophosphamide, especially if patients are of child-bearing years or if there is a potential contraindication to using cyclophosphamide, such as a previous history of bladder cancer.

Because of the nature of AAV, relapse is common. Therefore, a single course of therapy rarely achieves long-lasting remission. Repeat cycles of treatment are likely to be required, which accounts for the accumulation of higher doses of cyclophosphamide, especially in the pre-rituximab era. Therefore, although each individual course of therapy may only contain 6 g to 9 g, during a patient's lifetime, they may require treatment for several relapses, which would then start building up the total exposure to cyclophosphamide. Nevertheless, even though it is being slowly replaced, it presently remains an important aspect in the therapy of vasculitis.

Azathioprine is an immunomodulator with cytostatic properties. It inhibits cell division; it has been an effective immunosuppressant agent for decades. It was first used in combination with steroids and found to reduce mortality in systemic vasculitis in an open-label retrospective study of 64 patients.[66] The 5-year survival of patients given no therapy was 12%, and those given steroids alone had a 53% survival rate, whereas those treated with steroids plus another agent (mainly azathioprine but a few had cyclophosphamide) had a survival rate of 80%. It is an oral medication given at 2 to 2.5 mg/kg per day, and it has largely been superseded as an induction agent by cyclophosphamide. Azathioprine is usually now used as maintenance therapy once the disease has been controlled with another agent. In newly diagnosed AAV following induction with cyclophosphamide and glucocorticoids, rituximab was shown to be more effective in leading to sustained remission at 28 months when compared to azathioprine.[70] Following remission-induction with rituximab, rituximab was shown to be superior to azathioprine for preventing disease relapse in patients with AAV with a prior history of relapse.[71] Prolonged remission therapy with combination azathioprine and prednisolone for a duration of 48 months following initial diagnosis of AAV resulted in fewer relapses and improved renal survival when compared to withdrawal of treatment 24 months after initial diagnosis.[72] Azathioprine has been shown to be equivalent to MTX and superior to mycophenolate[66] as maintenance therapy. It is a relatively safe immunosuppressant and can be used safely throughout pregnancy.

MTX is popular among rheumatologists but less so among renal physicians who regard it with some suspicion because of its potential for nephrotoxicity. The latter is only the case for patients who have well-established renal disease (typically with a creatinine level greater than 300 μmol/L). MTX is an effective

immunosuppressant agent used very widely in the management of inflammatory arthritis and has found its place in the management of GPA, where studies have demonstrated its efficacy in comparison to oral cyclophosphamide.[66] However, it needs to be given continuously, rather than as an induction regimen over the short period of time. Although MTX is as effective as cyclophosphamide in inducing remission in GPA, stopping the drug inevitably leads to relapse. In terms of maintenance therapy, MTX has been shown to be equally as effective as cyclophosphamide in maintaining disease remission at 12 and 24 months, following remission-induction with pulsed cyclophosphamide, although levels of proteinuria were significantly lower at 24 months in the cyclophosphamide arm.[73] MTX is recommended for non-life-threating AAV, usually in combination with steroid treatment. MTX is available either as oral, intramuscular, or subcutaneous administration. The dose is 20 mg/week to 25 mg/week in most studies of vasculitis. It is contraindicated in pregnancy.

Cotrimoxazole, an antibiotic containing sulfonamide and trimethoprim, was fortuitously discovered to have beneficial effects in patients with GPA who had been treated coincidentally for infections. There has been a significant advance in our understanding of GPA, partly as a result of this historical experiment and partly based on suggestions that *S. aureus* plays a role in initiating disease by its effect on the nasal mucosa. Eradication of the organism has been suggested as one mechanism by which it works, although the drug is not particularly effective against this organism. It is more likely that the drug has an immunosuppressive effect in itself; it has been demonstrated to be effective in combination with low-dose steroids in a randomized trial of localized forms of GPA.[66] It is also commonly used as a prophylactic agent against *Pneumocystis jiroveci* infection; it is given three times per week for patients receiving other more potent immunosuppressant therapy, such as cyclophosphamide or even MTX (despite the potential for drug interactions leading to anemia).

Mycophenolate mofetil is a widely used transplantation drug that has been tested in AAV but is less effective than azathioprine as maintenance agent for patients who have achieved remission. Trial data comparing mycophenolate to cyclophosphamide revealed that cyclophosphamide was more effective than mycophenolate for remission-induction in patients with non-life-threatening relapses of AAV (azathioprine being used as maintenance therapy).[74] In patients with newly diagnosed AAV, although mycophenolate was shown to be non-inferior to cyclophosphamide in remission-induction at 6 months, higher rates of relapse were seen in the mycophenolate group (azathioprine being used as maintenance therapy).[75] Mycophenolate is typically given as 2 to 3 g/day as an oral dose, along with reducing courses steroids. It is contraindicated in pregnancy.

Cyclosporine is a well-established immunosuppressive drug that has been used for transplantation for many decades. Cyclosporine has been given to limited numbers of patients with systemic vasculitis, with one small well-conducted trial[76] in 32 patients with GPA. In combination with plasmapheresis, it was as effective as continuous oral cyclophosphamide as a maintenance agent. It is generally limited by its toxicity and is not routinely used.

Leflunomide, an antilymphocyte agent used extensively for the management of inflammatory arthritis, has been tested in patients with AAV in limited trials demonstrating its ability to maintain remission. Indeed, in a recent meta-analysis, it was reported to be superior to azathioprine, MTX, and mycophenolate as a maintenance agent for AAV, but more trial data are needed. It is an oral agent that is characterized by a very long half-life, and it is not suitable for use in pregnancy.

The role of hydroxychloroquine in mild forms of vasculitis is uncertain. There is anecdotal evidence that it is beneficial in patients with skin manifestations with small-vessel vasculitis. Its use probably stems from its known effects in the treatment of connective tissue diseases with skin and joint manifestations, such as SLE. Other similar agents, such as mepacrine and dapsone, have also been used for skin vasculitis with occasional reported positive outcomes. However, the potential toxicity for each of these agents should be considered alongside the relatively limited evidence for benefit.

Specific Immunotherapy

Better understanding of the pathogenesis of vasculitis (see section on pathogenesis) has led to the development of targeted immunotherapy for some of these diseases. Rituximab is an mAb against B cells and has been in widespread use for treatment of RA. Its role as an effective agent in AAV is well established with two randomized trials demonstrating efficacy comparable with cyclophosphamide (reviewed by Yates et al.).[66] Rituximab induction therapy is just as effective as cyclophosphamide for moderate and moderate-to-severe AAV. Indeed, there were no differences in remission rates or increases in eGFR at 18 months (regardless of ANCA type) when comparing rituximab plus glucocorticoids versus cyclophosphamide plus glucocorticoids, in both new and relapsing GPA and MPA. There were no differences in relapse rates at 6, 12, or 18 months; and there were no differences in adverse events.[77] At 24 months, rates of the composite outcome of death, end-stage renal disease and relapse did not differ between rituximab and cyclophosphamide, although B-cell return was associated with relapse in the rituximab arm.[78] Maintenance therapy with rituximab is a real possibility with the potential to provide long-term control and reduce relapse risk. The long-term consequences of repeat cycles of rituximab, however, are unexplored. The risks are hypogammaglobulinemia, which occurs in most cases, and the potential increase in incidence of infections. The most feared complication is the risk of reactivation of the John Cunningham (JC) virus leading to the complication of progressive multifocal leukoencephalopathy (PML), which has a very high mortality rate. The COVID-19 pandemic has reemphasized the need for the host to produce protective antibodies, raising the possibility that B-cell depleting agents need to be used with great caution.

Other Therapies

Belimumab continues to be investigated as a maintenance agent for AAV. It is a fully humanized IgG1γ mAb directed against soluble BLyS. Belimumab plus azathioprine and glucocorticoids for the maintenance of remission in AAV did not reduce the risk of relapse when compared against placebo.[79] Mepolizumab is a mAb directed against IL-5, which controls eosinophil production. Mepolizumab has been successfully used in the treatment of HES. In EGPA, Mepolizimab resulted in significantly higher levels of sustained remission in EGPA, compared to placebo, thus allowing for reduced glucocorticoid use.[80] IVIG has been available as a replacement therapy for patients with hypogammaglobulinemia for several years, and it is the standard of care

for KD, but its use in AAV has been limited. An initial study suggested relatively short-term benefit.[81] It has been suggested that IVIG can provide clinical benefit as a short-term adjunctive therapy in refractory or relapsing AAV, with rapid improvements in BVAS, ANCA levels, and CRP.[82,83] Plasmapheresis has been available for several decades. It is not entirely clear how it works; there are many theories suggesting the removal of circulating immune mediators is effective in reducing inflammation. Plasmapheresis has been widely used in the treatment of patients with severely impaired renal function and/or alveolar hemorrhage in AAV. It has been successful for rescue therapy in patients with very aggressive AAV or anti-GBM disease. The MEPEX trial demonstrated that it was able to reduce renal dysfunction in patients with severe AAV.[66] However, the long-term follow-up of the MEPEX trial demonstrated that the difference between patients treated with plasma exchange and those given methylprednisolone pulses (both as adjunct treatment alongside cyclophosphamide and steroid) did not last.[84] It has been suggested this is accounted for by the fact that many patients with severe renal disease had already developed irreversible changes to their kidneys and that renal dysfunction would have been secondary to damage rather than active disease. However, its use has recently been called into question as it failed to demonstrate a reduction in the incidence of death or end-stage renal failure in severe AAV. The same data did in fact also demonstrate non-inferiority using a reduced-dose glucocorticoid regimen compared to a standard-dose regimen with respect to death or end-stage renal failure.[2]

Plasmapheresis is effective in conjunction with antiviral therapy and steroids in the management of hepatitis B–related PAN.

Avacopan, an orally administered selective C5a receptor inhibitor, has shown promise in an early phase randomized placebo-controlled trial in effectively replacing high-dose glucocorticoids in the treatment of AAV.[69] A recent randomized, controlled trial comparing oral avacopan to oral prednisone on a tapering schedule in patients with AAV (where all patients received induction therapy with either cyclophosphamide or rituximab, followed by maintenance azathioprine). Avacopan was non-inferior, but not superior, to prednisone taper with respect to remission at week 26; and was superior to prednisone taper with respect to sustained remission at week 52. Encouragingly, the avacopan group required significantly less glucocorticoid treatment, and reduced glucocorticoid-associated toxicity, which points towards the future possibility of steroid-reduced, or perhaps even steroid-free, treatment of AAV.[85]

OUTCOMES

The majority of patients have a successful initial outcome. Either the condition is self-limiting in the case of more isolated forms of skin vasculitis, or the initial immunosuppressive therapy is successful. Over 94% of patients with generalized AAV would expect to survive the first 18 months,[66] whereas patients with more severe disease, especially with significant renal impairment, have a mortality of around 25% after 2 years.[66] This contrasts with over 80% likelihood of dying without adequate treatment. However, with current therapy, 5-year survival figures suggest around 25% to 30% mortality among AAV-affected patients.[66]

The bigger problem, however, is morbidity. The quality of survival for most patients with multiorgan disease is complicated by episodes of relapse in 50% to 70% of cases and low-grade grumbling disease, which never quite goes into full remission in up to a third of cases.[86] This is added to the comorbidity experienced by older patients, usually a combination of vasculitis-related damage, steroid-induced side effects, and the long-term consequences of immunosuppressive agents. In the first year of diagnosis, the most likely cause of mortality is active vasculitis or infection,[64] the latter being a surrogate measure of the severity in immunosuppressant therapy required to control the disease.

Long-term adverse outcomes in vasculitis can be measured using a structured VDI (see Assessment section above). One of the most important outcomes is the development of end-stage renal failure and the requirement for dialysis. It is likely that this is significantly reduced as a result of effective therapy given within the first 4 months of diagnosis. Transplantation is successful in patients with AAV, and these patients should be offered this treatment. Ten-year survival rates (32.5%) are similar to those reported for other patients without diabetes receiving a kidney transplant.[87] The immunosuppressive regimens used for maintaining the transplant (see Chapter 89) are often sufficient to keep the vasculitis in remission, but there is a need for ongoing review.

Infection is a significant concern, especially in the early course of disease when potent treatment is being commenced, especially high doses of steroids. The risk of serious infection requiring hospitalization is very high in the first year,[64] especially if the steroid doses remain high after 6 months. Interstitial lung disease (nonspecific interstitial pneumonia) is reported in around 20% of Japanese patients, especially those with MPA. This is a higher prevalence than that seen in other populations and may reflect genetic and environmental differences unique to Japan. Chronic neuropathy occurs in up to 65% of patients with AAV,[88] especially for patients with eosinophilic GPA and can be very distressing for patients. Upper airway disease generally continues to cause long-term problems in 65% of patients with GPA because of chronic mucosal damage causing symptoms of chronic nasal congestion, discharge, and discomfort.[89] Symptom relief is only partially successful in alleviating these problems. CVD among patients with small-vessel vasculitis is present in approximately 9% within 6 months of diagnosis[90] and four times greater in patients with AAV compared with the general population. The risk of cardiovascular events is about 14% within 5 years of diagnosis, especially in older patients who have baseline hypertension and MPO antibodies.[91] Cancer is associated with the presence of small-vessel vasculitis. It may predate as well as occur at the same time as diagnosis or develop subsequently, but it is recognized as a risk among patients treated with immunosuppressive and cytotoxic agents. Cancer of the bladder particularly has been an established risk arising from treatment with cyclophosphamide for many years; the original data from the 1970s suggested up to 33-fold increased risk of bladder cancer among patients treated with cyclophosphamide for vasculitis compared with background controls. However, this risk has been reduced with the use of more limited courses of cyclophosphamide (typically 3 to 6 months duration) and particularly with use of intermittent cyclophosphamide delivery. In a recent large series from the European Vasculitis Study Group (EUVAS), the only increased risk of cancer was for non-melanoma skin cancer, and this may also have reflected the use of azathioprine as well as use of cyclophosphamide.[92] Shang et al.[93] showed that in a meta-analysis of over 2500 patients,

the standardized incidence rate of late-occurring malignancies, particularly nonmelanoma skin cancer, leukemia, and bladder cancer, was 1.74 (95% CI = 1.37 to 2.21). We advise all of our patients to wear sun protection.

The ability to work is significantly affected by AAV; among 410 patients interviewed, 26% of those of working age were classified as work disabled.[94] The strongest influences on this outcome were fatigue, depression, high levels of damage (measured using the VDI), and being overweight. Patients' functional outcome can be variably affected by vasculitis and its treatment. Patients report impairment of function as measured by using generic tools, such as EQ-5D or the short form 36.[95] The impairment is similar to that found in other chronic diseases. Physical functions tend to be more affected than mental functions, especially in older patients with evidence of neurological involvement, usually peripheral neuropathy. Functional outcome is not directly correlated to disease activity, although in a Japanese cohort, 18 months after initiation of therapy, many aspects of function had started to improve.[96] One of the problems of determining long-term outcomes in patients with vasculitis is the compounding effect of the very intensive immunosuppressive therapy required to control disease. Over the last 3 decades, we have seen dramatic shift away from long-course cyclophosphamide toward short courses of intermittent dose therapy, but we are now witnessing an era when targeted biological therapies are able to take the place of cyclophosphamide. Therefore, eliminating the use of cyclophosphamide altogether in some patients may reset potential future outcomes. If this is coupled with a reduced use of glucocorticoid therapies and maintaining better disease control with less frequent relapses, the outcome may well be improved considerably for patients in the future.

ON THE HORIZON

- Improved understanding of the underlying pathogenic mechanisms in different forms of vasculitis is starting to lead to more logical, rational therapies, some of which have become established as standard of care or should be available in the near future.
- Rituximab is available and is being increasingly used in place of cyclophosphamide in the management of AAV. The role of rituximab in maintenance treatment, compared to azathioprine, is currently being explored, but reduced ability to produce protective antibodies may impose long-term risk for increased susceptibility to infection. Rituximab therapy is also effective in patients with cryoglobulinemic vasculitis, even when associated with the presence of hepatitis C. There is a concern that this might lead to reactivation of the virus and increase the risk of hepatoma or induce the development of the B-cell clone. However, better control of hepatitis C with effective antiviral agent is now possible.
- Multiple proinflammatory cytokines are being explored as therapeutic targets, although this will only allow for the suppression of common pathways in the end stage of inflammation.
- Mepolizumab has recently been shown to be effective in the treatment of EGPA in a large randomized controlled trial.
- Belimumab continues to remain under investigation, although when used in maintenance of remission in AAV (alongside azathioprine and glucocorticoids) it did not reduce the risk of relapse when compared against placebo.
- Blocking IL-6 may be of benefit for some patients.
- The discovery of the involvement of the C5 in AAV has led to trials demonstrating effective treatment of AAV with steroid-reduced or steroid-free induction-remission.
- The ultimate goal remains to identify upstream pathologies leading to vasculitis, which promises to fundamentally change the management of these devastating diseases, as it may permit the induction and maintenance of drug-free remission.

Large Vessel Vasculitides

Cornelia M. Weyand

Most tissues have compensatory mechanisms that allow them to sustain the damaging effects of acute and chronic inflammation, but medium and large arteries are organs without redundancy and limited regenerative capacity. Life is unsustainable unless the major arteries have uncompromised function. Accordingly, autoimmune and autoinflammatory damage to such arterial vessels leads to severe clinical consequences, immediately posing a threat for the loss of function of vital organs. When affected by inflammation, the aorta and its branches have two possible response patterns: (i) Damage to the vessel wall leads to dilatation, aneurysm formation, and rupture. Alternatively, the wall layers dissect. (ii) The inflammation initiates a maladaptive response to injury, resulting in vasoocclusion, disruption of blood supply, and organ ischemia.

In contrast to other vasculopathies, especially those related to atherosclerosis, vasculitides of the large muscular and elastic arteries are almost always associated with a syndrome of intense systemic inflammation.[1] Systemic inflammation is no longer considered a spillover of inflammatory mediators from the vasculitic lesions. Instead, systemic activation of the innate immune system appears to be a pinnacle event that initiates the processes leading to vessel wall inflammation. The coincidence of malaise, fever, wasting, and myalgias, with signs of ischemia caused by vascular failure, remains a critical clue for the physician when diagnosing and treating large vessel vasculitis (LVV).

The two major forms of LVVs are giant cell arteritis (GCA) and Takayasu arteritis (TA). In addition, aortitis can infrequently be seen in other diseases, such as infections, connective tissue diseases, sarcoidosis, and inflammatory bowel disease (IBD), and occasionally is diagnosed as an idiopathic syndrome. It is now recognized that aortitis can occur as a side effect of checkpoint inhibitor immunotherapy. Polymyalgia rheumatica (PMR) is a condition closely related to GCA; it occurs in the same patient population and often precedes or follows the clinical diagnosis of GCA.[2] Patients with PMR do not have typical vascular lesions; consequently, PMR is a vasculitic forme frust. Patients with PMR do have a systemic inflammatory syndrome indistinguishable from GCA, and approximately 10% of them eventually progress to full-blown vasculitis. Similarities in the vascular lesions of GCA and TA have been interpreted as revealing parallels in immunopathogenesis. More recent studies emphasize dissimilarities between both LVVs, including disease-specific autoantibodies in TA patients and a role of cytolytic CD8 T cells and natural killer (NK) cells in TA pathogenesis. Whether the systemic inflammatory reactions accompanying GCA, TA, and PMR have disease-specific elements remains unanswered, but this has opened the possibility of developing biomarkers that are urgently needed for clinical monitoring. Excellent progress has been made in unraveling the pathogenesis of GCA, and this will inevitably lead to improvements in diagnosis, long-term management, and broadening of the therapeutic armamentarium.

EPIDEMIOLOGY

GCA may be a very old disease, as suggested by historic evidence that more than 1000 years ago temporal artery removal was recommended by a physician in Baghdad. In 1932, Horton et al. at the Mayo Clinic in Minnesota recognized that GCA was a vasculitis based on dense temporal artery inflammation of two patients who were systemically ill and had severe headaches. The first reports of TA, or "pulseless disease," in young women surfaced in Japan in the 19th century. The syndrome was named after Dr. Takayasu, an ophthalmologist, who, in 1905, described peculiar optic fundus abnormalities caused by ischemia-driven collateral formation.

The strongest risk factor for GCA, TA, and PMR is age.[3] GCA and PMR are essentially absent in individuals younger than 50 years of age, and their incidence climbs continuously during the seventh and eighth decades of life. TA is almost exclusively diagnosed in individuals younger than 40 years of age, with peak incidence during the second and third decades of life. Women are affected more often by all three syndromes compared with men, with a 2:1 ratio in PMR and GCA and a 9:1 ratio in TA.[3,4]

Marked geographic variations in the incidence and prevalence of GCA, TA, and PMR have encouraged speculations that environmental exposures are key determinants in disease pathogenesis. GCA is the most frequent vasculitis in the Western world, with yearly incidence rates reaching 10 to 20 cases per 100,000 persons older than 50 years of age.[3] In general, PMR is diagnosed threefold to fourfold more frequently, with a prevalence of up to 1 case per 133 individuals older than 50 of age.[2] Iceland, Norway, Sweden, and Denmark are high-risk areas; higher incidence rates are also seen in Scandinavian immigrant populations in the United States. The risk is significantly lower in Hispanics and African Americans. Although TA can afflict all races, a predilection exists for individuals of Asian and Central and South American origins. Japan, Thailand, India, Turkey, and Central and South America are considered high-incidence regions. TA is a rare disease, with an annual incidence of 1 to 2 cases/million. The typical patient is a female in her 20 s to 30 s. In middle-aged men and women, it can be challenging to differentiate TA from rapidly progressing atherosclerotic disease, especially as both disease processes may coexist.

ETIOLOGY AND PATHOGENESIS

Abnormal innate and adaptive immune responses are essential pathogenic elements in medium-vessel vasculitides and LVVs. The resulting disease process separates GCA, PMR, and TA

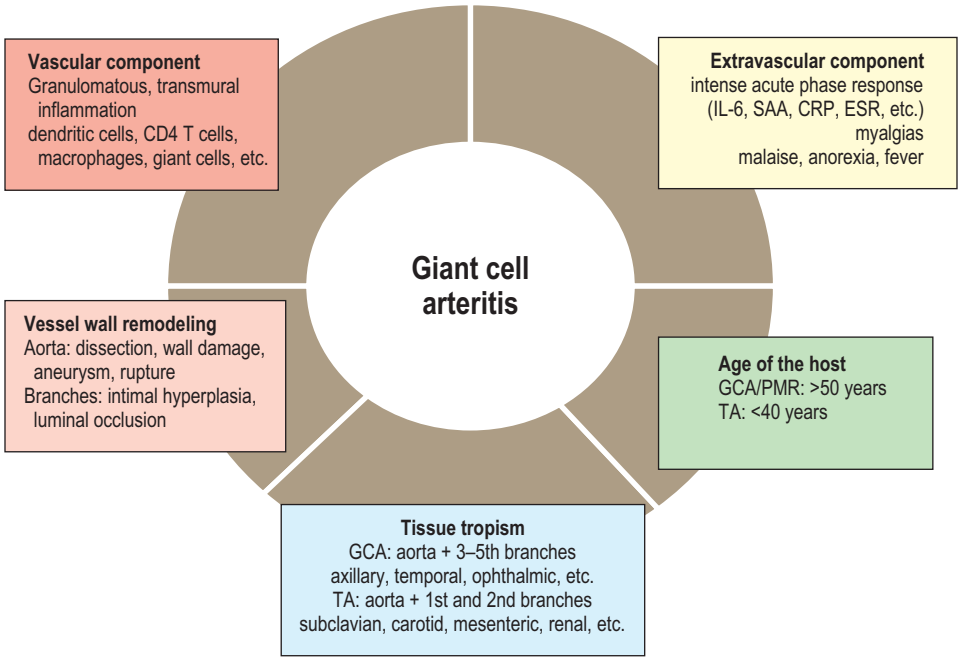

FIG. 60.1 Key Pathogenic Traits in Giant Cell Arteritis. Five hallmarks of disease represent fundamental pathogenic traits and distinguish giant cell arteritis *(GCA)* from other immune-mediated disorders. Vascular GCA (granulomatous vasculitis) is separated from extravascular GCA (systemic inflammation and intense hepatic acute phase response). Age remains the strongest risk factor and patients with GCA have a signature of immunosenescence. The stringent tissue tropism for selected vascular beds is suspected to reflect determinants of the tissue niche. Clinical complications are related to the patterning of vascular damage, spanning from wall destruction to luminal occlusion. *CRP*, C-reactive protein; *ESR*, erythrocyte sedimentation rate; *IL-6*, interleukin-6; *PMR*, polymyalgia rheumatica; *SAA*, serum amyloid A; *TA*, Takayasu arteritis.

from other vasculitides and from other autoinflammatory and autoimmune syndromes. Recent work has delineated disease-specific signatures, with the goal to mark the pinnacle abnormality triggering the disease and to discover intersection points that lend themselves for diagnostic and therapeutic purposes.

Pathogenic studies and careful clinical observation have prompted a substantial shift in the pathogenic model (Fig. 60.1): LVVs are now understood to be chronic conditions that target restricted vascular beds and have two major disease components: (i) granulomatous, intramural inflammation inducing vascular wall remodeling; and (ii) extravascular inflammation manifesting with an intense acute phase response, myalgias, and constitutional symptoms. Emerging data suggest at least partial autonomy in the pathogenic cascades of both disease components, predicting separate biomarkers, separate pathogenic mechanisms, and separate responses to immunosuppression. Similarities in tissue tropisms and histologic lesions of GCA and TA suggest some overlapping disease pathways, but abnormalities in cytolytic CD8 T cells and NK cells may be more relevant in TA. The etiopathogenesis of PMR is less well understood, but experimental evidence suggests that it represents a forme fruste of GCA, in which inflammatory attack to the vessel wall remains below a threshold, and standard histology describes noninflamed arteries.

Distinctive features—hallmarks of disease—provide clues to the fundamental pathogenic mechanisms (see Fig. 60.1), including a stringent age cutoff, a stringent tissue tropism for selected vascular territories (aorta and major branches), an extravascular disease module defined by an abrupt and intense acute phase response, a granulomatous transmural vasculitis, and two alternate patterns of vessel wall remodeling causing aortic wall destruction versus luminal occlusion in the branch vessels.

INNATE IMMUNE SYSTEM DEFECTS

Innate immune cells make critical contributions to the pathogenesis of LVVs, but where circulating monocytes and neutrophils encounter their activating stimuli remains unknown (Fig. 60.2). Circulating monocytes and macrophages are highly activated[5] and contribute to the array of proinflammatory cytokines measurably elevated in the serum of affected patients.[6] Altered neutrophil functionality has also been described.[7] Early in the disease process, circulating neutrophils resemble those induced by a lipopolysaccharide stimulus, displaying T-cell suppressive functions. Interleukin-8 (IL-8) and IL-6 are associated with neutrophil activation. IL-6, first described in the early 1990s, is highly elevated in GCA and PMR[8] and is explicitly steroid sensitive.[9] IL-6 acts as an inducer of the acute phase response in the liver, triggering production of C-reactive protein (CRP), serum amyloid A (SAA), and multiple other acute phase proteins. Accordingly, treatment with an IL-6 receptor–blocking antibody effectively reduces the laboratory abnormalities measured in patients with GCA.[10] Whether IL-6 has additional functions in the disease process, particularly in the inflamed vessel wall, is uncertain. Some acute phase proteins (*e.g.*, SAA) function as proinflammatory amplifiers. Although abnormal innate immunity dominates the extravascular component of LVVs, underlying mechanisms (*e.g.*, original triggers, site of activation, interface of systemic and vascular inflammation) are essentially unexplored.

Defects in innate immunity contributing to the early and late events in the vasculitic lesions are much better understood (Fig. 60.3).[11] A population of vessel wall–residing dendritic cells (vasDCs) have been identified in normal human arteries[12] localized at the adventitial–medial junction, close to the adventitial

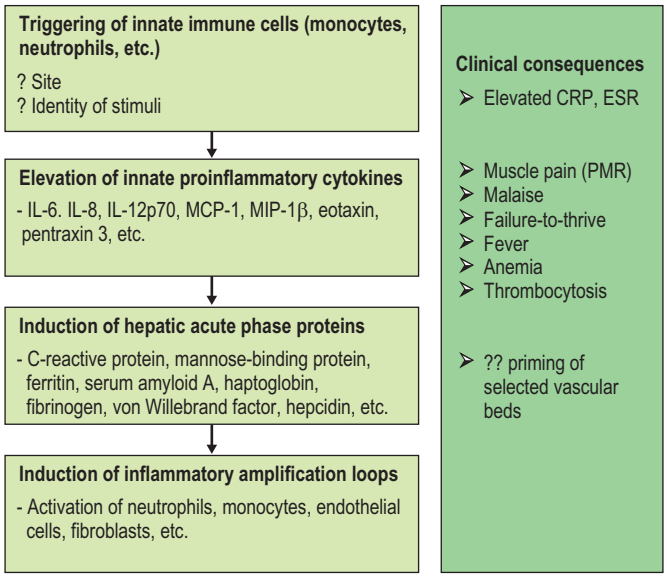

FIG. 60.2 Extravascular Giant Cell Arteritis. Circulating innate cells (monocytes, neutrophils, etc.) are highly activated and elicit a hepatic acute phase response. Acute phase proteins serve as biomarkers (C-reactive protein *[CRP]*, erythrocyte sedimentation rate *[ESR]*) of disease. Extravascular giant cell arteritis (GCA) is explicitly sensitive to corticosteroid therapy and to cytokine blockade. Whether the extravascular competent has a direct or indirect involvement in driving/sustaining granulomatous vasculitis remains unknown. Polymyalgia rheumatica *(PMR)* represents an isolated form of extravascular GCA. *IL*, Interleukin.

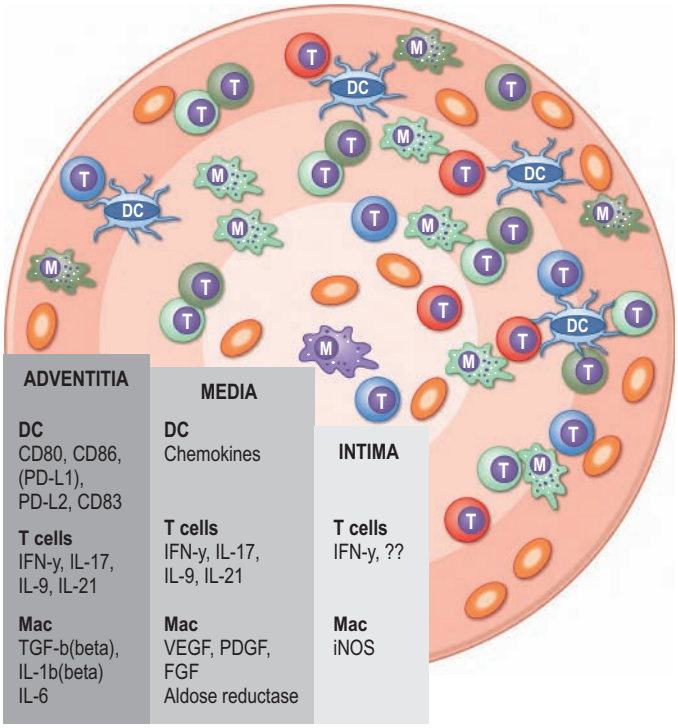

FIG. 60.3 Vascular Giant Cell Arteritis. T cells, macrophages, and dendritic cells *(DCs)* form granulomatous infiltrates in the vessel wall. DCs, present in healthy arteries at the adventitia-media border, serve as antigen-presenting cells and provide costimulatory signals but are deficient in the coinhibitory ligand programmed death ligand 1 *(PD-L1)*. Wall-infiltrating T cells are multifunctional, producing a broad spectrum of effector cytokines, including interferon *(IFN)-γ*, interleukin *(IL)*-17, IL-9, and IL-21. Macrophages, some of which transform into multinucleated giant cells, supply a multitude of cytokines, metalloproteinases, reactive oxygen species, growth factors, angiogenesis factors, and inducible nitric oxide synthase *(iNOS)*. Their functional commitment depends on their geographic location in the vessel wall. *FGF*, Fibroblast growth factor; *PDGF*, Platelet-derived growth factor*TGF-β*, Transforming growth factor-β; *VEGF*, Vascular endothelial growth factor.

microvascular network. Given their strategic positioning, they are believed to guard the artery's "backdoor." vasDCs serve a gatekeeper function in vasculitis, and stimulation of such vasDCs is a prerequisite to break the natural immunotolerance (immune privilege) of the arterial wall. Their activation presages vasculitis, as indicated by their transition from the resting state to the activated state in PMR arteries, where no vessel wall infiltrates are as yet detectable.[13] In frank vasculitis, vasDCs undergo expansion, penetrate deep into the wall, produce chemokines and cytokines, and express costimulatory ligands.[14] They may present local antigen to induce T-cell clonal expansion and, through their chemokine production, shape the composition of the intramural granulomatous infiltrates. Considering that vital arteries are protected by immune privilege, malfunction of endogenous vasDCs may, indeed, be the pinnacle defect-initiating vasculitis.

Other innate immune cells sequestered in the vasculitic lesions, specifically macrophages, are key inflammatory effector cells.[15] Multiple functional domains of macrophages have pathogenic relevance. The functional commitment of lesional macrophages is closely linked to their geographic location in the tissue site.[16] Intima-positioned macrophages produce inducible nitric oxide synthase, regulating vascular tone. Adventitial macrophages secrete cytokines (IL-1β, IL-6, transforming growth factor-β [TGF-β]), conditioning the local inflammatory environment. Granuloma formation and giant cells occur mainly in the media and at the media–intima border. Functional profiling of media-residing macrophages has connected them to tissue damage; they produce matrix metalloproteinases (MMP) and reactive oxygen species (ROS), provide antioxidant regulation, and supply growth factors for myofibroblasts and newly formed microvessels. Essentially, they drive the hyperplasia of the intimal layer that leads to luminal obstruction and tissue ischemia. Whether macrophage effector functions are fundamentally different in aortitis, compared with branch vasculitis, is unknown. Differences of tissue damage patterns (wall destruction versus luminal occlusion) suggest at least substantial variances (Fig. 60.4).

ADAPTIVE IMMUNE SYSTEM DEFECTS

The hallmark lesions in the vessel wall are granulomatous infiltrates, a mixture of highly activated macrophages, giant cells, and surrounding lymphocytes (see Fig. 60.3). The overwhelming majority of these lymphocytes are memory CD4 T cells. CD8 T cells are infrequent, and B cells are rare. Multinucleated giant cells are present in approximately 50% of patients, often localized at the intima–media border adjacent to the lamina elastica interna. Fragmentation of that elastic membrane is a hallmark of GCA.

Analysis of clonal CD4 populations has yielded identical T-cell receptors (TCRs) in independent temporal artery biopsies from the same patient, strongly supportive for antigen-dependent T-cell expansion.[17] Wall-embedded vasDCs serve

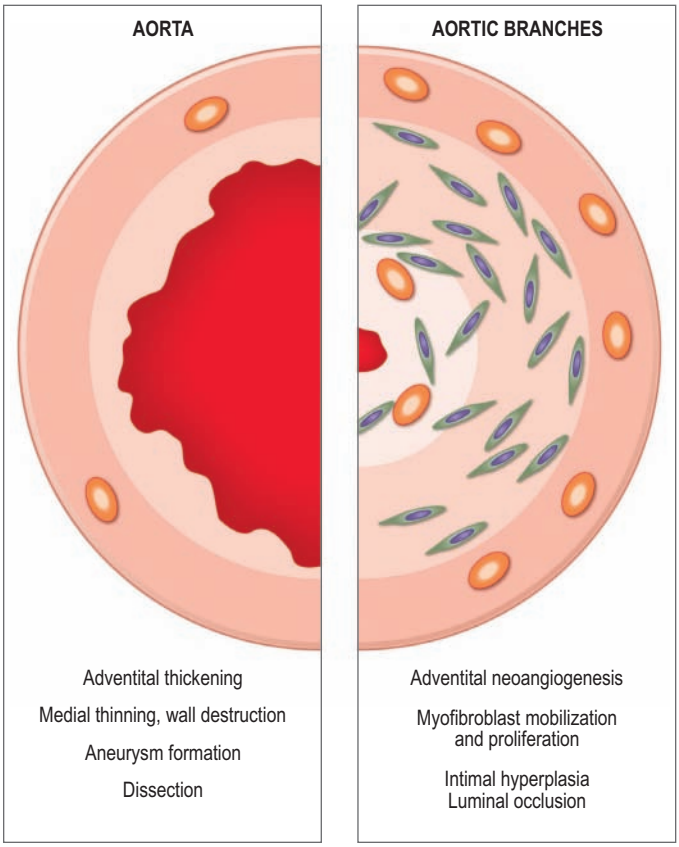

FIG. 60.4 Patterns of Vessel Wall Damage in Giant Cell Arteritis. Transmural granulomatous vasculitis results in two distinct damage patterns. Aortic inflammatory infiltrates destroy the wall, inducing dissection and aneurysm formation. As a result of neoangiogenesis and fibrosis, the adventitia expands. In the aortic branches, transmural granulomatous infiltrates predominantly elicit a maladaptive healing response, characterized by the mobilization, migration, and proliferation of myofibroblasts forming hyperplastic and lumen-obstructive neointima. Formation of neotissue is associated with microvascular neoangiogenesis in the intima, media, and adventitia. Intimal hyperplasia and neoangiogenesis are ultimately regulated through the intensity of the T-cell response in the vasculitic lesions.

as antigen-presenting cells (APCs); the nature of the antigen remains unknown, and reports about infectious agents have remained uncorroborated. Carefully designed experiments need to probe whether pathogens isolated from temporal artery tissue represent the vascular microbiota and whether they have a pathogenic role.

T helper 1 (Th1) cells are a key pathogenic element in GCA. Interferon-γ (IFN-γ), the Th1 marker cytokine, has multiple disease-relevant functions: activating endothelial cells and macrophages, regulating wall remodeling, inducing microvascular neoangiogenesis, and driving intimal-layer expansion.[11] IFN-γ is predominantly produced in the adventitia, where T cells are instructed by vasDCs. Th1 cells are present in untreated patients and persist despite prolonged corticosteroid therapy,[18] suggesting independence of vasculitogenic Th1 cells from the steroid-sensitive acute phase response and emphasizing their role as stabilizers of chronic-persistent lesions. During early vasculitis, Th1 cells are accompanied by Th17 cells, which are highly sensitive to steroid therapy and depleted from chronic lesions.[18] Comparative analysis of sequential temporal artery biopsies harvested from patients before and after treatment has demonstrated that adaptive immune responses evolve over the course of the disease and that different subpopulations of lesion-residing T cells are differentially responsive to immunosuppression.

Recent data have emphasized that the T-cell infiltrate in GCA-affected arteries is typically multifunctional and composed of a broad spectrum of functional lineages.[19] Besides Th1 and Th17 cells, Th9, Th22, and IL-21–producing T follicular helper (Tfh) cells are part of the infiltrate. Little is known about precise effector functions of these T cells, but lesional T-cell populations are functionally highly diverse, raising the possibility that a mixed set of antigens has vasculitogenic potential. Alternatively, the defect leading to granulomatous wall inflammation is the sequel of antigen-nonspecific defects.[19]

T cells have now been placed at the top of the artery's maladaptive response to injury, but precise effector pathways are not understood (see Fig. 60.4). Chronic aortitis leads to wall destruction and aneurysm formation. Dissection is increasingly recognized as a sequel of aortic wall inflammation. In rare cases, LVV results in the fatal complication of aortic rupture. In TA, direct cytotoxic function of CD8 T cells, NK cells, and γδ T cells has been implicated in local tissue injury.[20] Conversely, in the aortic branches, LVV typically causes luminal stenosis/occlusion by inducing lumen-obstructive neotissue. Proliferating myofibroblasts lay down matrix and build hyperplastic intima. Newly formed microvessels supply oxygen and nutrients to the thickening wall. How T cells instruct vascular cells to this maladaptive wound healing response and whether heterogeneity of such vascular cell populations imposes the disease's tissue tropism are the subjects of ongoing research. So far, the few wall-infiltrating B cells have not been assigned to a specific pathogenic mechanism.

KEY CONCEPTS

Large Vessel Vasculitis

- In humans, medium and large arteries have multiple wall layers and a wall structure substantial enough to be targeted by autoimmune disease.
- Vasculitis causes the rapid and concentric growth of hyperplastic intima, leading to luminal occlusion and ischemia of dependent tissues. Intramural inflammation of the aorta can result in wall damage followed by aneurysm formation and rupture.
- Because of the vital function and nonregenerative nature of large human arteries, the threshold for autoimmunity in the wall structures of such arteries must be explicitly high.
- Inflammatory infiltrates forming granulomatous vasculitis enter the vessel from the "back door," the adventitia, and not from the lumen.
- Besides their critical role as conduits for blood flow, medium and large arteries also possess immunoregulatory functions mediated by dendritic cells (DCs) indigenous to the vascular wall. DCs in each vascular territory express a distinctive pattern of Toll-like receptors (TLRs), giving each vessel its own immunologic identity.

Defective T Regulatory Cells and Insufficient Immune Checkpoints in Giant Cell Arteritis

Recent data have brought to the forefront that antigen-nonspecific immunoregulatory pathways have disease relevance in LVV, specifically in enabling unopposed and lasting adaptive immune responses to induce and sustain vessel wall inflammation.

Like in many chronic inflammatory lesions, GCA's arterial wall infiltrates lack sufficient antiinflammatory T regulatory cells (Tregs). This may be a consequence of the proinflammatory milieu, but recent studies have identified a novel mechanism of Treg-dependent immunosuppression that is nonfunctional in GCA. In healthy individuals, secondary lymphoid tissues are occupied by a population of CD8 Tregs that effectively control clonal expansion of CD4 T cells and thus the overall size of the CD4 T-cell compartment.[21] Such CD8 Tregs suppress activation and expansion of neighboring CD4 T cells by the directed transfer of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase 2 (Nox2)-containing exosomes. The population of $Nox2^+$ $CD8^+$ Tregs is distinctly low in patients with GCA and remains low with antiinflammatory therapy. Implicating Nox2 released by CD8 T cells in the threshold setting of CD4 T-cell immunity opens an entirely new perspective in vasculitis research and redirects the focus away from antigenic triggers that induce protracted macrophage activity.

A second immunoregulatory defect weakening proper control of CD4 T-cell immunity has been localized to the programmed death 1 (PD-1) immunoinhibitory checkpoint.[22] Inhibitory checkpoints are designed to protect tissue from excessive immune reactivity. PD-1 is expressed on activated T cells, the ligand PD-L1 is expressed on APCs. Triggering of PD-1 sends negative signals into T cells and stops their proliferation and polarization. DCs in patients with GCA, both lesional vasDCs and circulating DCs, are $PD\text{-}L1^{low}$. GCA T cells thus lack negative signaling and fail to undergo clonal contraction. Indeed, in inflamed temporal arteries, $PD\text{-}1^+$ T cells are strongly enriched. In human artery–chimeric mice, blocking PD-1 with antibody treatment exacerbates vasculitis, and wall-infiltrating $PD\text{-}1^+$ T cells produce a spectrum of effector cytokines (IFN-γ, IL-17, IL-9, IL-21, IL-22, etc.). Most importantly, PD-1–PD-L1 interactions in the artery have direct impact on the density of newly formed microvessels and the thickness of the hyperplastic intimal layer.[22] Hyperactive checkpoints are currently targeted therapeutically to unleash antitumor T-cell immunity. In cancer patients treated with checkpoint inhibitors, aortitis and vasculitis have been reported as immune-related adverse events.

CLINICAL FEATURES IN GIANT CELL ARTERITIS

CLINICAL PEARLS

Clinical and Epidemiologic Clues in Giant Cell Arteritis

- Patient older than 50 years of age.
- Female.
- Northern European heritage.
- Laboratory findings of a highly activated acute phase response (e.g., elevated erythrocyte sedimentation rate [ESR] and C-reactive protein [CRP]).
- Insidious onset of nonspecific symptoms (weight loss, night sweats, malaise, fever).
- Ischemia of ocular structures, cranial muscles, scalp, or upper extremities.

Clinical manifestations of GCA reflect the combination of a systemic inflammatory syndrome with vascular insufficiency (Table 60.1).[2] Increased sensitivity of vascular imaging methods and longer survival of affected individuals have made it clear

that most patients eventually have involvement of medium and large arteries. In some patients, the disease preferentially targets more peripheral branches of the aorta (*e.g.*, cranial arteries, such as the temporal artery). In others, the aorta and its proximal branches (*e.g.*, subclavian, axillary arteries) are involved to a major extent. In a subpopulation of patients, the clinical consequences of arterial inflammation are minimal, and these patients come to clinical attention because of failure-to-thrive or fever of unknown origin.

In cranial GCA, symptoms result from vascular stenosis of the neck and head arteries, most prominently the branches of the external carotid artery. Arteritis of the scalp arteries leads to the typical presentations of headaches and scalp tenderness. Patients report difficulties with wearing glasses or combing their hair. The headaches are often intense and unresponsive to standard analgesics. Headaches are a nonspecific clinical symptom, yet in an older individual with other findings of an inflammatory syndrome, physicians need to rule out GCA. Insufficient blood flow to the masseter muscles and the tongue causes jaw or tongue claudication, elicited by prolonged chewing and talking. Although this type of claudication is present in less than 30% of patients, it is clinically helpful because it rarely occurs outside of GCA. Similarly, painful dysphagia can be a useful clinical clue.

The orbits and the optic nerve are strictly dependent on blood supply from the external carotid system, particularly the

ophthalmic artery. GCA in ophthalmic artery branches, specifically the posterior ciliary arteries, leads to anterior ischemic optic neuropathy, presenting as sudden and painless vision loss. Typically, patients lose vision in the early-morning hours or wake up blind. Involvement of one eye may be followed by visual loss in the partner eye if the disease is not diagnosed and treated promptly. Besides anterior optic neuropathy, GCA can cause a number of ischemic complications in the orbits and along the visual axis, which may present as diplopia or partial vision loss.[15] If recognized and treated immediately, sight loss is preventable, which indicates that GCA should be considered an ophthalmologic emergency.

Chronic nonproductive cough can be related to arteritis in bronchial artery branches. If the vertebral and basilar arteries develop vasculitic stenosis, ischemia of the central nervous system manifests with transient ischemic attacks or frank stroke.

In patients with large vessel GCA, cranial symptoms may be minimal, and temporal artery biopsy can be negative.[23] Vascular insufficiency is focused on the upper-extremity vessels and the aorta. In rare cases, lower extremities are affected. Typically, patients have asymmetric blood pressure readings or experience total loss of upper-extremity blood pressure and pulse caused by occlusions in the distal subclavian and axillary arteries (Fig. 60.5). Patients with subclavian GCA are on average approximately 10 years younger at disease onset than those with dominant cranial manifestations. Diagnosis of large vessel GCA is often delayed because symptoms are nonspecific and systemic inflammation is less pronounced. Ischemic pain in the hands when using the arms can be combined with coolness and bluish discoloration. Gangrene of the fingertips is rare. Disability can be significant because patients have difficulties with activities of daily living. With stenotic lesions of the subclavian arteries, blood pressure readings are unreliable, requiring alternative strategies for blood pressure monitoring. Although carotid involvement is considered infrequent, it can be challenging to distinguish atherosclerotic disease and vasculitic disease. Patients with carotid GCA are at high risk for cerebral ischemic events. Aortic involvement preferentially targets the thoracic aorta and infrequently the abdominal aorta (Fig. 60.6). Dilation of the aortic root can lead to aortic insufficiency. Aortic aneurysms are often clinically silent. The diagnosis may first be made from tissue obtained surgically during aortic aneurysm repair. In extreme cases, the aortic wall ruptures.

The response pattern of arteries to inflammation may not include intimal hyperplasia, thus eluding luminal compromise. In such patients, the systemic inflammatory component dominates the clinical presentation. Fever, fatigue, malaise, weight loss, and depression are often intense enough to prompt a workup for a malignancy. GCA needs to be in the differential diagnosis in all cases of fever of unknown origin, particularly in older individuals. Patients with cranial GCA have abnormally thick and tender temporal arteries exhibiting nodularity and loss of pulses, whereas clinical findings in nonstenosing GCA can be unremarkable. Temporal artery biopsy needs to be pursued even if clinical examination does not suggest the diagnosis.

CLINICAL FEATURES IN POLYMYALGIA RHEUMATICA

PMR is diagnosed in patients experiencing pronounced stiffness and pain in the shoulder and pelvic girdle muscles (see Table 60.1).[2] Laboratory testing reveals a systemic inflammatory syndrome; arterial biopsy is negative for arteritis. Approximately 10% of patients with PMR without any signs of vascular inflammation will eventually develop full-blown vasculitis. Notably, PMR often occurs in patients with GCA, in approximately 40% of patients at disease onset. Tapering of immunosuppressive therapy in GCA is frequently associated with new or remittent PMR symptoms. Complaints are focused on muscle pain and stiffness, classically affecting the neck, shoulders, and pelvic girdle. The muscles of the torso may be involved. Peripheral arms and legs are spared. Muscle pain is most intense in the early morning and improves during the day. Inability to get out of bed, stand up from a chair, or get off the toilet seat should alert the physician to consider PMR. Some patients with PMR have synovitis or bursitis in their shoulder and hip joints[2] difficult to distinguish from seronegative polyarthritis. No diagnostic procedure that allows for the diagnosis of PMR is available; the syndrome remains an exclusion diagnosis in cases of myalgia combined with laboratory signs of systemic inflammation. On clinical examination, passive motion of shoulder and hip joints is maintained, but active motion is restricted because of pain. Muscle strength is often normal. Careful evaluation of the temporal arteries is warranted to avoid missing fully developed GCA.

CLINICAL FEATURES IN TAKAYASU ARTERITIS

The clinical manifestations of TA are diverse and depend on the affected vascular territory (see Tables 60.1 and 60.2). Initial symptoms are usually nonspecific and include fever, cough, malaise, weight loss, night sweats, myalgias, and arthralgias. Signs of vascular deficiency develop later in the disease course and generally are ischemic in nature. Geographic variations in disease pattern have been reported, likely reflecting the interplay between host risk genes and dysfunctional immunity. In North American, Japanese, and Korean patients, the aortic arch and its primary cervical and upper extremity branches are preferentially targeted, giving rise to aortic insufficiency, cerebral ischemia, face and neck pain, ocular ischemia, and the typical presentation of "pulseless disease" (Fig. 60.7). In patients in India, the abdominal aorta and renal arteries are more commonly affected, causing renovascular hypertension and the long-term risk of cardiac failure (Fig. 60.8).

Nonspecific complaints of headaches, syncope, and face and neck pain are often misinterpreted as stress-related problems, particularly in young women. Consequently, the diagnosis can be missed for months. Only a few patients come to clinical attention because of catastrophic neurologic symptoms related to brain ischemia. Helpful clues are differences in blood pressure, loss of pulses, and vascular bruits heard on clinical examination. Retinal neoangiogenesis, induced by hypoperfusion of the eye is now relatively rare, but fleeting visual abnormalities may indicate transient ischemic attacks. Signs of aortic insufficiency are unlikely to be encountered in early disease, but continuous monitoring for aortic dilation is an essential part of follow-up care. Coronary artery stenosis in a young patient must prompt the physician to rule out TA. In a subset of patients, the origins of mesenteric arteries are involved. Clinical consequences include weight loss, nausea, vomiting, diarrhea, and abdominal claudication, typically elicited by the increased intestinal blood demand following a meal.

Renal artery stenosis may be clinically silent and is often noticed in routine screening. Correct measurement of blood pressure can represent a pressing clinical problem if the upper-extremity arteries are affected. Involvement of the infrarenal aorta can lead to lower-extremity claudication. Musculoskeletal examinations are usually unrevealing, although joint and muscle pains are common.

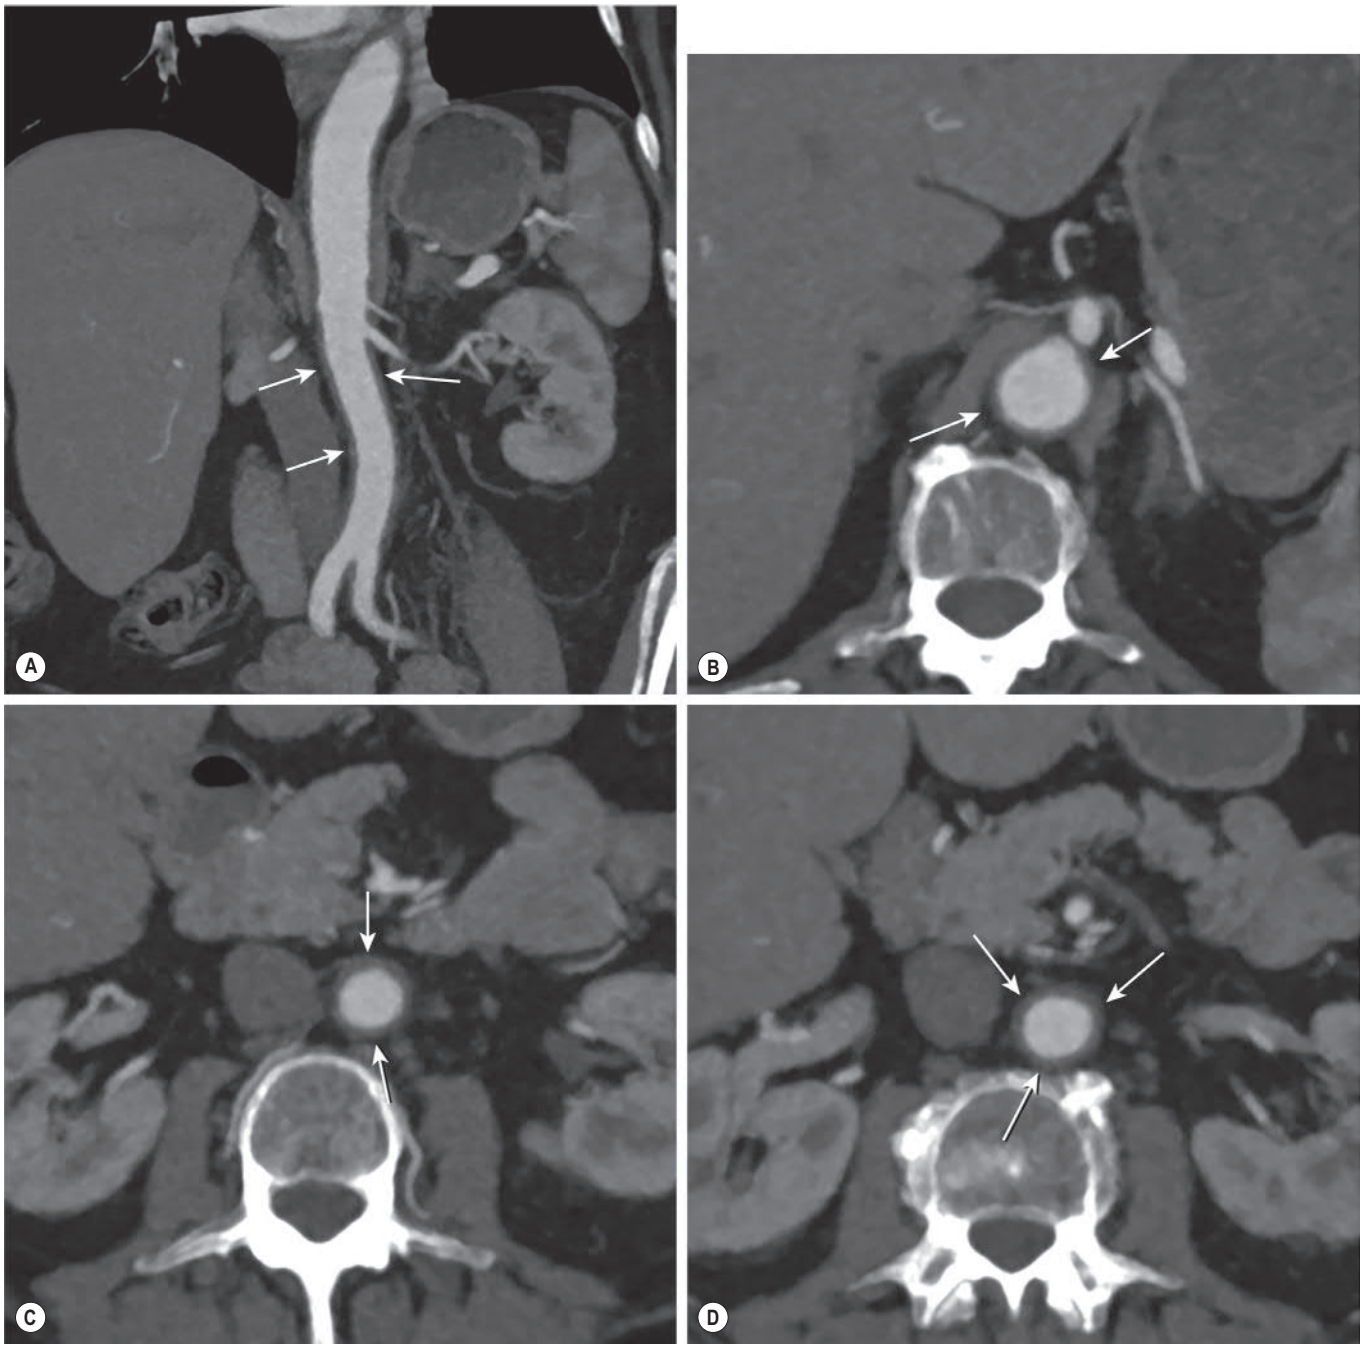

FIG. 60.5 Diagnostic Imaging in Giant Cell Arteritis: Computed Tomography Angiography. Contrast-enhanced computed tomography angiography (CTA) in a 74-year-old female with a temporal artery biopsy positive for giant cell arteritis. CTA imaging shows diffuse, circumferential mural thickening along the entire descending aorta and the abdominal aorta (Panel A). *Arrows mark* the thickened aortic wall. Axial images (Panels B–D) reveal the circumferential distribution *(arrows)* of the wall thickening from the distal arch to the intrarenal portion of the aorta. Thickness measurements can be used to monitor disease burden over time. The aortic diameter is within normal limits, indicating that the aortitis has not yet resulted in aneurysm formation. (Images were generated by Dr. D. Fleischmann, Department of Radiology, Stanford University.)

DIAGNOSIS

Classification criteria have been developed for GCA and TA to differentiate patients with LVV from those with other vasculitic entities (Tables 60.3 through 60.5).[24–26] Age at disease onset and the pattern of arteritis are clearly important for establishing the diagnosis and distinguishing between these two related vasculopathies. Diagnostic criteria for PMR remain a challenge (see Table 60.3) because they rely on nonspecific symptoms, such as muscle pain and stiffness and elevated erythrocyte sedimentation rate (ESR), all of which can occur in many other diseases.[2] No specific laboratory test is currently available to diagnose PMR. Therapeutic responsiveness of patients with PMR to low-dose corticosteroids is clinically helpful, emphasizing the need for objective diagnostic criteria.

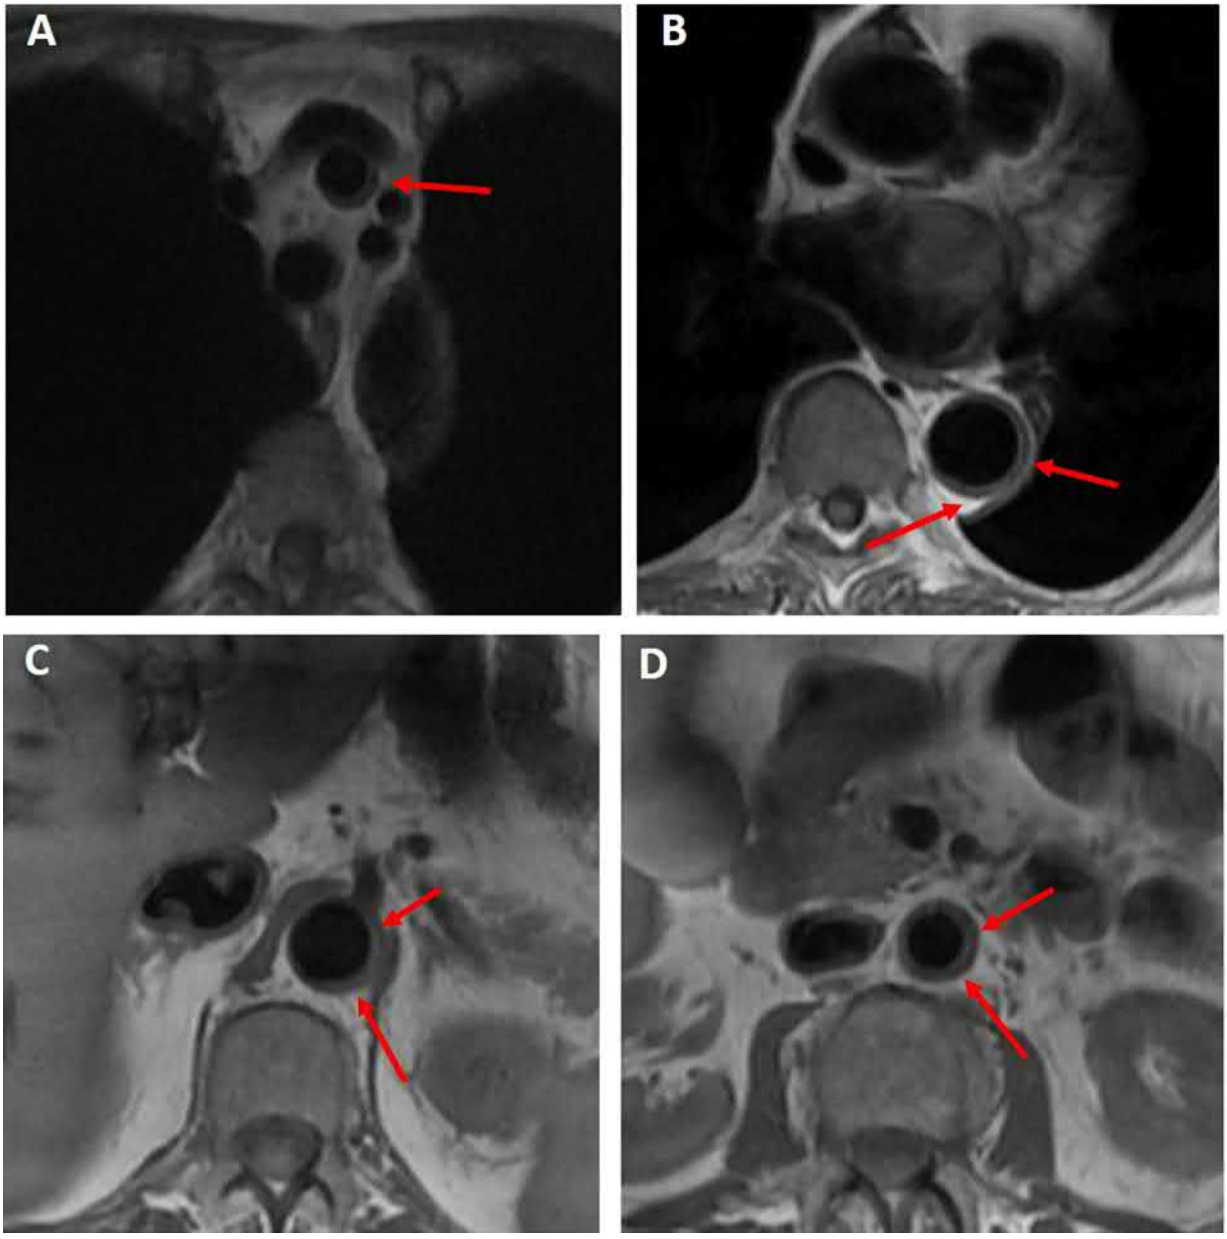

FIG. 60.6 Diagnostic Imaging in Giant Cell Arteritis: Magnetic Resonance Angiography. Contrast-enhanced magnetic resonance angiography of the chest and abdomen in the patient whose computed tomography angiography images are presented in Fig. 60.5. Double inversion recovery magnetic resonance images in the axial plane demonstrate diffuse, contiguous mural thickening of the great vessels (Panel A, brachiocephalic trunk) and the aorta (Panels B–D). *Arrows* are placed to mark the circumferential distribution of the mural thickening and compare luminal diameter and wall thickness at different levels of the vessels. (Images courtesy of Dr. D. Fleischmann, Department of Radiology, Stanford University.)

Laboratory Tests

In all three conditions—GCA, PMR, and TA—the laboratory tests indicate an intense acute phase response in a vast majority of patients.[2,27] In general, this is captured by measuring ESR or CRP. However, it is important to note that a subset of patients with GCA has normal ESR readings, even before initiation of immunosuppressive therapy. A normal ESR or CRP result is not sufficient to exclude the diagnosis, and further diagnostic work-up is required if the clinical suspicious is high. Other acute phase proteins, such as fibrinogen and SAA, are elevated as well. IL-6 is a potent inducer of hepatic acute phase proteins and is a sensitive marker of continuous systemic inflammation.[8,9] Other laboratory abnormalities, such as elevation of alkaline phosphatase, thrombocytosis, and anemia, are in line with a robust acute phase response.

Autoantibodies are not helpful beyond excluding differential diagnoses, such as rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), or antineutrophil cytoplasmic antibody (ANCA)-related vasculitides. Recently, two endothelial autoantigens have been identified in Takayasu disease, but autoantibody measurements have not yet entered diagnostic testing.[28]

Tissue Biopsy

In patients with TA, tissue biopsies are rarely available unless the patient had to undergo vascular reconstructive surgery. In most patients, the diagnosis is made based on imaging procedures revealing luminal and wall abnormalities in affected blood vessels.

In contrast, arterial biopsy remains a critical diagnostic approach in patients with GCA. Temporal arteries are easily

TABLE 60.2 Takayasu Arteritis: Relationship Between Clinical Symptoms and Affected Vascular Territories

Vascular Bed Involvement	Approximate Frequency (%)	Predominant Clinical Symptoms
Subclavian	90	Arm claudication, pulselessness
Common carotid	60	Visual defects, stroke, transient ischemic attack, syncope
Abdominal aorta	45	Claudication, hypertension, abdominal angina
Renal	35	Hypertension
Aortic arch/root	35	Aortic insufficiency, congestive heart failure
Vertebral	35	Dizziness, visual impairment
Celiac axis	20	Abdominal angina
Superior mesenteric	20	Abdominal angina
Iliac	20	Claudication
Pulmonary	10	Dyspnea, chest pain
Coronary	10	Myocardial infarction, angina

accessible, and a segment can be removed in an outpatient setting. Recommendations include harvesting 2 to 3 cm of the temporal artery, starting at the most symptomatic side. Frozen tissue sections can lead to a quick diagnosis of granulomatous vasculitis. Whether the second side should be biopsied during the same surgical procedure remains a matter of debate. In cohorts that included several hundred patients, vasculitis was detected in 2% to 3% of tissue samples from the second side if the first side was negative. If the clinical suspicion is strong, biopsy confirmation can be sought from a second-side biopsy immediately after the first biopsy or after careful monitoring of the patient for several weeks. Negative findings on temporal artery biopsy do not exclude the diagnosis of GCA but make it unlikely. In a retrospective cohort study, approximately half of the patients with subclavian GCA had no vasculitis in the temporal arteries, consistent with preferential involvement of certain vascular territories. There has been a trend toward considering negative biopsies as "falsenegative" and classifying patients with a negative biopsy as having GCA. This may lead to unnecessary immunosuppressive therapy, and the patient may not obtain a proper diagnosis. Findings that prompt biopsies (headaches, elevated acute phase reactants) are notoriously nonspecific, and both physicians and patients are anxious to avoid treatable blindness, biasing toward overtreatment. The temporal artery biopsy remains a powerful diagnostic tool and the major tool that allows unequivocal classification of the disease process. A technically proper temporal artery biopsy will detect vasculitis in the vast majority of patients.

Corticosteroid therapy does not eradicate pathologic findings of vascular wall infiltrates, and biopsy can still be valuable in making the diagnosis in patients on steroids. Approximately half of the patients remain biopsy positive, even after 1 year of corticosteroid therapy.[29]

Histomorphologic reports describe mononuclear cell infiltrates penetrating through all layers of the vessel wall (Fig. 60.9).[1] Recent discussions have focused on the diagnostic relevance of isolated inflammatory cell clusters in the adventitia or perivascular lymphocytes limited to small blood vessels. These findings may not be sufficient to indicate arteritis. Multinucleated giant cells may or may not be found. They tend to lie along the internal elastic lamina, at the junction between the media and the intima. Media destruction is not unusual, but findings of fibrinoid necrosis should prompt a search for different vasculitic entities. The vessel lumen is compromised by hyperplastic intima formed from proliferating fibroblasts, smooth muscle cells, and deposition of acid mucopolysaccharides.

The histology of TA is similar to that of GCA, making it difficult to dissect both syndromes in aortic tissue samples. Lymphocytes and plasma cells accumulate around vasa vasorum and form transmural infiltrates. Marked wall thickening with inflammatory tissue extending into perivascular structures is typical for TA (Fig. 60.10). Destruction of elastic membranes is often extensive and combined with patchy areas of media necrosis. Weakening of the vessel wall can lead to aneurysm formation. Inflammatory lesions may be arranged in a "skipped" pattern, with normal vessel wall segments alternating with stretches of intense destructive inflammation.

Physicians may encounter morphologic findings of granulomatous aortitis in patients undergoing aortic aneurysm repair without any prior diagnosis of vasculitis. Detailed work-up of these patients is necessary to identify those with undiagnosed PMR, GCA, or TA. Rare causes of aortitis, including IBD, sarcoidosis, syphilis, relapsing polychondritis, and connective tissue disease, should be ruled out. Isolated granulomatous aortitis is diagnosed as idiopathic aortitis. The pathogenesis and prognosis of this condition are essentially unknown.

Diagnostic Imaging

Modern imaging modalities have fundamentally changed the diagnostic approach to LVV. Indeed, diagnosing TA mostly depends on identifying vascular lesions in typical distribution by imaging.[30]

Conventional angiography still has its place in preoperative planning and can be combined with intravascular interventions. It provides ideal visualization of the vascular lumen not only for large but also for medium-sized arteries, such as the axillary and brachial arteries (see Fig. 60.5). Ultrasound (US)-based methods are extremely useful for screening carotid arteries, but they have also emerged as the method of choice for initial assessment of the distal subclavian arteries, vertebral arteries, renal arteries, and femoral arteries. US examination is the optimal method for long-term monitoring of vessel bypasses after revascularization procedures. Magnetic resonance imaging (MRI), magnetic resonance angiography (MRA), and computed tomography (CT) are currently widely used for evaluating the vascular tree. These methods provide excellent information on abnormalities of the vascular lumen and wall, also capturing abnormalities in the more peripheral arterial branches. CT imaging is fast, well tolerated by patients with claustrophobia, and allows excellent assessment of the aorta and its wall (see Fig. 60.7). However, it has the disadvantages of contrast loading and radiation exposure. With its inherent multiplanar imaging capabilities, magnetic resonance is used to examine neck vessels, the aorta, and proximal aortic branches (see Figs. 60.6 and 60.8). Great hope was placed on its potential to measure wall edema and intramural vascularity, which would make magnetic resonance useful for estimating disease burden and responses to therapy. Comparisons of imaging results, laboratory parameters of inflammation, and surgical biopsy specimens have been disappointing, cautioning that edema-weighted magnetic resonance should not be used as a sole means of measuring disease activity and therapeutic responsiveness. Both CT angiography and MRA are currently used routinely to monitor progression/regression of vascular involvement and have an important place in managing the chronic phase of GCA and TA.

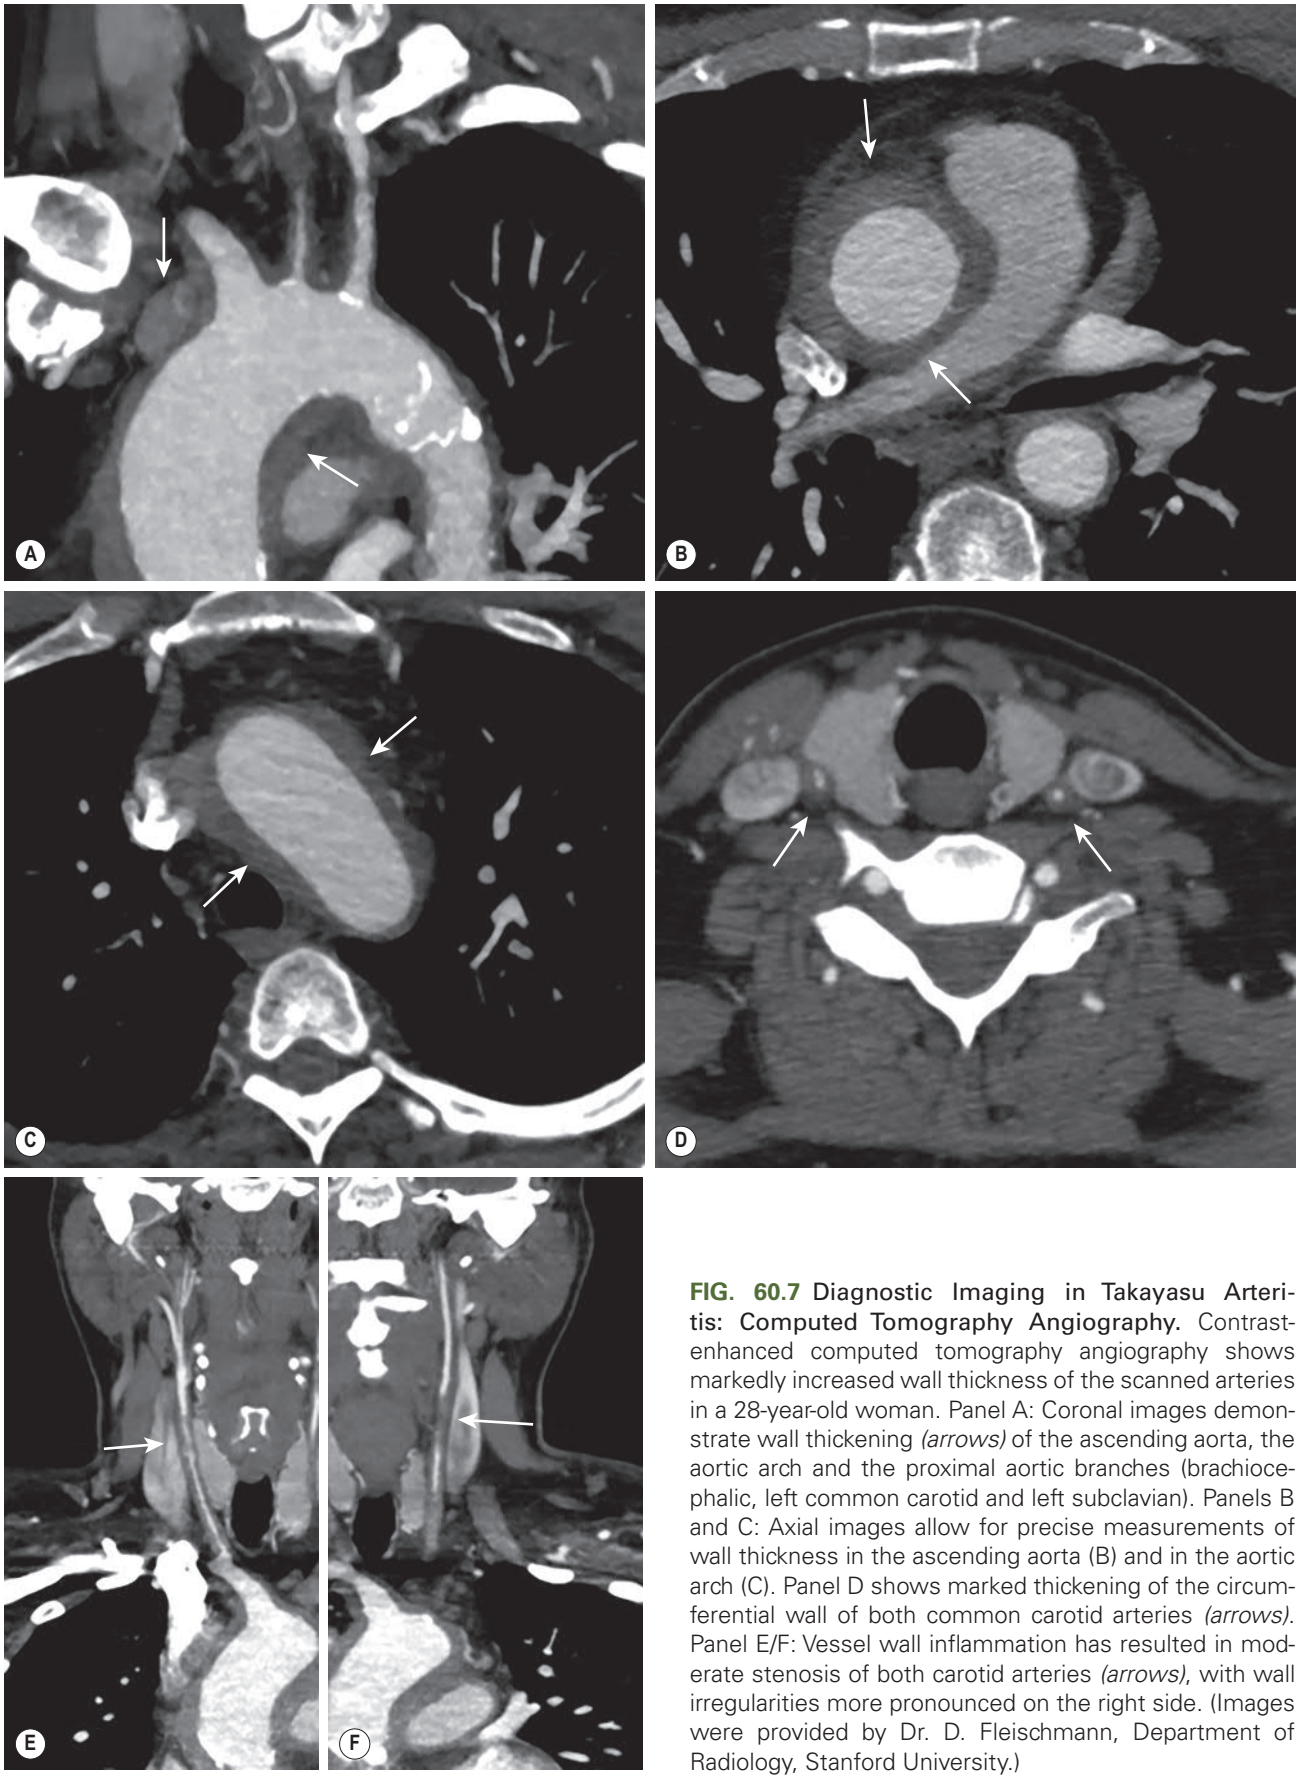

FIG. 60.7 Diagnostic Imaging in Takayasu Arteritis: Computed Tomography Angiography. Contrast-enhanced computed tomography angiography shows markedly increased wall thickness of the scanned arteries in a 28-year-old woman. Panel A: Coronal images demonstrate wall thickening *(arrows)* of the ascending aorta, the aortic arch and the proximal aortic branches (brachiocephalic, left common carotid and left subclavian). Panels B and C: Axial images allow for precise measurements of wall thickness in the ascending aorta (B) and in the aortic arch (C). Panel D shows marked thickening of the circumferential wall of both common carotid arteries *(arrows)*. Panel E/F: Vessel wall inflammation has resulted in moderate stenosis of both carotid arteries *(arrows)*, with wall irregularities more pronounced on the right side. (Images were provided by Dr. D. Fleischmann, Department of Radiology, Stanford University.)

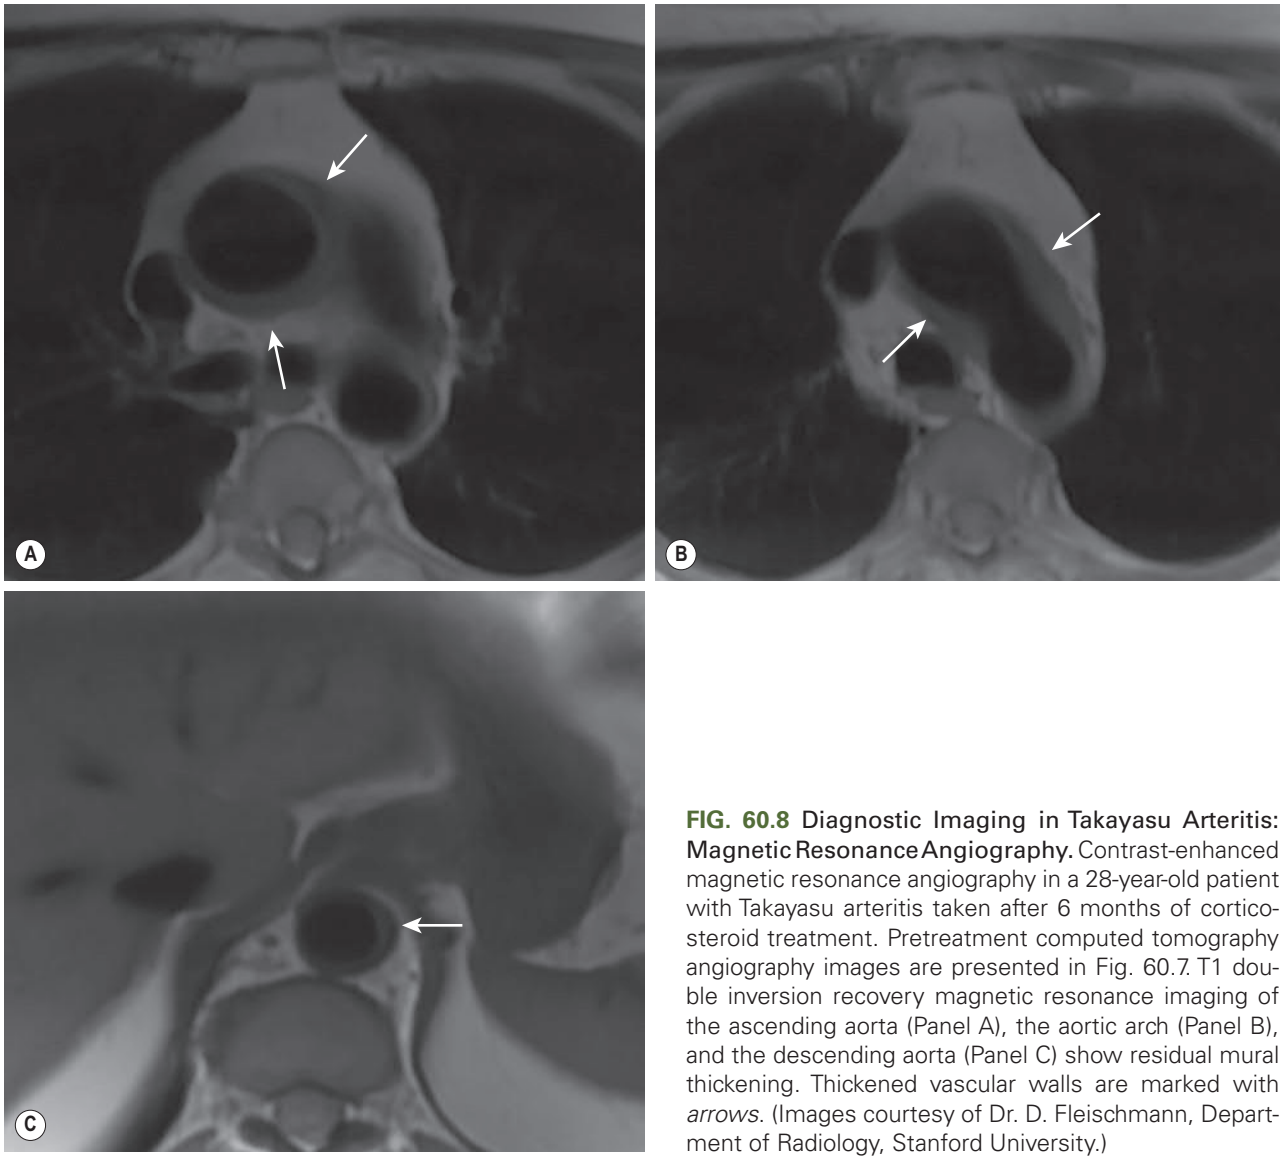

FIG. 60.8 Diagnostic Imaging in Takayasu Arteritis: Magnetic Resonance Angiography. Contrast-enhanced magnetic resonance angiography in a 28-year-old patient with Takayasu arteritis taken after 6 months of corticosteroid treatment. Pretreatment computed tomography angiography images are presented in Fig. 60.7. T1 double inversion recovery magnetic resonance imaging of the ascending aorta (Panel A), the aortic arch (Panel B), and the descending aorta (Panel C) show residual mural thickening. Thickened vascular walls are marked with *arrows*. (Images courtesy of Dr. D. Fleischmann, Department of Radiology, Stanford University.)

TABLE 60.3 American College of Rheumatology 1990 Classification Criteria for Giant Cell Arteritis[a] and Polymyalgia Rheumatica

Age at disease onset ≥50 years
New-onset or new type of headache
Temporal artery tenderness or decreased artery pulse
Elevated erythrocyte sedimentation rate (≥50 mm/h)
Histologic incidence of arteritis (characterized by a predominance of mononuclear cell infiltrates or a granulomatous process with multinucleated giant cells)

[a]A patient is classified as having giant cell arteritis if at least three of the five criteria are present.

Reprinted from Hunder GG, Bloch DA, Michel BA, et al. The American College of Rheumatology 1990 criteria for the classification of giant cell arteritis. . 1990;33:1122–1128, with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc. ©1990.*Arthritis Rheum*

TABLE 60.4 Provisional Classification Criteria for Polymyalgia Rheumatica

Age ≥50 years	Required
Bilateral shoulder ache	Required
Abnormal C-reactive protein (CRP) and/or erythrocyte sedimentation rate (ESR)	Required
Morning stiffness >45 min	2
Hip pain or limited range of motion	1
Absence of rheumatoid factor (RF) or anticitrullinated protein antibody (ACPA)	2
Absence of other joint involvement	1
A score of ≥4 is categorized as polymyalgia rheumatica.	

Reprinted from Dasgupta B, Cimmino MA, Kremers HA, et al. Provisional classification criteria for polymyalgia rheumatica: A European League Against Rheumatism/American College of Rheumatology collaborative initiative. *Arthritis Rheum.* 2012;64:943–954.

TABLE 60.5 American College of Rheumatology 1990 Criteria[a] for the Classification of Takayasu Arteritis

Disease onset at ≤40 years
Claudication of an extremity
Decreased brachial artery pulse
>10 mm Hg difference in systolic blood pressure between arms
Bruit over the subclavian arteries or the aorta
Arteriographic evidence of narrowing or occlusion of the entire aorta, its primary branches, or large arteries in the proximal upper or lower extremities

[a]For purposes of classification, a patient is classified as having Takayasu arteritis if more than three of the six criteria are fulfilled.
Reprinted from Arend WP, Michel BA, Bloch DA, et al. The American College of Rheumatology 1990 criteria for the classification of Takayasu arteritis. . 1990;33:1129–1134, with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc. ©1990. *Arthritis Rheum*

THERAPEUTIC MANAGEMENT

With increasing knowledge of the disease process and refinement of diagnosis and long-term treatment, the prognosis for patients with LVV has significantly improved. Life expectancy of patients with GCA is preserved. Follow-up studies of Japanese patients with TA have suggested good control of disease activity in about 75% of patients, with only 25% experiencing serious complications and cardiac manifestations determining long-term outcome. Whether vasculitis predisposes patients to accelerated atherosclerotic disease, given the combination of chronic inflammation and injury to vessel wall structures, is still being discussed. It is not known whether progression of atherosclerosis and its complications require a different management approach or whether standard vasoprotective measures (treating hypertension and hyperlipidemia, smoking cessation, etc.) are sufficient.

Pathogenic studies have pointed out that the traditional view of GCA as a self-limiting disease is incorrect.[9,19] To the contrary, granulomatous vasculitis has shown surprising resistance to immunosuppression, with vessel wall infiltrates persisting for greater than 12 months in almost 50% of patients despite appropriate immunosuppressive therapy. Based on examination of serial temporal artery biopsy specimens from patients before and after treatment, it is now clear that arteritis persists, albeit sustained by an immune network distinct from that in untreated patients.[18] It is unknown whether this persistent smoldering process requires treatment and what the risk/benefit ratio is for the older patient population affected by GCA. Unchanged life

THERAPEUTIC PRINCIPLES

Treatment of Large Vessel Vasculitides

- To prevent vision loss, patients with giant cell arteritis (GCA) require immediate treatment. Similarly, with the threat of catastrophic cerebral ischemia in Takayasu arteritis (TA), prompt initiation of therapy is imperative.
- Corticosteroids are the immunosuppressive drug of choice for large vessel vasculitides (LVVs). Often, the drugs must be given over a period of several years but may be clinically effective at very low doses.
- Clinical trials have failed to show convincing steroid-sparing effects for either methotrexate or tumor necrosis factor (TNF)-α blockade in GCA.
- A phase 3 clinical trial has demonstrated steroid-sparing effects of treatment with tocilizumab, an antibody against the interleukin-6 receptor
- Molecular studies of GCA vascular lesions have shown that early and untreated disease is characterized by two functional T-cell lineages; T helper 1 (Th1) and Th17 cells. Th17 cells respond rapidly to corticosteroids, whereas Th1 cells persist and promote chronic, smoldering vasculitis.
- A dual biopsy study in untreated and treated patients with GCA has demonstrated persistent vasculitis despite excellent control of peripheral inflammatory markers (erythrocyte sedimentation rate [ESR], C-reactive protein [CRP]), indicating separation of the vascular and extravascular disease component. Although extravascular disease (ESR, CRP, and myalgias) may be easy to control, vessel wall inflammation seems to be autonomous and difficult to suppress.
- Clinical experience (not evidence-based therapeutic trials) suggests that a combination of methotrexate, mycophenolate mofetil, or TNF-α–blocking agents with corticosteroids may be beneficial in controlling disease in some patients with TA.
- Close monitoring for diabetes, hypertension, and hyperlipidemia combined with bone-saving therapy should be part of the treatment regime in patients with LVVs on long-term corticosteroids.

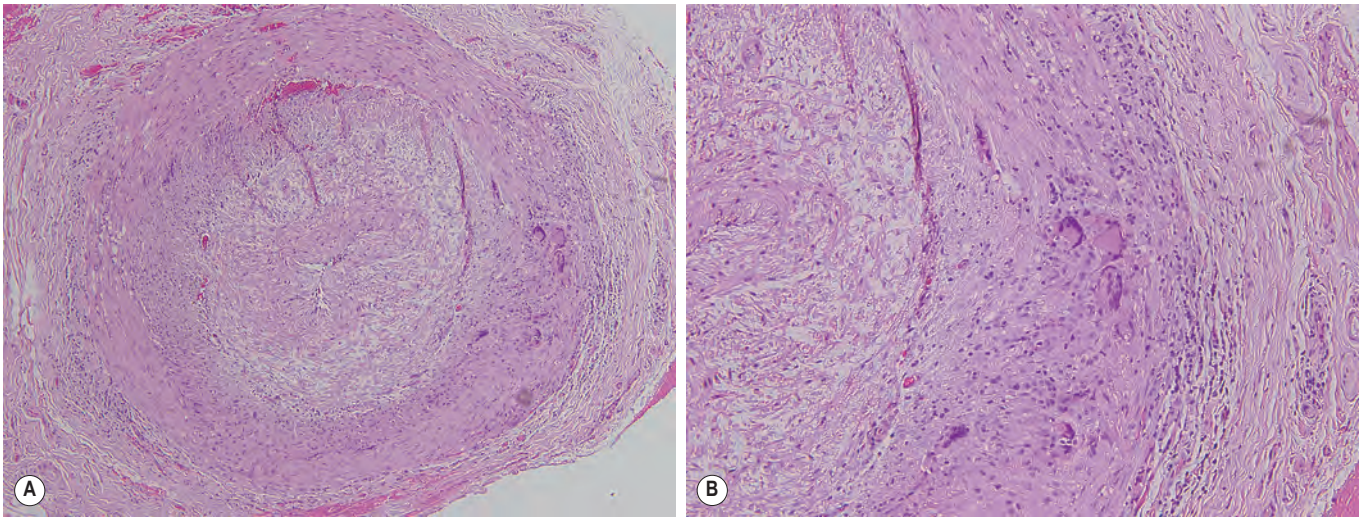

FIG. 60.9 Histomorphology of Giant Cell Arteritis. (A) Temporal artery cross-section with mononuclear infiltrates throughout all wall layers. The adventitia is infiltrated by round cells with cuffing of vasa vasorum by lymphocytes. The vessel lumen is occluded by intimal hyperplasia. (B) Higher magnification showing intense granulomatous inflammation with multinucleated giant cells in the proximal media and at the media–intima junction.

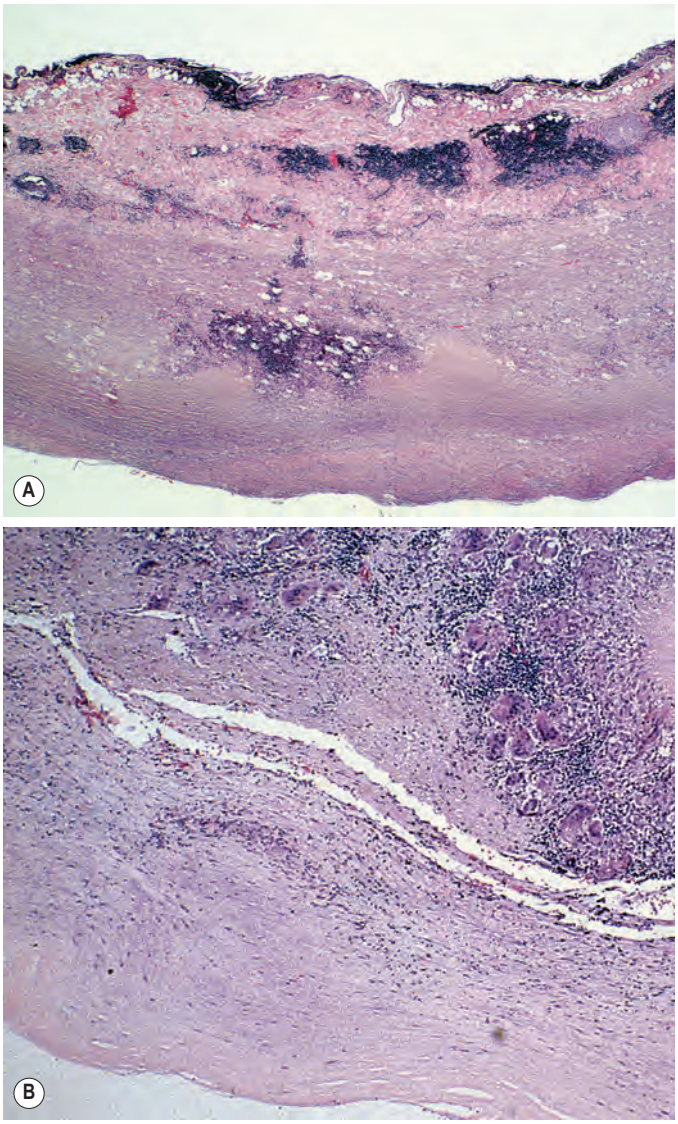

FIG. 60.10 Histopathology of Takayasu Arteritis. (A) Full-thickness section of the aortic wall shows dense mononuclear infiltrates in the adventitia and media. The intima is thickened and wavy; hematoxylin and eosin (H&E). (B) Florid granulomatous inflammation along the media–intima junction with numerous giant cells; H&E.

expectancy in GCA suggests adequacy of current management. Whether more intense immunosuppression or chronic maintenance therapy can prevent long-term complications, such as aortic aneurysm/dissection from GCA aortitis, and improve the overall prognosis is unknown. The ultimate decision depends on the cost/benefit analysis comparing the risk from smoldering disease with the risks imposed by long-standing immunosuppression. In that context, it is important to remember the profound impact of the immune aging process, which leaves older patients with an impaired immune system and amplifies the risk of immunosuppression.

Induction Therapy

In newly diagnosed patients with GCA, TA, and PMR, the immunosuppressants of choice are corticosteroids. Patients with GCA

ON THE HORIZON

- The vascular lesions of giant cell arteritis (GCA) are autonomous and self-maintained over prolonged periods. New therapeutic approaches are needed that can eradicate wall-residing immune cells.
- With extension of life span, patients may experience disease complications 20 years after diagnosis. Long-term immunosuppression may be required to protect the integrity of the large arteries.
- Several cellular activation pathways have disease relevance in GCA and Takayasu arteritis (TA). Interfering with cellular signaling through small-molecule reagents will provide new therapeutic opportunities.
- Patients with GCA have a defect in immunoprotective CD8 T regulatory (Treg) cells. Reconstituting Treg function emerges as a new therapeutic target.
- Patients with GCA have abnormalities in innate immune function (*e.g.*, hyperproduction of matrix metalloproteinase-9 (MMP-9) by monocytes). Monocyte reeducation represents a novel therapeutic strategy.
- Patients with GCA have a defective programmed death 1 (PD-1)/PD-ligand 1 immune checkpoint. Cancer patients treated with immune checkpoint inhibitors are at risk to develop aortitis/vasculitis.
- A subset of patients with TA build autoantibodies against endothelial surface receptors. The value of such autoantibodies to subset and monitor patients will need to be explored.

are started on a daily prednisone dose of 40 to 60 mg (approximately 1 mg/kg body weight). In patients with PMR, a daily dose of 20 mg prednisone is sufficient in almost all patients. The response is usually dramatic, with improvements within 24 to 48 hours. The promptness of clinical improvement is so exceptional that it has been suggested as a diagnostic criterion for PMR. The promptness of response may be limited to extravascular disease. Myalgias, fever, malaise, and headaches improve swiftly, in parallel with a fast reduction of acute phase reactants (CRP, IL-6, ESR). The vascular component is much more resistant to immunosuppression and may require a different therapeutic approach.

Once the condition is stabilized, steroid tapering is guided by close monitoring of the clinical presentation as well as laboratory markers of inflammation. In general, steroids should be reduced by 10% to 20% every 2 weeks. Monthly monitoring of ESR and CRP is mandatory to adjust therapy. Patients frequently return with signs or symptoms of recurrent disease as immunosuppression is lowered. Fortunately, disease exacerbations causing vision loss are infrequent. Disease flare-ups typically present with PMR symptoms or nonspecific manifestations of malaise and failure to thrive. In most patients, a transient small increase in the steroid dose reinstates disease control.

Much effort has been invested in identifying steroid-sparing agents. In a small study, treatment with pulse corticosteroids appeared to have long-term beneficial effects, reducing the overall steroid requirement and the rate of disease flare-ups.[31] Compared with the control arm, patients who received three initial steroid pulses (1000 mg methylprednisolone ×3 days, followed by oral steroids with a fast taper) had lower likelihoods of disease flare-ups. Particularly, once close to 10 mg/day of prednisone, these patients could tolerate steroid withdrawal significantly better, and most were taking 5 mg/day prednisone at 36 weeks.[31] The benefit from initial pulse therapy continued over subsequent months.

Several biologic agents have been explored or are currently undergoing testing in clinical trials.[32] Tumor necrosis factor-α (TNF-α) inhibitors may have a role in TA but had no steroid-sparing effect in GCA.[33] Preliminary study results suggest that

targeting T-cell costimulation with abatacept may prevent disease relapses in GCA. Ustekinumab, an antibody targeting IL-12 and IL-23, was reported to have potential efficiency in refractory GCA in a small open-label study. The IL-6 receptor blocker tocilizumab has been explicitly effective in reducing acute phase reactants (CRP, ESR) and in a phase 3 double-blind trial of tocilizumab given weekly or every other week demonstrated substantial steroid-sparing effect over a 1-year period.[10]

Maintenance Therapy

With a major shift in the pathogenic understanding of LVV, especially the realization that the disease process has two, partly independent components (extravascular, vascular) and that vasculitis persists chronically, the therapeutic needs for maintenance therapy have become the dominant issue for the treating physician. Patients with PMR are often managed successfully with low-dose corticosteroids (prednisone 5 mg daily) and typically are highly responsive to transient and very small dose increases (1 to 2 mg prednisone/day). Long-term management of patients with GCA and TA relies on low-dose corticosteroids as well unless there is objective evidence for progressive vascular wall inflammation. Unfortunately, no reliable biomarkers can separate the extravascular and vascular disease components, and no evidence has been presented that suppressing acute phase responses will ultimately restrict transmural vasculitis.

Methotrexate is considered to have mild-to-moderate steroid-sparing potential in GCA and PMR[34] but is more frequently used in TA. When given to human artery–severe combined immunodeficiency (SCID) chimeras, acetylsalicylic acid (aspirin) has marked antiinflammatory activities, with suppression of IFN-γ in vascular lesions. Clinical trials are needed to test whether this immunosuppressive action can translate into corticosteroid sparing. Because arteries are the primary targets of LVVs, the use of aspirin as an antiplatelet agent should be routinely recommended.

There is no evidence that immunosuppressants, such as azathioprine and cyclophosphamide, lower steroid needs, prevent vascular complications, or shorten the duration of steroid use. Whether any of the aforementioned biologic agents have a place to effectively suppress vessel wall inflammation and change the course of chronic disease is currently unknown.

An integral part of chronic immunosuppression with prednisone is regular monitoring for diabetes and hypertension. Patients should be encouraged to increase physical activity because steroid-induced myopathy occurs frequently. A major issue of chronic steroid treatment is the risk of excessive bone loss, possibly resulting from increased bone resorption and impaired bone formation. Several effective and safe therapies for osteopenia/osteoporosis are available. Calcium and vitamin D supplementation should be part of the therapeutic regimen.

In many, but not all, patients, immunosuppressive treatment can be discontinued 18 to 24 months after diagnosis. Markers of systemic inflammation may remain elevated, and continuous monitoring for aortic involvement and recurrence of cranial arteritis is recommended.

Most patients with PMR are sufficiently treated with an initial dose of 20 mg of prednisone per day. In some patients, 10 mg of prednisone can induce and sustain a clinical response. Steroids should be titrated to minimally needed doses to avoid side effects; tapering usually needs to be slow, over many months. In TA, long-term management should be tailored to individual patient conditions. It has been argued that patients should be maintained on a low dose of corticosteroids, such as 5 to 7 mg prednisone daily, even after successful control of active disease.

Given the age at disease onset in TA, preventive measures to counteract accelerated atherosclerosis and optimize blood pressure control are important aspects of management.

It has been suggested that up to 50% of patients with TA may require a second immunosuppressive agent. Steroid-sparing effects of methotrexate have been reported for some patients. Similarly, mycophenolate mofetil may have clinical efficiency, although published data are available only for a small patient cohort. Empirically, azathioprine may have a place in maintenance therapy of patients with TA. There may be a place for agents blocking TNF-α in patients with persistent disease activity. A randomized, double-blind, placebo-controlled, phase 3 trial of tocilizumab in Japanese patients with refractory TA did not meet the primary end point and disease progression in tocalizumab-treated TA patients has been reported, raising concerns that vascular inflammation in TA may be difficult to treat.[35,36]

Detecting and treating hypertension is an essential component of caring for patients with TA. Untreated hypertension leads to acceleration of atherosclerosis and cardiac insufficiency. In patients with upper-extremity involvement, obtaining accurate blood pressure measurements is a challenge and requires education of the patient and caregivers.

Revascularization Procedures

Besides pharmacologic therapy, revascularization procedures—including both surgical and endovascular interventions—have vastly broadened therapeutic options in patients with TA and large vessel GCA. To minimize the risk of complications, such as rapid reocclusion, vascular wall inflammation needs to be controlled before subjecting the patient to revascularization treatment. Conventional bypass grafts are still considered the method of choice in severely affected patients. Percutaneous transluminal angioplasty can be useful in managing renal artery stenosis or other short-segment lesions. Bypass surgery is needed in patients with cerebrovascular ischemia in whom catastrophic strokes may be prevented by bypassing critical stenosis of cervical vessels with grafts originating from the aortic arch. Reestablishing flow in the upper- and lower-extremity arteries can be complicated by multiple and long-segment stenosis, and arterial reconstructions with prosthetic graft materials or veins may be the only alternative to obtain long-term patency. Placing of conventional stents can be complicated by rapid restenosis, and it is unknown whether outcomes can be improved by drug-eluting stents. Occlusive disease of the coronary arteries usually represents a challenging clinical scenario, and most physicians opt for conventional bypass surgery. Surgical repair is the treatment of choice in patients with aortic regurgitation due to aortic wall and/or aortic valve inflammation.

Antiphospholipid Syndrome

Molly M. Daughety, Doruk Erkan, Michael D. Lockshin, and Thomas L. Ortel

Diagnosis of antiphospholipid syndrome (APS) requires that a patient has *both* a clinical event (thrombosis and/or pregnancy loss) *and* persistent antiphospholipid antibody (aPL), documented by a solid phase serum assay (anticardiolipin [aCL] and/or anti-β_2-glycoprotein-I [β_2GPI] enzyme-linked immunosorbent assay) or an inhibitor of phospholipid-dependent clotting (lupus anticoagulant [LA] test), or both (Table 61.1).[1] Antiphospholipid syndrome occurs as an isolated diagnosis, referred to as primary APS, or is associated with other systemic rheumatic diseases such as systemic lupus erythematosus (SLE).

The primary antigen to which aPL binds is β_2GPI (apolipoprotein H), a phospholipid-binding plasma protein. β_2GPI is normally present at a concentration of 200 μg/mL and is a member of the complement control protein family. Structurally, it consists of 326 amino acids arranged in five short consensus repeat domains. *In vivo*, β_2GPI circulates in a circular form that is maintained by interactions between the first and fifth domains. This circular form unfolds into an open form upon binding to phosphatidylserine on membranes of activated or apoptotic cells, including those of trophoblast, platelets, and endothelial cells, exposing the immunogenic site in the first domain. This binding may initiate cell activation, clearance of apoptotic cells by macrophages, and/or coagulation.[2]

KEY CONCEPTS

- aPL exist as a family of autoantibodies directed against phospholipid-binding plasma proteins, most commonly β_2-glycoprotein-I.
- The origin of aPL is unknown but is hypothesized to be an incidental exposure to environmental agents inducing aPL in susceptible individuals.
- In humans, cross-sectional and prospective cohort studies demonstrate that aPL can predict future thrombosis. The pathogenic mechanism is unknown; more than one mechanism may be involved.
- Concomitant prothrombotic risk factors may promote clotting in an additive manner in aPL-positive patients

Autoimmune aPL binds β_2GPI (β_2GPI-dependent aPL), which in turn binds negatively charged phospholipids. Drugs (such as chlorpromazine, procainamide, quinidine, and phenytoin), malignancies (such as lymphoproliferative disorders), and infectious agents (such as syphilitic and non-syphilitic *Treponema, Borrelia burgdorferi*, human immunodeficiency virus, *Leptospira*, or parasites) induce β_2GPI-independent transient aPL. β_2GPI-independent aPL are usually made up of low-titer aCL, which may bind directly to phospholipids and are rarely associated with thrombosis.

EPIDEMIOLOGY

Low-titer aCL occur in less than 10% of normal blood donors, and moderate- to high-titer aCL and/or a positive LA test occurs in greater than 1%. The prevalence of positive aPL tests increases with age. Because the differential diagnosis of vascular occlusion is broader than it is in young adults, particular care is necessary when diagnosing APS in older patients. Thirty to 40% of SLE patients and approximately one-fifth of rheumatoid arthritis patients have positive tests for aPL.

The strength of association between aPL and clinical events varies among studies. Although a number of studies have tried to estimate the annual thrombosis risk in asymptomatic aPL-positive patients, most of these studies have predominantly included patients with SLE. The annual risk of first thrombosis is probably very low (<1%/year) in aPL-positive individuals with no other systemic autoimmune diseases or risk factors for thrombosis, though well-controlled studies are lacking. However, aPL-positive patients with other systemic autoimmune diseases, such as SLE, are at increased annual risk for first thrombosis (<4%/year).

In patients without underlying SLE, it is estimated that approximately 10% of first-stroke victims have aPL, especially those who are young, as do up to 20% of women who have suffered three or more consecutive fetal losses.

ETIOPATHOGENESIS

Antiphospholipid antibodies exist as a family of autoantibodies directed against phospholipid-binding plasma proteins, most commonly β_2GPI. Such proteins bind negatively charged phospholipids (cardiolipin, phosphatidylglycerol, phosphatidylserine, phosphatidylinositol) but not zwitterionic or neutral phospholipids (phosphatidylethanolamine, phosphatidylcholine). Other phospholipid-binding plasma proteins are prothrombin, thrombomodulin, protein C, protein S, and annexins I and V. *In vivo*, the likely relevant phospholipid to which these proteins bind is phosphatidylserine, which is normally sequestered on the inner cell membrane but is exteriorized during cell activation and apoptosis. Annexins bind to exposed phosphatidylserine and create a "remove me" signal on cells.

The commonly accepted hypothesis regarding the origin of aPL states that incidental exposure to environmental agents, the

TABLE 61.1 Revised Sapporo Classification Criteria for the Antiphospholipid Syndrome[1]

Clinical Criteria

1. Vascular thrombosis[a]
   (a) One or more clinical episodes[b] of arterial, venous, or small-vessel thrombosis,[c] in any tissue or organ.
2. Pregnancy morbidity:
   (a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, *or*
   (b) One or more premature births of a morphologically normal neonate before the 34th week of gestation because of eclampsia, severe preeclampsia, or recognized features of placental insufficiency[d] *or*
   (c) Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomical or hormonal abnormalities and paternal and maternal chromosomal causes excluded.

Laboratory Criteria[e]

1. Lupus anticoagulant present in plasma, on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Haemostasis.
2. Anticardiolipin antibody of IgG and/or IgM isotype in serum or plasma, present in medium or high titer (*i.e.*, >40 GPL or MPL, or > the 99th percentile), on two or more occasions, at least 12 weeks apart, measured by a standardized enzyme-linked immunosorbent assay (ELISA).
3. Anti-β_2 glycoprotein-I antibody of IgG and/or IgM isotype in serum or plasma, (in titer >the 99th percentile) present on two or more occasions, at least 12 weeks apart, measured by a standardized ELISA.

Definite antiphospholipid syndrome (APS) is present if at least one of the clinical criteria and one of the laboratory criteria are met. Classification of APS should be avoided if <12 weeks or >5 years separates the positive antiphospholipid antibody (aPL) test and the clinical manifestation. In studies of populations of patients who have more than one type of pregnancy morbidity, investigators are strongly encouraged to stratify groups of subjects according to a, b, or c above.

[a]Coexisting inherited or acquired factors for thrombosis are not a reason for excluding patients from APS trials. However, two subgroups of APS patients should be recognized, according to (a) the presence and (b) the absence of additional risk factors for thrombosis. Indicative (but not exhaustive), such cases include age (>55 in men and >65 in women) and the presence of any of the established risk factors for cardiovascular disease (hypertension, diabetes mellitus, elevated LDL or low HDL cholesterol, cigarette smoking, family history of premature cardiovascular disease, body mass index ≥30 kg/m^2, microalbuminuria, estimated glomerular filtration rate (GFR) <60 mL/min), inherited thrombophilias, oral contraceptives, nephritic syndrome, malignancy, immobilization, and surgery. Thus, patients who fulfill the criteria should be stratified according to contributing causes of thrombosis.
[b]A thrombotic episode in the past could be considered as a clinical criterion, provided that thrombosis is proved by appropriate diagnostic means and that no alternative diagnosis or cause of thrombosis is found.
[c]Superficial venous thrombosis is not included in the clinical criteria.
[d]Generally accepted features of placental insufficiency include (1) abnormal or nonreassuring fetal surveillance test(s), for example, a nonreactive nonstress test, suggestive of fetal hypoxemia; (2) abnormal Doppler flow velocimetry waveform analysis suggestive of fetal hypoxemia, for example, absent end-diastolic flow in the umbilical artery; (3) oligohydramnios, for example, an amniotic fluid index of 5 cm or less; or (4) a postnatal birth weight less than the 10*th* percentile for the gestational age.
[e]Investigators are strongly advised to classify APS patients in studies into one of the following categories: I, more than one laboratory criteria present (any combination); IIa, LA present alone; IIb, aCL antibody present alone; IIc, anti-$\beta_2$glycoprotein-I antibody present alone.

Coagulation System–aPL Interaction

Inhibition of activation of protein C by the thrombomodulin–thrombin complex
Inhibition of activation of protein C via its cofactor protein S
Interaction between aPL and substrates of activated protein C such as factors Va and VIIIa Interaction between aPL and an annexin V anticoagulant shield

Complement Activation

Complement activation by aPL provokes thrombosis
Mutations in complement regulatory genes predispose to uncontrolled complement activation

antigens of which contain β_2GPI-like peptides, induces aPL in susceptible individuals via molecular mimicry. In experimental animal models, passive or active immunization with viral peptides, bacterial peptides, and heterologous β_2GPI induces polyclonal aPL and clinical events associated with APS. β_2GPI polymorphisms influence the generation of aPL in individuals but have only a weak relationship to the occurrence of aPL-related clinical events. Persons congenitally lacking β_2GPI, as well as β_2GPI knockout mice, appear normal.

In humans, although cross-sectional and prospective cohort studies demonstrate that aPL can predict future thrombosis, the pathogenic mechanism remains unknown; more than one mechanism may be involved (Table 61.2). Because high-titer antibodies can persist for years in asymptomatic persons and because positive aPL tests can precede symptoms for years, it is likely that vascular injury and/or endothelial cell activation will immediately precede thrombosis in persons bearing the antibody. Platelet activation followed by binding of aPL to platelet membrane phospholipid-bound annexins may initiate platelet adhesion and thrombosis. Antiphospholipid antibodies can inhibit phospholipid-dependent reactions in the coagulation cascade, such as protein C and protein S activation. Interaction between aPL and an annexin A5 anticoagulant shield is another potential mechanism.[2] Also, aPLs induce cellular activation through receptors such as annexin A2 and apoER2 and induce the release of microparticles from endothelial cells.[3]

More recently, the role of complement in thrombotic APS has been examined.[4] In a prospective study, complement activation in APS patients was investigated using surface deposition of C5b-9 and complement-dependent cell killing (modified Ham assay [mHam]). Persistent complement activation was observed in patients with triple aPL positivity, recurrent thromboses, and catastrophic antiphospholipid syndrome (CAPS), suggesting a strong association between complement activation and thrombotic events in APS (see Table 61.2). Furthermore, rare germline mutations in complement regulatory genes were detected in a majority of patients with CAPS, suggesting a predisposition to uncontrolled complement activation leading to a more severe thrombotic phenotype.[4]

In experimental animal models, aPL cause fetal resorption (a proxy for recurrent fetal loss) and increase size and duration of trauma-induced venous and arterial thrombi. Inhibiting

complement activation prevents experimental aPL-induced fetal death, and C5 knockout mice carry pregnancies normally despite the presence of aPL, implying that a complement-mediated effector mechanism is a requirement for fetal death to occur.

Asymptomatic aPL-positive individuals may require a second trigger event (such as oral contraceptives or surgical procedures) to develop a thrombotic event, referred to as the "second-hit hypothesis." Acquired, as well as inherited, risk factors for thrombosis may increase the risk of thromboembolic events in aPL patients.

A proposed pathogenesis for aPL-mediated thrombosis and placental injury begins with activation or apoptosis (by unknown triggers, possibly infectious or traumatic) of platelets, endothelial cells, or trophoblasts. Negatively charged phosphatidylserine migrates from the inner to the outer cell membrane. Circulating β_2GPI binds to phosphatidylserine, which is followed by aPL binding to a β_2GPI dimer, activating a complement and, through C5a, initiating a signaling cascade that induces cell surface tissue factor (TF) expression and adhesion molecules (e.g., ICAM-1). Other components of the innate immune system may also be activated, leading to a milieu that promotes platelet activation and thrombosis. In addition, aPL adversely affects the formation of a trophoblast syncytium, placental apoptosis, and trophoblast invasion, all processes required for the normal establishment of placental function. *In vitro*, pathogenic aPL induce adhesion molecules and enhance adherence of leukocytes to cultured endothelial cells.

FIG. 61.1 Livedo Reticularis in a Patient With Primary Antiphospholipid Syndrome.

DIAGNOSIS

Clinical Manifestations

The clinical manifestations associated with aPL represent a spectrum from completely asymptomatic to catastrophic APS (Table 61.3). The principal manifestations are venous or arterial thromboses and pregnancy losses. Except for their severity, the young age of affected patients, and atypical anatomical locations (e.g., Budd-Chiari syndrome, sagittal sinus), thromboses in APS do not clinically differ from other thromboses. Stroke and transient ischemic attack are the most common presentation of arterial thrombosis, whereas deep vein thrombosis and pulmonary embolism are the most common venous manifestations of APS. Glomerular capillary endothelial cell injury or thrombosis of renal vessels (thrombotic microangiopathy) causes proteinuria without celluria or hypocomplementemia and may lead to severe hypertension and/or renal failure.

Many patients have livedo reticularis (a lattice-like pattern of superficial skin veins) (Fig. 61.1), cardiac valve disease (vegetations, valve thickening, and dysfunction), or other nonthrombotic manifestations described in several studies, but not included in the revised Sapporo criteria[1] due to nonspecificity or rarity (Table 61.4). These manifestations by themselves do not classify a patient as having APS for clinical studies, but they add information to the diagnosis of individual patients. The pathogenesis of cardiac valve disease in APS is unknown, but it can be severe enough to require valve replacement. A putative association of aPL and increased risk of atherosclerosis exists, but this is controversial.[5] Some patients develop nonfocal neurological symptoms such as lack of concentration, forgetfulness, and dizzy spells. Small hyperintense lesions can be seen on magnetic resonance imaging (MRI), primarily in the periventricular white matter, but do not correlate well with clinical symptoms. Hemorrhagic complications are uncommon in patients with APS but may be seen in patients with severe thrombocytopenia or those who develop hypoprothrombinemia due to the development of antibodies of prothrombin that deplete the protein.

Pregnancy losses in patients with aPL typically occur after 10 weeks gestation, but earlier losses can occur. Patients with

TABLE 61.4 Noncriteria Features of the Antiphospholipid Syndrome

Type	Features
Clinical	Livedo racemose
	Autoimmune hemolytic anemia
	Thrombocytopenia (usually 50,000–100,000/mm^3)
	Multiple sclerosis-like syndromes
Laboratory	Immunoglobulin (Ig)A anticardiolipin and anti-β_2-glycoprotein-I antibodies
	Antiphosphatidylserine, phosphatidylinositol, phosphatidylglycerol, and/or phosphatidylethanolamine antibodies
	Antiprothrombin antibodies
	Antiphosphatidylserine-prothrombin antibodies

TABLE 61.5 Preliminary Criteria for the Classification of Catastrophic Antiphospholipid Syndrome

Criteria

1. Evidence of involvement of three or more organs, systems, and/or tissues[a]
2. Development of manifestations simultaneously or in <1 week
3. Confirmation by histopathology of small-vessel occlusion in at least one organ or tissue[b]
4. Laboratory confirmation of the presence of antiphospholipid antibody (aPL)[c]

Definite Catastrophic Antiphospholipid Syndrome (APS):

- All four criteria

Probable Catastrophic APS:

- Criteria 2–4 and two organs, systems, and/or tissues involved;
- Criteria 1–3, except no aPL confirmation 6 weeks apart due to the early death of a patient not tested before catastrophic episode;
- Criteria 1, 2, 4; or
  - Criteria 1, 3, 4, and development of a third event >1 week but less than 1 month after first despite anticoagulation.

[a]Usually, clinical evidence of vessel occlusions, confirmed by imaging techniques when appropriate. Renal involvement is defined by a 50% rise in serum creatinine, severe systemic hypertension, and/or proteinuria.
[b]For histopathological confirmation, significant evidence of thrombosis must be present, although vasculitis may coexist occasionally.
[c]If the patient had not been previously diagnosed as having APS, laboratory confirmation requires that the presence of aPL must be detected on two or more occasions at least 12 weeks apart (not necessarily at the time of the event), according to the proposed preliminary criteria for the classification of APS.

antiphospholipid syndrome may develop severe early preeclampsia and HELLP (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets) syndrome. Although placental infarction may be a cause of fetal growth restriction or death, non-thrombotic mechanisms of placental dysfunction are likely more important.

Catastrophic APS (CAPS) is a rare, abrupt-onset, life-threatening presentation. It is defined by multifocal thromboses associated with multi-organ failure occurring over a period of days in patients who meet laboratory criteria for APS. Proposed diagnostic criteria for CAPS are shown in Table 61.5. Early diagnosis can be a challenge, especially in patients with no history of APS or aPL-positivity, but diagnostic algorithms are available to facilitate diagnosis. Acute adrenal failure may be the initial clinical event, heralded by unexplained back pain and vascular collapse. Patients with CAPS often have moderate thrombocytopenia; fragmented erythrocytes can be seen, but they are less frequent than observed in hemolytic–uremic syndrome or thrombotic thrombocytopenic purpura. Renal failure and pulmonary hemorrhage may occur. Tissue biopsies show noninflammatory vascular occlusions involving both small- and medium-sized vessels.

Laboratory Tests

In the presence of characteristic clinical events, APS is diagnosed when patients have persistent aPLs, including moderate- to high-titer IgG, which may or may not be accompanied by IgM aCL or IgM aβ_2GP, and/or positive lupus anticoagulant (LA) test.[1] Approximately 80% of patients with positive LA tests have aCL, but only 20% of patients with positive aCL have positive LA tests. Some patients are only aβ_2GPI positive. Patients with positive LA tests are at higher risk for thrombosis than patients with aCL and/or aβ_2GPI alone. Several studies have shown that patients with all three tests positive have the highest risk for thrombotic complications, but this has not been consistently observed. LAs are detected in coagulation assays that detect the ability of aPL to interfere with phospholipid-dependent coagulation reactions. Guidelines from the International Society on Thrombosis and Haemostasis for diagnosis of LA[6] include the following:

1. Demonstration of a prolonged phospholipid-dependent coagulation screening test such as activated partial thromboplastin time (aPTT) or dilute Russell viper venom time (dRVVT).
2. Mixing patient plasma with normal plasma failed to correct the prolonged screening test, demonstrating the presence of an inhibitor.
3. Addition of excess phospholipid corrects or shortens the prolonged screening test, demonstrating phospholipid dependence.
4. Exclusion of other coagulopathies.

A positive screening coagulation test without confirmatory steps is not a positive LA test. Patients on anticoagulation may have false-positive or false-negative LA test results; thus, the LA test should be ordered when the patient is not receiving anticoagulation therapy, if possible.[6]

Interpretation of positive tests should take into account the following observations: moderate- to high-titer (>40 U) aCL or aβ_2GPI is more strongly associated with clinical events than is low-titer; LA is a more specific but less sensitive predictor of thromboses than other aPL tests;[7] multiple positive aPL tests impart a worse prognosis than does any single type of test[8]; and positive aPL tests require a repeat test after 12 weeks to exclude transient aPL.[1]

For most patients, laboratory results are stable over time. However, laboratory variability in the performance of these assays can be problematic. We showed that aPL results remain stable for at least three-quarters of subsequent tests during a mean follow-up of 2.4 years for the LA test, 3.5 years for the aCL test, and 1 year for the anti-β_2GPI test.[9] Based on same-day specimens, the consistency of aCL results among different commercial laboratories range from 64% to 88%, with moderate agreement for IgG and IgM, but marginal agreement for aCL IgA.[9]

Antiphospholipid antibody tests developed based on other phospholipids (*e.g.*, phosphatidylserine, phosphatidylinositol, or phosphatidylethanolamine) or prothrombin are not well standardized or widely accepted; their clinical significance is unknown. IgA aCL can rarely occur as the only aPL in patients with APS. When positive, an IgA aCL may justify a diagnosis of APS in LA- and aCL-IgG/IgM test-negative patients with clinically typical disease. A false-positive test for syphilis is not diagnostic for APS.

Antinuclear and anti-DNA antibodies occur in approximately 45% of patients with APS who are not diagnosed as having SLE. Thrombocytopenia occurs in APS and is usually modest (>50, 000/mm^3); proteinuria and renal insufficiency occur in patients with thrombotic microangiopathy. Erythrocyte sedimentation rate and hemoglobin and leukocyte count are usually normal in patients with uncomplicated APS, except during acute thrombosis. Complement levels are usually normal or only modestly low.

Imaging Studies

MRI studies show vascular occlusion and infarction consistent with clinical symptoms, without special characteristics, but multiple, otherwise unexplained, cerebral infarctions in a young person are more suggestive of the syndrome. Multiple, small, hyperintense, white matter lesions are common and do not

FIG. 61.2 Magnetic Resonance Imaging Demonstrating Multiple Periventricular White Matter Hyperintense Lesions.

unequivocally imply brain infarction (Fig. 61.2). Occlusions frequently occur in vessels below the resolution limits of angiography; hence angiography or magnetic resonance angiography is not indicated unless clinical findings suggest medium- or large-vessel disease. Echocardiography or cardiac MRI may show severe Libman-Sacks endocarditis and intracardiac thrombi.

Pathological Studies

Skin, renal, and other tissues show noninflammatory occlusion of all caliber arteries and veins, acute and chronic endothelial injury and its sequelae, and recanalization in late lesions. The finding of inflammatory necrotizing vasculitis suggests concomitant SLE or another connective tissue disease. There are no other diagnostic immunofluorescence or electron microscopic findings.

CLINICAL PEARLS

- The clinical manifestations of aPL represent a spectrum (from asymptomatic to catastrophic APS).
- Stroke and transient ischemic attack are the most common presentation of arterial thrombosis; deep vein thrombosis, often accompanied by pulmonary embolism, is the most common venous manifestation of APS.
- Pregnancy losses in patients with APS typically occur after 10 weeks gestation, but earlier losses also occur.
- Catastrophic APS is a rare, abrupt, life-threatening complication of APS, which consists of multiple thromboses with multi-organ failure occurring over a period of days.
- APS diagnosis should be made in the presence of characteristic clinical manifestations and *persistently* (at least 12 weeks apart) positive aPL.
- Warfarin, a vitamin K antagonist, is the preferred anticoagulant for patients with APS and a thrombotic event who are triple positive for aPL (*i.e.*, have lupus anticoagulant, anticardiolipin, and anti-β_2-glycoprotein I antibodies)

TREATMENT

Treatment recommendations for persistently aPL-positive patients are determined by the specific clinical indication (Table 61.6).

Asymptomatic Individuals

The ideal strategy for primary thrombosis prevention in asymptomatic, persistently aPL- positive individuals requires a risk-stratified approach based on aPL profile, age, systemic autoimmune diseases, traditional cardiovascular disease, or risk factors for venous thrombosis. Elimination of reversible risk factors for thrombosis (smoking, oral contraceptives) and prophylaxis during high-risk periods (surgical interventions or prolonged immobilization) is crucial for primary thrombosis prophylaxis in persistently aPL-positive individuals.

The role of aspirin for primary prevention of thrombosis in the asymptomatic aPL-positive individual is controversial. In one randomized, double-blind, placebo-controlled trial, low-dose aspirin (LDA) appeared to be no better than placebo in preventing first thrombotic episodes in asymptomatic persistently aPL-positive patients.[10] In contrast, a subsequent meta-analysis of seven retrospective observational studies of asymptomatic aPL carriers found that LDA reduced the risk of first thrombosis by half compared to those who did not use LDA.[11] The European League Against Rheumatism (EULAR) recently recommended the use of LDA in asymptomatic aPL-positive individuals with a high-risk aPL profile.[12] Risk prediction tools and prevention guidelines for cardiovascular disease in the general population, including an assessment of bleeding risk,

TABLE 61.6 Treatment Recommendations in Persistently Antiphospholipid Antibody–Positive Patients

Clinical Circumstances	Recommendation
Asymptomatic	No treatment[a]
Venous or arterial thrombosis	Warfarin international normalized ratio (INR) 2.0–3.0 indefinitely
Recurrent thrombosis	Warfarin INR 3.0–4.0 ± low-dose aspirin; or low molecular weight heparin
First pregnancy	No treatment[a]
Single pregnancy loss, <10 weeks	No treatment[a]
Recurrent fetal loss or loss after 10 weeks; history of no thrombosis	Prophylactic-dose[b] heparin with low-dose aspirin throughout the pregnancy, discontinue heparin 6–12 weeks postpartum
Recurrent fetal loss or loss after 10 weeks; history of thrombosis	Therapeutic-dose heparin[c] with low-dose aspirin throughout pregnancy, warfarin postpartum
Catastrophic antiphospholipid syndrome (APS)	Anticoagulation + corticosteroids + intravenous immunoglobulin or plasma exchange
Livedo reticularis	No treatment
Valve nodules or deformity	No known effective treatment: full anticoagulation if emboli or intracardiac thrombi are demonstrated
Thrombocytopenia, ≥30,000/mm^3	No treatment if asymptomatic with close follow-up and monitoring
Thrombocytopenia, <30,000/mm^3	Prednisone and/or intravenous immunoglobulin

[a]Aspirin 81 mg/day may be given.
[b]Prophylactic dose such as enoxaparin 30–40 mg subcutaneously (SQ) once daily.
[c]Therapeutic dose such as enoxaparin 1 mg/kg SQ twice daily or 1.5 mg/kg SQ once daily.

should be included when considering whether to use aspirin in asymptomatic aPL-positive individuals.

Avoiding unwanted pregnancies is an important part of primary prevention in aPL- positive patients. However, patients should be counseled to avoid using estrogen-containing oral contraceptives due to increased thromboembolic risk. While there are no reliable data regarding the safety of progestin-only contraception in this population, it is theoretically safer than estrogen-based contraception and is frequently used in clinical practice. A small retrospective review of women undergoing artificial reproductive technology procedures demonstrated no thrombotic events.

Venous and Arterial Thromboembolism

Anticoagulation with unfractionated heparin or low-molecular-weight heparin (LMWH) followed by a vitamin K antagonist (VKA) remains the treatment of choice for APS patients with thromboembolic events. For patients with a positive LA test that prolongs the aPTT, monitoring heparin can be accomplished by measuring anti-factor Xa levels.

Two prospective controlled studies concluded that recurrence of thromboses in APS patients could be prevented with VKA titrated to a target international normalized ratio (INR) of 2.0 to 3.0.[13,14] Although these studies provide strong evidence for standard-intensity anticoagulation after an aPL-related venous event, the management of recurrent venous thrombosis while on standard-intensity VKA is challenging. Based on limited evidence, guidelines support first ensuring VKA adherence and increasing frequency of INR monitoring. For VKA-adherent patients with recurrent thrombotic events, an increase of the INR target to 3.0 to 4.0, the addition of LDA, or a change to LMWH may be considered.[12]

The optimal management of APS with arterial thrombosis is not well established. EULAR recently recommended that patients with APS and arterial thrombosis should receive VKA, with or without LDA, to prevent recurrent events.[12] The data in support of this recommendation are limited, however, and others have suggested that aspirin alone (325 mg) could be used in these patients. Recently, a retrospective analysis compared recurrent thrombosis rates in APS patients with prior arterial events and found significant differences between patients treated with antiplatelet therapy (37.2%), anticoagulant therapy (23.7%), and anticoagulation with antiplatelet therapy (6.9%).[15] While these findings suggest that combination therapy is the optimal choice, one must take into account that anticoagulation was not standardized and that bleeding risk was not evaluated. Since the best secondary stroke prevention strategy remains unclear, treatment should be individualized, weighing the risk of recurrent thrombosis with the risk of major bleeding.

Despite the expanding use of direct oral anticoagulants (DOACs) in the treatment of patients with venous thromboembolism and the prevention of stroke in patients with atrial fibrillation, current data do not support DOAC use in APS patients. A randomized multicenter noninferiority study designed to evaluate the efficacy and safety of rivaroxaban compared with warfarin in high-risk (triple antibody positive) patients with thrombotic APS was terminated prematurely due to excessive thrombotic events in the rivaroxaban arm (19% vs. 3%).[16] A second study confirmed that recurrent thrombosis, particularly strokes, occurred more frequently in patients with thrombotic APS treated with rivaroxaban compared to VKA.[17] In addition, this study included all patients with APS, not just those with high-risk, triple-positive disease. Major bleeding events were similar between the two groups. Guidelines now recommend against the use of DOACs in APS patients with triple-positive aPL, particularly those with arterial thrombotic events.[12]

Thrombosis in aPL-positive patients typically has a high recurrence rate if anticoagulation is discontinued, and lifelong anticoagulation is usually recommended. A systematic review of the literature found that the available evidence in support of an association between the presence of aPL and risk of recurrent venous thromboembolism is of low quality, however, suggesting that indefinite anticoagulation may not be needed by all patients.[18] For example, it is unknown whether patients whose event was triggered by an acquired, reversible risk factor for thrombosis can discontinue anticoagulation or switch to aspirin when the trigger factor is eliminated. Normalization of the LA or aCL tests is *not* an indication to discontinue anticoagulation. For well-anticoagulated patients who continue to have thromboses, antiplatelet drugs, hydroxychloroquine, statins, intravenous immunoglobulin (IVIG), and plasmapheresis have theoretical bases for efficacy and have all been used.

There are no systematic studies of treatment for CAPS. Detailed reviews conclude that the most effective first-line treatment combines full-dose anticoagulation, high-dose corticosteroids, and plasmapheresis or IVIG. Concurrent treatment of the underlying precipitating factors is also recommended (e.g., infection or malignancy). Several case reports have described the successful use of complement inhibitor therapy to treat CAPS.

Pregnancy Morbidity

Pregnancy is a prothrombotic state. Management strategies in persistently aPL-positive patients should focus on the prevention of both pregnancy morbidity and maternal thrombotic complications.[5] In patients with a history of obstetric APS, a combination of heparin and low-dose aspirin is recommended.[18] Most experts in the field use LMWH (e.g., enoxaparin) due to lower risk of thrombocytopenia and osteoporosis—prophylactic doses for women with prior obstetric APS only, or full therapeutic doses for women with prior thromboses (see Table 61.6). Treatment begins after confirmation of pregnancy, continues until 48 hours before anticipated delivery (to allow epidural anesthesia), and resumes for 6 to 12 weeks postpartum (if no prior thromboembolism), or the patient is transitioned to warfarin postpartum for continued therapy. No studies unequivocally justify the treatment of women with aPL during a first pregnancy, women with only very early losses, or women whose aPL titers are low or transient. Nonetheless, it is common to offer such patients low-dose aspirin.

Other Clinical Manifestations of Antiphospholipid syndrome

There is no consensus for the treatment of patients with noncriteria and/or nonthrombotic manifestations of aPL. Corticosteroids and/or IVIG are the first-line treatments for severe thrombocytopenia. In general, patients with asymptomatic immune-mediated thrombocytopenia do not need treatment until the platelet count drops to less than 30, 000/mm^3. An open-label phase IIa pilot study of aPL found that rituximab may be effective in controlling some but not all noncriteria manifestations of APS, although aPL profiles did not change with treatment.[19]

Perioperative Management

Serious perioperative complications may occur despite prophylaxis. Patients with APS are at additional risk for

thrombosis when they undergo surgery. Thus, perioperative strategies should be clearly identified before any surgical procedure or before pharmacological and physical anti-thrombosis interventions are vigorously employed. In addition, periods without anticoagulation must be kept to an absolute minimum, and any deviation from a normal course should be considered a potential disease-related event.

Additional Therapeutic Considerations

There is experimental and clinical evidence in lupus patients that hydroxychloroquine (HCQ) might decrease the incidence of thrombosis, and *in vitro* studies have demonstrated that HCQ might protect endothelial cells and syncytialized trophoblast cell lines from the disruptive effect of antiphospholipid antibodies. In patients with systemic autoimmune diseases (particularly lupus), HCQ is commonly employed for disease control and should be considered independent of patients' aPL status. Unfortunately, a study investigating the efficacy of HCQ in primary prevention of thrombosis in aPL-positive patients without underlying autoimmune disease was terminated early due to low recruitment rate and significant cost increases of the study drug in the US. Prospective, randomized, controlled studies continue to be needed to determine the role of HCQ for the prevention and treatment of thrombosis in aPL-positive patients.

As previously discussed, initial trials of rivaroxaban for thrombotic APS were disappointing and failed to show noninferiority to VKA. At this time, providers should use caution recommending DOACs to patients with thrombotic APS, especially those with triple-positive disease or prior arterial thrombosis.

An emerging area of investigation is the role of complement inhibitors in the treatment of CAPS and thrombotic APS refractory to anticoagulation. There are several case reports describing the successful use of eculizumab in refractory APS patients.[20] However, a prospective, randomized clinical trial of complement inhibition in thrombotic APS is needed.

CONCLUSIONS AND TRANSLATIONAL RESEARCH

APS is a systemic autoimmune disease consisting of thromboses, pregnancy losses, and persistent high-titer aPL antibodies. Inflammation and complement activation are established mechanisms of aPL-related manifestations in murine models; however, definitive studies in humans do not exist. The disease is too variable clinically, and its mechanisms too diverse to expect that a single mechanism defined in a single model will apply to all aspects of this disease. Given that the mechanisms of aPL-induced thrombosis are not well understood, thrombosis is multifactorial, and that controversies exist about the strength of association between aPL and clinical events, drug development specific for aPL-positive patients has been challenging. Anticoagulation is the primary treatment today, but a future therapeutic approach will likely include immunomodulatory agents.

ON THE HORIZON

Translational Research in Antiphospholipid Syndrome

- A better understanding of the cellular mechanisms of aPL mediated clinical events that will help design better treatments that are specifically targeted.
- Identification of patients who are at risk for future/recurrent aPL-related events.
- Controlled studies of potentially useful medications such as hydroxychloroquine, complement inhibitors, or anti-B-cell therapies.

Immunohematologic Disorders

Kristin Ammon Shimano and Pierre Noel

INTRODUCTION

Congenital (primary) or acquired (secondary) immunodeficiencies, medications, and lymphoproliferative and rheumatologic disorders are frequently associated with immune-mediated cytopenias. These processes can affect erythrocytes, leukocytes, and platelets, individually or in combination. In this chapter, we address immune-mediated cytopenias of each hematologic component, discussing pathophysiology, clinical presentation, differential diagnosis, and treatment options.

IMMUNE-MEDIATED HEMOLYTIC ANEMIA

Immune-mediated hemolysis can be autoimmune, alloimmune, idiopathic, or secondary to drugs or other diseases. Regardless of the underlying cause, immunoglobulin G (IgG) or IgM (rarely IgA) antibodies are directed against antigens on the red blood cell (RBC) membrane (Table 62.1). These disorders can be categorized on the basis of the underlying cause and the type of anti-erythrocyte antibody that mediates the process. Autoimmune hemolytic anemias (AIHAs) are usually classified as warm or cold depending on the temperature at which the antibody attaches to RBCs. The three major categories of AIHA are warm autoimmune hemolytic anemia, cold agglutinin disease, and paroxysmal cold hemoglobinuria (PCH)—although mixed antibody and direct antibody test (DAT)-negative warm AIHA can also occur.

TABLE 62.1 Classification of Immune Hemolytic Disorders

Autoimmune

Warm Antibody-Mediated

Idiopathic
Secondary
Drugs, lymphoid malignancies, infections
Other autoimmune diseases

Cold Antibody-Mediated

Cold agglutinin disease
Idiopathic
Secondary
Infection, lymphoid malignancies

Paroxysmal Cold Hemoglobinuria

Idiopathic
Secondary to infections

Alloimmune

Secondary to red cell transfusions (alloantibodies, isoantibodies)
Secondary to fetal-maternal hemorrhage
Secondary to transplanted lymphocytes

Immunopathogenesis

The antigens for anti-erythrocyte IgG are usually proteins, the most clinically important of which are the Rh-associated glycoproteins (RhAG), D, C, c, E, and e expressed on the cell membrane.[1] In contrast, anti-erythrocyte IgM is directed at polysaccharides, which include the ABO and I-antigens (I, i) found on the anion and glucose transporter proteins in the RBC membrane.[2,3] Molecular mimicry in the setting of infection, neoantigen formation in the presence of drugs, polyclonal lymphocyte activation due to viral infection, or clonal outgrowth in the setting of lymphoproliferative disease may all contribute to antibody formation in different cases.[4]

Antibodies are distinguished by being "warm" or "cold" reactive, respectively, meaning that they bind antigens at core body temperature (warm), or they bind antigens preferentially at lower temperatures (cold) in the peripheral circulation or ex vivo. This distinction results from the different thermodynamics of binding to protein (hydrophobic) and polysaccharide (electrostatic) antigens.[3]

IgG antibodies typically bind at warm temperatures and IgM antibodies typically bind at cold temperatures, although there can be overlap and exceptions (e.g., the Donath-Landsteiner IgG antibodies that are seen in PCH). IgG and IgM also differ in their ability to fix complement, and this affects the resulting mechanism of hemolysis. To attach the first component of the classical complement pathway, two IgG molecules must bind in close proximity on the RBC. However, because of its pentameric structure, a single IgM molecule can initiate complement activation.

Erythrocyte-bound IgG becomes attached to the Fc receptors of splenic macrophages, which may engulf all or part of the cell or release lysosomal enzymes that digest its membrane (antibody-dependent cell-mediated cytotoxicity [ADCC]).[5] RBC fragments escaping from this encounter lose more membrane than cytoplasm and become spherical (spherocytes) as a consequence of this change in the surface-to-volume ratio. If IgG has initiated complement activation on the cell surface, binding of C3b to splenic macrophages will augment erythrocyte phagocytosis in the spleen.[6]

When IgM fixes complement, the process begins in the cooler peripheral circulation, where IgM binds to RBCs. If the amount of IgM bound is relatively high—with at least some of it remaining on the cell at 37°C (e.g., anti-A or anti-B isoantibodies)—the cascade of complement activation goes to completion. Doughnut-shaped holes are formed in the cell membrane that allow the influx of water and sodium, inducing intravascular osmotic rupture of the cell.[5] However, if the IgM elutes from the RBC as it returns to body core temperature, the complement reaction attenuates. In this circumstance, the components remain on the cell but do not cause intravascular hemolysis. Instead, the cells are cleared by hepatic macrophages via complement-binding sites.[7]

Warm Autoimmune Hemolytic Anemia

Warm autoimmune hemolytic anemia is the most common subtype, accounting for 70% to 80% of AIHAs in adults and ~50% in children.[8] The antibody is typically a polyclonal IgG antibody directed against the Rh complex on the erythrocyte. The hemolysis is predominantly extravascular, as there is little complement activation. Laboratory manifestations include microspherocytes visible on peripheral blood smear that are the result of partial phagocytosis and removal of RBC membrane in the spleen.

Cold Agglutinin Diseases

This type of hemolytic anemia is mediated predominantly by anti-I or anti-i IgM that agglutinates red cells at temperatures well below 37°C. These antibodies engage the complement pathway, resulting in C3b-mediated RBC phagocytosis mainly by Kupffer cells, whereas membrane-associated complex is a minor mechanism at low IgM titers. The severity of the clinical illness depends on the concentration of the IgM and its "thermal amplitude." Thermal amplitude describes the temperature range over which it binds to RBCs. For example, antibodies that exclusively bind at 4°C are only active in vitro, whereas those that bind at greater than 30°C can bind to RBCs as they circulate in the periphery and begin the process of complement fixation, which can persist even as the cells return to body core temperatures. The activity of the IgM is also determined by its relative affinity for the I- and i-antigens, which varies from one individual to the next. Laboratory manifestations include rouleaux—or stacked aggregations of RBCs—seen on peripheral smear due to the agglutination of erythrocytes by the homopentameric cold agglutinins. Clinically, acrocyanosis may be seen as red cells agglutinate in the cooler extremities, and dark urine may be seen due to significant intravascular hemolysis.

Two general types of cold agglutinin disease are recognized: a chronic idiopathic disease presenting in patients over age 50 years caused by monoclonal anti-I IgM, and a transient disease secondary to certain infections (e.g., mycoplasma, Epstein-Barr virus [EBV], cytomegalovirus [CMV]) caused by polyclonal anti-i and anti-I (see Table 62.1). Avoidance of cold environments is important in both categories of cold agglutinin disease. In addition, cold agglutinin disease can be associated with B-cell lymphoproliferative disorders, and this typically is responsive to rituximab and/or rituximab combined with fludarabine.[9]

Paroxysmal Cold Hemoglobinuria

PCH is caused by anti-P IgG that is very effective in fixing complement and producing intravascular hemolysis. The polyclonal IgG is known as the Donath-Landsteiner antibody. Although rare, it is most common in children following a viral illness and can be managed by avoidance of cold. In the past, it was more commonly associated with syphilis (see Table 62.1). There is also an autoimmune variety of PCH that may require immunosuppression with corticosteroids. Splenectomy is not helpful as a consequence of the fact that the hemolysis is intravascular.

Drug-Induced Immune Hemolysis

Over 125 drugs have been associated with immune hemolysis.[10] Cefotetan, ceftriaxone, and piperacillin currently account for over 80% of cases. The prognosis of drug-related immune hemolysis is much better than that of idiopathic hemolysis because the hemolysis stops once the offending drug has been removed. The drugs most commonly associated with fatal hemolytic anemia are cefotetan (8%) and ceftriaxone (6%).[10]

Although the biochemical mechanisms of drug-related immune hemolysis are not completely clear, several hypotheses are generally accepted. Most commonly, complexes of drug and IgG and/or IgM adsorb to the RBC surface and fix complement. The resultant intravascular hemolysis is acute and often severe enough to cause renal failure from toxicities of hemoglobin to renal epithelium.

A second, less common, mechanism develops primarily in patients receiving very high doses of penicillin (rarely used) for at least 1 week. High-titer antipenicillin IgG develops and binds to penicillin that is covalently attached to the RBC membranes. The resultant hemolysis is less acute than that caused by immune complexes but can be life-threatening.

In a third mechanism, a drug stimulates the production of an antibody that reacts with the patient's RBCs independently from the drug. Serologically, this antibody is indistinguishable from an idiopathic autoantibody. This has become rare as the use of the primary causal agent, methyldopa (an antihypertensive medication), has declined. Although these autoantibodies commonly cause positive clinical antibody tests (see below), they rarely cause hemolysis in vivo, and when they do, it usually ceases within 2 weeks of discontinuing the drug.

Diagnosis

With few exceptions, if the mechanism of hemolysis is immune mediated, an anti-RBC antibody can be demonstrated, either on the RBC surface, in serum, or both. With autoimmune hemolysis, IgG or IgM and/or complement components can be identified by a DAT, originally known as a *direct Coombs test* (Fig. 62.1). For this test, a patient's RBCs are washed and suspended in buffer. Surface-bound IgG is detected by adding a divalent anti-IgG antibody, which binds to IgG on adjacent RBCs and agglutinates them into visible aggregates. Because of its pentameric structure, IgM on the cells can cause agglutination without the addition of a second antibody. Even when IgM has been previously eluted from the cell surface as a result of warming in the central circulation, its earlier presence in vivo can be detected by telltale remnants of complement that are fixed to the RBC. In this setting, detection requires the addition of anticomplement antibody (e.g., anti-C3dg).

Alloantibodies can also be detected by the DAT if allogeneic RBCs from a previous transfusion are still circulating. If these have been cleared, however, RBC antibodies can be identified in the patient's serum by adding the serum to a panel of RBCs carrying different antigens. Agglutination is detected as described above; this constitutes the indirect antibody test.

CLINICAL PEARLS

In the work-up of hemolytic anemia, the following clinical laboratory studies provide important clues as to mechanism and may lead to a diagnosis of an immune hemolytic anemia.

Direct antibody test (DAT): The presence of antibodies on the surface of red blood cells (RBCs) suggests an immune-mediated hemolysis. The presence of antibody and complement on the surface of the RBC suggests drug-related hemolysis, whereas the presence of complement alone may suggest an immunoglobulin M (IgM) or cold antibody-related hemolysis.

Peripheral blood smear: Examination of the peripheral smear and various RBC indices (chiefly the mean corpuscular volume [MCV]) give mechanistic clues to the etiology of the hemolytic process. Immune-mediated hemolysis is characterized by spherocytosis, even microspherocytosis in severe cases, as antibody-coated RBCs traversing the reticuloendothelial system assume a spherical form, rather than that of a normal biconcave disc. The appearance of other pathologic forms, such as schistocytes, sickle cells, targets, or tear drop forms (dacrocytes), suggests other causes of hemolysis, such as thrombotic thrombocytopenic purpura (TTP), or mechanical, shear-induced hemolysis (e.g., aortic stenosis), sickle cell disease, thalassemia, or extramedullary hematopoiesis from bone marrow fibrosis, metastasis, or failure. Nucleated RBCs can be seen in any form of hemolytic anemia if it is severe enough.

Reticulocytes: Evaluation of the reticulocyte count indicates whether bone marrow is capable of making new erythrocytes in response to hemolysis.

Lactic acid dehydrogenase (LDH): The LDH is typically elevated with ongoing hemolysis, since LDH is an important housekeeping enzyme found in erythrocytes. LDH is found in cells from all tissues, each having a characteristic isoenzyme form of LDH. It is rarely necessary to distinguish LDH from RBCs from other tissue sources, but LDH isoenzyme 1 is the predominant form found in RBCs.

Bilirubin: As heme is released from RBCs, it is metabolized to bilirubin, which is glycosylated and then excreted via hepatic metabolism. Initially, as large amounts of heme are released and metabolized, the bilirubin is predominantly indirect bilirubin (unconjugated), and then it is converted to direct (conjugated) bilirubin. This can be altered by cholestasis, either from biliary obstruction or hepatic disease or Gilbert disease, or hepatic immaturity in the premature infant or newborn.

Haptoglobin: Haptoglobin is extremely sensitive to even small amounts of hemolysis. Its absence merely confirms that there is a significant hemolysis, but not its extent. The presence of normal haptoglobin effectively rules out significant hemolysis, and the return of measurable amounts of haptoglobin usually signals the end of hemolysis.

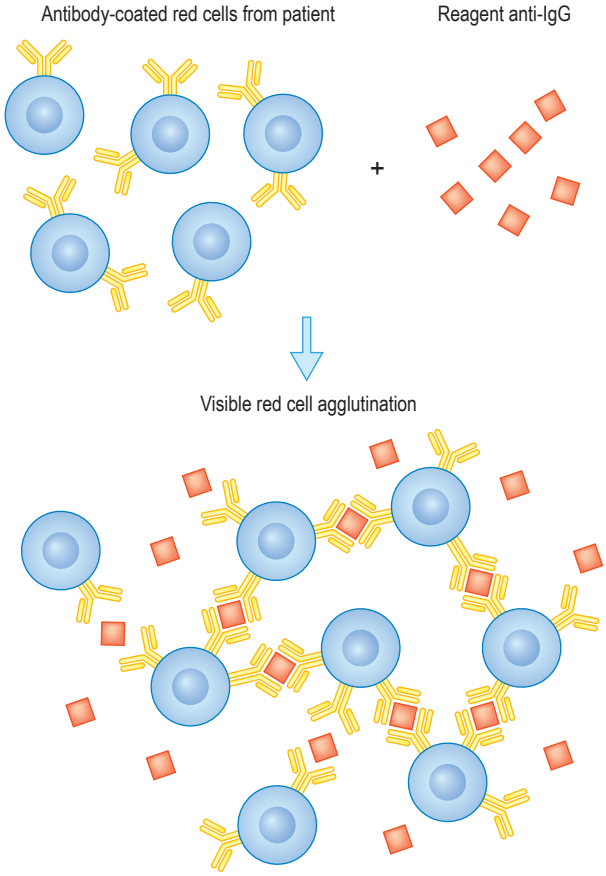

FIG. 62.1 The Direct Antibody Test (DAT). The test is positive when immunoglobulin G (*IgG*: *light blue triangles*)–coated red blood cells are cross-linked by anti-IgG antibody (*dark blue triangles*) to form visible cell aggregates. Cell-bound complement and/or IgM can be detected by using anticomplement or anti-IgM reagent antibodies.

Therapy

The first line of therapy in warm AIHA is corticosteroids, and 80% of patients achieve a partial or complete response to 1 mg/kg/day of prednisone (orally). Once a response is achieved, the prednisone dose is tapered slowly. Approximately 50% of patients require prednisone at a dose of 15 mg/day or less to maintain the hemoglobin level greater than 10 g/dL, and it may take up to 3 weeks for patients to achieve a response. Patients who do not respond in 3 weeks should be started on second-line therapy. It is estimated that long-term complete responses not requiring ongoing prednisone treatment can be achieved in 20% of patients.[11]

Transfusions are avoided except in patients with severe anemia or rapid hemolysis, in which case least incompatible RBC units are used. Splenectomy and anti-CD20 antibody (rituximab) are considered second-line therapy. Splenectomy is associated with short-term partial or complete responses in two-thirds of patients. The overall response rate to rituximab is approximately 80%, but rituximab is contraindicated in patients with untreated hepatitis B. The rare, but most severe, long-term complication of rituximab therapy is progressive multifocal leukoencephalopathy.[11]

The role of high-dose intravenous immunoglobulin (IVIG) remains controversial; its effectiveness remains to be determined in larger trials. Third-line therapy consists of other immunosuppressive agents (e.g., azathioprine, cyclophosphamide, alemtuzumab, mycophenolate mofetil, cyclosporine, sirolimus, or danazol in combination with steroids).[11,12] Plasmapheresis has been used with variable results. If the AIHA is secondary to an underlying disorder, treatment of the underlying disease may offer the most effective therapy.

The treatment of cold AIHA is largely supportive and requires avoidance of cold and pre-warming blood and fluids. Steroids are not useful in the treatment of cold AIHA. Patients with chronic monoclonal IgM-mediated disease may require therapy with rituximab, bortezomib, fludarabine, or

rituximab/bendamustine. Complement inhibition may have a role in therapy, although further study is needed.[13]

Patients with PCH are also treated with supportive therapy, warming, and transfusions as needed, although a subset of patients may respond to steroids.

IMMUNE-MEDIATED NEUTROPENIA

Immune neutropenia constitutes a heterogeneous group of acquired diseases in which the immune system responds to circulating neutrophils, selectively reducing their level to below 1500 cells/mm^3 (Table 62.2).

Neonatal Alloimmune Neutropenia

Transient neutropenia—analogous to neonatal immune hemolysis or thrombocytopenia—develops when IgG antineutrophil antibodies (ANAs) from either an allosensitized or autoimmune mother cross the placenta and destroy fetal neutrophils. The former can occur when there are discrepant maternal and paternal neutrophil-specific antigens, and the mother makes antibodies to paternal antigens that then cross the placenta. The latter occurs less commonly when antibodies from a mother with autoimmune neutropenia cross the placenta. In either case, neutropenia is typically present at birth and resolves spontaneously, as maternal antibodies usually disappear within 12 to 15 weeks, but occasionally it can persist as long as 24 weeks after delivery. It can result in serious infections in approximately 20% of cases.[14]

Primary Autoimmune Neutropenia

Primary autoimmune neutropenia, or benign neutropenia of childhood, is an antibody-mediated disease that presents commonly in early childhood.[15] Patients typically have normal blood counts at birth and develop neutropenia at 3 to 36 months of age. Children presenting at less than 2 years of age most commonly recover spontaneously within 2 to 3 years of diagnosis. The majority do not suffer from severe infections and in most cases are able to mount an appropriate neutrophil response. Nevertheless, some children, particularly those presenting at older ages or manifesting other autoimmune findings, develop a chronic neutropenia disorder. Primary immune neutropenia (in the absence of other disease manifestations) is less common in adults. Rigorous incidence data are lacking, but a small retrospective study found an annual incidence of 5 to 10 cases of primary or secondary neutropenia per 100,000 people.[16]

TABLE 62.2 Causes of Immune Neutropenia

Primary
Isoimmune neonatal neutropenia
Autoimmune neutropenia of childhood
Adult autoimmune neutropenia
Secondary
Systemic autoimmune disease
Rheumatoid arthritis (i.e., Felty syndrome)
Systemic lupus erythematosus
Sjögren syndrome
Lymphoproliferative malignancy
Large granular lymphocyte (LGL) leukemia
Lymphoma
Drug-Induced
Antiplatelets—ticlopidine
Inflammatory bowel disease drug—sulfasalazine
Antipsychotic—clozapine, phenothiazines
Antithyroid medications—propylthiouracil, methimazole
Retrovirals
Antibiotics—beta-lactams, cefepime, trimethoprim-sulfamethoxazole, vancomycin, rifampicin, quinine/quinidine
Diuretics—furosemide, spironolactone
Antiepileptic—lamotrigine
Rituximab, infliximab, etanercept

Neutropenia Associated With Systemic Autoimmune or Lymphoproliferative Diseases

Autoimmune neutropenia is more commonly found secondary to other disorders, such as systemic autoimmune disease or lymphoproliferative diseases, in adults. Secondary autoimmune neutropenia may also be seen in children in the setting of an underlying immunodeficiency or autoimmune disease, or in the setting of other immune cytopenias (Evans syndrome, or multilineage immune cytopenias). Most patients with active systemic lupus erythematosus (SLE) develop neutropenia as part of a more global leukopenia (Chapter 53).[17] Separately, a smaller subset develops severe neutropenia, presumably mediated by anti-neutrophil antibodies. Sjögren syndrome (Chapter 55) and other systemic autoimmune diseases are also sometimes complicated by immune neutropenia. Immune neutropenia develops in about 1% of patients with rheumatoid arthritis, most commonly (but not exclusively) in association with splenomegaly, a combination designated as Felty syndrome.[18] Patients typically express human leukocyte antigen-D related 4 (HLA-DR4) and have long-standing seropositive rheumatoid arthritis complicated by erosive joint disease, subcutaneous nodules, and/or leg ulcers. The natural history is often marked by repeated infection, with 5-year mortality rates of greater than 30% reported in some studies. The complex pathophysiology of this disorder is discussed elsewhere in detail (Chapter 52). Lymphoproliferative disorders, such as chronic lymphocytic leukemia (Chapter 77), can occasionally be complicated by immune neutropenia as well.

T-Cell Large Granular Lymphocyte Leukemia

Large granular lymphocytes (LGLs) are medium to large lymphocytes recognizable on light microscopy by their distinctive azurophilic granules (Fig. 62.2). These cells normally constitute

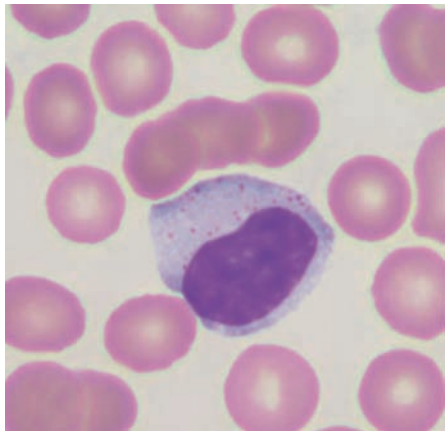

FIG. 62.2 The Large Granular Lymphocyte (LGL) Is a Moderate-Sized Lymphocyte Containing Several Distinctive Azurophilic Granules. Additional immunophenotyping is required to distinguish the CD3$^+$, CD8$^+$, CD57$^+$ T-LGL associated with neutropenia from CD16$^+$, CD56$^+$ natural killer (NK)-LGL.

less than 15% of circulating leukocytes and are composed of two major subsets. One is the natural killer (NK)-LGLs that express CD2, CD16, and CD56 and are not linked to neutropenia. The other, T-cell (T) LGLs, express CD2, CD3, CD8, and CD57 with or without CD16, a phenotype typical of antigen-stimulated mature CD8 effector T cells. Polyclonal and transient monoclonal expansions of these cells sometimes appear in response to viral infection or other immune stimuli without adverse effect. However, some patients develop an indolent lymphoproliferative disease characterized by the accumulation of an autonomous T-LGL clone in blood and other lymphoid organs, particularly bone marrow, the liver, and/or the spleen. Patients with this disease have a remarkably high incidence of immune neutropenia. Even in the absence of gross marrow involvement, over 80% have a neutrophil count of less than 2000/mm^3 at presentation, and at some point, 30% to 40% develop severe neutropenia with less than 500 neutrophils/mm^3.[19,20]

The pathophysiology resembles Felty syndrome in many respects. At the extremes, these syndromes are easily separable. Patients with classical Felty syndrome have severe rheumatoid arthritis, usually requiring antinflammatory therapy, incidentally complicated by late neutropenia. This is quite different from the pattern in patients with isolated T-LGL leukemia with neutropenia in the absence of clinical autoimmune disease. Although some clinicians have attempted to develop criteria for distinguishing Felty syndrome from T-LGL with pseudo-Felty syndrome, there is now substantial evidence that clonal T-LGL disorders are commonly found in rheumatology patients and that patients with clonal disorders seldom develop a progressive, neoplastic disorder. Conversely, although patients with T-LGL leukemia have a malignancy, it is typically quite indolent—and in these cases, the clinical course is often dominated by rheumatologic complications and/or neutropenia and not by progressive neoplastic disease.

Drug-Induced Immune Neutropenia

A wide variety of medications cause neutropenia. In some cases, it may be a direct toxic effect on marrow precursors, but in others it may be antibody-mediated (see Table 62.2 for common examples). Idiosyncratic drug-induced neutropenia is thought to be due to immune-mediated destruction of neutrophils. While the mechanism is not fully understood, antibodies to hapten-carrier complexes or inflammasome activation may play a role in the pathogenesis. Timing of the neutropenia may be months after initiation of the offending medication, or even after discontinuation in some cases, and mortality is around 5%.[21]

Rituximab (anti-CD20) is occasionally associated with late-onset neutropenia (LON). LON is typically self-limiting and of no significant clinical consequence; the occurrence and severity of LON may be associated with the total dose of rituximab and the myelotoxicity of the accompanying chemotherapy administered. LON appears to coincide with post-rituximab B-cell recovery. In varying studies the incidence of LON was 3% to 27%, the median time of onset was 38 to 191 days after rituximab, and the median duration was 5 to 17 days.[22]

Immunopathogenesis

Regulation of Antineutrophil Antibody Production

Isoimmune ANA production in pregnant women represents an "appropriate" immune response to foreign antigens (paternal neutrophil antigens). The production of autoimmune ANAs in other settings reflects immune dysregulation. Older studies attributed primary immune neutropenia of childhood to delayed maturation of T cells responsible for regulating B-cell responses. In this view, the spontaneous recovery usually observed reflects the eventual appearance of mature regulatory or inhibitory T cells. However, this hypothesis is not well supported with clinical laboratory data. Another hypothesis is that ANA production is triggered by molecular mimicry in the setting of a viral infection.[14] The cause of antibody production in other autoimmune diseases remains unclear. A significant proportion of patients with Sjögren syndrome will have neutropenia, with an increased association with anti-Ro/La antibodies.[23] In patients with SLE, as well, anti-SSA and -SSB antibodies are correlated with autoimmune neutropenia, possibly due to similarity between Ro/SSA and neutrophil antigens.[24]

Antibody Specificity

The most important target for antibody responses is the Fcγ receptor IIIb (FcγRIIIb), a low-avidity granulocyte-specific Fcγ receptor that binds IgG immune complexes. This cell surface protein—a glycosyl phosphatidylinositol-linked variant of CD16 selectively expressed on neutrophils—contains several highly immunogenic polymorphisms.[25] Human neutrophil antigen 1a (HNA-1a) and HNA-1b (previously designated NA1 and NA2) are two related polymorphic forms of FcγRIIIb.

Isoimmune neonatal neutropenia is associated with maternal IgG isoantibodies or autoantibodies that can be generated in response to polymorphic alloantigens, particularly polymorphisms affecting FcγRIIIb. Immune neutropenia in childhood is most commonly associated with IgG directed against the autoantigens HNA-1a and/or HNA-1b.[26] Sera from affected patients often also bind (albeit more weakly) to neutrophils expressing the alternative allele, and in some series, more than half the patients with this entity were shown to produce antibodies capable of binding to nonpolymorphic elements within FcγRIIIb. In one study, pan-specific FcγRIIIb antibodies were detected early in the disease course, and more specific HNA-1a and -1b antibodies were detected later.[27] In adults, it is often difficult to distinguish clinically immune neutropenia from nonimmune idiopathic neutropenia. Consequently, the sensitivity and specificity of antibody assays in this setting are uncertain. In general, antibodies against HNA-1a or HNA-1b are less common, and antibodies against surface receptors, such as CD11b/CD18 (CR3), are more common in older children and adults than in young children. Sera from patients with Felty syndrome and T-LGL leukemia are often positive in ANA assays. Interpretation of these results is complicated by the high incidence of nonspecific immune complexes in these populations, which may bind nonspecifically through Fc and complement receptors to the neutrophil surface. Indeed, because it is difficult to distinguish these two types of binding, the incidence of "true" ANAs in these syndromes remains uncertain. Detectable ANAs are low in titer or absent in most patients carefully studied with either diagnosis.[19,20]

Impact of Antibodies and Immune Complexes on Neutrophil Survival

There is quality experimental evidence that both ANAs and immune complexes can induce neutropenia in vivo. The relative importance of reversible sequestration and neutrophil destruction in inducing neutropenia varies with the experimental model, the character of the antibody/immune complex, spleen size, and presumably other factors as well.

The detection of ANAs in serum, however, does not automatically predict accelerated immune clearance of neutrophils in vivo. Some antibodies bind well to neutrophils under in vitro assay conditions without provoking neutrophil destruction in vivo. In part, this reflects the inability of these crude assays to distinguish effective from ineffective binding of immunoproteins.

Myelopoiesis in Immune Neutropenia

In primary immune neutropenia, bone marrow is typically normocellular or mildly hypercellular with an increased proportion of early myeloid forms (particularly myelocytes and promyelocytes) and decreased mature forms (neutrophils, bands, and metamyelocytes), a pattern designated "maturation arrest." Although maturation arrest can also be seen in a number of other diseases, in this setting it suggests an expansion in immature precursors with early release of mature components into blood. Rigorous kinetic studies in children with primary neutropenia are not available, but the available data suggest myelopoiesis in this setting is increased.

The findings are more complex in Felty syndrome and T-LGL leukemia. In vivo neutrophil kinetic studies and in vitro assays of marrow function often document reduced myelopoiesis in these settings.[19,20] This has been attributed to T-cell–mediated and cytokine-mediated suppression. T-LGL leukemia cells constitutively express Fas ligand on their surface and also release significant quantities of soluble Fas ligand into plasma in vivo. Reduced myelopoiesis in T-LGL leukemia and some patients with Felty syndrome may be linked to apoptosis instigated by the binding of Fas ligand expressed on the abnormal cells to Fas expressed on the surface of myeloid precursors.[20] Whatever the precise mechanism, reductions in myelopoiesis appear to be a common element in patients with these forms of secondary immune neutropenia.

Diagnosis

Clinical Presentation

Isoimmune neutropenia presents at birth and may persist for up to 6 months. Patients may have severe infections. Self-limiting primary autoimmune neutropenia typically presents in early childhood, with a median time to resolution of 2 years. Patients rarely have severe infections, and the occurrence of severe infection should prompt evaluation for other causes of neutropenia, such as severe congenital neutropenia or cyclic neutropenia. In older children and adults, neutropenia is more commonly associated with other systemic autoimmune disease, especially rheumatoid arthritis and SLE or T-LGL leukemia. Drug-induced neutropenia must always be considered in patients taking medications.

Laboratory Findings

Blood counts typically demonstrate isolated neutropenia, sometimes with monocytosis. More generalized leukopenia, anemia, and/or thrombocytopenia suggest concurrent SLE or a primary bone marrow disorder, especially aplastic anemia or myelodysplasia.

Examination of the blood film for evidence of abnormalities in other cell lines or increased numbers of LGL is essential. The persistent presence of greater than 2000 LGL/mm^3 for 6 months in itself is diagnostic of T-LGL leukemia; however, normal LGL counts in blood do not preclude this diagnosis. Perhaps a quarter of patients with T-LGL leukemia and immune neutropenia have fewer than 500 monoclonal LGL/mm^3 in blood.[20] The evaluation of patients with small T-LGL clones detected in blood on flow cytometric or molecular testing without clear tissue infiltration remains problematic. At least some of these patients probably have self- limiting "T-cell gammopathies of unknown origin" unassociated with overt lymphoproliferation or autoimmunity.

Bone marrow findings in immune neutropenias (as briefly reviewed above) can vary substantially. Perhaps the most important function of the bone marrow examination is to rule out hypoplasia/aplasia, myelocathexis, marked megaloblastic dysplastic changes, or abnormal infiltration with nonhematopoietic cells, each of which might suggest an alternative diagnosis. The marrow examination may also be helpful in confirming T-LGL leukemia.

Detection of Antineutrophil Antibodies. Antibodies are assayed clinically using indirect assays (i.e., by measuring the binding of antibodies from patient sera to fixed granulocytes from unrelated individuals). The granulocyte immunofluorescence test (GIFT), which exploits flow cytometry for detection, is most commonly used because of its high sensitivity. The granulocyte agglutination test (GAT) is less sensitive but is particularly valuable used in conjunction with GIFT to detect antibodies against HNA-3a or HNA-1b. Once the presence of an antibody has been confirmed, a monoclonal antibody-specific immobilization of granulocytes assay (MAIGA) is a valuable technique in identifying the target molecule recognized by the antibody, information that may be very helpful in identifying antibody specificity and in distinguishing granulocyte-specific antibodies from alloantibodies directed against HLA determinants. More precise epitope typing still requires a panel of granulocytes of varied phenotype. Unfortunately, to date, granulocyte panels are both difficult to prepare and impossible to store. Consequently, antibody typing remains a laborious task. At the second international granulocyte serology workshop, 12 centers independently tested a series of unknown sera. Many laboratories could detect strong HNA-1a antibodies, but the success rate was much lower in defining HNA-1b or HNA-2a antibodies, and individual laboratories varied greatly in their proficiency.[28]

Clinical Use of Antineutrophil Antibody Studies. Because of the lack of both sensitivity and specificity of ANA assays, primary autoimmune neutropenia in young children with neutropenia remains a clinical diagnosis. Using GIFT or GAT assays, ANAs can be detected in more than 70% of children with primary immune neutropenia. When both are used in tandem, the yield increases further. A strong positive result strongly supports the diagnosis of immune neutropenia. However, a negative result does not exclude the diagnosis.[29]

Primary autoimmune neutropenia in adults is difficult to distinguish from the ill-defined entity chronic idiopathic neutropenia. Because there is no "gold standard" for distinguishing immune disease from nonimmune disease in this setting, the diagnostic sensitivity and specificity of the ANA assays are unclear. Assays are positive in perhaps a third of adults referred with chronic neutropenia, and a positive result in the absence of other systemic autoimmune disease certainly supports a diagnosis of immune neutropenia. A negative result does not preclude an immune etiology, but it is more consistent with chronic idiopathic neutropenia.

In patients with systemic autoimmune disease or T-LGL leukemia, hyperglobulinemia and circulating immune complexes greatly complicate laboratory evaluation. ANA assays are frequently positive, even in the absence of neutropenia. Since the specificity of a positive result is low, its diagnostic value is very limited, and the clinician must be vigilant for other possible causes, especially drug-induced neutropenia.

Therapy

Overview

All patients with neutrophil counts below 1000/mm^3 have some increased risk of infection, but some remain asymptomatic even with absolute neutrophil counts of 500/mm^3 or less. Growth factors can usually improve neutropenia and reduce the risk of infection, but given their expense, inconvenience, and possible side effects, they should be reserved for use in patients with a very low count or a previous pattern of frequent infection. The indications for immunosuppressants, steroids, and splenectomy are more complex.

THERAPEUTIC PRINCIPLES

Immune Neutropenia

- Palliative treatment of neutropenia is reserved for patients with a neutrophil count below 500/mm^3 or recurrent infection.
- Recombinant granulocyte colony-stimulating factor (G-CSF) is the most effective single agent for palliating neutropenia.
- Immunosuppressive agents, steroids, and splenectomy are reserved for patients with persistent or refractory neutropenia or with other detrimental manifestations of systemic autoimmunity.

Colony-Stimulating Factors

Controlled trials are lacking in this disease setting, but granulocyte colony-stimulating factor (G-CSF) or granulocyte–macrophage colony-stimulating factor (GM-CSF) usually enhances neutrophil counts in each of the clinical groups discussed. Because of their safety, speed, and efficacy, they have replaced steroids and splenectomy as first-line symptomatic therapy. They should be used at the lowest effective dose.

Infants with alloimmune neutropenia may develop severe infections, and in those cases, G-CSF is indicated until resolution of the neutropenia. Because patients with primary autoimmune neutropenia typically have a benign course, they rarely require growth factor support. For the rare patients who do develop severe infections, or in the perioperative setting, however, G-CSF may be indicated, starting at a dose of 1 to 2 mcg/kg/day.[30]

Immunosuppressive Agents

Because disease is usually self-limiting and responsive to G-CSF when necessary, immunosuppressive agents are not used in children with primary immune neutropenia. Pediatric patients with secondary immune neutropenia will typically also respond to G-CSF, although immunosuppressants may be indicated if they have multilineage cytopenias or other autoimmune phenomena. Chronic low-dose methotrexate is considered first-line therapy for patients with Felty syndrome or LGL leukemia–associated neutropenia. Cyclophosphamide and cyclosporine are considered second-line therapy for LGL leukemia, and purine analogues, splenectomy, and alemtuzumab are considered third-line therapy for LGL leukemia.

Other Therapy

Each of the following treatments can be effective in reversing neutropenia, but their use has diminished considerably in recent years. IVIG can temporarily reverse neutropenia, particularly in children, most likely by blocking Fc receptors responsible for triggering neutrophil destruction. However, G-CSF, which is more convenient to administer and at least as effective, has largely replaced IVIG.

Splenectomy and steroids can each reduce immune destruction by suppressing the body's capacity to clear IgG- and complement-coated cells. Over a longer time frame, these treatments can also suppress antibody production—in the first case by removing a major site of production and in the second by reducing ANA production and blocking T-cell–mediated myelosuppression. Steroid therapy can reverse neutropenia in many patients, but steroids' long-term impact on outcome remains unclear. Given their risks and side effects, both splenectomy and steroids are generally reserved for patients resistant to CSFs and low-dose immunosuppressants.

Prophylactic Antibiotics

Where recurrent infection is a problem, oral trimethoprim–sulfamethoxazole (TMP-SMX) is commonly used for prophylaxis, particularly in children. This approach is very reasonable, given its success in other immunocompromised groups, but it has not been tested in a controlled trial. Immunization with pneumococcal and meningococcal vaccines is also recommended in situations where therapeutic splenectomy has been used or is being planned.

IMMUNE-MEDIATED THROMBOCYTOPENIAS

Immune Thrombocytopenia

KEY CONCEPTS

Immune Thrombocytopenic Purpura

- Antibody-mediated destruction or decreased production of platelets
- Both B and T cells important in etiology
- Clearance of platelets mediated by Fcγ receptors
- Diagnosis depends on:
  - Clinical presentation of low platelets
  - Exclusion of other causes of thrombocytopenia

Immune thrombocytopenia (ITP) is an autoimmune syndrome involving antibody and cell-mediated destruction of platelets. ITP can occur in the absence of an identified predisposing factor (primary ITP) or in the setting of an underlying immunodeficiency, immune dysregulatory syndrome, or autoimmune disease, drug exposure, infection, or other identified cause (secondary ITP). Definitions from an international working group recommend that a platelet count of $<100 \times 10^9$/L be required for diagnosis.[31]

Pathogenesis

In 1951, Dr. William Harrington infused plasma from patients with chronic ITP into himself and other healthy volunteers, resulting in transient thrombocytopenia in most of them, implicating a plasma-derived factor, subsequently identified by Shulman as IgG, the causative agent.[32] In the majority of patients, the underlying defects leading to autoantibody production

remain unclear. In some patients, ITP follows exposure to viral or bacterial antigens. Molecular mimicry appears to play a role in the development of self-reactive platelet antibodies following infections. Human immunodeficiency virus (HIV), hepatitis C virus (HCV), and *Helicobacter pylori* infections have been associated with ITP. *H. pylori* CagA antigen appears to cross-react with platelet antigens,[33] which may explain the association with ITP and *H. pylori* infection in adults. The most common epitopes for platelet antibodies in ITP are the platelet GPIIb/IIa and GPIb-IX receptors.[34] The autoantibodies serve as opsonins, resulting in the clearance of platelets by FcγR-bearing cells in the reticuloendothelial system through Syk-mediated phagocytosis (Fig. 62.3).[35] Antibodies are identified in only a subset of patients with ITP, however, and other immune processes also contribute to the pathogenesis of platelet destruction.[36] There is upregulation of genes involved in cell-mediated cytotoxicity via $CD3^+CD8^+$ T lymphocytes,[37] with T-helper 1 (Th1)–associated cytokines predominating.[38] Regulatory T cells (Tregs) are decreased,[39] and B-cell activation is increased.[40] There is evidence of suppression of megakaryopoiesis by both T lymphocytes[41] and ITP plasma/IgG.[42] In addition, megakaryocyte and platelet production are dependent on thrombopoietin signaling through binding to the Mpl receptor, and patients with ITP have reduced thrombopoietin levels despite the presence of low platelet counts.[43]

Laboratory Diagnosis

Immune-mediated thrombocytopenia is a diagnosis of exclusion and is typified by isolated thrombocytopenia. The presence of abnormalities in other cell lines should prompt investigation for other etiologies, including marrow failure syndromes, myelodysplastic syndrome, or leukemia. Peripheral blood smear examination is important to evaluate for the presence of schistocytes, leukocyte adhesion bodies in MYH-9-related disease, small platelets in Wiskott-Aldrich syndrome, and giant platelets in inherited macrothrombocytopenias and to exclude ethylenediaminetetraacetic acid (EDTA)–dependent platelet agglutination.

The diagnosis of ITP may be made based upon history, physical exam, blood counts, and peripheral smear exam. Bone marrow aspirate, biopsy, flow cytometry, and cytogenetics should be considered in patients older than 60 years of age and in patients with systemic symptoms. The detection of *H. pylori* with the urea breath test or stool antigen tests should be considered in adults. Routine serologic evaluation for HIV and HCV is recommended in adults. Baseline Igs (IgG, IgA, IgM) should be measured in adults to diagnose such conditions as common variable immunodeficiency (CVID) and selective IgA deficiency (Chapter 33) in which ITP is a common complication. For children who go on to have chronic ITP, a broader immune evaluation, including quantitative immunoglobulins, should be investigated.[44]

Antiplatelet antibody testing to specific platelet glycoproteins is not routinely recommended; the test is neither sensitive nor specific for ITP. Routine testing for anticardiolipin antibodies is not recommended in the absence of symptoms of antiphospholipid syndrome. DAT should be obtained if hemolytic anemia is suspected and in patients for whom anti-D antiglobulin treatment is considered. Blood group Rh(D) typing should be obtained if anti-D antiglobulin treatment is considered.

Where a microangiopathic process is evident—especially with concomitant renal failure, fever, or cognitive impairment—measurement of ADAMTS13 (A Disintegrin-like And Metalloprotease with ThromboSpondin type 13 motifs) is warranted to rule out TTP.

Therapy

In pediatric patients, the decision to treat ITP is guided primarily by the presence or absence of bleeding symptoms. Most pediatric patients without bleeding may be safely managed with close observation, while in adult patients, in most circumstances, the goals of therapy are to keep the platelet count above 30×10^9/L and to minimize toxicity. In the absence of hemostatic comorbidity, trauma, or surgery, intracranial hemorrhage is rare in patients with a platelet count above 20×10^9/L. Treatment of ITP should be individualized, but first-line therapies include corticosteroids, IVIG, or anti-Rh(D) in Rh(D)-positive, nonsplenectomized patients. Intravascular hemolysis, disseminated intravascular coagulation, and renal failure have been reported with the use of anti-Rh(D). Anti-Rh(D) should be avoided in patients with underlying hemolysis or a positive result of the DAT that is not the result of prior therapy.[36,44,45]

In adult patients, second-line therapy should be considered if there is absence of a robust response at 3 months or once significant steroid-related toxicity supervenes. Second-line therapy should be considered in pediatric patients who do not respond to first-line therapies or who have chronic ITP. The thrombopoietin receptor agonists (TPO-RAs) avatrombopag, eltrombopag, and romiplostim have shown significant sustained activity in patients with ITP. Romiplostim is administered subcutaneously and avatrombopag and eltrombopag orally. Increased bone marrow reticulin fibrosis has been described in some patients receiving TPO-RAs, though this is typically reversible upon discontinuation. Two-thirds of patients obtain a durable long-term remission following splenectomy. Patients should receive immunizations with the pneumococcal, *Haemophilus influenzae* type b, and the quadrivalent meningococcal vaccines before splenectomy. A single course of rituximab (anti-CD20) (375 mg/m^2 weekly for 4 weeks) is associated with 40% complete remission at 1 year and 15% to 20% complete remission at 5 years. Patients who relapse after an initial response usually respond to a second course. Rituximab is contraindicated in patients with active hepatitis B. Cases of multifocal leukoencephalopathy have been reported in HIV-negative patients treated with rituximab. Fostamatinib is an oral spleen tyrosine kinase (Syk) inhibitor recently approved as a second-line agent for use in adults with ITP.[46]

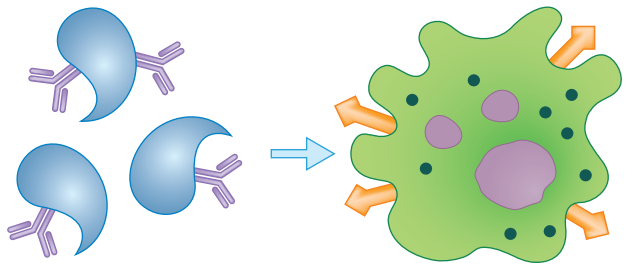

FIG. 62.3 Antibody-Bound Platelets Are Cleared From the Circulation by Binding of the Fc Domain of Immunoglobulin G (IgG) to FcγIIIA Receptors on Macrophages and Other Cells. The cross-linking of the macrophage receptors sets off a cascade of internal signaling that leads to increased expression of the inhibitory FcγIIB receptors (not shown).

A number of other therapies have been used with varying success in patients who are unresponsive to or ineligible for first- and second-line therapies. These agents include azathioprine, cyclophosphamide, cyclosporine, danazol, dapsone, mycophenolate mofetil, vinca alkaloids, and other immunosuppressants or combination therapies.

Drug-Induced Thrombocytopenia

Drug-induced thrombocytopenia (DITP) is an idiosyncratic immune-mediated reaction. The drug-dependent antibodies bind to specific epitopes on platelet surface glycoproteins only in the presence of the sensitizing drug. The drugs bind noncovalently and reversibly to platelets, commonly to GPIIb-IIIa and GPIb-V-IX, and also to the antibody. The Fab domains of the antibodies bind to the drug-platelet epitope. Drug-dependent antibodies inducing thrombocytopenia typically develop 1 to 2 weeks after exposure to a drug; exceptions to this rule include eptifibatide, tirofiban, and abciximab, as naturally occurring antibodies to these drugs can cause thrombocytopenia within a few hours of the first exposure. Thrombocytopenia with platelet counts frequently below 20×10^9/L develops acutely, recovery occurs 1 to 2 days after discontinuation of the drug and is usually complete after 1 week, but rarely thrombocytopenia persists for several weeks. Quinidine, quinine, rifampin, tegretol, TMP-SMX, vancomycin, danazol, acetaminophen, abciximab, eptifibatide, tirofiban, and gold salts are the most common culprits. Treatment consists of discontinuing the offending drug; platelet transfusions are sometimes necessary.[47]

Heparin-induced thrombocytopenia (HIT) is a special case that is caused by antibodies to platelet factor 4 (PF4)–heparin complexes. It can be associated with life-threatening thrombosis. The antibody-PF4-heparin complex activates platelets, resulting in a high risk of both arterial and venous thrombotic events. Thrombocytopenia occurs as a result of clearance of platelet aggregates induced by the antibody and usually appears 5 to 7 days after treatment with heparin (or low-molecular-weight heparin) unless a patient has been previously exposed to heparin. In the event of prior exposure, especially within the last 100 days, thrombocytopenia can occur within 1 day of heparin administration. Even small doses of heparin given as "flushes" to maintain intravenous catheter patency can be sufficient to cause HIT with thrombosis. Suspected HIT can be evaluated using the 4Ts clinical score (timing, degree of thrombocytopenia, presence of thrombosis, other etiologies for thrombocytopenia), an immunoassay, and a functional assay.[48] In cases of suspected HIT, all heparins should be stopped, and an alternative anticoagulant agent, such as the direct thrombin inhibitors argatroban or bivalirudin, should be used. Fondaparinux is an anticoagulant synthesized from the pentasaccharide core of the heparin molecule and may be another option for the treatment of HIT, since it binds to HIT antibodies but does not activate platelets and cause thrombosis. In cases of confirmed or strongly suspected HIT, anticoagulation should be continued at least until platelet recovery and for up to 3 months, because the risk of thrombosis persists in this group of patients. Direct oral anticoagulants that target thrombin or activated factor X or vitamin K antagonists may be used for long-term anticoagulation.

Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia (NAIT) is caused by maternal antibodies against the HPAs that the fetus carries but which the mother lacks (most commonly HPA-1a). NAIT caused by antihuman platelet antigen 1a (HPA-1a) antibodies occurs in 1 in 1250 pregnancies in the Caucasian population. Severe hemorrhage occurs in 1 in 12,500 to 1 in 25,000 pregnancies. NAIT is caused by maternal antibodies against paternally derived antigens on fetal platelets, most commonly HPA-1a. These antibodies cross the placenta and sensitize fetal HPA-1a–positive platelets, which are then removed in the spleen. Two percent of Caucasian women carry the less frequent HPA-1b and can be immunized against HPA-1a during pregnancy (25%) or at the time of delivery (75%). In most circumstances, first-time cases of NAIT are generally identified following the birth of a markedly thrombocytopenic neonate; antenatal management is, thus, only possible in subsequent pregnancies. There is risk of severe bleeding, including intracerebral hemorrhage in 10% to 20% of cases, which may occur in utero or postnatally, and it is very likely to recur if it has occurred in a previous pregnancy. Screening all pregnancies for NAIT is under evaluation in several countries. Antenatal management of NAIT consists of maternal administration of high doses of IVIG and corticosteroids.[49] NAIT may be diagnosed by parental platelet antigen typing and detection of alloantibodies in maternal serum that bind to specific paternal human platelet antigens not present on maternal platelets. Treatment of infants with NAIT includes transfusions with typed platelets if available, random-donor platelets, or administration of IVIG.[50]

AUTOIMMUNE MULTILINEAGE CYTOPENIAS

Some patients develop either simultaneous or sequential cytopenias of more than one cell lineage. Most frequently, this includes AIHA + ITP, but can also include AIN. This entity was described in 1949 by Evans and Duane[51] and has historically been referred to as Evans syndrome. The presence of multi-lineage cytopenias should prompt an evaluation for an underlying immunodeficiency or immune dysregulation syndrome. In a study of patients presenting in childhood, over half of patients with combined autoimmune cytopenias had evidence of secondary disease.[52] Autoimmune lymphoproliferative syndrome (ALPS) or ALPS-like disorder, combined immunodeficiency (CID), CVID, and other humoral defects were most common. A significant number also had non-hematologic manifestations of autoimmune disease.

The implications for treatment are salient as well, as targeted therapies may be warranted for treatment of immune cytopenias in specific underlying disorders. Sirolimus and mycophenolate mofetil are often effective for chronic control of cytopenias in ALPS. Costimulatory blockade with CTLA4-Ig may be used in patients with CTLA4 haploinsufficiency or LRBA deficiency, and interleukin-6 (IL-6) blockade or JAK inhibitors may be used in patients with gain-of-function mutations in the STAT pathway. As the genetic underpinnings of immune dysregulatory disorders are uncovered, it is likely that the therapies available to manage immune cytopenias in these settings will continue to evolve as well.

Bullous Diseases of the Skin and Mucous Membranes

Ralf J. Ludwig and Enno Schmidt

INTRODUCTION

Autoimmune blistering diseases (AIBDs) comprise a heterogeneous group of disorders that are characterized by autoantibodies deposited in the skin and adjacent mucous membranes. Autoantibody deposition leads to blisters and/or erosions in these tissues. AIBDs can be divided into two subgroups according to the anatomy of split formation. Pemphigus diseases demonstrate intraepidermal/epithelial splitting and pemphigoid disorders and dermatitis herpetiformis are characterized by subepidermal blistering.[1] This distinction dates back to 1953 when Walter Lever described intraepidermal split formation and loss of cell adherence between neighboring keratinocytes (acantholysis) as histopathological hallmarks of pemphigus, and subepidermal splitting disorders as *pemphigoid*.[2] In the 1960s, serum and skin-bound autoantibodies were described in pemphigus and pemphigoid diseases. In 1975, dermatitis herpetiformis was distinguished from the pemphigoid disease linear immunoglobulin A (IgA) dermatosis based on the pattern of IgA deposit in the skin.[1] Building on these observations, additional pemphigoid and pemphigus entities have been described, the target antigens of most AIBDs identified, and the pathogenic relevance of autoantibodies determined in various in vitro and mouse models.[3–5]

In this chapter, the target antigens, genetics, risk factors, comorbidities, and diagnosis of the three main pemphigus and six main pemphigoid diseases as well as dermatitis herpetiformis will be discussed. Photographs of these entities will be presented and approaches to management outlined. Characteristics of the rarer AIBD not detailed below are summarized in Table 63.1.

TARGET ANTIGENS AND DISEASE ENTITIES

Pemphigus Diseases

Pemphigus diseases comprise three major forms: pemphigus vulgaris, pemphigus foliaceus, and paraneoplastic pemphigus. Pemphigus vulgaris and pemphigus foliaceus account for more than 90% of pemphigus cases. Immunopathologically, pemphigus disorders are characterized by autoantibodies against structural proteins of the epidermal/epithelial desmosomes. Desmosomes are adherence structures that connect neighboring cells, including keratinocytes, to withstand mechanical forces. Desmoglein (Dsg) 1 and 3 are in integral parts of epidermal/epithelial desmosomes and have been identified as the major target antigens in pemphigus (Fig. 63.1).[6] Dsgs contain five extracellular domains (EC1 to EC5), a single transmembrane domain, and a cytoplasmic domain containing plakoglobin and plakophilin binding sites. The Dsg molecules are interconnected with each other via their N-terminal EC1 and EC2 domains, which are preferential targets of pemphigus autoantibodies.

Interestingly, in the great majority of pemphigus vulgaris and pemphigus foliaceus patients, the clinical phenotype is mirrored by the targeted Dsg molecule. While in pemphigus foliaceus, lesions are limited to the skin and the autoantibody response is restricted to DSG1, patients with the mucosal-dominant type of pemphigus vulgaris preferentially generate anti-DSG3 autoantibodies. In patients with the mucocutaneous type of pemphigus vulgaris. which presents with both mucosal and skin lesions, autoantibodies against both DSG1 and DSG3 are present. The remarkable relation of the autoantibody specificity and the clinical phenotype reflects the differences in the expression

TABLE 63.1 Characteristics of Very Rare Autoimmune Blistering Diseases

Disease	Main Target Antigen	Characteristics
Pemphigus Diseases		
Neonatal pemphigus	DSG3	Transient flaccid blisters and erosions of the newborn caused by the transplacental passage of anti-Dsg IgG from a mother with pemphigus
IgA pemphigus	DSC1, 2, 3, DSG1, 3	Also called intercellular IgA dermatosis; flaccid pustules; intercellular IgA staining of the epithelium by direct IF
Pemphigus herpetiformis	DSG1	Pruritic grouped vesicles, papules, and erythema; spared mucous membranes
Pemphigoid Diseases		
Lichen planus pemphigoides		Preceding and concomitant lichen planus; blisters and erosions independent of lichen planus lesions; treatment needs also to be directed against lichen planus that triggers the AIBD
Cicatricial pemphigoid	BP180 laminin 332	Mucous membranes not predominantly affected; lesions heal with scarring
Bullous systemic lupus erythematosus (SLE)	Type VII collagen	Preceding and concomitant SLE; blisters and erosions not restricted to LE lesions; typically in sun-exposed areas in woman with African background in the 3rd decade; rapid response to dapsone

AIBD, Autoimmune blistering disease; *BP180 NC16A*, extracellular part of the 16th non-collagenous domain of the 180 kDa bullous pemphigoid antigen; *Dsc*, desmocollin; *Dsg*, desmoglein; *IF*, immunofluorescence; *SLE*, systemic lupus erythematodes.
See references 1, 4, and 5.

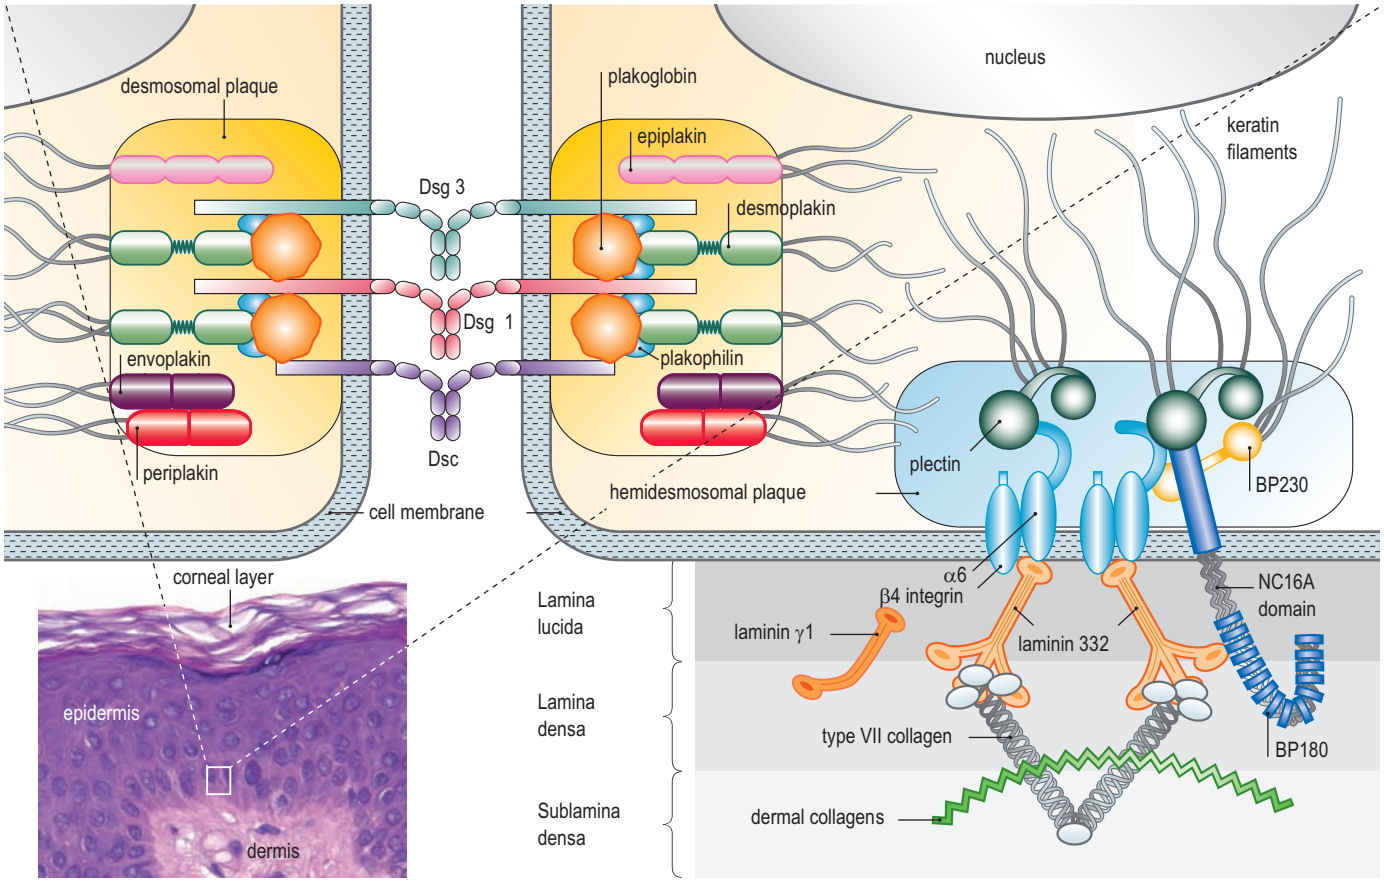

FIG. 63.1 Schematic diagram of the desmosome *(left)* and the dermal–epidermal junction (right). Only antigens that are targeted in autoimmune blistering diseases are shown. While only homophilic transinteractions between desmogleins *(Dsg)* and desmocollins *(Dsc)* are depicted, heterophilic interactions have also been described. Modified from Reference 31.

of the two Dsgs in the epidermis and surface-close mucosal epithelia. The Dsg compensation theory holds that when the adhesive property is compromised in one of them and they are expressed together in the same cell, the normal Dsg isoform can compensate for the other.[4,7]

In pemphigus vulgaris, in addition to antibodies against DSG1 and DSG3, reactivity against desmocollins (see Fig. 63.1), and various other molecules such as muscarinic and nicotinic acetylcholine receptors, pemphaxin, mitochondrial proteins, and thyroid peroxidase have been detected.[8,9]

In paraneoplastic pemphigus, autoantibodies mainly target DSG3 and the plakin proteins envoplakin and periplakin (see Fig. 63.1). In addition, autoantibodies against DSG1, desmocollins, the plakin proteins, desmoplakin I/II, plectin, epiplakin, and BP230 as well as the hemidesmosomal protein BP180 (type XVII collagen) and the 170 kDa proteinase inhibitor α_2-macroglobulin-like 1 have been reported with varying frequencies (see Fig. 63.1, Table 63.2).[4,10,11]

Pemphigoid Diseases and Dermatitis Herpetiformis

Six main pemphigoid diseases can be distinguished. In each, a target antigen has been identified on the molecular level, The autoantibodies recognize proteins at the dermal–epidermal junction (DEJ). The different diseases are distinguished by clinical appearance (e.g., mucous membrane pemphigoid [MMP] and pemphigoid gestationis), by the target antigens (e.g., anti-p200 pemphigoid and epidermolysis bullosa acquisita), and by the autoantibody isotype (e.g., linear immunoglobulin [IgA] disease). In bullous pemphigoid (BP), diagnosis is based on the combination of the three factors (see Table 63.2).

The DEJ, the cutaneous basement membrane zone of the skin (Chapter 24), connects the epidermis with the dermis. Four subregions can be distinguished by transmission electron microscopy: the basal cell plasma membranes of basal keratinocytes and the hemidesmosomal plaques, the lamina lucida, the lamina densa, and the sublamina densa. Hemidesmosomes are multiprotein focal adherens structures within the DEJ and contain the intracellular hemidesmosomal plaque and the anchoring filaments of the lamina lucida. Hemidesmosomes connect the intermediate filaments of the cytoskeleton of the basal keratinocyte with the dermal collagens via anchoring fibrils that mainly consist of type VII collagen (see Fig. 63.1).[12] Traditionally, pemphigoid diseases have been regarded as diseases with anti-hemidesmosomal antibodies, excluding epidermolysis bullosa acquisita, which is characterized by reactivity against type VII collagen. Here, we follow the more recent concept of pemphigoid disorders as diseases with autoantibodies against structural proteins of the DEJ, and thus include epidermolysis bullosa acquisita (see Table 63.2).[5]

A central molecule of the DEJ and main target antigen of different pemphigoid diseases is BP180, also termed BP antigen-2 and type XVII collagen. The 180 kDa BP180 is a transmembrane

TABLE 63.2 Autoantibody Specificities and Diagnostic Clues

Disease	Target Antigens	Diagnostic Clues
Pemphigus Diseases		
Pemphigus vulgaris	***DSG3***, *DSG1*	Mucosal lesions, positive Nikolsky sign, positive direct IF, serum antibodies against DSG3
Pemphigus foliaceus	***DSG1***	Crusted erosions, *no* mucosal lesions, positive Nikolsky sign, positive direct IF, serum antibodies against DSG1
Paraneoplastic pemphigus	***envoplakin***, **periplakin**, ***DSG3***, desmoplakin I/II, plectin, epiplakin, *BP230*, *BP180*, DSC1, 2, 3, *DSG1*, α_2-macroglobulin-like 1	Severe stomatitis, neoplasm, dyskeratosis and interface dermatitis, serum antibodies against plakins
Pemphigoid Diseases		
Bullous pemphigoid	BP180 ***NC16A***, *BP230*	Intense pruritus, tense blisters and erosions without predominant mucosal involvement, old age, serum IgG against BP180 NC6A; non-bullous variants may arise in up to 20% of patients
Mucous membrane pemphigoid	**BP180**, ***laminin 332***, *BP230*, laminin 311,[a] ($\alpha_6\beta_4$ integrin)[b]	predominant mucosal involvement
Pemphigoid gestationis	BP180 ***NC16A***, *BP230*	Pregnancy or postpartum period
Linear IgA disease	**LAD-1**, BP230 (IgA reactivity)	Tense blisters and erosions without predominant mucosal involvement; linear IgA staining at the DEJ without reactivity against type VII collagen; most frequent AIBD in children
Anti-p200 pemphigoid	p200 protein, laminin γ1	Tense blisters and erosions without predominant mucosal involvement, serum antibodies agaisnt the p200 protein
Epidermolysis bullosa acquisita	type VII ***collagen***	Mechanobullous and inflammatory variants; no predominant mucosal involvement, serum antibodies against type VII collagen, u-sertaed pattern by direct IF
Dermatitis herpetiformis	***transglutaminase 3***, *transglutaminase 2*	Intense pruritus, erythematous papules and vesicles; granular IgA deposits in dermal papillae by direct IF

[a]Laminin 311 shares the α_3 chain with laminin 332; antibodies against the β_1 and γ_1 chains have not been described.
[b]There is insufficient evidence for the recognition of $\alpha_6\beta_4$ integrin as target antigen in mucous membrane pemphigoid except for individual patients.
Main target antigens are indicated in **bold**. For target antigens in *italics*, commercial detection systems are available. Adopted from references 4 and 5.
AIBD, Autoimmune blistering disease; *DEJ*, dermal–epidermal junction; *Dsc*, desmocollin; *Dsg*, desmoglein; *IF*, immunofluorescence; *IgA*, immunoglobulin A; *LAD-1*, linear IgA disease antigen 1 (identified as soluble ectodomain of BP180).

glycoprotein of about 1500 amino acids that spans the lamina lucida before kinking back from the lamina densa into the lamina lucida (see Fig. 63.1).

In dermatitis herpetiformis, autoantibodies are directed against two enzymes, epidermal transglutaminase (TG3) and tissue type TG (TG2), with TG3 being the autoantigen.

KEY CONCEPTS

Target Antigens

- Most target antigens of AIBD have been described on the molecular level.
- The main target antigens of pemphigus are desmoglein 1 and 3 (DSG1 and 3).
- The main target antigens of pemphigoid diseases are BP180 (type XVII collagen), laminin 332, type XVII collagen, and an incompletely defined p200 protein.

EPIDEMIOLOGY

Incidence

The incidence of AIBD differs between populations. The most frequent AIBD in Central Europe and North America is BP. In central Europe and Scotland, the incidence of BP was calculated to be between 12 and 22 per million per year. A higher incidence of about 70 per million per year has been reported in the UK and Sweden. Moreover, in the UK, Germany, and France, the incidence of BP has at least doubled within the last 10 years, which may reflect the increasing age of the general population, the improved availability and quality of diagnostic assay, and the high association of BP with neurological and psychiatric diseases that have also been increasing.[5] The annual incidences of MMP and pemphigoid gestationis are approximately 2 per million and 1 per million, respectively. Linear IgA disease, anti-p200 pemphigoid, and epidermolysis bullosa acquisita are even rarer.

The incidence of pemphigus ranges from less than 1 per million per year in Switzerland and Finland to about 10 per million per year in Greece and Iran. The Jewish population has the highest incidence.[4] Pemphigus vulgaris arises three to five times more frequently than pemphigus foliaceus. In some rural areas of South America and North Africa much higher incidences of pemphigus foliaceus have been observed. During the 20th century, the prevalence of the so-called endemic pemphigus foliaceus reached 3% to 5% of the population in certain areas of South America, but more recently has considerably declined.[13]

Incidences of dermatitis herpetiformis are even more diverse in different populations. While extremely rare in individuals of Asian or African origin, the incidence in the UK and Scandinavia is 10 per million per year, with approximately 10% of patients with celiac diseases (Chapter 75) suffering from dermatitis herpetiformis. More recently, the incidence of dermatitis herpetiformis has decreased even though the incidence of celiac disease has increased. This may be explained by the increased awareness and use of screening tests for the latter disease leading to earlier treatment and thus reduced occurrence of dermatitis herpetiformis.[14]

Genetics

In contrast to pemphigoid diseases, a strong genetic susceptibility is seen with certain Human Leukocyte Antigen (HLA) class II

alleles (Chapter 5) in pemphigus and dermatitis herpetiformis.

*DRB1*04:02* and *DQB1*05:03* have been described as risk alleles for pemphigus vulgaris across several populations,[15] with the majority of pemphigus vulgaris patients expressing one of the two alleles. In pemphigus foliaceus, HLA DRB1*04 was the most frequently reported susceptibility allele.[4]

An additional four non-HLA genes have also been associated with pemphigus vulgaris: *DSG3* encoding for the pemphigus vulgaris autoantigen DSG3, *TAP2* encoding for an ATP-binding cassette transporter involved in antigen presentation (Chapter 6), *IL6* encoding for the pleiotropic cytokine interleukin-6 (IL-6) (Chapter 14), and *ST18* encoding a transcription factor involved in inflammation and apoptosis that is overexpressed in pemphigus vulgaris skin.[4,15]

In BP, only few genetic studies have been performed, reporting weak associations with *DQB1*03:01*, *DRB1*04:03*, and *DQA1*05:01*. A recent study from Germany found significant associations with *DQA1*05:05, DQA1*02:01*, and *DQB1*03:01*, as well as with the *ZNF385D* and *FGF14* genes that encode two transcription factors (unpublished). Susceptibility to MMP has been described with *DQB1*03:01*, *DRB*04*, and *DRB*11*, and with *GALC* encoding for the lysosomal enzyme β-galactocerebrosidase.[16] In linear IgA disease, associations with HLA *B8*, *Cw7*, *DR3*, *DR2*, and *TNF2* were found. In pemphigoid gestationis, there are associations with *DR3, DR4*, and the so-called C4 null allele. And in epidermolysis bullosa acquisita, there are associations with *DRB1*15:03*.[1]

Of all AIBD, dermatitis herpetiformis has the highest genetic association, with 5% to 10% of patients with first-degree relatives affected by celiac disease or dermatitis herpetiformis. In nearly all patients, either HLA-*DQ2* (combination of *DQA1*05:01* and *DQB1*02*) or *DQ8* (combination of *DQA1*03* and *DQB1*03:02*) can be found.[14]

Risk Factors

The high prevalence of pemphigus foliaceus in certain areas of South America and North Africa suggests the existence of specific triggering factors. In endemic pemphigus foliaceus, the salivary protein LJM11 of the sand fly *Lutzomyia longipalpis* was found to be cross-reactive with DSG1.[17] In non-endemic pemphigus, drugs such as penicillamine and captopril, exposure to pesticides, metal vapor, ultraviolet light, ionizing radiation, burns, surgery, and stressful life events are risk factors for pemphigus.[4]

In BP, a strong association with the use of the oral anti-diabetics dipeptidyl-peptidase IV inhibitors, in particular with vildagliptin, is observed.[18,19] The association with spironolactone and phenothiazines with aliphatic side chains is less pronounced. Not unsurprisingly, BP has developed in patients receiving immune checkpoint inhibitors. Trauma, burns, radiotherapy, UV radiation, and vaccination have also been associated with disease onset.[5] Linear IgA disease and epidermolysis bullosa acquisita can also be triggered by drugs, most frequently vancomycin and penicillins.[1]

Comorbidities

Pemphigus vulgaris and pemphigus foliaceus are associated with a variety of diseases. These include autoimmune disorders (e.g., autoimmune thyroid diseases and rheumatoid arthritis), neurological disorders, psoriasis, and hematological and solid malignancies.[4]

A strong association in BP is seen with neurological or psychiatric diseases. Indeed, between a third and half of all BP patients suffer from latter disorders, which include major cognitive impairment, Parkinson disease, stroke, epilepsy, and multiple sclerosis.[20] These findings are particularly intriguing since in the great majority of patients the neurological disease precedes BP and both target antigens, BP180 and BP230, are expressed in the central nervous system. This suggests that CNS diseases may trigger the skin manifestations.[5,20] Furthermore, an association has been shown between hematological malignancies and BP and, to a lesser extent, epidermolysis bullosa acquisita.[21] Concomitant Crohn disease has been reported in 10% to 20% of AIBD patients.[1] Psoriasis occurs in about a third of Japanese patients with anti-p200 pemphigoid.[22] Of note, about 25% of anti-laminin 332-reactive MMP patients develop a solid malignancy. Thus MMP warrants a throughout tumor search. Since laminin 332 is overexpressed in many solid tumors and involved in tumor spreading one may hypothesize that the tumor can trigger the AIBD.[1]

Mortality

Before the introduction of corticosteroids in the early 1950s, mortality in pemphigus vulgaris and pemphigus foliaceus was about 75%. At present, the risk of death is about two- to threefold higher than control populations. Infections, in particular pneumonia and septicemia, are the most frequent causes of death, followed by cardiovascular diseases and peptic ulcer disease. In paraneoplastic pemphigus, the 5 years mortality is two to three times higher than pemphigus vulgaris.[4] In BP, the 1-year mortality rate of between 15% and 40% is two- to threefold higher than age- and sex-matched controls and ranges.[5]

KEY CONCEPTS

Epidemiology

- Bullous pemphigoid is the most frequent AIBD.
- The incidence of bullous pemphigoid has increased fourfold over the last 20 years.
- Pemphigus and bullous pemphigoid are associated with other autoimmune disease and hematological malignancies (in pemphigus) and with neurological diseases (in bullous pemphigoid). Pemphigus vulgaris and dermatitis herpetiformis have a strong genetic background, with associations to *DRB1*04:02* and *DQB1*05*:03 in the former and HLA-*DQ2* and *DQ8* in the latter disease.

CLINICAL PRESENTATIONS

Clinical presentations may vary considerably between the different AIBDs and even between patients with the same disease. The unifying clinical hallmarks are blisters and/or erosions on the skin and/or surface-close epithelia. In some patients, in particular with BP, pemphigoid gestationis, and dermatitis herpetiformis, blisters and erosions can be absent and pruritic papules, urticarial erythema, and eczematous lesions prevail. The sex distribution is roughly equal in all AIBD with the obvious exception of pemphigoid gestations.[1,4,5] Children are rarely affected.[23] In-depth descriptions of the broad range of clinical pictures can be found in standard dermatological textbooks.[1,23,24]

Pemphigus

Pemphigus Vulgaris

The oral cavity, which shows enanthema, erosions, and ulcers (Fig. 63.2, A), is the main affected site in pemphigus vulgaris.

FIG. 63.2 Pemphigus Vulgaris. Erosions and a deep ulcer on the oral mucosa (A). Erosions and partly crusted erythematous plaques on the back and arms (B).

Nearly all patients will develop oral lesions. Pain is highly variable between patients. It ranges from minor to severe discomfort and may prevent food intake and thus be accompanied by rapid weight loss. All surface-close mucosal tissues may become involved. This includes the nose (e.g., hemorrhagic crusts), pharynx, larynx (e.g., hoarseness), urethra, glans penis, vulva, cervix, and the perianal region. In the mucocutaneous variant of pemphigus vulgaris, which occurs in about half of the patients, skin lesions arise in parallel with mucosal lesions. Skin lesions begin as flaccid blisters, erosions, and crusts (see Fig. 63.2, B). Subsequently, large areas may denude. Both mucosal and skin lesions heal without scarring. However, in patients with darker skin, hyperpigmentation of affected skin areas may be visible for many months.[1,4,24]

Pemphigus Foliaceus

In pemphigus foliaceus, mucosal surfaces are spared and lesions are restricted to the skin. They may present as erythema, "puff pastry–like" scales, and crusts, preferentially arising on the face, scalp, and seborrheic areas of the upper trunk (Fig. 63.3). Intact blisters are rare, due to the superficial splitting directly below the stratum corneum, which leads to rapid destruction of the blister roof upon mechanical stress.[1,4,24]

Paraneoplastic Pemphigus

The clinical picture is polymorphous with flaccid blisters, pustules, tense blisters as in BP, erythema multiforme–like erythema, and lichenoid lesions.[3,4,25] A severe stomatitis is nearly always present. Genital, nasal, and ocular mucosal tissues can also be affected. In almost all patients, a neoplasm is present at the time of diagnosis. It can be found by an extensive tumor search, or arise within the following months. Lymphoproliferative disorders can be detected in 70% to 80% of European patients. Others include thymoma, malignant solid tumors, and Castleman tumor. The latter tumor is the most frequent associated neoplasm in Asia. Bronchiolitis obliterans, explained by the ectopic expression of DSG3 in the lung, was found in 6% of European patients and 20% of Japanese patients.[4]

FIG. 63.3 Pemphigus Foliaceus. Widespread erythema, erosions, and "puff pastry–like" scaling on the back.

Pemphigoid Diseases

Bullous Pemphigoid

BP is a disease of the elderly, with a mean age at disease onset of 75 to 80 years. Nearly all patients with BP suffer from intense pruritus. In the classical bullous form, widespread tense blisters of variable sizes, erosions, and crusts appear on apparently normal or erythematous skin (Fig. 63.4, A). Urticarial erythematosus plaques may also develop (see Fig. 63.4, B). The flexural aspects of the limbs and abdomen are most commonly affected. Oral lesions can be found in 10% to 20% of cases. In the absence of severe superinfection, lesions heal without scarring. In a majority of patients, a non-bullous prodromal phase is seen with intense pruritus and unspecific erythematous lesions.[1,5,26] About 20% of patients present with non-bullous BP, including a large variety of clinical variants.[1,5,27] In some patients, the disease is limited to certain body parts, especially the pretibial area. Non-bullous or localized forms may remain as such or develop into classical BP.

Mucous Membrane Pemphigoid

MMP affects the oral cavity in 85% of patients (Fig. 63.5, A) followed by conjunctivae (65%), skin (25% to 30%), nasal mucosa (20% to 40%) (see Fig. 63.5, B), ano-genital area (20%), pharynx (20%), larynx (5% to 10%), and esophagus (5% to 15%). Except the oral cavity, lesions at all affected body sites tend to heal with scarring. Nasal lesions may present as hemorrhagic crusts and epistaxis, pharyngeal lesions are painful on swallowing, and the initial involvement of the larynx manifests as hoarseness. Esophageal disease may become symptomatic with dysphagia and heartburn. Ocular lesions usually start unilaterally with burning and foreign-body sensation. They may proceed to shortening of the inferior fornix, symblepharon, trichiasis, neovascularization, and, finally, blindness (see Fig. 63.5, C). In patients with only one affected mucosal site, terms related to location are applied (e.g., oral, ocular, or vulvar MMP). A thorough tumor search is required in patients with anti-laminin 332 MMP, since about 25% of patients develop a solid cancer.[1,5,26,26a,65]

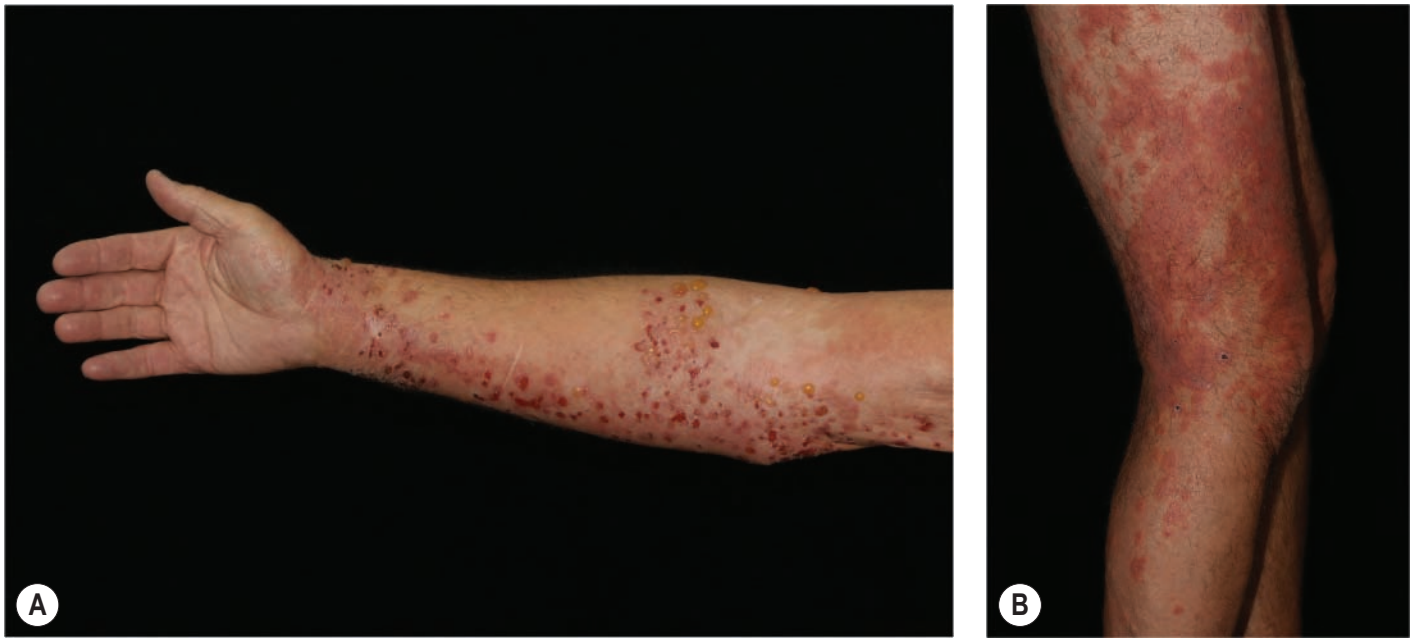

FIG. 63.4 Bullous Pemphigoid. Tense blisters and vesicles, erythematous plaques, and erythema on the right arm in the classical variant of bullous pemphigoid (A). Erythematous plaques, erythema, and a single vesicle on the right leg (B).

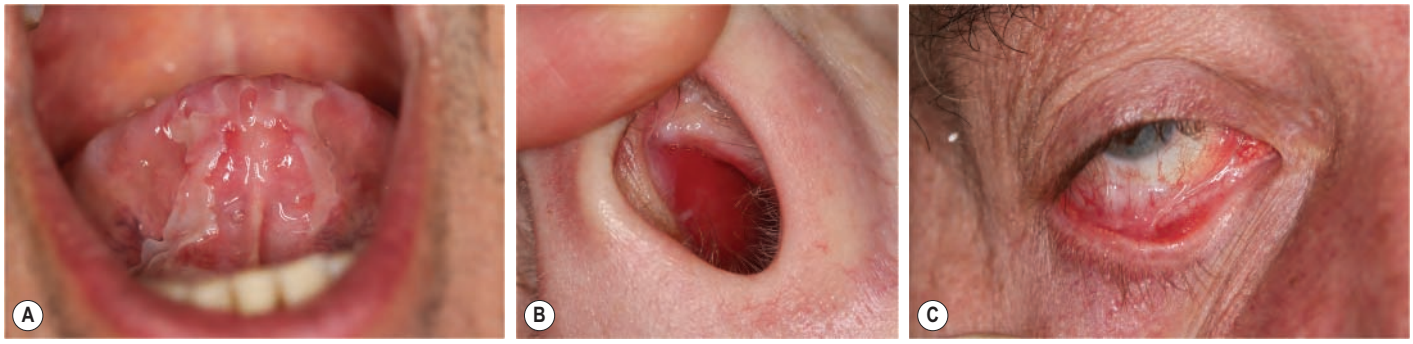

FIG. 63.5 Mucous Membrane Pemphigoid. Fibrin-covered erosions on the tongue (A), erosion on the nasal mucosa (B), conjunctival injections, shortening of the lower fornix, and symblepharon of the right eye (C).

Linear Immunoglobulin A Disease

Tense blisters, vesicles, urticated plaques, erosions, and erythema are the clinical hallmarks of linear IgA disease, or dermatosis. The clinical picture is virtually indistinguishable from BP and anti-p200 pemphigoid. However, blisters and vesicles tend to arise in an annular pattern in linear IgA disease, with blistering along the edge of lesions forming the so-called "string of pearls" or "cluster of jewels" sign. This sign is not exclusive to linear IgA disease. While the individual lesion does not differ between adults and children, in children lesions arise more abruptly and tend to involve the perioral area and perineum in addition to the other predilection sites, trunk and limbs. Mucosal lesions, mostly oral, nasal, and genital, occur in about 70% of patients. In patients with ocular scarring, the diagnosis of MMP is appropriate.[1,5,28]

Pemphigoid Gestationis

Frank blistering is rare. Erythematous papules, urticarial erythema, and papulovesicles predominantly develop on the periumbilical area in the second and third trimester as well as post partum. As in BP, intense pruritus is nearly always present. Disease onset in the first or second trimester. Blisters are associated with adverse pregnancy outcomes.[29]

Anti-p200 Pemphigoid

Most patients present with tense blisters on erythematosus or normal skin resembling BP (Fig. 63.6). Hands and feet appear to be favored, and oral and/or genital lesions may be present. Lesions usually heal without scarring.[22]

Epidermolysis Bullosa Acquisita

Two main clinical forms have been described: the classical mechanobullous variant in about a third of patients, and the inflammatory form (Fig. 63.7). In the classical mechanobullous variant, skin fragility, erosions, blisters, crusts, and scars on trauma-prone areas arise, and scarring alopecia, nail loss, and milia formation may occur. The inflammatory variant resembles other pemphigoid diseases such as BP, MMP, and linear IgA disease, and may arise together in the same patient.[1,5,26,30]

FIG. 63.6 Anti-p200 Pemphigoid. Tense blisters on the left foot and erythema, as well as erythematous plaques and papules on both legs.

Dermatitis Herpetiformis

Pruritic vesicles, erosions, and erythematous papules arranged in a grouped, so-called herpetiform pattern, are the clinical hallmarks of dermatitis herpetiformis (Fig. 63.8). Lesions tend to be symmetrical, predominantly affecting the extensor sites, in particular the nates, and heal without scarring. Some patients develop punctate purpura on the palms and soles.[28]

FIG. 63.7 Epidermolysis Bullosa Acquisita. Erosions, crusts, and erythema on the head, neck, and upper back in a patient with the inflammatory variant.

FIG. 63.8 Dermatitis Herpetiformis. Erythematous, partly excoriated or crusted papules and rare vesicles on the elbows.

KEY CONCEPTS

Clinical Presentation

- In pemphigus vulgaris, erosions arise on surface-close mucosal tissue. The oral cavity is nearly always affected and about half of the patients develop additional skin lesions.
- Lesions in pemphigus foliaceus are restricted to the skin.
- Pemphigoid diseases present with tense blisters and erosions and cannot be differentiated from each other based on the clinical picture alone.
- Bullous pemphigoid is a disease of the elderly with a mean age at disease onset of 75–80 years.
- In mucous membrane pemphigoid, mucosal lesions predominate.
- Patients with dermatitis herpetiformis rarely show frank blistering but extensively pruritic erythematosus papules and erosions.

DIAGNOSIS

Some clinical signs are typical of specific immunobullous diseases. For example, old age, tense blisters, and severe pruritus characterize BP, and flaccid blisters and a positive Nikolsky sign (induction of erosion by mechanical friction) characterize pemphigus vulgaris. Nevertheless, an AIBD cannot be diagnosed by clinical signs alone and requires the detection of tissue-bound and circulating autoantibodies.[4,5,31]

The diagnostic gold standard is the detection of tissue-bound autoantibodies by direct immunofluorescence (IF) microscopy of a perilesional biopsy. In pemphigus diseases, intercellular deposits of IgG and/or C3 (IgA in IgA pemphigus) are seen between neighboring keratinocytes/epithelial cells (Fig. 63.9). In pemphigoid disorders, direct IF reveals linear staining of IgG, IgA, and/or C3 at the DEJ. Within the linear staining, two patterns can be distinguished: a n-serrated pattern with arches closed at the top and a u-serrated pattern with arches closed at the bottom (Fig. 63.10). While a u-serrated pattern is restricted to an autoimmune reaction to type VII collagen (e.g., epidermolysis bullosa acquisita and bullous systemic lupus erythematosus), all other pemphigoid diseases show a n-serration pattern.[32] In dermatitis herpetiformis, granular deposits of IgA are seen in the dermal papillae (Fig. 63.11) and sometimes along the DEJ.

With the discovery of the molecular identity of most AIBD target antigens (see Tables 63.1 and 63.2) and advances in assays for detecting serum autoantibodies, most AIBD patients can be diagnosed by serology alone.

The most sensitive screening substrate for pemphigus antibodies is monkey esophagus (Fig. 63.12) and for pemphigoid diseases, human salt-split skin (Fig. 63.13). In the latter substrate, an artificial split within the lamina lucida of the DEJ is generated by incubation of normal human skin with 1 M NaCl solution. In this substrate, and depending on the target antigen, autoantibodies label the epidermal or dermal side of the artificial split (see Fig. 63.13). Standardized enzyme-linked immunosorbent assay (ELISA) systems detect antibodies against major AIBD target antigens. DSG1, DSG3, BP180, BP230, type VII collagen, and envoplakin are widely available and allow both the diagnosis and monitoring of serum autoantibody levels during the course of the disease (see Table 63.2).

Alternatively, a CE-certified multivariant indirect IF test that is based on Biochip technology can be applied. Here, various tissue substrates are placed as 1×1 mm miniature substrates, so-called biochips, in one incubation field on a routine laboratory slide (Fig. 63.14). This method allows the

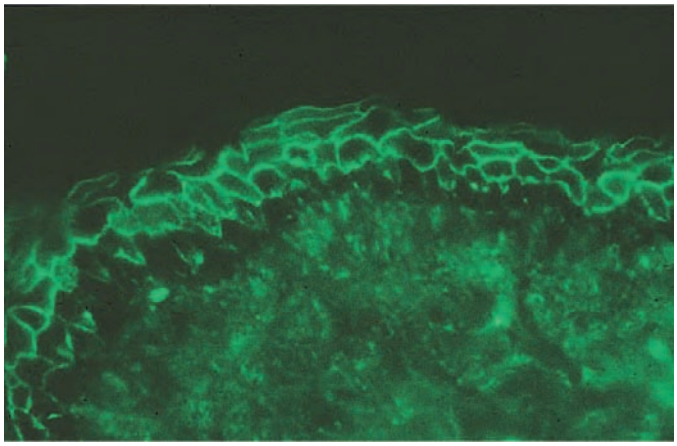

FIG. 63.9 Direct Immunofluorescence Microscopy in Pemphigus. A perilesional biopsy from a patient with pemphigus foliaceus shows intercellular deposits of immunoglobulin G in the epidermis in the typical rete-like pattern. A similar pattern is seen in pemphigus vulgaris.

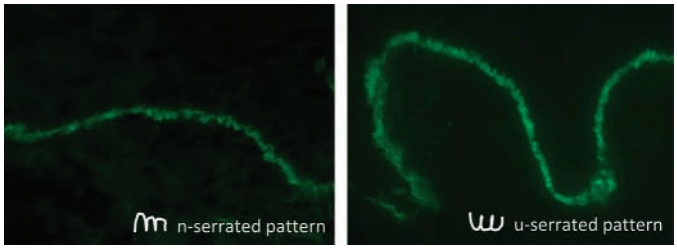

FIG. 63.10 Direct Immunofluorescence Microscopy in Pemphigoid Diseases. In perilesional biopsies, linear deposits of immunoglobulin G at the dermal–epidermal junction. In autoimmunity against type VII collagen (i.e., epidermolysis bullosa acquisita and systemic lupus erythematosus), a u-serrated pattern is seen with arches open at the top *(right)*. In all other pemphigoid diseases, an n-serrated pattern is observed with arches closed at the top *(left)*.

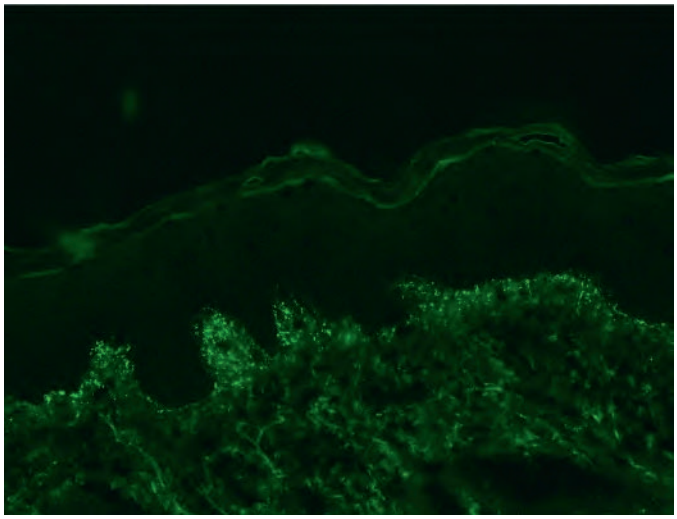

FIG. 63.11 Direct Immunofluorescence Microscopy in Dermatitis Herpetiformis. A perilesional biopsy reveals granular deposits of immunoglobulin A in the dermal papillae and along the dermal–epidermal junction.

simultaneous incubation of multiple miniature substrates and a standardized and rapid serological diagnosis of the major AIBD.[31] Substrates include monkey esophagus, salt-split skin, and rat bladder, recombinant BP180 NC16A, and human cells expressing recombinant forms of AIBD target antigens such as DSG1, DSG3, BP230, type VII collagen, and laminin 332. Detection of serum IgG antibodies against the BP180 ectodomain (in MMP), the p200 protein, and laminin γ1, as well as against IgA autoantibodies in pemphigoid and pemphigus diseases, are still restricted to specialized laboratories.

Traditionally, lesional histopathology has been the third diagnostic column for AIBDs. Histopathology allowed differentiation between subepidermal AIBD (pemphigoid and dermatitis herpetiformis) and pemphigus disorders.[2] Since histopathology cannot separate the different pemphigoid diseases, its diagnostic impact has been largely replaced by direct IF and serology. However, a lesional biopsy is still recommended in any patients with suspected AIBD in order to allow consideration of differential (alternative) diagnoses when direct IF and serology are negative or inconclusive. Differential diagnoses of AIBDs are detailed in the respective textbooks.[1,24,26,28]

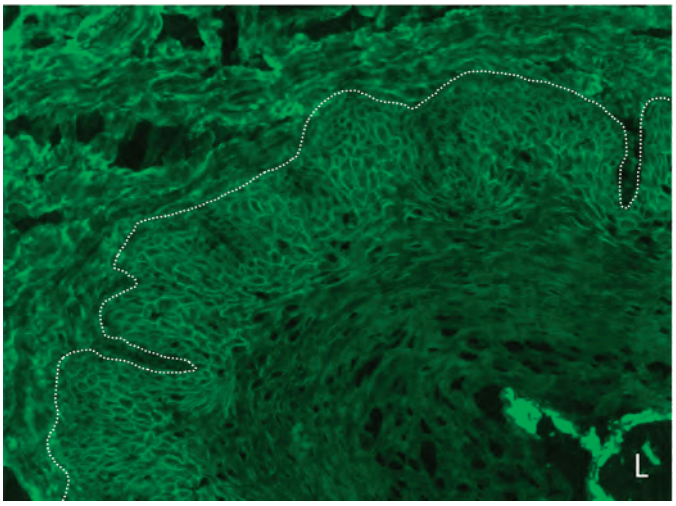

FIG. 63.12 Intercelluar staining of immunoglobulin G in the epithelium of monkey esophagus by indirect immunofluorescence microscopy of pemphigus serum. The basement membrane zone is indicated by a *dotted line*. *L*, Lumen of the esophagus.

KEY CONCEPTS

Diagnosis

- Direct IF microscopy of a perilesional biopsy remains the diagnostic gold standard of AIBD.
- Standardized, highly sensitive and specific ELISA systems and indirect IF assays based on recombinant forms of the major target antigens are widely available for most AIBD.
- At present, about 90% of AIBD can be diagnosed based on the clinical picture and serology.

PATHOPHYSIOLOGY

Pemphigus

In genetically susceptible individuals, the autoimmune reaction in pemphigus[3,4,6,33,34] is driven by autoreactive T and B lymphocytes. Autoreactive T cells are educated by antigen-presenting cells that present specific Dsg peptides via their HLA class II molecules encoded by the HLA class II risk haplotypes described above (Chapters 6 and 9). These Dsg-specific CD4 and IL-10-producing autoreactive T lymphocytes then drive the generation of Dsg-specific antibodies by B cells.[3,33]

The impact of autoantibodies against DSG1 and DSG3 in the pathogenesis of pemphigus is derived from several clinical and experimental observations (Fig. 63.15): (i) the transplacental transfer of maternal autoantibodies from mothers suffering from pemphigus can cause transient blistering in newborns, (ii) in nearly all patients with pemphigus foliaceus, and in the majority of pemphigus vulgaris patients, anti-Dsg IgG serum levels closely correlate with the extent of lesions, (iii) when cultured keratinocytes are treated with IgG from pemphigus patients or anti-Dsg3 IgG, degradation of the desmosomes is observed, (iv) incubation of sheets of cultured keratinocyte with pemphigus IgG leads to fragmentation of sheets mimicking acantholysis, (v) mice injected with pemphigus serum or anti-Dsg IgG develop intraepidermal splitting and macroscopic blistering,[35] (vi) blistering in mice is prevented after injection with pemphigus IgG depleted from anti-Dsg1/Dsg3 IgG, (vii) co-application of pemphigus IgG with a peptide that mediates Dsg3 crosslinking does not result in blistering of mice, and (viii) anti-Dsg3 IgG is induced leading to microscopic and macroscopic blistering in immunodeficient mice after adoptive transfer of lymphocytes from Dsg3-deficient mice that had been immunized with recombinant murine Dsg.[3,4,36]

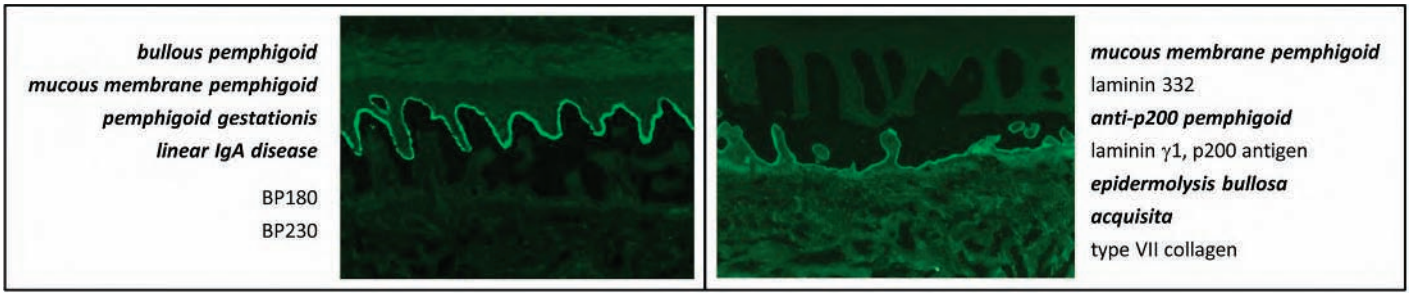

FIG. 63.13 Indirect Immunofluorescence Microscopy on Normal Human Salt-Split Skin. Serum autoantibodies against BP180 and BP230 in bullous pemphigoid, mucous membrane pemphigoid, pemphigoid gestationis, and linear immunoglobulin A (*IgA*) disease label the roof of the artificial split, while autoantibodies against laminin 332, the p200 antigen, and type VII collagen in mucous membrane pemphigoid, anti-p200 pemphigoid, and epidermolysis bullosa acquisita bind along the blister floor.

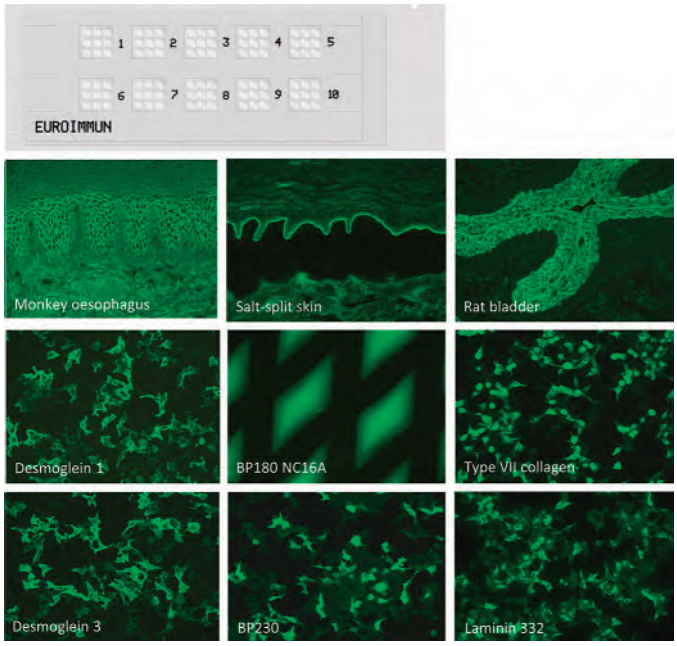

FIG. 63.14 Multivariant Indirect Immunofluorescence Microscopy Based on the Biochip Technology. Miniature substrates placed in an incubation field of a standard-sized laboratory slide allow the simultaneous detection of serum auto-antibodies with different specificities. Here, positive reactivities against monkey esophagus (intercellular epithelial staining in pemphigus), normal salt-split skin (epidermal staining in bullous pemphigoid), rat bladder (urothelium staining in paraneoplastic pemphigus), the human cell line HEK293 expressing recombinant desmoglein 1, desmoglein 3 (in pemphigus), type VII collagen (in epidermolysis bullosa acquisita), BP230 (in bullous pemphigoid), and laminin 332 (in mucous membrane pemphigoid) on the cells surface, respectively, as well as recombinant BP180 NC16A (in bullous pemphigoid) are compiled. (Courtesy of Euroimmun, Lübeck, Germany.)

However, not all anti-Dsg antibodies are pathogenic. This may explain the observation that serum anti-DSG3 levels in some pemphigus vulgaris patients do not correlate with disease activity and that lesions may persist when patients are in remission.[8] Pathogenic epitopes on DSG1 and DSG3 are Ca^{2+}- and conformationally dependent. They are mainly clustered in the EC1 and EC2 domain but can be found on the entire Dsg ectodomains. Interestingly, while the majority of pemphigus vulgaris patients with an initial mucosal variant and exclusive anti-DSG3 autoimmunity will eventually develop additional antibodies against DSG1 and skin lesions, epitope spreading within the Dsg molecules is rarely seen during the course of the disease.[3,4]

In pemphigoid diseases, a cascade of events including complement activation and Fc-receptor-mediated effects are pivotal for autoantibody-induced subepidermal blister formation (see below).[5] Monovalent fragments of anti-Dsg antibodies that lack the Fc portion can also cause acantholysis in vitro and in vivo.[4] The exact sequence of events in anti-Dsg antibody-mediated acantholysis has not yet been fully clarified. Three major mechanisms leading to acantholysis upon binding of anti-Dsg IgG have been identified: (i) direct interference with Dsg transinteraction, a phenomenon termed steric hindrance, (ii) remodeling of Dsg expression on the cell surface leading to internalization and depletion of Dsg from the cell membrane, and (iii) signaling events within the targeted keratinocytes.[3,4] The latter include activation of the p38 mitogen-activated protein kinase (MAPK), epidermal growth factor receptor, RHO GTPases, MYC, and caspases that interfere with the cytoskeletal architecture.[3,33,34,37] While these three mechanisms are sufficient for anti-Dsg IgG-mediated acantholysis, additional events mediated by soluble Fas ligand and non-desmoglein antibodies may also contribute to the pemphigus phenotype at later stages of the disease.[4]

The potential pathogenic role of non-desmoglein antibodies is exemplified by the finding of severe erosions and suprabasal splitting in mice deficient in epidermal Dsc1 as well as the pathogenic effects of anti-Dsc3 IgG in vitro and in a recent mouse model.[38] The contribution of antibodies against non-desmosomal antigens to the pathophysiology of pemphigus is suggested by the correlation of serum levels of anti-muscarinic acetylcholine receptor IgG with disease severity, and the co-pathogenic effect of antimitochondrial antibodies in addition to anti-Dsg IgG in vitro.[4,39]

KEY CONCEPTS

Pathophysiology of Pemphigus

- Anti-Dsg antibodies can induce acantholysis in vitro and in vivo independent of Fc-fragment-mediated mechanisms.
- Steric hindrance, remodeling of Dsg expression, and signal-transducing events are the three main pathogenic mechanisms leading to acantholysis after the binding of pemphigus autoantibodies. The in vivo relevance of non-desmoglein autoantibodies in the pathophysiology of pemphigus awaits further clarification.

Pemphigoid Diseases

The pathogenesis of pemphigoid diseases can be divided into three distinct steps (Fig. 63.16): (1) Loss of tolerance to pemphigoid disease autoantigens and production of autoantibodies, (2) circulation of autoantibodies, and (3) autoantibody-mediated tissue pathology. Insights into these steps has been obtained from genetic studies and the use of pemphigoid disease model systems.[40]

Loss of Tolerance to Pemphigoid Disease Autoantigens and Production of Autoantibodies

Loss of tolerance and production of pemphigoid disease–specific autoantibodies is associated with genes located within and outside the Major Histocompatibility Complex (MHC)/HLA-locus. In most pemphigoid disease, an association with certain HLA loci has been described.[41] Immunization-induced pemphigoid in mice also shows a strong association with the MHC region as well as outside the MHC.[41] The metagenome also has a significant impact on the generation of the autoantibody response in pemphigoid disease. In BP patients, the skin microbiome (Chapter 23) is distinct from that of healthy controls.[42] This difference is of functional relevance, at least in mice, as a low diversity of the skin microbiome prior to induction of experimental pemphigoid disease by immunization is associated with a high risk of developing skin lesions, while a high diversity of the skin microbiome confers protection from clinical disease manifestations.[43]

Regarding the cellular requirements that lead to the loss of tolerance to pemphigoid disease antigens and autoantibody production (see Fig. 63.16, A), data from experimental murine pemphigoid disease identified B cells, dendritic cells, and macrophages as key antigen-presenting cells that induce the CD4 T cell-dependent autoantibody production of B cells. Interestingly,

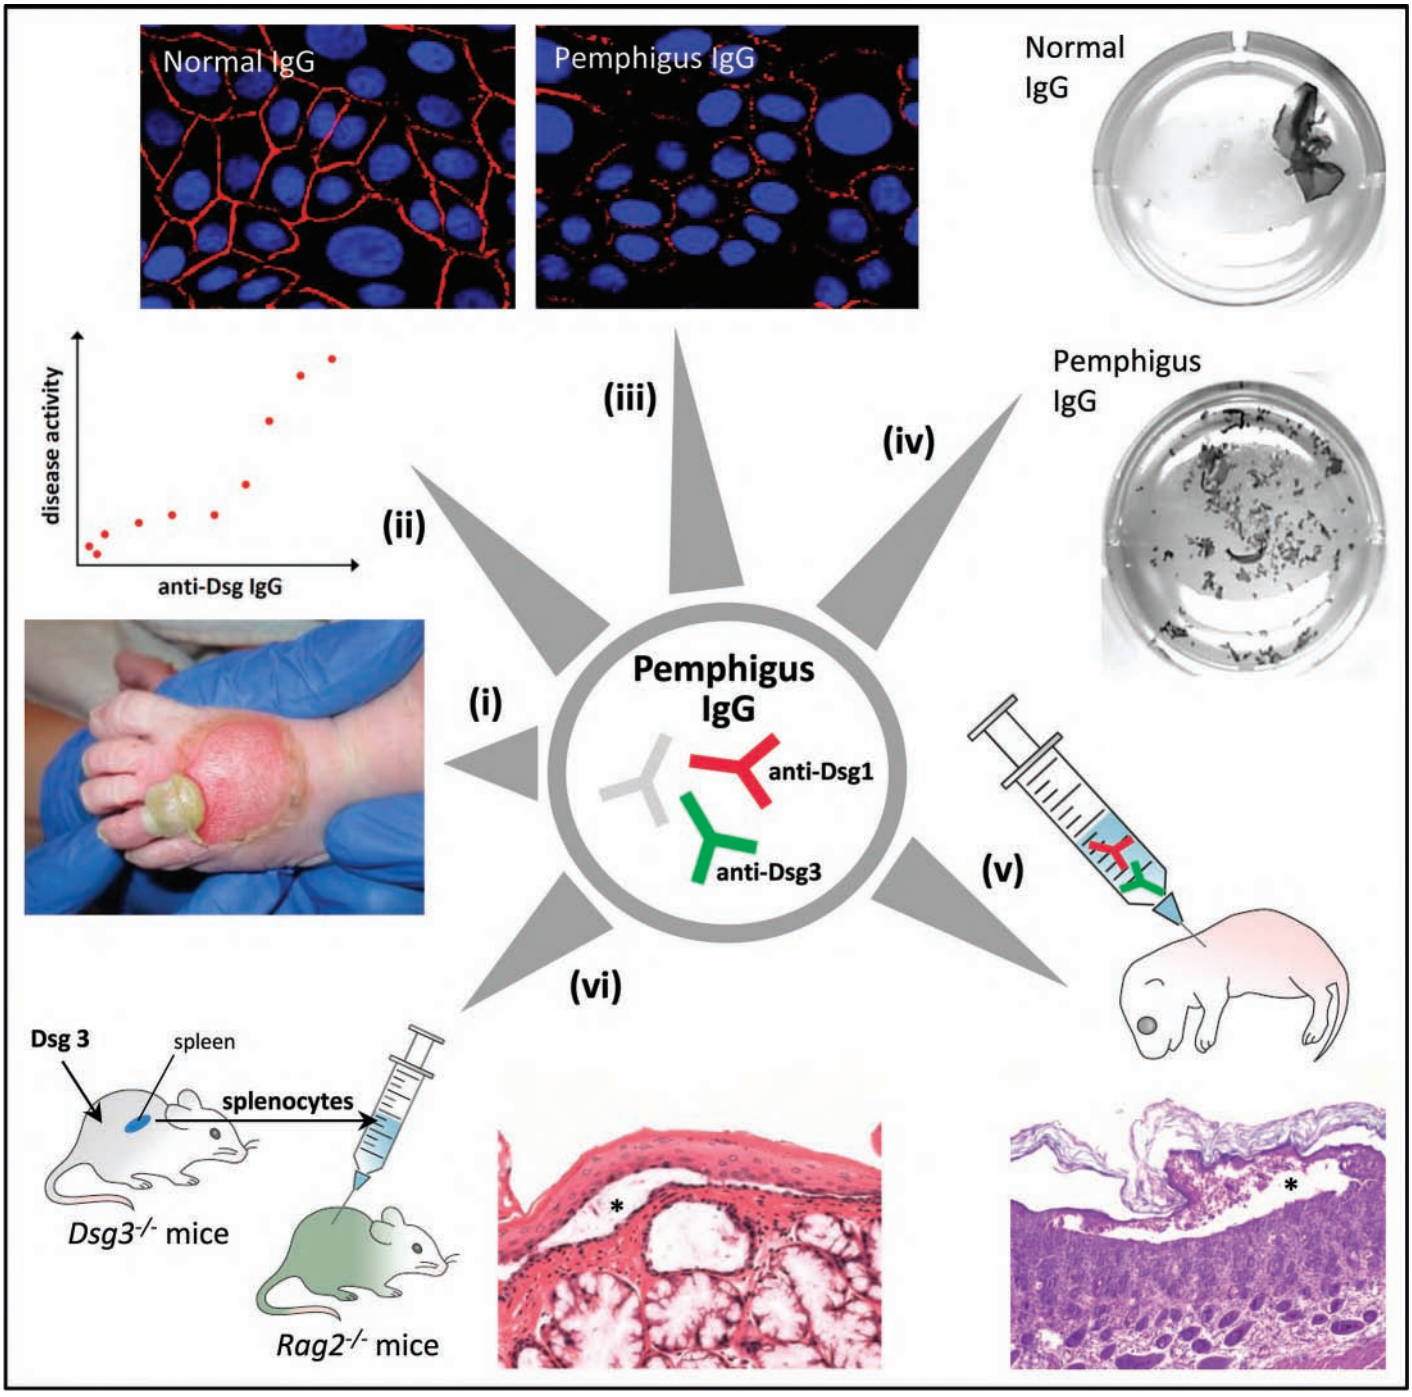

FIG. 63.15 Pathogenic Potential of Pemphigus Autoantibodies Based on Different Clinical and Experimental Observations. (i) The transplacental transfer of maternal autoantibodies from mothers with pemphigus may cause transient blistering in newborns, (ii) close correlation between the extent of lesions and anti-desmoglein (*Dsg*) immunoglobulin G (*IgG*) serum levels in most pemphigus patients, (iii) desmosome degradation in cultured keratinocytes after incubation with pemphigus IgG, (iv) acantholysis of cultured keratinocyte sheets upon treatment with pemphigus IgG, (v) intraepidermal splitting (*) and macroscopic blistering (not shown) in mice injected with pemphigus serum or anti-Dsg IgG,[35] and (vi) induction of anti-Dsg3 antibody production and microscopic (*) and macroscopic (not shown) blistering in immunodeficient *Rag2*$^{-/-}$ mice after adoptive transfer of lymphocytes from Dsg3-deficient (*Dsg3*$^{-/-}$) mice after immunization with recombinant Dsg3.[36] (Clinical picture in (i) courtesy Susann Ott, Department of Pediatrics, Klinikum Bayreuth, Bayreuth, Germany. FIG. 63.16 Pathogenesis of Pemphigoid Diseases. Pemphigoid disease pathogenesis can be divided into three distinct pathways: loss of tolerance and autoantibody production, circulation of autoantibodies, and autoantibody-induced tissue pathology. (A) Antigen-presenting cells *(APC)* and CD4 T cells promote expansion of autoreactive B cells that develop into autoantibody-producing plasma cells. This process is enhanced by the presence of B-helper neutrophils. In mice, this process almost exclusively occurs in peripheral lymph nodes, where the majority of pemphigoid disease-specific autoreactive B/plasma cells are found. (B) Once in the circulation, the half-life of immunoglobulin G (IgG) autoantibodies is maintained by the neonatal Fc receptor *(FcRn)*, which protects all IgG from proteolysis after uptake by endothelial cells. (C). In the skin, neutrophils bind to the immune complexes located at the dermal–epidermal junction, become activated and release reactive oxygen species (*ROS*) and specific proteases, which induce subepidermal blistering and cutaneous inflammation. (D) Extravasation of neutrophils (and other effector cells) from the bloodstream into the skin is mediated by an interaction of CD18 and ICAM-1. (E) Binding of neutrophils to the immune complexes at the dermal–epidermal junction is mediated by activating FcγR. This triggers a complex intracellular signaling cascade, which ultimately leads to mediator release by the neutrophils. Among those are the blister- and inflammation-driving ROS and specific proteases, as well as cytokine release. The latter enhances the extravasation and activation of neutrophils. In addition to engagement of activating FcγR, soluble mediators, such as leukotriene B4 *(LTB4)*, further promote neutrophil activation. (f) In addition to neutrophils, monocytes/macrophages, NK- and γδ T cells promote inflammation in pemphigoid diseases, while regulatory T cells *(Treg)* dampen neutrophil extravasation into the skin. *C1q*, Complement component 1q; *Erk*, extracellular-signal regulated kinases; *FGR*, Tyrosine-protein kinase; Fgr *Fliii*, Flightless I; *HCK*, Tyrosine-protein kinase HCK; *HSP90*, heat shock protein 90; *NCF1*, neutrophil cytosolic factor 1; *PIK3CB*, Phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit beta; *RORa*, RAR Related Orphan Receptor A.

neutrophils act as B helper neutrophils in these models, as their depletion leads to reduced autoantibody concentrations. Very little has been published on the molecular requirements of this phase of pemphigoid disease pathogenesis. So far, only Granulocyte–macrophage colony-stimulating factor (GM-CSF) is known to promote autoantibody production in experimental pemphigoid, presumably through the recruitment of B helper neutrophils into peripheral lymph nodes, where antigen-specific B/plasma cells are found.[41]

Circulation of Autoantibodies

Once generated, autoantibodies are released into the bloodstream (see Fig. 63.16, B). With few exceptions (e.g., linear IgA disease),

the majority of autoantibodies in pemphigoid diseases are IgG. The relative long half-life of IgG antibodies, as opposed to the other Ig isotypes, is due to the constant rescue of IgG from proteolysis by the neonatal Fc receptor (FcRn). Hence, blockade of FcRn has emerged as a potential therapeutic target for the treatment of pemphigoid disease.[44] When observed by multiphoton microscopy, autoantibodies rapidly bind to their target skin antigen.

Autoantibody-Mediated Tissue Pathology

After binding to their target skin antigens, pemphigoid disease autoantibodies form immune complexes at the DEJ (see Fig. 63.16, C–F). In most cases, this leads to inflammation and subsequent inflammation-dependent subepidermal blistering. Recent evidence also implicates inflammation-independent pathways that induce blisters.[45] In inflammation-dependent blistering, the formation of immune complexes promotes a proinflammatory milieu. This process is dependent on both the Fab and the Fc components of the autoantibodies. Binding of the autoantibodies to their target antigen induces the release of proinflammatory cytokines from the keratinocytes. This is best described for BP, where incubation of keratinocytes with anti-BP180 NC16A IgG induces time- and dose-dependent release of IL-8. In mice, several cytokines (e.g., GM-CSF, IL-1, Tumor necrosis factor [TNF], LTB4) and anaphylatoxins (e.g., C5a) can promote the influx of immune cells into the skin. In contrast, other cytokines with increased expression in experimental pemphigoid disease demonstrate anti-inflammatory activities. For example, IL-6 induces expression of IL-1 receptor antagonist, which counteracts the disease-promoting effects of IL-1. Ultimately, this leads to a CD18/Intercellular adhesion molecule-1 (ICAM-1)-dependent extravasation of effector leukocytes into the skin. Among these, neutrophils are the major disease-driving cell type.

In the skin, neutrophils bind to the immune complexes located at the DEJ. In mice, this is mediated by the activating FcγR III and IV. In humans, it is facilitated by FcγR IIA and IIIB. FcγR-dependent binding of neutrophils to the immune complexes induces an intracellular signaling cascade involving SYK, p38 MAPK, ERK1/2, AKT, PI3Kβ/δ, Hsp90, RORα, PDE4, Src kinases, and CARD9. Ultimately, this results in the release of specific proteolytic enzymes and reactive oxygen species (ROS), which induce cutaneous inflammation and subepidermal blistering. In addition to neutrophils, monocytes/macrophages, NK-, and γδ T cells promote blistering in pemphigoid diseases, while regulatory T cells dampen skin inflammation in pemphigoid disease.[46]

The role of mast cells is controversial: while mast cells are reportedly essential for the induction of experimental pemphigoid in neonatal mice, their depletion had no effect on clinical disease manifestation in antibody transfer–induced epidermolysis bullosa acquisita in adult mice. Based on critical evaluation of the mast cell–deficient mouse strains in these different studies, these observations suggest that mast cells are activated but not essential for pathogenesis in/of pemphigoid disease.[41]

The mechanisms underlying the resolution of inflammation in pemphigoid disease[47] are incompletely understood. In addition to C5aR2, IL-6, IL10, proresolving lipid mediators, and regulatory T cells, flightless I (Flii) has been implicated in the resolution in pemphigoid.[47,48]

Inflammation-independent pathways to blister formation have also been identified. For example, the binding of autoantibodies targeting the BP180 induces internalization of BP180, which leads to a decrease in the strength of adhesion to the underlying matrix.[49] Autoantibody binding also impairs pro-adhesive protein–protein interactions in the DEJ, which further weakens the adhesion of keratinocytes to the underlying matrix.

Experimental Models

Most of the above insights have been obtained by using pemphigoid disease animal models (Fig. 63.17, Table 63.3). So far,

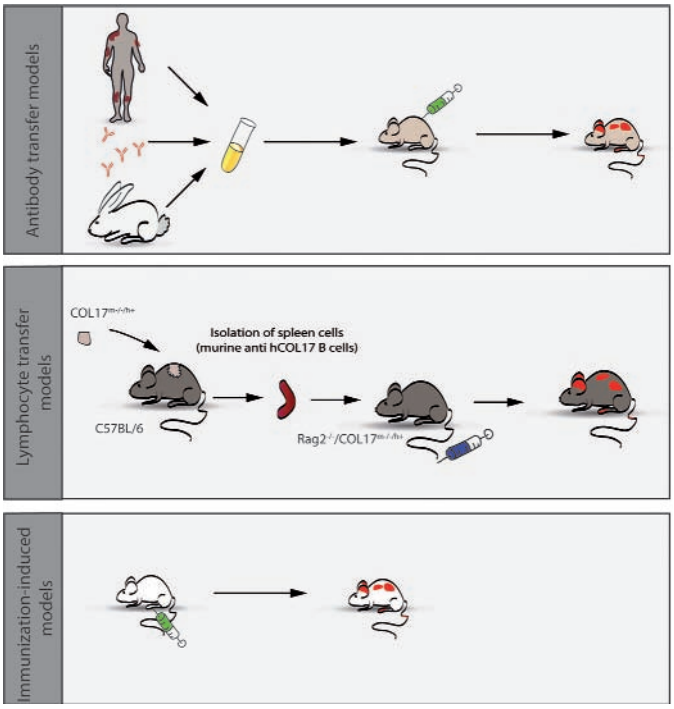

FIG. 63.17 Mouse Models of Pemphigoid. (A) In (auto)antibody transfer-induced pemphigoid, (auto)antibodies targeting a specific autoantigen in pemphigoid—that is, type XVII collagen (BP180)—are obtained from patients, generated recombinantly or obtained from rabbits immunized with the murine autoantigen. These (auto)antibodies are then injected into mice, which develop disease within a relatively short timeframe (days). When using these antibody transfer–induced models, reactivity of the (auto) antibodies with the skin of the recipient mouse has to be considered. These models reflect key pathogenic events of the autoantibody-induced tissue damage in pemphigoid, while not duplicating events leading to the generation of autoantibodies. (B) In the lymphocyte transfer-induced pemphigoid mouse models, wild-type C57Bl6 mice are immunized against human (h) type XVII collagen *(COL17)* by transplantation of skin from a murine (m) COL17-deficient / hCOL17 transgenic mouse. This leads to an adaptive immune response against human type 17 collagen (hCOL17). When lymphocytes from these mice are injected into immunodeficient *Rag2*$^{-/-}$, m*COL17*-deficent/hCOL17 transgenic mice, experimental bullous pemphigoid is induced. This model is ideal to investigate the interplay between T and B cells, as well as antibody transfer–induced tissue damage in pemphigoid. (C) In the immunization-induced pemphigoid disease models, pemphigoid is induced by immunization of susceptible mouse strains with the murine autoantigen. This leads to the development of an adaptive immune response against the used autoantigen, with subsequent development of clinical disease in the majority of the mice. This model reflects all aspects of pemphigoid disease pathogenesis, and allows therapeutic interventions for drug testing.

there are three principal mechanisms by which experimental pemphigoid can be induced in mice: First, by transfer of (auto) antibodies targeting specific pemphigoid autoantigens, such as type VII collagen or BP180. Second, by transfer of pemphigoid disease–specific lymphocytes into immunodeficient mice that express the corresponding autoantigen. Third, by immunization of susceptible mouse strains with the respective pemphigoid disease autoantigen.

The in vivo pathogenicity of anti-BP180 autoantibodies was demonstrated in 1993, when Liu and colleagues immunized rabbits with the immunodominant stretch of murine BP180 and transferred the rabbit anti-mouse BP180 IgG into neonatal mice.[50] For epidermolysis bullosa acquisita, the injection of anti-type VII collagen IgG in adult mice is currently the most frequently used pemphigoid mouse model.[40] The injection of anti-laminin 332 IgG into adult mice results in the replication of the clinical characteristics of the human disease (e.g., oral, ocular, and skin lesions).[51] These models allow in-depth investigations solely focused on autoantibody-induced tissue damage in pemphigoid. There are many pitfalls that need to be considered (such as altered or absent cross-reactivity of the human autoantibodies with the mouse antigens). Recently, a detailed protocol has been published that describes the step-by-step induction of experimental epidermolysis bullosa acquisita.[40]

The lymphocyte transfer–induced model of pemphigoid is based on the principle that mice that do not express the (auto) antigen develop an adaptive immune response toward this particular antigen (e.g., BP180). This immune response can be enhanced by immunization of these "autoantigen-deficient" mice with the autoantigen. Lymphocytes from these mice are then transferred into immunodeficient mice that express the autoantigen. The "auto"-reactive lymphocytes are stimulated by the presence of autoantigen, and experimental pemphigoid disease develops. This principle has been established for BP:[52] Here, wild-type C57Bl/6 mice were immunized against human BP180 by the transplantation of skin from mouse *COL17*-deficient, human COL17 transgenic mice. Consequently, these mice develop an adaptive immune response against hBP180. Transfer of lymphocytes from wild-type mice transplanted with hCOL17 transgenic mice into *mCOL17*-deficient, hCOL17-transgenic immunodeficient RAG2-deficient mice induces experimental BP in the recipient mice.[52]

Experimental pemphigoid disease in mice can also be induced by immunization of susceptible mouse strains. In these models, susceptible mouse strains are immunized with pemphigoid disease antigens (e.g., BP180 or type VII collagen). A specific autoantibody response is observed in most strains. However, only very few inbred strains (e.g., SJL/J) develop clinical disease.[53] The immunization-induced epidermolysis bullosa acquisita model is very robust, with a disease penetrance of 60% to 80% within 10 weeks after immunization. Disease persists over weeks after a single immunization. Hence, this model is also well-suited to evaluate the potential therapeutic effects of innovative treatment strategies.

In addition to experimental pemphigoid in mice, in vitro model systems mirror several aspects of pemphigoid disease pathogenesis. Among disease-specific in vitro model systems are: (1) immune complex-induced neutrophil activation, (2) ex vivo dermal–epidermal separation in cryosections of skin incubated with pemphigoid autoantibodies and neutrophils, and (3) the indirect complement fixation assay.[54,55]

KEY CONCEPTS

Pathophysiology of Pemphigoid Diseases

- Loss of tolerance to pemphigoid disease antigens is a complex interplay of (meta)genetics with environmental factors (drugs), and requires cells of the adaptive and innate immune system.
- FcRn maintains the long half-life of pathogenic pemphigoid disease-specific autoantibodies of the IgG subclass. Pemphigoid disease autoantibodies promote tissue pathology primarily through inflammation-dependent pathways, although inflammation-independent pathways can also play a role.

Dermatitis Herpetiformis

Dermatitis herpetiformis is regarded as the cutaneous manifestation of celiac disease (Chapter 75). In basically all patients with dermatitis herpetiformis, some degree of gluten-sensitive enteropathy can be found in small bowel biopsies. In genetically susceptible individuals (i.e., individuals with the MHC class II DQ2 or DQ8 variants, which are shared by patients with dermatitis herpetiformis and celiac disease), exposure to gluten initiates an autoimmune response against gliadin. Gliadin is the alcohol-soluble fraction of gluten, a family of grain proteins present in wheat, rye, and barley, but not oats. Once gliadin is absorbed via the lamina propria, glutamine residues within gliadin are deaminated by tissue transglutaminase (TG2), a process that may lead to optimal antigen presentation to T cells by HLA-DQ2-positive antigen-presenting cells. Subsequently, IgA antibodies against gliadin, deaminated gliadin, gliadin crosslinked to TG2, and TG2 are generated. TG2-specific IgA antibodies are the serological hallmarks of celiac disease, while IgA reactivity against epidermal transglutaminase (TG3), characteristic for dermatitis herpetiformis, may develop during the continued exposure to gliadin via epitope spreading later in the disease course. Deposition of anti-TG3 IgA in the dermal papillae attracts neutrophils and their release of ROS and enzymes disrupts the DEJ.[28,56]

KEY CONCEPTS

Pathophysiology of Dermatitis Herpetiformis

- Dermatitis herpetiformis has a strong genetic disposition. While in most patients both anti-TG2 and TG3 reactivity develops, TG3 is the autoantigen of dermatitis herpetiformis.

TREATMENT

Pemphigus

Pemphigus Vulgaris und Pemphigus Foliaceus

Since the 1950s, oral corticosteroids have been the therapeutic backbone of pemphigus. The initial dosage is usually 0.5 to 1.0 mg/kg/day predniso(lo)ne in patients with moderate pemphigus (pemphigus disease area index >15 and ≤45), and 1.0 to 1.5 mg/kg/day in patients with severe pemphigus (pemphigus disease area index >45). In addition, potentially corticosteroid-sparing agents are applied. This can include azathioprine, mycophenoles, and cyclophosphamide,[57] although cyclophosphamide is less commonly used due to its toxicity. These regimens led to complete remissions in 15% to 20% of patients.[4] Since 2002, an increasing number of patients with severe and refractory pemphigus have been treated off-label with rituximab, a monoclonal antibody against the CD20 antigen on B lymphocytes that depletes CD20-positive B cells from the circulation for 6 to 12 months (Chapters 7 and 85). In a recent randomized controlled trial with newly diagnosed pemphigus vulgaris and pemphigus foliaceus patients, a clear superiority of rituximab over a standard corticosteroid regimen was demonstrated.[58] Subsequently, rituximab was approved by the Food and Drug Administration (FDA) (in 2018) and the European Medicines Agency (EMA) (in 2019) for the treatment of moderate to severe pemphigus vulgaris, and is recommended as first-line therapy for this group of patients.[57,59] In refractory patients, immunoadsorption, high-dose intravenous immunoglobulins, or intravenous corticosteroid pulses are recommended.[57,59]

Paraneoplastic Pemphigus

This pemphigus disease is most likely triggered by the underlying neoplasm. Consequently, oncological therapy is paramount. Systemic corticosteroids, rituximab, immunoadsorption, and high-dose intravenous immunoglobulins have been successfully used as treatment for the AIBD.[4]

THERAPEUTIC PRINCIPLES

Pemphigus

- Rituximab, or its biosimilar, is recommended as first-line therapy for moderate and severe pemphigus vulgaris and foliaceus. After repeated infusions, complete remission off therapy occurs in about 90% of patients.
- Multiple rituximab infusions are required in about a quarter of patients.
- Treated patients may develop severe adverse events including hypogammaglobulinemia, pneumonia, septicemia, and/or reactivation of chronic infections (e.g., herpes simplex, herpes zoster, viral hepatitis, or HIV). When rituximab is not available, the combination of long-term high-dose corticosteroids with potentially corticosteroid-sparing agents such as azathioprine or mycophenoles is recommended.

Pemphigoid Diseases

Bullous Pemphigoid

Systemic (usually prednis[ol]one, 0.5 mg/kg/day) or superpotent topical corticosteroids are the basis of BP treatment.[60–62] If applied as recommended, over 90% of the patients go into remission within 4 weeks.[60] If remission has been achieved, corticosteroids are tapered over several months to prevent relapse. Despite this, relapse occurs in 30% to 50% of the patients while tapering or after stopping corticosteroid treatment. The use of potentially corticosteroid-sparing adjuvant agents is still mainly based on few randomized controlled trials or case series and includes, with regional preferences, dapsone, doxycycline, azathioprine, mycophenoles, and methotrexate. In refractory or severe BP, anti-CD20, intravenous immunoglobulin (IVIG) infusions, and immunoadsorption have been applied successfully.[61–63] Based on a recent prospective and controlled clinical trial, doxycycline is an alternative to first-line corticosteroid treatment. Compared to corticosteroids, doxycycline treatment has fewer adverse events but is also less effective.[64]

Pemphigoid Gestationis

Since pemphigoid gestationis is self-limiting in nearly all patients, the treatment aims to relieve the symptoms and is usu-

ally based on oral (predniso[lo]ne, 0.25 to 0.5 mg/kg/day) and/or lesional topical corticosteroids. Since pemphigoid gestationis has been associated with prematurity and fetal growth restriction, a close cooperation with gynecologists is recommended.[29]

Anti-p200 Pemphigoid

In anti-p200 pemphigoid, similar therapeutics as in BP are applied. Usually, anti-p200 pemphigoid responds better than BP and prednis(ol)one (0.5 mg/kg/day) with or without dapsone, doxycycline or azathioprine are given. However, no data from randomized controlled trials are available.[22]

Mucous Membrane Pemphigoid

Treatment of MMP depends on affected mucosal sites as well as disease severity. The guideline of the European Academy of Dermatology and Venereology recommends treating mild MMP (e.g., limited to oral and nasal mucosa) with dapsone or tetracycline with or without topical corticosteroids, and in case of ineffectiveness, with oral corticosteroids combined with mycophenoles. In severe MMP (e.g., extended oral lesions, severe genital lesions, laryngeal, tracheal, or esophageal involvement), cyclophosphamide with or without oral corticosteroids is recommended as first-line approach followed by rituximab and high-dose IVIG.[65] In MMP with ocular involvement, a step-ladder approach including topical agents and various immunomodulants and immunosuppressants is recommended.[65]

Epidermolysis Bullosa Acquisita

Like severe MMP or its ocular involvement, epidermolysis bullosa acquisita is notoriously difficult to treat. In a retrospective case series, on average 9 months were required to induce remission despite generalized immunosuppressive therapy. Basically, similar treatments to those used in BP and pemphigus are employed, with systemic corticosteroids being the therapeutic backbones. In addition, colchicine may be used in mild cases. A recent meta-analysis of treatment outcomes in over 1000 patients showed that rituximab or high-dose IVIG were significantly more often associated with remission than other treatments.[66]

THERAPEUTIC PRINCIPLES

Pemphigoid Diseases

- Corticosteroids remain the backbone of pemphigoid disease treatment.
- The corticosteroid-sparing effect of the currently applied adjuvant immunomodulants and immunosuppressants has not been clearly established.
- Prevention of relapse after stopping corticosteroid treatment is challenging in bullous pemphigoid.
- Safer treatments of bullous pemphigoid are required. More effective treatments for mucous membrane pemphigoid and epidermolysis bullosa acquisita are needed.

Dermatitis Herpetiformis

Treatment consists of a gluten-free diet and dapsone. Dapsone resolves the usually considerable pruritus within 2 to 3 days, an effect so impressive that it has been employed for the diagnosis of the disease (*ex juvantibus*) before immunopathological tests were available. Dapsone, however, does not affect the intestinal pathology. Thus, initial therapy is recommended with a gluten-free diet in combination with dapsone, and tapering of dapsone after several months of strict gluten-free diet according to clinical symptoms.[28]

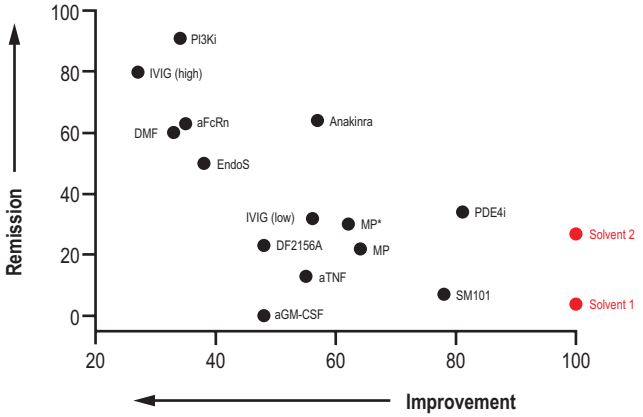

FIG. 63.18 Therapeutic Approaches in Experimental Pemphigoid Disease. Clinical responses to antiinflammatory agents applied in immunization-induced epidermolysis bullosa acquisita. In all experiments, epidermolysis bullosa acquisita was induced by immunization and treatments were started when the mice had 2% or more of their body surface area affected by skin lesions. Treatment periods vary from 2 to 6 weeks. In some experiments, SJL/J mice were used, while in others, B6.s mice were included. Remission is defined as the proportion of mice that had a lower affected body surface area at the end of the treatment period compared to the affected area at randomization. Improvement is defined as clinical disease severity of treated mice in relation to solvent-treated animals. If more than one dose of the drug was used, the most effective concentration is shown. *aFcRn*, anti-FcRn antibody; *aGM-CSF*, anti-GM-CSF antibody; *aTNF*, eternacept; *DF2156A*, allosteric CXCR1/2 inhibitor; *DMF*, dimethyl fumarate; *EndoS*, endoglycosidase derived from *Streptococcus pyogenes*; *IVIG (high)*, intravenous IgG administered every 3rd day; *IVIG (low)*, administered once per week; *MP**, MP from an independent experiment; *MP*, methylprednisolone; *PDE4i*, PDE4 inhibitor roflumilast; *PI3Ki*, phosphatidylinositol-3-kinase δ inhibitor LAS191954; *SM101*, recombinant soluble non-glycosylated version of the FcγRIIb. THERAPEUTIC PRINCIPLES

Dermatitis Herpetiformis

A gluten-free diet, initially combined with dapsone, will lead to complete remission of dermatitis herpetiformis.

ON THE HORIZON

In pemphigus, randomized controlled trials with inhibitors of neonatal FcR (FcRn), Bruton tyrosinkinase (BTK), and B-cell activating factor (BAFF or BLYS) are currently active. Phase Ib studies with DSG3-containing nanoparticles and DSG3-specific chimeric autoantigen receptor T cells are being conducted.[4,67] Study of pemphigoid disease model systems has led to the emergence of several novel therapeutic targets, including cytokines (e.g., TNF, GM-CSF, IL-17), signal transduction molecules (e.g., SYN, PDE4, PI3K), and several distinct targets linked to the complement system. New drugs for already well-known targets in pemphigoid disease (e.g., complement system) are being developed for the use in pemphigoid disease (Fig. 63.18). Ongoing clinical trials for BP are evaluating the efficacy and safety of ixekizumab (anti-IL-17, phase II), NPB-1 and efgartigimod (anti-FcRn, phase III), AC-203 (inflammasome inhibitor, phase II), bertilimumab (anti-eotaxin, phase II), benralizumb (anti-IL-5R, phase III), nomacopan (anti-C5a/ LTB4, phase III), and rituximab (anti-CD20, phase III).

ACKNOWLEDGMENTS

We thank Beke Linnemann, Lübeck, for help with the clinical pictures and Marina Kongsbak-Reim and Dr. Maike Holtsche, Lübeck, for the immunofluorescence photographs. We are indebted to Carolin Mahlerwein, Lübeck, for the graphical design of Fig. 63.1 and parts of Fig. 63.15, as well as to Katja Bieber, Lübeck, who generated Figs. 16 and 17.

Immunology of Psoriasis

Cristina Albanesi

CLINICAL AND HISTOLOGIC FEATURES OF PSORIASIS

Psoriasis is a common chronic, relapsing immune-mediated disease that involves the skin and small joints of genetically predisposed individuals. It affects approximately 2% of the general population, with more than half of patients presenting in the first three decades of life.

There is a wide spectrum of cutaneous manifestations. The clinical spectrum of psoriasis includes plaque, guttate, small plaque, inverse, erythrodermic, and pustular variants.[1] The most common and well-recognized morphologic presentation of psoriasis is the plaque type, which can vary from pinpoint to large lesions (Fig. 64.1).

The disease is characterized by the formation of demarked erythematous plaques with large scaling. The scales are a result of a hyperproliferative epidermis with premature maturation of keratinocytes and incomplete cornification. There is retention of nuclei in the stratum corneum (parakeratosis). The mitotic rate of the basal keratinocytes is increased when compared with normal skin. This leads to a thickening of the epidermis (acanthosis), which is marked by elongated rete ridges that form fingerlike protrusions into the dermis. The granular layer of the epidermis (the starting site of terminal keratinocyte differentiation) is strongly reduced or missing. The epidermis is infiltrated by neutrophils and activated CD8 T lymphocytes. Within the dermis, there is an inflammatory infiltrate composed mainly of $CD3^+$ T cells, dendritic cells (DCs), macrophages, mast cells, and neutrophils. Elongated and dilated blood vessels in the dermal papillae represent a further histologic hallmark of psoriatic skin lesions (Fig. 64.2).[1]

KEY CONCEPTS

- Psoriasis is a common chronic-relapsing immune-mediated skin disease affecting approximately 2% of the general population.
- A complex set of gene variants, rather than a single gene, predispose the patient to an aberrant response to environmental factors.
- There is infiltration of effector immune cells into both the epidermis and dermis, which promotes hyperproliferation of the epidermis, premature maturation of keratinocytes, and incomplete cornification.
- The epidermis is thickened, with elongated rete ridges forming protrusions into the dermis.
- Primary effector cells are dermal dendritic cells (DCs), in particular plasmacytoid DCs (pDCs), whose activation can depend on DNA-LL37 or RNA-LL37 complexes released by injured keratinocytes. This leads to a massive production of interferon (IFN)-α.
- pDC-released IFN-α or RNA-LL37 complexes released by keratinocytes activate myeloid DCs (mDCs), which in turn induces type 1 and type 17 T-cell responses.
- A T helper 22 (Th22) response is also pathogenetically induced.
- Pathologic cytokines include T cell–derived lymphokines, such as IFN-γ, tumor necrosis factor (TNF)-α, interleukin (IL)-17, IL-22, and antigen-presenting cell–derived cytokines, such as IL-12 and IL-23.
- T lymphocytes and DC establish the inflammatory cytokine milieu influencing keratinocyte proliferation and immune responses.
- Intrinsic alterations of keratinocytes in the activation of signal transduction pathways (i.e., STAT3, RAS) further amplify psoriatic processes.

IMMUNE-RELATED GENETIC FACTORS PREDISPOSING TO PSORIASIS

The genetic basis of psoriasis has long been recognized, because family members of patients with psoriasis are at greater risk of developing the disease. The concordance rate of psoriasis is approximately 70% in monozygotic twins and 20% in dizygotic twins, depending on the study and population.[2] The mode of inheritance is complex. It is thought that rather than a single disease gene there is a complex set of gene variants that lead to an aberrant response to environmental factors. Several allelic variants or single nucleotide polymorphisms (SNPs) have been identified. Classic genome-wide association studies (GWAS) have pointed to additional susceptibility loci and polymorphisms. At least 34 chromosomal loci have been identified. These have been labeled as *psoriasis susceptibility loci* 1 through 34 (*PSORS1* through *PSORS34*).[3]

The genes identified by GWAS can be grouped into four signal transduction and gene regulation pathways involved in epidermal differentiation, in inflammation, and in innate and adaptive immunity (Fig. 64.3).[3] First, skin barrier function pathways have been strongly associated with psoriasis. Several studies have identified the late cornified envelope *(LCE)* gene cluster, which is highly expressed in psoriatic skin, and corneodesmosin *(CDSN)* and coiled-coil, x-helical rod protein 1 (*CCHCR1)*, which are highly polymorphic genes that map to the *PSORS1* locus. Candidate gene studies have also implicated the β-defensin gene cluster *(DEFB)* on chromosome 8 and interferon (IFN) induced with helicase C domain 1 *(IFIH1)*, which are both involved in the protection against microbial agents. The second pathway involved candidate genes found within nuclear factor κB (NF-κB) genes and their related pathways, as well as in a genetic region involved in inflammatory responses and in the modulation of Th immune responses. Association studies point to tumor necrosis factor (TNF)–induced protein 3 *(TNFAIP3)* and TNFAIP3-interacting protein 1 *(TNIP1)*, which regulate the activity of NF-κB and can induce keratinocyte hyperproliferation. In

FIG. 64.1 Clinical Features of Plaque Psoriasis. Scaly, erythematous, sharply demarcated plaques in different sizes and shapes are hallmarks of psoriasis.

Caucasian populations, association studies have pointed to TNF receptor–associated factor 3–interacting protein 2 *(TRAF3IP2)*, a gene that encodes a protein that interacts with the *NF-κB/REL* subunit.[3] The third and potentially largest pathway, in terms of numbers of genetic loci implicated in psoriasis, influences T-cell signaling. Gene loci include *SOCS1* (suppressor of cytokine signaling1), *STAT3/5 A/5B* (signal transducer and activator of transcription3/5 A/5B), interleukin *(IL)-12B*, *IL-23A*, and *IL-23R*. The latter gene is involved in the regulation of Th17 and Th1 responses. Specific haplotypes of *CTLA4* (cytotoxic T-lymphocyte antigen), which encodes a protein that downregulates activation of T lymphocytes, have been associated.[3] The fourth pathway is linked to antigen presentation, and involves human leukocyte antigen *(HLA)-C* and *ERAP1*.[3]

As is the case in many immune-mediated diseases, the major genetic determinant of psoriasis, which contains the majority of allelic variants is located within the HLA complex on chromosome 6p21 (see Chapter 5). In the case of psoriasis, this is identified as the *PSORS1* locus. This locus spans the class I region of the major histocompatibility complex (MHC) and encompasses nine genes, including *HLA-C, CDSN*, *CCHCR1*, and *TNFA*, that are highly polymorphic. Among these, the *HLA-Cw6* allele is the susceptibility genetic factor most highly associated with psoriasis, even though more than 100 HLA-C variants have been described. High-density polymorphism analysis has identified several SNPs within the minimal promoter region of HLA-C, which affect HLA-C expression. Among HLA-C haplotypes, *HLA-Cw6* is associated with early-onset (type I), compared with late-onset (type II) psoriasis.[4] In addition to HLA-Cw6, significant associations with HLA-B13, HLA-B17, HLA-B37, HLA-B57, HLA-Cw7, and class II molecules HLA-DR4 and HLA-DR7 in psoriasis have been identified. Exciting evidence has emerged for an interaction between HLA-C and ERAP1 (involved in trimming peptides to enable effective loading and processing onto MHC class I) in psoriasis.

Despite the strong genetic evidence and the obvious immunologic function of HLA-C to regulate both innate and adaptive responses, functional studies addressing the precise mechanism by which *HLA-Cw6* alleles predispose to psoriasis are still missing. HLA-C interacts with natural killer (NK) cell KIR receptors, and thus it is possible that susceptibility to psoriasis reflects differences in both antigen presentation and NK cell regulation.[4]

EFFECTOR CELLS AND IMMUNE MECHANISMS OPERATING IN PSORIASIS

The primary pathogenic mechanism involved in the onset of psoriasis in predisposed individuals appears to follow their exposure to certain trigger factors (Fig. 64.4). These range from nonspecific stimuli, such as skin trauma (termed the *Koebner effect*), to more specific triggers, such as pathogens (i.e., streptococci) or drugs (i.e., lithium, IFN-α). All of these factors

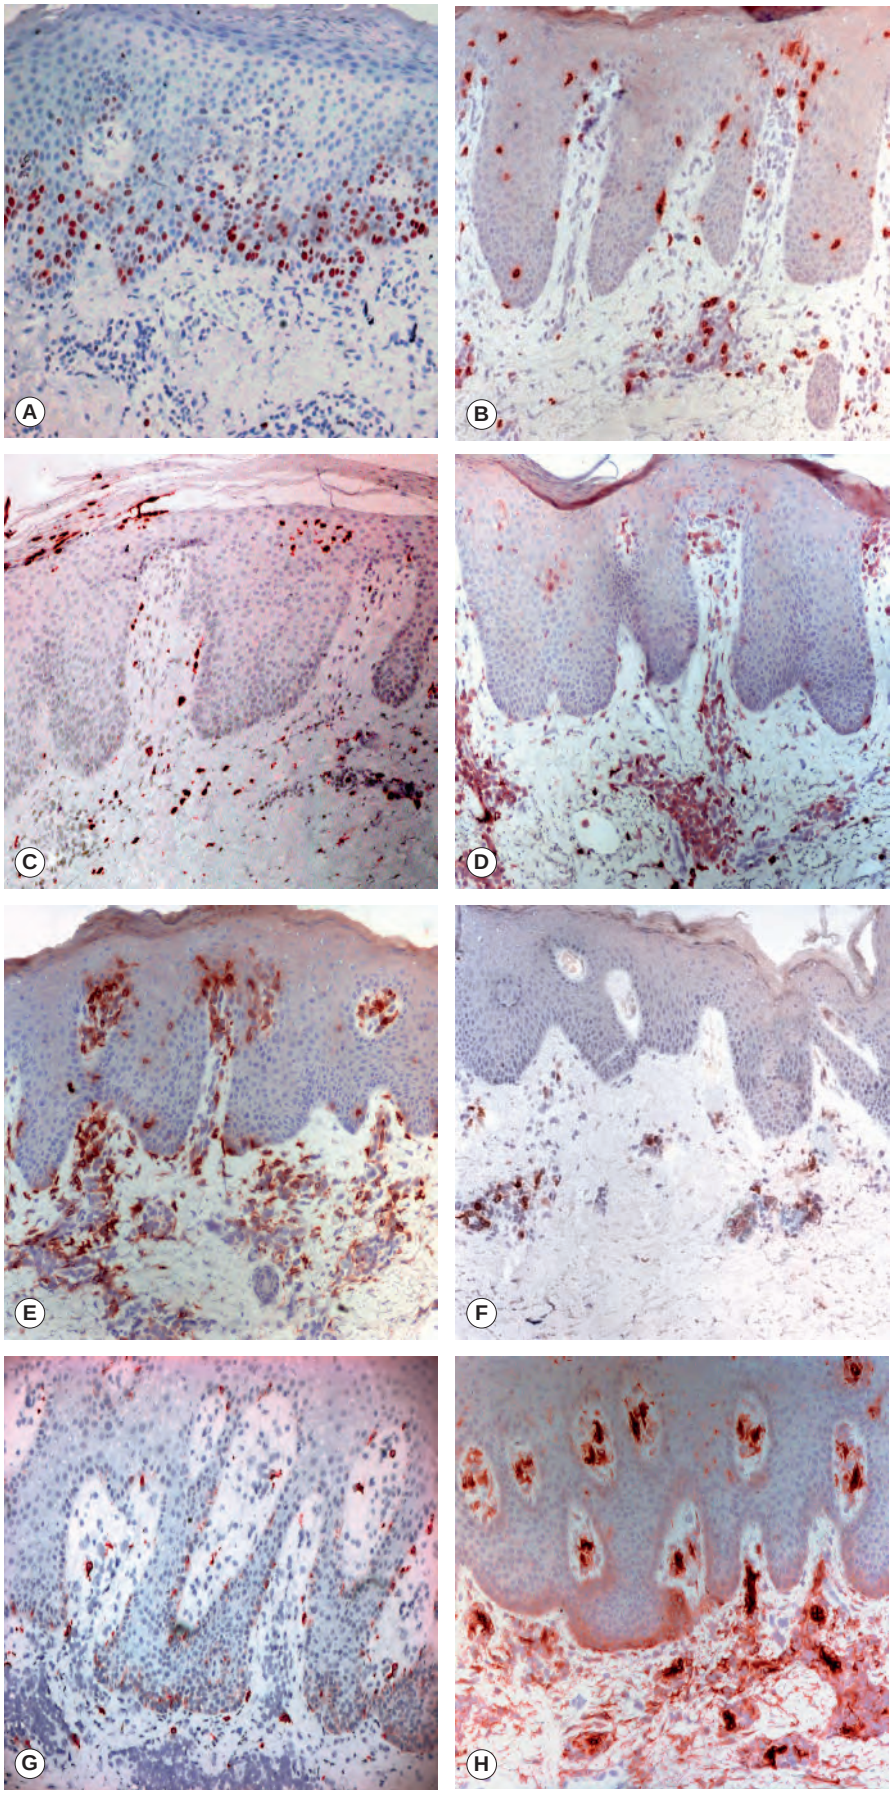

FIG. 64.2 Histologic Components of a Mature Psoriatic Plaque. Psoriatic skin lesions are characterized by a hyperproliferative epidermis showing an increased mitotic rate of the basal keratinocytes (A, Ki67 immunostaining). As a consequence, the epidermis thickens, with elongated rete ridges that form typical fingerlike protrusions into the dermis. The epidermis becomes infiltrated by activated CD8 T lymphocytes and neutrophils (B and C, immunostaining for CD8 and CD15, respectively). Within the dermis, an inflammatory infiltrate mainly composed of $CD3^+$ T cells (D), $CD11c^+$ dendritic cells (E), BDCA-2^+ plasmacytoid dendritic cells (F), c-kit^+ mast cells (G), and neutrophils (C) is observed. Elongated and dilated ICAM-1^+ (H) blood vessels in the dermis represent another histologic hallmark of psoriatic skin.

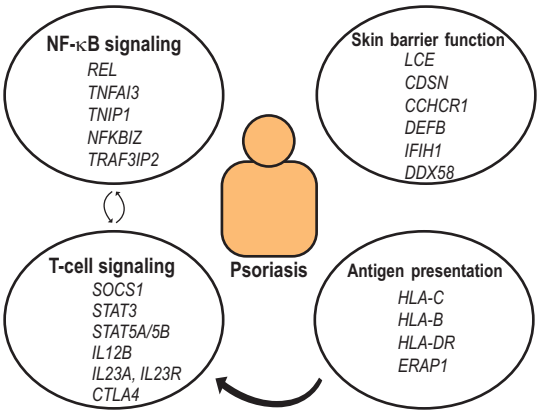

FIG. 64.3 The Psoriasis Genetic Pathway Identified by Genome-Wide Association Studies. A schematic representation of genetic variants within psoriasis-related risk loci that are highly represented in the psoriatic population (allele frequency ≥0.3). They can be grouped into broad immunologic intersected processes, including those involved in skin barrier function, inflammatory pathways (NF-κB pathway) and immune responses (T-cell signaling and antigen presentation). *Arrows* signify the cross-talk between the immune pathways shown. *CDSN*, Corneodesmosin; *DEFB*, β-defensin gene cluster; *HLA*, human leukocyte antigen; *LCE*, late cornified envelope; *NF-κB*, nuclear factor kappa B.

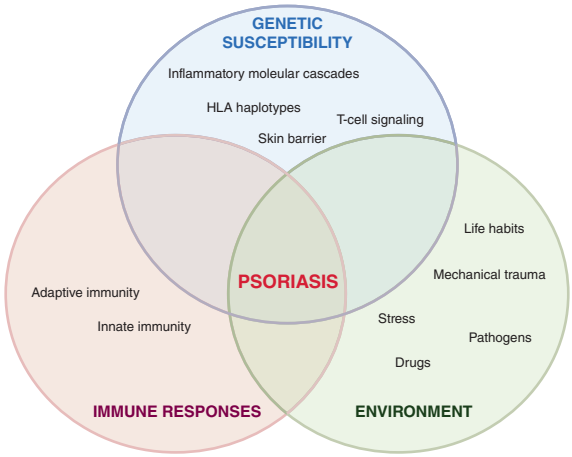

FIG. 64.4 Extrinsic and Intrinsic Factors That Can Contribute to the Development of Psoriasis. The disease occurs in genetically predisposed individuals that carry one or more allelic variants of psoriasis susceptibility genes (i.e., genes involved in skin barrier function, inflammatory and T-cell signaling, and determining specific human leukocyte antigen [*HLA*] haplotypes). Dysregulated innate and adaptive immune responses can follow exposure to certain environmental triggers.

generate a pathogenic cascade that culminates in the expansion of lesional and/or circulating T cells in the psoriatic skin.[5,6]

In the past, much effort has been devoted to understanding the link between the trigger stimuli and the pathogenic T-cell cascade that leads to psoriasis. A number of studies have demonstrated that type-1 IFN represents this link.[5,7] The prototypical type I IFN, IFN-α, is abundantly produced by plasmacytoid dendritic cells (pDCs) during the acute phase of psoriasis (Fig. 64.5, A). In turn, IFN-α indirectly stimulates keratinocyte immune activation and maturation of myeloid DCs (mDCs), with the consequent beginning of an adaptive immune response phase. This results in the establishment of an IL-23/IL-17 and IL-12/IFN-γ inflammatory environment in psoriatic skin, with DC-derived IL-23 and IL-12 promoting Th17 and Th1 cell effector functions, respectively.[6,8,9]

Innate lymphoid cells (ILCs) and innate-like γδ T cells are also critical contributors to plaque development. They release considerable levels of type 17 cytokines.[10] Mast cells and neutrophils represent additional, innate sources of IL-17 in psoriatic skin.[5]

The leukocyte infiltrate present in active psoriatic skin establishes a cytokine milieu that dictates specific and pathogenic gene signatures in resident skin cells (see Fig. 64.5, B). Cytokine-activated keratinocytes overexpress a number of inflammatory mediators that aberrantly amplify and sustain the psoriasiform tissue reactions (Fig. 64.5, C). Intrinsic defects and/or alterations of keratinocytes in their immune response to proinflammatory cytokines are fundamental to the induction of psoriatic processes, as demonstrated in genetically manipulated mouse systems.

Plasmacytoid Dendritic Cells as Inducers of Primary Immune Responses in Psoriasis

pDCs (see Chapter 6) are characterized by a plasma cell morphology and a distinctive surface phenotype ($CD4^+$, $CD45RA^+$, $CD123^+$, $BDCA\text{-}2^+$, $BDCA\text{-}4^+$, $CD62L^+$, cutaneous lymphocyte-associated antigen $[CLA]^+$, and $CD11c^-$). They are considered key effector cells in antiviral defense due of their ability to produce large amounts of type I IFN.[11] Upon viral stimulation, pDCs differentiate into a unique type of mature DC and induce an IFN-α–dependent activation of bystander mDCs with the ability to induce Th1-responses (Chapter 11), thus providing a necessary link between innate and adaptive immunity (see Chapter 3).[11]

Several studises have demonstrated that pDCs infiltrate psoriatic skin and that pDC-derived IFN-α initiates the expansion of autoimmune T cells, leading eventually to the skin lesions of psoriasis.[5,7,12,13] Blocking of type I IFN signaling with neutralizing antibodies to IFN-α/β receptors (IFN-AR1 and 2) or BDCA-2 inhibits the activation and expansion of pathogenic T cells, as well as the development of a psoriatic phenotype. The mechanisms responsible for the IFN-α-induced expansion of T cells in psoriasis depend on the capability of IFN-α to favor cross-presentation of sequestered tissue-specific autoantigens by mDCs, and to enhance the survival of autoreactive Th1-cell bias through the induction of T-bet and IL-12$R\beta_2$ expression.[13] The pathogenic role of IFN-α is also suggested by the observations that its signaling signature (i.e., type I IFN, IFNAR1, IFNAR2, STAT1, IRF1, and IRF7) is present in resident skin cells of psoriatic plaques[12,14] and that psoriasis is exacerbated in patients treated with recombinant IFN-α for unrelated conditions (i.e., viral infections or tumors), or with imiquimod, a Toll-like receptor (TLR) agonist that induces production of IFN-α.

The molecular mechanisms leading pDCs to produce type I IFN involve the activation of TLR7 and TLR9 (see Chapter 3), intracellular receptors that recognize viral/microbial nucleic acids within endosomal compartments. In psoriatic skin, pDCs can be activated to produce massive amounts of type I IFN in response to extracellular self-DNA coupled to the endogenous antimicrobial peptide LL37, which is known to be overexpressed in psoriatic skin.[15] LL37 breaks innate tolerance to self-DNA by

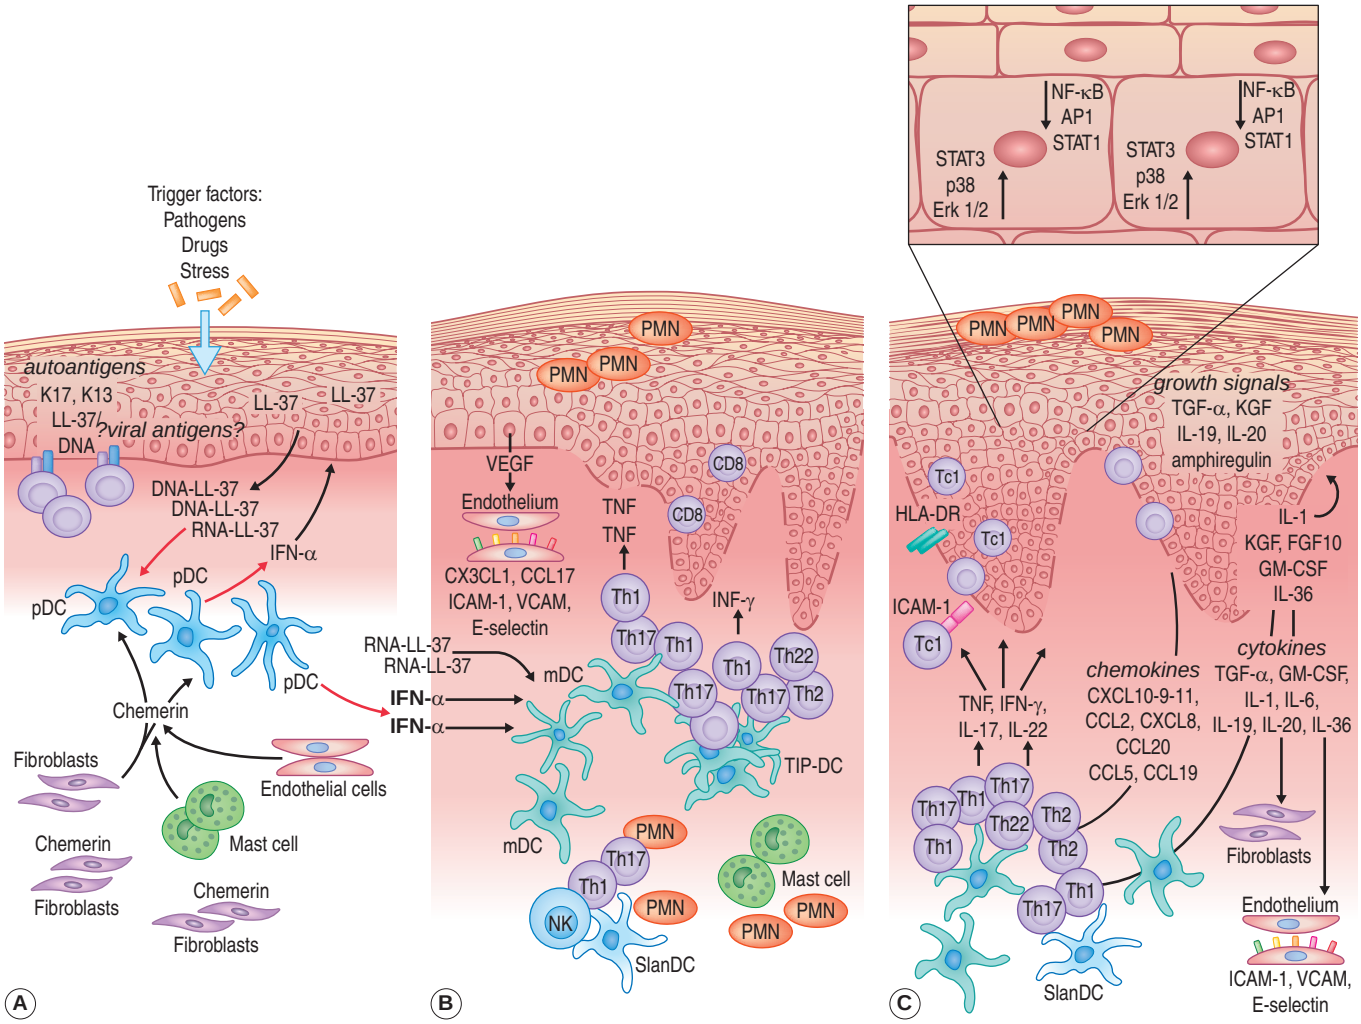

FIG. 64.5 Scheme of Pathogenic Mechanisms Operating in Psoriasis. The psoriatic lesion starts to evolve after keratinocytes are injured (e.g., by physical trauma or bacterial products). Thereafter, a cascade of events, including the formation of complexes formed by keratinocyte-derived DNA and the cathelicidin LL37, leads to the activation of plasmacytoid dendritic cells *(pDCs)* that routinely patrol psoriatic skin (A). In the early phase of disease development, other pDCs are recruited by the chemokine chemerin, which is derived primarily from dermal fibroblasts and, to less extent, mast cells and endothelial cells. These pDCs are induced to release high amounts of interferon *(IFN)-α*. IFN-α locally activates keratinocytes and participates in the activation processes affecting mDCs. Subsequently, DCs migrate into draining lymph nodes and induce the differentiation of naïve T cells into effector cells, such as type 17 T-helper *(Th17)* or type 17 T- cytotoxic *(Th17) (Tc)* cells and type 1 Th1 or Tc1 cells. These effector T cells recirculate into psoriatic skin, proliferate, and produce massive amounts of proinflammatory cytokines, such as IFN-γ and tumor necrosis factor *(TNF)*. Effector cells also include innate immunity cells, such as innate lymphoid cells *(ILC)* and γδ T cells, which routinely patrol the skin (B). TNF is abundantly released by dermal DCs, mainly represented by inflammatory DCs. Skin Langerhans DCs also reinforce immunity in psoriasis by interacting with and potentiating the activity of both neutrophils (PMN) and NK cells, as well as inducing Th1 and Th17 responses. IFN-γ, TNF, and interleukin *(IL)*-17 are responsible for the activation of resident skin cells, in particular keratinocytes, which respond to cytokines with a stereotypical set of genomic responses leading to synthesis of inflammatory mediators (C). Keratinocytes are also targets of T cell–derived IL-22 that, together with IL-17, induces proliferation and de-differentiation of psoriatic keratinocytes in a signal transducer and activator of transcription 3 *(STAT3)*-dependent manner. Keratinocyte-derived chemokines, cytokines, and membrane molecules have a major role in maintaining the recruitment of leukocytes into inflammatory sites. Because of their intrinsic defects, psoriatic keratinocytes aberrantly respond to cytokines and show altered intracellular signaling pathways, including STAT3 and RAS cascade (C). The uncontrolled hyperproliferation and differentiation observed in psoriatic skin could also derive from dysregulated production of tissue growth factors and regulators, such as transforming growth factor *(TGF)*-α, keratinocyte growth factor *(KGF)*, amphiregulin, granulocyte macrophage–colony-stimulating factor *(GM-CSF)*, fibroblast growth factor-10 *(FGF-10)*, *IL*-19, IL-20, and IL-36 produced by keratinocytes and fibroblasts. Psoriatic keratinocytes produce and capture from melanocytes autoantigens (i,e., nucleic acid/LL37 complexes, ADAMTSL5, PLA2G4A) capable of inducing clonal T-cell responses. Finally, the inflammatory cytokine milieu also influences the immune functions of fibroblasts and endothelium, with the latter being critical for leukocyte trafficking and extravasation.

forming aggregated and condensed structures that can trigger a robust IFN-α induction via TLR9, as well as form complexes with RNA and activate pDCs through TLR7. In parallel, LL37/RNA can alert mDCs through their TLR8, driving T-cell activation and production of cytokines found in psoriasis. This finding suggests a fundamental role for LL37 in alerting resident skin pDCs of tissue damage associated with cell death and the release of self-DNA.[15]

pDCs are typically absent in unperturbed skin and peripheral tissues under homeostatic conditions. However, they can be detected in prepsoriatic skin during the acute phase of the disease.[13] At this stage, BDCA-2$^+$ pDCs infiltration correlates with the transient high IFN-α local expression and with massive presence of innate immunity cells (i.e., neutrophils, mast cells, macrophages) in the skin. On the contrary, pDCs are almost absent in long-lasting and chronicized lesions.[12,13] Importantly, pDC recruitment in psoriatic skin is strictly associated with the expression of the chemokine (see Chapter 15) chemerin, which is temporally produced by dermal fibroblasts and active during psoriatic plaque development. pDC migration toward fibroblast-derived chemerin is completely dependent on the expression of ChemR23 receptor on pDC. Compared with other chemokines potentially active on pDC (CXCL10 and CXCL12), chemerin is the main, if not the only, protein responsible for the pDC chemotactic activity released by fibroblasts in psoriatic skin.[12]

Dendritic Cell Driving of T-Cell Responses in Psoriatic Skin

Although pDCs are responsible for triggering psoriasis, mDCs are the main amplifiers of local inflammation. Dermal mDCs are dramatically increased in psoriasis. Targeted immunotherapy reduces their quantity, supporting the concept that mDCs have a key pathogenetic role in psoriasis.[13,16] Dermal mDCs are found at the dermal–epidermal junction, as well as throughout the whole dermis. mDCs are able to capture extracellular antigens for presentation to T cells and also intracellular antigens from adjacent cell types via cross-presentation (see Chapter 6). mDCs within psoriatic lesions are intrinsically stronger stimulators of T-cell proliferation compared with DCs derived from peripheral blood or from the skin of healthy patients. mDCs uniformly express CD11c, and they can be further subdivided on the basis of expression of CD1c (BDCA-1). Steady-state skin has a predominance of CD11c$^+$ CD1c$^+$ resident DCs, whereas CD11c$^+$ CD1c$^-$ mDCs predominate in psoriatic inflammation.[13,16]

A small fraction of CD11c$^+$ CD1c$^+$ DC bears "maturation" markers, such as DC-LAMP, CD83, and endocytic receptor DEC-205/CD205, suggesting that they could function as conventional DCs and present antigens to T cells to trigger acquired immune responses.[13,16] These rare, phenotypically mature cells, often aggregating in dermal clusters, could be required for rapid antigen presentation to local T cells or for ongoing "micro-" immune responses.

During psoriasis development, dermal CD11c$^+$ DC mature and acquire a CD1c$^-$ HLA-DR$^+$ CD45$^+$ CD14$^-$ DC-specific ICAM-3–grabbing nonintegrin (DC-SIGN)$^+$ phenotype.[13] These inflammatory mDCs are CCR7$^+$ and respond to the chemokine CCL19, suggesting that they may migrate to draining lymph nodes for antigen presentation.

CD11c$^+$ CD1c$^-$ inflammatory DC express very high levels of the enzyme inducible nitric oxide synthase (iNOS) and TNF-α. These DC can be considered the human equivalent of TIP-DC (TNF-α and iNOS-producing DC), which have been shown in mice to have effector functions in clearing some bacterial infections.[13]

TNF-α in turn targets resident skin cells, including keratinocytes and endothelial cells. TNF-α induces expression of ICAM-1 on keratinocytes, facilitating the adhesion of circulating leukocytes. Moreover, TNF-α can stimulate keratinocytes and dermal fibroblasts to produce the potent neutrophil chemoattractant CXCL8, as well as the proinflammatory cytokines IL-6 and IL-1, which help to generate and maintain Th17 cells (see Chapters 11 and 14).[14]

Inflammatory DCs also produce other cytokines (*e.g.*, IL-23 and IL-12), which are strictly linked to psoriasis. IL-12 mainly induces IFN-γ production and Th1/Tc1 polarization, whereas IL-23 also stimulates IL-17 and IL-22 release by type 17 and type 22 T cells.[6,8,9] Evidence for a role of both TNF and IL-23 in psoriasis includes the therapeutic success of the TNF-α blockers and, more relevantly, the monoclonal antibodies against p40 or p19 subunits of IL-23.[6,8]

Another population of inflammatory mDCs, defined by the selective expression of the 6-sulfo LacNAc residue on the P-selectin glycoprotein ligand 1 membrane molecule, has been identified in psoriatic skin.[17] 6-Sulfo LacNAc$^+$ DCs (slanDCs) have a well-defined phenotype (CD1c$^-$, CD11c$^+$, CD16$^+$, CD14$^-$) that clearly distinguishes them from classic CD1c$^+$ blood DC (CD1c$^+$, CD11c$^+$) or pDC (BDCA-2, BDCA-4). SlanDCs produce more TNF-α, IL-23, IL-12, IL-1β, and IL-6 and can thus induce Th1/Th17 cells. SlanDCs also reinforce innate immunity in psoriasis by interacting with and potentiating the activity of neutrophils (Chapter 39) and NK cells (Chapter 12).[17]

The function of another DC subset, the Langerhans cell (Chapter 23), is still controversial. Langerhans cells are found only in the epidermal compartment, where they are similar in number and phenotype in lesional and nonlesional skin. However, they fail to migrate in response to proinflammatory stimuli (see Chapter 24). Recent studies have shown that Langerhans cells can produce IL-23 as inflammatory DC and are located in the close proximity to pathogenic skin T cells. Interestingly, Langerhans cells from patients who achieved almost complete remission after anti-TNF-α treatment can release higher levels of IL-23 when compared with healthy volunteers. This observation supports the view that Langerhans cells may be associated with the recurrence of psoriasis.[16]

Activation of T Lymphocytes and Establishment of the Cytokine Milieu Influencing Keratinocyte Proliferation and Immune Functions

Psoriasis lesional skin contains many inflammatory CD3$^+$ T cells in both the papillary dermis and the epidermis, determining the epidermal hyperplasia and inflammation picture (Fig. 64.6). Immunophenotyping of these T cells shows that they are primarily activated memory T cells that express the cutaneous lymphocyte antigen (CLA). They belong to distinct subsets of CD4$^+$ and CD8$^+$, Th1/Tc1, Th17/Tc17, and Th22/Tc22 lymphocyte subsets.

Psoriatic T-cell responses are triggered in response to (auto) antigens primarily derived from keratinocytes. They are captured by DCs located at the dermal–epidermal junction of psoriatic skin. To date, three autoantigens have been identified in keratinocytes and found to be involved in the pathogenesis of psoriasis.[4,14,18] In up to 75% of psoriatic patients, LL37 is recognized

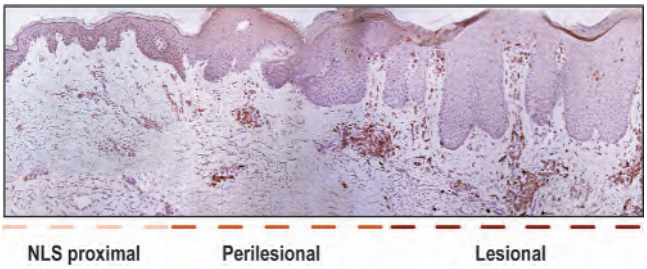

FIG. 64.6 CD3⁺T Lymphocyte Pattern in Psoriasis. Both acute and chronic phases of psoriasis can be found within the same psoriatic plaque, being comprehensive of nonlesional (NLS) proximal to perilesional and lesional areas, with markers of chronic inflammation (i.e., CD3⁺ T cell accumulation in the dermis) predominantly present in lesional skin. Psoriatic skin also shows inflammatory CD3⁺ T cells in the epidermal compartment, which contribute to epidermal hyperplasia and an inflammatory milieu. *NLS,* Nonlesional skin.

as autoantigen by circulating CD4 and CD8 T cells with a cytokine and skin-homing receptor profile typical of psoriatic skin T cells (IFN-γ^{high}, IL-17^{high}, CLA^+, $CCR6^+$, and $CCR10^+$).[15,18]

Phospholipase A2 group IVD has been identified in psoriatic keratinocytes as an important player in the generation of psoriasis autoantigens. The latter include nonprotein neolipids that are recognized by CD1a-restricted T cells, thereby inducing the production of IL-22 and IL-17A. These lipid antigens can be transferred from keratinocytes to neighboring antigen-presenting cells through released exosomes.

Disintegrin and metalloprotease domain containing thrombospondin type 1 motif-like 5 (ADAMTSL5), a protein modulating microfibril functions and identified as autoantigen presented by melanocytes in an HLA-C*06:02-restricted fashion, has been also been localized in keratinocytes throughout the psoriatic epidermis.[4,18]

Keratinocytes can also activate pathogenic T cells by presenting viral or bacterial products. Human papillomavirus-5 DNA and reactive antibodies against virus-related particles have been found in psoriasis. Infections by *Streptococcus* commonly associate with psoriasis, and *Streptococcus*-derived superantigens can be presented to T lymphocytes by MHC class II–bearing keratinocytes. Psoriatic antigens are assumed to be keratinocyte-derived molecules sharing structural homology with streptococcal proteins, which could therefore induce autoreactive T-cell responses against skin components.[14]

Based on the analysis of infiltrating cell types, their secreted products, and genetic signatures present in lesional skin, psoriasis has been considered for many years as a type 1 (i.e., Th1)-mediated reaction, with IFN-γ playing a prominent role. However, other cytokines and T-cell subsets are pivotal in inducing inflammatory responses in psoriasis. These include Th17 and Th22 cells, which produce large amounts of IL-17 and IL-22. These two cytokines, together, mediate most of the epidermal hyperplasia by impairing keratinocyte differentiation and inducing their premature maturation and aberrant cornification.[14,19]

IL-17 activates keratinocytes to produce neutrophil and T cell–recruiting chemokines (i.e., CXCL1/CXCL2/CXCL8 and CCL20, respectively) as well as antimicrobial peptides (i.e., LL37 and S100 family members).[14,19] Thus IL-17 is a central actor in a pathogenic loop linking T cells and keratinocytes.

T cell–derived IFN-γ and TNF-α activate a plethora of inflammatory pathways in resident skin cells, in particular keratinocytes and endothelial cells.[14,19] Each cytokine regulates distinct responses with a certain degree of synergism in regulating gene expression induction/inhibition. Most of the effects induced by IFN-γ are potentiated by TNF. TNF intracellularly activates NF-κB, a transcription factor regulating gene expression frequently in collaboration with the transcription factor STAT1 induced by IFN-γ. TNF induces expression of intercellular adhesion molecule-1 (ICAM-1) on resident skin cells, permitting the adhesion and extravasation of circulating leukocytes.[14] Moreover, TNF stimulates the production of several chemokines active on immune cells, as well as proinflammatory cytokines, in particular IL-6 and IL-1, which sustain Th17 expansion.[14] Importantly, TNF, together with IL-17, induces IL-36γ in psoriasis lesions. This in turn promotes expression of antimicrobial peptides and chemokines recruiting neutrophils and Th17 cells, as well as interferes with terminal differentiation and cornification process of the epidermis.[20]

Transcriptional profiling studies conducted on lesional psoriatic skin showed that the IFN-γ signature predominates, even though IL-17 and TNF also potently induce a vast panel of genes.[14,19] A number of studies demonstrated a central role of IL-22 in psoriasis pathogenesis by activating STAT3-dependent genes involved in differentiation and proliferation processes. However, this cytokine induces a limited panel of genes compared with IL-17, as detected in human lesional psoriatic skin. Among them, the chemokines CXCL1, CXCL2, CXCL8, and CCL20 and the antimicrobial peptides HBD-2, HBD-3, and S100 proteins are induced by IL-22.[14,19]

Although T lymphocytes are required for the development and persistence of immune responses in psoriatic skin, endogenous defects in keratinocytes determining an aberrant response to lymphokines may be concomitantly relevant for psoriasis. An increasing number of allelic variants of genes controlling keratinocyte inflammatory activation, as well as proliferation and differentiation processes in the epidermis, has been associated with psoriasis.[3] Among them, a number of SNPs were found in genes encoding molecules involved in IL-17 or TNF responses, even though functional studies correlating their presence to keratinocyte susceptibility to these cytokines are lacking and controversial. For instance, allelic variants were found in *NFKBIZ*, *TRAF3IP2*, and *TNFAIP3* genes encoding IKBζ, Act-1, and the Act1-dependent A20 protein, respectively, all involved in IL-17 molecular signaling. However, no clear evidence linking these SNPs to enhanced or reduced responses of keratinocytes to IL-17 exist. In fact, Act-1 gene variants overexpressed in human keratinocytes could decrease as well as enhance Act-1–mediated IL-17 signaling, depending on the SNP type. Variants of *NFKBIZ* could also influence keratinocyte response to TNF-α because IKBζ is a transcriptional cofactor of p50 subunit of NF-κB, the main mediator of TNF-α signaling.

Finally, data from mice with engineered epidermal phenotypes also showed that overactivation in keratinocytes of molecular cascades, such as STAT3- or RAS pathways, determines the development of psoriasiform lesions that closely resemble human psoriasis. Similarly, the abrogation of JunB in keratinocytes triggers a skin phenotype with the histologic features of psoriasis, including marked hyperplasia of the epidermis and dense dermal inflammatory cell infiltrates.

Innate Immune Cells Are Fundamental for the Induction of Psoriatic Processes

Several studies have demonstrated the role of innate immunity cells in the development of inflammation in psoriasis patients (see Fig. 64.5). Among them, ILC is a class of immune cells bearing lymphoid morphology but no immune cell lineage markers.[10] ILC in situ mapping in psoriatic skin revealed that lesions contained a prominent population of T-bet$^+$ ILC1 and RORγ$^+$ ILC3 subsets, with nearly absent GATA3$^+$ ILC2. ILC1s are similar to Th1 cells and secrete type 1 cytokines, such as IFN-γ and TNF, whereas ILC3s can be divided into natural cytotoxicity receptor (NCR)$^+$ ILC3s and NCR$^-$ ILC3s17 and produce IL-17 and/or IL-22. These subsets of ILCs were found to reside beneath the dermal–epidermal junction and in close proximity to T lymphocytes, suggesting a potential functional relationship between these cells. This provides new insight into shared mechanisms between psoriasis and innate immunity.[10] Driving of ILC3 responses and IL-17 production are strongly dependent on IL-23, which can be also produced by infiltrating macrophages during the early phase of the disease. It has been proposed that the IL-23/IL-17 axis could be established early in psoriatic skin by innate immunity cells and precede adaptive immune responses.

Together with ILC, the γδ T cells, an innate-like T-cell population involved in surveillance of epithelial surfaces, are also critical contributors to plaque development by releasing considerable levels of IL-17 and IL-22. Similarly, mast cells and neutrophils can represent innate sources of IL-17 in psoriatic skin. Neutrophils also release IL-36, and in turn induce IL-36 in keratinocytes, thereby establishing neutrophil extracellular trap (NET)osis, a defense mechanism operating in psoriasis and based on the formation of cytosolic granule proteins containing autoantigens. NETosis is also fundamental for macrophage priming, Th17 activation, and immune cell recruitment in early psoriasis.[20]

Finally, macrophages can produce high levels of psoriasis-associated cytokines (*e.g.*, IL-23 and TNF). The latter are produced mainly in response to IL-36, which acts on IL-36R–bearing antiinflammatory M2 macrophages, driving them to a proinflammatory M1 phenotype.[20]

ON THE HORIZON

- Continued development of immunomodulatory biologics that target pathogenic molecules. These agents are potentially highly effective in psoriasis and include anti–tumor necrosis factor (TNF) biologics, anti-interleukin (IL)-12/23 inhibitors, anti–IL-17 and IL-17R inhibitors, and anti–IL-23p19 drugs.
- Correlation between drug response variability and the presence of specific genetic variants.
- Validation of these results in adequately powered patient cohorts.
- The discovery of new pharmacogenomic biomarkers, simultaneously present in different genes involved in intersected pathogenic pathways, which could be predictive for the responsiveness of psoriatic patients to biologic drugs.

CONCLUSIONS

Psoriasis results from a complex interplay between environmental and genetic factors. Early upstream events occurring in the disease include activation of innate immunity cells, including pDCs, ILCs, neutrophils, and macrophages, and the generation of effector T cells that migrate into the psoriatic skin lesions and expand there. Cross-talk between keratinocytes and immune cells amplifies inflammation and is responsible for chronicity. Recent research has identified a number of immunologic mechanisms involved in psoriasis progression. This has led to the development of new, pathogenesis-based therapies. Although recent progress is remarkable, much remains unknown, especially regarding how to prevent the condition and how to develop drugs with appropriate risk–benefit and long-term profiles. Future work must take into account these aspects to establish therapeutic and preventive approaches that lead to improved patient outcomes.

Myasthenia Gravis

Patricia M. Sikorski, Linda L. Kusner, and Henry J. Kaminski

Myasthenia gravis (MG) is a rare immune disease with a prevalence of 200 to 400 cases per million.[1] Patients have characteristic weakness that is worsened with activity. Muscle weakness is mediated by pathogenic autoantibodies that impair neuromuscular transmission by targeting functionally important proteins of the neuromuscular junction (NMJ), primarily the nicotinic acetylcholine receptor (AChR). However, non-AChR components of the NMJ, such as muscle-specific kinase (MuSK) and low-density lipoprotein receptor-related protein 4 (Lrp4), are also targeted in a minority of patients negative for AChR antibodies. Although the use of experimental animal models of MG has led to well-defined roles of autoantibodies in contributing to immunopathology of the disease, the cellular basis for the development and maintenance of pathogenic antibodies is multifactorial and less well understood. This chapter focuses on the structure and function of myasthenic autoantigens at the NMJ and how pathogenic mechanisms of autoantibodies contribute to the spectrum of disease phenotypes in MG patients.

DISEASE DIAGNOSIS AND CLASSIFICATION

The fundamental manifestation of MG is fluctuating muscle weakness that worsens with repeated muscle use and improves with rest. Heterogeneity in the pattern and severity of weakness exists among patients, but general categories can be used to define patients by clinical characteristics. First, patients may have disease limited to the ocular muscles leading to ptosis or double vision, so-called ocular myasthenia, while the remainder have generalized weakness not limited to the eye muscles. Initial presentation of the disease for about two-thirds of patients involves the ocular muscles, which progresses to generalized MG in a majority of patients.[2,3] The MG Foundation of America Clinical Classification separates patients across the degree of severity from ocular (class 1) to mild, moderate, and severe (classes 2 to 4) and an MG crisis (class 5), which stipulates patients that require respiratory support. The classification further identifies class 2 to 4 patients having predominant weakness of cranial nerve innervated muscle with limited general weakness (subclass b) or the reverse (subclass a). Patients rarely have remarkably isolated weakness (e.g., weakness limited to the neck extensor muscles producing "head drop" or foot drop from ankle dorsiflexor muscles or breathing muscle weakness in absence of more general weakness).

The clinical diagnosis can be confirmed using serological testing. In about 85% to 90% of patients, anti-AChR antibodies are detected in serum, whereas a minority (5% to 10%) of the patients produce antibodies targeting other proteins in the muscle or NMJ, such as MuSK or Lrp4.[4] About half of ocular MG patients produce AChR antibodies with the remainder being seronegative. MuSK antibody patients rarely exhibit purely ocular MG. In patients without serum autoantibodies, electrophysiological testing can confirm diagnosis. In upwards of 80% of patients, a decremental pattern is seen following repetitive nerve stimulations (Fig. 65.1).

Single fiber electromyography evaluates variations in timing of junctional activation and may be detected in expert hands in over 90% of patients.[2] The classic diagnostic evaluation (edrophonium test) involves the administration of cholinesterase inhibitor with an examiner monitoring for unequivocal improvement in muscle strength. In the United States the edrophonium test is not commonly performed because of drug availability and safety concerns; however, the evaluation can be an extremely useful adjunct in diagnosis of seronegative patients.

As the pathophysiological heterogeneity of MG has been refined, categorization has been further refined. AChR antibody-positive patients are subdivided based on disease onset (early onset <45 years [EOMG] or late onset >45 years [LOMG]). The EOMG subtype patients are more likely to have thymic hyperplasia with high levels of AChR antibodies. In contrast, LOMG patients are considered to more often have thymic atrophy, although a recent study of specimens from a surgical study did not support this contention.[5] Thymoma-associated MG patients essentially always have AChR antibodies and tend to have a worse clinical course. As discussed, patients are also categorized by autoantibody status.

CLINICAL PEARLS

- Essentially all patients will have ptosis or double vision at some time during their illness
- Pupillary response, sensation, and reflexes are always normal in myasthenia gravis.
- Significant variation in weakness occurs over a day and over weeks to months

NEUROMUSCULAR TRANSMISSION

The NMJ is a chemical synapse formed between the terminal end of the motor neuron and the muscle fiber that is critical for transmitting signals to the fiber for muscle contraction. Neuromuscular transmission involves release of acetylcholine (ACh) from the nerve ending into the junctional cleft, which then binds to the nicotinic AChR highly concentrated on the postjunctional membrane of the muscle, known as the motor endplate. The binding of ACh to AChR results in opening of ligand-gated ion channels with resultant influx of primarily sodium ions, leading to endplate depolarization that stimulates an action potential generation to initiate muscle contraction. The endplate potential (EPP) is terminated by diffusion of ACh and its rapid hydrolysis by acetylcholinesterase (AChE) anchored to the basal lamina of the synaptic cleft.

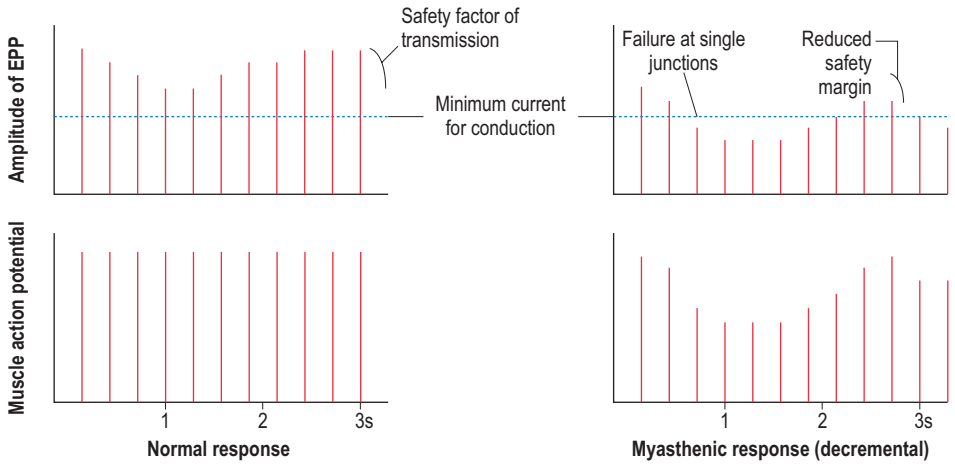

FIG. 65.1 Neuromuscular Transmission in Normal and Myasthenic Subjects. With repetitive stimulation there is a reduction in the efficiency of acetylcholine (ACh) release, with a subsequent recovery in efficiency as the train of stimuli continues. Although the endplate potential *(EPP)* fluctuates at the normal junction, sufficient current is generated to stimulate an action potential of constant magnitude. At the myasthenic junction, however, the amplitude of the EPP in response to a given amount of ACh is reduced. Under conditions of inefficient ACh release (for example, repetitive stimulation), the minimum current for conduction is not generated, resulting in a profile of action potentials that shows a progressive decline or "decrement" with subsequent recovery.

The spontaneous release of ACh from a synaptic vesicle with subsequent binding to AChRs leads to measurable depolarization, known as a miniature endplate potential (MEPP). As a result of motor nerve activation multiple vesicles release ACh to produce summation of MEPPs and an EPP that exceeds the threshold necessary to produce an action potential of the muscle. The ratio between the EPP and threshold required to generate an action potential is known as the safety factor. Postsynaptic folding, the density of AChR, and endplate sodium channels all determine the magnitude of the safety factor. If the EPP fails to reach the threshold for depolarization, an action potential is not generated and the muscle does not contract.

In 1964, electrophysiological studies of a muscle biopsy taken from an MG patient demonstrated that the amplitude of MEPPs was diminished.[6] Studies of the motor endplate ultrastructure in MG muscle determined several postsynaptic abnormalities, including simplification of postsynaptic regions, accumulation of debris in the synaptic space, and a reduction in AChR. The deficiency of AChR decreases the amplitude of MEPP and subsequent EPP, reducing the safety factor for neuromuscular transmission. Any additional stressor, such as repetitive activity, will lead to a greater likelihood of transmission failure among those endplates that have a compromised safety factor.

Differential Muscle Involvement in Myasthenia Gravis

The pattern of muscle weakness markedly varies across patients, but the reasons are poorly understood. Differences in the physiological properties of the NMJ across muscles and their response to autoantibody-mediated injury are likely to play a part in muscle susceptibility, as well as the specific autoantibody profile of an individual MG patient. Extraocular muscles (EOM) are particularly susceptible to MG and several differences between skeletal muscle and EOM may account for their increased susceptibility to injury. Simple histological assessment and gene expression profiling differentiate EOM. The NMJ of EOM are anatomically distinct in that they contain both singly and multiply innervated muscle fibers. These NMJs morphologically exhibit less prominent synaptic folds, and few postsynaptic AChRs, leading to a lower safety factor.[7] In EAMG models, changes in RNA expression profiles related to muscle injury and decreases in mRNA level for several cell-surface complement regulators was observed in EOM.[8] Collectively, these observations suggest that the selective involvement of EOM in MG may be due to subtle differences in properties of NMJs across muscles.

KEY CONCEPTS

Involvement of Anti-Acetylcholine Receptor Antibodies in the Pathogenesis of Myasthenia Gravis (MG)

- Anti-acetylcholine receptor antibodies are found in the serum of 85% to 90% of patients with MG
- IgG and complement are deposited at the postsynaptic junction
- Transfer of serum IgG from patients with MG to mice induces neuromuscular blockade

AUTOANTIGENS IN MYASTHENIA GRAVIS AND THEIR ROLES IN NEUROMUSCULAR TRANSMISSION

Neuromuscular transmission is dependent on highly specialized transduction machinery present at the postsynaptic membrane. The specialized postsynaptic ultrastructure at the motor endplate is highly organized to efficiently and rapidly respond to neurotransmitters released from the nerve terminal, which requires properly clustered AChRs and a complex pattern of synaptic folds on the postsynaptic membrane. The aggregation of AChRs is an intricate process that relies on the agrin-Lrp4-MuSK signaling cascade.

Agrin, a heparan sulfate proteoglycan, is released by motor nerve terminal and binds Lrp4, which then bind MuSK to stimulate homodimerization and transphosphorylation of MuSK. These events stimulate intracellular signaling events that include adaptor proteins Dok7, Tid1, and rapsyn, and result in AChR clustering and stabilization. The autoantibodies against extracellular or transmembrane proteins are pathogenic in MG either directly or indirectly by affecting AChR function and quantity, ultimately resulting in structural alteration or tissue injury (Fig. 65.2).

Acetylcholine Receptor

The nicotinic AChRs are located on top of the postsynaptic folds at the motor endplate at a density of 10,000/μm^2. AChRs are membrane proteins belonging to a superfamily of ligand-gated ion channels consisting of five transmembrane subunits: two α_1 subunits, one β_1 subunit, one δ subunit, and either one γ subunit (embryonic) or ε subunit (adult) to form an ion channel (Fig. 65.3)

Ion channels are gated pores that allow passive flow of ions down electrochemical gradients to induce a cellular response. Upon ligand binding (ACh) to the α subunit, the receptor structure is converted into a channel opening within microseconds to allow the flow of positive ions, leading to endplate depolarization and initiation of action potential. The concentration and arrangement of AChRs at the postsynaptic membrane is critical to ensure successful synaptic transmission. Maintaining the concentration is dependent on signals from the motor neurons to accumulate and stably maintain AChRs and other postsynaptic proteins at restricted synaptic sites.

Muscle-Specific Kinase

The release of agrin, a sulfated proteoglycan secreted by motor neurons, induces the assembly of AChR clusters by interacting with Lrp4 and activation of MuSK. MuSK is selectively expressed in skeletal muscles, co-localizes with AChRs in the postsynaptic membrane, and plays an important role in regulating the high density and clustering of AChRs at the NMJ. Genetic studies have shown that reducing expression of MuSK in mice destabilizes and disassembles postsynaptic membranes, signifying it is a key component in maintaining synaptic function.[9]

MuSK is a member of the RTK class of protein kinases, which consist of an extracellular ligand-binding domain, a single transmembrane spanning region, and a cytoplasmic region that includes a tyrosine kinase domain.[10] MuSK, however, is not a typical tyrosine kinase that relies on ligands that bind directly to the receptor. Rather, it is activated by ligands that do not directly bind it and instead bind a separate accessory component. The extracellular region, or ectodomain, of MuSK contains three immunoglobulin (Ig)-like domains that mediate ligand binding critical for MuSK activation. Biochemical and structural studies determined that the first and second Ig-like domains are important for binding agrin and its co-receptor, Lrp4.[11] MuSK activation triggers homodimerization and autophosphorylation that results in a signaling cascade, resulting in the redistribution of muscle-derived proteins including AChRs, rapsyn, and MuSK at the postsynaptic site and become stably localized in clusters beneath the nerve terminal.

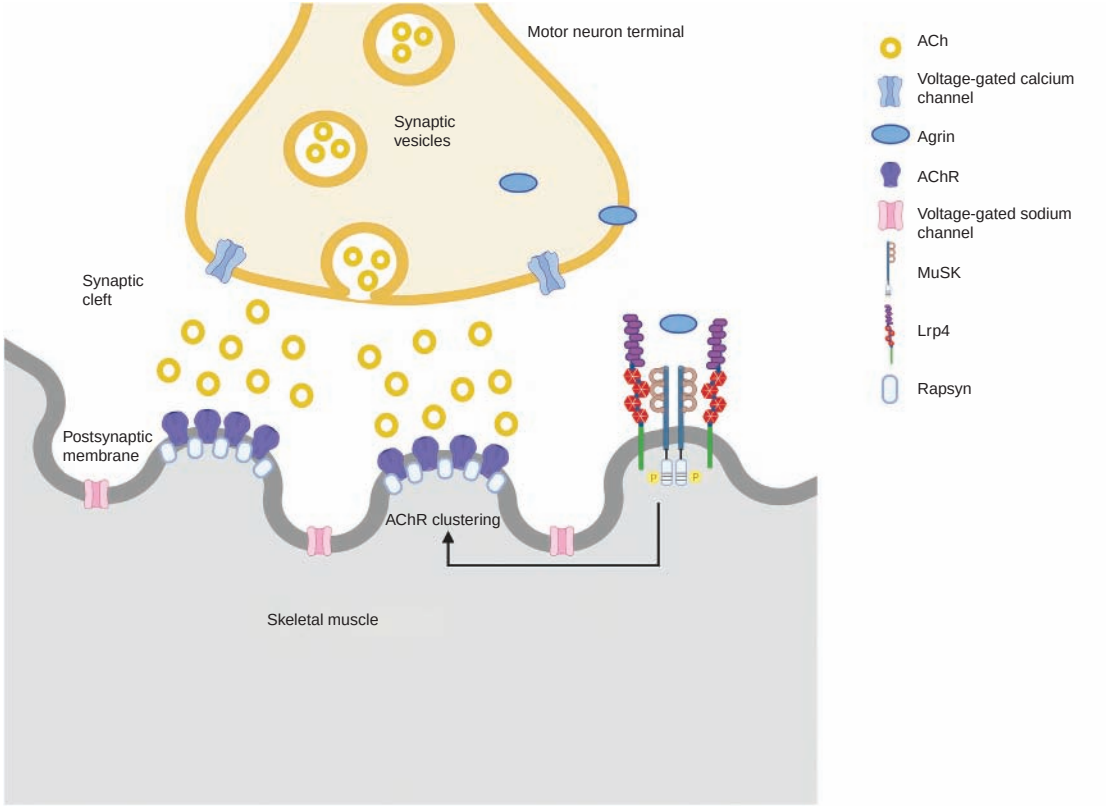

FIG. 65.2 Schematic Representation of the Neuromuscular Junction. Vesicles of acetylcholine *(ACh)* released from the motor neuron into the synaptic cleft in response to impulses conducted down nerve axons. ACh binds AChRs, with the opening of the ion channel and generation of endplate potential. Postsynaptic organization in the skeletal muscle includes AChR clusters at the top of the postsynaptic folds and voltage-gated sodium channels in the troughs. The agrin-Lrp4-MuSK complex is critical for proper AChR clustering. Agrin released from the motor neuron binds MuSK-coreceptor Lrp4 and induces MuSK autophosphorylation. Activation of MuSK stimulates signaling pathways that promote rapsyn-induced clustering of AChR. (Figure generated using BioRender). *AChR*, Acetylcholine receptor; *Lrp4*, low-density lipoprotein receptor-related protein 4; *MuSK*, muscle-specific kinase.

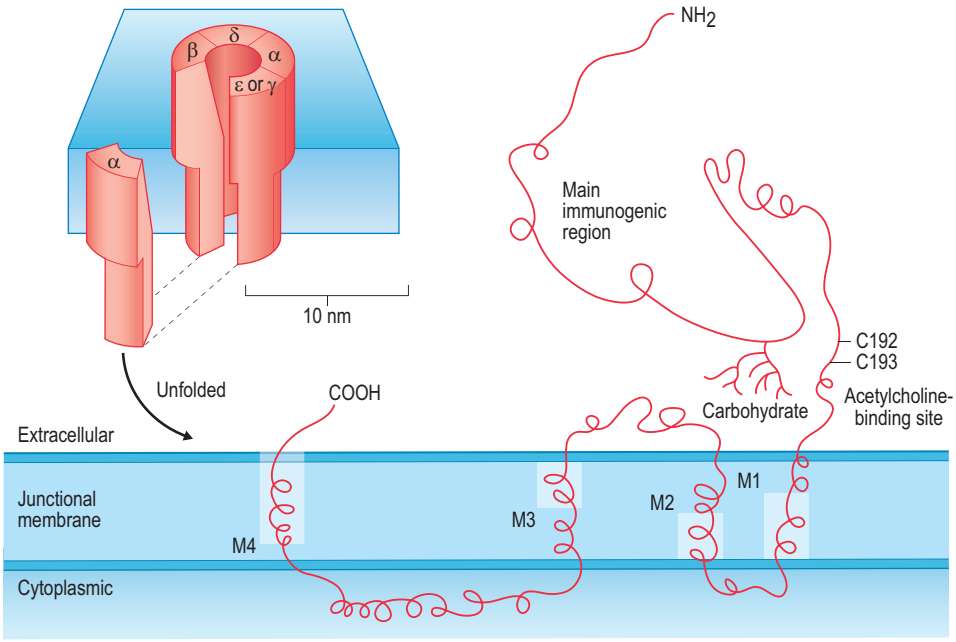

FIG. 65.3 The Acetylcholine Receptor. The subunits of the acetylcholine receptor—α, β, δ, and γ or ε—are arranged like barrel staves around the central ion pore. Each subunit winds through the junctional membrane four times (sites M1, M2, M3, and M4). In the unfolded view of the α subunit, the amino-terminal end of the α subunit is extracellular, where it is accessible to acetylcholine, which binds at the site shown (amino acids 192 and 193). In myasthenia gravis, autoantibodies may bind to various epitopes of all subunits, but a high proportion of autoantibodies bind to the main immunogenic region of the α subunit.

Low-density Lipoprotein Receptor-related Protein 4

Lrp4 is a receptor for neural agrin and subsequently forms a complex with MuSK. Members of the low-density lipoprotein (LDL) receptor-related protein (LRP) family have diverse biological functions, including specific roles in the development and function of the mammalian nervous system. Lrp4 is a single subunit transmembrane protein with a large extracellular domain that contains low-density lipoprotein repeats and is concentrated at the NMJ. Like MuSK- and agrin-deficient mice, genetic screens revealed that mice with mutations in *lrp4* died at birth and did not form NMJ.[12] Thus, Lrp4 plays a role in maintaining and stabilizing the NMJ structure and functions by increasing MuSK activity.

EXPERIMENTAL MODELS TO STUDY MYASTHENIA GRAVIS

Experimental autoimmune MG (EAMG) is induced by immunization of MG autoantigen (AChR, MuSK, or Lrp4). Another model is referred to as passive transfer MG (PTMG) and is the result of injection of pathogenic autoantibodies. The availability of transgenic and knockout mice is an important instrument in identifying the molecular mechanisms underlying the disease. However, several important differences between human and rodent immune responses exist that may impact the applicability to translational work, such as differences in antibody isotype production in response to immunization and species-specific differences in complement activity. Furthermore, there are several aspects of MG pathogenesis that cannot be studied using these models, including the absence of spontaneous disease and lack of thymic involvement and pathology. EAMG has been a critical tool in elucidating the pathogenic mechanisms of autoantibodies in impairing neuromuscular transmission, but also in investigating novel therapeutic approaches.

MECHANISMS OF IMMUNOPATHOGENESIS

MG fulfills the Witebsky postulates that define the criteria of autoimmune disease, which require (1) an autoimmune reaction in the form of autoantibodies or cell-mediated immune reactions, (2) that the autoantigen is known, and (3) an autologous response causes similar disease in an animal model.[13] The immunopathology of MG has been attributed to IgG class autoantibodies specific to the proteins at the postsynaptic membrane of the NMJ and cause organ-specific damage. This is further supported by the short-term improvement of NMJ transmission and muscular strength for patients undergoing plasmapheresis to remove autoantibodies. Anti-AChR antibodies (IgG1 and IgG3 subtypes) are detected in 85% to 90% of MG patients, whereas 5% to 10% of patients are anti-AChR negative and have antibodies against MuSK (IgG4 subtype) and Lrp4 (IgG1 and IgG2 subtypes). Passive transfer of human antibodies to rodents recapitulates the disease in animals, demonstrating that these autoantibodies are responsible for impaired neuromuscular transmission. Furthermore, these autoantibody deposits have been detected at the NMJ in patients and in experimental animal models. These autoantibodies, however, exhibit both structural and functional heterogeneity, which likely contributes to the broad and variable spectrum of muscle group involvement in MG patients.

Role of Pathogenic B cells

B cells play a critical role in the immunopathogenesis of MG as they secrete autoantibodies that target the NMJ, making them an attractive target for therapeutic intervention. The depletion of plasma cells, or antibody-producing cells, with bortezomib reduced anti-AChR titers and weakness in rats.[14] Treatment of MG patients with

rituximab, a treatment targeting CD20+ B cells, has been shown to be effective in refractory MuSK+ MG patients.[15] However, the study of these pathogenic B cells is limited by the exceptionally low frequency of 0.1% to 1% of these cells in peripheral blood. Recent advances in molecular biology are advancing ways to better isolate and characterize these B cells. Novel technologies such as single cell RNA sequencing provide an exciting way forward to better characterize these rare subpopulations of autoreactive B cells and gain further insights in understanding the cellular basis for disease that may lead to novel therapies to target these cells.

The immunological mechanisms contributing to the development and maintenance of autoreactive B cells in MG that produce these autoantibodies are not well understood. Defects in B-cell tolerance checkpoints were found in both AChR and MuSK MG patients.[16] Apoptosis is an important mechanism in central B-cell tolerance that eliminates self-reacting immature B cells from the repertoire of naïve immature B cells in the bone marrow. However, a fraction of B cells is able to escape this stringent selection process. The selection and maturation of these autoreactive B cells in the periphery relies on the strength of the B-cell receptor (BCR) signals it receives as well as survival signals such as B-cell-activating-factor (BAFF). Serum levels of BAFF are elevated in MG patients, but do not correlate with disease severity. Autoreactive B cells from MG patients and EAMG models express an anti-apoptotic marker known as survivin.[17] Furthermore, survivin vaccination in EAMG attenuated disease severity and decreased survivin-positive CD20+ cells, suggesting it plays a role in maintenance of autoreactive B cells. The factors that regulate and promote survivin expression in several autoimmune diseases, including MG, have yet to be elucidated.

Pathogenic Autoantibodies

The differences in clinical phenotypes associated with the subtypes of MG can be attributed to their differences in serum autoantibody targets. Here, we discuss the well-characterized molecular pathogenic mechanisms of autoantibodies in MG and their contribution to disease outcomes.

KEY CONCEPTS

Effects of anti-AChR antibodies in MG pathology:
- Reduced numbers of receptors
- Widening of synaptic cleft
- Injury to synaptic membrane

Mechanisms of damage and reduced neuromuscular transmission:
- Complement-dependent damage to muscle endplate
- Enhanced rate of AChR degradation
- Block of cholinergic binding sites

Acetylcholine Receptor Autoantibodies

The pathogenicity of AChR antibodies was first reported in the 1970s. Passive transfer of either human AChR antibodies or immunization of animals with AChR has been shown to induce EAMG in rodents.[18] These antibodies are polyclonal and heterogeneous, primarily of the IgG1 and IgG3 subtypes, and are directed against the α_1- extracellular domains containing the immunogenic region of overlapping epitopes. Together, these antibodies decrease levels of AChR and reduce postsynaptic folding. However, disease severity does not correlate with serum levels of AChR antibodies and patients with AChR-antibody positive MG exhibit high variability in the distribution of muscle weakness. These observations indicate that additional factors could contribute to disease severity, such as genetic factors, capacity of autoantibodies to activate the complement system, and qualitative differences in antibodies, including variations in IgG isotype distribution, epitope specificities, and binding avidity to AChR.

There are three known effector mechanisms of AChR antibodies that reduce the density of AChR and affect the structural integrity of the postsynaptic region, resulting in impaired neuromuscular transmission (discussed below).

Complement Activation and Destruction of Neuromuscular Junction

The classical pathway (CP), an antibody-dependent activation of the complement system leading to direct lysis of targeted cells, is considered the major contributor to destruction of the postsynaptic membrane in MG. AChR antibodies that bind the NMJ activate the CP and result in membrane attack complex (MAC) formation. The presence of immune complexes and C3 at the motor endplate, the localization of the MAC at the junctional folds, and evidence of injury of the postsynaptic membrane in MG patients demonstrates a role for complement contributing to loss of AChR and NMJ ultrastructure. EAMG-induced mice deficient in complement proteins C3 and C4 were resistant to EAMG. The presence of immune complexes at the NMJ in these EAMG animals did not result in the MAC and reduced AChR. Furthermore, administration of C5 complement inhibitor, an siRNA to silence C5 expression, or anti-C5 antibody was shown to limit the severity of EAMG by ameliorating weakness and reducing C9 deposition at the NMJ.[19] Recently, treatment of MG patients with eculizumab, an antibody that prevents the enzymatic cleavage of C5, has been demonstrated to reduce severity of generalized AChR-antibody-positive MG.[19]

Experimental targeting of CP-specific components such as C1q and C4 have shown to be effective in alleviating EAMG. However, the alternative pathway (AP) is estimated to contribute up to approximately 80% of C3b activation, which rapidly amplifies complement activation and deposition by utilizing CP C3b to generate AP C3 convertases. Recently, an antibody blocking AP convertase formation by targeting Factor B protected rats from EAMG and MuSK positive MG patients were shown to exhibit higher consumption of AP Factor B, but not CP component C4,[20,21] suggesting a possible role for the AP in MG. Both soluble and membrane-bound regulators play an important role in regulating the AP amplification loop on cell surfaces. Studies have shown that membrane bound decay accelerating factor (DAF) is critical for protecting from exacerbated disease in EAMG models.[19] Furthermore, a single nucleotide polymorphism (SNP) in the human *DAF* gene has been associated with severe ocular MG.[22] Thus, these findings indicate that targeting multiple points of complement system activation is an important clinical target for MG treatment.

Acceleration of Acetylcholine Receptor Degradation (Antigenic Modulation)

The main antigenic region (MIR) of AChR consists of conformational-dependent epitopes targeted by a majority of AChR antibodies. AChR antibody binding to MIR is oriented in a way that promotes cross-linking of two AChRs by a single antibody. Early studies indicated that AChR antibodies increased the rate of AChR degradation. The bivalent nature of IgG autoantibodies

promotes cross-linking of AChRs in the membrane, resulting in rapid endocytosis and degradation and further contributing to a reduced number of AChR at the postsynaptic membrane.[23]

Receptor Blockade

AChR antibodies in MG sera are polyclonal and exhibit heterogeneity in antigenic specificity. Not all AChR antibodies have the capacity to cross-link two AChRs or activate complement, and thus may exhibit different functionalities. AChR antibodies were additionally shown to block the alpha-bungarotoxin binding site of the receptor[24] and thus are characterized by their ability to block the ACh-binding sites and interfere with ACh released at the NMJ to impair neuromuscular transmission.

Muscle-Specific Kinase Autoantibodies

About 5% to 10% of MG patients have autoantibodies against MuSK. Either immunization with MuSK or passive transfer of human MuSK antibodies have also been shown to induce pathology in mice. Patients with these autoantibodies have more prominent involvement in facial and bulbar weakness and exhibit more respiratory crises, whereas limb weakness is not common. These antibodies are typically subtype IgG4, and unlike AChR antibodies, do not activate complement or bind Fc receptors. Furthermore, the IgG4 antibodies have structural differences in the Fc region and can exchange Fab arms with other IgG4 molecules, which renders them bispecific (i.e., recognizing two different antigen) and functionally monovalent; hence they do not cross-link antigen.

The pathogenic mechanisms of MuSK antibodies that lead to failure of neuromuscular transmission are distinct from those observed in AChR MG. Passive transfer of human MuSK antibodies to mice revealed structural changes at the postsynaptic membrane, such as diminished AChR and MuSK densities, suggesting that the mechanisms in MuSK MG may involve changes in the function and distribution of key molecules at the NMJ.[25,26] Epitope mapping and functional studies of MuSK antibodies demonstrated they predominately recognize the N-terminal Ig-like domain of MuSK, inhibiting the MuSK-Lrp4 interaction, preventing MuSK dimerization and autophosphorylation, impairing the clustering of the AChR, ultimately resulting in impaired neuromuscular transmission.[27] However, MuSK antibodies are also heterogeneous, containing other IgG subclasses and recognizing other domains on MuSK. The pathogenic mechanisms of these antibodies are not yet well understood. Importantly, the distinct immunopathogenesis of MuSK antibodies indicates that therapies targeting complement would not be suitable treatment for this MG patient subtype.

Lrp4 Autoantibodies

Some patients without AChR and MuSK antibodies have been identified to possess autoantibodies that bind Lrp4. Mice immunized with Lrp4 or passive transfer of Lrp4 antibodies to naïve mice promoted weakness and NMJ defects similar to those of MuSK-EAMG.[28,29] Furthermore, Lrp4 antibodies from mice immunized with Lrp4 were shown to diminish agrin-induced MuSK phosphorylation of C2C12 myotubes and fix complement in vitro, demonstrating potential pathological mechanisms of these antibodies.

Role of Thymus Pathology

The thymus is a primary lymphoid organ that provides a specialized environment for T-cell development, maturation, and negative selection of self-reactive T cells. Most AChR antibody-positive MG patients have thymic pathology, indicating a strong likelihood that the thymic abnormalities are critical for development of MG. Follicular hyperplasia is most commonly observed in 65% to 75% of early-onset patients, whereas 10% of patients have a thymoma. Thymectomy in these patients is associated with clinical improvement and a decrease in AChR antibodies. However, the exact mechanisms by which these thymic pathologies promote autoreactivity in MG is not clear.

Thymuses with follicular hyperplasia in MG have increased numbers of lymphoid germinal centers that is not typical. In AChR antibody positive MG, the degree of follicular hyperplasia often correlates with serum levels of AChR antibodies, suggesting thymic hyperplasia is associated with autoantibody production. Several pathological alternations of the hyperplastic thymuses in MG patients cumulatively provide a rich microenvironment for immune sensitization to AChR. First, both medullary thymic epithelial cells and myoid cells have been shown to express AChR or AChR-like proteins.[30] Second, both thymic effector and regulatory T cells in these MG patients exhibit immunoregulatory defects. Lastly, the presence of increased germinal centers in the thymus is associated with a heterogeneous population of B cells that have undergone clonal expansion and somatic hypermutation.[31] MG patients with thymic hyperplasia have high levels of CXCL13, a chemokine involved in homing B cells to lymphoid tissue, in serum and in the thymus.[32] The expression of BAFF and APRIL, two critical B-cell survival factors, is also abundant in hyperplastic thymuses,[33] which could play a role in differentiation and survival of autoreactive B cells.

About 10% of MG patients have a thymoma. These thymic tumors in MG patients are derived predominately from cortical epithelial cells and exhibit reduced medullary areas. The lack of a functional medulla in thymoma patients may play a role of promoting dysregulated tolerance mechanisms, which includes altered expression of autoimmune regulator AIRE and regulatory T cells (Tregs) and defective expression of human leukocyte antigen (HLA) class II molecules. Furthermore, the epithelial cells are surrounded by mature T cells and express muscle protein epitopes such as AChR, allowing for intrathymic autosensitization to self-antigen. The presence of follicular helper T cells, which play a role in germinal center formation, B-cell maturation, and antibody production, may also play a role in these processes. Together, these studies strongly suggest that thymic pathology in MG patients is associated with a microenvironment associated with dysregulated self-tolerance mechanisms.

KEY CONCEPTS

Pathogenic Roles of Thymus in Myasthenia Gravis

Pathological
- 65% to 75% of MG patients have follicular hyperplasia with germinal centers
- 10% have thymoma

Clinical
- Improvement after thymectomy
- Decrease in AChR antibodies

Immunological
- AChR subunits expressed on myoid cells and thymic epithelial cells
- AChR-reactive T and B cells localized in the thymus
- AChR antibodies secreted by thymic B-cell lineage
- Decreased thymic regulatory T cell (Treg) function
- Overexpression of proinflammatory cytokines and chemokines

Role of T cells

MG is a B-cell-mediated T-cell-dependent disease. B cells require interactions with $CD4^+$ helper T cells to generate high-affinity AChR antibodies. Autoreactive T cells specific for AChR have been detected in both generalized and ocular MG patients. It is unclear how these T cells break tolerance and regulate autoantibody production, but evidence suggests that different subpopulations of CD4 T helper cells and their effector cytokines may be involved in the pathogenesis of MG. Tregs play a role in regulating helper T cells by maintaining immune homeostasis and regulating autoreactive cells. Both circulating and thymic Tregs from MG patients are unable to suppress responder T cells and were associated with reduced levels of Foxp3.[34] Th17 cells have also been implicated, as their frequency and their cytokines are both increased in MG patients with thymoma. Recently, a novel T-cell library assay to screen for rare antigen-reactive T cells demonstrated that $CCR6^+$ memory T cells from MG patients, but not healthy controls, produced INF-γ and IL-17 in response to AChR.[35] The subpopulations of helper T cells prominent in MuSK MG is not yet defined; however, cytokine analyses of T cells from these patients demonstrate that CD4 and CD8 T cells also have increased Th1 and Th17 cytokine responses upon in vitro stimulation.[36]

EAMG models have also been used to investigate and validate the role of T cells and their effector cytokines in the pathogenesis of MG. Studies investigating the role of Th1 effector IFN-γ in EAMG are contradictory in their phenotypes. However, IL-12/IL-23 and IFN-γ double knock-out mice were shown to develop EAMG, indicating Th1 cells may not be necessary to induce an autoimmune condition.[37] These DKO mice exhibited a similar level of IL-17 production and had reduced Treg suppressive activity compared to wild-type mice, suggesting these Th subsets may play an important role. Another study demonstrated that the balance of helper T-cell subsets is dysregulated during the development of disease, with a particular upregulation of Th17 cells.[38] However, based on these studies, how these effector cells contribute toward the development of EAMG is not clear.

Recently, evidence of locally produced complement by activated lymphocytes has demonstrated a novel role for the complement system in regulating the function of T cells. Autocrine signaling through anaphylatoxin receptors C3aR and C5aR promotes Th1 and Th17 effector responses, and absence of this signaling results in polarization of $Foxp3^+$ Tregs in the murine model (reviewed in Le Friec et al.[39]). Deficiency in DAF, a membrane-bound regulator of complement activation, also results in enhanced T-cell responses and leads to exacerbation of several experimental autoimmune diseases, indicating a suppressive role in T-cell function. Interestingly, early-onset MG patients with thymic pathologies demonstrated increased complement activation in the thymus, with increased levels of C1q and C3, increased expression of anaphylatoxin receptors (C3aR, C5aR), and decreased expression of complement regulatory proteins CD46 and CD55.[40] However, the role of complement regulation of T cells has not yet been investigated in the context of MG. Given the evidence of complement activation in the thymus and its known role in regulating effector T-cell responses, this novel line of inquiry could provide additional insight into possible mechanisms of dysregulated T-cell responses in MG.

Epigenetic Factors: Role of miRNAs

Genetic studies and genome-wide association studies have identified several important genetic loci associated with disease and development of MG, including several HLA alleles, *TNIP1*, and *TNF-α* (reviewed in Avidan et al.[41]). Environmental factors, such as infection, microbiota, drugs, and pollutants can also cause epigenetic changes that may contribute to MG. The initiation of MG is thought to be multifactorial, involving genetic and environmental influences.

Emerging evidence of aberrant microRNA expression has been associated with several diseases, including autoimmunity. These regulatory small non-coding RNAs regulate posttranscriptional gene expression by binding to complementary sequences in the 3′ untranslated regions (UTRs) of target mRNAs. Several miRNAs that are known to regulate immunity through proliferation, apoptosis, and differentiation of immune cells have recently been found to be differentially expressed in MG patients.[42,43] The thymus pathology in MG, as described above, involves changes in the miRNA express for $AChR^+$ EOMG, and TAMG. Regulation of these miRNAs is associated with germinal center formation, such as miR-7, miR-24, miR-139, miR-143, miR-145, miR-146, miR-150, miR-452, miR-548, or thymic inflammation, such as miR-125b, miR-146, or miR-29.[44] The changes in the miRNAs due to MG do not reflect the miRNAs necessary for development of the thymus, suggesting the mechanism of dysregulation does not involve upregulation of fetal pathways. Circulating miRNA demonstrate differences based on MG classification. Generalized $AChR^+$ EOMG and LOMG express elevated miR-150-5p and miR-21-5p and is reduced with immunosuppression. However, miR-30e-5p is also elevated in generalized LOMG $AChR^+$ patients' sera. With circulating miRNAs, $MuSK^+$ MG patients demonstrate higher levels of the let-7 family. The expression of elevated miRNA-150-5p in circulation is lowered with thymectomy. Thus, circulating miRNAs may serve as biomarkers for disease progression or therapeutic response. miRNAs in MG may also function to regulate genes involved in immune B-cell survival and cytokine production, which can contribute to MG pathogenesis and thus can also serve as therapeutic targets. Due to the multiple binding sites and regulation of miRNA on various pathway, the role of specific miRNAs in MG remains unknown and requires further investigation.

TREATMENT

Treatment of MG needs to be individualized based on a patient's severity of weakness, autoantibody status, age, gender, and comorbidities. Guidelines for therapeutic approaches have been proposed by groups across the globe. Although there is commonality, there are also differences that highlight variations in care patterns across nations.[45–47] The following sections provide a brief overview of therapies that is not designed to guide therapy. For a comprehensive review of MG treatment, see reference Wang et al.[48]

ACETYLCHOLINESTERASE INHIBITORS

For mild to moderate weakness, AChE inhibitors, most commonly pyridostigmine bromide, are the first line of treatment and for some are the only therapy required.[49] By retarding the hydrolysis of ACh at the NMJ, they increase the chance of

achieving an EPP to activate an action potential at the injured NMJ. Despite the elegant solution to the electrophysiological defect, pyridostigmine usually does not resolve weakness, must be dosed every few hours, and patients often have adverse effects of activation of the muscarinic cholinergic receptors, in particular nausea, bloating, and diarrhea.

CORTICOSTEROIDS

Oral corticosteroids are the most consistently effective medication for MG but also have the poorest adverse-effect profile.[50] Expert opinion and investigations vary considerably in what the ideal dosing should be, but all regimens are provided for months and often years at doses that produce complications.[4,47] A large minority, perhaps a third of patients respond poorly or are intolerant. Treatment resistance is likely related to variations in lymphocyte sensitivity to corticosteroids and unknown factors that define disease severity. Corticosteroids act by binding the glucocorticoid receptor and thereby influence transcriptional pathways that are known to impact apoptosis of lymphocytes and reduce proinflammatory cytokine activity.

THYMECTOMY

As described above, thymic pathology is a hallmark feature of MG for many patients and removal of the thymus in AChR-antibody-positive MG was found to be beneficial in a randomized controlled trial compared to prednisone therapy alone.[51] However, upwards of 30% of patients did not derive significant benefit, indicating that there continues to be a maintenance of pathogenic antibody production. All patients with a thymoma must have it removed to prevent local spread or more malignant transformation, but resection of the tumor and residual thymus does not produce remission. Patients who are seronegative or with MuSK antibodies are not thought to have thymic pathology and thymectomy is generally not performed.

IMMUNOSUPPRESSANTS

Because of the limitations of corticosteroids, a number of immunosuppressants are used in the treatment of MG, usually to reduce the burden of corticosteroid treatment. The importance of steroid sparing is so important that many clinical trials have used reduction of overall corticosteroid dose as a primary outcome measure for efficacy. The first agent to be used was azathioprine,[4] which inhibits purine synthesis leading to inhibition of lymphocyte replication.[52,53] Azathioprine may take more than a year to have a treatment effect and carries an increased risk of neoplasia, particularly lymphoma, with long-term use. Azathioprine also carries a risk of significant hepatotoxicity and myelosuppression. A commonly used agent in the United States is mycophenolate mofetil, which inhibits the de novo pathway for purine synthesis[54] leading to selective inhibition of lymphocyte proliferation. Several months are required to observe a treatment effect. Overall, mycophenolate is well-tolerated, but significant leukopenia and atypical infections may occur. Mycophenolate is a teratogen and should not be used for women intending to become pregnant and may increase the risk of malignancy. Tacrolimus and cyclosporine are calcineurin inhibitors, which produce modulation of T-cell activation. Cyclosporine was first applied to MG treatment in the 1980s, demonstrating a steroid-sparing effect but with significant renal toxicity and increased rates of hypertension. Tremor and paresthesias may also occur and generally resolve after dose adjustment. Tacrolimus has a better safety profile and is widely used in Japan and in Europe.

Other immunosuppressives have been less commonly used. Methotrexate is another inhibitor of pyrimidine and purine syntheses and expected to inhibit cellular proliferation of autoreactive lymphocytes. Despite its frequent use in other autoimmune disease, it is not often used for MG and a randomized controlled trial of methotrexate did not find a steroid-sparing effect. Methotrexate can cause liver injury and significant anemia. Oral and intravenous cyclophosphamide has been used for patients failing other therapies. Cyclophosphamide inhibits lymphocyte replication and has been found to affect the balance of Th2 and Th1 cells, reduce proinflammatory cytokines, and modulate dendritic cell activation. Autologous hematopoietic stem-cell transplantation has been used in combination with cyclophosphamide. Cyclophosphamide can produce severe adverse effects including having carcinogenic and teratogenic potential.[48]

INTRAVENOUS IMMUNOGLOBULIN AND PLASMA EXCHANGE

Intravenous immunoglobulin (IVIG) and plasma exchange are used for significant MG exacerbations, with both therapies designed to reduce levels of pathogenic antibody rapidly but with no effect on antibody production. In rare situations, patients are provided chronic treatment in order to avoid adverse effects of prednisone and immunosuppression, but remission would not be expected with such a treatment plan. IVIG has been considered to have multiple effects on the immune system, but the predominant effect is likely through anti-idiotype recognition and interference with antibody recycling through neonatal Fc receptor (FcRn) pathways. Improvement from IVIG infusion may be seen within days but is often on the order of weeks. Headache is common during and soon after infusion and some patients experience flu-like symptoms and mild rash. Rarely, thrombosis may occur, leading to pulmonary embolism, stroke, and myocardial infarction. Plasma exchange is performed with resins designed to remove proteins of certain molecular weights, particularly circulating antibodies. A total of no more than six exchanges are done with benefit observed at times after one exchange; however, patients may take 2 weeks to improve. Significant complications are related to the large-bore catheters used by some centers to perform exchanges. Plasma exchange and IVIG have similar efficacy, with IVIG having fewer adverse events.

ECULIZUMAB

Eculizumab was approved for use by the US Food and Drug Administration (FDA) for generalized AChR-antibody-positive MG in 2017. The drug is a monoclonal antibody directed against the C5 component of complement. From use in other complement-mediated diseases and MG, eculizumab has been found to have a good safety record, but does carry the potential risk of infection with capsulated bacterium, particularly meningococcus, leading to the requirement for appropriate pre-treatment vaccination. Rarely a patient may be treatment resistant because of a genetic variant of the C5 epitope to which it binds. Eculizumab also suffers from being an extremely expensive drug with a cost of several hundred thousand dollars per year in the United States. Clinical trials have shown benefit for use of eculizumab in AChR+MG patients.[55] Eculizumab

has been the first therapeutic to be approved for treatment of MG through the FDA.

THERAPIES UNDER DEVELOPMENT

In the last decade there has been an explosion of therapeutic development for MG. There are several motivations for this, but the detailed understanding of key aspects of MG pathophysiology, as described above, is the key driver, coupled with significant unmet need. For detailed and more expansive discussion please see reference Wang et al.[48] Below we describe therapies that have been under evaluation.

REDUCING EFFECTOR ACTIVITY: MODERATION OF AUTOANTIBODY LEVELS AND COMPLEMENT INHIBITION

Inhibition of IgG recycling is the subject of two phase 3 trials. IgG molecules in circulation undergo endocytosis by endothelial cells, where the IgG binds the FcRn, and are then returned to the circulation.[56] Monoclonal antibodies against the FcRn disrupt FcRn-IgG interaction, which results in IgG catabolism leading to a reduction of serum IgG levels, including pathogenic antibodies. The validation of complement inhibitor therapy has led to motivation to improve on eculizumab. A small-molecule inhibitor of C5, administered as a daily subcutaneous injection, was found safe with a signal efficacy in a phase 2 study.[57]

MODERATING PROINFLAMMATORY SIGNALS

Focused moderation of proinflammatory signals has been a target of therapy with disappointing results. Etanercept, a TNF-α inhibitor, reduced steroid requirements in a small number of patients; however, some patients worsened with treatment. Because of elevated BAFF, serum levels and its role in promoting B-cell activation, as well as promising preclinical data, belimumab, an antibody directed toward BAFF, was initiated but failed to show an efficacy signal.[58]

Lymphocyte-Targeted Therapy

Nearly all B cells express the cell-surface antigen CD20. Rituximab, a chimeric IgG1 monoclonal antibody that targets CD20, is commonly used in clinical practice, but to date there has not been a clinical trial to confirm its efficacy. A phase 2 trial for patients with AChR antibody-positive MG failed to show reduction of corticosteroid dose. In a prospective, non-randomized study of MuSK antibody-positive patients, rituximab reduced the prednisone dose together with clinical improvement. Antibody-producing cells are mostly CD20 negative and would not be directly affected by rituximab. Bortezomib and ixazomib are proteasome inhibitors used in the treatment of cancers of lymphocytic origin. Each has been assessed in animal models of MG with benefit and applied to other autoimmune diseases but has not moved to clinical testing. CD19-directed antibodies are also being considered for clinical trials in MG. With the central role of lymphocytes in autoantibody production one could expect a significant therapeutic benefit; however, the emergence of the COVID-19 pandemic leads to a significant concern of exacerbation of the severity of the infection and a poor response to vaccination, if used.

As described above, T cells drive the B-cell activity of MG. Abatacept is a drug composed of the extracellular domain of human cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) and a modified Fc region of human immunoglobulin leading to blockade of the co-stimulatory signal to activate T cells that is mediated by CD80/CD86. Abatacept inhibits T-cell activation, resulting in reduced levels of proinflammatory cytokines that are implicated in MG. Monoclonal antibodies targeting the CD40–CD40L interaction are undergoing clinical trials (NCT02565576). Antigen-presenting cells constitutively express CD40 on their surface. Activated CD4 T cells interact with CD40 through CD40L (CD154), leading to enhanced humoral immune responses. Preclinical studies have been positive.

Induction of Tolerance

Several preclinical studies have been performed to induce tolerance by administration by various routes of nonpathogenic portions of the AChR. A phase 1b study of CV-MG-101 is underway. CV-MG01 is a combination of two synthetic peptides that complement the structure of the main immunogenic region of the AChR. The hope is for the exogenous peptide to induce anti-idiotypic and anti-clonotypic responses against binding sites of antigen receptors on autoreactive lymphocytes and reduce their activation. Stem-cell transplantation approaches have also been used in a limited number of patients to re-induce a state of tolerance as the new immune system repopulates. This is reserved for a small number of highly treatment-resistant patients and has had mixed results.

ON THE HORIZON

Future Directions for the Development of Immunomodulatory Therapies

Development of MG-specific immunotherapies based on immunopathogenic events:

- Molecular pathways driving autoantibody production
- B-cell-lineage inhibitors
- Anti-apoptotic markers on autoreactive B cells
- Aberrant microRNA expression
- Complement inhibitors targeted to the NMJ

FUTURE STUDIES

MG has long been considered to be among the best understood autoimmune disorders, fulfilling strict criteria of autoimmunity. With the discovery that autoantibodies drive its final effector mechanism, antibody removal approaches, such as plasma exchange, IVIG, and FcRn inhibition, have been applied as therapies. Definition of complement destruction as a driver of NMJ injury spanned application of complement inhibitors for MG. Although these treatments can produce dramatic improvement, they also identify patients who remain treatment resistant and do not ultimately moderate autoantibody generation. Existing immunosuppressive therapies act broadly and also do not effectively eliminate production of autoantibodies. Although the presence of autoantibodies is a good biomarker for disease diagnosis, autoantibodies do not predict the response to treatment, disease progression, or disease severity. In order to improve therapeutic development, including reducing the time of clinical trial, improvement in biomarkers, and illuminating the defects leading to induction, as well as maintenance of autoantibody production, additional study will be required. Given the advances in the last decade we can hope that the next decade will bring the field closer to these discoveries.

Multiple Sclerosis

Andrew R. Romeo and Benjamin M. Segal

Multiple sclerosis (MS), a chronic inflammatory demyelinating disorder of the central nervous system (CNS), is the most frequent cause of nontraumatic neurologic disability among young adults in the Western Hemisphere. Although MS is widely considered a disease of North America and Europe, there is increasing evidence that it is more common in other regions of the world than previously appreciated, including Asia and the Middle East. The median age of presentation is between 28 and 31 years, in part responsible for the disproportionately high social and economic toll of the disease. Furthermore, the incidence of MS is increasing for unknown reasons. Fortunately, there have been dramatic advances in the treatment of relapsing forms of MS over the past 20 years, spurred by the introduction of a growing number of disease-modifying therapies (DMTs), and more are actively under development. These treatments significantly decrease the risk of future relapse and lesion formation. Consequently, the implications of a relapsing-remitting (RR) MS diagnosis have changed considerably in the span of a generation. Despite this success, significant challenges remain. There is a dire need for more effective treatments that slow or halt disability accumulation in patients with progressive forms of MS, and for interventions that restore lost neurologic functions across MS subsets.

CLINICAL SUBSETS AND PHENOMONOLOGY

Relapsing-Remitting Multiple Sclerosis

In the majority of cases (85% to 90%), MS presents with a RR course, characterized by discrete episodes of neurologic dysfunction (relapses) separated by clinically quiescent periods (remissions). The frequency of relapses can vary widely between people with MS, as well as during different time periods of an individual's disease course. Currently, no clinical features or biomarkers have been identified that are predictive of relapse rate. The signs and symptoms of relapses are also diverse and unpredictable, because lesions can form at any site in the CNS, spanning the cerebrum, brainstem, cerebellum, optic nerves, and spinal cord. The peripheral nervous system is spared.

MS lesions are visualized in CNS white matter via magnetic resonance imaging (MRI) (Fig. 66.1). Symptomatic lesions generally occur in locations where nerve fibers converge to subserve a common function. Typical presentations of RRMS include optic neuritis with monocular visual deficits (secondary to lesions in the optic nerve); myelitis with weakness and numbness in the extremities, sometimes accompanied by incontinence (due to spinal cord lesions); and brainstem syndromes manifested by imbalance, tremor, double vision, slurred speech, or swallowing difficulties. Serial MRI studies have demonstrated that the majority of MS lesions are actually clinically silent; redundant nerve fiber tracts are abundant, and large areas of cerebral white matter are committed to personality traits and cognitive skills. Consequently, CNS tissue damage may be inflicted surreptitiously during clinical remissions, making MRI a more sensitive indicator of disease activity than the history or neurologic exam.

People with MS often recover function following a clinical relapse, partially or fully, particularly during the early clinical course. Old symptoms can temporarily reemerge when core body temperature is elevated due to infection, strenuous exercise, or environmental conditions. This unmasking of latent deficits, called the Uhthoff phenomenon, is a consequence of the physiologic slowing of axon signal propagation that normally occurs at high core body temperatures. In healthy individuals the degree of slowing has no clinical consequence, but in MS patients it may precipitate the decompensation of white matter tracts already compromised by demyelination and axonal drop out.

Secondary Progressive Multiple Sclerosis

During the course of RRMS, relapses decrease in frequency over time and sometimes disappear completely. In the vast majority of cases they are replaced by an insidious, gradual accumulation of disability, referred to as the secondary progressive (SP) stage. Progressive myelopathy, hemiparesis, and/or gait imbalance are common. Subcortical dementia is increasingly recognized as a feature of the disease. Longitudinal natural history studies conducted before DMTs were widely available found that the majority of RRMS patients transitioned to an SP stage within 15 to 25 years of initial disease presentation. A 2010 epidemiologic study of MS patients in British Columbia found that the median time to secondary progressive multiple sclerosis (SPMS) onset was 21.4 years.[1] Factors that are associated with both a shorter time to, and younger age at, evolution to SPMS include male gender, the presence of motor symptoms at clinical onset, and history of poor recovery from relapses. Previous longitudinal observational and retrospective cohort studies that investigated whether treatment with first-generation DMTs alters the time to reach SPMS yielded conflicting results. However, a prospective study of 517 patients actively treated with second-generation DMTs found that rates of worsening and evolution to SPMS were substantially lower when compared with earlier natural history studies of untreated patients.[2]

The cellular and molecular mechanisms underlying the conversion from an RR to an SP course are poorly understood. Some investigators have questioned the relevance of neuroinflammation during the SP stage and have evoked neurodegeneration (in the form of neuronal death, mitochondrial dysfunction of axons, wallerian degeneration, and gliosis) as

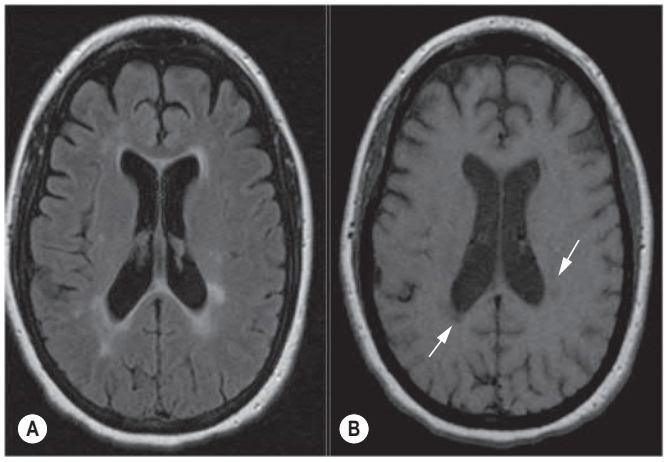

FIG. 66.1 (A) T2-weighted fluid-attenuated inversion recovery (FLAIR) magnetic resonance imaging (MRI) image of the brain of a multiple sclerosis patient showing hyperintense lesions located in the periventricular and subcortical white matter. (B) T1-weighted MRI image showing T1-black holes (*arrows*), indicative of profound axonal loss, and generalized atrophy with enlarged ventricles.

primarily responsible for the clinical deterioration that ensues following an initial period of immune-mediated damage.[3] Conversely, there is evidence of persistent immune dysregulation in SPMS, although it may differ from RRMS with regard to the cytokine networks and leukocyte subsets involved, as well as the distribution of infiltrating cells within the CNS.[4–6] Previously, a number of DMTs that are therapeutically beneficial in RRMS were found to be ineffective in slowing disability accumulation in SPMS.[7] However, potent lymphocyte-targeting therapies (cladribine and siponimod) were recently shown to curtail CNS tissue damage and clinical progression in subsets of individuals with SPMS, particularly those with ongoing or recent inflammatory activity ("active SPMS"), as indicated by superimposed clinical relapses and/or new T2 or enhancing lesion formation.[8,9] The management of SPMS still largely involves alleviation of symptoms, optimization of residual functions, and prevention of complications.

Primary Progressive Multiple Sclerosis

Primary progressive multiple sclerosis (PPMS) is distinguished from SPMS by the absence of an antecedent RR phase. Otherwise, the clinical features of SPMS and PPMS can be indistinguishable. The most common clinical phenotype is spastic paraparesis, followed by cerebellar dysfunction, and hemiplegia. There are striking demographic differences between PPMS and RR/SPMS. PPMS tends to present at an older age (peaking in the fifth and sixth decades) than RRMS (which peaks in the third and fourth decades). Although RRMS occurs two to three times more frequently in females than males, in PPMS the sex ratio is closer to 50:50. The neuropathologic and radiologic features of PPMS overlap extensively with those of SPMS, leading some investigators to conclude that PPMS and SPMS belong to the same disease spectrum. Familial clusters of MS that include members with PPMS and others with RR/SPMS, support that viewpoint. Possibly, analogous to SPMS, acute inflammatory lesions form during early stages of PPMS, prior to overt clinical progression, but happen to arise exclusively in clinically silent areas. Other investigators have argued that PPMS is a distinct disease entity driven initially and primarily by neurodegenerative processes.[3] This stance is supported by the general failure of first-generation immunomodulatory agents to attenuate the course of PPMS. Conversely, treatment with ocrelizumab, a B cell–depleting monoclonal antibody, delayed disability progression in a subset of relatively young subjects with PPMS.[10] The positive trial of siponimod in active SPMS is reminiscent of the positive trial of ocrelizumab in PPMS.[9] The pathogenesis of progressive MS, including PPMS, appears heterogeneous; the relative contributions of inflammation and neurodegeneration to clinical outcomes likely vary between patients.

CLINICAL PEARLS

- Multiple sclerosis (MS) presents with a relapsing-remitting course in the majority of cases (85%–90%).
- The symptoms and signs experienced by MS patients are diverse; lesions can form at any site in the central nervous system, including the optic nerves, cerebrum, brainstem, and spinal cord.
- The rate, severity, and symptoms of relapses are highly variable and unpredictable.
- Most MS lesions form silently; magnetic resonance imaging scans are a more sensitive gauge of disease activity than the history or neurologic exam.
- Acute relapses tend to decrease in frequency over time and are typically replaced by a gradual accumulation of disability. This later phase of disease is referred to as secondary progressive MS (SPMS).
- Less frequently, MS begins with a progressive course, referred to as primary progressive MS (PPMS).

DIAGNOSIS

The McDonald criteria are the most widely used guidelines for diagnosing MS. Originally proposed by the International Panel on Diagnosis of Multiple Sclerosis in 2001, they were revised most recently in 2017 (Table 66.1).[11] An MS relapse is "a clinical episode with patient-reported symptoms and objective findings typical of MS, reflecting a focal or multifocal inflammatory demyelinating event in the CNS, developing acutely or subacutely with a duration of at least 24 hours, with or without recovery, and in the absence of fever or infection." RRMS is, by definition, a dynamic multifocal inflammatory demyelinating disease of the CNS. Therefore the demonstration of lesion dissemination in time and space is essential for diagnosis. Dissemination in space can be demonstrated by objective clinical evidence of involvement of two or more sites in the CNS (based on neurologic exam and/or delayed latencies on evoked potential testing) or by the presence of T2-weighted MRI lesions in at least two of the following areas in the CNS: periventricular, juxtacortical/cortical, infratentorial, and spinal cord. The criterion for dissemination in time can be satisfied by either two or more distinct clinical relapses, one relapse followed by the interval appearance of a new lesion on serial MRI scans, or the simultaneous presence of gadolinium-enhancing (i.e., acute inflammatory) and nonenhancing MRI lesions. The presence of cerebrospinal fluid (CSF)-specific oligoclonal bands may substitute for clinical and/or radiographic demonstration of dissemination in time.

When a patient has had one clinical attack typical of inflammatory demyelination, and the criterion for dissemination in time is not satisfied, the diagnosis is clinically isolated syndrome (CIS). The presence of two or more typical demyelinating lesions on MRI, that do not localize with the presenting

TABLE 66.1 Revised McDonald Criteria for Diagnosis of Relapsing-Remitting Multiple Sclerosis (in a patient presenting with a clinical attack)

Number of Clinical Attacks	Number of Lesions With Objective Clinical Evidence[a]	Additional Data Needed for Diagnosis
≥2	≥2	None
≥2	1, with clear-cut historical evidence of a previous attack involving a distinct neuroanatomic location	None
≥2	1	Dissemination in space (an additional clinical attack implicating a different CNS region or by MRI)
1	≥2	Dissemination in time (an additional clinical attack or a new T2-hyperintense lesion or gadolinium-enhancing lesion on subsequent MRI) *or* CSF-specific oligoclonal bands
1	1	Dissemination in space *and* Dissemination in time or CSF-specific oligoclonal bands

[a]Objective clinical evidence includes an abnormality on neurologic examination, MRI, optical coherence tomography, or evoked potential testing, corresponding to the neuroanatomic location suggested by the clinical attack.
CNS, Central nervous system; *CSF*, cerebrospinal fluid; *MRI*, magnetic resonance imaging.

neurologic deficit(s), substantially increases the risk that CIS will convert to clinically definite MS in the following 5 to 10 years. With increased utilization of MRI, CNS lesions typical of demyelinating plaques may be incidentally discovered in an individual with no history of clinical exacerbations suggestive of CIS or MS. This condition has been termed radiologically isolated syndrome (RIS). In one study of 451 RIS subjects, 34% of individuals experienced an acute neurologic episode consistent with a demyelinating event, or progressive neurologic decline lasting at least 12 months, within a 5-year period from the first brain MRI study.[12] Interestingly, of those who developed symptoms, 9.6% fulfilled criteria for PPMS.

There are no clinical features or biomarkers that are pathognomonic for MS; it is essential to rule out competing diagnoses. The presence of unique oligoclonal bands and/or elevated immunoglobulin G (IgG) index in the CSF (indicative of primary antibody production in the CNS/intrathecal compartment) supports a diagnosis of MS. However, both findings are observed in a wide range of neuroinflammatory conditions, including subacute sclerosing panencephalitis, neurosarcoidosis, Lyme disease, and systemic lupus erythematosus with CNS involvement.

A diagnosis of PPMS requires 1 year of disease progression independent of relapses, plus two of the three following criteria: (i) at least one T2 hyperintense lesion in the periventricular, juxtacortical/cortical, or infratentorial regions; (ii) at least two T2-hyperintense spinal cord lesions, and (iii) the presence of oligoclonal bands on CSF analysis.

RISK FACTORS

Genetic Risk Factors

A monozygotic twin whose co-twin has MS has a 20% to 30% risk of developing the disease, and the corresponding risk for a dizygotic twin is 2% to 5%. The incidence of MS in the general population is approximately 0.1%. The risk of MS drops with increasing genetic distance, suggesting genes play a significant (but incomplete) role in determining MS susceptibility. The human leukocyte antigen (HLA) region of chromosome 6p 21.3 represents the strongest MS susceptibility locus genome wide and has been implicated in all ethnic populations thus far studied. It accounts for up to 10.5% of genetic variance underlying risk.[13] The primary signal maps to the *HLA-DRB1* gene in the class II segment of the locus (in particular the variant *HLA-DRB1*15:01*), implicating a role of CD4 T-cell responses in MS pathogenesis.[14] A class I variant (implicating CD8 T-cell responses), *HLA-A*02*, has been associated with protection from MS.[14] Genome-wide association studies (GWAS) have revealed more than 100 non-HLA susceptibility loci, each of which contributes a small amount to MS risk. Strikingly, most of these map to regions containing genes implicated in immunologic, rather than neuronal or glial, pathways. Genes involved in T helper (Th) cell differentiation are overrepresented, including the interleukin (IL)-2 receptor α chain and the IL-7 α chain, which modulate T-cell proliferation and survival. More than one-third of the MS susceptibility loci overlap with regions previously identified in GWAS of other autoimmune diseases, including celiac disease, type 1 diabetes, rheumatoid arthritis, and/or inflammatory bowel disease. Together these data provide support for a primary immunologic, as opposed to neurodegenerative, etiology of MS. An unresolved question is whether genetic variants affect the clinical course of RRMS, including such features as relapse rate or severity, and time to conversion to the SP stage. Genetic variants have yet to be identified that are predictive of responsiveness to DMT. Epigenetic modifications are a growing area of interest.

Environmental Risk Factors

Twin concordance rates in MS have been used to highlight the importance of heredity in MS susceptibility. Paradoxically, the same data can be used to argue for the importance of environmental influences; more than 70% of monozygotic twins of individuals with MS do not develop the disease. Despite arduous attempts, no convincing evidence has been produced for genetic, epigenetic, or transcriptome differences that explain MS discordance among monozygotic twin pairs. The risk of MS appears to be predicated on a complex interplay between genetic and environmental factors.

Geographic Prevalence Patterns

One of the most convincing illustrations of the impact of the environment on the development of MS is its geographic distribution. The prevalence of MS is highest in the Scandinavian countries, Canada, and Scotland and lowest in the equatorial regions. Kurtzke and colleagues described a latitudinal gradient in MS prevalence across the United States, peaking in the Northern states and gradually declining towards the South.[15] Similar latitudinal gradients have been observed in Europe, Australasia, and Japan. Prepubescent children who migrate assume the risk of their adopted country, whereas adults carry forward the risk of the location where they spent their childhood. An environmental

agent encountered in childhood that acts as a predisposing factor for the development of MS later in life has yet to be identified.

Vitamin D

Vitamin D modulates multiple components of the adaptive and innate immune responses, likely suppressing autoimmune inflammation. The discovery of a protective role of vitamin D in MS may explain, in part, the geographic distribution of MS. Ultraviolet light catalyzes the conversion of vitamin D to its bioactive form, and the prevalence of MS is highest in regions with relatively low annual sunlight exposure. In a large prospective study, the risk of MS decreased with increasing serum levels of 25-hydroxyvitamin D.[16] Therefore interventions that raise the level of 25-hydroxyvitamin D might have a prophylactic protective effect on healthy individuals who are predisposed to develop MS, such as the first-degree relatives of MS patients. Numerous independent prospective studies have found an inverse relationship between dietary or supplemental vitamin D intake in adults and future risk of MS. There is accumulating evidence that low serum 25-hyroxyvitamin D levels and low dietary vitamin D intake during pregnancy increase the risk of MS in the offspring. Prospective and retrospective studies have found an association between higher levels of 25-hydroxyvitamin D and lower risks of relapse and radiologic disease activity in individuals with established MS.[16] Multiple add-on studies examining vitamin D supplementation support a beneficial effect on MS disease activity. A randomized controlled trial of vitamin D supplementation in RRMS is currently underway in 16 academic centers (ClinicalTrials.gov identifier: NCT01490502).

Infection

Another prognostic factor for development of MS is primary infection with Epstein-Barr virus (EBV) as an adult, indicated by emergence of EBV-specific IgM antibodies in the serum.[17] The odds of MS risk are estimated to be more than 10 times higher among EBV-positive than EBV-negative persons. EBV infection could promote MS pathogenesis via "molecular mimicry," in which a microbial epitope shares sequence similarities with a self-peptide (see Chapter 51). T-cell receptors (TCRs) that cross-react with structurally homologous EBV and myelin antigens have been discovered in the 1 peripheral CD4 TCR repertoire of individuals with MS.[18] Peripheral CD4 T cells that express such cross-reactive TCRs could be activated during EBV infection, enabling them to cross the blood–brain barrier (BBB), encounter their cognate myelin antigen within the CNS white matter, and initiate MS lesion formation. An alternative theory involves CNS infiltration by EBV-infected B cells. B cells expressing EBV messenger RNA and proteins have been detected in meningeal follicle-like structures and inflamed cortical lesions in SPMS brain tissue.[19] EBV-driven expansion and activation of meningeal B cells could potentially contribute to the formation of the follicle-like structures, which have been associated with large subpial cortical MS lesions and a more aggressive clinical course.[6]

Although infectious agents such as EBV have been implicated in MS pathogenesis, other pathogens may have a therapeutic effect. Cytomegalovirus (CMV) seropositivity has been associated with reduced risk of MS.[14] It has been proposed that, in addition to high levels of sunlight exposure, endemic helminth infection is one of the factors responsible for the low prevalence of MS in tropical regions. Infection with helminths is protective in animal models of MS.[20] Regulatory B cells, Th2 cells, and/or eosinophils and immunosuppressive cytokines, such as IL-4, IL-10, and transforming growth factor-β (TGF-β), have been implicated in the protection. Several small prospective studies showed that MS patients naturally infected with different species of parasitic worms had a milder disease course and lower MRI inflammatory activity than uninfected patients.[21] Antiparasite treatment was associated with exacerbation of MS. Mechanistic substudies suggest that parasites modulate MS disease activity by boosting the frequency of IL-10 and TGF-β–producing regulatory T and/or B cells.

Obesity

Early adulthood obesity, measured by elevated body mass index (BMI), confers an approximately twofold increased risk of MS.[14] Obesity in girls is associated with an increased risk of pediatric MS or CIS. Higher weight in adolescence and young adulthood is associated with an earlier age at the onset of MS. A mendelian randomization analysis of large GWAS for MS and BMI, respectively, found that one standard deviation increase in genetically-determined BMI conferred a 41% increase in the odds of MS.[22] A number of theories have been proposed for a mechanistic link between obesity and MS risk. First, obesity is known to cause a systemic proinflammatory state, possibly mediated by adipose-derived hormones that create a milieu conducive to the differentiation and/or activation of autoimmune effector cells. Alternatively, there is evidence that genetically elevated BMI decreases 25-hydroxyvitamin D levels. It is unknown if obesity influences MS disease course.

Cigarette Smoking

A substantial body of literature indicates that cigarette smoking increases the risk of MS. A meta-analysis revealed a dose–response relationship between cigarette pack-years and MS risk.[23] Based on data collected from the Swedish National MS Registry, it was estimated that each additional year of smoking after diagnosis accelerates the time to conversion to SPMS by 4.7%; the association between cigarette smoking and risk of conversion from RRMS and SPMS has borne out in meta-analysis.[24] There is growing evidence that passive exposure to smoking may be a risk factor for MS, although data are mixed. Cigarette smoking may interact with HLA and other genetic variants to increase MS risk.[14] It is postulated that cigarette smoking promotes an inflammatory environment in the respiratory system, stimulates autoreactive lymphocytes via cross-reactivity, and promotes breakdown of the blood-brain barrier (BBB). Cigarette smoking may have direct toxic effects on neurons and/or glia.

Sex Hormones

Similar to other autoimmune diseases, MS prevalence is higher among women (2:1 to 3:1), but men with MS often have a worse prognosis.[25] MS relapse rates decline during pregnancy, particularly in the third trimester, and rebound in the first 3 months postpartum before returning to the prepregnancy rate. Parity may impact the risk of MS. These observations have led to the hypothesis that certain female sex hormones may play a protective role in RRMS. Estriol is an estrogen unique to pregnancy. Synthesized by the fetal–placental unit, estriol reaches its highest levels in the last trimester. A randomized, double-blinded, placebo-controlled phase 2 trial of estriol in combination with glatiramer acetate (GA) versus placebo plus GA showed a reduction in the annualized relapse rate at 2 years in the estriol-treated group.[26] Animal model studies indicate that estrogens, including estriol, have antiinflammatory and neuroprotective

effects through engagement of estrogen receptors expressed on leukocytes and CNS-resident cells, respectively.

Testosterone has neuroprotective effects in animal models of MS, and decreased testosterone levels in males with MS were reported to be associated with disability. In a small open-label phase 2 clinical trial, testosterone treatment appeared to arrest gray matter (GM) loss (and even to reverse GM atrophy in the right frontal cortex), as quantified using voxel-based morphology, in 10 male patients with MS.[27]

Microbiome

Commensal microorganisms of the intestines (gut microbiota) influence immune homeostasis, possibly playing a role in autoimmune disease. Germ-free mice (wild-type mice treated with oral antibiotics to eliminate commensal bacteria) are relatively resistant to the induction of experimental autoimmune encephalomyelitis (EAE), the most widely used animal model of MS.[28] Germ-free mice that are colonized with segmented filamentous bacteria or that received fecal transplants from MS patients develop EAE.[29] Collectively, these observations have led to the contention that specific microbiota promote encephalitogenic T-cell responses, via expression of bacterial proteins that cross-react with myelin antigens or production of metabolites that drive effector T-cell polarization. Certain microbial products could cross the BBB and activate glial cells. The majority of publications on the MS microbiome have found no major difference in gut microbiota diversity between MS cases and controls.[30] However, subtle taxonomic differences have been detected, with consistent patterns emerging across studies. In some studies, exposure to immunomodulatory drugs was associated with individual taxonomic differences. Of note, these studies were generally too small to adequately assess potential effect modifiers. Several larger studies are ongoing.

KEY CONCEPTS

Risk Factors

- The risk of multiple sclerosis (MS) is determined by a combination of genetic and environmental factors.
- The majority of MS susceptibility loci map to regions containing genes implicated in immunologic pathways, including human leukocyte antigen (HLA) class II molecules, the interleukin (IL)-2 receptor and the IL-17 receptor.
- Relapse rates decline during the third trimester of pregnancy, in association with high serum levels of estriol.
- Environmental risk factors include low vitamin D levels, exposure to the Epstein-Barr virus as an adult, cigarette smoking, and childhood obesity.

PATHOLOGIC FEATURES OF MULTIPLE SCLEROSIS

White Matter Lesions

The hallmark of MS pathology is the focal demyelinated lesion, or "plaque," present in the white matter of the optic nerves, brain, and spinal cord. Acute lesions are invariably associated with focal breakdown of the BBB and perivascular inflammatory infiltrates. MS infiltrates are dominated by T cells (with a relatively high CD8:CD4 ratio) and myeloid cells (blood-derived monocytes/macrophages and activated microglia). Macrophages/monocytes and activated microglia are spatially associated with disintegrating myelin sheaths and they actively take up myelin debris. Oligodendrocyte apoptosis and loss varies widely between lesions. Frequent sites of lesion formation include the subcortical and periventricular cerebral white matter, middle cerebellar peduncles, and posterior columns of the cervicothoracic spinal cord. In the brain, infiltrates frequently follow the course of pericallosal venules, resulting in "Dawson fingers," which are oblong lesions oriented perpendicular to the long axes of the lateral ventricles (Fig. 66.2).

Classic actively demyelinating plaques are primarily seen during the RR stage of disease and generally drop in frequency with increasing disease duration. Lesions more typical of progressive forms of MS have been termed "chronic active" or smoldering, and "chronic silent" or inactive. Chronic active plaques are distinguished by a rim of activated microglia and deposits of complement at the lesion edge, surrounding a hypocellular and gliotic core. They are slowly expansive as a consequence of active demyelination at the lesion edge. In contrast, chronic silent plaques have a sharp border. Other characteristics of silent plaques include prominent loss of oligodendrocytes and axons, pronounced astrogliosis, and a paucity of macrophages and activated microglia. Immunopathologic changes in the so-called normal-appearing white matter (NAWM), outside of plaques, are pervasive in progressive MS but have also been observed in RRMS. These changes consist of diffuse axonal injury and microglial activation, as well as scattered lymphocytes.

MS is widely classified as a demyelinating disorder. This is due to the fact that a large number of the nerve fiber segments traversing plaques demonstrate myelin loss with relative axonal sparing. However, it is now recognized that axonopathy also occurs and is, in fact, an early and prominent feature of acute MS lesions. Axonal damage results in dysmorphic mitochondria, focal swellings, fragmentation, and frank transections with terminal bulbs at the stumps. Mitochondrial abnormalities and focal swellings have been observed in fully myelinated axons within MS lesions, suggesting that they can occur independent of demyelination.[31] In animal models of MS, axons with

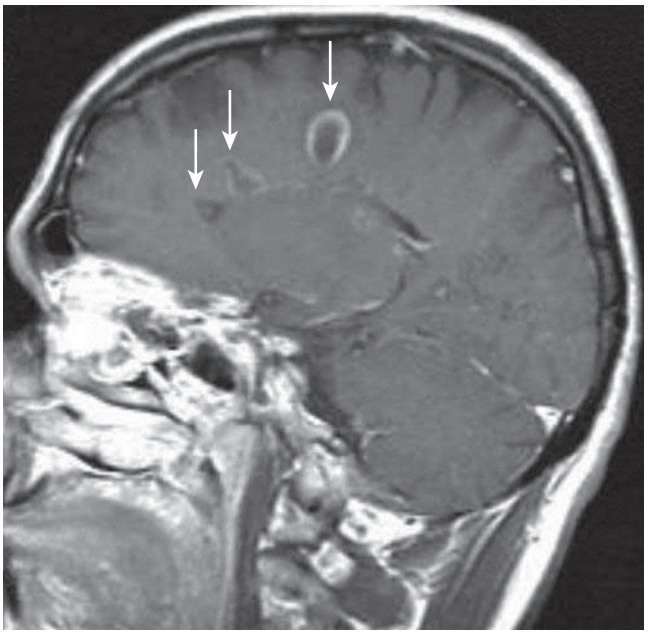

FIG. 66.2 A postgadolinium T1-weighed magnetic resonance image of the brain showing Dawson fingers *(arrows)*.

abnormal mitochondria are restricted to areas of immune infiltration, and progressive axonal changes correlate with the density of infiltrates.[31] Hence it is likely that the axonal damage is directly mediated by direct contact with inflammatory cells. Although demyelination can be reversed to some extent by remyelination, axonal transection is irreversible. Clinic-pathologic investigations have found that permanent motor disability in MS correlates with loss of corticospinal tract axons more so than with degree of demyelination.

Gray Matter Lesions

MS was traditionally considered a white matter disease. It is now established that the gray matter (GM) is affected as well. Three types of cortical lesions have been described: leukocortical (which span the gray and white matter), intracortical, and subpial. All of these lesions show demyelination and oligodendrocyte loss, microglial activation, neuritic transections, neuronal death, and reduced presynaptic terminals. Subpial lesions are the most common. They can cover long distances of the cortical ribbon and usually extend to cortical layer III or IV. Cortical lesions are not visible on conventional MRI scans and require special staining to be appreciated in CNS tissue sections. This explains why they were not recognized as common features of MS until recently. In fact, cortical demyelination and GM atrophy are evident from the earliest stages of disease, even before a clinically definite diagnosis can be made, and continue to advance at an increasing rate throughout the disease course. Extensive cortical demyelination is evident in the forebrain and cerebellum during progressive MS. GM atrophy in individuals with MS correlates strongly with cognitive deficits and clinical disability.[32]

Meningeal Inflammation

White blood cell counts tend to be within normal limits or only slightly elevated in the CSF of most patients with MS. Nonetheless, there is growing recognition that low-grade diffuse meningeal inflammation, as well as focal perivascular meningeal inflammation, are common. Meningeal inflammation is most prominent in progressive forms of MS but is prevalent in early MS as well. The meningeal infiltrates are topographically associated with cortical lesions. Lymphoid follicle-like structures, composed of proliferating B cells, T cells, and follicular dendritic cells, have been observed in up to 40% of autopsied brains from individuals with SPMS.[6] In almost every case the follicles reside in deep sulci and abut an underlying subpial lesion, suggesting that toxic factors are released by the inflammatory cells and diffuse into the brain parenchyma. The presence of lymphoid follicles has been associated with a more severe clinical course, shorter disease duration, and younger age at death.

KEY CONCEPTS

Pathology

- The hallmark of multiple sclerosis (MS) pathology is the focal demyelinated lesion, or "plaque," with perivascular inflammatory infiltration and focal blood–brain barrier breakdown.
- Axonopathy is an early and prominent feature of acute MS lesions.
- Central nervous system damage includes demyelination, oligodendrocyte apoptosis and loss, and axonal swellings and transections.
- Gray and white matter are both affected.
- The pathologic features of MS are heterogeneous and evolve over time.

IMMUNOPATHOGENESIS

Animal Models of Multiple Sclerosis

According to the current dogma, MS is an autoimmune disease mediated by CD4 T cells reactive against myelin antigens. The identification of HLA class II, *IL-2Rα*, and *IL-7Rα* as MS genetic susceptibility loci is consistent with a role of CD4 T cells in MS pathogenesis. An autoimmune etiology is further supported by the animal model, experimental autoimmune encephalomyelitis (EAE). EAE is a multifocal inflammatory demyelinating disease of the CNS that has striking histologic and clinical similarities to MS (Figs. 66.3 and 66.4). It has been induced in a wide variety of mammalian species (including nonhuman primates, but most commonly in rodents) by vaccination against MHC class II-restricted myelin epitopes. EAE can be transferred from myelin-vaccinated mice to syngeneic naïve hosts with purified CD4 T-cell lines or clones. These encephalitogenic myelin-specific CD4 T cells invariably fall within the Th1 or Th17 lineage and produce the proinflammatory cytokines interferon (IFN)-γ and IL-17, respectively, in response to antigenic stimulation (see Chapter 11).[33] Both Th1 and Th17 cells produce granulocyte–macrophage colony-stimulating factor (GM-CSF), a monocyte mobilizing and growth factor that plays a critical role in many models of EAE. Upon activation in the periphery, myelin-reactive CD4 T cells upregulate adhesion molecules and chemokine receptors, thereby acquiring the ability to cross the BBB. After infiltrating the CNS, they are reactivated by local antigen-presenting cells (APCs), such as perivascular macrophages or microglia, which constitutively express surface MHC class II molecules bound to myelin peptides. GM-CSF, as well as other Th1 and/or Th17 cytokines, are subsequently released in situ and initiate an inflammatory cascade, resulting in the production of chemokines, mobilizing factors, and vasoactive substances, upregulation of adhesion molecules on cerebrovascular endothelium, and, consequently, the recruitment of myeloid cells and lymphocytes from the circulation to the nascent plaque. GM-CSF may drive the differentiation of infiltrating monocytes and CNS-resident microglia into $CD11c^+$ dendritic cells, which are among the most potent APC. Adoptive transfer studies with labeled donor T cells have demonstrated that the myelin-specific T cells remain clustered in the perivascular space throughout lesion development. A secondary wave of myeloid cells infiltrates deep into the CNS white matter, associates with nodes of Ranvier, and directly inflicts damage to the myelin sheath and axons (see Figs. 66.3 and 66.4).[31]

Immune Dysregulation in Patients With Multiple Sclerosis

Studies on the frequency of myelin-reactive T cells in MS patients are conflicting; some investigators report a significantly higher incidence of myelin-specific peripheral blood mononuclear cells (PBMCs) in individuals with MS compared with age- and gender-matched healthy controls (HC), whereas others report no significant difference.[5] Many of the earlier studies that found no differences between patients and HC used proliferation as a measure of T-cell reactivity and nonhuman myelin proteins for antigenic stimulation. In contrast, several laboratories have found that untreated RRMS patients have increased frequencies of PBMC that produce IFN-γ or IL-17 in response to ex vivo challenge with human myelin basic protein (MBP), human proteolipid protein (PLP), or their constituent peptides.[4,34] IFN-γ

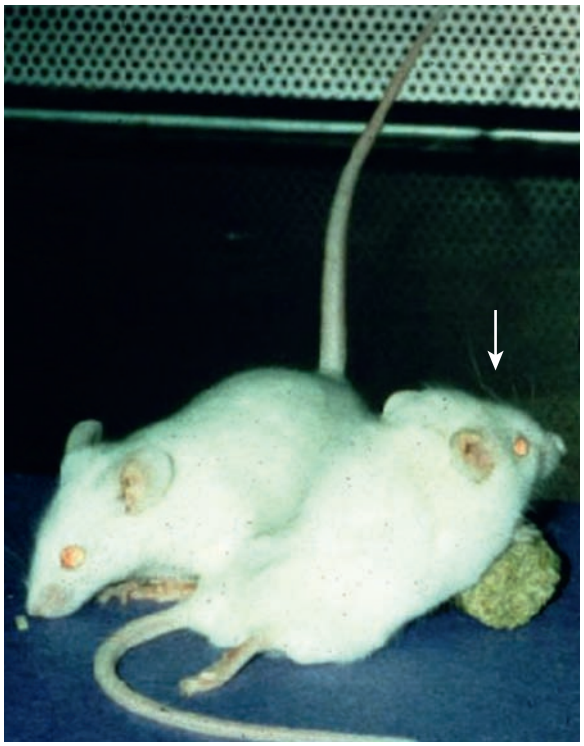

FIG. 66.3 A mouse with experimental autoimmune encephalomyelitis (EAE) *(arrow)* and a healthy litter mate. The mouse with EAE has a limp tail and hind limb weakness.

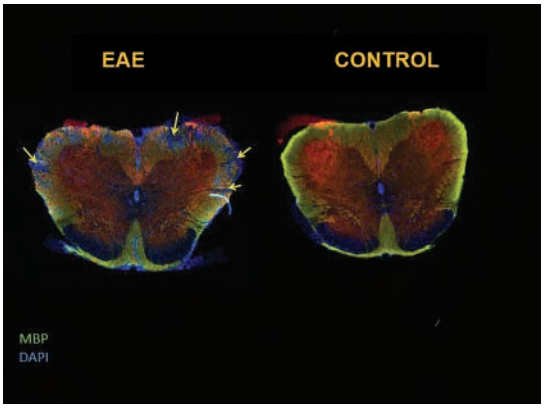

FIG. 66.4 Immunofluorescent histology of spinal cord sections from a mouse with experimental autoimmune encephalomyelitis *(EAE) (left)* and a healthy control *(right)*. White matter tracks were stained with a monoclonal antibody specific for myelin basic protein (*green*). The nuclei of inflammatory cells are stained with 4′,6-diamidino-2-phenylindole *(DAPI)* (*blue*). The arrows point to areas of demyelination. *MBP*, Myelin basic protein.

responses to PLP peptides correlated with level of clinical disability.[34] T cells that coexpress IL-17 and IFN-γ T cells were identified in brain tissue of MS patients, and circulating lymphocytes obtained from MS patients were found to have an increased propensity to differentiate into IL-17/IFN-γ double producers.[35] IL-17/IFN-γ coexpressing T cells, and IL-17–producing T cells that convert into IFN-γ producers (so-called ex-Th17 cells), have been implicated in the pathogenesis of some EAE models.

There is an increasing appreciation that the cytokine dysregulation that occurs during EAE and MS is heterogeneous. Hence clinically identical forms of EAE can be induced with stable murine Th1 or Th17 cells independently.[36] Subsets of MS patients were recently identified that consistently mounted either IFN-γ– or IL-17–skewed responses to human MBP over the course of a year, while others exhibited mixed or oscillating responses.[33] Diversity in the immune pathways that drive MS pathology holds important implications for the development of a more personalized approach to the management of patients in the future. Indeed, Th1- and Th17-mediated forms of EAE show different patterns of responsiveness to the same immunomodulatory drugs.[36]

Perhaps the strongest evidence of an autoimmune basis of inflammatory demyelination in humans comes from clinical trials of immunomodulatory agents. RRMS patients were treated with an altered peptide ligand (APL) of MBP with the intention of tolerizing MBP-reactive T cells or deflecting their differentiation towards an immunosuppressive, regulatory, or an innocuous Th2 phenotype. Unexpectedly, administration of the APL was temporally associated with expansion of circulating MBP-reactive Th1 cells and clinical worsening in a subgroup of patients.[37] In contrast, as will be discussed in detail later, drugs that impede lymphocyte trafficking to the CNS or deplete lymphocytes from the periphery reduce MS relapse rates and the accumulation of MRI lesions.

DISEASE-MODIFYING THERAPIES

Prior to 1993, corticosteroids were the only class of drugs routinely used to treat MS. Corticosteroids accelerate the rate of recovery from acute exacerbations, but there is little evidence they alter ultimate clinical outcomes or prevent subsequent disease activity. The US Food and Drug Administration (FDA) approved IFN-β-1b (Betaseron) in 1993 for the management of RRMS, beginning a new era in MS therapeutics. A host of additional DMT have since been approved, all of which significantly reduce the annualized relapse rate (ranging from 25% to perhaps 80%), and the frequency of gadolinium-enhancing (acutely inflamed) MRI lesions. The introduction of DMT has represented a major advance in the treatment of individuals with RRMS and has had a profound impact by mitigating morbidity and enhancing quality of life.

Recombinant Interferon Beta

IFN-β is a type I IFN with potent antiviral properties and pleiotropic effects on the innate immune system. Recombinant IFN-β was first trialed in MS based on the contemporaneous theory that the disease was caused by an active viral infection of the CNS. Recombinant IFN-β therapy was serendipitously found to significantly reduce annualized MS relapse rates. It is manufactured as five different commercial products, all of which are self-administered by either subcutaneous or intramuscular injection. There are two distinct structural forms. IFN-β-1a is produced in mammalian cells and has the same sequence as the naturally occurring compound, whereas IFN-β-1b is produced in modified *Escherichia coli* and has a Met-1 deletion and a Cys-17 to Ser mutation. IFN-β-1a is glycosylated, and IFN-β-1b is nonglycosylated. Studies of the efficacy of IFN-β in RRMS have yielded remarkably consistent results across different formulations of the drug. In multiple randomized, double-blinded placebo-controlled trials, IFN-β therapy reduced annual relapse rates by 20% to 35%.[38] However, approximately 30% of MS patients do not respond. Recent trials of novel DMT have used IFN-β as an active comparator. The mechanism of action of IFN-β in MS has

not been definitively elucidated. Proposed mechanisms include induction of the immunosuppressive cytokine IL-10, inhibition of pathogenic Th17 cells, and stabilization of the BBB via direct effects on cerebrovascular endothelium.

Glatiramer Acetate

GA is composed of a mixture of polypeptides of different lengths and sequences, synthesized by the randomized polymerization of four amino acids (glutamic acid, lysine, alanine, and tyrosine), and is administered subcutaneously. These are the most prevalent amino acids in MBP, a candidate autoantigen in MS. It was originally thought that GA would act as a competitive antagonist of MBP peptides for binding to MHC class II molecules on APC. Subsequent mechanistic studies did not support that theory. Alternative hypotheses include immune deviation of myelin-reactive T cells from a destructive Th1 to an innocuous Th2 phenotype, increase in frequency and function of $FOXP3^+$ regulatory CD4 T cells or regulatory CD8 T cells, and induction of antiinflammatory type II monocytes. A pivotal trial of GA versus placebo in 1995 demonstrated a mean reduction in the relapse rate of approximately 30%.[38]

Teriflunomide

Teriflunomide is an oral pyrimidine synthesis inhibitor approved for relapsing forms of MS. It is the active metabolite of leflunomide, which has been used for years in the treatment of rheumatoid arthritis. Teriflunomide has broad immunosuppressive effects, including a cytostatic effect on proliferating T and B lymphocytes. In a pivotal phase 3 trial, teriflunomide reduced annualized relapse rate by 31% compared with placebo.[38]

Dimethyl Fumarate and Diroximel Fumarate

Dimethyl fumarate (DMF) is the methyl ester of fumaric acid. Prior to being tested as a DMT in MS, DMF was used as a biocide in furniture and shoes to prevent the growth of molds during storage or transport. A combination of DMF and three other fumaric acid esters was marketed in Germany as a treatment for psoriasis. In two phase 3 trials, oral DMF was demonstrated to decrease the annualized relapse rate of adults with RRMS by approximately 34% to 50% compared with placebo.[39] DMF therapy is often associated with lymphopenia, but therapeutic efficacy does not appear to be inversely related to lymphocyte counts. In the postmarketing setting, several cases of progressive multifocal leukoencephalopathy (PML), a rare viral infection of the brain caused by the JC virus, were reported in patients taking DMF who had persistent lymphopenia. The mechanism by which DMF suppresses MS disease activity remains unclear.

The most common side effects of DMF are flushing and gastrointestinal upset. Diroximel fumarate, a novel oral fumarate that causes less gastrointestinal adverse effects than DMF, was recently FDA approved for the treatment of relapsing forms of MS. DRF undergoes rapid cleavage in the gut to monomethylfumarate, the same pharmacologically active metabolite as DMF.

Fingolimod and Siponimod

During homeostasis, sphingosine-1-phosphate (S1P)-1-signaling drives lymphocyte egress from lymph nodes into the bloodstream. Fingolimod is an orally administered S1P1 receptor modulator that effectively traps myelin-specific T cells in lymph nodes so that they cannot reenter the circulation and gain access to the CNS. In a 24-month randomized, double-blinded placebo-controlled trial, fingolimod was shown to reduce annualized relapse rates by 50%.[38] In a phase 3 randomized, double-blind, placebo-controlled trial, fingolimod did not slow disease progression in patients with PPMS. Fingolimod does not distinguish between pathogenic and protective lymphocytes, and a number of opportunistic infections have emerged as complications of the treatment. Patients taking fingolimod are susceptible to herpes virus infections, particularly shingles. Consequently, patients are screened for immunity to varicella zoster before commencing treatment. In the postmarketing setting, PML and cryptococcal meningitis have been reported in fingolimod-treated patients with no, or only distant, prior exposure to immunosuppressive drugs. Other potential side effects of fingolimod include macular edema, bradycardia, and atrioventricular block, which may be secondary to cross-binding of the drug to the S1P1, S1P2, and S1P3 receptors in the cardiovascular system and on retinal endothelial cells.

Siponimod is a selective S1P receptor modulator (S1P1 and S1P5); this selectivity confers low risk of bradycardia and atrioventricular block when the drug is appropriately titrated, while still reducing the risk of relapse and new lesion accumulation in patients with RRMS. In a phase 3 double-blind, placebo-controlled trial in SPMS, siponimod was found to significantly reduce risk of confirmed disability progression at 3 and 6 months.[9] Secondary analyses suggested that patients who experienced relapses in the 2 years prior to enrollment were preferentially responsive to siponimod. Siponimod is labeled for use in relapsing forms of MS, including active SPMS.

Cladribine

Cladribine is a synthetic purine analogue that preferentially depletes peripheral B and T lymphocytes.[38] This preferential effect on B and T cells owes to relatively higher levels of deoxycytidine kinase, an enzyme necessary for conversion of the prodrug to its active form, in these cells. Intravenous cladribine is used for treatment of hairy cell leukemia. Oral cladribine is approved for treatment of RRMS and active SPMS; dosing is weight based and consists of repeated short courses. This dosing strategy intentionally induces lymphopenia and then allows for immune reconstitution. In a phase 3 placebo-controlled trial, oral cladribine reduced annualized relapse rate by approximately 58%; nearly 80% of patients remained relapse free at 96 weeks. Potential adverse effects include severe lymphopenia, infection (specifically herpes zoster), teratogenicity, and malignancy.

Natalizumab

Natalizumab is a humanized monoclonal antibody against the cell adhesion molecule α_4-integrin, which is widely expressed on lymphocytes and monocytes. Natalizumab is believed to mediate its ameliorative effects in RRMS by blocking interactions between the very late antigen (VLA)-4 (a heterodimer composed of the α_4-and β_1-integrin chains) on leukocytes with its cognate ligand, vascular cell adhesion molecule (VCAM)-1, on cerebrovascular endothelial cells. VLA-4/VCAM-1 interactions are required for the passage of lymphocytes and monocytes past the BBB. In a phase 3 placebo-controlled trial, natalizumab reduced the relapse rate at 1 year by 68% and the number of gadolinium-enhancing MRI lesions at both 1 and 2 years by more than 90%.[39] The most serious complication of natalizumab treatment is PML; there have been more than 700 reported cases. Factors that increase the risk of natalizumab-associated PML include JC virus seropositivity, duration of treatment more than 2 years, and prior exposure to immunosuppressive drugs (e.g., cyclophosphamide, azathioprine, or mycophenolate mofetil).

Alemtuzumab

Alemtuzumab is a humanized anti-CD52 monoclonal antibody that globally depletes circulating T and B lymphocytes via antibody-dependent cell-mediated cytotoxicity, complement-dependent cytolysis, and induction of apoptosis. CD52 is primarily expressed on the cell surface of T and B lymphocytes, but it is also expressed at lower levels on macrophages, eosinophils, and natural killer (NK) cells. Hematopoietic stem cells do not express CD52, allowing the subsequent repopulation of circulating lymphocyte pools following alemtuzumab treatment, which occurs at variable rates between lymphocyte subsets. Reconstituted circulating T-cell pools have been found to be enriched in $CD4^+CD25^{high}CD127^{low}FOXP3^+$ regulatory T cells that might be responsible, in part, for the long-lasting therapeutic effect of alemtuzumab, which has been observed in some individuals. In a 2-year, rater-masked, randomized controlled phase 3 trial, previously untreated RRMS patients were randomly allocated to receive intravenous alemtuzumab or subcutaneous IFN-β-1a.[38] Alemtuzumab was given once per day for 5 days at baseline and once per day for 3 days at 12 months. Relapse rates were reduced 54.9% in the alemtuzumab group compared with the IFN-β-1a group. In an independent study, alemtuzumab reduced relapse rates and the risk of sustained accumulation of disability in RRMS patients refractory to first-line DMT.[38] Although alemtuzumab suppressed new MRI lesion formation and superimposed relapses in patients with SPMS, it did not prevent clinical progression or progressive cerebral atrophy.[7] Extension studies of alemtuzumab indicate that a substantial portion of patients treated with only two cycles of alemtuzumab have durable treatment effect out to 5 years.

The principal adverse effect of alemtuzumab in MS is antibody-mediated autoimmune disease, most commonly Graves disease. Idiopathic thrombocytopenic purpura, Goodpasture syndrome, and antiglomerular basement membrane disease have been reported less frequently. The underlying mechanism is not fully understood but may be a consequence of early recovery of immature B cells in the absence of regulatory T cells. Another possibility is that homeostatic T-cell proliferation following lymphocyte ablation leads to the generation of chronically activated oligoclonal CD4 and CD8 T cells capable of producing proinflammatory cytokines. Alemtuzumab therapy has been associated with opportunistic infections, including listeriosis.

B Cell–Depleting Monoclonal Antibodies

A role of B cells in the pathogenesis of MS has been suspected since the discovery of unique oligoclonal bands in the CSF of the majority of individuals with MS. Nonetheless, B cells are not a prominent component of the perivascular infiltrates in MS lesions. This apparent paradox has been resolved, at least in part, by the discovery of lymphoid follicle-like structures, in the meninges of some individuals with MS (as previously discussed). The most direct evidence for a role of B cells as effector cells in MS pathogenesis comes from trials of monoclonal antibodies directed against CD20, a B-cell surface molecule. CD20 is expressed on pre-B cells and mature B cells and not on antibody-secreting plasma cells. Rituximab, a chimeric monoclonal anti-CD20 antibody, induces a rapid depletion of circulating B cells lasting approximately 6 to 9 months. In a phase 2 clinical trial of rituximab in RRMS, subjects in the active treatment arm experienced a significant reduction in clinical relapses and in the formation of new or enhancing MRI lesions when compared with subjects in the placebo arm. Ocrelizumab is a next-generation fully human recombinant anti-CD20 monoclonal antibody that binds to a different epitope from rituximab, and with higher affinity. In two large phase 3 studies, ocrelizumab reduced the annualized relapse rate in subjects with RRMS by nearly 50% compared with IFN-β-1a over a 2-year period.[38] In addition, ocrelizumab delayed confirmed disability progression by approximately 40% and the total number of gadolinium-enhancing lesions by more than 90% compared with IFNβ-1a.

Interestingly, some patients with progressive MS might also benefit from the depletion of $CD20^+$ cells, particularly if there is evidence of ongoing neuroinflammatory activity at the time of treatment initiation. Rituximab significantly delayed the time to confirmed disease progression in a subset of PPMS patients who had gadolinium-enhancing lesions on baseline MRI of the brain. The benefit was most dramatic in subjects aged younger than 51 years. In a placebo-controlled trial of ocrelizumab in individuals with PPMS between 18 and 55 years of age, ocrelizumab was associated with lower rates of clinical and MRI progression.[10] The FDA granted ocrelizumab "breakthrough therapy designation" for PPMS.

The mechanism by which B cell–depleting therapy ameliorates MS does not appear to be reduction in antibody titers. Rituximab depletes B cells from the CSF of RRMS patients with little effect on CSF IgG levels. B cells are APC, and there is some evidence that they are important for sustaining myelin-specific Th17 responses in MS. The frequency of GM-CSF–producing B cells was found to be elevated in RRMS.[40] Hence ocrelizumab and rituximab may eliminate an important cellular source of GM-CSF, a monocyte/macrophage mobilizing cytokine that has been strongly implicated in the pathogenesis of EAE. Disruption of meningeal follicle-like structures is yet another putative mechanism of action that might be particularly relevant to progressive forms of MS.

THERAPEUTIC PRINCIPLES

- Corticosteroids accelerate the rate of recovery from multiple sclerosis (MS) relapses, but there is little evidence that they impact the ultimate degree of recovery or the future clinical course.
- There are a growing number of US Food and Drug Administration (FDA)-approved disease-modifying therapies (DMTs) that reduce annualized relapse rates in patients with relapsing-remitting MS by approximately 20% to 80%
- Newer-generation DMTs either deplete lymphocytes, inhibit their expansion, or block their migration to the central nervous system.
- DMTs differ in efficacy and safety profiles. Opportunistic infection, in particular progressive multifocal leukoencephalopathy, has been observed in association with several DMT.
- The choice of DMT must be customized for on an individual basis, taking into account disease activity and risk tolerance.

FUTURE DIRECTIONS

Dramatic advances have been made in the management of RRMS, but much remains to be done. The DMTs currently in use have global effects on lymphocytes as opposed to specifically targeting autoreactive Th1 and Th17 cells. Consequently, protective as well as pathogenic immune responses may be undermined, increasing the risk of infection. Furthermore, DMTs are only modestly

effective in progressive forms of disease. Critical goals of the MS research community currently are to better define the cellular and molecular mechanisms that link neuroinflammation to end-organ injury (namely demyelination and axonopathy) and to elucidate the pathogenic pathways that underlie clinical progression. It is also imperative to develop a deeper understanding of endogenous obstacles to repair pathways in the CNS. This knowledge could ultimately lead to the discovery of laboratory-based surrogate biomarkers of both acute and chronic disease activity, as well as drugs that block, or even slow, disability accumulation in progressive MS and promote remyelination and axonal regeneration across clinical subtypes.

ON THE HORIZON

- The introduction of disease-modifying therapies has represented a major advance in the treatment of individuals with relapsing-remitting multiple sclerosis (MS). However, these drugs have global effects on lymphocytes, thereby increasing the risk of infection. A future goal will be to develop drugs that specifically target pathogenic leukocytes and/or autoreactive lymphocytes.
- Disease-modifying therapy is currently focused on the modulation of lymphocytes. Drugs that target innate immune cells may enhance MS therapeutics in the future.
- There is still a dire need for drugs that slow, or even halt, disability accumulation in progressive forms of MS and that are effective in older patients without evidence of recent neuroinflammatory activity.
- An increased understanding of the mechanisms by which inflammatory cells inflict central nervous system damage, and the endogenous obstacles to repair pathways in MS, may inform the development of neuroprotective and neuroregenerative agents.

Autoimmune Peripheral Neuropathies

Marinos C. Dalakas

Autoimmune peripheral neuropathies (APNs) occur when immunological tolerance to peripheral nerve components (myelin, Schwann cell, axon, and motor or ganglionic neurons) is lost. In some neuropathies, there are pathogenic antibodies or cytotoxic T lymphocytes against peripheral nerve antigens, but in others the immune-mediated mechanisms are undefined or suspected when the neuropathy coexists with another systemic autoimmune disease or viral infection.

This chapter reviews the most common autoimmune neuropathies (Table 67.1), their clinical features, diagnostic criteria, the prevailing autoimmune phenomena, and effective therapies.

ACUTE INFLAMMATORY POLYNEUROPATHY: GUILLAIN-BARRÉ SYNDROME(S)

Guillain-Barré syndrome (GBS) is characterized by acute (within 1 week) or subacute (within 4 weeks) ascending motor weakness, mild or moderate sensory abnormalities, occasional cranial nerve involvement, and muscle or radicular pain.[1–4] Tendon reflexes are reduced but can be normal, especially in axonal GBS. It is a disease of all ages that occurs sporadically with an incidence of 0.8 to 1.9 (median 1.1) per 100,000.[4] In typical cases, the disease peaks by the fourth week, a sign conventionally used to separate GBS from chronic inflammatory demyelinating polyneuropathy (CIDP), in which the disease begins slowly and usually reaches a nadir after at least 2 months. There are, however, patients with CIDP (perhaps up to 16%) with subacute onset and monophasic course falling between the two timeframes and still others with an even more acute onset, reaching a nadir within 6 to 8 weeks resembling GBS.[1–4] Distinguishing GBS from acute-onset CIDP can be at times challenging and becomes clear in retrospect, although proposed criteria may help separate the two early in the disease course.[1–4]

After reaching the clinical peak, there is a recovery period that varies from weeks to more than a year according to disease subtype or severity at onset; rapid initial progression over less than 7 days, quadriparesis, need for mechanical ventilation, age greater than 60 years, and preceding diarrheal illness are signs associated with incomplete recovery or worse outcome. GBS is not one but several syndromes, reflecting the varying degree of involvement of the motor or sensory nerve fibers and the myelin sheath or the axon. The GBS subtypes, or GBS variants,[1–4] include:

- *Acute inflammatory demyelinating polyneuropathy (AIDP)*, which accounts for the majority (probably 80%) of patients. In classic cases, the weakness starts from the legs and spreads up to the arms, intercostal and diaphragmatic muscles, and facial or bulbar muscles. At times, the weakness may be limited to one or two limbs or to cranial nerves. Patients need to be monitored for impending respiratory failure: hence the need for early admission to intensive care units (ICUs). Autonomic dysfunction occurs in up to 65% of patients and may cause cardiac arrhythmias or hemodynamic changes.[1–4]
- *Acute motor axonal neuropathy* (*AMAN*), which exhibits primary axonal damage caused by massive acute demyelination and inflammation, as occurs in experimental allergic neuritis (EAN) when animals are immunized with a high dose of myelin antigen,[1–4] or by a primary axonal event mediated by macrophages. These patients have a fulminant course with paralysis and electrical inexcitability of motor nerves as early as 3 to 5 days after onset.[1–4] In contrast to AIDP, involvement of cranial nerves is infrequent, and reflexes are normal or increased, especially early in the disease. AMAN is common in Asia and Central South America, accounting for 30% to 65% of all GBS cases in these regions.[1–4] Recovery is variable; some patients recover within days as a result of resolution of conduction block, but others have slow or poor recovery because of excessive axonal degeneration.[1–4] Infection with *Campylobacter jejuni* appears to trigger many of these cases.[1–4] A number of patients also have high levels of antiganglioside GM1 antibodies.[1–4]
- *Acute motor–sensory axonal neuropathy (AMSAN)* is similar to AMAN, but with concurrent involvement of the sensory axons, and has a pathomechanism similar to AMAN, including frequent antibodies against GM1 and GD1a gangliosides.
- *Miller Fisher syndrome (MFS)* is characterized by acute onset of ophthalmoplegia, gait ataxia, normal sensation, and areflexia.[1–6] In some patients pharyngeal, facial, trunk, and respiratory muscles are involved; rarely it can present as ocular nerve palsies.[1–5] MFS is also distinct because of the presence of a unique immunoglobulin G (IgG) antibody against GQ1b ganglioside.[1–5]
- *Sensory ataxic GBS* results from the involvement of roots and ganglionic neurons. Some of these patients have antibodies to GD1b ganglioside, probably forming a continuum with MFS because they share autoantibodies with the same sialic groups.[2,3,5]
- *Acute pandysautonomic neuropathy* affects ganglionic neurons and causes pure autonomic dysfunction.[1–4]

Diagnosis

The diagnosis, often suspected on clinical grounds, is confirmed with elevated cerebrospinal fluid (CSF) protein and electrophysiological studies consistent with active demyelination or nerve inexcitability.

CSF protein may be normal in the early phase of the disease, but it can be as high as 1000 mg/dL by the sixth week. The elevated CSF protein is probably related to root inflammation but, as the blood–nerve barrier becomes impaired, serum albumin and IgG

TABLE 67.1 Common Autoimmune Neuropathies

- Guillain-Barré syndrome(s) (GBS)
- Chronic inflammatory demyelinating polyneuropathy (CIDP) and its variants
- Polyneuropathy associated with IgM monoclonal gammopathy
- Multifocal motor neuropathy with conduction block
- Polyneuropathy, organomegaly, endocrinopathy, myeloma, and skin changes (POEMS) syndrome
- Cryoglobulinemic polyneuropathy
- Paraneoplastic neuropathies associated with anti-Hu or CRMP-5 antibodies
- Autoimmune autonomic neuropathies
- Vasculitic neuropathies
- Possibly autoimmune small fiber sensory neuropathy with neuropathic pain
- Infectious neuropathies (human immunodeficiency virus [HIV], cytomegalovirus [CMV], Epstein-Barr virus [EBV], and herpes virus infections; Lyme disease; leprosy; Chagas disease; diphtheria; others)

may enter freely into CSF, contributing further to protein elevation. CSF cell count is normal (or slightly increased <50 cells per microliter); there is, however, lymphocytosis when GBS occurs in conjunction with viral infections, such as human immunodeficiency virus (HIV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), or Lyme disease. When CSF protein is very high, papilledema can develop because of impaired reabsorption of CSF and raised intracranial pressure. Oligoclonal IgG bands can be seen. Nerve conduction studies can be normal early in the disease but remain helpful to distinguish AIDP from AMAN or AMSAN. They also have prognostic value because features of demyelination suggest higher chances of needing mechanical ventilation, whereas severe axonal loss from the outset predicts poor outcome.[1–4] Differential diagnosis of GBS should include other forms of acute flaccid paralysis, such as brainstem stroke; brainstem encephalitis; acute motor neuron involvement caused by poliomyelitis or West Nile virus infection; acute myelopathy; disorders of neuromuscular transmissions, such as myasthenia gravis or botulism; acute inflammatory or necrotizing myopathies; periodic paralysis; and rare causes of acute neuropathy, such as porphyria, toxins, and vasculitis. Also important to consider is the critical illness polyneuropathy.

Antecedent Events

Two-thirds of GBS patients give a history of a flu-like illness or acute dysenteric episodes that precede the development of GBS by 1 to 3 weeks.[1–4,6–8] Among the implicated viruses are CMV, EBV, herpesvirus, hepatitis A, HIV, Zika virus, and coronavirus (COVID-19). Among bacteria, infection with *Mycoplasma pneumoniae* and, most importantly, *C. jejuni* may be present in greater than 25% of the patients and in some parts of the world up to 50%.[1–4] *Campylobacter* is of special interest because it contains glycoconjugates that share epitopes with the peripheral myelin, as discussed later. Two vaccines—one against rabies and the other against the swine flu A/New Jersey influenza strain that caused an outbreak of GBS in 1976[1–4]—have been associated with GBS. Rabies vaccine that contains brain material is followed by GBS in about 1 in 1000 cases. Despite anecdotal reports, there is no convincing evidence that the incidence of GBS is increased in association with other vaccines. Recent viral epidemics or pandemics have been triggering factors for GBS. Zika virus, an arbovirus in the family of Flaviviridae, which emerged in South America countries, is estimated to cause GBS in 0.24 per 1000 Zika infections.[6] Most of Zika-associated GBS have AMAN with rapid disease evolution—within 4 to 6 days—and antiglycolipid antibodies in 31% of the patients.[6] COVID-19 can also trigger GBS based on many well documented series.[7,8] The most characteristic finding of COVID-19–triggered GBS were preceding, or concomitant, signs of anosmia and ageusia and frequent presence of cranial neuropathies including ophthalmoplegias.[7,8] Antibodies to GD1b gangliosides have been seen in two patients and the possibility of molecular mimicry was raised because the COVID-19 spike protein also contains ganglioside moieties.[7,8] Surgery can precede the development of GBS in some patients;[1–4] surgical stress, release of nerve autoantigens, or infections have been implicated. Three drugs—gold, perhexiline, and suramin at high doses—have been causally associated with acute demyelinating neuropathy.[2,3] GBS has occurred in patients who suffer from neoplasms, especially lymphoma, melanoma, and Hodgkin disease and rarely as a complication of immune checkpoint inhibitors.[1–4,9] Interestingly, GBS is rarely seen as part of another connective tissue disorder.

Immunopathology of Guillain-Barré Syndrome

GBS is an inflammatory demyelinating polyneuropathy in which an immune attack, triggered by various antecedent events, is directed against peripheral nerve antigens including myelin, axon, or nodes of Ranvier. Both cellular and humoral immune components have been implicated.[1–4]

Cellular Factors

Endoneurial inflammatory infiltrates throughout the nerves, roots, or plexuses[1–4] and segmental demyelination in areas associated with the lymphoid infiltrates, especially macrophages, are prominent in typical GBS. Macrophages, which are the most prominent cells in contact with nerve fibers, break through the basement membrane of healthy Schwann cells and make direct contact with the outermost myelin lamellae, leading to lysis of the myelin sheath (macrophage-mediated demyelination). Cytokines and chemokines released by the activated T cells or complement activation may increase capillary permeability and facilitate transmigration of additional macrophages or T cells. When the demyelination is extensive or chronic, it is followed by axonal degeneration.[1–4] The effectiveness of remyelination and degree of axonal regeneration dictate the prospects of clinical recovery.

The T-cell mediated process in GBS is mostly derived by analogy to the animal model of EAN, which resembles GBS in pathology and clinical course.[1–4] Animals sensitized to whole human nerve or various myelin proteins, such as P0, P2, and the neutral glycolipid galactocerebroside, develop segmental demyelination with macrophages and T-cell infiltrates. In EAN, T cells are sensitized against myelin and can passively transfer the disease to healthy animals. Interleukin-2 (IL-2) and soluble IL-2 receptors are increased during the acute phase, suggesting T-cell activation. Furthermore, lymphocytes from GBS patients exert myelinotoxic activity when applied to cultures of myelinated axons.

Humoral Factors and Antiganglioside Antibodies

There is much stronger evidence that circulating serum factors are responsible for GBS. On clinical grounds, this is supported

by the beneficial effect of plasmapheresis, presumably by removing putative antibodies. On laboratory grounds, it is supported by the variety of autoantibodies detected in patients' sera. Serum from the acute phase of GBS can demyelinate rodent dorsal root ganglionic extracts in a complement-dependent manner. Furthermore, GBS serum injected into rat sciatic nerves causes demyelination and conduction block. Complement-fixing IgM antibodies against a human peripheral nerve myelin glycolipid that contains carbohydrate epitopes, as well as high-titer antibodies against various sulfated or acidic glycosphingolipids, are present in several patients with GBS.[1–5]

Gangliosides are present in all tissues but are especially abundant in the nervous system. Their lipid portion lies in the cell membrane, and their signature sugar residues are exposed at the extracellular surface bearing one or more sialic acid molecules, such as one sialic acid ganglioside (GM1), two (GD1a), three (GT1a), or four (GQ1b).[1–5] Although they do not form a common "GBS antigen," different gangliosides are involved in different GBS subtypes. They are of pathogenic relevance because immunization of rabbits with GM1 and GD1b induces acute neuropathy with histological features of AMAN.[1–5] Their pathogenicity was also confirmed by an inadvertent experiment in humans who had received ganglioside injections for various maladies and developed AMAN accompanied by anti-GM1 antibodies.[10] Additionally, antibodies to GQ1b or GD1a cause conduction block at the motor nerve terminals in a mouse phrenic nerve preparation.[1–6] Similar effects were noted with anti- GalNAc-Gd1a antibodies from a patient with AMAN.

IgG antibodies reacting with GM1, GD1a, GalNAc-GD1a, and GM1b are found in 80% of cases with axonal GBS (AMAN and AMSAN), but in the most common GBS subtype AIDP, ganglioside-specific antibodies are uncommon. Among gangliosides, the one that clearly correlates with a specific clinical syndrome is GQ1b, associated with the MFS-variant where IgG anti-GQ1b antibodies are present in greater than 90% of these patients.[1–5] In contrast, IgM-anti-GQ1b antibodies are found in chronic IgM paraproteinemic polyneuropathies,[5] as discussed later. Anti-GQ1b IgG antibodies are also found in postinfectious ophthalmoplegias and in GBS cases with ophthalmoplegia.[1–5] Anti-GQ1b antibody binds the paranodal regions of oculomotor nerves III, IV, VI, and may block impulse propagation at the nodes of Ranvier, resulting in conduction block. Many patients with GQ1b antibodies also have antibodies to GD1a. The recent finding of GD1b antibodies in two COVID-19–triggered GBS patients with ophthalmoplegia is of great interest as this pandemic is still evolving.[7,8]

The reasons for different clinical syndromes in connection with specific gangliosides remains unclear, but distribution, accessibility, and density or configuration of gangliosides at different sites may be critical factors. For example, there is more GM1 in ventral than dorsal roots: hence the predominantly motor neuropathy seen with anti-GM1 antibodies. There is also more GQ1b and possibly GD1b in oculomotor nerves, which may explain their involvement in MFS and COVID-19–triggered GBS.

Molecular Mimicry: Relationship Between *Campylobacter jejuni* and Gangliosides

Antecedent infection with *C. jejuni* has been commonly associated with AMAN. The strain of *C. jejuni*-associated AMAN (Penner D:19 serogroup) is, however, different from those causing common enteritis and is more likely to have the genes for enzymes that synthesize sialic acid in the bacterial wall, mimicking ganglioside GM1, GD1a, or GQ1b.[1–5] These patients have a higher incidence of anti-GM1 antibodies, suggesting cross-reactivity between epitopes in the lipooligosaccharide in the bacterial wall and nerve ganglioside.[1–5] Furthermore, injection of lipooligosaccharides extracted from *C. jejuni* into rabbits induces acute neuropathy with anti-GM1 antibodies identical to those found in AMAN.[1–5] Additionally, immunization of mice with these lipooligosaccharides generates a monoclonal antibody that reacts with GM1, binds to human peripheral nerve, and blocks muscle action potentials in muscle–spinal cord cocultures exactly as the anti-GM1 IgG extracted from GBS patients. Carbohydrate mimicry between the bacterial lipooligosaccharide and human GM1 is therefore an important cause of AMAN. Because *C. jejuni* is a common cause of a diarrheal illness worldwide, and diarrhea is an antecedent event in up to 50% of GBS patients, *Campylobacter* is a triggering factor for GBS in certain parts of the world. Isolation of *Campylobacter* from stools early in acute GBS varies from 44% to 88% of patients, and IgG or IgM *Campylobacter*-specific antibody titers are seen in a higher percentage (36%) of patients with GBS than in controls (10%).

Molecular mimicry may not be limited to *C. jejuni* because GM1 and GQ1b epitopes are also found in the bacteria wall of *Haemophilus influenzae*, which can also trigger GBS. Similarly, *Cytomegalovirus*-triggered GBS has been associated with IgM anti-GM2 antibodies. Molecular mimicry is also a factor in *M. pneumoniae*, which precedes GBS in 5% of cases and stimulates antibodies against human galactocerebroside, the main glycolipid in peripheral nerves.[1–5] Molecular mimicry may also play a role in Zika-associated GBS as antiglycolipid antibodies were found in 31% of these patients.[6] It may also be the case in some COVID-19–triggered GBS because GD1b antibodies were detected in 2 of 10 tested cases, and COVID-19 spike protein contains gangliosides and various sphingoglycolipds.[7]

Molecular mimicry between epitopes of disease-triggering viral proteins and myelin components may result in sensitization of cross-reactive T cells that stimulate B cells to produce specific antibodies against myelin components or recruit macrophages as effector cells. A combination of cellular and humoral factors probably participates in this process.[1–4] Circulating cytokines triggered by the initiating infections could also upregulate intercellular adhesion molecule (ICAM)-1 expression on the endothelial cells facilitating the entrance of activated T cells or antibodies to the endoneurial parenchyma. Of relevance, ICAM-1 is increased in patients with GBS.[1–5] A scheme summarizing the immunopathogenic mechanism is shown in Fig. 67.1.

Antibodies to paranodal antigens neurofascin and contactin, seen in CIDP subsets, as discussed later, have also been detected in a small number of GBS patients. These antibodies may potentially cause conduction block or paranodal axonal degeneration and could explain the rapid reversibility or slow recovery seen in several patients with AMAN.[1–5]

CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

CIDP is the most common form of chronic APN, with prevalence as high as 9/100,000.[1–3,11,12] It is also the most gratifying

KEY CONCEPTS

Autoimmunity in Guillain-Barré Syndrome

Cellular Factors

- The peripheral myelin or the Schwann cells are targets.
- Activated macrophages are the dominant endoneurial cells and lift the outermost myelin lamellae, lysing the superficial myelin sheaths.
- Peripheral blood lymphocytes exert myelinotoxic activity in vitro.
- Levels of interleukin-2 (IL-2) and soluble IL-2 receptors are increased during the acute phase of the disease and decline during recovery.

Humoral Factors

- Serum exerts a complement-dependent demyelination in vitro.
- Intraneural injections of serum from patients with acute Guillain-Barré syndrome (GBS) cause demyelination and conduction block.
- IgG, IgM, and membranolytic attack complex are detected immunocytochemically on the patients' nerves.
- High IgG antibody titers against peripheral nerve acidic glycolipids (GM1, GQ1b) are detected in the sera of patients with acute motor axonal neuropathy (AMAN) and Miller Fisher syndrome (MFS). The GQ1b ganglioside is a specific antigen for MFS. Emerging data suggest that GD1b ganglioside antibodies are seen in some COVID-19–triggered GBS
- There is a high incidence of antibodies to *Campylobacter jejuni*, and GM1, with molecular mimicry between *Campylobacter* and nerve gangliosides.
- Injection of lipooligosaccharides extracted from *C. jejuni* causes AMAN and elicits GM1 antibodies in rabbits.
- Antiganglioside antibodies extracted from patients with GBS block muscle action potentials in vitro.

chronic APN because it is treatable in the majority of cases. CIDP can be considered the chronic counterpart of GBS because of the various clinical, electrophysiological, histological, and laboratory similarities. CIDP differs from GBS predominantly by its tempo, mode of evolution, prognosis, and responsiveness to steroids. First described as a "steroid-responding relapsing polyneuropathy," CIDP shares with GBS a variety of common autoimmune features.

Clinical Features and Disease Variants

The typical CIDP is characterized by progressive, symmetrical, proximal, and distal muscle weakness, paresthesias, sensory dysfunction, and impaired balance that evolve slowly over at least 2 months.[1–3,11,12] Tendon reflexes are absent or reduced. Cranial nerves rarely may be affected. The course can be monophasic with stepwise progression, but also relapsing with even spontaneous remissions necessitating the need to periodically evaluate the usefulness of continuing immunotherapies. Because the demyelination is multifocal, affecting roots, plexuses, and proximal nerve trunks, the clinicopathological picture may be variable, accounting for the different manifestation of symptoms and signs.[1–3,11,12] CIDP variants include the asymmetrical, unifocal or multifocal, motor–sensory form (Lewis-Sumner syndrome); pure motor; sensory or sensory ataxia; and the distal variant.

Diagnosis

The CSF protein is elevated, up to sixfold, without pleocytosis (except if an infection coexists). Nerve biopsy shows demyelination and remyelination, occasional epineurial or

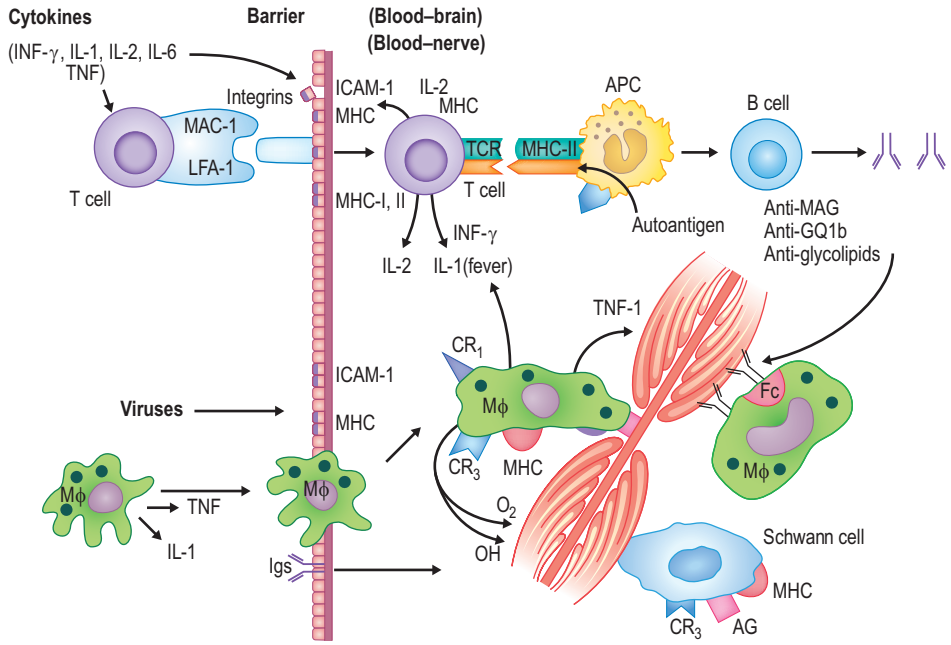

FIG. 67.1 Sequence of Events in the Mechanisms of Immune-Mediated Demyelinating Polyneuropathy. Cytokines lead to increased expression of major histocompatibility complex class I *(MHC-I)* and intercellular adhesion molecules (ICAM-1), allowing the sensitized T cells and macrophages to exit the endothelial cell wall and traffic to the peripheral nerve. There they recognize myelin antigen and induce a macrophage-mediated demyelination. The antigen-presenting cells (*APCs*; probably Schwann cells or macrophages), in concert with MHC class II *(MHC-II)* expression, interact with CD4 T cells and lead to clonal expansion of B cells, producing antibodies against various peripheral nerve antigens. *AG*, antigen; *APC*, antigen-presenting cell; *CR*, complement receptor; *GQ1b*, gangliocide GQ1b antibody; *Igs*, immunoglobulins; *IL-1,2,6*, Interleukin-1,2,6; *INF*, interferon; *LFA-1*, lymphocyte function associated antigen-1; *MAG*, myelin-associated glycoprotein; *MHC*, major histocompatibility complex; *OH*, hydroxyl radical; *TCR*, T cell Receptor; *TNF*, Tumor necrosis factor.

endoneurial T cells, and several macrophages scattered or in small perivascular clusters in the endoneurium (Fig. 67.2).[1–3,12,13] Electrophysiological testing is fundamental for the diagnosis by demonstrating demyelination in motor and sensory fibers. including slow conduction velocity, prolonged distal motor or sensory latencies, prolonged F-wave latencies, and conduction block with dispersion of the compound muscle action potentials. An associated axonal loss is common in the majority of cases. A variety of diagnostic criteria have been proposed to capture the most pertinent of the aforementioned features; the revised European Federation of Neurological Societies/Peripheral Nerve Society (EFNS/PNS) guidelines seem most appropriate, offering 81% sensitivity and 96% specificity in capturing patients more likely to respond to immunotherapies.[1–3,12] Routine CSF testing and nerve biopsy are not mandatory for diagnosis, but can be helpful when the electrophysiological results are not clear or need to exclude other causes.[3,12] Concomitant diabetes is an important factor because it is more frequent in CIDP and is needed to dissect if any neuropathy component is diabetes related. Other neuropathy causes that should be excluded are paraneoplastic, IgM paraproteinemias (IgG or IgA monoclonal gammopathy of undetermined significance [MGUS] can be seen in CIDP), myelomas, vasculitis, alcoholism, neurotoxic drugs, or family history.

KEY CONCEPTS

Autoimmunity in Chronic Inflammatory Demyelinating Polyneuropathy

- Activated macrophages are the predominant endoneurial cell, displacing the Schwann cell cytoplasm, disrupting myelin, and lysing superficial myelin lamellae.
- Complement-fixing IgG and IgM antibodies are deposited on the myelin sheath.
- IgG antibodies to acidic glycolipids LM1, GM1, or GD1b and against the 28-kDa P0 myelin proteins are detected in the sera of some patients.
- There is upregulation of DR and B-7 costimulatory molecules in Schwann cells and macrophages.
- Serum IgG can induce conduction block when injected into rat nerves.
- Up to 25% of patients with *chronic inflammatory demyelinating polyneuropathy* (CIDP) harbor specific antibodies against antigens in the nodes of Ranvier; in 10% of them these antibodies have been identified as directed against neurofascin-155 and contactin-associated protein (CASPR), causing conduction block.

Immunopathogenesis

Activated T cells, macrophages, complement, and autoantibodies seem to work in concert with each other to induce an immune attack against peripheral nerve antigens (see Fig. 67.1).[2,3,11,12] No triggering factors have been identified, however.

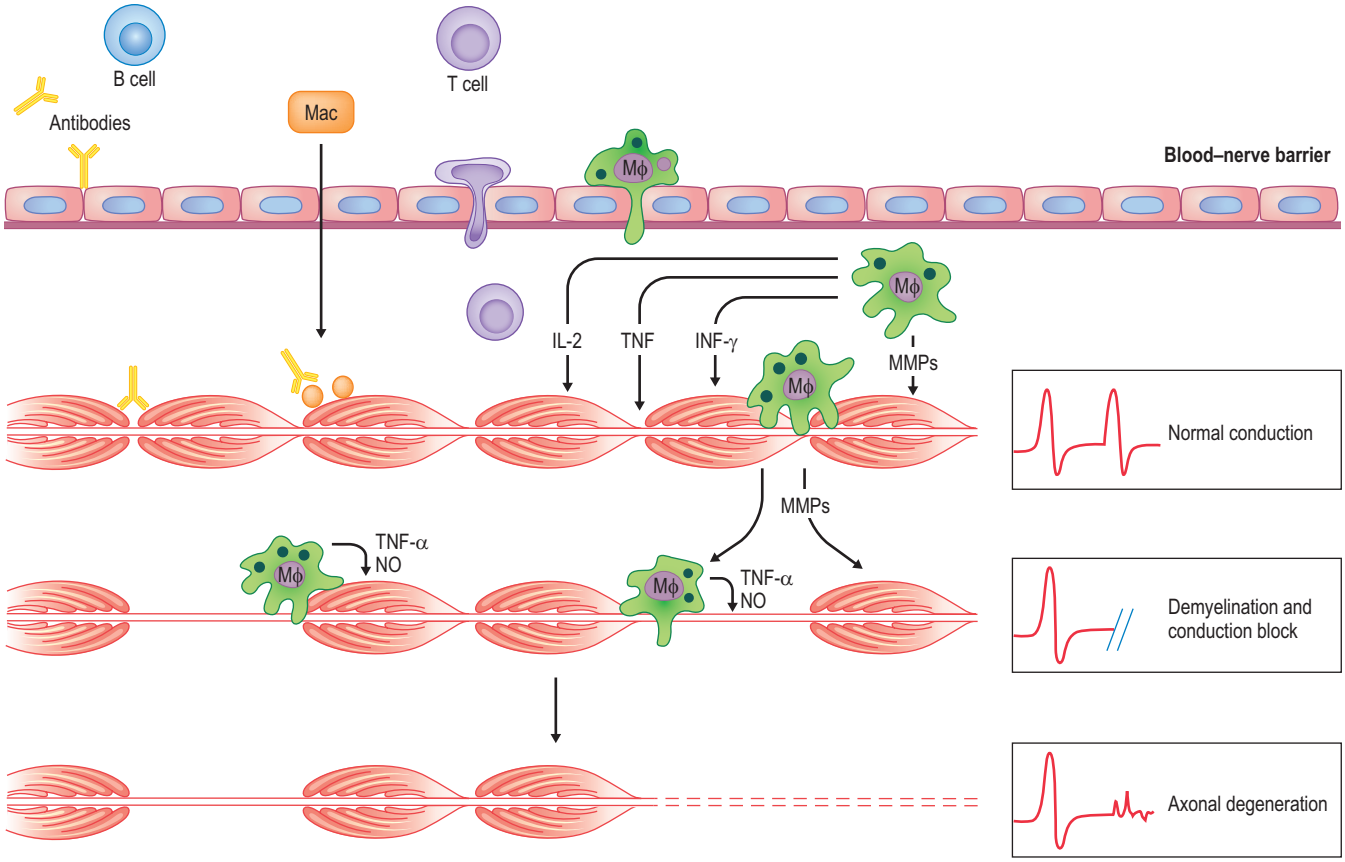

FIG. 67.2 Diagrammatic Scheme of the Main Cellular and Humoral Factors Implicated in the Demyelinating Process of Chronic Inflammatory Demyelinating Polyneuropathy (CIDP) Leading to Axonal Loss. Activated macrophages (Mϕ) and T cells cross the endothelial cell wall of the blood–nerve barrier and reach the myelinated fibers. Activated, TNF-α-positive Mϕ invade the myelin sheath, causing Mϕ-mediated segmental demyelination. Axonal loss secondary to demyelination, probably enhanced by TNF-α and metalloproteinases, may become prominent in the chronic phases of the disease. Other cytokines, T cells sensitized to unidentified antigens, and putative antibodies may participate. *IFN*, Interferon; *IL*, interleukin; *MMP*, metalloproteinase; *Mϕ*, activated macrophage; *NO*, nitrous oxide; *TNF*, tumor necrosis factor.

The predominant endoneurial mononuclear cells are macrophages that constitute the final effector cells associated with demyelination; macrophages express activation markers probably induced by cytokines released by autoreactive T cells in situ or the circulation. These cells penetrate the basement membrane of the Schwann cell, displace the cytoplasm, and split the myelin lamellae.[1–3,12,13] Macrophages and Schwann cells may serve as antigen-presenting cells because they express human leukocyte antigen (HLA)-DR and costimulatory molecules B7-1 (CD80) and B7-2 (CD86), whereas their counterreceptors cytotoxic T lymphocyte antigen-4 (CTLA-4) and CD28 are expressed on rare endoneurial CD4 T cells.[2,3,13] B7-2–deficient mice also develop CIDP.[13] Soluble adhesion molecules, cytokines, and metalloproteinases, detected in serum and CSF, facilitate lymphoid-cell transmigration across the blood–nerve barrier. Although T cells are not prominent, the few endoneurial CD8 and CD4 cells have monoclonal or oligoclonal restrictions in their T-cell receptor repertoire, implying an antigen-driven T-cell response.[2,3,12]

Although pathogenic antigens remain elusive, humoral factors seem to play a role as supported by the beneficial effect of plasmapheresis. That antibodies may be implicated dates back to 40 years ago when complement-fixing IgG and IgM were first found deposited on the patient's myelin sheath.[14] Antibodies to glycolipids LM1, GM1, or GD1b also have been seen in some patients, more frequently than in controls.[2,3,11] Overwhelming evidence the last 5 years shows that molecules associated with saltatory conduction at the nodes of Ranvier are more meaningful targets[1–4,11,15–18] because functional blockade in these regions can best account for the rapid improvement noticeable within days after plasmapheresis or intravenous immunoglobulin (IVIG). Antigenic targets at the nodes of Ranvier are seen in approximately 10% of CIDP patients and include pathogenic antibodies against neurofascin-186, moesin, and gliomedin (at the node); and neurofascin-155 (NF155), contacting CASPR 1 (CNTN1), and connexins (at the paranode).[1–4,11,15–17] These antibodies are of the IgG4 subclass causing disadhesion of the myelin lamellae without fixing complement. Of interest, anti-NF155– and CNTN1-positive patients have distinct clinical phenotypes with more severe disease, axonal involvement, tremors, sensory ataxia, and suboptimal response to IVIG;[1–4,11,15–17] they respond, however, to rituximab that effectively depletes IgG4 from short-lived plasma cells.

Overall, the immunopathogenetic scheme proposed for GBS (see Fig. 67.1) is also applicable to CIDP. Molecular mimicry can be implicated in rare CIDP cases associated with melanoma because the carbohydrate myelin epitopes GM2, GM3, and GD3 are also expressed on melanoma cells, and antibodies against melanoma cells react with myelin glycoproteins.[18] The axonal involvement accompanying or following demyelination in CIDP and GBS is depicted in Fig. 67.2 and the nodal antigens in Fig. 67.3.[2,3,11,15,16]

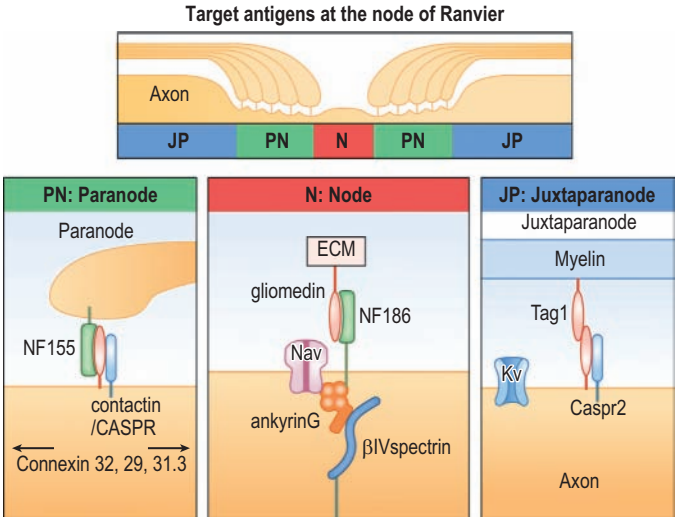

FIG. 67.3 Main proteins in the nodal (*N*), paranodal (*PN*), and juxtaparanodal (*JP*) regions in the nodes of Ranvier implicated as antigens in acquired demyelinating neuropathies (Guillain-Barré syndrome [GBS] and predominantly chronic inflammatory demyelinating polyneuropathy [CIDP]). The two main antigenic targets in CIDP are neurofascin-155 and CASPR2 located in the paranodal regions; antibodies against these proteins are detected in the serum of 10% of patients with CIDP, resulting in conduction block and paranodal axonal changes that probably account for resistance to intravenous immunoglobulin (IVIG).[4,13]

MULTIFOCAL MOTOR NEUROPATHY WITH CONDUCTION BLOCK

Multifocal motor neuropathy (MMN) is a distinct disease that, although rare with prevalence of 0.6/100,000, should be recognized early because it is treatable. It affects males more than females and presents with progressive weakness, atrophy, and areflexia. MMN often begins in the hands and is prominent in distal muscle groups supplied by many individual peripheral nerves (multifocal).[1–3,19] It differs from vasculitic neuropathy because it has slow onset, is painless, and affects only the motor nerve fibers. It also differs from the motor variant of CIDP because it is multifocal, distal, and asymmetrical. MMN is sometimes misdiagnosed as lower motor neuron disease, especially when patients experience cramps and fasciculations, and treatment is delayed. In contrast to lower motor neuron disease, MMN progresses very slowly, the weakness is within distributions of peripheral nerves and not multisegmental, while cranial musculature is often spared. CSF protein is normal, in contrast to the motor CIDP variant. MMN is electrophysiologically distinct because it exhibits multifocal conduction blocks only in motor nerves; sensory conduction remains normal across the nerve segments with motor block.

Up to 50% of MMN patients have high IgM antibodies to GM1 ganglioside, which activate complement in association with disease severity[1–3,19] but their pathogenic role is uncertain. GM1 antibodies can also be seen in other autoimmune neuropathies and up to 25% of amyotropic lateral sclerosis (ALS) patients. The reason for the selective motor involvement is unclear. Differences in the antigenic specificities of myelin components between motor and sensory fibers are suspected because the ceramide composition of gangliosides differs between sensory and motor fibers. MMN responds remarkably well to IVIG.

POLYNEUROPATHIES ASSOCIATED WITH MONOCLONAL GAMMOPATHIES OF UNDETERMINED SIGNIFICANCE

A distinct subset of acquired polyneuropathies has been associated with a circulating paraprotein (see Chapter 79). Although neuropathy occurs in a setting of myeloma, plasmacytoma, or Waldenström macroglobulinemia, the majority of patients with paraproteinemic neuropathies do not have a lymphoproliferative

disease, and the MGUS. Up to 1% of normal people greater than 50 years of age may have MGUS but the incidence increases to 1.7% above 70, reaching up to 6% above the age of 90. Monoclonal gammopathies, however, are 10 times more frequent in patients with polyneuropathy than in an age-matched control population, and almost 10% of patients with acquired polyneuropathy have MGUS.[2,3,20] If these gammopathies are categorized into subclasses, the incidence of polyneuropathy among patients with IgM monoclonal proteins is as high as 50%,[2,3,20] implying that almost 50% of patients with IgM MGUS may have or will develop polyneuropathy. At present, polyneuropathies with MGUS comprise 10% of patients with acquired neuropathy.[2,3,20] Patients with demyelinating polyneuropathy associated with IgG or IgA MGUS are indistinguishable from CIDP and the MGUS is coincidental and causally unrelated to neuropathy. In contrast, polyneuropathy associated with IgM MGUS is a distinct clinicopathological entity, and the IgM is considered pathogenic, often directed against myelin glycoproteins or glycolipids.[2,3,20–23]

Some patients with paraprotein may have an associated amyloidosis derived from the variable region of the Ig light chain, primarily λ. When amyloidosis is present, the neuropathy is painful and often accompanied by autonomic symptoms of orthostatic hypotension, impotence, and impaired gastric motility.

ANTIBODIES TO MYELIN-ASSOCIATED GLYCOPROTEIN (MAG) IN PATIENTS WITH IgM MGUS (ANTI-MAG NEUROPATHY)

Most of these patients present with a sensory, large-fiber, demyelinating polyneuropathy that manifests as sensory ataxia.[1–3,20,21] Others have a sensorimotor polyneuropathy with mixed demyelinating and axonal features. CSF protein is often elevated. Nerve conduction studies typically demonstrate distal demyelination with prolonged distal motor and sensory latencies. Sural nerve biopsy shows a diminished number of myelinated axons. On electron microscopy, there is splitting of the outer myelin lamellae, linked to the presence of IgM deposits in the same area of the split myelin sheath.[1–3,20,21]

Approximately 50% of these patients react with MAG, a 100 kDa glycoprotein of the central and peripheral nerve myelin, as well as other glycoproteins or glycolipids that share antigenic determinants with MAG.[2,3,20–23] The anti-MAG IgM paraproteins co-react with an acidic glycolipid in the ganglioside fraction of peripheral nerve, identified as a sulfoglucuronyl glycosphingolipid (SGPG).[2,3,20–23] In contrast to MAG, which is mostly present in the central nervous system, SGPG is only in the peripheral nerves. In some patients with IgM MGUS the IgM also reacts with various gangliosides, most commonly those that contain either a disialosyl moiety, such as GD1b, GQ1b, GT1b, GalNac-GM1b, and GalNAc-GD1a, or two gangliosides that share epitopes with GM2, or a combination of GM2 and GM1, GM1 and GD1b.[2,3,20–23] More than half of the IgM paraproteins recognize MAG and SGPG, and 75% of the rest recognize ganglioside antigens, indicating that acidic glycolipids are the most common antigenic epitopes.[2,3,20–23] The glycolipids implicated in immune-mediated neuropathies are depicted in Fig. 67.4.

Anti-MAG antibodies are detected readily in patients' sera with ELISA or preferably with Western blot. Because anti-MAG–reacting sera always recognize the SGPG glycolipid, the assay is often performed by using SGPG as antigen instead of purified human MAG. It is preferable, however, to use MAG as the target antigen so as not to miss low-affinity antibodies because IgM binds to MAG with 10 to 100 times higher affinity compared with SGPG.

The following factors suggest that MAG antibodies are related to the cause of the neuropathy.[2,3,20–23]

1. IgM and complement are deposited on the patient's myelinated fibers suggesting that activated complement may be needed in the induction of demyelination.
2. IgM recognizes neural cell adhesion molecules and colocalizes with MAG on the areas of the split myelin lamellae, suggesting involvement in myelin disadhesion. Skin biopsies from these patients have also confirmed the presence of IgM, complement C3d, and MAG deposition on the dermal myelinated fibers with concurrent loss of nerve fibers.[24]
3. Serum from these patients injected into feline peripheral nerve causes complement-dependent demyelination and conduction block;[25] the injected IgM binds to the outer layer of the myelin sheath.
4. Systemic transfusion of anti-MAG IgM paraproteins produces segmental demyelination in chickens,[26] with the IgM splitting the myelin lamellae, similar to human neuropathy.
5. Immunization of cats with purified SGPG causes ataxic neuropathy, similar to human disease, with inflammation of the dorsal root ganglionic neurons.[27]

KEY CONCEPTS

Autoimmunity in Polyneuropathy With IgM Monoclonal Gammopathy

- In more than 50% of patients IgM is an antibody against two antigens, myelin-associated glycoprotein (MAG) and sulfoglucuronyl glycosphingolipid (SGPG).
- In many patients with non-MAG–reacting monoclonal IgM, the IgM recognizes *(i)* gangliosides containing disialosyl moieties, including GM1, GM2, GD1b, GD1a, and LM1; *(ii)* sulfatides; and *(iii)* rarely, chondroitin sulfate.
- Overall, in at least 75% of patients the IgM recognizes gangliosides that appear to be the primary antigenic targets.
- IgM is deposited on the homologous myelin sheath and fixes complement.
- IgM, when deposited on the myelin sheath, results in disadhesion and separation of the myelin lamellae and disruption of normal myelin function.
- Intraneural injection of anti-MAG–reacting IgM or passive transfusion into experimental animals causes segmental demyelination, whereas complement-fixing IgM is immunolocalized to the myelin sheath, causing myelin separation.
- Immunization of cats with purified SGPG causes an ataxic neuropathy, similar to the one seen in humans, with involvement of the dorsal root ganglia.

POLYNEUROPATHY, ORGANOMEGALY, ENDOCRINOPATHY, MYELOMA, AND SKIN CHANGES (POEMS SYNDROME)

A subset of patients with malignant IgG or IgA monoclonal proteins have polyneuropathy with osteosclerotic myeloma. Most of them have POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, and *s*kin changes).[1–3,28] Not included in the acronym are sclerotic bone lesions, giant lymph node hyperplasia (Castleman disease), papilledema, pleural effusion,

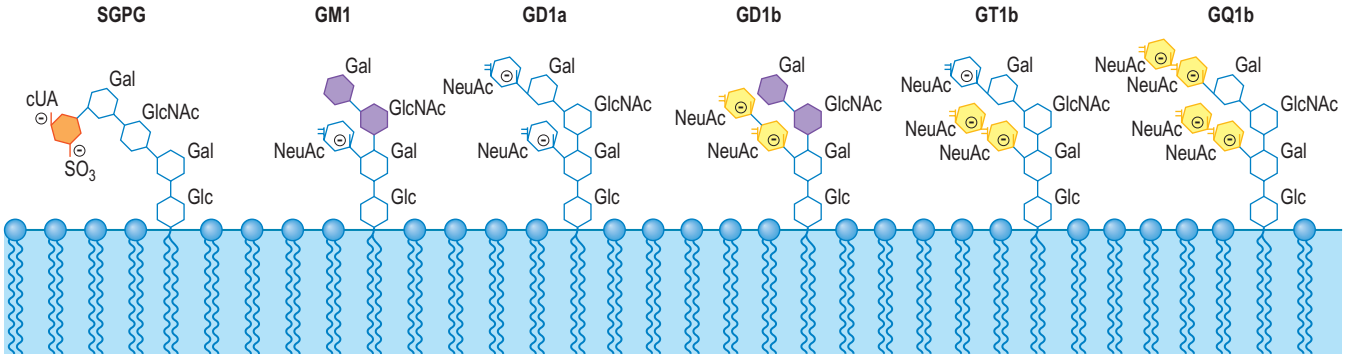

FIG. 67.4 Glycolipids Implicated as Antigens in Immune-Mediated Neuropathies. Sulfate-3-glucuronyl paragloboside (SGPG) is the glycolipid sharing a carbohydrate epitope with myelin-associated glycoprotein (MAG), and the terminal sulfated glucuronic acid is a key part of the epitope. GM1 is the ganglioside implicated in motor nerve disorders, and in most cases the terminal Gal (β1–3) GalNAc epitope, which is shared with GD1b, is involved. The disialosyl moiety implicated in sensory neuropathies consists of NeuAca2—8NeuAc—and is present in GD1b and GT1b gangliosides, as well as the simpler GD2 and GD3 gangliosides (not shown). GQ1b ganglioside, which is the target antigen in Miller Fisher syndrome (MFS), has two disialosyl moieties. Although GD1a ganglioside has two sialic acid residues, they are not linked to each other, so antibodies to GD1a do not cross-react with anti-GD1b antibodies. The color-coded sugar moieties represent key aspects of the various epitopes, but carbohydrate sequences recognized by the antibodies may include additional sugar residues. *Gal*, Galactose; *GalNAc*, *N*-acetylgalactosamine; *Glc*, glucose; *G1cNAc*, *N*-acetylglucosamine; *GlcUA*, glucuronic acid; *NeuAc*, *N*-acetylneuraminic acid (sialic acid).

edema, ascites, and thrombocytosis.[28] More than 50% of patients with osteosclerotic myeloma of the IgA or IgG type have sensorimotor polyneuropathy with mixed demyelinating and axonal features and high CSF protein. The neuropathy tends to be associated with leg edema, hyperpigmentation, sclerodermatous thickening, and hypertrichosis with dark hair. Endocrinopathy most often includes gonadal failure, amenorrhea, impotence, gynecomastia, hypothyroidism, diabetes, or elevated prolactin levels. The IgG class is slightly more common than the IgA, with λ light chain present in the majority of patients.[28] Bone lesions can be sclerotic, solitary, or multiple, sparing the skull and the extremities. Pathological changes in lymph nodes resemble those of Castleman disease, which can also be associated with polyneuropathy.[28] There is imbalance of proinflammatory cytokines with increased IL-1β, IL-6, and tumor necrosis factor-α. Vascular endothelial growth factor (VEGF) may play a major role because it induces rapid increase in vascular permeability and angiogenesis.[28]

In some patients, the neuropathy responds to steroids, tamoxifen, or alkylating agents. In others, it responds to removal or irradiation of the solitary sclerotic lesion, suggesting that the tumor may secrete neurotoxic factors. IVIG and plasmapheresis are ineffective. Autologous stem cell transplantation may result in significant improvement with reduction of VEGF, improved nerve conduction velocity, and increased survival.[29]

CRYOGLOBULINEMIC NEUROPATHY

Cryoglobulins are proteins that precipitate in the cold and redissolve when heated. There are three types of cryoglobulin: type I, which is monoclonal, often of the IgM and IgG class; type II, which is mixed polyclonal, with one monoclonal (often monoclonal IgM with polyclonal IgG); and type III, which is polyclonal (often IgM and IgG). Polyneuropathy occurs most often with mixed cryoglobulinemias and presents with distal sensorimotor involvement or as mononeuropathy multiplex. Nerve biopsy shows perivascular inflammatory cuffing with axonal degeneration. Patients also have purpura, polyarthralgias, cutaneous vasculitis, Raynaud phenomenon, renal involvement, and increased incidence (up to 90%) of hepatitis C infection.

PARANEOPLASTIC PERIPHERAL NEUROPATHIES WITH ANTI-HU OR CRMP-5 ANTIBODIES

Peripheral neuropathy in patients with cancer is either related to the systemic effects of the tumor or, more often, to various chemotherapeutic agents that typically presents as painful dysesthesias. The most distinct immune-related neuropathy is the *paraneoplastic sensory neuronopathy* (PSN), often associated with small cell lung cancer, breast cancer, lymphomas, or thymomas.[30] It might be the presenting symptom of the underlying neoplasm typically characterized by gait ataxia with choreoathetotic movements related to loss of proprioception in the feet and hands, and distal paresthesias. Strength is normal. Some patients may have autonomic dysfunction. CSF protein is increased and electrophysiology shows axonal sensory neuropathy. PSN is a sensory neuronopathy caused by a variable degree of inflammation in the dorsal root ganglionic neurons. Typically, the patients have specific IgG anti-Hu autoantibodies directed against a closely spaced group of proteins with a molecular weight of 35 to 40 kDa.[30] The antibodies are in higher titers in the CSF, suggesting intrathecal synthesis. The Hu protein may also be expressed in the tumors. Because low-titer anti-Hu antibodies are seen in 20% of patients with small cell lung cancer even without neurological symptoms, PSN may represent an autoimmune reaction against antigens shared by both the tumor cells and the dorsal root ganglionic neurons. Anti-Hu antibodies are helpful markers in suspecting occult small cell lung cancer in patients presenting with sensory ataxic neuropathy. Some patients may also have other paraneoplastic antibodies, such as collapsing response mediator protein (CRMP-5), often referred to as anti-CV2.[30] Immune neuropathies are also seen with immune-checkpoint inhibitors, most often GBS or CIDP, responding to immunotherapies.[9]

AUTOIMMUNE AUTONOMIC NEUROPATHIES

Autoimmune autonomic neuropathy (AAN) is highlighted by high-titer antibodies against the ganglionic nicotinic acetylcholine receptors (Gn-AChRs).[31] Patients present with a subacute (within 4 weeks) or chronic (within months) onset of neurogenic orthostatic hypotension, with systolic blood pressure reduction of at least 30 mm Hg or mean blood pressure reduction of at least 20 mm Hg within 3 minutes of head tilting. Onset may be preceded by viral infections. Patients may also exhibit parasympathetic/enteric symptoms including sicca (dry eyes, dry mouth); abnormal pupillary responses; gastrointestinal symptoms (postprandial nausea and vomiting leading to weight loss); and neurogenic bladder. Some symptoms can be passively transferred to mice injected with the patient's IgG while rabbits immunized with a fragment of Gn-AChRs exhibit autonomic failure similar to human disease, suggesting that the antibodies may be pathogenic.[30] Because Gn-AChRs have been found in small cell lung carcinoma cell lines, cancer may be a potential initiator of ganglionic autoimmunity.

A subset of patients with these symptoms do not have Gn-AChRs and an autonomic autoimmune ganglionopathy is circumstantially suspected when symptoms occur in a setting of an underlying autoimmune neurological or rheumatological disease. It has been generally difficult to clinically distinguish whether some of these patients have an organic autonomic nervous system autoimmunity or a functional disorder.

POSSIBLY AUTOIMMUNE SMALL FIBER SENSORY NEUROPATHIES, NEUROPATHIC PAIN, AND NEURAL ANTIBODIES

Small fiber sensory neuropathy (SFN) is now one of the commonest neuropathies. Patients present with diffuse pains, intolerance to light touch, allodynia or hyperalgesia, and some with autonomic features. They typically have normal neurological examination including sensation, reflexes, strength, balance, and nerve conduction studies.[32] Reduced distal intraepidermal nerve fiber density is seen on skin biopsy. The condition represents involvement of unmyelinated C-fibers, thinly myelinated A-δ somatosensory fibers, and possibly autonomic neurons, leading to diffuse painful dysesthesias. In several patients these symptoms overlap with other painful disorders such as fibromyalgia and erythromelalgia. When all causes are excluded, they are categorized as idiopathic. A functional component may at times be prominent. There is recent emphasis on autoimmunity because almost 20% of the patients may have a systemic autoimmune or rheumatic disease such as Sjögren syndrome, celiac disease, rheumatoid arthritis, or nonspecific immunological abnormalities such as extractable nuclear antigen antibodies.[32,33] Some patients anecdotally respond to IVIG.[32] Although no underlying autoimmunity has been identified, two nonspecific autoantibodies, one against *trisulfated heparin disaccharide (TS-HDS)*, a disaccharide component of the glycosylation moieties of heparin and heparan sulfate, and another against *fibroblast growth factor-3 (FGFR3)*, a secreted cell surface receptor, have been more frequently detected in such patients than controls.[34]

MONONEUROPATHY MULTIPLEX AND LOCALIZED, ISOLATED VASCULITIS OF THE PERIPHERAL NERVES

Polyneuropathy is a common manifestation of systemic vasculitis. It occurs in patients with polyarteritis nodosa; connective tissue diseases; hypersensitivity vasculitis; Churg-Strauss syndrome; temporal arteritis; and viral infections, especially retroviruses and hepatitis. It classically presents as mononeuritis multiplex affecting several individual nerves with painful weakness and paresthesias caused by ischemia and infarcts due to inflammation of endoneurial blood vessels. There is, however, a distinct vasculitic entity localized only to the peripheral nerve, known as *isolated peripheral nerve vasculitis* (PNV) with presentation similar to vasculitic neuropathy but without any systemic organ involvement, negative serology, and slower onset and progression. PNV involves the small and medium-sized arteries of the epineurium and perineurium and causes ischemic changes within the peripheral nerve. The diagnosis is confirmed with nerve biopsy of the sural or superficial peroneal nerve often combined with muscle biopsy for higher diagnostic yield. PNV has a better prognosis compared to systemic vasculitides and is a treatable form of neuropathy.

NEUROPATHY WITH VIRUSES

Neuropathy can be seen in a setting of infectious, viral, or bacterial processes such as Lyme disease, CMV, hepatitis, herpes, human immunodeficiency virus, or COVID-19 as a manifestation of triggered autoimmunity rather than direct infection of the nerves: most commonly included are GBS, CIDP, acute ganglioneuritis, Bell palsy, mononeuritis multiplex, or even small fiber sensory neuropathy seen early in the infection, or rarely as the presenting manifestation of the infection. The best studied cases are due to HIV where immunocytochemical studies have shown HIV in rare endoneurial macrophages, but not within Schwann cells or axons. There is strong expression of HLA class I and II molecules on Schwann cells, endothelial cells, and macrophages, but sparse CD8 and CD4 T cells (Fig. 67.5).[31]

A rare neuropathy seen in later-stage HIV infection is a lumbosacral polyradiculoneuropathy related to CMV. It affects roots and sensory ganglia and presents with lower-extremity muscle weakness, sacral and distal paresthesias, areflexia, muscular atrophy, and sphincteric dysfunction resembling cauda equina syndrome. CMV inclusions are within Schwann cells or endothelial cells (Fig. 67.6).[31] Presently, the commonest neuropathy in HIV patients is a sensory axonal neuropathy manifested with distal painful dysesthesias and areflexia most often related to antiretroviral drugs.

TREATMENT

APNs are clinically important because they are potentially treatable with various immunosuppressive, immunomodulating, or chemotherapeutic agents. The author's approach to the treatment is as follows.

Guillain-Barré Syndrome

Supportive Care

The dramatic reduction in the mortality of GBS is mainly attributed to early ICU care, improved respiratory support, and control of autonomic cardiac dysregulation. A patient with GBS is best monitored in an ICU, even if respiratory compromise is not evident at the time of admission; when vital capacity drops or bulbar weakness is severe, intubation is necessary.

Plasmapheresis

In double-blind controlled studies, plasmapheresis has been effective if performed within the first week from onset. Five or six

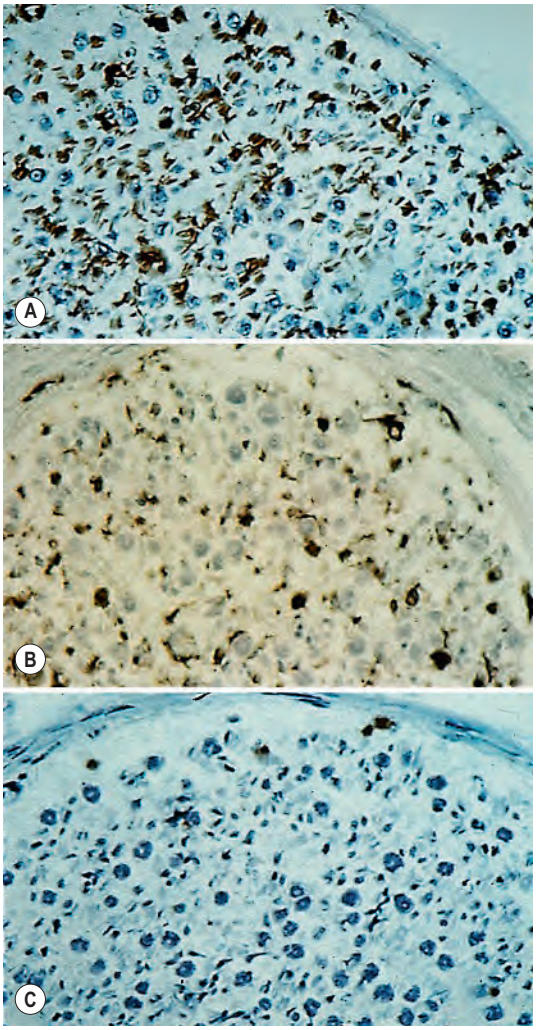

FIG. 67.5 Serial sections of a nerve biopsy from a patient with human immunodeficiency virus (HIV)–chronic inflammatory demyelinating polyneuropathy stained for (A) human leukocyte antigen (*HLA*)-*DR*, (B) macrophages, and (C) CD8 T cells shows that the majority of the endoneurial cells are macrophages. Only rare CD8 cells are noted.

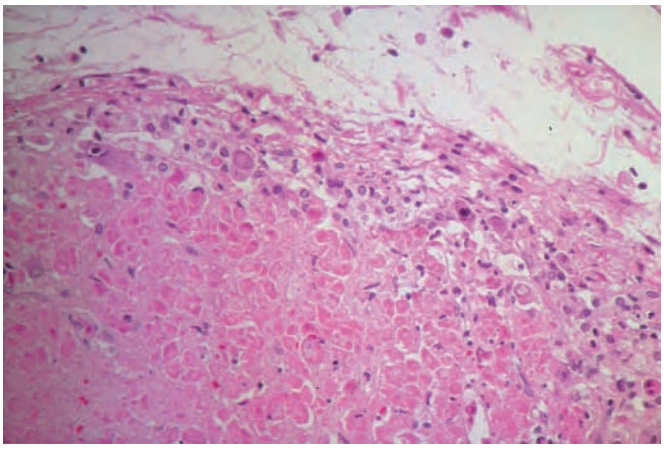

FIG. 67.6 Cross-section of a root from a patient with human immunodeficiency virus (HIV)–associated Guillain-Barré syndrome (GBS) shows cytomegalovirus inclusions within the Schwann cell.

exchanges, one every other day, are sufficient. Early relapses can occur in 20% of patients, who may require a second series.[1–4] In mild cases two exchanges are sufficient and in moderate cases four are optimal.

Intravenous Immunoglobulin

Based on two controlled studies,[1,4] IVIG (see Chapter 82), given at 2 g/kg over 2 to 5 days, is as effective as plasmapheresis, with no added benefit when the two procedures were combined. The decision as to which treatment to choose is governed by circumstances, availability of treatment modality, experience, age of the patient, and other associated conditions. Early relapses can also occur with IVIG, as often as with plasmapheresis. IVIG has become the therapeutic choice worldwide because it is easy to administer and more readily available for early therapy initiation. In spite of anecdotal reports that a second IVIg course may be beneficial, recent data from a controlled study suggest that a second IVIg infusion is not helpful or safe in severely affected GBS patients unresponsive to the first course. Steroids are ineffective and may even increase the incidence of future relapses. Combining IVIG with IV methylprednisolone has shown no added benefit.

Chronic Inflammatory Demyelinating Polyneuropathy

Prednisone

CIDP was originally described as a steroid-responsive polyneuropathy with its efficacy later proven in a small controlled study.[1–3,11,12] Whenever used, a high-dose regimen of 80 to 100 mg prednisone daily is preferred, followed by tapering to every-other-day dosing. Azathioprine, cyclosporine, methotrexate, or mycophenolate are ineffective as steroid-sparing agents.[1–3,11]

Intravenous Immunoglobulin

In several controlled studies,[1–3,11,12] IVIG has been effective and approved as first-line therapy. Monthly maintenance therapy is needed, preventing relapses in up to 60% of patients. A recent controlled trial showed that subcutaneous immunoglobulin (SCIG) is as effective, but whether it is preferable by the patients has not been documented[35] especially since a number of patients relapsed after transitioning from IVIG to SCIG.[35]

Plasmapheresis

It is also effective in controlled studies.[1–3,11,12] After a series of six plasma exchanges, maintenance therapy, with one exchange at least every 8 weeks, may be required. IVIG has now replaced plasmapheresis in most centers.

Polyneuropathy with Paraproteinemias

Patients with benign IgG or IgA demyelinating polyneuropathies respond in a manner similar to CIDP. Patients with malignant paraproteinemias should be treated with chemotherapy, as needed for the underlying disease. When the neuropathy is axonal, treatments are generally disappointing.

For IgM anti-MAG demyelinating polyneuropathies, treatments with prednisone plus chlorambucil, plasmapheresis, and IVIG[2,3,20] has shown a variably marginal or minimal benefit. Rituximab is, however, the most promising therapy,[20] providing

efficacy in almost 40% of the patients in a small double-blind study, as confirmed later with a larger study,[19] even though both did not reach significance. Additional, uncontrolled series with many patients have confirmed that rituximab is effective in 30% to 40% of these patients.[20]

MULTIFOCAL MOTOR NEUROPATHY

MMN responds very well only to IVIG, which is the treatment of choice based on controlled trials. In difficult cases, cyclophosphamide or rituximab may be promising, but no controlled studies have been carried out.[1–4]

Paraneoplastic Neuropathy

Anecdotally, some of these patients have responded to plasma exchange or IVIG, but overall this neuropathy has not been consistently responsive to available therapies.

Vasculitic Neuropathies

For isolated peripheral nerve vasculitis, a combination of prednisone 1.5 mg/kg/day with cyclophosphamide 2 mg/kg/day orally, or 1 g/m^2 intravenously monthly for 6 months, is the treatment of choice. Plasmapheresis has been tried in cryoglobulinemic neuropathies, with variable results.

HIV Neuropathies

GBS and CIDP in a setting of HIV are treated with the same therapies as in HIV-negative patients, with IVIG being the preferable choice. Ganciclovir may be helpful in CMV-related polyradiculoneuropathy.

Possibly Autoimmune Small-Fiber Sensory Neuropathies

This is a difficult group of patients to provide effective therapies because the autoimmunity is unclear. In some patients steroids and IVIG can be anecdotally effective. Tricyclic antidepressants, carbamazepine, gabapentin, Lyrica (pregabalin), topiramate, and Cymbalta (duloxetine) are the preferable therapies. Topical capsaicin in various combinations may provide some pain relief.

ON THE HORIZON

- Identification of common causes that break tolerance, either in connection with the gut microbiome or exogenous agents, and expansion of the current limited data on molecular mimicry between nerve glycoproteins and viral or bacterial antigens.
- Development of neuroimaging capabilities to image peripheral nerves and dorsal roots in vivo and quantify inflammation, demyelination, and axonal degeneration, providing an accessible and reliable tool for diagnosis and monitoring response to therapies, in a model similar to magnetic resonance imaging (MRI) in multiple sclerosis. Nerve ultrasound seems now promising.
- Performance of proteome studies and systematic autoantigenomic approaches to identify biomarkers of nerve autoimmunity that may lead to specific therapies.
- Trials with target-specific therapies for acute and chronic demyelinating neuropathies, *applied in combination with the existing therapies*, targeting early in the disease process complement activation, regulatory T-cell (Treg) functions, key proinflammatory cytokines, and B cells.
- Identification of agents and trophic factors that could prevent axonal degeneration from the outset, promote remyelination, prevent axonal loss, or trigger axonal regeneration and reverse, early in the disease process, a seemingly "permanent" clinical deficit.

ACKNOWLEDGMENTS

The author thanks the various Neurology Fellows who provided excellent care to his patients; and Drs. Amjad Ilyas and Richard Quarles for help with immunochemistry of MAG and SGPG and gangliosides.

Immunologic Renal Diseases

Tilo Freiwald, Meryl Waldman, and Behdad Afzali

The immune system is a major pathological component of many human diseases. Kidney diseases are no exception, with compelling clinical, pathological, and experimental data implicating immune-mediated injury, particularly in diseases of the glomeruli.[1] Physiological immunity requires complex interactions between both innate and adaptive arms of the immune system and tissue-derived signals. Humoral factors, including complement, coagulation and inflammatory factors and their regulators, interplay with cellular processes, to alter cellular behavior, microvascular biology and recruit mediators of tissue healing and repair. Underlying this constellation are genetic risk factors that modulate these responses to predispose, or to protect against, nephritogenic responses and loss of kidney tissue.

Despite these insights, primary events directing/perpetuating immunological reactivity against kidney tissues remain poorly understood. The dearth of knowledge about the molecular mechanisms of immunological processes inciting and propagating kidney injury translates to a narrow armamentarium of poorly efficacious and nonspecific immunosuppressive therapies. These remain broad-spectrum and toxic, causing susceptibility to infection, cancer, metabolic and cardiovascular diseases. There are three reasons for the deficiencies in understanding of the immunological bases of human nephrology, namely over-reliance on animal models that partially resemble human disease, the unknown duration of disease prior to presentation, and categorization of kidney diseases according to structural changes rather than molecular level events occurring within cells and tissues. The advent of multi-omics technologies and machine learning approaches promises to address at least some of these deficiencies by integrating nucleic acid, protein structural information, and others, cross-sections in an unbiased manner across populations at different stages of disease.[2] Nephrologists are, accordingly, optimistic about the near future, anticipating significant progress.

In this chapter we focus mainly on glomerular diseases, for which some of the pathophysiological mechanisms are understood. Immune-mediated kidney injury can be incited by several mechanisms, ranging from normal immune responses causing incidental kidney injury (*e.g.*, postinfectious glomerulonephritis, serum sickness) to loss of tolerance to self-components, causing autoimmunity. Autoimmune responses can be directed against antigens shared between kidneys and extra-renal tissues (*e.g.*, antineutrophil cytoplasmic autoantibodies [ANCAs]) or directed specifically against kidney components (*e.g.*, anti-glomerular basement membrane [GBM] disease). Dysregulated immunity generating nephritogenic immune complexes (such as, in lupus nephritis) can also occur.[1] In some cases, we have uncovered candidate antigens inciting nephrogenic autoimmunity, such as phospholipase A2 receptor (PLAR2), antibodies against which cause some subsets of primary membranous nephropathy (MN).

In all these cases, current best practice to evaluate patients with immune-mediated kidney disease involves attention to urinalysis, the type and quantity of proteinuria, renal function, presence/absence of common immune biomarkers and ultrastructural examination of kidney tissues by biopsy. A renal ultrasound scan to identify structural lesions and to determine chronicity of injury (chronically damaged kidneys are often small, acutely injured kidneys are often normal size or slightly enlarged and may be echogenic) is often performed.

HEMATURIA

Red blood cells (RBCs) can enter the urine either via the upper or lower urinary tract. Upper urinary tract RBCs from glomeruli typically appear as dysmorphic *acanthocytes* and should prompt referral to nephrology for further evaluation. Lower urinary tract RBCs from the calices, ureters, bladder or urethra typically appear normal and are usually investigated by a urologist to rule out an occult malignancy.

Cellular casts in the urine are formed by aggregation around tubular proteins, such as Tamm-Horsfall protein. Erythrocyte and/or leukocyte casts typically indicate glomerular or tubular inflammation and, therefore, glomerulonephritis or interstitial nephritis, respectively (Fig. 68.1).

PROTEINURIA

Loss of the size-selective and/or charge-selective properties of the glomerular capillary wall or disruptions of glomerular epithelial cells, called podocytes, allows plasma proteins, especially albumin, to leak into the filtrate causing glomerular proteinuria. Tubulointerstitial nephropathy, on the other hand, impairs reabsorption of normally filtered low-molecular-weight proteins, resulting in low-grade proteinuria (rarely >2 g/day) with generally low albumin content. Thus, heavy proteinuria of greater than 2 g/day is often glomerular in origin or occurs because of frank blood in the urine.

Filtration of abnormal plasma proteins, termed paraproteins, can also cause proteinuria by overwhelming the reabsorptive capacity of renal tubules. This "overflow" proteinuria may be undetected by albumin-sensitive dipstick screening and may require urine immunofixation electrophoresis. Paraproteinemia may also be undetected or underestimated by plasma electrophoresis; measuring serum free light chains directly is a more sensitive method (Fig. 68.2).

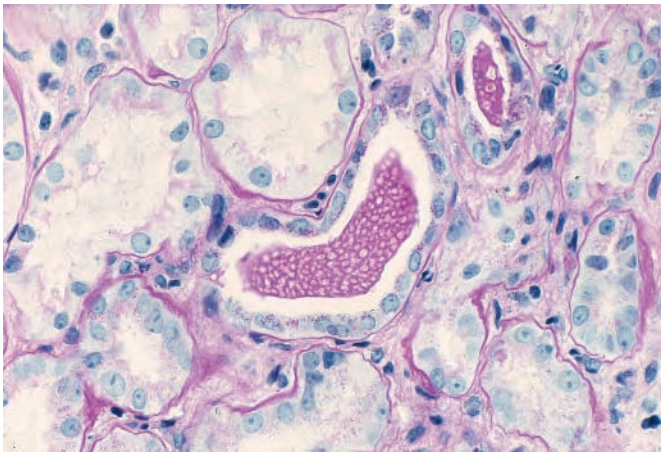

FIG. 68.1 Red Blood Cell Cast. Cast present *in situ* within the lumen of a distal renal tubule (periodic acid–Schiff [PAS] stain).

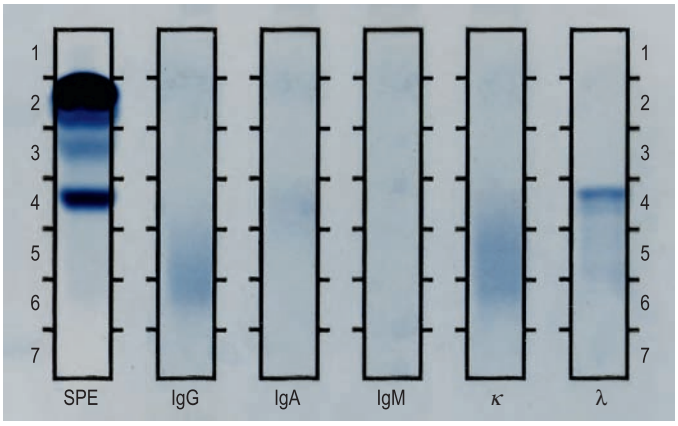

FIG. 68.2 Immunofixation Electrophoresis of Urinary Protein. Proteins in a concentrated urine protein are separated in six replicate lanes by standard protein electrophoresis. Separated proteins are identified by overlaying specific antisera to immunoglobulin *(Ig)*G, IgA, IgM, κ, and λ. In this example, a monoclonal paraprotein composed of λ light chain is identified as an intense narrow band in the far right lane. *SPE,* Serum protein electrophoresis.

NEPHROTIC SYNDROME

Nephrotic syndrome is clinically characterized by heavy proteinuria of greater than 3.5 g/day, hypoalbuminemia, edema, hyperlipidemia, and lipiduria. Conditions that typically have diffuse glomerular disease, including MN and systemic lupus erythematosus (SLE), are more likely than others with common focal disease, such as IgA nephropathy, to cause nephrotic syndrome. Diseases causing significant glomerular necrosis, such as ANCA-associated vasculitis, do not characteristically cause nephrotic syndrome since necrotic glomeruli lose filtration capacity.

ACUTE NEPHRITIC SYNDROME

Acute nephritic syndrome is glomerulonephritis characterized by glomerular hematuria, sub-nephrotic proteinuria, fluid retention and hypertension. A variant called rapidly progressive glomerulonephritis (RPGN) is defined by ≥50% loss of glomerular filtration rate over 3 months, and generally greater than 50% of glomeruli show severe injury, manifest as cellular crescents on biopsy.

TABLE 68.1 Indications for Renal Biopsy

1. Active "nephritic" urine sediment
   - Dysmorphic erythrocytes: >10 per high-power field
   - Cellular casts: erythrocyte or leukocyte
2. Proteinuria >2 g/day
3. Abnormal renal function
   - Associated with the above features of active nephritis
   - Particularly important if the duration of renal disease and/or rate of change are unknown
4. Document indications for use of high-risk therapeutic interventions

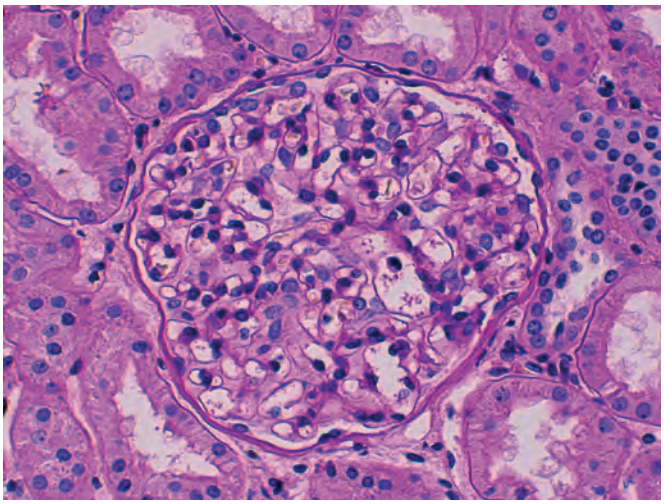

FIG. 68.3 Normal Glomerular Architecture. The glomerular capillary loops are patent and have normal thickness. Neither increased endocapillary cells nor expanded mesangial matrix encroach upon the patency of the capillary lumina (periodic acid–Schiff [PAS] stain).

RENAL BIOPSY

Renal biopsy is often indicated to establish or confirm a tissue diagnosis, clarify the type of renal injury, establish the stage of disease, formulate prognosis and direct therapy. Some important indications for renal biopsy are listed in Table 68.1. Light microscopy of a normal glomerulus is illustrated in Fig. 68.3. Some of the histological types of kidney injury will be discussed below.

MINIMAL CHANGE DISEASE

KEY CONCEPTS

Minimal Change Disease

- Most common cause of nephrotic syndrome in children
- High rate of response to glucocorticoids
- Cyclophosphamide is useful for those who relapse frequently
- Renal prognosis is characteristically excellent
- A subset may have or progress to unsampled focal segmental glomerulosclerosis

Childhood nephrotic syndrome is mainly caused by minimal change disease (MCD). MCD in adults with nephrotic syndrome is rarer.[3]

Clinical Features

MCD is almost always associated with precipitous and severe nephrotic syndrome without a systemic disease. Microscopic hematuria is not uncommon in adult patients. Proteinuria exclusively comprising albumin is characteristic; standard immunological screening tests are usually normal. Kidney biopsy establishes a diagnosis of MCD.

Etiology and Pathogenesis

The basic lesion of MCD is loss/neutralization of anionic proteoglycans in glomerular capillary loops. Dissipation of the negative-charge barrier allows anion-charged albumin to pass freely. Interdigitating podocyte foot processes form a second barrier to glomerular leakage of protein, called *slit diaphragms*. These podocyte foot processes and slit diaphragms are disrupted in MCD.

The cause of MCD remains idiopathic. There is evidence of immune dysregulation, involving cell-mediated immunity, supported by a tendency of MCD to become manifest or to relapse after a viral infection (*e.g.*, measles) or an allergic reaction. Some cases occur in association with Hodgkin lymphoma. MCD typically has a favorable response to immunosuppressants. Likewise, MCD relapses are associated with reduced regulatory T cells (Tregs).

Another hypothesis regarding causation of MCD invokes a circulating immune factor that causes increased glomerular permeability[4] (see "Focal Segmental Glomerulosclerosis"). Since patients respond to B-cell depletion with rituximab (a cytolytic monoclonal antibody against CD20 on B cells), a B-cell permeability factor cannot be ruled out.

Pathology

Generally, MCD biopsies appear normal by light microscopy. Electron microscopy shows characteristic pathological lesions of podocyte foot process fusion diffusely around glomerular capillaries.

Treatment

MCD is sensitive to glucocorticoids; greater than 90% of children enter remission within a few weeks of starting treatment. In adults the response to glucocorticoids is lower and more delayed. A substantial portion of those with MCD suffer long-term complications: some are steroid-resistant from the start; others are steroid-dependent for disease control; others still relapse frequently and suffer substantial steroid toxicity over time. Alkylating agents such as cyclophosphamide increase response rates and reduce relapse rates. The calcineurin inhibitors cyclosporine (CSA) and tacrolimus (Tac) are alternative steroid-sparing agents, but relapses frequently occur with withdrawal of these agents. Rituximab, mycophenolate mofetil (MMF) or azathioprine are alternative steroid-sparing agents, particularly in patients who are steroid-dependent or relapse frequently.

Risk of progression to end-stage kidney disease is extremely low in true MCD. Sampling errors on kidney biopsy account for mistaken diagnosis of MCD in some cases that are, in fact, focal segmental glomerulosclerosis (FSGS). It is debated whether MCD and FSGS represent different manifestations of one disease (with MCD progressing to FSGS), or if they are different diseases.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

KEY CONCEPTS

Focal Segmental Glomerulosclerosis

- Nephrotic syndrome with progressive renal insufficiency
- Glomerular permeability factor in plasma of some cases
- Unpredictable responses to glucocorticoids or cyclophosphamide
- Cyclosporine effective, but relapses common upon withdrawal
- Moderately high relapse rate in renal allografts

FSGS is a common primary glomerular disease in adults. Compared to patients with MCD, those with FSGS have higher frequency of microscopic hematuria, more persistent nephrotic syndrome, poorer response to immunosuppressants, and higher risk of progression to end-stage kidney disease. Incidence of FSGS as a cause of nephrotic syndrome is increasing, particularly among Black patients.

Etiology and Pathogenesis

Diverse etiologies may disrupt the podocytes, causing histological FSGS. Genetic mutations of the podocyte proteins podocin and nephrin cause a subset of FSGS in children and young adults. Circulating permeability factors, including soluble urokinase-type plasminogen activator receptor, have been proposed as mediators of podocyte injury in "primary" FSGS. Alternatively, podocytes may have increased surface expression of the transmembrane protein B7-1 (CD80) that stimulates T cells, leading to foot process effacement. "Secondary" FSGS may result from drug toxicities (*e.g.*, pamidronate), viral infection (*e.g.*, human immunodeficiency virus [HIV]), or maladaptive hemodynamic stress (*e.g.*, obesity or reduced nephron mass). A higher incidence of FSGS in African Americans is partially related to their increased frequency of *APOL1* gene polymorphisms, which may have been positively selected due to a protective role against trypanosomiasis.[5]

Pathology

The renal pathology of FSGS, as the name implies, is sclerosis of portions, or segments, of only some glomeruli in the sampled area. Segmental podocyte damage and detachment are seen, together with irregular foot process fusion, collapse of glomerular capillaries and marked increases in matrix and collagen accumulation. Segmentally sclerotic areas typically stain nonspecifically for IgM and C3 (but not immunoglobulin [Ig] G or IgA), particularly in areas of glomerular tuft hyalinosis (representing trapped plasma constituents), which do not represent classic immune complexes. One classification scheme divides FSGS into five variants: tip, perihilar, cellular, collapsing, and not otherwise specified[6] (Fig. 68.4). Collapsing FSGS, is associated with viral infections, notably HIV, and follows an aggressive course.

Treatment

Hypoalbuminemia and nephrotic range proteinuria are common in primary, but not secondary, FSGS, which typically cause sub-nephrotic proteinuria, with normal or near-normal serum albumin, no edema, and focal, rather than diffuse, foot process

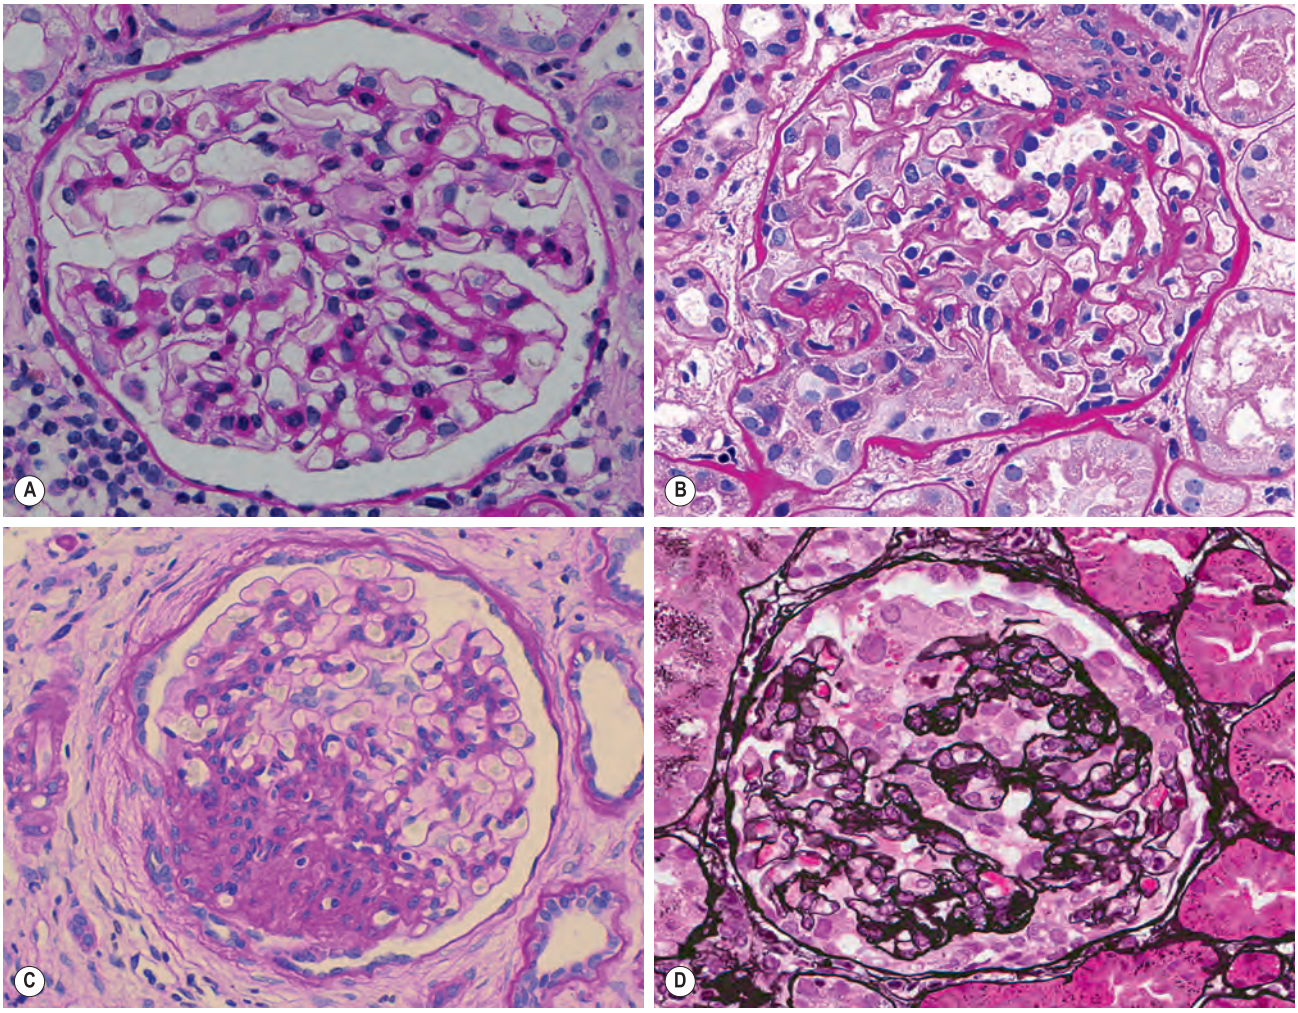

FIG. 68.4 Focal Segmental Glomerulosclerosis (FSGS). Several forms of glomerular lesions are seen in FSGS, often within the same biopsy: (A) minimal abnormality (periodic acid–Schiff [PAS] stain); (B) tip lesion manifested by segmental glomerular tuft lesion near the origin of the proximal tubule (PAS stain); (C) classical perihilar lesion (PAS stain); and (D) collapsing glomerulopathy; the glomerulus is globally contracted with wrinkling of the basement membranes; this is associated with hyperplasia of podocytes surrounding the glomerular capillaries (methenamine silver stain).

effacement. Genetic forms of FSGS should be considered in cases occurring at a very young age and in patients with steroid-resistance.

Treatment of genetic and hyperfiltration-induced FSGS focusses on reno-protection with angiotensin antagonists and lipid-lowering agents. Treatment of other forms of FSGS is similar to MCD, including immunosuppression with prednisone, cyclophosphamide, calcineurin inhibitors, or mycophenolate mofetil. There are mixed outcomes with rituximab in FSGS, particularly for steroid-resistant cases.[7] Complete remission of proteinuria is less common in FSGS than MCD. Relapses and progression to end-stage kidney disease (ESKD) remain a major concern, particularly in patients who are steroid-resistant and who frequently relapse. Several novel therapies targeting immunological, inflammatory, and costimulatory pathways are currently under investigation, including blockade of CD80 with cytotoxic T lymphocyte antigen 4-Ig (CTLA-4-Ig). Primary FSGS is at high risk of recurrence in patients receiving kidney transplants, reflecting the presence of an injurious circulating factor.

MEMBRANOUS NEPHROPATHY

KEY CONCEPTS

Membranous Nephropathy

- Common cause of nephrotic syndrome in adults
- Autoantibodies to several proteins, including phospholipase A_2 receptor (PLA_2R), detectable in large percentage of patients with primary MN
- Several secondary causes: SLE, drugs, chronic hepatitis, malignancies
- One-third of patients have spontaneous remission
- One-third of patients develop end-stage renal disease within a decade
- Protracted nephrotic syndrome confers risks of cardiovascular and thromboembolic events
- Therapies: steroids, alkylating agents, calcineurin inhibitors, rituximab, lipid-lowering drugs, angiotensin antagonists

MN is present in ~20% of adults with nephrotic syndrome. It is a less frequent cause of nephrotic syndrome in children. Primary MN was traditionally a diagnosis of exclusion after

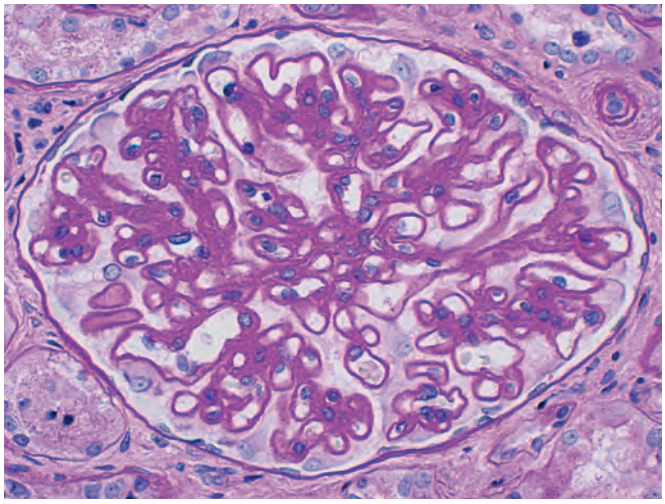

FIG. 68.5 Membranous Nephropathy. Capillary walls are nearly uniformly thickened but remain widely patent. Cellularity of the glomerulus is normal (periodic acid–Schiff [PAS] stain).

considering drugs, infections, neoplasms, and systemic illnesses (*e.g.*, SLE). Many cases of primary MN are now known to have antibodies against defined antigens, such as M-type phospholipase A2 receptor (PLA_2R), permitting diagnosis by screening for these antibodies.

Etiology and Pathogenesis

MN is characterized by subepithelial "*epimembranous*" immune deposits containing IgG and complement. Immune complexes are likely formed *in situ* by interaction between a pathogenic antibody and a constitutive glomerular antigen or an antigen ectopically planted in the glomerulus. The majority (70% to 80%) of patients with primary MN have circulating autoantibodies to PLA_2R, a receptor expressed in glomerular podocytes.[8] Antibodies to thrombospondin type-1 domain containing 7 A protein (THSDA7A), neutral endopeptidase and neural epidermal growth factor-like 1 protein (NELL-1) have been identified in smaller subsets of patients.[9,10]

Clinicopathological Features

MN generally presents with nephrotic syndrome. Renal biopsy is usually required, although serological testing for autoantibodies (*e.g.*, anti–PLA_2R) may be informative if renal biopsy is contraindicated. Light microscopy shows uniform thickening of the glomerular capillary walls without endocapillary cell proliferation (Fig. 68.5). Subepithelial and/or intramembranous deposits are seen on electron microscopy (Fig. 68.6). PLA_2R in glomerular immune deposits (by immunofluorescence or immunohistochemistry) favors a diagnosis of primary MN. A good proportion of secondary MN cases have mesangial deposits. However, diagnosing secondary MN relies on identifying clinical risk factors and finding abnormalities in laboratory and radiological data.

Natural History

The course of primary MN is highly variable. On average, one-third of patients remit spontaneously, one-third achieve partial remission and one-third progress to ESKD. Persistent proteinuria and impairment of renal function are long-term features of the latter two-thirds of patients.

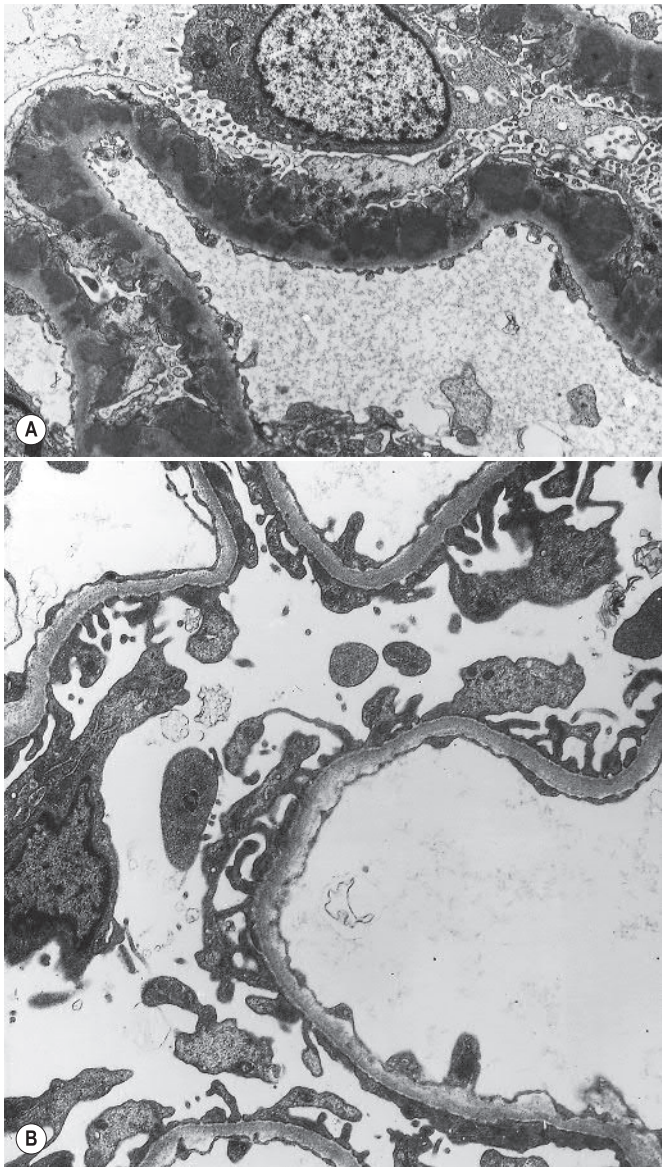

FIG. 68.6 Membranous Nephropathy (Ultrastructure). (A) Electron micrograph demonstrates heavy, dark-staining immune complex deposits along the outer surface of the glomerular basement membrane and beneath the epithelial foot processes (hence the terms *subepithelial* or *epimembranous deposits*). Note the thickening and projections of the gray-staining basement membrane between the electron-dense deposits. (B) Ultrastructure of a normal glomerular capillary wall for comparison.

Baseline characteristics, for example, severe nephrotic syndrome, hypertension, low GFR, are associated with poor outcomes. Protracted high-grade nephrotic-range proteinuria is a strong predictor of adverse renal outcomes. Some studies suggest that baseline PLA_2R autoantibody titers correlate with disease activity, with high titers a being a risk factor for decline of renal function.[11]

Treatment

Management of MN usually includes diuretics to reduce edema, lipid-lowering drugs, anticoagulants to prevent

thromboembolic complications, and anti-hypertensives. Angiotensin antagonists have a substantial antiproteinuric effect. All patients receive combinations of these measures. Low baseline, or decreasing, anti-PLA_2R antibody levels may predict spontaneous remission, favoring conservative therapy for 3 to 6 months, whereas high baseline, or increasing, anti-PLA_2R antibody levels encourage the rapid start of immunosuppression. Therapy with corticosteroids and cytotoxic drugs (usually cyclophosphamide) significantly increase rates of remission and slow renal function loss in patients with persistent nephrotic syndrome. There is increasing enthusiasm for first line use of rituximab based on two controlled trials demonstrating its superiority over anti-proteinuric therapy alone or cyclosporine.[12] Other anti-B-cell drugs are under evaluation, including belimumab.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

KEY CONCEPTS

Membranoproliferative Glomerulonephritis

- Histologically classified into immune complex–mediated glomerulonephritis or complement-mediated glomerulonephritis based on immunofluorescence staining pattern
- C3 glomerulopathy characterized by C3 accumulation in the glomeruli in the form of electron-dense deposits.
- Genetic or acquired abnormalities in the activation of the alternate alternative complement pathway associated with C3 glomerulopathy
- Response to immunosuppressive drug treatment generally poor
- Tends to recur in renal allografts

MPGN is a morphological entity encompassing a heterogeneous group of diseases with similar appearance on light microscopy. The pattern of injury is mesangial matrix expansion, increased cellularity and thickening of the glomerular capillary walls, giving them a double contour appearance. These changes make the glomerulus appear lobulated (Fig. 68.7).

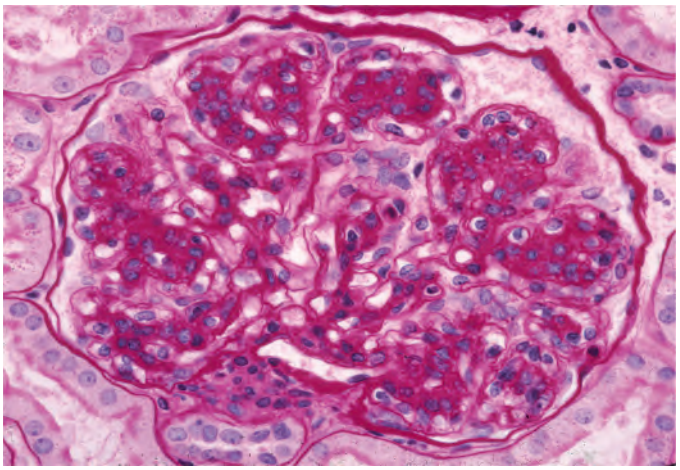

FIG. 68.7 Membranoproliferative Glomerulonephritis (MPGN). Glomerulus exhibits the typical lobulated appearance of this disease. Markedly increased mesangial cells and matrix in all of the lobules. Mesangium extends outward into the capillary loops and forms double contours with the glomerular basement membrane (periodic acid–Schiff [PAS] stain).

Etiology and Pathogenesis

Until recently MPGN was classified into three types: type 1 characterized by subendothelial deposits; type II by intramembranous electron dense deposits in a ribbon-like pattern (also called dense deposit disease [DDD]); and type III by subendothelial and subepithelial deposits (Fig. 68.8). This older classification also distinguished between secondary causes when an etiology was identifiable.

New insights into MPGN have resulted in re-classification of this disease into only two sub-types, Ig-mediated or

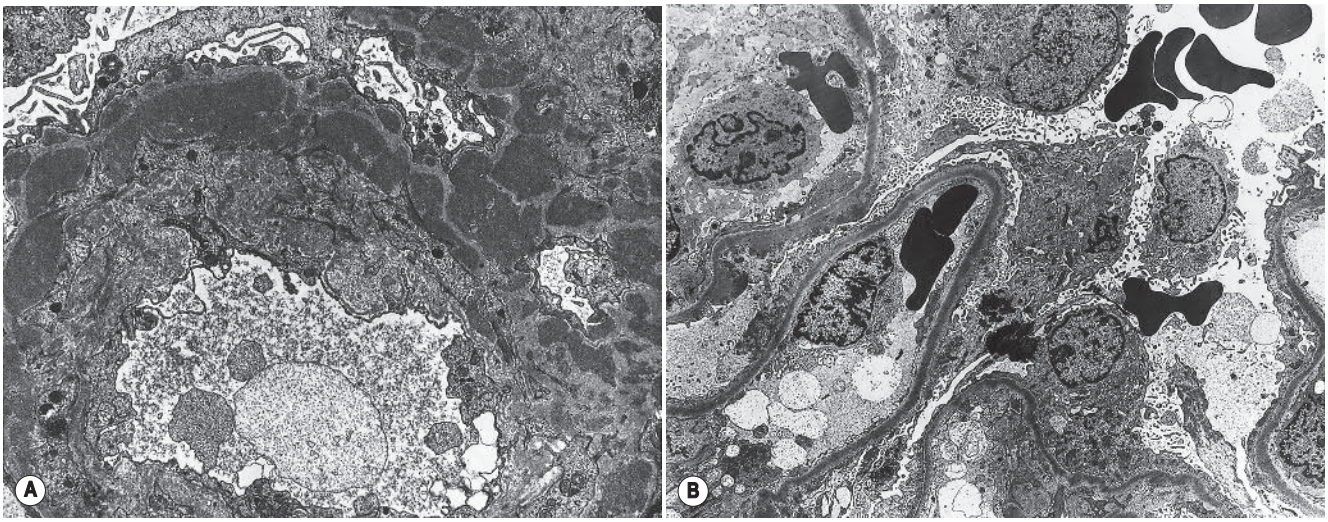

FIG. 68.8 Membranoproliferative Glomerulonephritis (MPGN) Ultrastructure. (A) Capillary wall is markedly thickened and contains heavy, dark-staining, electron-dense immune complexes in the subendothelial space. Mesangium (lighter material) extends into the capillary loop, where it is interposed between the basement membrane and the endothelium; the process gives the appearance of a massively thickened capillary loop on hematoxylin and eosin (H&E) staining, and the split appearance by periodic acid–Schiff (PAS) and silver stains. (B) Dense deposit disease; capillary loops contain smooth, continuous, linear dense material within the basement membrane.

complement-mediated disease, based on patterns and compositions of deposits assessed by immunofluorescence. This recognizes that some cases of MPGN result from immunoglobulin (Ig) deposition with secondary complement activation, whereas others arise from primary abnormalities of complement activation. The presence of both Ig and complement component 3 (C3) indicates an Ig-mediated process, in which immune complexes are deposited that activate the classical complement pathway. In contrast, C3 staining without significant Ig deposition implies an antibody-independent means of complement activation, indicating primary dysregulation of the alternative complement pathway (Fig. 68.9). Such diseases are now grouped under the umbrella term, "C3 glomerulopathy" (C3G), which encompasses both C3 glomerulonephritis (C3GN) and DDD.[13] A diagnosis of C3G prompts evaluation for genetic mutations of complement regulatory proteins (*e.g.*, factor H or factor I) or acquired autoantibodies to regulatory proteins (*e.g.*, C3 nephritic factor or anti-factor H). C3 nephritic factor, an autoantibody to C3 convertase, is frequently detected in C3G. C3 nephritic factor stabilizes C3 convertase, rendering it resistant to control by factor H, leading to persistent C3 activation and deposition of alternative pathway activation products in glomeruli.

The list of etiologies causing MCGN is long but includes infections (*e.g.*, with hepatitis C virus, see below), monoclonal gammopathies, autoimmune diseases (especially SLE) and complement disorders.

Pathology

MPGN shows endocapillary proliferation and positive findings on immunofluorescence. Double contour appearance to the GBM, best seen with silver stain, represents synthesis of GBM-like material from capillary wall remodeling. Irregular capillary wall subendothelial and mesangial deposits are seen by electron microscopy in Ig-mediated MPGN; small intramembranous and subepithelial deposits are also present in C3GN. The hallmark of C3GN is dominant staining for C3 by immunofluorescence in the mesangium and glomerular capillary walls (see Fig. 68.9).

Double contours of the GBM are also present in conditions with chronic endothelial injury, including thrombotic microangiopathy, transplant glomerulopathy, and preeclampsia, and show histological appearance of MPGN by light microscopy. However, in these settings there are no associated immune deposits and immunofluorescence is negative for Ig and C3.

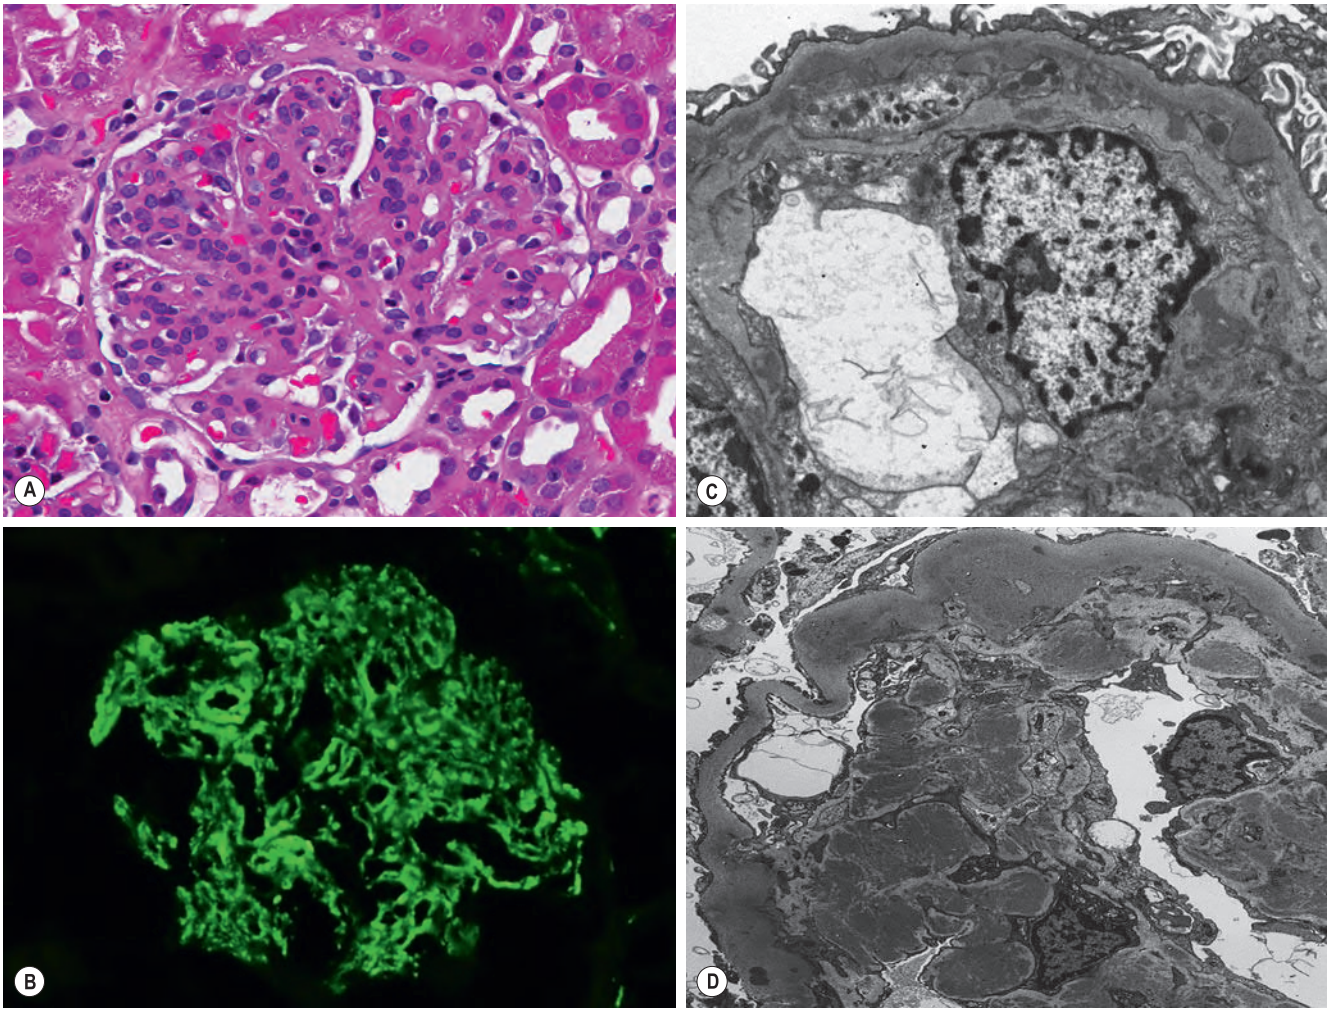

FIG. 68.9 C3 Glomerulopathy. (A) Glomerulus exhibiting the characteristic membranoproliferative pattern (hematoxylin and eosin [H&E] stain). (B) Immunofluorescence showing prominent glomerular staining for C3 complement. (C and D) Electron microscopy ultrastructure showing mesangial interposition giving a double contour of the glomerular capillary wall, as well as interposed electron dense deposits in the subendothelial space and the mesangium.

Clinical Presentation

Presentation of MPGN is characteristically as chronic low-grade nephropathy. Some patients experience nephrotic syndrome and even RPGN. Hypocomplementemia is common. In immune complex-mediated MPGN, serum C4 levels are generally low, reflecting classical pathway activation. C3 may be normal or mildly decreased. In complement-mediated MPGN C4 levels are normal, and C3 is typically low, consistent with alternative pathway activation. However, a normal serum C3 does not exclude the diagnosis. Renal outcomes in C3GN are variable, with up to 30% of patients progressing to ESKD. Prognosis for DDD is worse, with ~50% progressing to kidney failure. Idiopathic MPGN and MPGN from complement dysregulation tend to recur in renal allografts; recurrences of both types of MPGN worsen graft survival.

Treatment

Existing treatment trials for MPGN pre-date the new classification system and our appreciation of the distinct mechanisms of pathogenesis. Thus, their relevance is questionable because of the heterogeneity of patient populations. The new diagnostic categories will better define groups of patients with similar pathogenesis, enabling more rational approaches to targeted therapy in the future.

Management of MPGN relies on identifying any reversible/treatable underlying causes, such as hepatitis C virus (HCV) infection. Treatment of the underlying cause can reverse the kidney pathology and eliminate risk of aggravating occult etiologies, such as viral infection, with immunosuppression.

There is no consensus regarding treatment of "idiopathic" immune complex–mediated MPGN. Most immunosuppressants have been used with variable success, including prednisone alone or combined with either MMF or cyclophosphamide. There are limited data on rituximab for this disease. Optimal treatment of C3GN remains unclear but likely needs to be individualized based on correct identification of defects in the alternative complement system (genetic vs acquired autoantibodies). Infusions of fresh frozen plasma to replace missing complement factors may be beneficial for some. Immunosuppression with corticosteroids, rituximab, and MMF is theoretically beneficial in cases resulting from pathogenic antibodies to complement regulatory proteins, but is unproven. Eculizumab, a mAb blocking activation of C5 complement (C5b-9), has been tested in small series, but data remain inconclusive. New complement blocking agents may also hold promise.[14]

POSTINFECTIOUS NEPHROPATHIES

Many infections can cause immune-mediated nephropathies. Some of the more common ones are described here.

Viral Infections

Hepatitis B Virus

Hepatitis B virus (HBV) has several histological renal manifestations, the commonest being MN, which can occur in association with antibodies against PLA_2R,[15] MPGN, and vasculitides affecting the kidneys (causing RPGN or large vessel involvement). Clinical presentation is usually nephrotic syndrome, often with microscopic hematuria. Renal biopsy shows MN with positive immunofluorescence for Ig, C3, and some IgM. In some cases, HBV viral antigens are detectable within glomeruli. Electron microscopy shows subepithelial and intramembranous deposits, but there may also be mesangial and subendothelial deposits.

Therapy for HBV-associated kidney disease is focused on treating the virus using antivirals, because immunosuppressants may promote viral replication. Interferon-α (IFNα) or nucleoside/nucleotide analogues, such as lamividine, entacavir, adefovir, tenofovir, and telbivudine are commonly used. Treatment with nucleoside/nucleotide analogues is often for several years. Immunosuppression with corticosteroids with or without cyclophosphamide or rituximab is cautiously considered in patients with RPGN, but concomitant antiviral therapy is required.

Hepatitis C Virus

HCV is an established cause of kidney disease. The virus has a similar spectrum of pathogenicity as HBV, but the most common manifestation is MPGN, occurring in the context of type II mixed cryoglobulinemia, in which mixtures of antibodies of different classes and clonalities precipitate at temperatures below 37°C. Immune complex deposits within glomeruli are seen containing HCV, anti-HCV antibodies and virus-related (or unrelated) cryoglobulins. HCV also causes MN and vasculitides affecting the kidneys.

Treatment of HCV-associated nephropathy is aimed at the underlying cause with antiviral drugs. Prognosis has greatly improved with introduction of newer antiviral agents supplanting IFNα and ribavirin. HCV-specific antivirals are usually used in combinations, such as sofosbuvir plus ledipasvir, which are highly effective and in most cases curative.[16] Evidence for antiviral treatment in HCV-related kidney disease comes mostly from IFN-based regimens, which reported remission of proteinuria and hematuria and improvement of renal function. There are limited data regarding the use of the newer antiviral agents in HCV-associated glomerulonephritis, but these hold promise.[17] In severe progressive renal disease and/or vasculitis, treatment with rituximab or pulse intravenous steroids and cyclophosphamide may be warranted in conjunction with antivirals. Rituximab and plasma exchange may provide additional benefit in severe HCV-associated cryoglobulinemia refractory to antiviral therapy.[18]

Human Immunodeficiency Virus

HIV infection may cause a number of kidney manifestations. Chief is classical HIV-associated nephropathy (HIVAN), the first kidney disease associated with HIV infection. HIVAN is a collapsing form of FSGS accompanied by tubular microcysts and interstitial inflammation. It is usually seen in patients with AIDS but is occasionally diagnosed in less advanced HIV infection or even before acute HIV seroconversion. HIVAN classically has significant proteinuria and rapidly progressive kidney disease, often with hypertension and echogenic kidneys on ultrasound. HIVAN displays a striking racial predilection for Black patients, suggesting that genetic influences may be important.[19]

Other renal abnormalities have also been described with HIV, including IgA nephropathy, lupus-like glomerulonephritis, postinfectious glomerulonephritis, MPGN, MN, cryoglobulinemic glomerulonephritis, fibrillary and immunotactoid

glomerulopathy, and thrombotic microangiopathy.[20] Tubulointerstitial changes related to drug toxicity, acute interstitial nephritis, or superimposed viral, fungal, or mycobacterial infections may also be present.

The mainstay of treatment for HIVAN is antiretroviral therapy (ART), regardless of CD4 lymphocyte counts. Highly effective therapies for HIV have reduced the frequency of HIVAN and greatly improved the renal prognosis. Evidence for initiating ART in other HIV-associated immune complex glomerular diseases is inconclusive, but its use is a rational approach. Use of standard immunosuppressive drugs in this immunocompromised population is controversial.

Bacterial Infections

Poststreptococcal Glomerulonephritis

KEY CONCEPTS

Infection-Related Nephropathies

- *Viral:* Hepatitis B—membranous nephropathy; hepatitis C—cryoglobulinemic membranoproliferative glomerulonephritis; human immunodeficiency virus (HIV)—focal segmental glomerulosclerosis (HIV nephropathy)
- *Bacterial (mainly gram-positive):* Nephritogenic streptococcal infections, prosthetic device (shunt) infections, subacute bacterial endocarditis, chronic deep tissue abscesses—mainly diffuse or focal proliferative glomerulonephritis

Poststreptococcal glomerulonephritis (PSGN) is a classic immune complex–mediated glomerulonephritis caused by dermal or throat infection with nephritogenic strains of group A streptococci. PSGN has bimodal epidemiology, with peak incidence in children and in those over the age of 60. Latency between upper respiratory infection and nephritis is 7 to 10 days, and 2 to 4 weeks after skin infection. Anti-streptococcal antibody titers are usually measured to demonstrate a preceding streptococcal infection. Anti-streptolysin O titers and anti-DNase B titers are most frequently elevated in upper respiratory and skin infections, respectively.

PSGN is a nephritic syndrome, with smoky or rust-colored urine, generalized edema, hypertension, and nephritic urine sediment. Proteinuria is typically mild. Patients have rising titers of anti-streptolysin and depressed C3 early in nephritis but normal/minimally depressed C4, indicating alternative complement pathway activation. Significant numbers of patients also have rheumatoid factor. Other auto-reactive antibodies have also been described in PSGN.

Glomerular injury results from passive glomerular trapping of circulating immune complexes composed of nephritogenic bacterial antigens and IgG antibody, or by *in situ* formation of immune complexes. This is followed by immune cell recruitment, production of chemical mediators and cytokines, and local activation of complement and coagulation cascades that drive inflammatory responses.

Proliferative glomerulonephritis, with leukocyte infiltration, granular immune deposits of IgG and C3, and dome-shaped electron-dense subepithelial deposits (humps) are characteristic. Prognosis is excellent in children; with supportive care, almost all recover. Progressive renal failure accompanied by hypertension is more common in adults. Kidney biopsy is rarely needed in children but may be warranted if there is atypical presentation or evolution.

The classic childhood form is rarely seen in developed countries but is common in developing countries, thus remaining the commonest cause of acute childhood nephritis in the world. However, there is also an increase in incidence of non-streptococcal PSGN or "infection-related" glomerulonephritis in older patients with multiple comorbidities, especially diabetes, HIV and malignancy. These clinical variants are usually related to infections with bacteria such as *Staphylococcus aureus*, irrespective of methicillin-sensitivity, and may be characterized by IgA-dominant glomerular immune complex deposition.

Current therapies rely on culture-guided systemic antibiotics, especially in older patients, in whom MRSA may be the causative agent. Steroids are used in selected cases, in which crescents and severe interstitial inflammation are present.

IgA Nephropathy

KEY CONCEPTS

Immunoglobulin A Nephritis

- Common cause of asymptomatic microscopic hematuria, recurrent macroscopic hematuria, and/or low-grade proteinuria
- Spectrum of disease, including idiopathic IgA nephritis and IgA vasculitis (previously called Henoch-Schönlein purpura); IgA in skin and renal biopsy samples
- Mostly benign prognosis, especially in children
- Patients with progressive renal insufficiency and/or crescentic glomerulonephritis warrant trial of glucocorticoids and/or cytotoxic drug therapy

IgA nephropathy (IgAN) is the most common primary glomerulonephritis worldwide.[21] IgAN can affect patients of all ages, especially children and young adults, with a male preponderance.[22] There are geographical and ethnic differences in the prevalence of IgAN, with the highest frequency found among East Asians. IgAN is very uncommon in individuals of African ancestry. This observation and examples of familial clustering of IgA nephropathy favor an important element of genetic susceptibility.

The spectrum of presentations of IgAN is relatively broad. IgAN may be discovered during evaluation of asymptomatic microscopic hematuria. Alternatively, patients, especially children, can present with recurrent episodes of macroscopic hematuria that occur within 24 to 48 hours after an infection, usually an upper respiratory infection or gastroenteritis. A transient elevation in serum creatinine has been associated with macroscopic hematuria in about one third of cases. This has been attributed to tubular injury and obstruction caused by intraluminal RBC casts. A small percentage of patients present with either nephrotic syndrome or an acute RPGN characterized by edema, hypertension, renal insufficiency, and hematuria.

IgA vasculitis (IgAV), also known as Henoch-Schönlein purpura, which typically involves the gastrointestinal and dermatological systems, may also affect the kidneys and present with features similar to IgA nephropathy.

Pathology

The characteristic findings on light microscopy are mesangial cell proliferation and mesangial matrix expansion. Electron microscopy typically reveals electron-dense deposits that primarily limited to the mesangium, but a few deposits may also be present in subendothelial and subepithelial locations. The

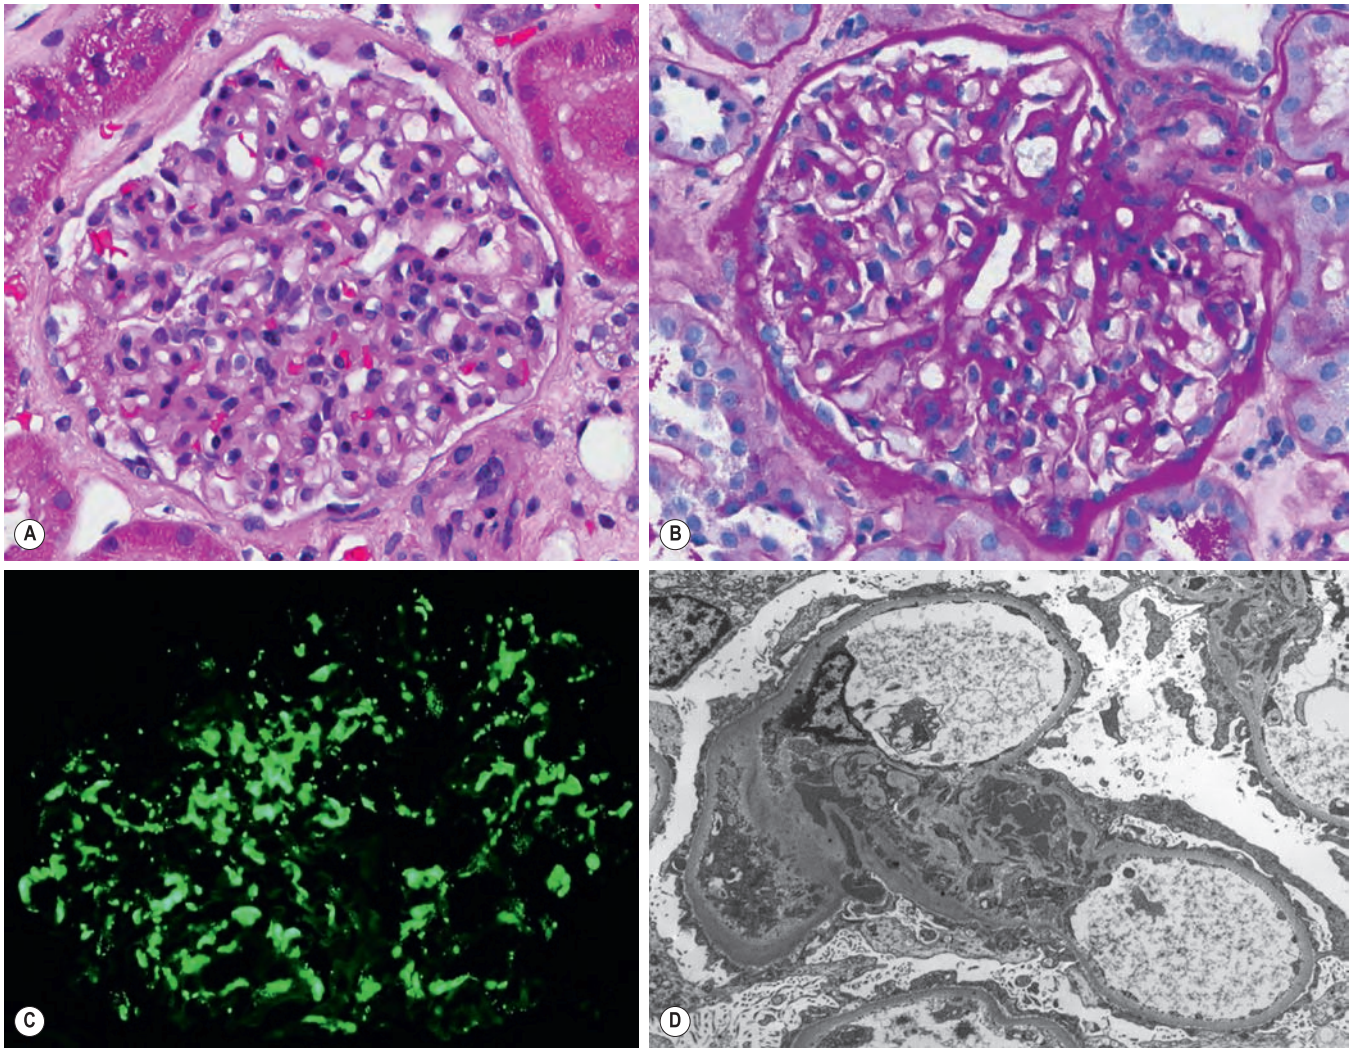

FIG. 68.10 Immunoglobulin A Nephropathy (IgAN). (A) hematoxylin and eosin (H&E) stain and (B) periodic acid–Schiff (PAS) stain: Glomeruli manifest modestly increased mesangial hypercellularity and expanded mesangial matrix. (C) Immunofluorescence showing predominantly IgA deposition within the mesangium. (D) Electron microscopy showing deposits mainly within the mesangium, but not along peripheral capillary loops.

pathognomonic finding on immunofluorescence microscopy is globular deposits of IgA, often accompanied by C3 and IgG, in the mesangium and, to a lesser degree along the glomerular capillary wall (Fig. 68.10).

Etiology and Pathogenesis

Aberrant glycosylation of *O*-linked glycans in the hinge region of IgA1 resulting in increased serum levels of galactose-deficient IgA1 (Gd-IgA1) plays a pivotal role in pathogenesis of IgAN. The aberrantly glycosylated IgA1 is recognized by antiglycan antibodies and leads to circulating IgA immune complexes that preferentially deposit in the mesangium, provoking local injury. A genetic predisposition to IgAN has been linked with polymorphisms involving both innate and adaptive immunity and the alternative complement pathway. A "second hit" may be needed in predisposed individuals. Infections may play a role because episodes of macroscopic bleeding often coincide with mucosal infections, including upper respiratory tract (synpharyngitic) or gastrointestinal infections.

Natural History

Patients with IgAN who have low-grade proteinuria (<1 g/day) have a good renal prognosis and a low risk of progression. However, at least one-third of patients with IgAN eventually progress to ESKD. Twenty years after apparent disease onset the probability of renal failure is 25%, and the probability of some renal dysfunction is 50%. Hypertension occurs frequently as the disease progresses and portends a poor prognosis. Other clinical features associated with poor prognosis include older age at disease onset, persistent proteinuria greater than 1 g/day, and persistent azotemia.

Treatment

The most effective treatment of progressive IgAN remains undefined and controversial. Angiotensin antagonists are recommended to control blood pressure, reduce proteinuria, and slow the rate of deterioration of renal function. A large trial (STOP-IgA nephropathy) showed that glucocorticoid monotherapy or a regimen that included prednisolone,

cyclophosphamide, and azathioprine did not have a significant beneficial effect on preservation of kidney function.[23] However, a course of oral steroids may be considered in patients with high-grade proteinuria, and cytotoxic drugs are indicated in a small subset of patients with crescentic rapidly progressive IgAN. A targeted-release formulation of budesonide added to optimized blockade of the renin-angiotensin system reduced proteinuria in a recent trial.[24] There are conflicting data about the value of fish oil dietary supplements (eicosanoids) in preventing renal progression in patients with IgAN. The practice of tonsillectomy in IgAN has not been clearly established. The lack of effective therapy has provided the impetus for several clinical trials testing novel therapies. Thus far, a small trial of rituximab has not shown compelling evidence for a benefit in IgAN.

Antineutrophil Cytoplasmic Antibodies–Associated Renal Vasculitis

KEY CONCEPTS

Antineutrophil Cytoplasmic Antibodies–Associated Renal Vasculitis

- Renal vasculitis with glomerular involvement includes microscopic polyangiitis (MPA), granulomatosis with polyangiitis (GPA), and necrotizing crescentic glomerulonephritis (renal-limited vasculitis)
- Associated with ANCAs
- Rapidly progressive glomerulonephritis is common; early treatment includes pulse methylprednisolone, cyclophosphamide, rituximab, or possibly plasma exchange
- Maintenance therapy: azathioprine, rituximab

ANCAs are associated with a distinct form of vasculitis that can affect many different types of vessels and any organ in the body. ANCA-associated vasculitis (AAV; see Chapter 59) is categorized into four main types: microscopic polyangiitis (MPA), granulomatosis with polyangiitis (GPA, formerly called Wegener granulomatosis), eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg-Strauss syndrome), and renal limited vasculitis. As shown in Table 68.2, the patterns of ANCAs differ, depending on the type of vasculitis.

Renal involvement is common in AAV but varies in type and severity. It occurs more frequently in MPA (90%) and in GPA (80%) and less frequently in EGPA (45%). Clinically, RPGN is a common manifestation of these renal vasculitides characterized by the presence of hematuria, sub-nephrotic proteinuria, active urinary sediments, and renal failure. Systemic disease may also produce clinical features pertaining to other organ involvement, for example hemoptysis from pulmonary hemorrhage or upper respiratory tract symptoms. Some patients present with overlap syndromes, showing features of both AAV and anti-GBM disease (see below).

TABLE 68.2 Prevalence of Antineutrophil Cytoplasmic Antibodies in Renal Vasculitis

	ANCAs TEST POSITIVITY (%)	
Type of Renal Vasculitis	P-ANCAs or Anti-Mpo	C-ANCAs or Anti-Pr3
Polyarteritis nodosa	10–20	10–20
Microscopic polyangiitis	50–80	10–20
Granulomatosis with polyangiitis (Wegener granulomatosis)	10–20	80–90
Necrotizing and crescentic GN	50–80	10–20

MPO, Myeloperoxidase; *PR3*, proteinase 3.

Pathology

The ANCA vasculitides produce similar types of kidney abnormalities, affecting predominantly, but not exclusively the glomeruli (Fig. 68.11). Histological examination usually reveals glomerular lesions that are characteristically focal and segmental in distribution, with fibrinoid necrosis and crescent formation. Breaks in the GBM may be seen. There may be accompanying necrotizing arteritis. In contrast to immune complex–mediated vasculitis, ANCA-associated vasculitis usually has little or no Ig deposition in injured glomerular vessels, with minimal or negative staining by immunofluorescence, a so-called pauci-immune pattern. Patients with large percentage of cellular crescents (>50%) typically present with severely reduced renal function but have a good chance for recovery of renal function with treatment, whereas those with a greater percentage of globally sclerotic (scarred) glomeruli are less likely to recover renal function.[25]

Treatment and Prognosis

ANCA-associated renal vasculitis tends to be severe and fulminant. The systemic features of these diseases impart a high mortality. Indeed, in the pre-steroid era these conditions had close to universal mortality. Thus, early detection is critically important in management. Even with early diagnosis, approximately one-third of patients will progress to renal failure within 5 years. Relapsing courses in patients with microscopic polyangiitis, underscore the importance of prompt induction treatment followed by maintenance therapy. Glucocorticoids are important in the early treatment of renal vasculitis. Cyclophosphamide-based regimens are very effective in inducing remission in patients with AAVs. Most advocate daily oral cyclophosphamide regimens, but intermittent pulse cyclophosphamide may be substituted to reduce the toxicity of extended therapy. In patients with severe pulmonary hemorrhage or rapidly progressive glomerulonephritis caused by renal vasculitis, pulse methylprednisolone, followed by prednisone and daily cyclophosphamide, is clearly indicated. Adjunctive plasma exchange is commonly used in cases of aggressive pulmonary–renal syndrome or life-threatening disease. Rituximab has become a valuable alternative to cyclophosphamide for induction treatment based on the results of two pivotal prospective randomized controlled trials.[26] Maintenance therapy is usually given for 12 to 18 months after achieving remission. Azathioprine has been the mainstay of maintenance therapy in AAVs after remission induction, but rituximab is likely to have a prominent role in maintenance therapy, as indicated by favorable results from recent trials.[27] The latest clinical evidence also suggests a role for inhibition of terminal complement components in the management of AAV, with phase 2 studies suggesting that avacopan (an inhibitor of the C5a receptor) can be effective in replacing high-dose steroids and a phase 3 study ("ADVOCATE") due to report shortly.

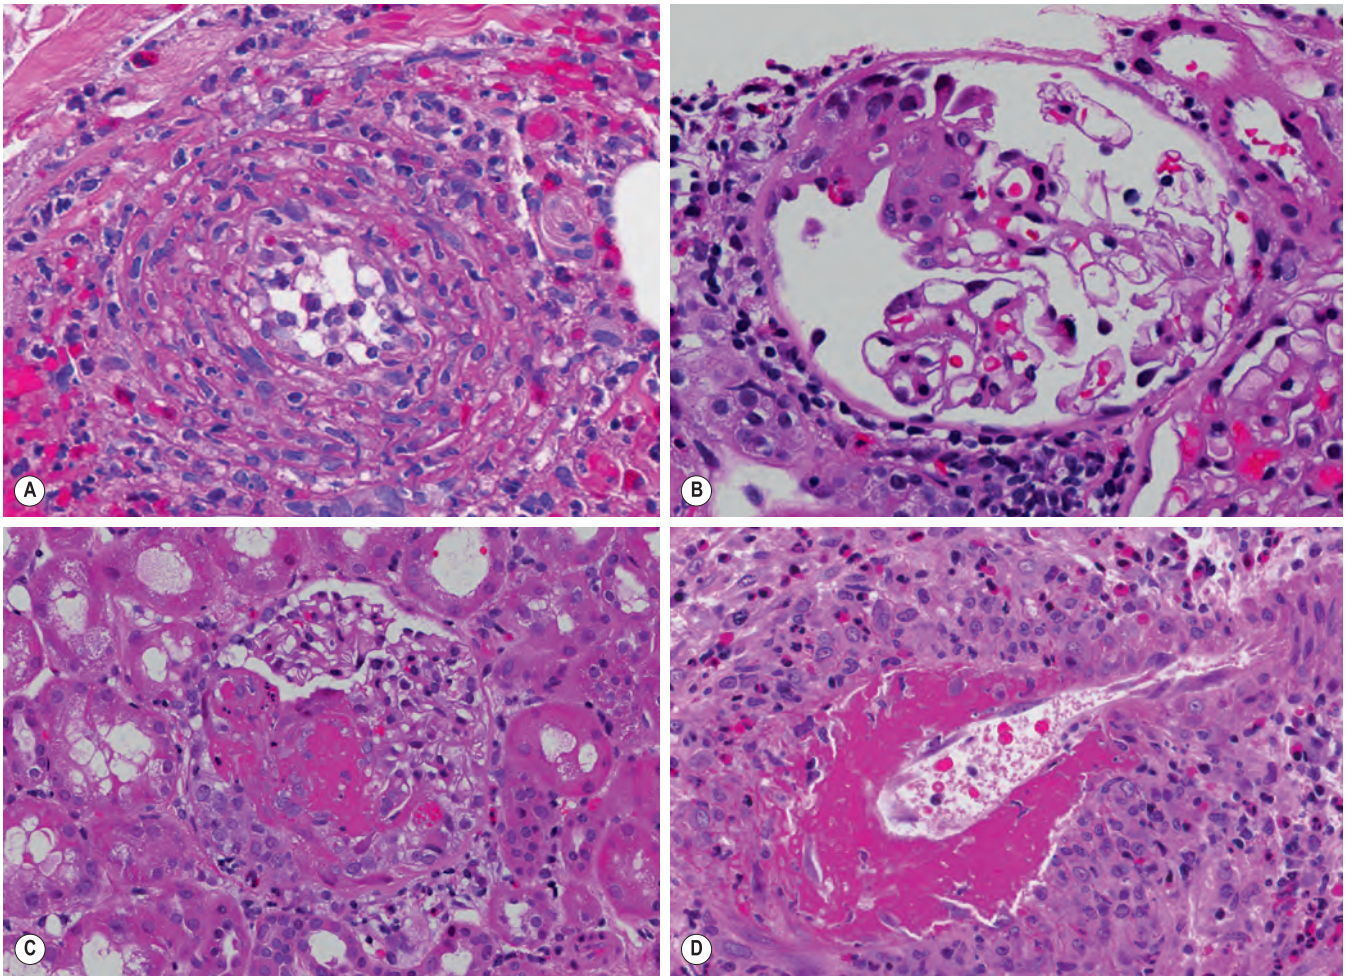

FIG. 68.11 Antineutrophil Cytoplasmic Antibody (ANCA)–Associated Systemic Vasculitis. (A) Skin biopsy showing leukocytoclastic vasculitis of a small dermal artery (hematoxylin and eosin [H&E] stain). (B) Glomerulus illustrating a characteristic segmental proliferative lesion forming an adhesion to the Bowman capsule in an early and mild case (H&E stain). (C) Glomerulus with classical fibrinoid necrosis and an associated cellular crescent of a more severe and rapidly progressive case (H&E stain). (D) Necrotizing vasculitis in a small renal artery in an extreme case of ANCA-associated renal vasculitis; large numbers of eosinophils are present in the perivascular inflammatory infiltrate (H&E stain).

Anti-Glomerular Basement Membrane Antibody-Mediated Nephritis (Goodpasture Disease)

KEY CONCEPTS

Anti–Glomerular Basement Membrane Disease

- Circulating anti-GBM antibody
- Associated with pulmonary hemorrhage
- Rapidly progressive glomerulonephritis with cellular crescents and linear deposits of IgG
- Treated with high-dose steroids, cyclophosphamide, plasma exchange

Anti-GBM disease is a rare, but classic immune-mediated cause of severe pulmonary-renal syndrome. The cardinal pathogenic factor is an autoantibody to a component of type IV collagen, specifically the noncollagenous domain 1 of the α_3 chain subunit. within the GBM or the alveolar basal membrane.[28] These autoantibodies lead to GBM rupture with development of crescentic glomerulonephritis (Fig. 68.12) and account for the pathognomonic finding of linear deposition of IgG along the glomerular capillaries as assessed by immunofluorescence microscopy. In contrast to AAV, the glomerular lesions of anti-GBM disease typically appear to be of the same age, suggesting a single moment of onset of the disease.

The genesis of anti-GBM antibodies in sporadic cases is unknown. It is postulated that an inciting event such as viral infection, or exposure to environmental factors, such as hydrocarbons or tobacco, perturbs the normal conformation of collagen in the basement membrane, exposing previously cryptic epitopes on the α_3 subunit and eliciting the pathogenic autoantibody response. This disease can occur paradoxically in normal kidneys transplanted into patients with Alport syndrome, the latter caused by mutations in the α-chains of type IV collagen, because the normal collagen is recognized as being foreign and elicits a humoral immune.

Clinically, malaise, weight loss, fever, or arthralgia may be the initial features of anti-GBM disease. Some patients present with isolated renal involvement, but more typically,

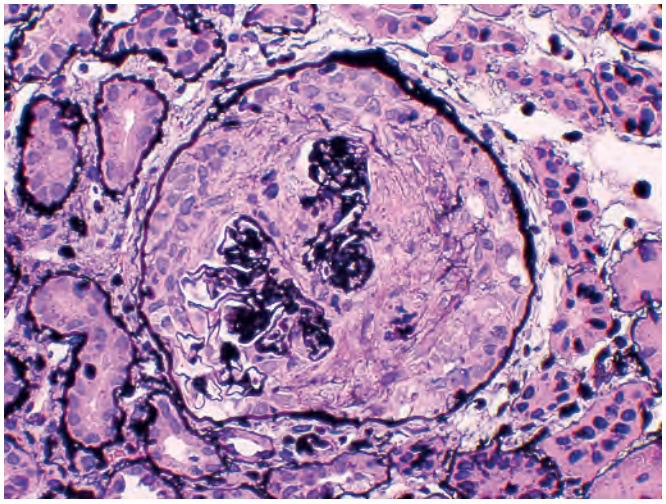

FIG. 68.12 Anti-Glomerular Basement Membrane (GBM) (Goodpasture) Disease. A circumferential cellular crescent fills the Bowman capsule and compresses the glomerular tuft (Silver stain).

pulmonary hemorrhage with hemoptysis accompanies acute renal failure. The devastating nature of the disease warrants aggressive treatment. Pulse methylprednisolone, cyclophosphamide, and plasma exchange are early indicated in the course of Goodpasture disease.[29] The role of rituximab in this disease requires further study. Reversibility of renal disease is unlikely if renal function is substantially impaired or oliguria ensues before treatment is started. Immunosuppressive treatment is normally continued until the patient has been in sustained clinical remission and anti-GBM titers are minimal or absent for at least 3 months. In contrast to AAV, anti-GBM is a "one-hit" disease and does not relapse.

Lupus Nephritis

KEY CONCEPTS

Lupus Nephritis

- *Class I:* normal glomeruli by light microscopy in patients with SLE
- *Class II, mesangial:* Immunosuppressive treatment is usually not indicated unless patient has proteinuria >1 g/day despite renin–angiotensin–aldosterone system blockade, especially if urine sediment is nephritic
- *Class III, focal nephritis and class IV, diffuse nephritis:* MMF or intravenous cyclophosphamide (IVCYC) plus glucocorticoids for induction followed by MMF or azathioprine plus low-dose corticosteroids as maintenance therapy
- *Class V, Membranous nephropathy:* Alternate-day prednisone with MMF, or alternatively bimonthly pulse cyclophosphamide or low-dose daily cyclosporine

SLE (see Chapter 52) is a systemic inflammatory disease of unknown etiology that can affect most organs in the body. The majority of patients with SLE have some degree of glomerular disease, but the presentation, course and outcome of lupus nephritis has a wide spectrum. Lupus nephritis occurs more often and is associated with less favorable outcomes among Hispanic, Asian, Native American, and especially African American populations compared with Caucasians. Nephritis is a major cause of morbidity and mortality and accounts for a large portion of all hospital admissions in patients with SLE.

Pathogenesis

Several different mechanisms may be involved in the pathogenesis of lupus nephritis, resulting in a wide spectrum of renal lesions. Deposition of immune complexes in the kidney appears to be the initiating event in proliferative lupus nephritis; however, only a subset of immune complexes appears to be nephritogenic. DNA and anti-DNA antibodies are known to be concentrated in glomerular deposits in the subendothelial space and are likely to play a central role in the pathogenesis of proliferative lupus nephritis. Unfortunately, there are fewer insights into the pathogenesis of lupus MN with its characteristic epimembranous immune deposits. Only a small proportion of patients with lupus MN have antibodies against the PLA_2R antigen. Although T cells are almost certainly involved in autoantibody production, it is unknown whether they have a direct role in the pathogenesis of lupus nephritis.

Clinical Features

Patients with lupus nephritis can have the full spectrum of renal presentations, reflecting the broad extent of renal involvement. Asymptomatic hematuria or proteinuria may be the presenting features, but they often progress to nephritic and/or nephrotic syndrome. Hypertension, azotemia, nephritic urine sediment (with hematuria and cellular casts), hypocomplementemia and high anti–double-stranded DNA (dsDNA) titers are more commonly found in patients with proliferative lupus nephritis. RPGN is usually associated with the appearance of cellular crescents and may be superimposed on severe proliferative or membranous forms of lupus nephritis.

Pathology

The former classification of renal biopsy in lupus nephritis by the World Health Organization (WHO) was revised by an international committee in 2004 (Figs. 68.13–68.15). A summary of the histological features in each class of lupus nephritis can be found in Table 68.3.

Treatment

In 2012, the American College of Rheumatology (ACR), the European League Against Rheumatism (EULAR), and the European Renal Association–European Dialysis and Transplantation Association (ERA-EDTA) published their recommendations for the management and treatment of patients with lupus nephritis.[30,31] Immunosuppressive treatment of mesangial classes of lupus nephritis (classes I and II) is usually not indicated (ACR). However, the distinction between early mesangial lesions that are in transition to more ominous classes that reflect mild and stable nephropathy is difficult. Consequently, treatment with prednisone alone or in combination with azathioprine has been recommended for patients with proteinuria that exceeds 1 g/day despite blockade of the renin–angiotensin–aldosterone (RAA) system, especially if the patient also has a nephritic urinary sediment (EULAR/ERA-EDTA). For patients with focal or diffuse proliferative glomerulonephritis (classes III and IV), ACR and EULAR/ERA-EDTA recommended mycophenolate mofetil (MMF) or intravenous cyclophosphamide (IVCYC) plus glucocorticoids. Low-dose IVCYC (500 mg IV every 2 weeks in six doses) offers a favorable balance of efficacy and relatively low toxicity for Caucasian patients with Western or Southern

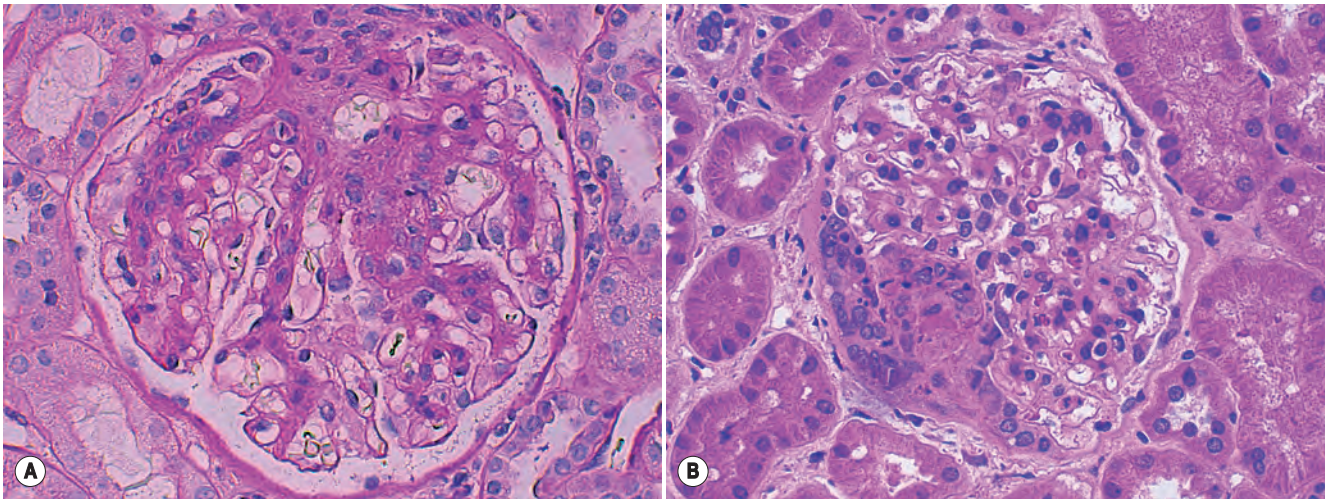

FIG. 68.13 Classes of the Pathology of Lupus Nephritis (1). (A) Class II, mesangial proliferative lupus nephritis; mesangial areas are expanded by cells and matrix but the peripheral capillary loops remain widely patent (periodic acid–Schiff [PAS] stain). (B) Class III, focal lupus nephritis; solid lesion at the lower right portion of this glomerulus demonstrates segmental fibrinoid necrosis. Note the nuclear fragments (karyorrhexis) in the fibrinous exudate (hematoxylin and eosin [H&E] stain.)

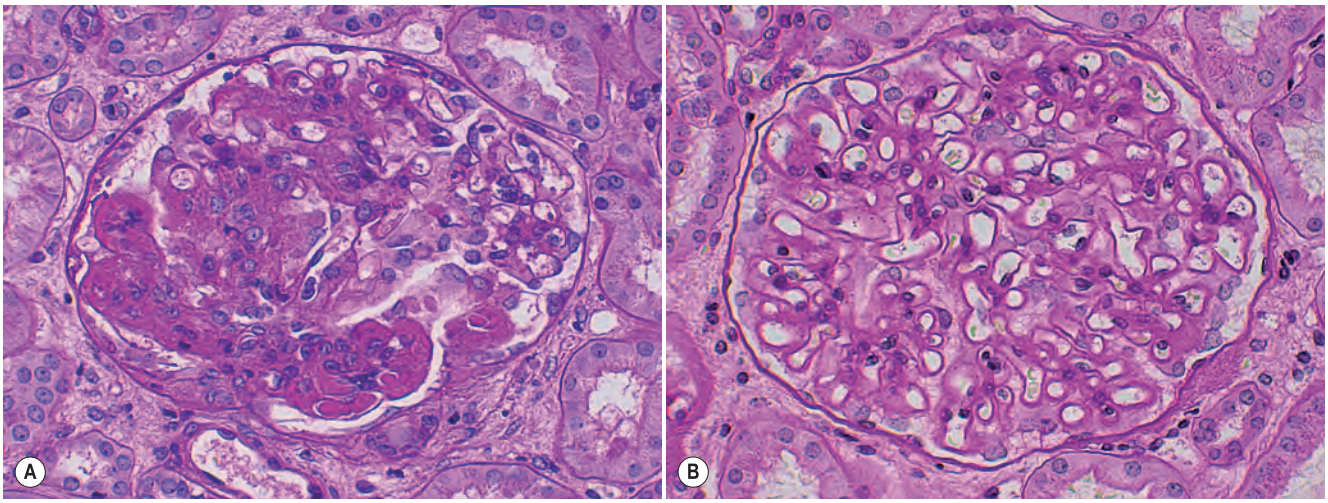

FIG. 68.14 Classes of the Pathology of Lupus Nephritis (2). (A) Class IV, diffuse lupus nephritis; glomerulus with irregular but nearly global changes, including obliteration of many capillary loops resulting from endocapillary hypercellularity, "wire loop" thickening and hyaline thrombi (periodic acid–Schiff [PAS] stain). (B) Class V, membranous lupus nephritis; glomerulus shows minimally increased mesangial cellularity with thickened but widely patent capillary loops (PAS stain).

European ancestry. Higher dose, monthly IVCYC for 6 months, plus 3 daily IV infusions of methylprednisolone initially, followed by prednisone has also been recommended for patients with ominous clinical and histological prognostic indicators, including cellular crescents and fibrinoid necrosis. ACR and EULAR/ERA-EDTA recommend either azathioprine (AZA) or MMF as maintenance therapy for patients showing a favorable response after initial immunosuppressive therapy. Although AZA and MMF appeared to be equally effective maintenance therapies in a European study, patients randomized to maintenance therapy with MMF had better outcomes than those randomized to AZA in a larger study conducted worldwide. The duration of maintenance immunosuppressive therapy involves careful consideration of the risks of another renal flare-up versus the risks of drug toxicity. EULAR/ERA-EDTA recommend at least 3 years of therapy in patients showing improvement after initial treatment. In general, we have offered a comparable recommendation that treatment should continue for at least 1 year after remission of renal disease to prevent exacerbations.

Neither IVCY nor MMF is universally effective in the management of lupus nephritis, hence the search for more efficacious treatment regimens, including rituximab, belimumab (binds to BAFF), immunomodulators (*e.g.*, laquinimod), cytokine inhibitors, immunoablation without or with stem-cell reconstitution, and immunological co-stimulation inhibitors (*e.g.*, CTLA-4-Ig), continues.[32,33] The importance of these ongoing efforts to investigate novel approaches to treatment is underscored by observations that although the risk of renal failure caused by lupus nephritis decreased from the 1970s to the mid-1990s (coincident with the increased use of cyclophosphamide), that risk has shown a reverse trend and increased slightly in the last two decades.[34]

For patients with "pure" class V lupus MN and nephrotic-range proteinuria, both the ACR and the EULAR/ERA-EDTA

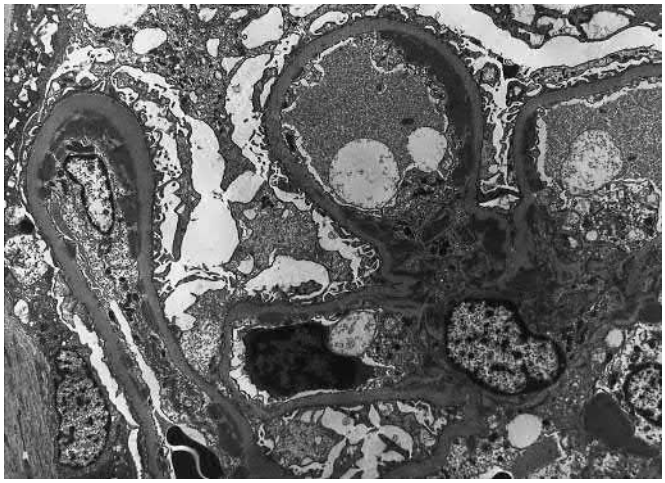

FIG. 68.15 Ultrastructure of Proliferative Lupus Nephritis. Electron microscopy demonstrates the characteristic mesangial deposits (dark materials interspersed within the centrally located amorphous, gray mesangial matrix) and subendothelial deposits (dark materials extending along the peripheral capillary loops).

TABLE 68.3 International Society of Nephrology/Renal Pathology Society 2004 Classification of Lupus Nephritis

Class	Histologic Features/Comments
I. Minimal mesangial	Normal light microscopy (LM); mesangial deposits by immunofluorescence (IF) and electron microscopy (EM)
II. Mesangial proliferative	Pure mesangial hypercellularity and matrix expansion *IF* and *EM:* mesangial immune deposits
III. Focal	Glomerular capillary obliteration in <50% of nephrons as a result of proliferation or sclerosis *LM:* Increased numbers of mesangial, endothelial, and/or hematogenous cells. Active inflammatory lesions (karyorrhexis, fibrinoid necrosis, adhesion to the Bowman capsule, cellular crescents, interstitial inflammatory infiltrates). Wire loop lesions. Hyaline thrombi *IF* and *EM:* Mesangial and peripheral capillary loop (subendothelial) immune complex deposits
IV. Diffuse	Qualitatively similar histologic lesions as in class III. Glomerular capillary obliteration involving >50% of nephrons. Subsets defined as primarily global (class IV-G) or primarily segmental (class IV-S) involvement
V. Membranous	*LM:* Regular thickening of the peripheral capillary loops of the glomerulus. Mesangial expansion *EM:* Subepithelial, intramembranous, mesangial (but no or very rare subendothelial) immune complex deposits
VI. Advanced	>90% global sclerosis without residual active lesions

have recommended oral prednisone and MMF. A prospective controlled trial showed that both IVCYC and cyclosporine A (CSA) were more effective than steroids alone in inducing remission of proteinuria in lupus MN, but that relapse of nephrotic syndrome occurred significantly more often in the CSA group than in the IVCYC treatment group.

Systemic Sclerosis (SSc, Scleroderma) Renal Disease

KEY CONCEPTS

Nephropathies of Selected Connective Tissue Diseases

- *Scleroderma renal crisis:* Predominantly renal vasculopathy; moderate to severe (high renin) hypertension with progressive renal failure—treated with angiotensin-converting enzyme inhibitors (ACEIs); additional antihypertensive agents may be needed
- *Primary Sjögren syndrome:* Distal renal tubular acidosis, nephrogenic diabetes insipidus, interstitial nephritis, hypokalemia, and/or renal calculi; rarely glomerulonephritis

The most common and potentially devastating renal manifestation of systemic sclerosis (see Chapter 56) is scleroderma renal crisis (SRC).[35] Most cases of SRC occur within 4 years of the onset of systemic sclerosis in patients with diffuse cutaneous scleroderma affecting the proximal extremities and the trunk, although some may have a scleroderma renal crisis without dermatological features. Several characteristics of the disease, including rapid progression of skin thickening, palpable tendon friction rubs, anti-RNA polymerase III antibody, recent-onset cardiac events (*e.g.*, pericardial effusion or heart failure), new-onset anemia (especially if associated with microangiopathic hemolysis and thrombocytopenia), and recent treatment with high-dose corticosteroids, help identify patients at increased risk for developing SRC. A classic clinical presentation may obviate the need for renal biopsy. However, renal biopsy may be necessary in atypical cases. For example, about 20% of SRC cases occur before the diagnosis of scleroderma has been established. Patients with scleroderma can rarely also develop other renal diseases, such as ANCA-associated vasculitis, which are important to recognize because they require treatments different from those usually recommended for SRC.

Scleroderma renal crisis is characterized by abrupt onset of renin-mediated moderate to severe hypertension, rapid deterioration of renal function, and proteinuria, which is usually nonnephrotic. Associated findings may include microangiopathic hemolysis, hypertensive encephalopathy including seizures, hypertensive retinopathy, acute left ventricular failure, and pulmonary edema. Normotensive renal crisis occurs infrequently and may be recognized by the presence of microangiopathic hemolysis with or without unexplained azotemia. The primary pathogenic process appears to be a renal vasculopathy involving predominantly the interlobular arteries and arterioles. Marked intimal thickening with an attendant "mucoid" appearance, and fibrinoid necrosis in the absence of vasculitis, are common and characteristic of the disease (Fig. 68.16). Immune deposits are rarely observed by fluorescence or electron microscopy studies.

Although a variety of treatments have been proposed for patients with scleroderma, none has been proven to be consistently efficacious. The most significant therapeutic advance in the treatment of SRC is the use of angiotensin-converting enzyme (ACE) inhibitors (ACEIs), which have dramatically increased the 1-year survival of patients with SCR. Prompt treatment with ACEIs is recommended for hypertensive and normotensive SRC because these agents may reverse the process by interfering with angiotensin II–mediated vasoconstriction and by inhibiting the degradation of bradykinin, a potent vasodilator, by ACE. Despite this impressive impact of ACEIs on clinical outcomes, approximately one-third to one-half of patients still progress to early death or renal failure. This has prompted continued investigation of additional treatment strategies, including blockade

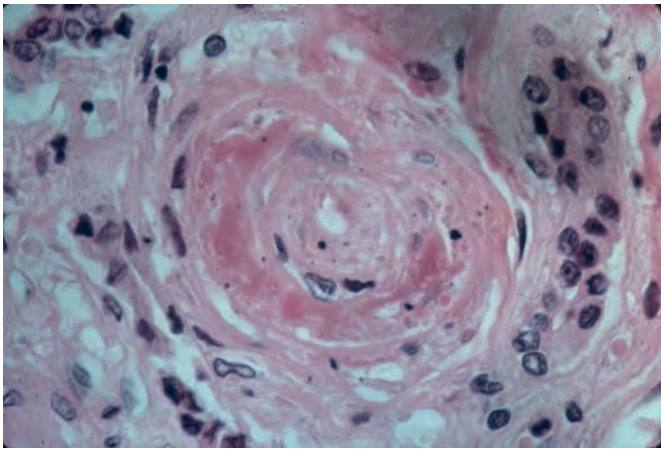

FIG. 68.16 Scleroderma Renal Crisis. Renal arteriole demonstrates extensive fibrin deposition (dark material) within multiple layers of its wall. The lumen is further compromised by severe swelling and intimal hyperplasia (Masson trichrome stain).

of the RAA system at multiple sites, for example, with a direct renin inhibitor as well as a potent vasodilator such as prostacyclin or an endothelin receptor antagonist.

Renal Disease of Primary Sjögren Syndrome

A variety of renal manifestations occur in approximately one-third of patients with primary Sjögren syndrome (see Chapter 55), including tubular dysfunction (proximal or, more often, distal renal tubular acidosis), Fanconi syndrome, hypokalemia that may be profound and associated with paralysis, Bartter syndrome, Gitelman syndrome, nephrogenic diabetes insipidus), as well as renal calculi, nephrocalcinosis, interstitial nephritis, pseudolymphoma, necrotizing vasculitis, and glomerulopathy.[36] Studies of renal pathology among patients with primary Sjögren syndrome have shown that acute and/or chronic tubulointerstitial nephritis is the predominant lesion. A diverse range of glomerular diseases, including MN and proliferative glomerulonephritis (focal or diffuse, and membranoproliferative), have been reported in primary Sjögren syndrome. In such cases, the possibility of overlap with SLE should be considered. Immunosuppressive therapy for renal manifestations of primary Sjögren syndrome should be individualized on the basis of activity and severity of the glomerular and/or tubulointerstitial nephritis. Patients with serious complications of tubular dysfunction may warrant immunosuppressive therapies based on preliminary evidence that autoantibodies (against, for example, carbonic-anhydrase-II) as well as cell-mediated injury likely contribute to at least some of those disorders.

Thrombotic Microangiopathies

KEY CONCEPTS

Thrombotic Microangiopathies

- Thrombotic microangiopathies (TMA) can be hereditary or acquired and the main primary forms are complement-mediated TMA (atypical hemolytic uremic syndrome, aHUS), Shiga-toxin-mediated TMA (ST-HUS) and ADAMTS13 deficiency–mediated TMA (TTP, thrombotic thrombocytopenic purpura)
- Key clinical findings are microangiopathic hemolytic anemia (MAHA), thrombocytopenia, and acute kidney injury
- Treatment according to the etiology, plasma exchange being the mainstay of acute therapy

Thrombotic microangiopathies (TMA) are a heterogeneous group of diseases of either hereditary or acquired etiology that share the clinical findings of microangiopathic hemolytic anemia (MAHA) and thrombocytopenia.[37] Peripheral blood smears reveal fragmented erythrocytes, which result from shearing injury in the microvasculature. The common pathologic features are arterial and capillary microthrombi formation and characteristic endothelial and vessel wall damage. Based on a number of advances in pathophysiological insight, diagnostic tests and treatment in the recent years the nomenclature has been modified to reflect causality. Below are the main primary causes of TMA. In addition, a range of secondary causes of TMA, among them pregnancy, severe hypertension, glomerular diseases or certain drugs, have been described.

ADAMTS13 deficiency–mediated TMA (thrombotic thrombocytopenic purpura, TTP) features predominantly neurologic symptoms, with acute kidney injury occurring rarely. ADAMTS13 deficiency can be hereditary or acquired based on autoantibodies against the metalloprotease. Treatment consists of acute plasma exchange and prophylactic plasma transfusions and glucocorticoids in the course of the disease.

In Shiga-toxin-mediated TMA (ST-HUS) a prodromal diarrheal disease is followed by TMA with acute kidney injury and occasionally neurological abnormalities. *Escherichia coli*, serotype O157:H7 and *Shigella dysenteriae* are the most common toxin-producing bacteria and often occur in outbreaks. Treatment is supportive, with patients commonly requiring dialysis.

Complement-mediated TMA (atypical hemolytic uremic syndrome, aHUS) is a prototypic disease of complement dysregulation. The complement system is a highly conserved part of the innate immune system, with its key components C3 and C5. It mediates immune cell and platelet activation, endothelial cell damage and pathogen opsonization. Activation can happen through the classical pathway with an antibody signal, the lectin-pathway through a pattern recognition signal, or through the alternative pathway (tick-over). Complement-mediated TMA is thought to be based on uncontrolled alternative pathway activation, either caused by loss-of-function mutations in regulatory complement genes (*e.g.*, *CFH*, *CFI*, *CD46*) or gain-of-function mutations in effector genes (*e.g.*, *CFB*, *C3*). By far the most common defect is in complement factor H (*CFH*), which constitutes 10% of the cases. Importantly, most genetic mutations show incomplete penetrance. Environmental triggers, such as pregnancy or infection, are often necessary to trigger the disease. Rarely, antibodies against CFH or CFI proteins are found.

Clinical features of complement-mediated TMA are commonly acute kidney injury and hypertension. Treatment is based on plasma exchange and the complement factor C5 inhibitor, Eculizumab. Treatment duration with eculizumab remains unproven. Treatment failure should prompt screening for genetic causes or autoantibodies. The other TMAs also feature complement activation, but it is less clear if this is a primary event or bystander effect. The use of complement inhibitors is controversial here.

The success of eculizumab in treating aHUS has prompted a new interest in complement inhibitors and the complement system itself. Drugs under investigation include inhibitors targeting C5AR1 and MASP2, and long-acting formulations of C5 inhibitors.[38] Recent evidence points to the existence of intracellular C3 and C5 complement systems in many cells.[39] An unresolved field remains the understanding of the integration and inter-connection of the intracellular and extracellular complement pathways.

ON THE HORIZON

- The advent of new genetic and molecular techniques and new disease models has led to exciting progress in our understanding of the biology of the glomerulus, the pathogenesis of many glomerular diseases, and the influence of genetic variants on disease predisposition and progression.
- These insights should lead to better noninvasive diagnostic techniques, biomarkers, and predictors of prognosis and relapse and facilitate a more personalized approach to therapy rather than a one-size-fits-all approach.
- Novel targeted therapies are on the horizon that will interrupt or modulate the underlying pathophysiology of the individual diseases and also halt the downstream pathways of injury and fibrosis common to all of the glomerular diseases.

Immunologic Mechanisms of Atherosclerosis and Myocarditis

Peter Libby and Andrew H. Lichtman

Immunologic mechanisms contribute critically to many cardiovascular diseases. This chapter will focus on atherosclerosis—an example of a common vascular disease—and myocarditis—an immune-mediated disease of the heart itself.

IMMUNOLOGICAL MECHANISMS THAT CONTRIBUTE TO ATHEROSCLEROSIS

Immunological mechanisms participate in all phases of atherosclerosis from lesion initiation through the long clinically silent or stable phase of lesion progression, culminating in the thrombotic complications that bring patients to the attention of physicians most dramatically.[1–3]

Atherosclerosis Initiation

The normal artery has a tri-laminar structure (Fig. 69.1).[4] The outermost layer, the adventitia, contains fibroblasts, nerve endings, and mast cells. Occasionally, lymphoid collections localize in the adventitia. The middle layer, the tunica media, consists of multiple layers of arterial smooth muscle cells (SMCs) embedded in layers of extracellular matrix. In medium-sized muscular arteries where atherosclerosis occurs most commonly, a collagen and elastin-rich matrix predominates. In larger elastic arteries, such as the aorta, lamellae of elastin surround layers of SMC.

The innermost layer of all arteries consists of a monolayer of endothelial cells (ECs) that abut a basement membrane. The internal elastic lamina separates the tunica media from the intima. In most human arteries affected by atherosclerosis, the intima contains extracellular matrix with occasional resident SMCs. Portions of arteries particularly predilected to develop atherosclerotic plaques often contain cushions of intimal SMCs even early in life. This complex structure of the tunica intima in humans differs from many experimental animals, such as the mouse or the rabbit, in which the intima is thin and lacks resident SMCs.

The EC monolayer in contact with the blood displays remarkable homeostatic properties under normal circumstances (Fig. 69.2, *left hand column*). The endothelial monolayer can maintain blood in a liquid state during prolonged contact, a property seldom found at other natural or synthetic surfaces. The ability to resist thrombus accumulation depends on a tightly orchestrated series of functions depicted in Fig. 69.2. The normal anti-coagulant mechanisms associated with the undisturbed endothelial surface include expression of thrombomodulin, and heparan sulfate-like molecules that can activate antithrombin III. The enzymes urokinase-type plasminogen activator (uPA) and tissue-type plasminogen activator (tPA) regulate fibrinolysis at the surface of the endothelial monolayer should a thrombus form. The normal endothelium resists prolonged contact with leukocytes that circulate in blood. Normal ECs produce nitric oxide, a gas that promotes smooth muscle relaxation and hence vasodilatation.

These salutary functions can change when EC encounter danger signals, such as pro-inflammatory cytokines, pathogen-associated molecular patterns (PAMPs), or danger-associated molecular patterns (DAMPs) (see Fig. 69.2, *middle column*).[5] Engagement of selective receptors in the case of cytokines or pattern-recognition receptors, such as the toll-like receptors (TLRs) in the case of PAMPs and DAMPs, instigates a program of functions that disrupts the normal homeostatic properties of the endothelium. Pro-coagulant and anti-fibrinolytic mechanisms prevail over anti-coagulant, anti-thrombotic, and endogenous fibrinolytic mechanisms as shown in Fig. 69.2. The endothelial cell activated by inflammatory mediators can produce the potent pro-coagulant tissue factor and plasminogen-activator inhibitor-1 (PAI-1), the inhibitor of the endogenous pro-fibrinolytic enzymes uPA and tPA.

Stimulation by pro-inflammatory mediators elicits the expression by EC of molecules that mediate the adhesion of various classes of leukocytes (Fig. 69.3, *left hand*).[4] E-selectin, a prototypical endothelial-leukocyte adhesion molecular, participates in acute inflammatory responses by recruiting polymorphonuclear leukocytes. Vascular cell adhesion molecule-1 (VCAM-1) expressed by EC interacts with the integrin cognate ligand very late antigen-4 (VLA-4) on leukocytes involved in chronic inflammatory responses, such as atherosclerosis, notably monocytes and lymphocytes. EC themselves and subjacent SMC in the arterial intima can produce chemotactic and chemoattractant cytokines that can stimulate the directed migration of adherent leukocytes into the intima.[6] The recruitment of leukocytes represents an early step in the formation of atherosclerotic lesions. In animals that develop hypercholesterolemia, either through dietary or genetic manipulation, lipid deposits—composed of free cholesterol or, within cells, cholesteryl esters—also accumulate. Many have ascribed a pro-inflammatory role to low-density lipoprotein (LDL) particles that have undergone oxidation in the environment of the intima, shielded from plasma antioxidants. While various forms of oxidized lipoproteins and lipids localize within the nascent atheroma and atherosclerotic plaques, their causal role in inciting inflammation remains incompletely established.[7]

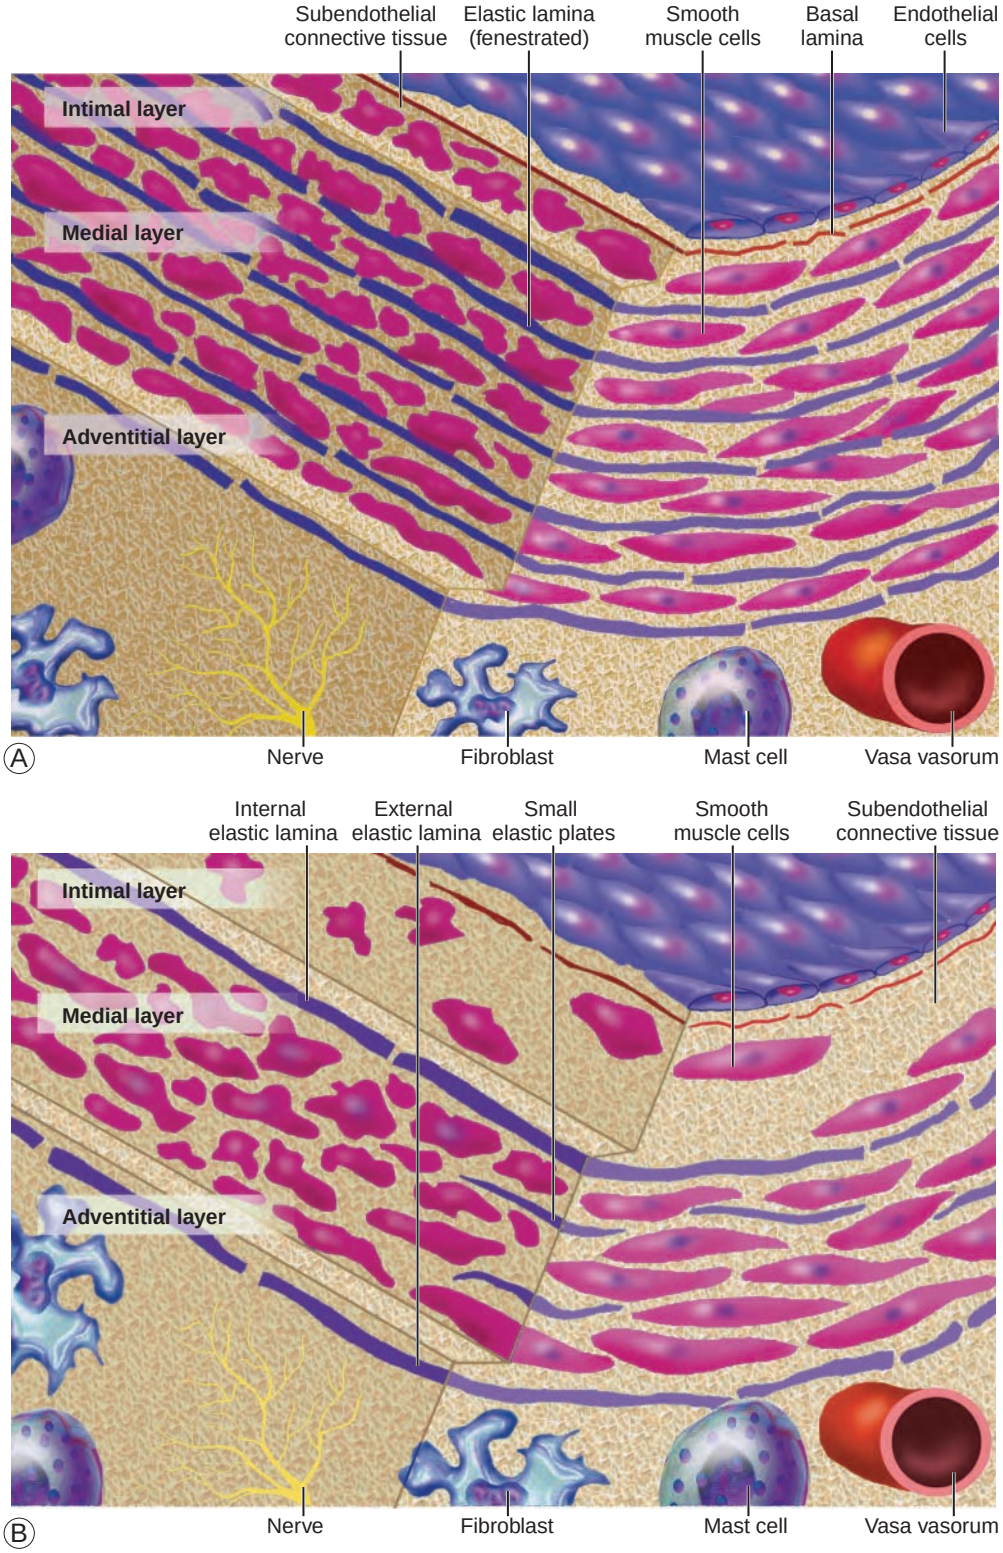

FIG. 69.1 The Structures of Normal Arteries. (A) Elastic artery. Note the concentric laminae of elastic tissue that form sandwiches with successive layers of smooth muscle cells (SMCs). Each level of the elastic arterial tree has a characteristic number of elastic laminae. (B) Muscular artery. In the muscular artery, a collagenous matrix surrounds the SMCs, but the architecture lacks the concentric rings of the well-organized elastic tissue characteristic of larger arteries. From Libby P. The Vascular Biology of Atherosclerosis. In: Libby P, Bonow RO, Mann DL, Tomaselli GF, Bhatt DL, Solomon SD, eds. *Braunwald's Heart Disease* (12th ed). Philadelphia: Elsevier 2022:425–441.

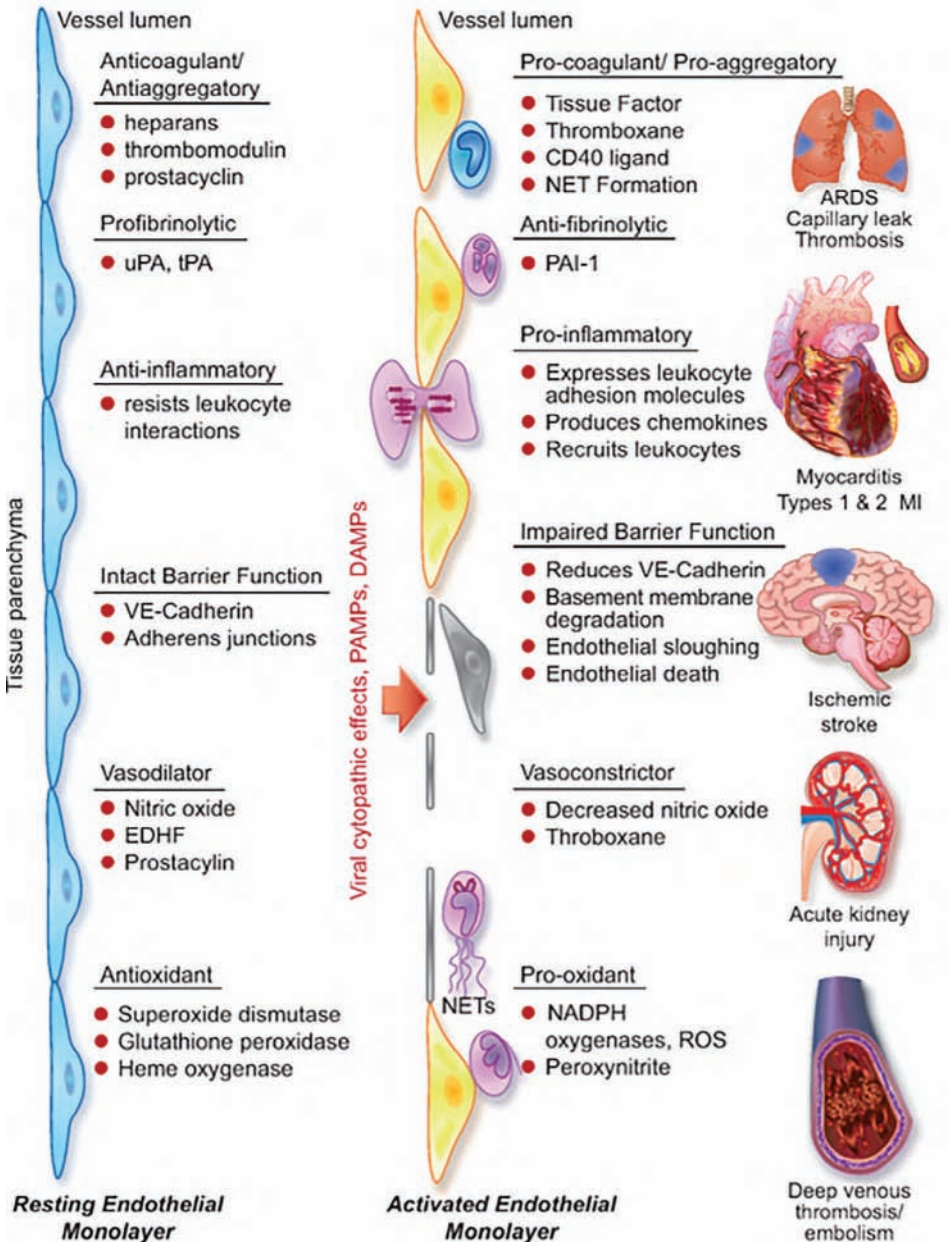

FIG. 69.2 Endothelial Activation During Acute Inflammation and Mechanisms of Organ Damage. The left side of the diagram shows a resting endothelial monolayer with the endothelial cells of squamous morphology resting on an intact basement membrane. The homeostatic mechanisms displayed by the resting endothelium include the listed properties as detailed in the text. When the endothelial cells undergo the cytopathic effect of a viral infection such as SARS-CoV-2, or encounter pathogen-associated molecular patterns (PAMPs) derived from viruses or bacteria such as lipopolysaccharide, proinflammatory cytokines such as IL-1 or TNF, or damage-associated molecular patterns (DAMPs) derived from dead or dying cells, the endothelial cells become activated. The endothelial cells display more columnar morphology. They can express adhesion molecules that attract leucocytes and chemokines that direct their migration into the subendothelial space. Sloughing of endothelial cells uncovers the thrombogenic basement membrane. Adherent neutrophils can undergo formation of neutrophil extracellular traps (NETs) that provide an amplifier for endothelial damage mediated in part by IL-1α. Inflammatory activation of endothelial cells can disrupt VE-cadherin, largely responsible for the integrity of the endothelial barrier function. Activated endothelial cells can also express matrix metalloproteinases that can degrade the basement membrane and further interrupt endothelial barrier function. In small vessels, such as those that embrace alveoli in the lung, this impaired barrier function can lead to capillary leak. These various disturbances in endothelial function, depicted in the middle part of the diagram, lead to end-organ damage including adult respiratory distress syndrome and thrombosis in the lungs, predispose to plaque rupture and thrombosis in coronary arteries, and affect the microvasculature leading to myocardial ischemia and damage. The thrombotic diathesis provoked by endothelial dysfunction can also predispose towards strokes. Microvascular as well macrovascular injury can potentiate acute renal failure. Hepatic dysfunction can also result from microvascular thrombosis among other mechanisms. Deep venous thrombosis can occur as endothelial disfunction represents an important part of Virchow's triad, and sets the stage for pulmonary embolism. Thus, loss of the endothelial protective and unleashing of the mechanisms depicted can lead to multiorgan system failure that characterizes the advanced stages of COVID-19. (From Libby P, Lüscher T. COVID-19 is, in the end, an endothelial disease. *European Heart J.*2020;41(32):3038–3044.)

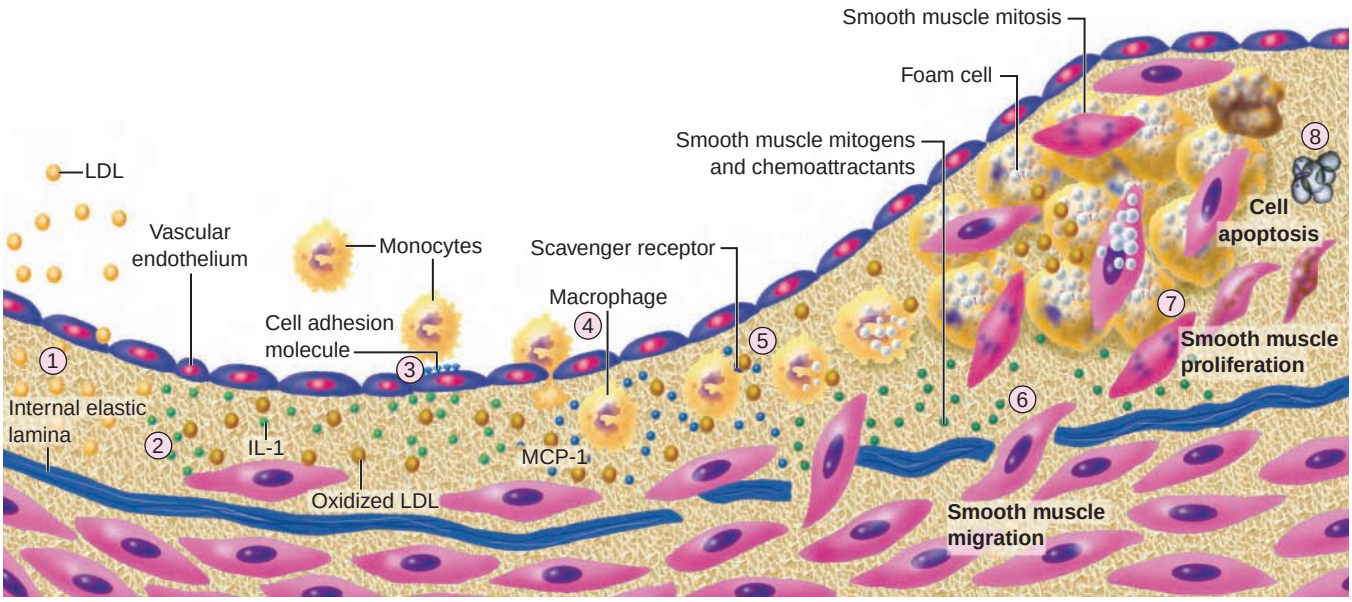

FIG. 69.3 Schematic of the Evolution of the Atherosclerotic Plaque. (1) Accumulation of lipoprotein particles in the intima *(yellow spheres)*. The modification of these lipoproteins is depicted by the darker color. Modifications include oxidation and glycation. (2) Oxidative stress, including products found in modified lipoproteins, can induce local cytokine elaboration *(green spheres)*. (3) The cytokines thus induced increase expression of adhesion molecules (*blue stalks* on endothelial surface) for leukocytes, which cause their attachment and chemoattractant molecules that direct their migration into the intima. (4) Blood monocytes, on entering the artery wall in response to chemoattractant cytokines such as monocyte chemoattractant protein 1 (MCP-1), which encounter stimuli such as macrophage colony-stimulating factor that can augment their expression of scavenger receptors. (5) Scavenger receptors mediate the uptake of modified lipoprotein particles and promote the development of foam cells. Macrophage foam cells are a source of mediators, such as cytokines and effector molecules, like hypochlorous acid, superoxide anion (O_2^-), and matrix metalloproteinases. (6) Smooth muscle cells (SMCs) migrate into the intima from the media. (7) SMCs can then divide and elaborate extracellular matrix, promoting ECM accumulation in the growing atherosclerotic plaque. In this manner, the fatty streak can evolve into a fibrofatty lesion. (8) In later stages, calcification can occur (not depicted) and fibrosis continues, sometimes accompanied by SMC death (including programmed cell death or apoptosis), yielding a relatively acellular fibrous capsule surrounding a lipid-rich core that also may contain dying or dead cells and their detritus. *IL*, Interleukin; *LDL*, low-density lipoprotein. (From Libby P. The Vascular Biology of Atherosclerosis. In: Libby P, Bonow RO, Mann DL, Tomaselli GF, Bhatt DL, Solomon SD, eds. *Braunwald's Heart Disease* (12th ed). Philadelphia: Elsevier 2022:425–441.)

Once leukocytes have taken up residence within the intima, they—as well as the intrinsic arterial wall cells—ECs and SMCs can elaborate mediators that stimulate the migration and proliferation of SMCs (see Fig. 69.3, *right hand*). Proteins such as platelet-derived growth factor (PDGF) can beckon SMC usually resident in the tunica media to enter the intima. In the normal media and under basal circumstances, the generally quiescent SMCs contain considerable contractile proteins. The SMCs that have undergone stimulation by mediators such as PDGF not only migrate and proliferate but contain less contractile protein and produce more extracellular matrix macromolecules, such as interstitial collagens and elastin as well as proteoglycans and glycosaminoglycans. These modulated SMCs elaborate much of the extracellular matrix that comprises a substantial portion of the volume of atherosclerotic plaques.

The mononuclear phagocytes are not the only leukocytes that enter the intima during atherogenesis. T lymphocytes and B lymphocytes, while less numerous than mononuclear phagocytes, also populate nascent atheromata.[8] These T lymphocytes can orchestrate pro-inflammatory and pro-oxidant functions of the more numerous macrophages through elaboration of mediators such as interferon gamma (IFN-γ). In addition to T helper 1 cells (Th1) that can elaborate IFN-γ when activated, lesions contain Th2 cells that elaborate IL-4 and IL-10. During the evolution of the atheroma, a prolonged tug-of-war between pro-inflammatory and anti-inflammatory lymphokines plays out. The role of Th17 cells in atherosclerosis remains controversial.

Lesion Progression

During these initial phases of atherogenesis described above, different classes of mononuclear leukocytes and modulated SMCs have taken up residence in the intima, accompanied by cholesterol or cholesteryl ester. Lesion complication (Fig. 69.4) involves elaboration of extracellular matrix by the activated SMCs. Transforming growth factor-beta (TGF-β), elaborated by regulatory T cells (T_{reg}), potently stimulates the production of interstitial forms of collagen by SMCs but may also limit smooth muscle proliferation. The blood monocytes mature into tissue macrophages when recruited into the atherosclerotic lesion. In mice, these mononuclear phagocytes can also proliferate during later stages of lesion development.[9] The tissue macrophages display considerable heterogeneity. Indeed, the complexity of macrophage populations determined from initial forays into single-cell messenger RNA sequencing appears considerable.[10] The tissue macrophages can express scavenger receptors that can take up modified lipoproteins promoting intracellular accumulation of cholesterol esters in lipid droplets within the cytoplasm.[4] The classical

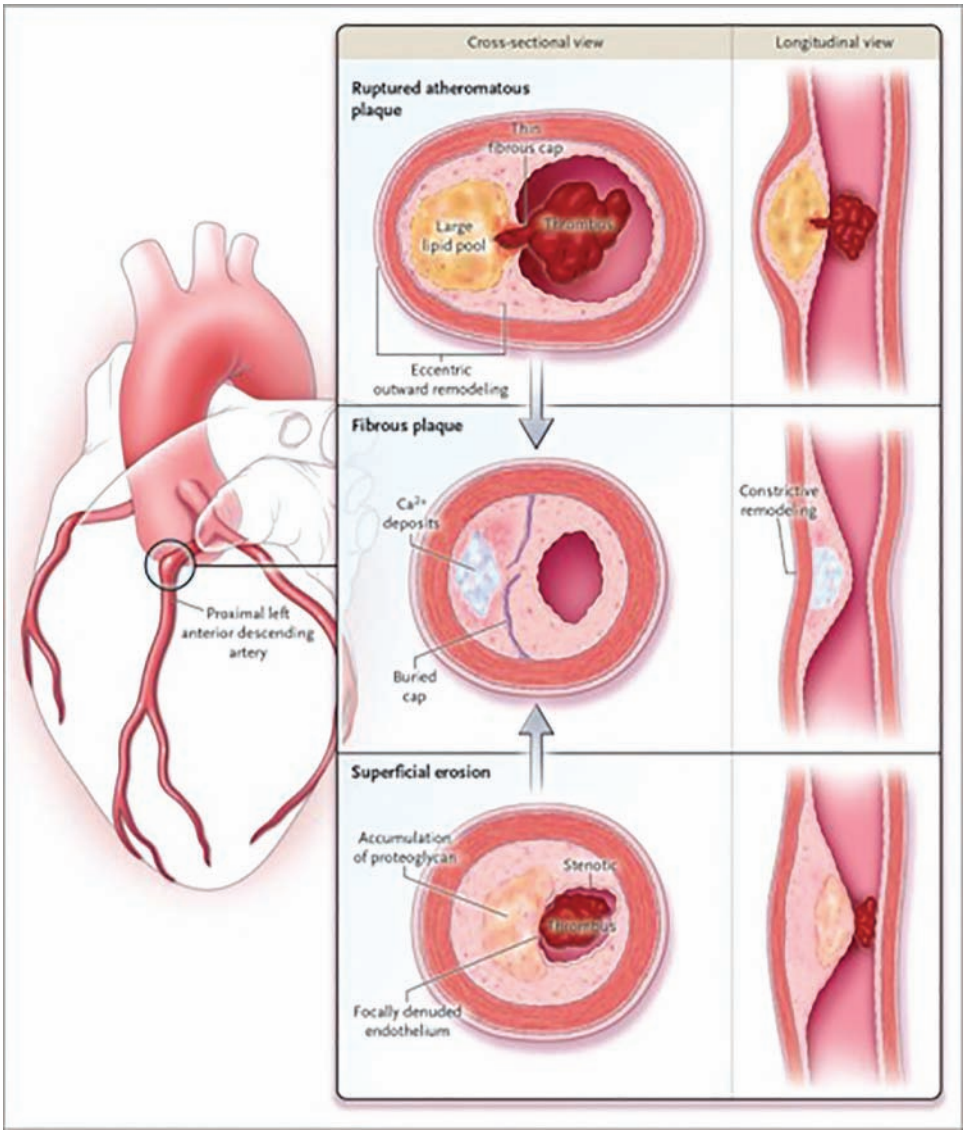

FIG. 69.4 Characteristics of Atherosclerotic Plaques Associated with Various Presentations of Coronary Artery Disease. This figure depicts the characteristic morphologic features of coronary atherosclerotic plaques that associate with three distinct clinical presentations. The representation of the cardiac surface *(left)* shows an atherosclerotic plaque affecting the proximal left anterior descending coronary artery. The cross-sectional and longitudinal views of the artery portray typical lesion types in greater detail. The two top images show an eccentric, positively remodeled atheroma with a thin fibrous cap that has fractured and caused a thrombus to form. The healing of plaques that have disrupted can yield the formation of a more fibrous lesion (shown in the middle pair of images). Stenotic, fibrous plaque can cause stable ischemic syndromes (*e.g.*, demand angina pectoris) as a result of narrowing of the arterial lumen. In this situation, plaques can display "buried caps," the result of a prior disruption of the fibrous cap that triggered thrombosis, followed by healing, fibrosis, and often constrictive (inward) remodeling. This process can promote the progression of a nonocclusive, atheromatous, lipid-rich plaque to a stenotic, more fibrous, calcified plaque. The bottom pair of images shows a proteoglycan-rich plaque that instigated thrombosis due to superficial erosion of the endothelial monolayer. (Libby P. Mechanisms of acute coronary syndromes and their implications for therapy. *N Engl J Med.* 2013;368:2004–2013.)

LDL receptor undergoes tight regulation by intracellular cholesterol levels under the control of the sterol regulatory element proteins (SREBPs). Thus, it is difficult to load cells with cholesterol through the classical LDL receptor as the very accumulation of cholesterol inhibits the expression of the usual LDL receptor. Hence, the importance of the scavenger receptors, which are lower affinity and high-capacity receptors that can mediate the internalization of modified cholesterol, bypassing the tightly regulated LDL receptor.

Lipid-laden macrophages can undergo cell death by apoptosis or pyroptosis. When these cells die, they extrude their lipid content into the extracellular space. Cholesterol crystals composed of cholesterol monohydrate can form both within macrophages and in the extracellular space. The cholesterol crystals can coactivate the inflammasome that activates interleukin (IL)-1-beta and can thus promote pyroptosis. Generally, apoptotic cells do not tarry in tissues because of rapid phagocytosis, and therefore, do not incite inflammatory responses as do necrotic cells. However, within

atherosclerotic plaques, it appears that phagocytosis of dead or dying cells, a process denoted efferocytosis, works inefficiently leading to the buildup of inflammatory cellular debris within the plaque. Ultimately, the accumulation of lipid and cellular detritus lead to formation of a central lipid or necrotic core in the evolving atherosclerotic plaque. Typically, a fibrous cap comprised of SMC and interstitial collagen overlies the lipid core. These various mechanisms lead to the formation of the mature lipid-rich atherosclerotic plaque (see Fig. 69.4).

Under normal circumstances, microvessels perfuse only the outer third of the adventitia of arteries. As atherosclerotic plaques evolve, they can acquire a microcirculation due to angiogenesis.[11,12] The neovessels that form at the base of plaques in this manner exhibit friability and can have impaired barrier function, favoring the extravasation of erythrocytes and stimulating local thrombi within the vascular walls, providing another source of platelet-derived mediators that can stimulate SMC proliferation and extracellular matrix production.

Lesion Complication

Atherosclerotic plaques can progress to form arterial narrowings or stenoses that can limit blood flow, causing lack of supply of oxygen (ischemia) due to impeded blood flow in the areas subtended by the stenosed vessel (see Fig. 69.4, *middle*). Such stenoses can arise by SMC proliferation and accumulation of extracellular matrix molecules, such as interstitial collagens, elastins, proteoglycan, and glycosaminoglycans. Yet, such progressive growth to flow-limiting lesions, usually accounts for chronic ischemia, producing chest discomfort (angina pectoris), under conditions of increased oxygen demand due, for example, to physical effort or mental stress. Such gradual narrowing of the artery *per se* seldom leads to the acute thrombotic complications of atherosclerosis that cause acute coronary syndromes, such as myocardial infarction. Rather, a physical disruption of the atherosclerotic plaque most frequently provokes the blood clots that precipitate acute coronary syndromes (see Fig. 69.4).[13] The most common form of plaque disruption involves a frank rupture or fissuring of the plaque's fibrous cap that overlies the lipid core (see Fig. 69.4, *top*). Indeed, lesions that have provoked a fatal thrombus often have a fractured, thin fibrous cap that overlies a lipid core rich in procoagulants, such as tissue factor produced by plaque macrophages and SMC. When the coagulation proteins in blood gain access to the procoagulants within the plaque due to a fissure, a thrombus can rapidly ensue.

The macrophages within the plaque can produce enzymes that degrade the constituents of the arterial extracellular matrix when stimulated by pro-inflammatory mediators. These enzymes include the matrix metalloproteinases (MMPs) specialized in breakdown of interstitial collagens (MMPs 1,8, and 13) and cysteinyl proteinases such as cathepsins S, K, or L that can degrade elastin. The overproduction of these enzymes by macrophages within the plaque can disrupt the usually protective fibrous cap, rendering it thin, friable, and susceptible to rupture, thus setting the stage for a fracture and precipitation of an acute thrombotic event (Fig. 69.5).[13] IFN-γ elaborated by activated plaque T lymphocytes can inhibit the production of new collagen by SMC required to repair and maintain the protective extracellular matrix of the fibrous cap. IFN-γ can also enhance the proteolytic, oxidative, and pro-inflammatory functions of lesional macrophages, further destabilizing the plaque. A rupture of the plaque's fibrous cap causes two-thirds to three-quarters of acute coronary syndromes.

Another mechanism known as superficial erosion, can also cause acute thrombotic complications of atherosclerotic plaques (see Fig. 69.4, *bottom*).[14] Indeed, in an era of effective lowering of LDL, and with improved treatment of hypertension and more widespread smoking cessation, plaque rupture due to the thin-capped lipid-rich atheroma appears to be becoming less prevalent.[15] Superficial erosion now accounts for a quarter to a third of acute coronary syndromes.

Superficial erosion also appears to depend on innate immune processes. For example, activation of Toll-like receptor-2 (TLR-2) on endothelial cells, perhaps in response to fragments of hyaluronic acid that form within the subjacent intima, can sensitize SMC to apoptosis, sloughing, and impaired ability to repair a rent in the monolayer.[16] When patches of EC slough, they expose basement membrane, which can activate platelet accumulation. Polymorphonuclear leukocytes can accumulate at these sites and form neutrophil extracellular traps (NETs). These filamentous structures consist of strands of the granulocyte's nuclear DNA that unwind when relieved of constraints into nucleosomes.[17] NETs bind the constituents of polymorphonuclear leukocyte granules and also capture tissue factor from the blood, presenting these pro-inflammatory, pro-oxidant, and pro-thrombotic mediators at the surface of the endothelium.[18] NETs thus serve as a solid-state reactor that favors thrombus formation and accumulation. Plaque disruption due to fracture of the fibrous cap or to superficial erosion due to desquamation of lumenal EC underly the vast majority of acute coronary syndromes. Similar mechanisms may pertain to thromboses responsible for many ischemic strokes that arise from the extracranial cerebral arteries and may also complicate aortic atheromata.

Therapeutic Implications of Inflammation in Atherosclerosis

The scientific literature is replete with experimental studies that support a role for various pro-inflammatory pathways—both activation of innate and adaptive immunity—in atherosclerosis in all phases. Moreover, biomarker studies in humans support a relationship between inflammatory status and the manifestations of atherosclerosis, including thrombotic complications. C-reactive protein—measured by a highly sensitive assay (hsCRP)—remains the best validated of these biomarkers of inflammation, but the literature with other indices of inflammation build a highly congruent case that inflammation correlates with risk of atherosclerosis and its complications. Yet, until recently, the causality of inflammation in atherosclerosis remained an open question. The Canakinumab Anti-Inflammatory Thrombosis Outcome Study (CANTOS) was the first to close this loop of causality in humans.[19] CANTOS enrolled over 10,000 individuals who had sustained an acute coronary syndrome and received state-of-the art treatment mandated by guidelines for preventing recurrent events. Yet, despite treatment with highly effective LDL-lowering statins, aspirin, beta-adrenergic blocking agents, and when appropriate inhibitors of the renin angiotensin system, CANTOS selected individuals who had an indication of residual inflammation as disclosed by an hsCRP above median for the population, 2 mg/L. The participants randomly received placebo or one of three doses of canakinumab, a human monoclonal antibody that selectively neutralizes IL-1β. After a median follow up of 3.7 years, canakinumab produced a significant 15% reduction in recurrent myocardial infarction or stroke or cardiovascular death. This result substantiated the causality of

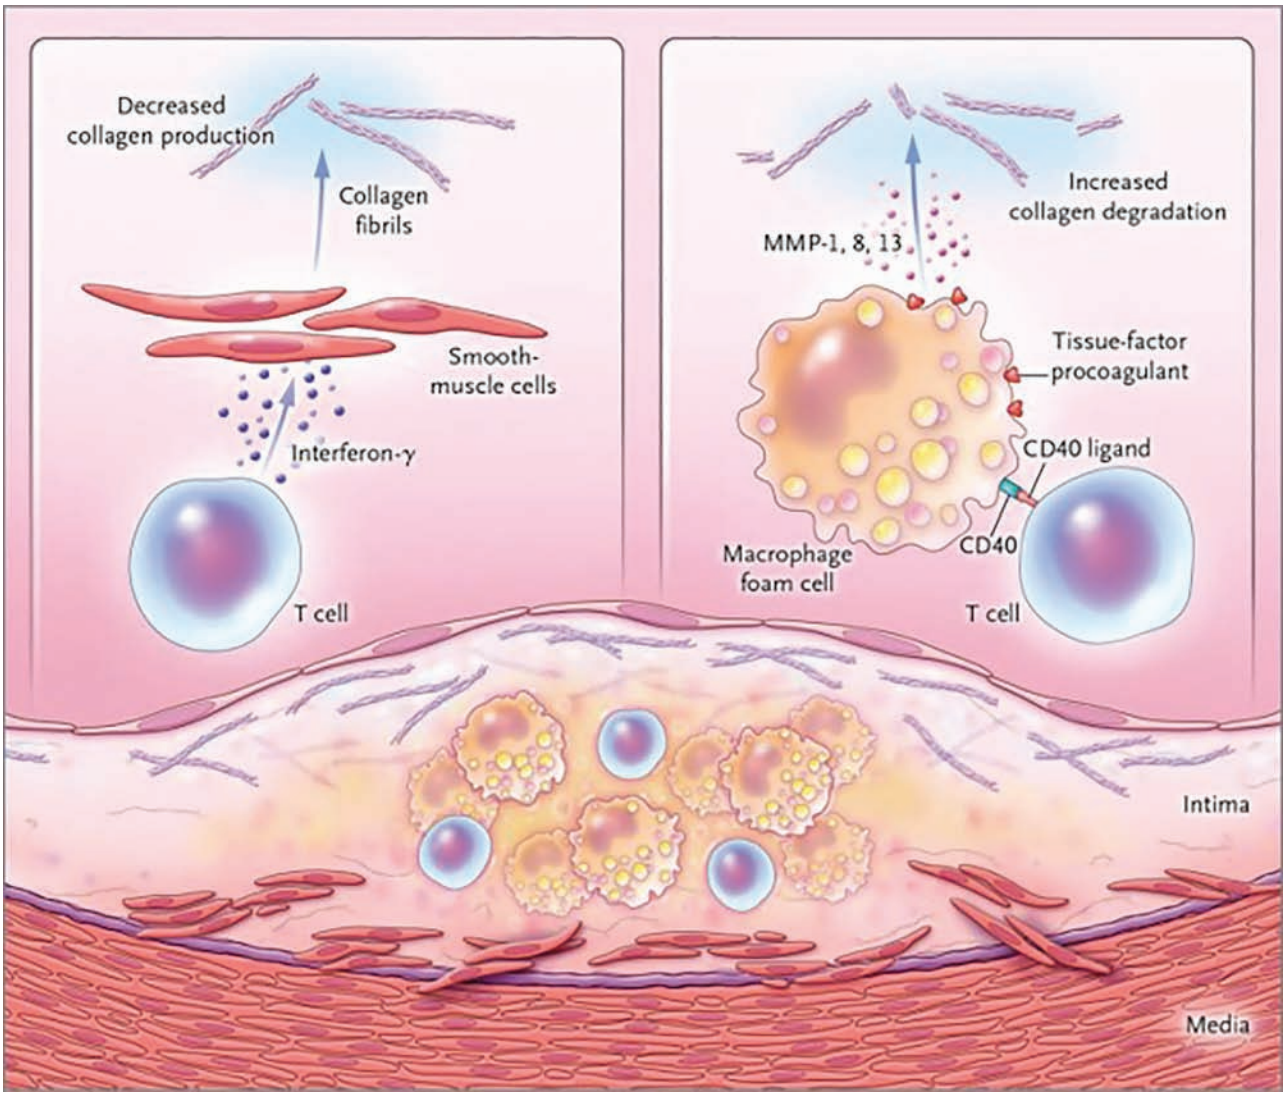

FIG. 69.5 **Inflammatory Pathways Predisposing Coronary Arteries to Rupture and Thrombosis.** A cross-section of an atheromatous plaque at the bottom of the figure shows the central lipid-rich core that typically contains macrophage foam cells *(yellow)* and T lymphocytes *(blue)*. The intimal and medial layers also contain arterial smooth-muscle cells *(red)*, which elaborate the arterial extracellular matrix including interstitial collagen (depicted as triple helical coiled structures). Activated T cells (of the Th1 helper T-cell subtype) secrete interferon-γ. This cytokine inhibits the synthesis of the new collagen that confers strength upon the plaque's protective fibrous cap *(upper left)*. The T lymphocytes can also stimulate lesional macrophages to express CD40 ligand (CD154), which ligates its receptor (CD40). This inflammatory signal provokes the overproduction of interstitial collagenases (matrix metalloproteinases [MMPs] 1, 8, and 13) that can attack the usually very stable collagen triple helix that lends tensile strength to the plaques cap *(top right)*. CD40 binding can also elicit overproduction of the potent procoagulant tissue-factor by macrophages. In this manner, inflammatory signaling places the collagen in the plaque's fibrous cap in double jeopardy—decreased synthesis and increased degradation—a recipe for rendering the fibrous cap liable to rupture. The augmented tissue-factor production in response to inflammatory stimulation favors thrombus formation in the ruptured plaque. These mechanisms contribute to inflammations ability to trigger the thrombotic complications of atherosclerosis such as the acute coronary syndromes. (Libby P. Mechanisms of acute coronary syndromes and their implications for therapy. *N Engl J Med*. 2013;368(21):2004–2013.)

pro-inflammatory immune responses in human atherosclerotic complications. In a pre-specified on-treatment analysis, individuals treated with canakinumab who achieved a greater than median drop in hsCRP showed an over 30% reduction in cardiovascular and total mortality (Fig. 69. 6). Canakinumab was associated with a small, but statistically significant, increase in infections, including fatal infections. The infections probably arose from impaired host defenses due to IL-1β blockade. The increase in infections were balanced by a remarkable reduction in the incidence and deaths due to cancer, primarily lung cancer, in the enrolled population. This observation has spawned numerous studies of neutralization of IL-1β as an adjutant therapy to combat lung cancer. A number of mechanisms may contribute to these various benefits of IL-1β neutralization observed in CANTOS (Fig. 69.7).

The canakinumab-treated patients in CANTOS exhibited many other benefits, including reduced hospitalizations for heart failure and less frequent incidence of anemia. Arthritis

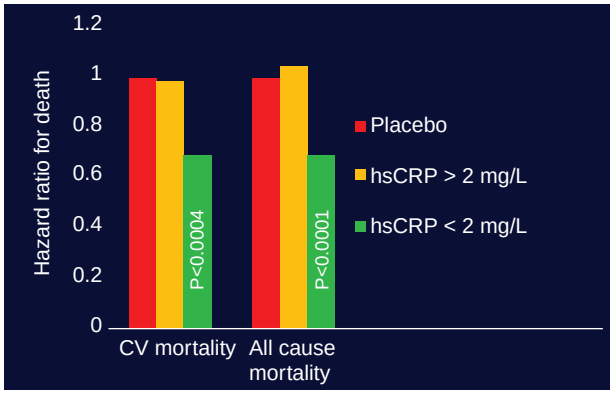

FIG. 69.6 Responders to Canakinumab had Mortality Benefit in the On-Treatment Analysis from CANTOS. Multivariable adjusted hazard ratios (HR) for prespecified cardiovascular outcomes according to on-treatment, high-sensitivity C-reactive protein (hsCRP) levels above or below 2 mg/L after drug initiation. HRs adjusted for age, gender, smoking, hypertension, diabetes, body mass index, baseline hsCRP, baseline low density lipoprotein-cholesterol. This on-treatment analysis underwent numerous sensitivity analyses to assess possible confounding that affirmed the conclusion. (Data from Ridker PM, MacFadyen JG, Everett BM, et al. Relationship of C-reactive protein reduction to cardiovascular event reduction following treatment with canakinumab: a secondary analysis from the CANTOS randomised controlled trial. *Lancet*. 2018;391(10118):319–328.)

symptoms declined strikingly in the canakinumab-treated patients, and acute gouty arthritis fell by over 50%. The CANTOS trial thus opened a new window on atherosclerosis therapy by proving that a directed anti-inflammatory intervention that did not alter atherogenic lipoproteins could provide cardiovascular benefit on top of all standard treatments.

Another anti-inflammatory intervention, colchicine, has also shown benefit in patients with coronary artery disease. The COLCOT study demonstrated a greater than 25% reduction in recurrent cardiovascular events in patients within a month of acute myocardial infarction who randomly received low-dose colchicine 0.5 mg daily.[20] The LoDoCo2 study showed a similar reduction in events in patients with stable coronary artery disease with a like colchicine treatment.[21] The mechanisms of colchicine's anti-inflammatory effects remain incompletely understood.

Thus, we now possess information that supports the efficacy of two anti-inflammatory interventions in atherosclerosis. Numerous possibilities and questions remain in moving the field of anti-inflammatory therapies in atherosclerosis forward.[22,23] Could allocation of anti-inflammatory therapies to individuals who have not yet sustained an acute coronary syndrome prove beneficial? What biomarkers would permit the precise allocation of an anti-inflammatory intervention in this circumstance?

One possibility arises from the recent observation that individuals who have clones of leukocytes that arise from somatic mutations in a subset of known leukemia driver genes have a markedly accentuated risk of atherosclerotic events.[24]

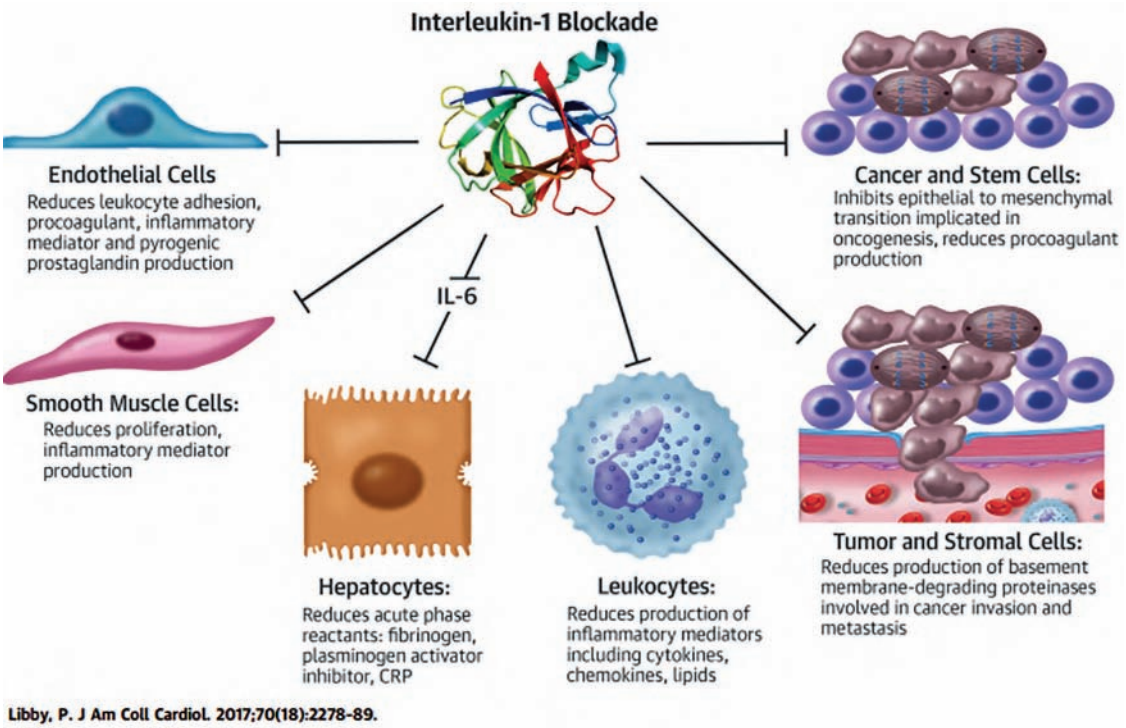

FIG. 69.7 Some Effects of IL-1 Blockade on Cellular Functions. Interleukin (IL)-1 alters many functions of cells that can participate in disease pathogenesis, including such conditions as atherosclerosis, thrombosis, oncogenesis, and invasion and metastasis of tumors. A number of the actions of IL-1 on hepatocytes, among them the induction of the acute phase response, depend on IL-6, a cytokine downstream of a protein induced by IL-1. Concordant evidence from human genetics supports the causality of IL-6 in atherothrombosis. CRP = C-reactive protein. (From Libby, P. Interleukin-1 beta as a target for atherosclerosis therapy: biological basis of CANTOS and beyond. *J Am Coll Cardiol*. 2017;70(18):2278–2289.)

Experimental studies have documented an increase in the inflammasome–IL-1β–IL-6 pathway in animals engineered to resemble humans with clonal hematopoiesis due to somatic mutations. Individuals who inherit a variant in the IL-6 receptor that interferes with IL-6 signaling have a remarkable decrease in atherosclerosis events compared to individuals who lack the low-function variant, but only if they bear clonal hematopoiesis mutations.[25] Thus, individuals found to have clonal hematopoiesis due to these mutations could benefit from a therapy that interrupts IL-6 signaling. Such a genotype-directed anti-inflammatory intervention would represent an example of a precision therapy that would limit treatment to those with particular propensity to benefit.

Many other anti-inflammatory therapies have become candidates for clinical evaluation in the context of atherosclerosis. These include pro-inflammatory cytokines, as well as a number of inhibitors of other pro-inflammatory pathways or mediators.[23] Yet, pharmacologic inhibition of p38MAP kinase and inhibitors of various phospholipases that give rise to pro-inflammatory phospholipids have not reduced cardiovascular events in rigorous randomized trials. A pilot trial is evaluating manipulation of adaptive immunity in atherosclerosis. Low-dose IL-2 can stimulate the activity of regulatory T cells that may limit inflammation during atherosclerosis.[26] Vaccination furnishes another strategy that manipulates adaptive immunity that might modulate atherosclerosis.[27] Indeed, a number of approaches to vaccinating against apolipoprotein B, the major apolipoprotein of LDL, have undergone development, although no clinical trials have yet proven efficacy of a vaccination approach.

In conclusion, we now have abundant experimental evidence that both adaptive and innate immunity operate in atherosclerosis. Recent clinical and human genetic studies provide direct support for the operation of innate immune pathways in human atherosclerosis. A number of therapeutic avenues that target inflammation merit further investigation to make inroads against the unacceptable residual burden of risk despite contemporary standard of care. Such approaches might ultimately prevent recurrent events and those with established atherosclerosis, but also forestall the initial manifestations of atherosclerosis in selected individuals.

MYOCARDITIS: IMMUNE RESPONSE THAT DAMAGES THE HEART

Immune Status of the Heart Under Homeostatic Conditions

Human life depends on uninterrupted electrochemical function of the heart, and that function depends on a non-redundant anatomy of myocardial cells that have essentially no regenerative capacity. Innate and adaptive immune responses invariably lead to some degree of tissue damage, even if they are initiated by microbial infections. Therefore, these responses pose a substantial danger to uninterrupted cardiac function. The dense microvascularity of the heart—needed for efficient delivery of oxygen to contracting myocytes—carries the liability of easy access for circulating immune cells to enter the myocardium. These risks have likely exerted selective pressures for the coevolution of immune-suppressive mechanisms that raise the bar for initiation of immune responses in the heart. Such mechanisms would block the accidental activation of circulating T cells, including autoreactive T cells, that may migrate into the heart at a low frequency. A relative "immune-privileged" state of the heart is reflected in the low number of T cells present in the healthy myocardium, unlike the chronic "physiologic" inflammation characteristics of many other organs and tissues.

Although the mechanisms for the relatively privileged state of immunity in the healthy heart is not well understood, several cellular and molecular components likely contribute. One mechanism is the presence of tissue-resident macrophages, which populate the myocardium during fetal development and acquire anti-inflammatory homeostatic properties from cardiac tissue-specific signals.[28] Furthermore, mediators generated during an innate immune response or early during adaptive T cell–mediated responses rapidly induce immunoregulatory mechanisms in the myocardium. These include the induction of endothelial expression of the immune checkpoint molecule PD-L1 by type 1 interferons and interferon-γ, which serves to limit reactivation of effector T cells that enter the heart.[29] These mechanisms may fail in the setting of certain cardiotropic microbial infections, a genetic susceptibility for autoimmunity, or a combination of both. When adaptive immune responses in the heart do occur, they can manifest as a heterogeneous spectrum of clinical syndromes all grouped under myocarditis. Initial innate immune responses can evoke dysfunctional adaptive immune responses, including effector T cells and antibodies that may then engage innate immune effector molecules and cells to contribute to structural damage.

Inflammation in the myocardium in older adults most often arises from innate immune responses to ischemic injury resulting from coronary artery disease, less commonly at all ages by innate and adaptive responses to infection and more rarely as a manifestation of autoimmunity. Adaptive immune responses in the heart, mediated by antibodies and T cells, may be specific for microbial antigens (*e.g.*, the Streptococcus in rheumatic heart disease), or in the case of autoimmunity, myocardial antigens. In all cases, myocardial immune responses may lead to acute loss of heart function and often result in structural changes that lead to dilated cardiomyopathy with chronic heart failure.

Myocarditis

Myocarditis includes several different clinical-pathological conditions with the common characteristic of myocardial inflammation, most often involving lymphocytes and macrophages, that causes injury and functional impairment of the myocardium (Table 69.1).[30,31] The term myocarditis is not used to describe the inflammatory response that rapidly develops after ischemic injury. The clinical presentation of myocarditis is highly variable, depending on the underlying cause and when the patient comes to medical attention. Signs and symptoms often include fatigue, shortness of breath, chest pain, palpitations, electrocardiographic (ECG) findings of arrythmias and atrioventricular block, echocardiographic or MRI findings of right or left ventricular wall motion defects, and valvular dysfunction, elevated serum markers (troponins, erythrocyte sedimentation rate and C-reactive protein). Most of these findings can reflect ischemic heart disease unrelated to myocarditis, and often, the presumptive diagnosis of myocarditis is one of exclusion after coronary artery disease, myocardial infarction, and heart failure due to other causes have been ruled out. Details of different modes of presentation are described in Cardiology textbooks. Constellations of symptoms, physical exam, ECG, imaging, and clinical laboratory tests can only lead to a diagnosis of clinically suspected myocarditis. A definitive diagnosis of myocarditis,

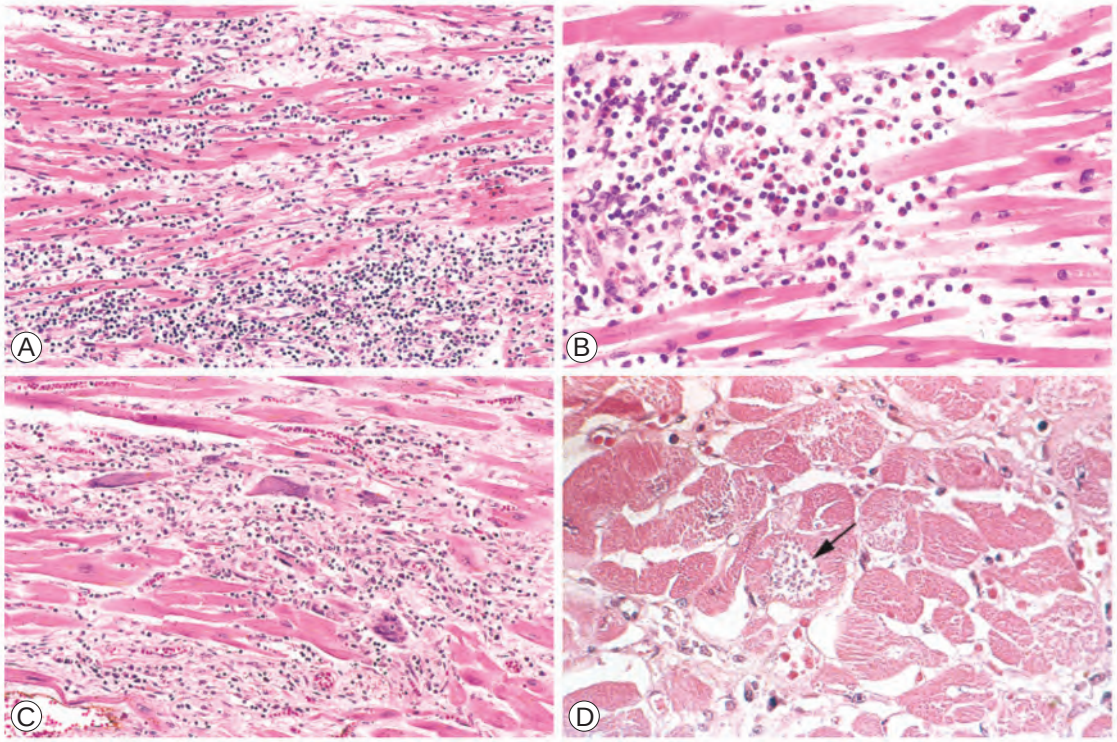

FIG. 69.8 Myocarditis. (A) Lymphocytic myocarditis, associated with myocyte injury. (B) Hypersensitivity myocarditis, characterized by interstitial inflammatory infiltrate composed largely of eosinophils and mononuclear inflammatory cells, predominantly localized to perivascular and expanded interstitial spaces. (C) Giant-cell myocarditis, with mononuclear inflammatory infiltrate containing lymphocytes and macrophages, extensive loss of muscle, and multinucleated giant cells. (D) The myocarditis of Chagas disease. A myofiber distended with trypanosomes *(arrow)* is present along with inflammation and necrosis of individual myofibers. (From Kumar V, Abbas AK, Fausto N, Aster, JC. *Robbins and Cotran pathologic basis of disease*. Chapter 12, 8th ed. Philadelphia: Elsevier; 2020.)

and subclassification of the type of myocarditis, requires histopathologic examination of endomyocardial biopsies (EMBs) or heart issue obtained at autopsy (Fig. 69.8). Specific criteria for the pathologic diagnosis of different types of myocarditis, also called inflammatory cardiomyopathies, have been published and updated (Table 69.2).[32] These criteria include the immunohistochemical identification and quantification of infiltrating T and B lymphocytes, monocytes or macrophages, neutrophils, and eosinophils, accompanied by assessment of infectious agents by polymerase chain reaction (PCR) or *in situ* hybridization. However, EMB is not done routinely in many medical centers, and while generally quite safe in experienced hands, may have increased risks in very ill patients with acutely dilated hearts. Furthermore, EMB-based diagnosis can have low sensitivity due to sampling issues, if the inflammatory process in the myocardium is not diffuse. Therefore, our knowledge of the etiology and immune mechanisms of human myocarditis still relies in large part on correlations with extracardiac immune variables (blood cell counts and phenotype, plasma proteins) and extrapolations from animal research. The following discussion will focus on the immunological features of different forms of human myocarditis, including those of known association with infections, and those without known infectious causes.

Infectious Myocarditis

Infections of the myocardium appropriately fall into a discussion of immune-mediated cardiovascular diseases for two principal reasons. First, much of the pathophysiology of infections in the heart result from the immune response to the etiologic agent, beyond their direct cytopathic effects. Second, autoimmune myocarditis, in which the adaptive immune system specifically targets cardiac antigens, appears to frequently arise as a complication of myocardial infections, especially virial myocarditis. All classes of microbes can infect cardiac tissue and cause an inflammatory response that impairs cardiac function (Table 69.1). Most cases of myocarditis in North America, Europe, and Asia are a result of viral infections, but in South and Central America, *Trypanosoma cruzi* is the most frequent cause of acute and chronic myocarditis.

Viral myocarditis is diagnosed in patients with clinical findings generally associated with myocarditis (discussed above) paired with evidence of acute viral infection, such as increased titers of virus-specific antibodies and detection of viral antigens or nucleic acids in the blood, or molecular detection of viral nucleic acid or immunohistochemical detection of viral proteins in EMBs. Historically, the most common viruses associated by serology with acute myocarditis have been Coxsackievirus, other enteroviruses, adenoviruses, hepatitis C virus, cytomegalovirus, and influenza virus. Currently, the most frequently identified viral genomes by PCR of EMBs are parvovirus B19 and Epstein-Barr virus, hepatitis C virus, and Human Immunodeficiency Virus (HIV). PCR-based detection of viral nucleic acids in myocarditic hearts does not prove the etiologic role of those viruses—especially common endemic viruses, such as parvovirus—but ongoing viral genome studies of EMB samples may shed further light on this question.

TABLE 69.1 Causes of Myocarditis

Cause	Clinical/Pathologic Syndrome
Infections of Myocardium	
Viruses (e.g., coxsackievirus, ECHO, influenza, HIV, Epstein-Barr virus, cytomegalovirus, parvovirus)	Acute and chronic viral myocarditis, chronic; dilated cardiomyopathy
Bacteria (e.g., rickettsia)	Cardiac rickettsial vasculitis
Helminths (e.g., trichinosis)	Cardiac trichinellosis
Fungi (e.g., Candida)	Cardiac candidiasis
Protozoa (e.g., *Trypanosoma cruzi*, *Toxoplasma gondii*	Acute and chronic Chagasic myocarditisCardiac toxoplasmosis
Effects of non-cardiac infection on the heart	
Corynbacterium diphtheriae	Diphtheriae toxin myocarditis
Neisseria meningitidis	Meningococcal myocarditis
Immune-mediated	
Post-viral autoimmune	Chronic lymphocytic myocarditis, dilated cardiomyopathy
Poststreptococcal autoimmune	Rheumatic fever/carditis, chronic rheumatic heart disease
Hypersensitivity (e.g., drug reactions)	Eosinophilic myocarditis
Unknown trigger	Sarcoidosis, isolated cardiac
Unknown trigger	Giant cell myocarditis
Unknown trigger	Necrotizing eosinophilic myocarditis
Manifestations of systemic autoimmune disease	Systemic lupus erythematosus cardiitis, Cardiac involvement in systemic sarcoidosis,Giant cell myocarditis with IBD, other autoimmune diseases, Necrotizing eosinophilic myocarditis, Eosinophilic granulomatosis with polyangiitis (EGPA)

TABLE 69.2 Histopathological Classifications of Myocarditis

Histopathological Type	Histopathology	Most Common Clinical Associations
Acute lymphocytic myocarditis	Patchy infiltration of CD3+ T lymphocytes, with minimal fibrosis	Viral and autoimmune
Chronic lymphocytic myocarditis	Myocardial fibrosis accompanied by lymphocytic infiltration.	Viral and autoimmune
Giant cell myocarditis	Extensive areas of inflammation, predominantly with CD68+ macrophages, often multinucleated giant cells, as well as T cells and eosinophils, with associated myocardial necrosis.	Isolated or autoimmune disease
Eosinophilic myocarditis	Mixed lymphocytic and myeloid infiltrate with significant numbers of eosinophils; little myocardial damage in hypersensitivity form of disease; marked necrosis in rare form of disease.	Drug hypersensitivity or associated with autoimmune disease with eosinophilia (*e.g.*, Churg Strauss)
Granulomatous: Sarcoidosis	Noncaseating granulomas and lymphocytic infiltrate and fibrosis	Isolated or systemic sarcoidosis
Neutrophilic myocarditis	Neutrophilic abscesses often with bacteria	Systemic bacterial infection

The many different virus species identified as causative agents in myocarditis cases exert highly diverse cytopathic effects, including variability in cell types that are infected and injured. Nonetheless, the fundamental steps in the initiation and progression of anti-viral immune responses, which contribute to the pathophysiology of infection, appear to be similar across different viral infections of the heart.[33,34] The innate response to viruses in any tissue begins with recognition of viral nucleic acids by pattern recognition receptors (PRRs), including endosomal Toll-like receptors (TLRs)-3,-7,-8, and -9; cytosolic RNA sensors such as Rig-like receptors (RLRs) and nucleotide-binding oligomerization domain 2 (NOD2); and cytoplasmic DNA sensors that engage the cGAS-STING pathway.

Mouse studies have shown that either RNA and DNA viruses can cause essentially indistinguishable forms of myocarditis in the same strain of mice, which argues for the stereotypical innate anti-viral response that initiates disease in response to different viruses. Some experimental evidence implicates many of these receptors in both protection against viral infection, as well as pathological inflammation caused by virus, mostly in mouse Coxsackievirus (CV) B3 myocarditis.[35] The role of these innate-pattern recognition pathways in human viral myocarditis derives support from circumstantial evidence of expression and increases in several of the components of the pathways in human myocarditic hearts. Each of these pathways can provide anti-viral protection through activation of interferon-response factors (IRFs), which increase expression of type-1 interferon genes. In addition, most of these pathways also enhance inflammation through activation of Nuclear Factor kappa B (NF-κB), which enhances expression of acute inflammatory cytokines and factors that initiate adaptive immune responses. Such mouse studies illustrate a precarious balance between early innate immune protection against the virus and inflammation that results in acute and chronic myocardial injury.

The histopathological form of myocarditis that associates most frequently with viral cardiac infection is lymphocytic myocarditis. The adaptive immune response to viruses in mouse and human hearts is characterized by infiltrating effector T cells, B cells, and monocyte-derived macrophages, with foci of myocyte necrosis. Immunohistochemical interrogation of endomyocardial biopsies (EMBs) has established accumulation of both CD8 and CD4 T cells into hearts of patients with viral myocarditis, consistent with studies in mouse CVB3 myocarditis.[36] Mouse studies have implicated a pathogenic role of perforin/granzyme mediated CTL killing of myocytes, as well as inflammatory injury driven by CD4 Th1 and Th17 cells. CD8 and CD4 T cells are inferred to be pathogenic in human viral myocarditis hearts as well, based on the detection of these effector cells in tissue samples. Antibodies specific for many different myocardial proteins are found in the blood and in heart tissues of mice and humans with viral myocarditis (discussed below), but there is little evidence that they mediate substantial injury.

SARSCoV2, the etiologic agent of COVID-19, associates strongly with cardiac damage, as determined by cardiac troponin elevation and indices of edema and fibrosis in cardiac magnetic resonance studies.[37] Cardiac pericytes—the cells that invest the coronary microvasculature—express angiotensin-converting enzyme 2 (ACE-2), the enzyme that SARSCoV2 uses as a receptor. Some reports describe a fulminant myocarditis associated with SARSCoV2. Yet, actual infection of cardiac myocytes and a clear-cut myocarditis due to SARSCoV2 seems at present less common as a cause of myocardial damage in those with COVID-19 than an imbalance between oxygen supply and demand. Dysfunction of the endothelium does contribute to many complications of COVID-19.

T. cruzi infection (Chagas disease) is the most common infectious cause of myocarditis worldwide, with most cases occurring in South and Central America and Mexico.[38] Approximately 30% of infected people will develop some degree of chronic Chagasic cardiomyopathy (CCC). Acute myocarditis caused by *T. cruzi* infection of cardiac myocytes is usually mild or asymptomatic when transmitted by the insect vector (triatomine bug) bite but is often severe when transmitted by ingestion of contaminated food or juice, often leading to fulminant disease with heart failure and up to 10% mortality. In this acute form of the disease, there appear to be strong innate and adaptive immune responses, likely initialized by direct myocytopathic effects of the organism. Inflammatory infiltrates in acute chagasic myocarditis include neutrophils, NK cells, macrophages, T cells, and plasma cells. Most Chagas heart disease does not begin with symptomatic acute myocarditis but proceeds chronically after asymptomatic infection with progressive scarring of the myocardium over 10 to 20 years, eventually causing arrhythmias and biventricular heart failure without a known history of acute disease. CCC appears to be driven by persistent infection, documented by histology and molecular techniques, causing chronic inflammation, which damages tissue but fails to eradicate the infection. In murine studies, CD8 cytotoxic T lymphocytes are required to control infection, and an effective CTL response requires Th17 cells or other sources of IL-17. In humans, the CTL response becomes ineffective over time and the T cells acquire a dysfunctional or exhausted phenotype. Although autoantibodies specific for cardiac antigens can be detected in CCC patients, there is no evidence that they are pathogenic.

Autoimmune Myocarditis

Autoimmune myocarditis can develop as a consequence of known microbial infection, as one component of multiorgan/systemic autoimmune disease, as an isolated heart-only autoimmune disease with unknown connection with infection, or as a complication of cancer immunotherapy. In all cases, there is a failure in tolerance to cardiac antigens, but as is the case for most autoimmune diseases, the mechanisms of that failure are not well understood.[39] Self-tolerance to cardiac antigens requires a combination of central and peripheral tolerance mechanisms. Central tolerance to cardiac antigens is induced during B- and T-cell development in bone marrow or thymus, respectively, by deletion of immature lymphocyte clones specific for self-antigens. Peripheral tolerance is needed to prevent activation of naïve cardiac-specific lymphocyte clones that escaped central tolerance and depends on immune checkpoint regulatory molecules and regulatory T cells (T_{reg}). These peripheral tolerance mechanisms may inhibit priming of naïve lymphocytes in secondary lymphoid organs (SLOs) or block activation of effector lymphocytes that are generated in the SLOs.[40]

Autoimmune Myocarditis Associated With Infection

Viruses are the most common class of microbes implicated worldwide in infections that precede autoimmune myocarditis. The identification of a virus or other microbes responsible for myocarditis is accomplished only in a minority of cases. Therefore, although infection in the heart is a likely antecedent cause of many cases of chronic autoimmune myocarditis or idiopathic dilated cardiomyopathy, the causal connection is rarely proven. A progression from acute viral myocarditis to an acute autoimmune phase progressing to chronic dilated cardiomyopathy has been well characterized in certain inbred strains of mice infected with Coxsackievirus (Fig. 69.9), and this has served as a model for understanding the pathogenesis of autoimmune myocarditis in humans. The distinction between active infectious myocarditis and antecedent autoimmune myocarditis in both experimental animals and humans is often blurred because circulating autoantibodies specific for various cardiac antigens, such as myosin heavy chains and beta-1 adrenergic receptors are often found concurrently with biopsy-derived evidence of microbial infection, but the pathogenicity of such antibodies in human disease has not been established. Even if there is persistent detection of viral nucleic acid the relative contribution of autoimmune versus antiviral responses to cardiac injury is unclear.

Rheumatic heart disease is a cardiac manifestation of acute rheumatic fever (ARF), which is a systemic autoimmune complication of group A streptococcal pharyngeal infections. ARF begins 2 to 3 weeks after infection and includes carditis, arthritis, chorea, and cutaneous lesions. The cardiac component is an acute pancarditis affecting the pericardium, myocardium, and endocardium. A subset of patients will suffer from scarring of valves (most commonly mitral and aortic), leading to regurgitation and/or stenosis and chronic heart failure. Acute rheumatic carditis is a T-cell and antibody-driven inflammatory reaction that apparently arises as a result of antigen-mimicry between streptococcal antigens and human cardiac antigen. Antibodies that recognize conformational epitopes of streptococcal M protein and N-acetyl-beta-D-glucosamine cross-react with human myosin epitopes, and rodent studies show that streptococcal M protein immunization can cause inflammation of myocardium and cardiac valves. There is also evidence for the presence of myosin-specific autoantibodies in acute rheumatic fever patients that cross-react with N-acetyl-beta-D-glucosamine and M protein. A pathognomonic feature of this condition is the presence of granuloma-like Aschoff bodies in the myocardium, consisting of T cells, activated macrophages, fibrin, and necrosis. There is no definitive identification of peptide epitopes shared by streptococcal and cardiac proteins.

Autoimmune Myocarditis Without Known Infection

Idiopathic lymphocytic myocarditis shares clinical and histopathological features of many cases of viral myocarditis and is usually associated with markers of autoimmunity directed against the heart—including circulating anti-alpha-myosin and anti-beta adrenergic receptor antibodies—without evidence of causal viral infection.[39] As is the case in viral myocarditis, the

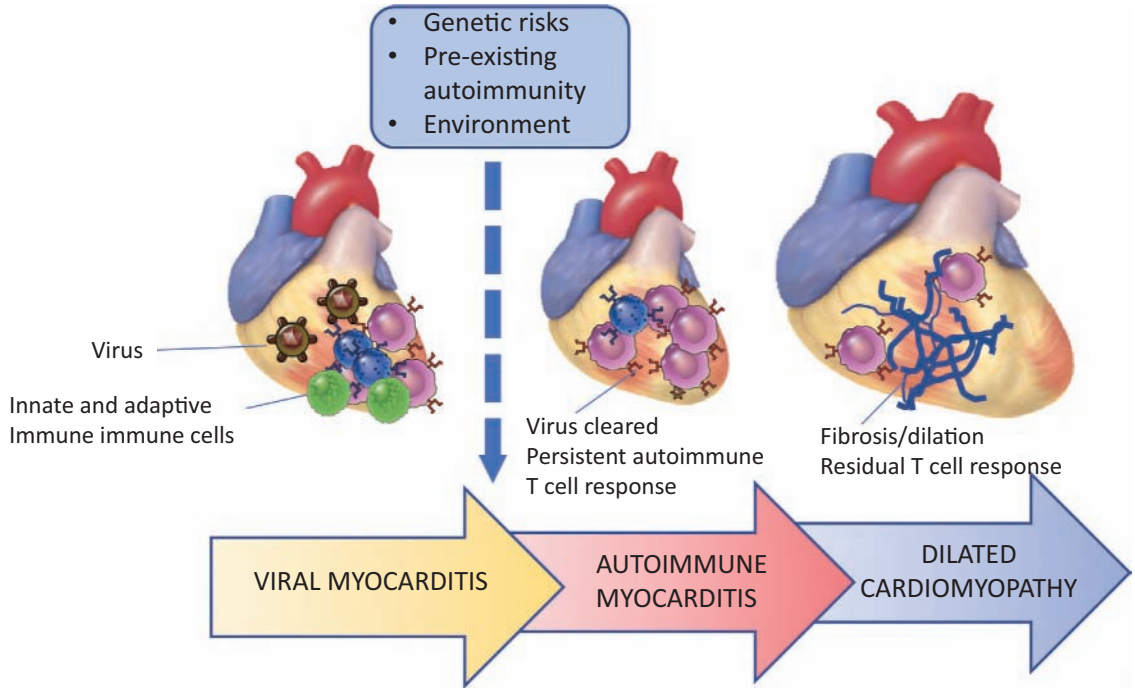

FIG. 69.9 Progression from Viral Myocarditis to Autoimmune Myocarditis and Dilated Cardiomyopathy. This scheme is based on experimental evidence from mice with coxsackievirus-induced myocarditis and experimental autoimmune myocarditis, as well as correlative human clinical data. Virus infection of myocardium evokes an innate immune response, which in turn promotes virus-specific T-cell responses, characterized by CD4 and CD8 effector T-cell infiltration accompanied by macrophages. A subset of patients, with as of yet poorly identified risk factors, go on to develop a T-cell driven autoimmune myocarditis, independent of persistent viral infection, likely induced by myocyte injury with release of self- antigens in a inflammatory milieu. The autoimmune phase in mouse models is largely a CD4 helper T-cell cytokine-driven process. Over time—weeks in mice, years in humans—progressive fibrosis of injured myocardium leads to heart failure with chamber dilation.

pathogenic role of the auto-antibodies is uncertain. Pathologic diagnosis is often made in late stages of the disease, usually in patients with a clinical diagnosis of dilated cardiomyopathy, rendering it difficult to rule out that viral infection initiated the disease.

Idiopathic giant cell myocarditis (GCM) is a rare disorder that most often presents with heart failure and is fatal or requires transplantation in about 90% of patients within 5 months of diagnosis. GCM is a diagnosed by histopathologic examination of endomyocardial biopsies, from myocardial cores removed for ventricular assist device (VAD) placement, or autopsy. Characteristic findings include diffuse infiltration by lymphocytes, macrophages, plasma cells and eosinophils, numerous multinucleated giant cells expressing macrophage markers, and foci of myocardial necrosis.[41] Giant cells also characterize cardiac sarcoidosis, where they usually localize within well-formed, non-necrotic granulomas. There is no evidence for microbial infection in GCM. Circumstantial evidence suggests autoimmunity or other forms of immune dysregulation are central to the pathogenesis GCM. About 20% of cases occur in patients diagnosed with other autoimmune/inflammatory diseases, and early treatment with calcineurin inhibitors slows disease progression and reduces mortality. Cardiac myosin immunization of rodents can induce myocarditis with giant cells. To date, no specific antigen has been identified that drives the human disease.

Eosinophilic myocarditis includes several different clinical entities in which eosinophils provoke cardiac inflammation.[42] The most common cause of myocardial eosinophilic inflammation appears to be hypersensitivity reaction to any one of a large number of drugs. These cases of hypersensitivity myocarditis rarely result in myocyte necrosis, but some patients present with heart failure. Acute necrotizing eosinophilic myocarditis is a rare and frequently lethal disorder that often presents with fulminant heart failure and demonstrates diffuse eosinophilic inflammation with necrosis. Thrombosis appears to be more frequent in eosinophilic myocarditis compared to viral myocarditis. This disorder may occur as an isolated cardiac disease or more commonly in patients with systemic eosinophilic autoimmune disorders, such as eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome). Other conditions in which eosinophilic inflammation is seen in the heart include Loeffler endomyocardial disease, parasite infections, and idiopathic hypereosinophilic syndrome.

Myocarditis Associated With Systemic Autoimmune Diseases

Myocarditis reportedly occurs more frequently in patients with systemic autoimmune diseases than the general population. Up to 10% of patients with systemic lupus erythematosus (SLE) will develop clinically diagnosed myocarditis, and autopsy studies indicate there is myocarditis in up to 50% of SLE patients. However, the limited information available from histopathologic examination in these cases suggests that the myocardial inflammation may be a response to ischemic damage caused by immune complex vasculitis rather than cardiac-antigen specific

autoimmunity. Clinical data suggest that patients with Sjögren syndrome, vasculitis, and polymyositis are also at higher risk for myocarditis, although in most of these cases histopathologic examination does not confirm the diagnosis. An example of autoimmune myocarditis associated with risk for another autoimmune disorder has been described in autoimmune (type 1) diabetes (T1D) patients who have a myocardial infarction. Most of these patients additionally suffer from a post-infarction syndrome that clinically resembles myocarditis. Almost 90% of these patients develop antibody and T-cell responses to cardiac alpha-myosin, while post-MI T2D patients do not.

Immune Checkpoint Blockade-Associated Myocarditis

Immune checkpoint blockade (ICB)-associated myocarditis is a recently emerged clinical entity which occurs in cancer patients treated with ICB drugs.[43,44] ICBs include monoclonal antibodies that block the function of CTLA-4, PD-1, or PD-L1 molecules that are required to regulate T-cell responses and prevent autoimmunity. More than 50% of ICB-treated cancer patients develop one or more immune-related adverse events (IRAEs), involving any one of many different organs and tissues. Patients with ICB-myocarditis present with acute onset heart failure or arrythmias, at times ranging from days to months after initiation of ICB therapy. ICB-associated myocarditis can occur in patients treated with only anti-CTLA, only anti-PD-1, or both antibodies. Histopathologic examination of tissue from autopsies and endomyocardial biopsies show CD4 and CD8 T-cell infiltration along with macrophages, and some myocardial necrosis. Although ICB myocarditis is relatively rare (~0.1% to 1% of ICB-treated patients) compared to other ICB-induced IRAEs, it appears to be one of the most lethal autoimmune T-cell-mediated processes. Preclinical studies showing the importance of CTLA-4 and PD-1/PD-L1 in protecting the heart from autoimmune myocarditis support this pathophysiologic scheme.[45] Some studies demonstrate oligoclonality of T-cell infiltrates, shared clones of T cells in the heart and tumor of individual patients and shared genes expressed by tumor and myocardium. However, the target cardiac antigens are not known. Skeletal myopathy can also occur in conjunction with ICB-associated myocarditis, as can a myasthenia gravis-like syndrome, indicating shared epitopes between these two types of striated muscle.

Cardiac Allograft Rejection

Heart transplantation is performed over 5000 times per year worldwide to treat end-stage heart failure due to many causes, including myocarditis. Certain forms of rejection of transplanted hearts involve immune effector mechanisms seen in myocarditis of native hearts, and transplantation medicine has to some degree informed the clinical approach to treating myocarditis. Other than testing for blood group compatibility and the presence of preformed allo-antigen-specific antibodies in the recipients' blood, both of which might cause hyperacute rejection and immediate graft failure, there are no other measures routinely taken to minimize allogeneic differences between the donor and recipient. Nonetheless, current immunosuppressive regimens allow for ~90% one-year patient survival and an average allograft half-life of ~10 years. The frequency of acute rejection episodes is highest early after transplantation, peaking at about 1 month and affecting from 10% to 30% of patients. Acute rejection is often diagnosed by routine serial EMBs of asymptomatic patients but may present with signs and symptoms of left ventricular dysfunction and heart failure. A standardized pathologic grading system for cardiac allograft rejection published by the International Society for Heart and Lung Transplantation[46] is widely used. Acute rejection is most often mainly T-cell-mediated (ACR), but antibody mediated (AMR) or a combination of both, also occur. The most likely target antigens are donor HLA proteins not shared by the host. ACR is characterized by an infiltrate of activated CD4 and CD8 T cells in the myocardium, with myocyte necrosis in severe cases. The appearance is similar to many cases of idiopathic autoimmune myocarditis. Myocytes and endothelial cells in the vicinity of lymphocyte infiltrates will often show evidence of activation by T-cell cytokines, including expression of HLA-DR and adhesion molecules. Often, significant left ventricular dysfunction may not be associated with significant myocyte damage on biopsy, perhaps reflecting disruptive effects of T-cell cytokines on the contractile function of myocytes, without overt cell necrosis. AMR is diagnosed by the presence of microvascular damage, thrombi, hemorrhage, neutrophilic inflammation, myocyte necrosis and the detection of Ig and complement fragments bound to capillary walls. These findings are consistent with allo-antibody-mediated complement activation in and damage to capillaries, leading to ischemic injury to myocytes. Acute rejection is prevented by chronic administration of various combinations of immunosuppressive drugs including calcineurin inhibitors, mTOR inhibitors, anti-metabolites, and corticosteroids. Treatment of an acute rejection episode usually involves changes in the dose or type of drugs, including the temporary use of T- or B-cell-depleting antibodies. For a discussion of allograft vasculopathy, please see Libby, Hasan, and Nohria in Bhatt Cardiovascular Therapeutics.[47]

CLINICAL IMPLICATIONS OF CARDIAC INFLAMMATION

The broad range of etiologies and clinical manifestations of myocardial inflammation pose unmet diagnostic and therapeutic challenges. Current diagnostic approaches short of myocardial biopsies do not reliably distinguish different immunopathological processes taking place in the heart, and pathological diagnoses of biopsies remain largely descriptive. Experimental forms of myocarditis in mice have provided robust evidence for the progression from viral infections in the heart to cardiac-specific autoimmunity to chronic injury and dilated cardiomyopathy, and mouse studies have shown that helper T-cell responses to defined epitopes of myocardial proteins can drive this progression. However, translation of the findings about T-cell subsets, cytokines, and autoantibodies involved in mice to treat effectively and specifically most forms of human myocarditis has lagged. There are no consistently effective treatments for acute lymphocytic myocarditis. Corticosteroid treatment is inconsistently effective in treating active lymphocytic myocarditis, including ICB-related myocarditis. Immunosuppressive drugs that target T-cell activation, such as calcineurin inhibitors, can delay progression of giant cell myocarditis, but such drugs have no proven benefit in more common forms of lymphocytic myocarditis. In the case of viral myocarditis, such treatments may impair anti-viral immunity and, thus, enhance cardiac injury due to virial cytopathic effects. For a fuller discussion of these therapies, please consult Libby, Hasan, and Nohria in Bhatt Cardiovascular Therapeutics.[47]

Progress in this clinical arena will require further characterization and understating of the immune responses in the human heart. This will involve application of new approaches for interrogating those responses, including identifying relevant immune-cell subsets by gene- and protein-expression technologies, determining the relevant specificities of lymphocytes that drive many of these disorders and clinical trials of specific immunomodulatory drugs.

Autoimmune Thyroid Diseases

Laura C. Lane, Simon H.S. Pearce, and Anna L. Mitchell

GRAVES HYPERTHYROIDISM

KEY CONCEPTS

Classification of Autoimmune Thyroid Disease

Autoimmune hyperthyroidism	Graves disease
Autoimmune thyroiditis	Hashimoto thyroiditis
	Atrophic thyroiditis
	Postpartum thyroiditis

Graves disease (GD) is a common autoimmune condition that accounts for the majority of cases of hyperthyroidism in the developed world. Its pathogenesis is unique among the autoimmune endocrinopathies because a key feature is the presence of stimulating autoantibodies directed against the thyrotropin (thyroid-stimulating hormone [TSH]) receptor, which mimic the action of TSH, a native hormone produced in the pituitary, to drive thyroid overactivity. Interestingly, thyroid dysfunction is commonly associated with other extrathyroidal manifestations of GD, the most common being Graves ophthalmopathy (GO).

Epidemiology

GD is one of the most common autoimmune diseases, with a prevalence of approximately 1% in women in the developed world.[1] It is more common in iodine-sufficient countries, where it accounts for 60% to 90% of cases of hyperthyroidism.[2] GD is seven times more common in women than in men and may affect individuals at any age; however, the peak incidence occurs between the ages of 35 and 40 years.

Etiology

GD is a complex genetic condition, implying that environmental stimuli precipitate disease in genetically predisposed individuals who harbor multiple susceptibility alleles. A large Danish twin study estimated that approximately 80% of the propensity to develop GD is attributable to genetic factors.[3] Further evidence for the heritability of GD comes from the observation that it clusters within families. Up to one-quarter of individuals with GD have a first-degree relative with the condition or with another autoimmune thyroid disease, such as autoimmune hypothyroidism (AH).[4] Should an individual have a sibling with GD, it is estimated that the relative risk (λ_s) of that individual developing GD is approximately 10-fold that of the background population, which is comparable with that of other heritable autoimmune conditions, such as type 1 diabetes, which has a λ_s of 15.

A number of genetic loci have been shown to contribute to GD susceptibility (Fig. 70.1). These genes encode proteins in biologic pathways that regulate immune system activity or thyroid biology.[4,5] The major histocompatibility complex (MHC) region on chromosome 6p21 is associated with multiple autoimmune conditions. Human leukocyte antigen (HLA) genes found within the MHC region play a vital role in pathogen and self-peptide recognition and therefore have a clear role in immunity and in establishing and maintaining immune tolerance (see Chapters 10 and 90).

In European populations, the primary association between MHC and GD is with alleles of the class II MHC genes. The *HLA-DR3* allele is detected twice as frequently in subjects with GD as in healthy controls (i.e., 50% of GD subjects vs. 25% of controls). At the protein level, neutral amino acids alanine or glutamine are substituted for positively charged arginine at position 74 in the HLA-DR peptide-binding pocket, which is thought to alter the binding-pocket configuration, more readily allowing self-peptides to enter the antigen binding site.[5] Importantly, 50% of individuals with GD do not have the *HLA-DR3* allele, implying that there is unlikely to be a single antigenic epitope responsible for GD.

The cytotoxic T-lymphocyte antigen-4 *(CTLA4)* gene (chromosome 2q33) encodes a costimulatory molecule expressed on the surface of activated T cells, which plays a pivotal role in downregulating T-cell responses and in checking T-cell activation, emphasizing the contribution of inhibitory signals in setting immune response thresholds (see Chapter 10). The *CT60* single nucleotide polymorphism (SNP) downstream from the 3′ untranslated region (3′UTR) was found to influence GD susceptibility (odds ratio [OR] 1.5) and has been suggested as a possible etiologic variant; however, contributions from other variants, such as at codon 17 in the CTLA-4 signal peptide remain likely.[6] Approximately 50% of individuals from healthy European populations carry the autoimmune "susceptible" *CTLA4* haplotype; therefore other important factors are clearly at play. CTLA-4 polymorphisms also contribute to susceptibility to type 1 diabetes, autoimmune adrenal insufficiency, celiac disease, and several other autoimmune conditions.

Products of several other genes involved in immunoregulation have allelic variants associated with GD, including CD25, CD40, PTPN22, PD-L1, IFIH1, BACH2, SCGB3A2, and FCRL3. In addition to these variants in immune regulatory pathways, loci specific to GD have been identified on the basis of known thyroid pathophysiology. The gene encoding the TSH receptor (TSH-R) on chromosome 14q31 is an obvious candidate for GD, as the TSH-R is directly stimulated by autoantibodies in affected individuals. Although initial studies reported conflicting results, a definite association between a number of SNPs in intron 1 of the *TSHR* gene and GD has now been confirmed in Whites.[5] The mechanism by which these intronic SNPs confer disease susceptibility is unknown.

Despite years of research into the genetic etiology of GD, 30% to 40% of the inherited susceptibility has yet to be accounted for. This "hidden" heredity is a common theme in genetically complex traits, but it is likely to be owing to rare genomic variants, polymorphisms in regulatory DNA

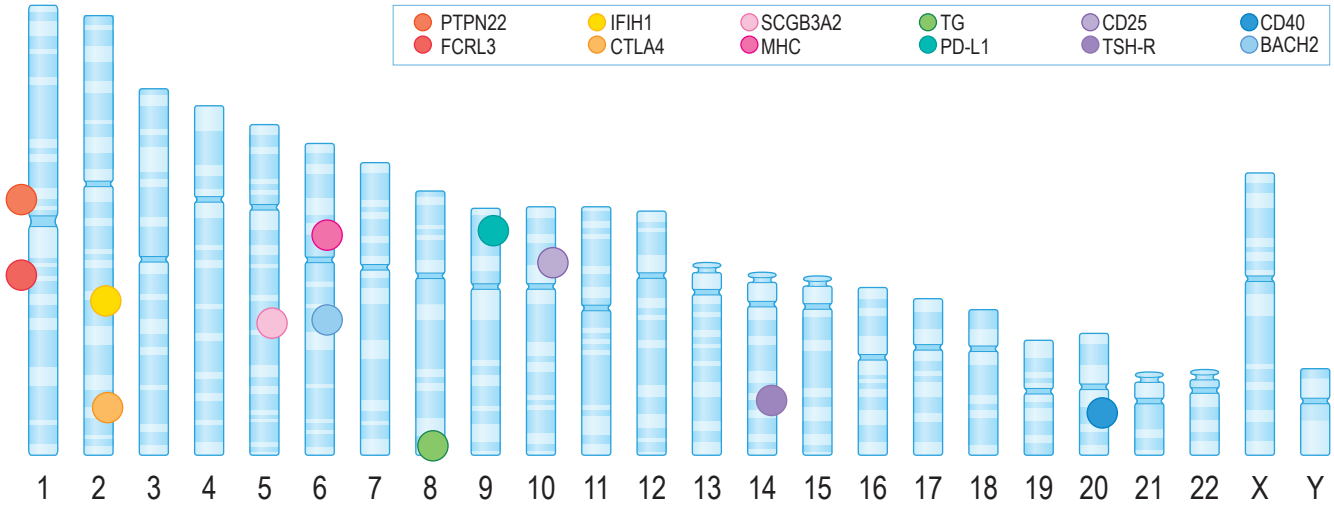

FIG. 70.1 Schematic Diagram to Illustrate the Loci that have been Associated with Graves Disease to Date. Each locus is shown on its respective chromosome, with chromosome 1 depicted on the left and chromosome Y on the right. *MHC*, Major histocompatibility complex; *PD-L1*, programmed death 1/ligand 1; *TSH-R*, thyroid-stimulating hormone receptor.

sequences, including noncoding or microRNAs (miRNAs), and/or epigenetic factors.

GD is one of the few autoimmune conditions for which links to environmental factors have been definitively established.[7] Iodine is one of the most common precipitants of thyroid dysfunction. With regard to GD, more cases are observed in iodine-sufficient areas. A study of individuals in Iceland, where iodine intake is high, and age-matched individuals in East Jutland, Denmark, where iodine intake is low, showed that the incidence of GD was more than double in the higher-iodine environment.[2]

Cigarette smoking also influences GD susceptibility and severity, in particular of GO. Meta-analysis of eight studies showed the OR for developing GD was 3.3 for current smokers compared with that for lifelong nonsmokers.[8] The same study also revealed that current smokers are more likely to develop GO compared with nonsmokers (OR 4.4). Cigarette smoke extract has been shown in vitro to stimulate adipogenesis and glycosaminoglycans (GAGs) production by orbital fibroblasts (OFs), which accumulate in the orbital tissues in GO.[9]

Stress appears to influence both GD disease onset and clinical course. Individuals with GD retrospectively reported more negative life events in the preceding year compared with matched controls.[10] In a population-based study, individuals with clinically diagnosed stress disorders were found to have an increased risk of many different forms of autoimmunity, including autoimmune thyroid diseases.[11]

Changes in immune system function appear to influence the onset of GD. During pregnancy, which is a relatively immunosuppressed state, hyperthyroid GD is often mild and can be managed with smaller doses of antithyroid drugs. In some cases, it remits entirely, allowing the individual to stop medication in the short term. However, in the postpartum period, when the immune system normalizes, there is typically worsening or relapse of GD. A similar phenomenon is seen in individuals who have been significantly immunosuppressed and then have recovered. For example, new-onset GD has been reported in people who have been successfully treated with highly active antiretroviral therapy (HAART) for human immunodeficiency virus (HIV) infection. During treatment, as the immune system recovers, immune activation increases. T cells are exposed to thyroid antigens, resulting in an autoimmune response at the time of immune reconstitution.[12] A similar phenomenon has been seen in individuals with multiple sclerosis (MS) treated with alemtuzumab (ALZ), the lymphocyte-depleting anti-CD52 antibody. An alternative explanation is the weakening of physiologic antiinflammatory pathways, which unleashes the immune system. As more novel biologic agents become available, particularly for cancer treatment, this phenomenon is likely to become more common.

KEY CONCEPTS

Environmental Factors Known to Influence Graves Disease Susceptibility

- Smoking
- Iodine
- Stress
- Immune system reconstitution states
  - Postpartum state
  - Successful treatment of human immunodeficiency virus (HIV) with highly active antiretroviral therapy (HAART)
  - T-cell depletion therapy (e.g., alemtuzumab)
- Infections (e.g., hepatitis C)

Immunopathogenesis

Histologically, the thyroid in GD is characterized by a diffuse lymphocytic infiltrate, consisting of both T and B cells, associated with thyrocyte hyperplasia (Fig. 70.2). Although T cells play a major role in inflammatory cell recruitment, cytokine secretion, antigen recognition, and thyrocyte damage, infiltrating B cells also produce antibodies, including those that drive hyperthyroidism. The major autoantigens in GD are the TSH-R, the thyroid peroxidase (TPO) enzyme, and thyroglobulin (Tg). More than 95% of patients with GD have detectable circulating TSH-R autoantibodies (TRAbs),[13] which are necessary for hyperthyroidism, and approximately 90% have detectable TPO autoantibodies.[14] Antibodies directed against the sodium iodide symporter and the apical iodide transporter, pendrin, have been reported in smaller numbers of patients.[14]

GD is unique among autoimmune conditions in that the TRAbs directly stimulate thyroid gland activity. This is

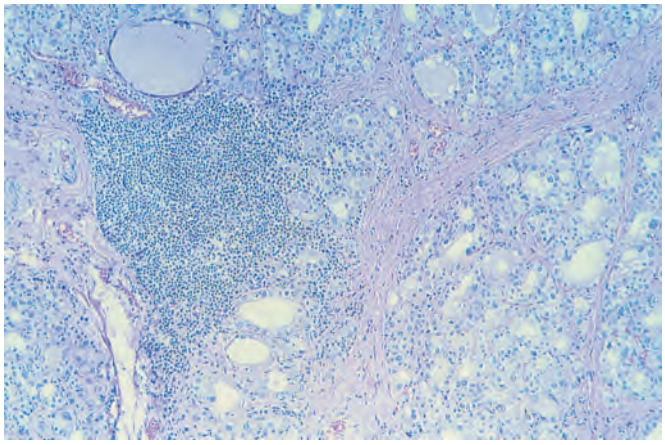

FIG. 70.2 Diffuse lymphocyte Infiltrate and Thyrocyte Hyperplasia in a Patient with Graves Disease.

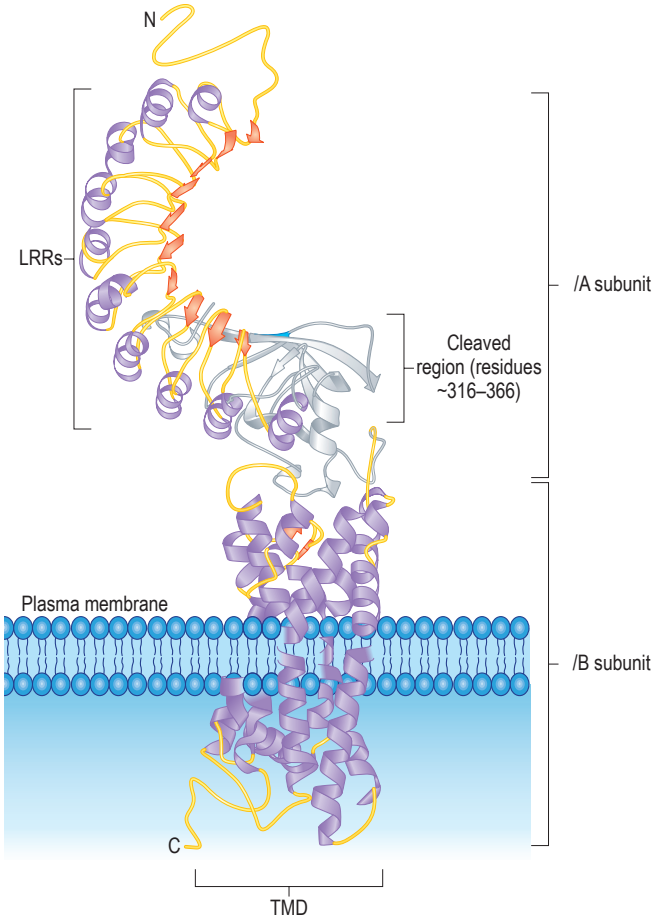

FIG. 70.3 Structure of the Thyroid-Stimulating Hormone Receptor. *LRRs*, Leucine-rich repeats; *TMD*, transmembrane domain. (Courtesy R. Latif; adapted from Davies TF, Ando T, Lin RY, et al. Thyrotropin receptor-associated diseases: from adenomata to Graves' disease. *J Clin Invest*. 2005;115:1972–183.)

exemplified by neonatal GD, where maternal TRAbs cross the placenta, resulting in transient hyperthyroidism in the newborn. However, although TRAbs are sufficient to result in transient hyperthyroidism in these infants, these autoantibodies are not sufficient per se to result in the persistent thyroid autoreactivity of true GD. TRAbs are classically immunoglobulin G1 (IgG1) subclass and target an epitope in the amino terminal region of the leucine-rich repeat motif in the extracellular domain of the TSH-R (Fig. 70.3).[15] When the autoantibody binds to the TSH-R, this activates intracellular G proteins, which, in turn, induce transcription of genes, such as *TPO* and *TG*, via the cyclic adenosine monophosphate (c-AMP) and phospholipase C pathways. This results in thyrocyte hyperplasia and increased thyroid hormone synthesis. The TSH-R antibody–induced expression of TPO and Tg, which are also thyroid antigens, may be a mechanism for disease perpetuation. TRAbs can also be "blocking" in nature and prevent receptor activation, causing hypothyroidism. These two types of autoantibodies can also coexist, resulting in fluctuating thyroid function. Thus, although it is common to equate GD with hyperthyroidism, individuals with GD may occasionally be hypothyroid or euthyroid (presenting with GO).

TPO antibodies can be of IgG subclass 1, 2, or 4 and typically circulate in concentrations 1000-fold higher than those of TRAbs. They are directed against two structurally complex regions of the TPO molecule, the epitopes involving residues from both the myeloperoxidase-like and the complement control protein-like domains. TPO antibodies may have pathogenic significance in that they can fix complement and target the thyrocyte for cell-mediated cytotoxicity. In contrast to TRAbs, they do not appear to either stimulate or block the enzymatic activity of TPO.

Clinical Presentation

Hyperthyroid GD can present with manifestations affecting almost any organ system in the body, and, as with many endocrine conditions, affected individuals may report a gradual onset of nonspecific symptoms, typically over a period of months. This often leads to a delay in seeking medical attention and in the initial diagnosis being made. The signs and symptoms of GD can be divided into those associated with hyperthyroidism in general and those specific to GD. These are summarized in Table 70.1.

CLINICAL PEARLS

Clinical Signs Specific to Graves Disease

- Graves orbitopathy
- Thyroid bruit
- Thyroid acropachy
- Pretibial myxedema

Investigation and Diagnosis of Graves Disease

The diagnosis of GD is a clinical one, supported by laboratory investigations. Imaging is occasionally required if the diagnosis is in doubt. Thyrotoxicosis is diagnosed biochemically on the basis of an elevated serum free triiodothyronine (fT_3) or free thyroxine (fT_4) in the presence of a completely suppressed TSH. TRAbs are highly sensitive for GD, and assays are now widely available. TRAbs should be measured in all thyrotoxic patients in order to reach a positive diagnosis. They are clinically useful, even if a patient has extrathyroidal signs of GD, such as GO or pretibial myxedema, because they can be monitored to ascertain response to treatment. TPO antibodies are also often measured as a surrogate for thyroid autoimmunity.

Imaging is reserved for individuals in whom the diagnosis is not clear (e.g., hyperthyroid patients with negative TRAb). Radionuclide scanning (e.g., ^{99}Tc or ^{123}I) is favored over ultrasonography, because the former gives functional information on the activity of the thyroid gland, although Doppler flow studies

TABLE 70.1 Common and Rarer Clinical Manifestations of Hyperthyroidism

Common	Rare
Neuropsychiatric	
Anxiety	Chorea
Fatigue and exhaustion	Collapse (periodic paralysis)
Fine tremor	Pseudobulbar palsy
Restlessness and fidgeting	Spasticity
Gastrointestinal	
Increased appetite	Hepatosplenomegaly
Loose stools	
Increased frequency of defecation	
Nausea	
Weight loss	
Cardiorespiratory	
Palpitations	Congestive cardiac failure
Shortness of breath on exertion	
Tachycardia (sinus, atrial fibrillation)	
Peripheral vasodilation, flushing

Thyroid bruit	

are making ultrasound evaluation of the thyroid increasingly informative (Fig. 70.4). In GD, there is diffuse uptake in the thyroid gland on radionuclide scanning.

Management of Graves Disease

The management of hyperthyroid GD can be divided into three broad categories: medical management, radioiodine (radioactive iodine [RAI]) treatment, and surgery.[16]

Medical Management—Antithyroid Drugs

The thionamide drugs (carbimazole, its metabolite methimazole, and propylthiouracil) compete with Tg to act as substrates for iodination by TPO. Once iodinated, they are metabolized peripherally, depleting thyroid iodine stores. When the thyroid iodine stores are depleted and the intrathyroidal thionamide concentration is high enough, thyroid hormone synthesis is abrogated. Most individuals become euthyroid following 4 to 8 weeks of treatment; however, euthyroidism may take longer to achieve in those with poor medication compliance or with a history of recent iodide exposure. Following initial treatment, thionamides may either be administered as a fixed high dose, with levothyroxine supplementation to prevent hypothyroidism (known as a "block and replace" regimen), or at progressively lower doses, titrated to allow adequate thyroid hormone generation. Following 6 to 18 months of thionamide treatment, approximately 50% of patients will remain in remission following cessation of therapy. There is no improvement in remission rate in individuals with GD who are treated for longer than 18 months. Lower TRAb levels at the time of medication cessation are associated with higher chances of remission.[17] The mechanism of the thionamide-induced remission in GD remains obscure; however, the lymphocytic infiltrate in the GD thyroid is rapidly abolished by thionamide treatment, and serum TRAb and TPO autoantibodies also decrease during treatment, suggesting an immunomodulatory effect. It is telling that several induced murine models of thyroiditis can be ameliorated by thionamide treatment, suggesting an immunomodulatory role that is distinct from the antithyroid hormone synthesis action. If the patient's disease relapses following medical treatment, definitive treatment should be considered, as a second course of thionamide treatment rarely induces prolonged remission.

FIG. 70.4 ^{99}Tc Pertechnetate Radionuclide Scan Image from an Individual with Graves Disease Showing Diffuse Uptake Throughout the Thyroid Gland.

Definitive Treatment

RAI therapy (^{131}I) and surgical thyroidectomy are both efficacious treatments for GD, effectively removing functional thyroid tissue and rendering the patient hypothyroid and dependent on levothyroxine replacement over the long term. RAI therapy takes advantage of the thyroid's ability to concentrate iodine. RAI is administered orally and concentrates in the thyroid, primarily emitting beta-radiation to produce local thyrocyte DNA damage. These cells then undergo necrotic change, and the thyroid atrophies over the subsequent year. RAI renders more than 80% of those with GD hypothyroid and needing long-term

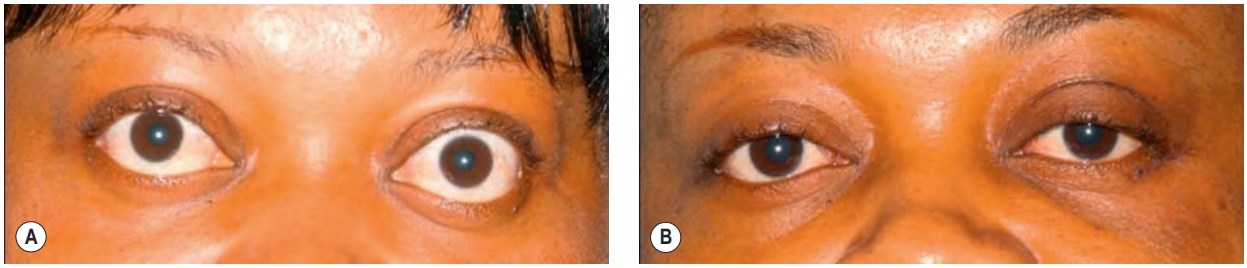

FIG. 70.5 (A) Clinical photograph of the eyes of an individual with Graves ophthalmopathy prior to treatment. (B) Clinical photograph of the same patient's eyes following surgical orbital decompression and rehabilitative surgery.

thyroid hormone replacement. RAI is generally well tolerated, and long-term follow-up studies in adults have shown reassuring results with regard to carcinogenicity. RAI is absolutely contraindicated in pregnancy and should be avoided in those with active, inflammatory GO. Total or near-total thyroidectomy is also an effective treatment for GD and is particularly suitable for individuals with a large goiter, those with severe hyperthyroidism who cannot tolerate thionamides, or in those with active GO when RAI is relatively contraindicated. The complications of thyroidectomy include change in voice because of intraoperative damage to the recurrent laryngeal nerve and hypocalcemia (often transient) caused by parathyroid gland damage.

GRAVES OPHTHALMOPATHY

Epidemiology

GO is the most common extrathyroidal manifestation of GD. It is clinically apparent in 25% to 50% of those presenting with GD, although almost all patients have radiologic changes consistent with GO to some degree. The peak age of incidence is in the fifth and seventh decades of life. GO precedes thyroid gland dysfunction in approximately 20% of patients, arises at the same time in 40%, and occurs after diagnosis of thyroid dysfunction in the remaining 40%. Males, older adults, and smokers are more likely to have severe disease. Ninety-three percent of cases of GO occur in those with hyperthyroid GD. However, 3% and 4% of GO occurs in hypothyroid and euthyroid patients, respectively. A proportion of these patients with "euthyroid Graves" will eventually become hyperthyroid; however, some will remain hypothyroid or euthyroid despite the presence of TRAbs.

Etiology

GO shares many etiologic factors with GD. Smoking is the major environmental risk factor, with smokers or ex-smokers four times more likely to develop GO compared with lifelong nonsmokers. The number of cigarettes smoked per day correlates with the risk of developing GO, suggesting a "dose-dependent" effect. RAI therapy is also known to occasionally cause flare-ups of GO. This is thought to be largely related to uncontrolled post-RAI hypothyroidism. Smokers and those with active GO seem particularly susceptible to this complication, and therefore RAI is relatively contraindicated in patients with active GO.[18]

Immunopathogenesis

The molecular mechanism that links thyroid dysfunction with GO remains incompletely understood. The TSH-R is widely believed to be the primary autoantigen linking the thyroid and the orbit. OFs have been shown to express cell-surface TSH-R, and TSH stimulation *in vitro* results in an increase in intracellular cAMP. Mechanistically, the orbital changes that occur in GO are better understood. TRAbs that bind to the TSH-R on OFs (or possibly other OF receptors, such as the insulin-like growth factor receptor; IGF-1R) are believed to activate OFs to secrete cytokines and chemokines, which attract lymphocytes and other inflammatory cells. These infiltrate the orbital tissues, augmenting further the proinflammatory cytokine environment, causing OFs to proliferate and to secrete excessive GAGs.[19] GAGs accumulate in the extraocular muscles, increasing their size. These matrix molecules are also osmotically active, resulting in edema and swelling of surrounding tissues.

In addition, the adaptive arm of the immune system is thought to interact via HLA and CD40 molecules expressed by the OFs to increase autoantigen presentation, thus perpetuating the cycle. OFs are also thought to differentiate into adipocytes, resulting in increased retroorbital fat deposition. The resulting inflammation gives rise to redness and oedema of the orbital tissues, with the cellular proliferation and GAG accumulation producing proptosis (protrusion of the eyeball from the socket), increased intraorbital pressure, and restriction of eye movements.[19]

Diagnosis and Clinical Presentation

When the clinical signs of GO are associated with thyroid dysfunction and circulating TRAb, the diagnosis is generally straightforward. If proptosis is completely unilateral or GO features occur without upper lid retraction, then the diagnosis needs to be confirmed by imaging, because the differential diagnosis for unilateral proptosis is a space-occupying retroorbital lesion. Patients with GO may complain of gritty, watery, or uncomfortable eyes, with or without a change in appearance (upper eyelid retraction, soft tissue swelling, redness of the eyes, and proptosis) (Fig. 70.5). Diplopia occurs if eye movements are restricted by stiffness of the extraocular muscles or high intraorbital pressure. Deteriorating visual acuity and color desaturation are sinister symptoms in GO, indicating incipient optic neuropathy.

GO has a predictable and generally monophasic natural history (Fig. 70.6). There is an early phase of increasing disease activity that can be targeted by medical therapy, and it is followed by a plateau phase and then gradual improvement until a stable, inactive phase is reached. GO manifestations can be classified in two ways: on the basis of severity, which indicates the extent of functional, anatomic, and cosmetic features; and on the basis of activity, which denotes the intensity of any acute inflammatory reaction. Severity of GO is assessed using the "NO SPECS" classification system (Table 70.2, A), and activity is assessed using the Clinical Activity Score (CAS) (see Table 70.2, B). A CAS

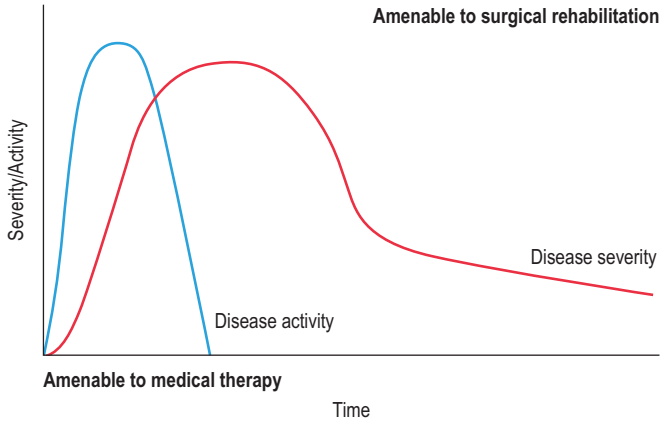

FIG. 70.6 Rundle Curve Illustrating the Natural History of Graves Ophthalmopathy.

of 3 or more indicates active GO.[18] These classifications allow determination of which patients require treatment and which therapy is most appropriate.

Treatment

Patients with GD (with and without GO) should be strongly encouraged to stop smoking and offered smoking cessation support. The general health benefits of smoking cessation are numerous; in addition, smokers are more likely to relapse after a course of medical therapy compared with nonsmokers.

In parallel to restoring and maintaining euthyroidism, the successful treatment of GO depends on staging the activity and severity of the disease. In patients with mild, active GO, an observational policy can be used with symptomatic measures, such as artificial tears and dark glasses. Selenium supplements, at a dose of 100 µg twice daily for 6 months, have been shown to significantly improve quality of life, slow disease progression, and reduce ocular involvement in these patients.[20] All patients with GO, with the exception of those with very mild disease (which is often transient) should be assessed in a joint multidisciplinary thyroid eye clinic, comprising ophthalmologists, oculoplastic surgeons, and endocrinologists. In those with moderate to severe, active, and progressive GO, a course of oral or intravenous (IV) glucocorticoids (steroids) is indicated. Orbital radiotherapy is also efficacious in people with active inflammation and diplopia, but because it has a delayed onset of action, it often needs to be used in conjunction with other therapies, such as steroids or orbital decompression surgery. In patients with sight-threatening optic neuropathy, high-dose IV steroids are used, and orbital pressure is relieved by urgent orbital decompression surgery. In patients whose eyelids do not close completely, eye ointments and protective eye pads are essential to protect the eyes against corneal damage and ulceration. Once disease activity has burned out, rehabilitative surgery can greatly improve the function and cosmetic appearance of the eyes. Orbital decompression, strabismus correction, and eyelid surgery are commonly used procedures.[21]

FUTURE DEVELOPMENTS FOR GRAVES HYPERTHYROIDISM AND OPHTHALMOPATHY

Conventional treatment of GD with surgery, RAI, or antithyroid drugs has not substantially changed over the past 50 years.

TABLE 70.2 Assessment of Graves Ophthalmopathy

A: The "NO SPECS" Classification System to Assess the Severity of GO

- Class 0—No signs or symptoms
- Class 1—Only signs (limited to upper lid retraction and stare, with or without lid lag)
- Class 2—Soft tissue involvement (edema of conjunctivae and lids, conjunctival injection, etc.)
- Class 3—Proptosis
- Class 4—Extraocular muscle involvement (usually with diplopia)
- Class 5—Corneal involvement (primarily due to lagophthalmos, the inability to completely close the eyelids)
- Class 6—Sight loss (caused by optic nerve involvement)

B: The Clinical Activity Score (CAS) to Assess Activity of GO

A single point is scored for each of the features present. Each feature has equal weighting. A higher score indicates more active disease.

- Spontaneous orbital pain
- Gaze-evoked orbital pain
- Eyelid swelling that is attributed to active GO
- Eyelid erythema
- Conjunctival redness that is considered to be due to active GO
- Chemosis
- Inflammation of caruncle or plica
- Increase of >2 mm in proptosis
- Decrease of >8 degrees in uniocular ocular excursion in any one direction
- Decrease of acuity equivalent to 1 Snellen line

GO, Graves ophthalmopathy.

There remain significant unmet needs with these strategies, resulting in the demand for new therapeutic options. Novel approaches including biologic, small-molecule, and peptide immunomodulation are currently at various stages of development. Furthermore, in light of the significant side effects associated with steroid treatment and low patient satisfaction with current therapies, steroid-sparing therapeutic agents are of particular interest for GO.

The novel immunomodulatory therapies currently being investigated, some of which have shown potential efficacy in preclinical or phase II studies, include targeting various aspects of B-cell activity, such as blocking of the costimulatory CD40 interactions, the B cell–activating factor (BAFF), and antibody recycling. However, the most widely studied B-cell therapy is rituximab, a CD20 monoclonal antibody (mAb) that depletes circulating B cells and appeared to be potentially efficacious in early studies. However, in two randomized controlled trials (RCTs) in individuals with moderate to severe active GO, results have been conflicting, and therefore further studies are needed. Other agents investigated in GO include the novel immunotherapeutics, tocilizumab (TCZ) and teprotumumab, both of which have demonstrated positive findings in GO. The anti–interleukin-6 (IL-6) receptor TCZ is a recombinant humanized IgG1 mAb that inhibits IL-6 binding to the IL-6 receptor, inhibiting the proinflammatory effects of IL-6. An RCT, which included 32 patients with moderate-to-severe corticosteroid-resistant GO, reported significant improvements in GO severity and activity (CAS <3 achieved in 86.7% vs. 35.2% in placebo). In addition, an RCT has demonstrated that targeting the orbital IGF1 receptor with teprotumumab results in a significant improvement in inflammatory eye signs, proptosis, and patient quality of life in those with GO.

TSH-R–specific immunotherapeutics including TSH-R–blocking antibodies, TSH-R–specific peptide immunotherapy, and small-molecule TSH-R antagonists are in various stages of development from preclinical to phase I trials. The key advantage of TSH-R–specific approaches is that it provides a direct, targeted approach that theoretically avoids disruption of immune system function. Novel agents have been evaluated to a limited extent and are subject to further ongoing studies.

AUTOIMMUNE HYPOTHYROIDISM

The most common cause of AH is chronic (or lymphocytic) autoimmune thyroiditis. There are two variants, atrophic and goitrous (Hashimoto thyroiditis).

Epidemiology

In populations living in iodine-sufficient areas, AH is common, affecting 1% to 10% of the population. The prevalence increases with age, with 3% to 20% of individuals older than 75 years being hypothyroid. Like GD, AH is more common in women than in men. In a UK community survey, the incidence of hypothyroidism in women was 3.5/1000/year, which increased to 13.7/1000/year in women between 75 and 80 years of age. In men, the incidence was just 0.6/1000/year.[22]

Etiology

AH, like GD, is a complex genetic condition. Familial clustering provides evidence for a genetic etiology, which, in several studies, appears stronger than that for GD. The λ_s for AH is estimated to be between 10 and 45, suggesting that AH is more heritable compared with GD. In families with autoimmunity, frequently a mixture of individuals affected by AH and GD are seen, suggesting some shared genetic factors. The differing prevalence of AH in different ethnic groups, with AH being more common in White than in Black populations, also supports a genetic background. Knowledge about the genetics of AH is limited.

The MHC class II *HLA-DR3, HLA-DR4*, and *HLA-DR5* alleles have been associated with AH in Whites only. Conflicting results have been reported for *HLA-DQ* alleles. One study reported that the *HLA-DQ* alleles *DQA1*0301* and *DQB1*0201* confer susceptibility to AH in Whites, with certain *HLA-DQ* alleles (*DQA1*0102* and *DQB1*0602*) reported to confer a protective effect.

In common with GD, the *CTLA-4* gene also appears to influence AH susceptibility. Three *CTLA-4* polymorphisms have been associated with AH in several populations. An A/G SNP located downstream of the 3′UTR (designated CT60), an A/G polymorphism at codon 17, and a 106-bp microsatellite repeat in the 3′UTR of exon 3. A locus on chromosome 8q24 containing the Tg gene was linked to AH, and several SNPs were subsequently studied in AH individuals with modest reported ORs for association of between 1.32 and 1.56. Other loci implicated in AH susceptibility include the tumor necrosis factor *(TNF)-α* gene, *PTPN22, CYP27B1*, T-cell receptor (TCR) genes, and several immunoglobulin genes and cytokine regulatory genes.

In contrast to GD, environmental factors in AH susceptibility have been challenging to identify. However, the role of iodine is widely accepted because population studies have reported an increase in the prevalence of thyroid lymphocytic infiltration and autoantibodies following public health salt iodization programs. Infectious agents have also been implicated in susceptibility to AH. Several studies have identified an increased prevalence of IgG and/or IgA antibodies to virulence-associated outer membrane proteins of *Yersinia enterocolitica* in AH patients and in relatives of individuals with AH, suggesting that susceptibility genes for *Yersinia* infection may also confer risk for AH.

The effect of radiation, either "internal" (nuclear "fallout" or from RAI treatment) or "external" (radiotherapy or direct exposure during a nuclear accident), on AH susceptibility has been extensively studied. Following the nuclear reactor accident at Chernobyl, a rise in thyroid autoantibodies was noted 15 years following exposure; however, this was not accompanied by thyroid dysfunction. Long-term follow-up studies of thyroid function in Japanese survivors of the atomic bombings of Nagasaki and Hiroshima have demonstrated a clear link between radiation exposure and thyroid cancer; however, the association with AH remains disputed. One study, at 40-year follow-up, demonstrated a significant relationship between dose of radiation exposure at Nagasaki and AH. However, a further study, at more than 50 years of follow-up, showed that radiation exposure did not correlate with either the occurrence of thyroid autoantibodies or AH.[23]

Immunopathogenesis

The mechanisms by which tolerance to thyroid antigens is lost in the first instance remain obscure. It appears that both a susceptible genetic background and a permissive environment are required before AH develops. Notably, AH is much more frequent in the autoimmune polyendocrinopathy type 1 (APECED) syndrome than GD, suggesting that central thymic T-cell selection, and therefore central tolerance, may be more important in AH than in GD. Histologically, lymphocytic infiltrates can be seen in the thyroid, consisting of both T and B cells (Fig. 70.7). These infiltrates can be diffuse or focal. Scarring and fibrosis may also be seen, with destruction of the normal thyroid architecture and an absence of colloid in thyroid follicles. An IgG4-positive histologic variant of Hashimoto thyroiditis has been proposed, although neither diagnostic criteria nor clinical significance have been clearly established.[24]

Both cell-mediated and humoral immune mechanisms are important in the continuing thyroid damage seen in AH. T cells play a pivotal role in both the initiation and perpetuation of AH. Studies in which researchers induced hypothyroidism in Rag1-deficient transgenic mice that were unable to produce autoantibodies confirm this.[25] T cells respond to antigen-presenting cells (APCs) and release cytotoxic and lytic factors, which result in thyrocyte death. Thyroid follicular cells have themselves been demonstrated to express HLA class II molecules, suggesting that they may also have a direct role in antigen presentation.

The humoral immune response is also important in AH. More than 90% of individuals with AH have detectable TPO antibodies. Autoantibodies directed against Tg and, to less degree, the TSH-R are also commonly detected. In vitro, TPO antibodies can fix complement and directly induce cell damage. Their presence within thyroid follicles in AH patients suggests they may have the same effect in vivo, although the thyrocyte destruction found in the *Rag1*-deficient mouse suggests TPO antibodies are not necessary for AH. Interestingly, the epitopes recognized by TPO antibodies in both GD and AH overlap, and there is no disease specificity for the targeted TPO domain. TRAbs found in rare patients with AH are likely to exert a blocking or antagonist effect, thus inducing hypothyroidism. As thyroid hormone secretion falls, increasing thyrocyte stimulation by elevation of serum

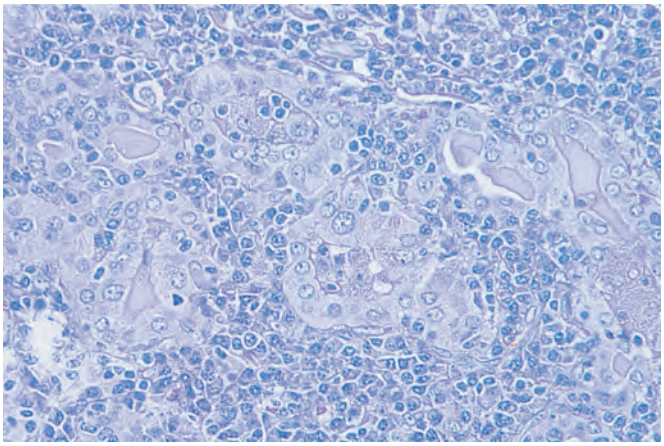

FIG. 70.7 Lymphocytic Infiltration of the Thyroid in a Patient with Autoimmune Hypothyroidism.

TSH may induce or augment thyroid autoantigen expression (*e.g.*, TPO, Tg), thereby perpetuating the autoimmune response.

Clinical Presentation

Hypothyroidism can result in changes in almost every organ system in the body (Table 70.3). Initially, the signs and symptoms may be subtle and nonspecific, including tiredness, cold sensitivity, and constipation. Hypothyroidism is frequently diagnosed incidentally following blood tests for another problem. The typical goiter palpable in Hashimoto thyroiditis is moderate in size and firm with a finely granular surface. Individuals often report a gradual increase in size over a number of years. However, rapid growth is unusual. In atrophic AH, the size of the thyroid gland is reduced.

Investigation and Diagnosis

Hypothyroidism is detected biochemically by a raised serum TSH with reduced fT_4. AH is differentiated from other forms of hypothyroidism by the presence of circulating autoantibodies, including TPO and Tg. On ultrasound scanning, the thyroid gland appears finely heterogeneous and hypoechoic, predating serum autoantibody positivity in some.

Reflecting the effects of hypothyroidism on multiple organ systems, many biochemical and hematologic abnormalities, such as mild anemia, hyponatremia, or elevated serum creatine kinase, transaminases, lactate dehydrogenase, and low-density lipoprotein (LDL) cholesterol, are also commonly detected in patients with AH.

Management

AH requires lifelong treatment with thyroid hormone replacement therapy. The most commonly prescribed is synthetic thyroxine, levothyroxine ($L–T_4$), which is widely available and inexpensive. Except for individuals with known heart disease or the very old, a full, weight-related replacement dose (≈1.6 µg/kg/day) should be started. Once the patient is on a stable dose, thyroid function should be assessed annually to ensure that the patient continues to receive the appropriate dose. Some commonly prescribed medications, such as calcium and iron supplements, and proton pump inhibitors interfere with the absorption of $L–T_4$, and patients should be advised to take these at least 4 hours before or after their $L–T_4$ to ensure maximum absorption.

TABLE 70.3 Common and Rare Clinical Manifestations of Hypothyroidism

Common	Rare
Neuropsychiatric	
Lethargy	Cerebellar ataxia
Impaired cognitive function	Deafness
Slow speech	Psychosis

Goiter (in Hashimoto thyroiditis)	
Reduced basal metabolic rate	
Increased sensitivity to exogenous insulin	
Abnormal lipid metabolism	

Subclinical Hypothyroidism

Although the need to treat individuals with overt AH is universally accepted, it is unclear whether thyroid hormone replacement is beneficial in individuals with persistent subclinical hypothyroidism (increased serum TSH, but fT_4 and fT_3 within the normal reference range on at least two separate occasions).[26] Progression to overt hypothyroidism from this state occurs in approximately 2% of individuals per year who are TPO antibody negative, increasing to 5% per year if antibodies are present. Persistent subclinical hypothyroidism has been associated with a number of markers of cardiac and vascular dysfunction in observational studies, including left ventricular diastolic dysfunction, increased vascular resistance, and atherosclerosis.

A randomized clinical trial demonstrated no beneficial effects of treatment with levothyroxine in older adults (≥65 years old) with persistent subclinical hypothyroidism, although unfortunately few patients had TSH levels greater than 10 mIU/L and it did not include assessment of circulating TPO autoantibody titers which would indicate the cohort more likely to have progressive hypothyroidism and therefore possibly benefit from long-term levothyroxine therapy. Although this study was underpowered to assess cardiovascular outcomes, normalization of TSH with levothyroxine was associated with no difference in carotid intima-media thickness and carotid atherosclerosis in these patients.

CLINICAL PEARLS

Management of Persistent Subclinical Hypothyroidism

- If thyroid-stimulating hormone (TSH) is elevated, immediate treatment should be offered:
  - In pregnancy
  - Preconception, if planning a pregnancy.
- If TSH is elevated but less than 10 mIU/L, a trial of treatment can be offered:
  - To individuals with convincing symptoms of hypothyroidism.
- If TSH is greater than 10 mIU/L, treatment should be offered:
  - To individuals younger than the age of 70 years
  - To individuals older than the age of 70 years if there is a clear history of hypothyroid symptoms or there are significant risk factors for cardiovascular disease.

FUTURE DEVELOPMENTS

The genetics of AH remains understudied considering its frequency as the commonest autoimmune disease in humans. Considerable work remains to be done on whether treatment of subclinical hypothyroidism is beneficial. Given the insidious nature of the development of AH, it remains a good target for a preventive immunotherapeutic intervention, if a safe and economic treatment can be found.

OTHER FORMS OF THYROIDITIS

The term *thyroiditis* relates to conditions resulting in inflammation of the thyroid gland. A number of etiologies have been described, including infection, radiation exposure, drugs, and autoimmune factors. A common pattern to the natural history of several thyroiditides is frequently seen, involving an initial thyrotoxic phase of 1 to 3 months, followed by a rapid drop in serum thyroid hormones and a transient hypothyroid phase, often lasting another 1 to 4 months. During the thyrotoxic phase, preformed thyroid hormone stores are released from the thyroid follicles, leading to thyrotoxicosis, which may be severe. The hypothyroid phase follows when these preformed stores are exhausted, and the thyroid has become depleted of hormones. In approximately 90% of cases this hypothyroidism is transient, but in some cases, it never resolves.

POSTPARTUM THYROIDITIS

Postpartum thyroiditis (PPT) is a common endocrine condition that manifests within 1 year following pregnancy.[27] It affects between 5% and 10% of women in the general population. PPT is classically a biphasic disorder, consisting of a period of transient thyrotoxicosis (median onset 12 to 14 weeks postpartum) followed by a period of transient hypothyroidism (median onset 18 to 20 weeks postpartum); however, a monophasic (thyrotoxicosis or hypothyroidism alone) or reversed biphasic (hypothyroidism followed by thyrotoxicosis) pattern can also occur. During pregnancy, there is a state of relative immune tolerance, followed by a rebound in immune function following delivery, coinciding with the occurrence of PPT. The presence of thyroid autoantibodies and a lymphocytic infiltrate on thyroid biopsy supports an autoimmune basis for this condition.[27]

Clinically, the thyrotoxic phase of PPT is often mild, resulting in symptoms of fatigue and irritability, which can be misdiagnosed as postnatal depression. If the thyrotoxic episode is short, it may even go unnoticed. Neck pain is not a feature. Women with PPT who are thyrotoxic may benefit from a beta-blocker, such as propranolol, for symptom relief. Antithyroid drugs are not effective, as the thyrotoxicosis is caused by release of preformed thyroid hormones. Following the episode of thyroid dysfunction, 10% to 20% of women remain permanently hypothyroid.[27] In women who have had PPT and then recovered, an annual assessment of thyroid function is recommended because their risk of long-term hypothyroidism is considerable.[27] In those women who return to being euthyroid, there is a 75% risk of PPT in subsequent pregnancies and a 50% risk of permanent hypothyroidism at 7 years.

IMMUNOMODULATION AND THYROID DYSFUNCTION

Agents that modulate the immune system are increasingly being used as a treatment in various settings, either to induce, or alternatively, deplete and "reconstitute" the immune system. This disruption of immune homeostasis and costimulatory pathways lowers the threshold for the initiation of inflammation or autoimmunity. Thyroid dysfunction is one of the commonest endocrine sequelae of immunomodulatory therapies.

Alemtuzumab

ALZ, an anti-CD52 mAb licensed to treat MS, depletes both T and B lymphocytes to allow immune reconstitution with the aim of restoring a tolerogenic environment. Although used successfully to treat MS, up to 41% of those receiving ALZ will develop some form of thyroid autoimmunity, of which the vast majority is GD.[28]

The precise mechanism by which ALZ causes thyroid autoimmunity remains uncertain, but it is proposed to result from the proliferation of T cells during immune reconstitution, disrupting self-tolerance and driving the humoral autoimmune response. These patients can demonstrate an unpredictable course, and often present with fluctuating thyroid hormone levels due to the presence of both blocking and stimulating TRAbs.[28] The treatment of thyroid dysfunction, including GD, is largely the same as for those with spontaneous onset disease, although whether the prognosis is the same for ALZ-induced GD remains disputed.

Immune Checkpoint Inhibitors

Costimulatory "immune checkpoint" proteins are essential components of the normal immune system, negatively regulating the immune response to protect against uncontrolled immune destruction of healthy cells. CTLA-4 and programmed death

1/ligand 1 (PD-1/PD-L1) are inhibitory cell-surface receptors that suppress T-cell activation.

These targets have been exploited in the development of mAb for use in cancer immunotherapy, to modulate the immune system by blocking inhibitory checkpoints, resulting in T-cell activation and immune destruction of tumor cells.[29]

Unfortunately, this therapeutic approach often generates inflammatory immune-related adverse effects (irAEs), which often result in endocrinopathies, most commonly affecting the pituitary and thyroid gland.[30] Thyroid dysfunction, including hypothyroidism, thyrotoxicosis, and painless thyroiditis, is more frequently associated with anti–PD-1-antibodies. The combined use of anti–PD-1 and anti–CTLA-4 therapies has been associated with a 22% incidence of either thyroiditis or hypothyroidism, with a variable onset of thyroid dysfunction, occurring at a median of 8 weeks following the start of treatment.[30]

The natural course of thyroid dysfunction in these patients can be rapidly destructive, with an initial asymptomatic thyrotoxicosis followed by likely permanent hypothyroidism.[30] The potentially asymptomatic nature of the associated thyroid dysfunction highlights the importance of monitoring through routine laboratory surveillance.[30] However, it is important to be aware that a low TSH may be a manifestation of hypophysitis, rather than thyroid gland dysfunction.

The growing use of immunomodulatory therapeutics is influencing thyroid disease epidemiology, resulting in an expanding patient group with immune-related thyroid dysfunction that is likely to continue to grow with increasing use of these novel therapeutics.

TRANSLATIONAL RESEARCH

ON THE HORIZON

New Approaches to Therapy of Graves Disease

- Novel immunotherapeutic agents for Graves orbitopathy.
- Novel therapies targeting B-cell activity, including blocking of CD40-CD40L interactions, B cell–activating factor (BAFF) and immunoglobulin recycling.
- Thyroid-stimulating hormone receptor (TSH-R) therapies including TSH-R–blocking antibodies, TSH-R–specific peptide immunotherapy, and small-molecule TSH-R antagonists for the management of Graves hyperthyroidism.

The major challenge of the next 5 to 10 years is to take novel immunotherapeutic agents, including "biologics" that have been developed for rheumatic disorders into the clinical arena for autoimmune thyroid diseases. The primary target of these efforts should be GO, which remains a disfiguring condition, often with substantial functional impairment of vision and associated low quality of life. Phase III studies using TCZ and teprotumumab have demonstrated positive findings, leading to US Food and Drug Administration (FDA) approval for teprotumumab in the treatment of GO. Early diagnosis of GO and development of markers that predict progressive or severe disease will also be helpful in identifying patients for early intervention. Novel therapies for the treatment of Graves hyperthyroidism including those that target various aspects of B-cell activity and the TSH-R–specific immunotherapeutics remain under investigation. These agents might have a role in patients who are unlikely to gain medical remission from thionamide antithyroid drugs or in those for whom rapid control of hyperthyroidism is desirable.

Type 1 Diabetes

Leonard C. Harrison

Diabetes mellitus is not a single disease but a metabolic syndrome in which different mechanisms lead to deficiency of insulin and/or impaired insulin action and persistent hyperglycemia. The American Diabetes Association classified diabetes into four categories based on etiology rather than age of onset (juvenile-onset versus adult-onset) or requirement for insulin therapy (insulin-dependent versus noninsulin-dependent).[1] The vast majority of cases of diabetes—approximately 10% and 90%—are classified as type 1 and type 2 diabetes, respectively. This chapter focuses on type 1 diabetes, which results from an absolute deficiency of insulin secondary to the loss of pancreatic β cells. Type 1 diabetes is classified as 1 A (immune-mediated) or 1B (idiopathic), primarily depending on the presence or absence, respectively, of pancreatic islet autoantibodies. However, as discussed below, type 1 A diabetes (T1DA) and type 1B diabetes (T1DB) also differ in their natural history and clinical features.

Diabetes is diagnosed on the basis of the following criteria[1]: symptoms in association with a casual plasma glucose ≥200 mg/dL (11.1 mmol/L) OR a fasting plasma glucose ≥126 mg/dL (7.0 mmol/L) OR 2-hour plasma glucose ≥200 mg/dL (11.1 mmol/L) in an oral glucose tolerance test (OGTT; 75 g glucose in water). Without symptoms, the diagnosis of diabetes must rest on confirmation of a raised plasma glucose concentration. A further diagnostic criterion introduced by the World Health Organization (WHO) in 2011, in particular for the diagnosis of type 2 diabetes, is a confirmed blood glycated hemoglobin (HbA_{1c}) ≥48 mmol/mol (6.5%). Because HbA_{1c} is an integrated measure of glycemia over many weeks, it is not suitable for diagnosing children or in the following circumstances: suspected type 1 diabetes; symptoms of diabetes for <2 months; acute illness; medication that may increase blood glucose (*e.g.*, steroids, anti-psychotic drugs); pregnancy. The criteria for diagnosing gestational diabetes (in pregnancy) are stricter: fasting plasma glucose ≥101 mg/dL (5.6 mmol/L) or 2-hour plasma glucose in an OGTT ≥140 mg/dL (7.8 mmol/L).

The classic symptoms and signs of T1DA, secondary to high concentrations of blood glucose, are polyuria, polydipsia and unexplained weight loss; others include fatigue, increased hunger, impaired visual acuity due to changes in the refractive index of the vitreous humor, tingling or numbness in the hands or feet resulting from sensory nerve changes, and vaginal irritation caused by *Candida* infection. If diabetes is undiagnosed or untreated, failure to metabolize glucose may lead to the breakdown of fat, resulting in ketonemia and ketoacidosis, with nausea and hyperventilation preceding life-threatening ketoacidotic coma. In children who present with the classic symptoms, T1D can be diagnosed clinically. However, in Caucasians the diagnosis can be confirmed, and in older individuals and in less clear-cut cases clearly established, by detecting circulating autoantibodies to islet antigens. Autoantibodies to insulin (IAA), glutamic acid decarboxylase 65,000 mol. wt. isoform (GADA), insulinoma-like antigen-2 (IA-2A) and zinc transporter-8 (ZTA) are markers of β-cell autoimmunity that usually appear many months to years before symptoms and therefore denote high risk for clinical disease.[2–5] Islet autoantibodies are detected in the majority of Caucasian children with T1DA (compared with ≤1% of the background population), but in only ≈50% of Hispanic and African American children with diabetes, an increasing number of whom have T2D and, in some cases, T1DB. Negative results for islet autoantibodies in children with diabetes should also flag the possibility of relatively rare genetic disorders of β cells, viz. monogenic maturity-onset diabetes of the young (MODY) and sulfonylurea receptor syndromes. That the presence of autoantibodies to two or more islet antigen specificities is so predictive of clinical T1DA has led to a paradigm shift in defining T1DA primarily as an autoimmune β-cell disorder ("ABCD")[6] and to its staging: autoantibodies to two or more islet antigen specificities define Stage 1; loss of β-cell mass/function leading to abnormal plasma glucose concentrations defines Stage 2; and symptomatic clinical disease defines Stage 3.[7]

The hallmark of T1DA is progression to absolute insulin deficiency within several years after clinical diagnosis. The connecting peptide in proinsulin (C-peptide), secreted in equimolar amounts to insulin, is used as a surrogate for insulin to evaluate residual β-cell function, because measurement of plasma insulin may be inaccurate in the face of treatment with exogenous insulin or the presence of IAA or insulin antibodies induced by exogenous insulin. The area under the curve of plasma C-peptide after a mixed meal tolerance test (MMTT) is the gold standard for assessing β-cell function and has been used as the primary outcome in clinical trials of immune therapy in recent-onset Stage 3 type 1 diabetes. However, the MMT requires repeated venous blood sampling for up to four hours and is not convenient in routine clinical settings, in which β-cell function is of increasing interest with the introduction of immune therapies for T1DA. To facilitate assessment of β-cell function, an algorithm incorporating clinical variables and biochemical measures at a single time-point has been shown to be an accurate substitute for the full MMTT, including for the identification of treatment effects in Stage 3 T1DA.[8]

Although children with T1DA have lost most of their β-cell function at diagnosis, the measurement of plasma C-peptide is not a reliable way of distinguishing T1D, especially at diagnosis. Hyperglycemia impairs β-cell function and—when corrected by rehydration and insulin replacement—can be followed by a

"honeymoon phase" of partial recovery of β-cell function and a decreased requirement for exogenous insulin that may last many months. Several years after diagnosis, most young children display little residual β-cell function; however, in older children and adults, residual C-peptide secretion has been observed for many years and may be associated with better glycemic control.

Classically, T1DA was considered a disease of "juvenile onset" in normal-weight individuals, in contrast to type 2 diabetes in middle-aged, overweight individuals. However, this view requires reappraisal.[9] First, up to 10% of adults who present with diabetes diagnosed initially as T2D have evidence of low-grade islet autoimmunity manifest by the presence of GADA, and occasionally IA-2A or ZTA. As they appear to have a slowly progressive form of autoimmune β-cell destruction, termed *latent autoimmune diabetes in adults* (LADA), their number doubles the prevalence of T1DA. Second, the "obesity epidemic" has impacted on T1D and T2D stereotypes. "Hybrid" types with β-cell autoimmunity and insulin resistance ("double diabetes") are becoming increasingly common, characterized by weaker immune (lower avidity autoantibodies, predominantly GADA) and lower risk genetic (human leukocyte antigen [HLA] alleles) markers. Obesity is associated with low-grade immune inflammation and insulin resistance that may promote and uncover latent β-cell autoimmunity in individuals with lower-risk genes for T1DA.

T1DB excludes known specific causes of β-cell dysfunction, such as monogenic diabetes. It encompasses forms of ketosis-prone diabetes initially described in West Africans and African Americans[10] and subsequently in other ethnic groups, but rarely seen in Caucasians. Obesity and relatively well-preserved residual β-cell function were features of the African cases. T1DB also includes "fulminant diabetes" initially described in Japan, where it may account for 15% to 20% of new-onset T1D.[11,12] Fulminant diabetes is associated with widespread mononuclear cell infiltration of both the exocrine and endocrine pancreas and elevated concentrations of serum pancreatic amylase, elastase, and lipase in individuals with HLA susceptibility genes for T1D.[12] Case reports have associated it with acute viral infection and drug hypersensitivity reactions, but its etiology remains unclear. In Caucasians, T1D in which islet autoantibodies are undetectable has been called T1DB, but this may reflect assay insensitivity or the waxing and waning of autoantibodies over time. A classification of diabetes that hinges on the presence or absence of islet autoantibodies is not ideal. β Cell–specific T cells, not islet autoantibodies, are the effectors of β-cell damage, and autoantibodies and autoreactive T cells to islet antigens can be reciprocally related.[13] In addition, the more recent discovery of autoantibodies to ZT8 suggests the possibility that other target islet antigens remain to be discovered and might be markers of particular subtypes of T1D. For example, in fulminant diabetes, the clinical picture suggests that if autoimmunity is involved it also includes the exocrine pancreas. Furthermore, in contrast to T1DA, in which there is an extended preclinical history of islet autoimmunity, autoantibodies may not be present at the time when fulminant diabetes presents acutely.

CLINICAL PEARLS

- In Caucasian children, the diagnosis of T1D can be made on the basis of classic clinical features.
- Islet autoantibodies are present in more than 90% of Caucasian children presenting with diabetes but in only about 50% of Hispanic or African American children, some of whom have T2D.
- The presence of islet autoantibodies confirms the diagnosis of type 1A diabetes (T1DA).
- Islet autoantibodies are detected in the first 3 years of life in the majority of Caucasian children who go on to develop T1DA.
- The risk for T1DA increases with the number and titer of islet autoantibodies.
- The T1D stereotype of the thin juvenile is beginning to overlap with the T2D stereotype of the obese, insulin-resistant adult.
- T1DB has been characterized by an absence of islet autoantibodies and often a more fulminant natural history, but T1DA and T1DB have overlapping pathologic features and diagnostic separation based on islet autoantibodies is not ideal.

EPIDEMIOLOGY AND NATURAL HISTORY OF T1DA

The incidence of T1DA varies widely across the world, being highest among Caucasians of Northwestern Europe and countries to which they have emigrated (Fig. 71.1). This, in part, reflects the population distribution of HLA risk genes, which account for up to half of the lifetime risk for T1DA. However, the incidence of T1DA is rising in many countries on a background of lower-risk HLA alleles. In Western societies, the incidence in childhood has more than doubled since the 1980s and has been rising at ≈3% annually, particularly among younger children.[14] The same trend is also occurring in other countries, such as Kuwait and Saudi Arabia and some regions of India and China, where Western lifestyles have been adopted but where the prevalence of high-risk HLA haplotypes for T1DA is much lower. As in T2D, environmental factors may increase the penetrance of risk genes for T1DA. In the case of HLA genes in Caucasians, the increasing incidence of T1DA is accounted for by children with intermediate-risk (DR 4,4 or DR 3,3) or low-risk (DR 4,X or DR 3,X) phenotypes, not the highest-risk HLA phenotypes (DR 3,4; DQ 2,8).[15] These lower-risk phenotypes are also seen in non-Caucasians and adults with T1DA. The greatest number of children with diabetes will soon be found in the most populous regions of the world, India and China.

T1DA affects both sexes equally in childhood, with a slight excess of males in early adult life. Of newly diagnosed cases, no more than 10% to 15% have a family history of T1DA. However, studies of affected families have yielded major insights into the genetics and natural history of T1DA. In T1DA relatives, the rate of progression to clinical diabetes is positively associated with the number and titer of islet autoantibodies,[2,3,5] the number of HLA class 2 risk alleles (*DR3, DR4*) and specific HLA class I alleles (*A24*),[16] and the degree of insulin resistance[17] and is negatively correlated with age. The specificity of islet autoantibodies is also important. IAAs are more often the first sign of islet autoimmunity in children who are followed from birth and, of all the autoantibodies, has the highest predictive value.[2–5] In Europe, North America, and Australia, birth cohort studies of children with a T1DA relative have shown that the development of diabetes by the age of 18 years is almost always associated with the appearance of islet autoantibodies in the first few years of life.[5] Of children with ≥2 islet autoantibodies before the age of 3 years, 57% (95% confidence interval [CI] 51.7% to 62.3%) and 74.8% (95% CI 69.7% to 79.9%) progressed to diabetes by 6 and 10 years of age, respectively. With a single islet autoantibody, 14.5% progressed to diabetes by 10 years of age. [5]

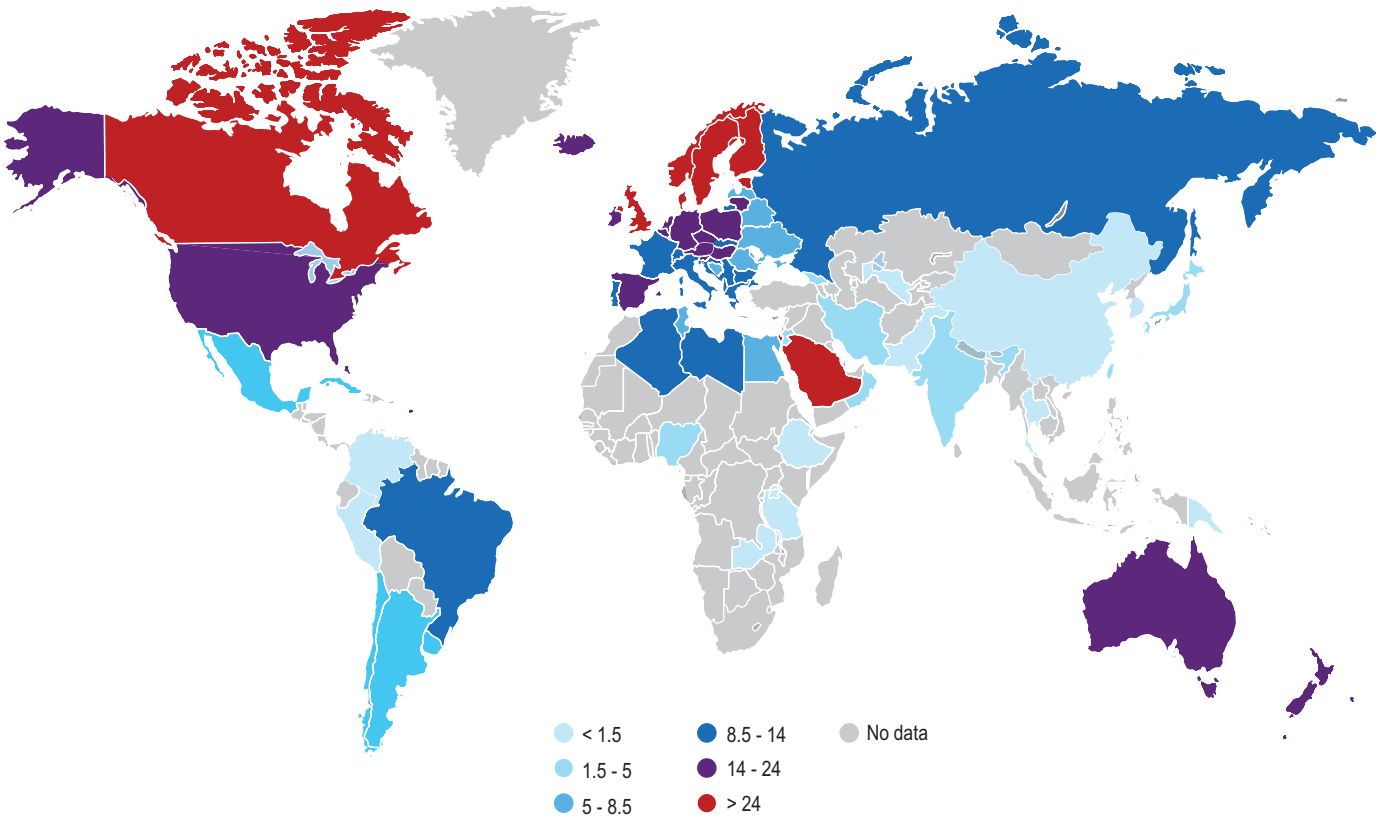

FIG. 71.1 Global Incidence of type 1A diabetes (T1DA) in 100,000 children ages 0 to 14 years per year. (From *IDF Diabetes Atlas*, 7th ed. Brussels, Belgium: International Diabetes Federation; 2015.)

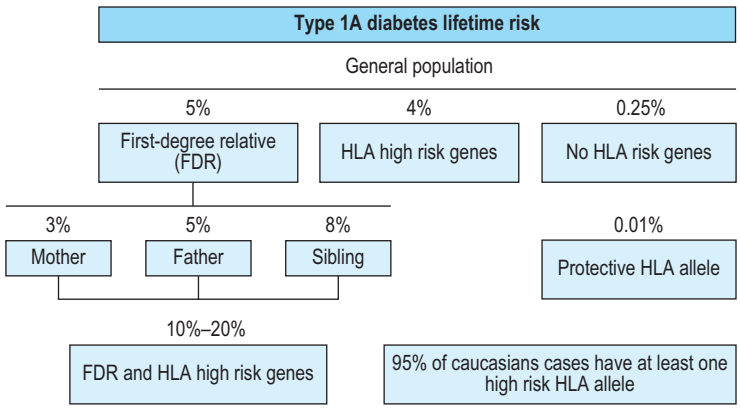

FIG. 71.2 Lifetime risk of type 1A diabetes. *HLA*, Human leukocyte antigen.

Men with early-onset T1DA are more likely to transmit diabetes to their offspring compared with women (Fig. 71.2), but it is not clear whether this results from genomic imprinting of a gene expressed only from a paternally inherited allele, protection from the mother including via her microbiome, or other possible reasons. Risk for T1DA is also greater in later-born offspring. The peak age of incidence in children is at the cusp of puberty, a time when the body's requirement for insulin increases along with an increase in insulin resistance. Like the seasonal autumn–winter peak in diagnosis attributed to viral infections, this is likely to be "the straw that breaks the camel's back" on a background of longer-standing autoimmune β-cell disorder.

PATHOGENESIS: NATURE AND NURTURE

In the contemporary model for the staged natural history of T1DA (Fig. 71.3), the pattern and rate of β-cell loss is depicted as linear, but it is more likely to be episodic—reflecting direct (*e.g.*, virus, chemical toxin) or indirect (*e.g.*, diet, pollutants,

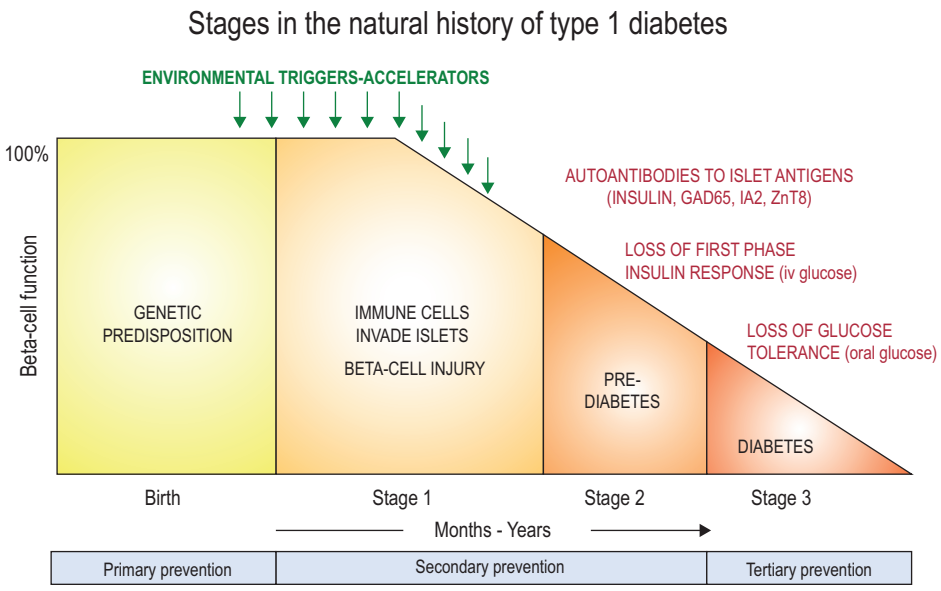

FIG. 71.3 Natural history of type 1A diabetes.

microbiome) interactions between the environment and β cells. Furthermore, there is evidence that immune activation and β-cell destruction may be accelerated in the late preclinical stage. The appearance of predictive islet autoantibodies in the first years of life[5] means that the stage for developing T1DA is set very early, even before birth, on a background of genetic susceptibility. These early years provide clues to environment–gene interactions that lead to immune dysfunction and disease, now being sought in pregnancy-birth cohort studies.[18]

It is generally accepted that β-cell destruction in T1DA is mediated by autoreactive T cells, the ultimate effectors being CD8 cytotoxic T cells (Fig. 71.4). The evidence for this is unequivocal in the inbred nonobese diabetic (NOD) mouse model of T1DA, which shares several key features with T1DA in outbred humans (Table 71.1) despite 65 million years of evolutionary distance. The molecular mechanisms of β-cell death, gleaned mostly from the NOD mouse, encompass a combination of both apoptosis induced by activation of extrinsic (*e.g.*, tumor necrosis factor [TNF] receptor or Fas ligation) or intrinsic (*e.g.*, endoplasmic reticulum [ER] stress) pathways and necroptosis induced by cytotoxic CD8 T-cell granule components (granzymes and perforin), reactive oxygen species (ROS), or ischemia. However, these findings cannot be simply extrapolated to humans in whom access to the pancreas is limited. Studies of pancreas biopsies and organ-donor pancreas—more recently from the Network for Pancreatic Organ Donors with Diabetes (nPOD; www.jdrfnpod.org)—have not revealed the florid immune cell infiltration of islets (insulitis) seen in NOD mice but rather patchy insulitis predominantly from CD8 T cells and macrophages. Confirming earlier findings,[19] HLA class I is hyperexpressed by islets together with immunoreactive interferon-α (IFN-α), even in atrophic islets lacking insulin, which is evidence for the presence of viral nucleic acid. A key question is: why are β cells specifically targeted? The answer may lie in insulin itself. Central to the concept of autoimmune disease is the notion that the pathology is driven by loss of immune tolerance to self-antigens. In the case of T1DA, considerable evidence, direct in the NOD mouse, identifies (pro)insulin as a key disease-initiating self-antigen (Table 71.2).

TABLE 71.1 The Nonobese Diabetic Mouse as a Model of Human Type 1A Diabetes

Feature	NOD Mouse	Human
Preclinical stage	Yes	Yes
Gender	F > M	M > F after puberty
Genetic susceptibility		
MHC class II 57 non-Asp	Yes (I-Ag7)	Yes (HLA-DQ8)
Polygenic non-MHC	Yes	Yes
Environmental influence on gene penetrance	Yes	Yes
Disease transmission via bone marrow	Yes	Yes
Mononuclear cell infiltration of islets (insulitis)	Marked	Moderate
Other organs	Yes	Sometimes
Impaired immune regulation	Yes	Yes
Autoantigens:		
(Pro)insulin	Yes	Yes
Glutamic acid decarboxylase	Yes	Yes
Clinical response to autoantigen-specific therapy	Yes	Not yet shown

NOD, Nonobese diabetic.

GENES

The concordance for T1D in monozygotic twins, who are almost genetically identical, approaches 50%. This indicates that both genetic and environmental–epigenetic mechanisms contribute to disease. Large case/control studies and genome-wide association studies (GWAS) have identified over 40 chromosomal loci associated with risk for T1DA (Fig. 71.5).[20] Many are weak associations defined by single-nucleotide polymorphisms (SNPs) and the genes with which the SNPs are in linkage and/or their functional contribution to pathogenesis are not yet known. Different combinations of genes/susceptibility loci in different environmental contexts most likely lead by different routes to the final outcome of β-cell destruction, consistent with phenotypic–clinical heterogeneity in T1D. Nevertheless, what is

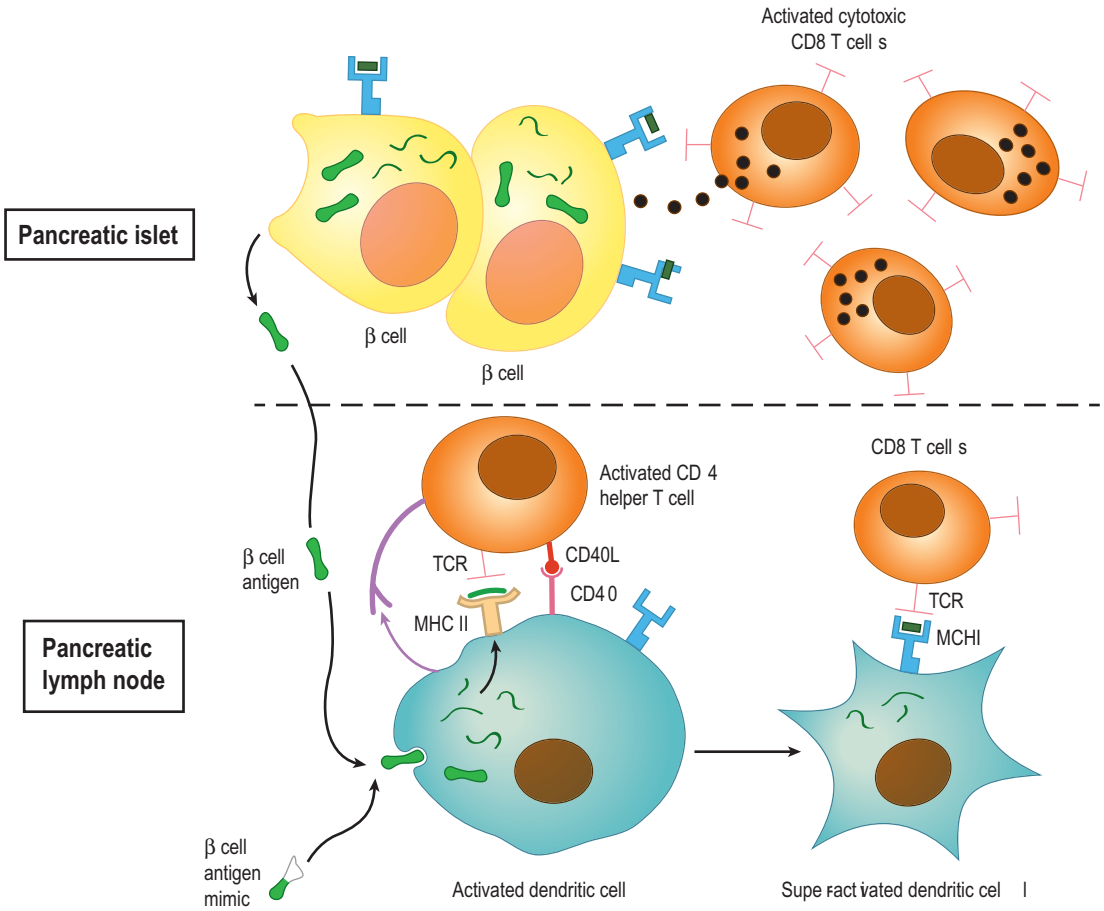

FIG. 71.4 Immune mechanisms of β-cell destruction in type 1A diabetes.

TABLE 71.2 Evidence for the Key Role of Proinsulin as Primary Autoantigen in Type 1A Diabetes

- β Cell–specific (except for thymus)
- Second strongest genetic locus in humans (*IDDM2*)=VNTR 5′ of INS allelism correlates with proinsulin transcription in the thymus
- Early target of autoimmunity in humans and nonobese diabetic (NOD) mice
- Main target of T cells isolated from islets of NOD mice and humans with T1DA

Genetic manipulation in the NOD mouse:

- Transgenic expression of proinsulin (but not glutamic acid decarboxylase) in antigen-presenting cells (APCs) prevents insulitis/diabetes
- Transfer of hematopoietic stem cells (HSCs) or myeloid progenitors encoding proinsulin in APC progeny prevents diabetes
- Knockout of proinsulin II (expressed in thymus) accelerates diabetes
- Induction of mucosal tolerance to (pro)insulin prevents diabetes

clear across populations globally is the dominance of the HLA locus (IDDM1) as the single most important genetic contributor to T1D risk (see Table 71.1), accounting for about half the lifetime risk. The highest risk HLA haplotypes in Europeans are DR3 (*DRB1*03:01-DQA1*05:01-DQB1*02:01*) and DR4 (usually *DRB1*04:01* or **04:04* with *DQA1*03:01-DQB1*03:02*). On the other hand, the HLA DQ6 haplotype *DQA1*01:02-DQB1*06:02*, in linkage with DR15 (*DRB1*15:01*), is dominantly protective for T1DA. After the HLA loci, the next most important contribution is from the insulin gene (*INS*) locus (IDDM2), which maps to a variable number of tandem repeats (VNTR) 5′ of the coding sequence. Apart from the HLA loci, IDDM2 is still the only locus for which genome-wide association is reflected by linkage, which might be explained by disease heterogeneity. Long (class III) and short (class I) VNTR alleles are associated, respectively, with higher and lower transcription of proinsulin messenger RNA (mRNA) in medullary thymic epithelial cells (mTECs) under the control of the autoimmune regulator gene (*AIRE*)[21] and with lower and higher T1DA risk.[22] We infer, therefore, that IDDM2 controls the extent of deletion of proinsulin-specific T cells during their intrathymic development, which would predict that the long VNTR should be associated with fewer proinsulin-specific T cells in the periphery; the evidence for this is equivocal, perhaps because of the challenge of measuring islet antigen-specific T cells in human blood. The *INS* polymorphism is unique to humans. Mice, instead, have two insulin genes: *INSI* is expressed in the β cell and *INSII* in the thymus, and the latter is decreased in the NOD mouse. In summary, IDDM2 provides a genetic mechanism for autoimmune targeting of proinsulin and the β cell.

Most of the other candidate genes (see Fig. 71.5) are involved in immune function and are associated with other autoimmune diseases. For example, a nonsynonymous gain-of-function polymorphism in *PTPN22* (lymphoid tyrosine phosphatase) enhances T-cell suppression, which may impair negative selection of autoreactive T cells in the thymus. Polymorphisms around *IL2RA* (interleukin-2 [IL-2] receptor α chain; CD25) and *IL2* itself are associated with impaired IL-2 signaling, which impairs

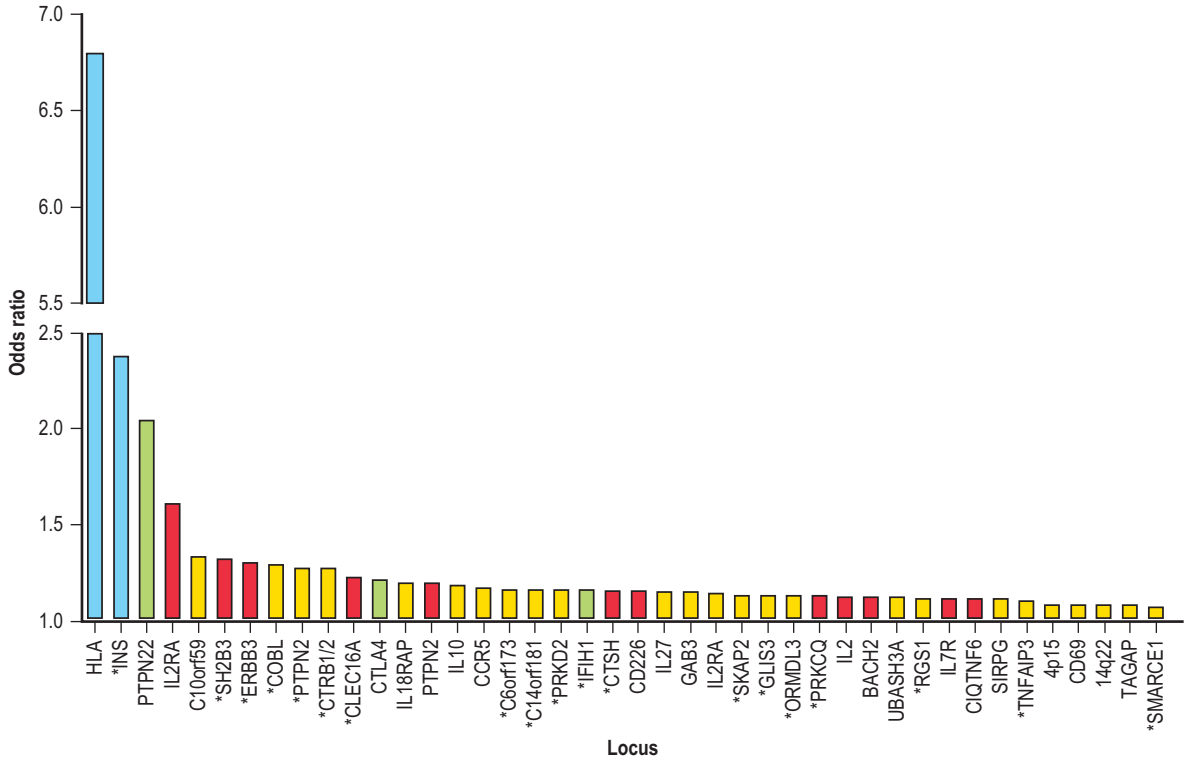

FIG. 71.5 Candidate genes in type 1A diabetes (T1DA). The *y*-axis shows the odds ratio for risk alleles at each of the loci on the x-axis.[20] The majority of the known genes are involved in immune responses, and many (marked *) are expressed in islets. Colors indicate era of identification: *blue* 1970–2000; *green* 2001–2006; *red* 2007–2008; *yellow* 2009–2010.

the generation and maintenance of regulatory T cells (Tregs) in both humans and NOD mice. Polymorphisms involving the *VDR* (vitamin D receptor) and *CYP27B1* (25-hydroxyvitamin vitamin D3 1-α-hydroxylase) and *IFIH1* (IFN-induced with helicase C domain 1, which enhances the type I IFN response to virus infection) are clues to gene–environment interactions in T1DA.

β CELLS

Why are β cells selectively destroyed by immune inflammation that involves the whole islet that also contains glucagon-secreting α cells and other endocrine cells? In the case of T1DB, the whole pancreas appears to be targeted. First, cytotoxic CD8 T cells recognize autoepitope peptides (*e.g.*, from insulin) presented by hyperexpressed HLA class I proteins on β cells. Second, because of their unique metabolic wiring, β cells may contribute to their own death at the hands of the immune system; evidence for "assisted suicide" is compelling.[23] Studies of rodent islets indicate that β cells lack efficient antioxidant and free radical scavenging mechanisms and are especially sensitive to mitochondrial oxidative and ER stress in response to cytokines and granzymes, but whether this applies equally to human islets is unresolved. Finally, other than insulin, many candidate T1D genes identified in GWAS are transcribed in β cells and encode proteins that interact with the immune system. Moreover, in response to inflammation, human islets generate hundreds of RNA splice variants for proteins, which, if translated as neoantigens, might not be subject to immune tolerance.

Although it is still unclear whether human β cells are more sensitive than other autoimmune target cells to immune effectors, what is clear is that having undergone apoptotic or necrotic death, β cells are not restorable in the face of autoimmune memory.

KEY CONCEPTS

Evidence that Type 1A Diabetes Is an Autoimmune Disease

- Association with other autoimmune diseases, including autoimmune polyendocrinopathy syndromes (*e.g.*, APS-1 due to mutations in *AIRE*)
- Presence of autoantibodies and T cells reactive with islet-cell antigens
- Strong association with specific human leukocyte antigen alleles and haplotypes and immune-response genes
- Transfer of disease by bone marrow or development of disease in the healthy pancreas transplanted from an identical twin without diabetes to the twin with T1DA
- Neonatal onset associated with loss of natural Tregs due to mutations in *FOXP3* (immune dysfunction/polyendocrinopathy/enteropathy/X-linked syndrome)

ENVIRONMENT—OUTSIDE AND INSIDE

The environment in its protean manifestations may impact β-cell function in multiple ways (*e.g.*, by activating innate immunity to, in turn, drive adaptive immunity to β cells in people at genetic risk for T1DA) by specifically activating innate immune cells (macrophages) in the islets to release inflammatory cytokines (IL-1β, TNF). This elicits oxidative ER stress or induces posttranslational modifications in β-cell proteins that

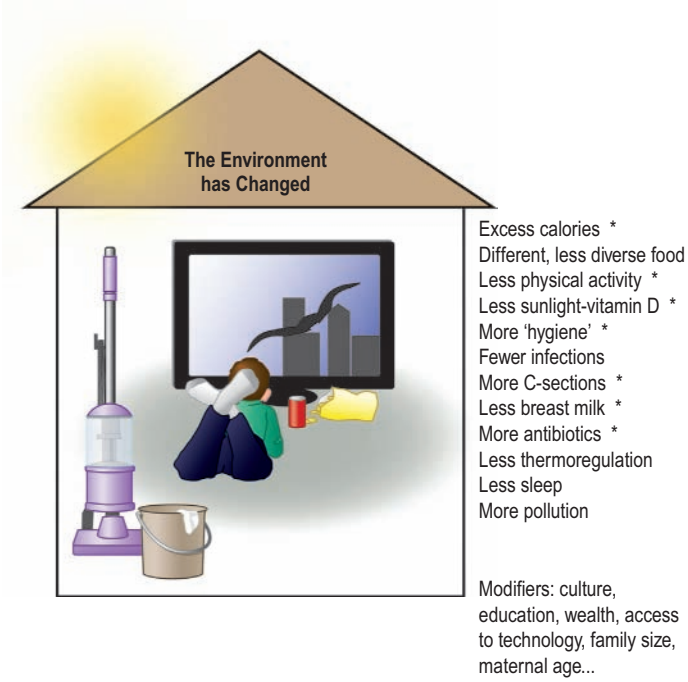

FIG. 71.6 Changes in the modern environment. Those shown to be associated with an increased risk for type 1A diabetes in humans or nonobese diabetic mice are indicated (*).

render them immunogenic, and promotes obesity and insulin resistance, thereby increasing the workload of the β cell.

The environment in Western societies has changed dramatically in many ways during the last century (Fig. 71.6), and some of these changes have been associated epidemiologically or in animal studies with development of T1DA.[9] An index of the contemporary "exposome" is the ongoing rise in the prevalence of obesity. When children at increased genetic risk for T1DA (with a T1DA first-degree relative) were monitored from birth, weight gain in the first 2 to 3 years of life was shown to be a risk factor for islet autoimmunity.[24] When such at-risk children developed islet autoantibodies and were then followed up over time, those with insulin resistance progressed most rapidly to clinical diabetes.[17] Whether insulin resistance is a risk factor for the development of islet autoimmunity is an open question that should be answered by ongoing pregnancy–birth cohort studies.[18] If insulin resistance synergizes with impaired insulin secretion to promote T1DA, then lifestyle factors must be considered in the efforts to forestall or prevent T1DA.

Excessive energy consumption leading to obesity is part of a complex interplay of related factors that promote low-grade inflammation and insulin resistance. These include a poor-quality diet and lack of physical exercise, sunlight (vitamin D), and sleep. The highly processed fast-food "Western" diet lacks diversity of components, plant-derived prebiotics, and complex carbohydrates (starches and fiber), is high in saturated fats and in sucrose and fructose sugars, and contains added artificial preservatives, emulsifiers, and sweeteners. All of these alter the composition of the gut microbiome and reduce its diversity, which is a feature found in children at risk for T1DA.[25] Diets containing a diverse range of plant products (cereals, fresh fruits, and vegetables) provide complex carbohydrates for fermentation by colonic bacteria to short-chain fatty acids (SCFAs), which are anti-inflammatory.[26] The influence of the environment on T1DA is evidenced by comparing highly developed Finland and geographically adjacent and ethnically similar but less modernized Russian Karelia. Finland has the highest incidence of T1DA in the world, currently around 60 cases/100,000 population ≤14 years of age, six-fold higher than Karelia. This difference could reflect a relatively lower rate of childhood infections (in Finland), in keeping with the "hygiene hypothesis."[27] It has also been associated with differences in gut microbiome composition[25] (see below).

Virus infection has long been considered a trigger of T1DA, consistent with increased expression of HLA class I and IFN-α observed in islets of humans with T1DA.[19] Enteroviruses are the leading candidates,[28] based mainly on the temporal association with the onset of clinical T1DA, but the significance of this has to be weighed against the long pre-symptomatic prodrome of T1DA. Viral mechanisms in T1DA could be direct or indirect (*e.g.*, infection of β cells, infection of the exocrine pancreas with bystander death of β cells, mimicry between T-cell epitopes in a viral protein and β-cell autoantigens, or activation of endogenous retroviruses in β cells by environmental agents). If an exogenous virus were clearly identified, then protective vaccination early in life would be the logical approach to primary prevention. However, even if a particular enterovirus strain were shown directly to be diabetogenic, vaccination may be a challenge because of the many thousands of strain variants, the only one for which a vaccine exists being poliovirus. There is no scientific evidence that any form of vaccination triggers T1DA.

Rotavirus is the most common cause of gastroenteritis in young children. The discovery of strong sequence similarities between T-cell epitopes in the VP7 protein of rotavirus and the IA2 and GAD islet antigens in autoantibody-positive children led to speculation that molecular mimicry with rotavirus might contribute to islet autoimmunity (reviewed in Harrison, *et al.*[29]). Subsequently, in the Australian BabyDiab Study, rotavirus infection was associated over time with the first appearance of, or an increase in, islet autoantibodies in children before they developed diabetes.[29] Moreover, rotavirus has been shown to infect β cells in islets from mice, pigs, and monkeys and causes transient involution of the pancreas and hyperglycemia in a Toll-like receptor 3 (TLR3)–dependent manner in mice.[29] Cross-reactive immunity between ubiquitous rotaviruses and islet autoantigens may not be directly diabetogenic but could complement and sustain the immune response to direct infection of β cells. Evidence for rotavirus was strengthened by the finding that the incidence of T1DA in young children had decreased following the introduction of routine rotavirus vaccination in Australia in 2007.[29] This was confirmed in a larger study in the USA,[30] but requires further validation in other locations.

The microbiome—the trillions of microorganisms (bacteria, fungi, archaea, protozoa, and viruses; Chapter 22) and their millions of genes and proteins that reside within the human mucosae, skin, and secretions—has gained increasing attention as a bellwether of health and disease ("dysbiosis"). Most microbiome analyses are based on DNA extraction and polymerase chain reaction (PCR) amplification of regions of the 16S ribosomal RNA (rRNA) gene that are conserved among bacteria. Although other internal regions of the 16S gene are variable and enable taxonomic classification from the phylum to genus level, 16S sequencing does not have the sensitivity to distinguish individual species and their strains. Direct metagenomic sequencing

of all species, as well as analysis of their transcriptomes, epigenomes, and functions, will be required to fully comprehend the role of the microbiome in T1DA and other chronic immune–inflammatory diseases. The marked difference in the incidence of T1DA between Finland and neighboring Karelia was associated in Finnish children with a decrease in gut bacterial diversity, dominance of the phylum Bacteroidetes, and relative deficiency of butyrate-producing bacteria.[25] These changes were seen after the appearance of autoantibodies, suggesting that they followed, rather than preceded, the disease process. However, in a further small study in Finnish children, metagenomic sequencing identified an increase in the abundance of *Bacteroides dorei*, which peaked around 7 to 8 months of age with the introduction of solids and preceded the appearance of islet autoantibodies. Gut *Bacteroides* species are abundant in Finnish children, including *B. dorei* that produces a lipopolysaccharide (LPS) endotoxin, which inhibits the immunostimulatory activity of *Escherichia coli* LPS and protects against diabetes in NOD mice. These findings suggest that an approach to lowering the environmental contribution to T1DA may be through intervention with prebiotics, probiotics, or other means that favorably alter the composition of the gut microbiome.

KEY CONCEPTS

Type 1A Diabetes: Epidemiology, Environment, and Genes

- Incidence is increasing due to the impact of a changing environment.
- Environment factors enable increasing penetrance of lower-risk human leukocyte antigen alleles.
- Environmental factors are multifactorial but generally "pro-inflammatory" and impact via microbiome dysbiosis and epigenetic modifications on gene expression to cause immune dysregulation in early life.

TREATMENT AND PREVENTION

Treatment of the metabolic syndrome of T1D is focused on optimizing blood glucose control with various modes of insulin delivery to prevent the short- and long-term complications of hyperglycemia. Over the past 40 years, the quality of life and prognosis of individuals with T1DA have greatly improved due to the introduction of pure, recombinant forms of human insulin injected by syringe or continuously via pump, blood glucose self-monitoring, and better blood pressure control. However, individuals with T1DA have not been rescued from a life sentence, and their blood glucose control remains less than physiological. The "cure" of T1DA requires transplantation of insulin-secreting cells or their progenitors or the regeneration of β cells *in situ*, in conjunction with approaches to prevent allograft rejection and/or recurrence of autoimmunity. The cure for T1DA also requires prevention. Currently, in some economically developed societies, allografts of whole pancreas or isolated islets are offered on a limited scale and at considerable cost to individuals with T1DA who suffer life-threatening and uncontrollable complications such as hypoglycemia "unawareness". However, shortage of donor tissue, cost, and the need for life-long immune suppressive agents militate against this approach. Longer-term, genetically engineered pig islet xenografts may overcome the tissue supply barrier. Stem cells, in particular autologous induced pluripotent stem cells (iPSCs), remain the great hope—but scale-up from proof-of-concept in rodents to translation in humans remains a challenge.

The incidence of spontaneous autoimmune diabetes in inbred NOD mice is decreased by many immune and other (environmental) interventions early in the disease course, although most are only effective in a proportion of mice and delay disease onset. Nevertheless, the findings in the NOD mouse suggest that T1DA may be preventable in outbred humans, especially with intervention before the onset of islet autoimmunity or very soon thereafter. Prevention of T1DA can be classified as primary (before onset of islet autoimmunity), secondary (after onset of islet autoimmunity), and tertiary (after onset of clinical disease) (see Fig. 71.3). Neonatal screening based on HLA genotyping to identify genetically at-risk individuals is a basis for primary prevention; but even in countries with a high incidence of T1DA, this still would have only modest predictive value and would need to be at least practical and safe, if not efficacious, to justify an intervention. Immune modifying agents that are effective when used at a relatively earlier stage in other autoimmune diseases are less likely to be effective in Stage 3 T1DA, after clinical onset, when most β cells have been destroyed. Indeed, most clinical trials of tertiary prevention, with more than 70 different agents since the early 1980s, have failed to demonstrate a sustained effect to preserve residual β-cell function, with several notable recent exceptions (Table 71.3).[31,32] Even so, the decline in C-peptide secretion was not slowed indefinitely in individuals with stage 3 disease. However, the more recent finding that the onset of clinical disease in individuals with stage 2 disease treated with the anti-CD3 monoclonal antibody, teplizumab, was delayed by 2 years (48.4 months compared to 24.4 months in placebo controls) indicates that immunotherapeutic intervention is likely to succeed if administered early in pre-clinical T1DA.[32] Accepting the paradigm shift that T1DA is primarily an autoimmune β-cell disorder could profoundly change the approach to its prevention. A further benefit of diagnosing T1DA early in the asymptomatic stage, based on evidence of underlying pathology, is that it markedly reduces the risk of life-threatening ketoacidosis associated with the classic symptomatic presentation.

Based on the key role of proinsulin in driving β-cell autoimmunity, the NOD mouse has provided "proof-of-concept" for antigen-specific vaccination strategies.[33] In health, immune responses to autoantigens are regulated to prevent development of autoimmune diseases. Autoantigen-specific immunotherapy aims to boost or restore autoantigen-specific immunoregulatory mechanisms. Allergen-specific immunotherapy has been shown in randomized trials to be effective in ameliorating allergic asthma and rhinitis. Such "negative vaccination" can be achieved in several ways: by administering antigen via a "tolerogenic" route (mucosal, dermal), cell type (resting dendritic cell), mode (with blockade of costimulation molecules), or form (as an "altered peptide

TABLE 71.3 Agents Shown in Randomized Trials to Preserve β-Cell Function in Stage 3 T1DA*

Anti-CD3 monoclonal antibody (OKT3)—teplizumab or otelixizumab
Anti-CD20 monoclonal antibody—rituximab
CTLA-4 Ig—abatacept
Anti-thymocyte globulin
Anti-CD2 monoclonal antibody—alefacept

*Following demonstration of its effect to preserve C-peptide secretion in individuals with stage 3 T1D, teplizumab was shown to delay the onset of clinical disease by a median of 2 years in individuals with stage 2 disease.

ligand"). Mechanisms of antigen-induced tolerance include deletion and/or anergy of effector T cells and induction of regulatory T cells (iTregs). Of clinical importance is the ability of iTregs to exert antigen-nonspecific "bystander" suppression. Thus, by direct cell contact and/or the release of soluble immunosuppressive factors, such as IL-10, iTregs impair the function of antigen-presenting DCs to elicit effector T-cell responses to the same or other antigens presented locally in the lesion or draining lymph nodes. Bystander suppression does not require that the "tolerizing" antigen is necessarily the primary driver of pathology. Its clinical importance is that it obviates specificity restrictions imposed by polymorphisms in the HLA and human T-cell receptors.

In NOD mice, administration of insulin, proinsulin peptides, or proinsulin DNA via oral or naso-respiratory routes, acting locally on the mucosal immune system, induces Tregs and decreases the incidence of diabetes. Results of randomized trials of insulin or GAD in relatives at risk for T1DA (ClinicalTrials.gov) have been summarized elsewhere.[31–33] In the DPT-1 oral insulin trial, islet autoantibody-positive relatives with a 5-year diabetes risk of 25% to 50% received 7.5 mg human insulin or placebo daily for a median of 4.3 years. There was no effect overall, but posttrial hypothesis testing revealed a 4-year delay in diabetes onset in participants with significant IAA at entry. This outcome led to a follow-up international trial by TrialNet in islet autoantibody-positive relatives using the same dose of 7.5 mg daily, which is not optimal because on a body-weight basis it is very small compared with the dose required to induce protective iTregs in the NOD mouse. Again, there was no effect of oral insulin overall, but a significant delay in clinical diabetes onset in a sub-group of participants with more marked loss of insulin secretory function.

Apart from dose, other variables have not been systematically tested in humans, in part because of the expense and duration of prevention trials. These variables include route of administration, form of the antigen, combinations of antigen with antigen-nonspecific agents, and the nature of induced immune responses. Unfortunately, surrogate markers of a potential therapeutic response have not been included in most trials. Oral delivery might not be optimal because proteins are degraded after ingestion, and the concentration or form of peptide reaching the upper small intestine is variable and unpredictable. T-cell responses observed after naso-respiratory administration of a peptide are not observed after oral administration. In a randomized trial of nasal insulin in individuals with recent-onset T1D not initially requiring insulin treatment, participants in the nasal insulin arm had markedly blunted insulin antibody responses after subsequent subcutaneous insulin.[34] This was the first demonstration, in humans, of immune regulation induced by mucosally administered exogenous autoantigen. Although this result is a rationale for further disease endpoint trials, a Finnish study[35] found no evidence that nasal insulin (1 unit/kg daily) altered the rate of progression to diabetes in islet-autoantibody-positive children <3 years of age. However, these children were at very high risk, and many appeared to have had borderline β-cell function. As in the oral insulin trial, markers of an insulin bioeffect and evidence of immune tolerance were not reported. In the Intranasal Insulin Trial II (INIT II) in Australia, New Zealand, and Germany (unpublished), higher doses of nasal insulin (44 or 440 IU) were administered weekly for a year to T1DA relatives who had autoantibodies to at least two islet antigens (≈40% risk of diabetes over 5 years). Nasal insulin was associated with evidence of immune tolerance to insulin, but this did not translate into protection from clinical T1DA. The promise of antigen-specific therapy, therefore, has yet to be realized in humans. If a balance between pathogenic and protective T cells is deterministic for disease development, then antigen-specific therapy is most likely to be effective as a primary preventive strategy. Once disease has been initiated, insulin- or other islet-antigen-specific approaches may be applicable as complementary therapy with immune-modifying agents that inactivate or delete the burden of pathogenic effector cells.

ON THE HORIZON

- Closed-loop insulin delivery—blood glucose monitoring devices will become more refined, cheaper, and widely available.
- "Linking the -omes" (exposome–microbiome–metabolome–epigenome) across time in early life will provide new insights into how environment–gene interactions lead to immune dysregulation in type 1A diabetes (T1DA).
- Manipulation of the gut microbiome via scientifically formulated probiotics and prebiotics will be explored for primary prevention of T1DA.
- Antigen-specific vaccination, *e.g.*, with insulin, will be applied for the primary prevention of T1DA.
- Success in delaying the onset of stage 3 clinical T1DA by treatment of high-risk stage 2 individuals with anti-CD3 monoclonal antibody heralds a new era of T1DA prevention trials.
- Recognition that T1DA is primarily an immune disease, an autoimmune β-cell disorder, and only secondarily a metabolic disorder will accelerate the application of immune modifying therapies to the prevention of clinical T1DA.

Immunologic Lung Diseases

Scott M. Matson, Joyce S. Lee, and Andrew P. Fontenot

The lung serves as an interface between the environment and the sanctuary of the body. The defense systems of the upper airways clear the majority of inhaled particulates. Those particulates that evade the upper-airway defenses are combated by the innate and acquired immune responses. Essentially all autoimmune diseases arise from the inappropriate activation of autoreactive CD4 T cells, as well as autoreactive B cells responsible for pathogenic autoantibodies. Immunologic lung diseases develop when the normal mechanisms of immune self-tolerance fail. This chapter considers the pulmonary manifestations of these disorders.

INFLAMMATION OF INTERSTITIAL LUNG DISEASES

In the normal host, the resident alveolar macrophage is the predominant cell type in fluid from the bronchoalveolar lavage (BAL). Resident alveolar macrophages function to ingest and degrade the inhaled antigenic load, clear pulmonary surfactant, and tonically suppress the development of inappropriate immune responses. Relatively few lymphocytes are present in the normal lung parenchyma. However, after stimulation by the relevant antigen in the lung-draining lymph nodes, antigen-specific lymphocytes migrate to the lung and participate in inflammatory responses. In addition to lymphocytes, other inflammatory and immune cells accumulate in the lung of patients with immunologic lung disease, including neutrophils, eosinophils, and other mononuclear cells, depending on the underlying disease. Within normal alveoli, the major cellular constituents are alveolar macrophages and epithelial cells. Resident dendritic cells also project dendrites through the tight junctions of the alveolar epithelium to sample the alveolar space. An initial insult typically involves the type I alveolar epithelial cell, which results in release of chemokines that recruit and activate inflammatory cells, allowing for resolution of inflammation and repair of injured tissue (Fig. 72.1). With either prolonged exposure or failure to adequately clear an inhaled antigen, persistent inflammation results in extracellular matrix deposition, culminating in tissue remodeling, progressive collagen deposition, and pulmonary fibrosis. Impaired ventilation and gas exchange occur as a consequence of lung fibrosis, resulting in patient morbidity and mortality. With destruction of type I alveolar epithelial cells, exposure of the underlying basement membrane can cause further inflammation. Proper restoration of the epithelial barrier is critical for resolution of lung inflammation. Type II alveolar epithelial cells can serve as progenitor cells that migrate and differentiate into type I alveolar epithelial cells to re-establish an intact lung epithelium.

Macrophages and lymphocytes have also been localized to areas of pulmonary fibrosis in patients with immunologic lung diseases including idiopathic pulmonary fibrosis (IPF), systemic sclerosis, and rheumatoid arthritis.[1–3] In the lung, macrophages can be divided by their location into alveolar or interstitial macrophages. Resident alveolar macrophages are dependent on several cytokines for their development (such as interleukin-34 [IL-34], colony stimulating factor 1, and the transcription factor PU.1).[1–3] These yolk-sac-derived macrophages are self-renewing,[2,3] maintained at a stable number throughout life, and are localized on epithelial surfaces and lining fluid of the alveoli and airways. With relatively poor antigen-presenting ability, they remove inhaled particles and bacteria. Conversely, interstitial macrophages are derived from hematopoietic stem cells and are located in the tissue spaces between the alveoli.[4] In the context of lung injury, interstitial macrophages greatly increase in number. Although interstitial macrophages have less phagocytic activity than alveolar macrophages, they have increased ability to present antigens to T cells. Upon activation, these macrophages express a variety of cytokines, including tumor necrosis factor (TNF) and monocyte chemotactic protein-1 (MCP-1). In addition to antigen presentation to T cells, macrophages are important for lung fibrosis and tissue remodeling in immunologic lung diseases through secretion of specific growth factors such as transforming growth factor-β (TGF-β), insulin-like growth factor-1 (IGF-1), platelet-derived growth factor (PDGF), and fibroblast growth factor (FGF).

T cells are also associated with lung fibrosis. For example, T cells have been located in areas of interstitial fibrosis and honeycombing with relative sparing in areas of normal lung in patients with IPF.[5] In connective tissue disease-associated interstitial lung disease (ILD), T cells are diffusely distributed throughout the lung and within focal lymphoid aggregates.[6] In animal models, depending on their phenotype, T cells can be either pro-fibrotic or anti-fibrotic. CD8 T cells have been found in high proportion in BAL and surgical lung biopsy samples from patients with IPF, as well as patients with systemic sclerosis, but their role in these immunologic lung diseases is not well understood.

Different subsets of CD4 T cells (Chapter 11) have been implicated in the pathogenesis of immunologic lung diseases. T-helper cell-1 (Th1) cells express interferon-gamma (IFN-γ). Although IFN-γ is a potent pro-inflammatory cytokine, it has anti-fibrotic [t.o] effects through inhibiting fibroblast proliferation and collagen expression. Th2 cells are defined by expression of IL-4, IL-5, and IL-13. In contrast to IFN-γ, Th2 cytokines have been shown to promote lung fibrosis. Therefore, the

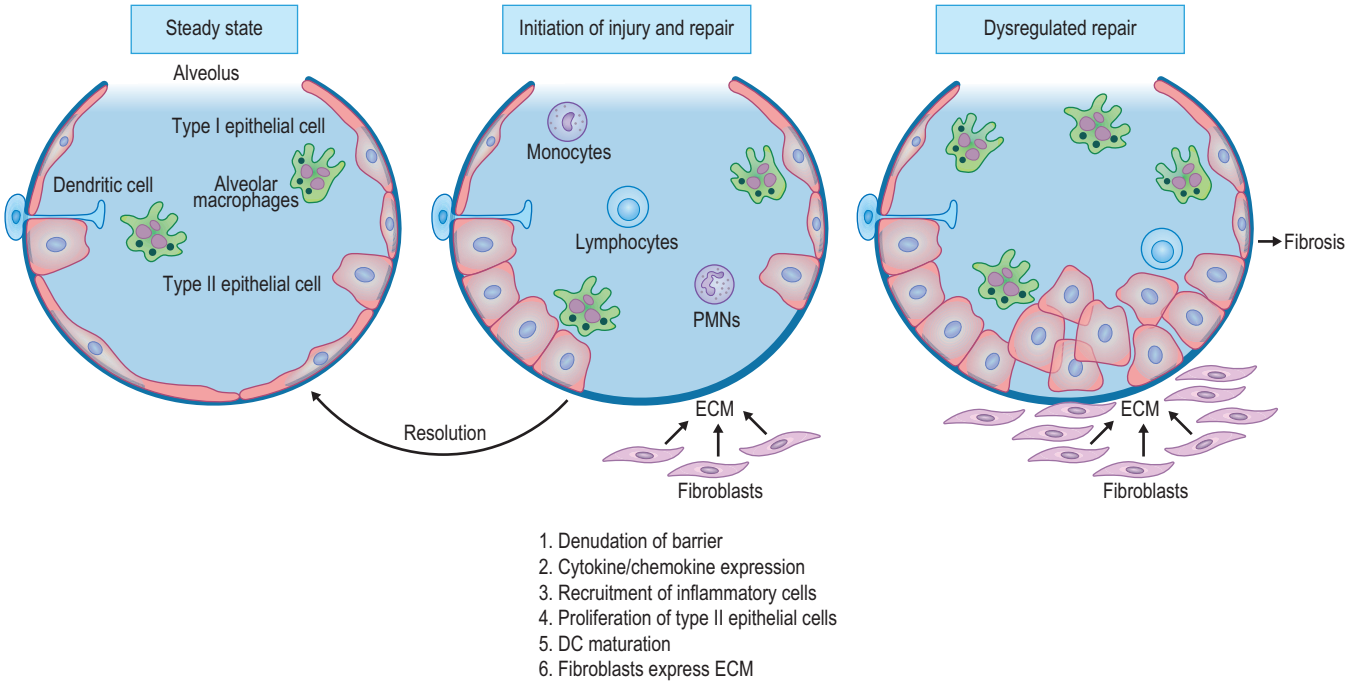

FIG. 72.1 Pathogenesis of Interstitial Lung Disease. In the healthy lung, the alveoli maintain an anti-inflammatory state to prevent unwanted inflammation. The predominant cells in the healthy alveolus are macrophages and types I and II epithelial cells. Upon injury, there is denudation of the epithelial barrier, resulting in the expression of cytokines/chemokines, recruitment of inflammatory cells, proliferation of type II epithelial cells, dendritic cell *(DC)* maturation, and expression of extracellular matrix *(ECM)* by fibroblasts. This inflammatory milieu leads to the resolution of inflammation and repair of lung injury. Conversely, in the presence of either prolonged antigen exposure or an inability to clear antigen, persistent inflammation ensues, resulting in extracellular matrix deposition with subsequent tissue remodeling, fibrosis, and permanent lung dysfunction. *PMNs*, Polymorphonuclear neutrophils.

balance between Th1/Th2 T cells through expression of different cytokines affects the development of pulmonary fibrosis.[7] Th17 cells express IL-17A and -17F, which are potent inflammatory cytokines important for the recruitment of neutrophils to areas of inflammation. Th17 cells have been implicated in the development of lung fibrosis in murine models.[8] Conversely, regulatory T cells (Tregs) suppress pathogenic T-cell responses that promote inflammation (Chapter 13). In patients with IPF, Tregs may be less able to suppress expression of cytokines by Th1 and Th2 cells, suggesting that Tregs are important in regulating inflammatory lung disease and pulmonary fibrosis.[9]

IDIOPATHIC INTERSTITIAL PNEUMONIAS

The idiopathic interstitial pneumonias (IIPs) are a group of diffuse inflammatory and/or fibrotic lung disorders that include idiopathic pulmonary fibrosis (IPF), acute interstitial pneumonitis (AIP), desquamative interstitial pneumonitis (DIP), respiratory bronchiolitis-associated interstitial lung disease (RB-ILD), nonspecific interstitial pneumonitis (NSIP), cryptogenic organizing pneumonia (COP), lymphocytic interstitial pneumonia (LIP), and idiopathic pleuroparenchymal fibroelastosis (IPPFE).[10] The diagnosis of IIPs requires the exclusion of connective tissue diseases (CTDs), drug toxicity, and environmental exposures, and a thoracoscopic lung biopsy may be required. In addition, some patients with IIPs have clinical features suggesting an underlying autoimmune disorder. However, these subjects do not meet established criteria for a CTD. A joint European Respiratory Society and American Thoracic Society task force has proposed the term "interstitial pneumonia with autoimmune features" (IPAF), as well as clinical classification criteria for affected subjects.[11] Importantly, the distinction between these various disorders is of clinical relevance since response to treatment and outcomes may differ.

Idiopathic Pulmonary Fibrosis

IPF is the most common diffuse idiopathic parenchymal lung disease. Despite the nomenclature, idiopathic pulmonary fibrosis has known genetic factors that increase the risk for the development of IPF.[12,13] IPF is characterized by progressive clinical deterioration despite available therapy. Although IPF has characteristic clinical, radiographic, and histologic appearances, other interstitial lung diseases, including the CTDs, drug reactions, and environmental exposures, can mimic these findings.

Clinical Manifestations

CLINICAL PEARLS

Idiopathic Pulmonary Fibrosis

- IPF is one of the most common causes of diffuse parenchymal lung disease, of unknown etiology, and is characterized by insidious onset of cough and dyspnea.
- The histopathologic pattern of IPF is usual interstitial pneumonitis.
- A confident diagnosis of IPF based on high-resolution computed tomography alone can only be made in one-third of cases.
- IPF is generally a fatal disorder, characterized by relentless progression and a 5-year survival of 30%–50%.
- Pirfenidone and nintedanib appear to slow disease progression in IPF.

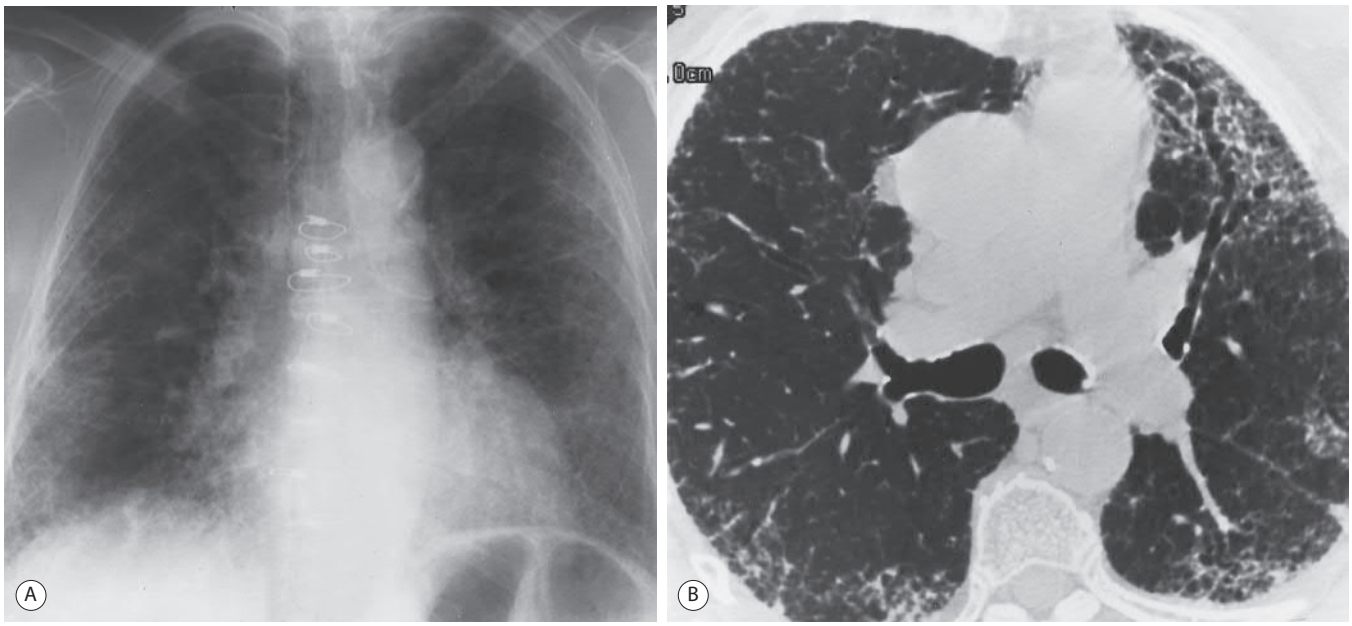

FIG. 72.2 Radiographic Manifestations of Idiopathic Pulmonary Fibrosis. (A) Chest radiograph in a patient with idiopathic pulmonary fibrosis showing diffuse, coarse reticular opacities with a lower lung zone predominance. Cystic radiolucencies, consistent with honeycombing, are evident. (B) High-resolution computed tomography shows peripheral reticular opacities, honeycombing, and traction bronchiectasis.

The exact incidence and prevalence of IPF are uncertain, although the incidence in North America has been reported between 2.8 and 19 cases per 100,000 people per year.[14] Both the incidence and prevalence of IPF increase with age, with most patients presenting between 50 and 70 years of age. Most patients present with the insidious onset of exertional dyspnea and a dry, nonproductive cough. Physical examination reveals dry, end-inspiratory crackles, with digital clubbing being common.

The chest radiograph typically shows diffuse reticular opacities, predominantly in the peripheral lower lung zones. High-resolution computed tomography (HRCT) findings include peripheral and basilar predominant and subpleural reticular abnormalities, cysts in the periphery of the lung (honeycombing), and traction bronchiectasis in addition to a paucity of ground-glass opacities (Fig. 72.2, A and B).[15] These radiographic changes often precede the onset of symptoms, and serial chest imaging usually reveals progressive loss of lung volume.

The typical physiologic abnormalities in IPF are those of a restrictive lung disease with a low diffusing capacity for carbon monoxide (DLCO) and severe gas exchange abnormalities exacerbated by exercise.

Histopathology

The gross appearance of the lungs in IPF shows a nodular pleural surface while histopathologic examination reveals usual interstitial pneumonitis (UIP).[16] UIP is characterized by nonuniform and variable distribution of the interstitial changes. At low magnification, alternating zones of interstitial fibrosis, inflammation, honeycombing, and normal lung can be seen (Fig. 72.3, A). At higher magnification, derangement of alveolar walls with fibroblast proliferation and fibrosis occur. Honeycomb change refers to enlarged airspaces lined by metaplastic bronchial epithelium and surrounded by walls thickened with collagen (see Fig. 72.3, B). The earliest finding in UIP is the fibroblast focus, a lesion consisting of distinct clusters of fibroblasts and myofibroblasts in a loose connective tissue matrix within the alveolar wall, with minimal interstitial inflammation or intra-alveolar macrophage accumulation (see Fig. 72.3, C).[16] Tables 72.1 and 72.2 compare the clinical and pathologic features of UIP, DIP, RB-ILD, and NSIP.

Pathogenesis

The pathogenesis of IPF is poorly understood, but current evidence suggests that fibrosis results from aberrant wound healing in response to repetitive injury and is mediated through an interplay between immunologic, genetic, and environmental factors (Fig. 72.4).[12] Some cases of IPF are familial, inherited as an autosomal dominant trait with variable penetrance. Dysregulated expression of a mucin gene, *MUC5B*, has been associated with development of familial forms of IPF and confers the greatest genetic risk for the development of IPF.[13] Mutations in the telomerase ribonucleoprotein complex associated with telomere shortening have also been linked with familial interstitial pneumonia.[12]

In the normal lung, the interstitium is thin and delicate with few lymphoid cells and fibroblasts. Following initiation of the inflammatory process, damage to the alveolar epithelial cell occurs, followed by vascular leak, fibroblast activation and proliferation, extracellular matrix synthesis, and activation of the innate immune system.[12] The release of danger-associated molecular patterns from dead or dying cells results in macrophage activation. Following activation, alveolar macrophages secrete IL-1, IL-8, TNF, PDGF, and IGF-1. This cytokine milieu promotes the activation and recruitment of neutrophils and lymphocytes to the area of alveolitis.

T lymphocytes, which accumulate in the alveolar space and interstitium, express an activated phenotype, including the

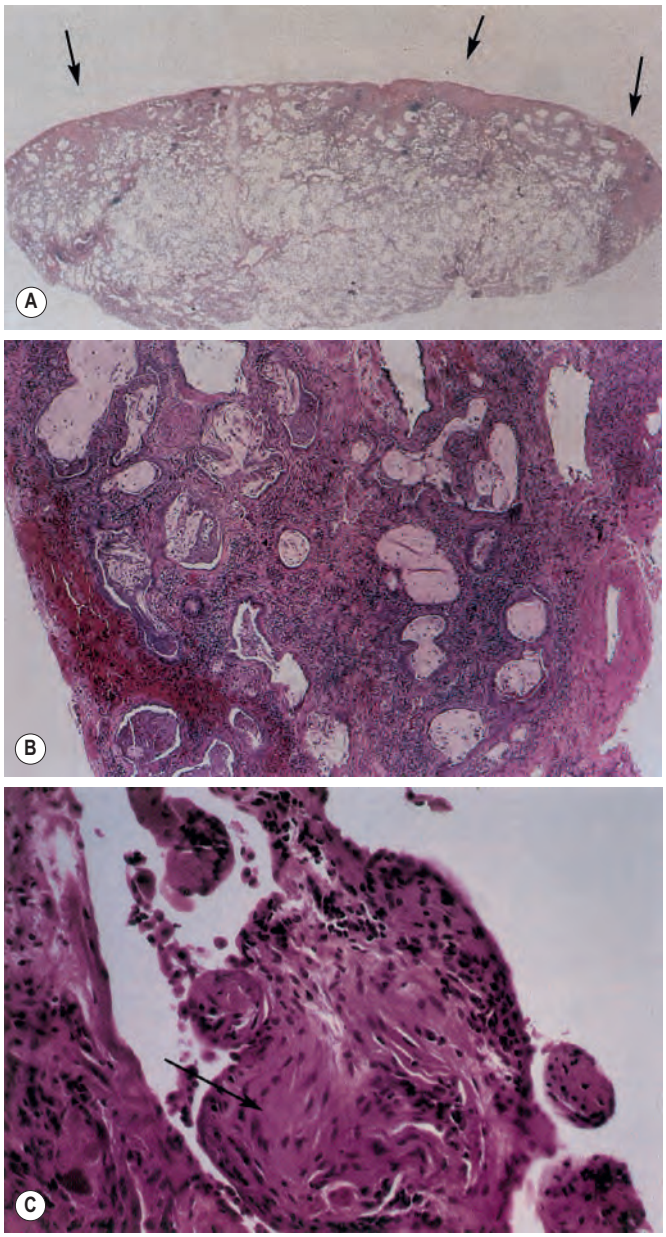

FIG. 72.3 Histopathology of Usual Interstitial Pneumonitis (UIP). (A) Low-magnification photomicrograph of UIP showing the variegated appearance from one field of view to the next, with areas of dense subpleural fibrosis *(arrows)* separated from other areas of normal lung. (B) High-magnification photomicrograph of UIP showing honeycomb change characterized by enlarged airspaces filled with mucin and separated by fibrosis. (C) Fibroblast focus in UIP is characterized by clusters of spindle-shaped fibroblasts *(arrow)* in a loose connective tissue matrix within the alveolar wall.

expression of human leukocyte antigen (HLA)-DR and IL-2 receptors. Following activation, CD4 T cells evolve into three major subsets distinguished by the cytokines produced (Chapters 11 and 14). In IPF, T cells expressing a Th2-type phenotype predominate, producing IL-4, -5, and -13. In addition, the Th17 cytokine, IL-17A, has been linked to the development of bleomycin-induced lung injury and collagen deposition.[17,18] Evidence also suggests that IPF patients have oligoclonal CD4 T-cell expansions that proliferate in response to antigens present in diseased tissue. Regulatory T-cell function may be impaired in patients with IPF.[9] In addition, immune complexes have been identified in the serum and lungs of IPF patients.[19]

In addition to their role as scavengers, alveolar macrophages are vital in the repair phase of inflammation. However, the distinguishing feature between a self-resolving inflammatory process and a fibrotic response, as seen in IPF, is the accumulation of collagen. Evidence suggests that the fibrotic process in IPF is a consequence of dysregulation of both collagen synthesis and degradation. Macrophage-derived growth factors, including TGF-β, PDGF, and IGF-1, stimulate fibroblast proliferation and collagen deposition. Adequate resolution of an inflammatory process requires matrix degradation. Matrix metalloproteases produced by macrophages and fibroblasts are involved in matrix degradation, and control of metalloprotease production involves substances known as tissue inhibitors of metalloproteases (TIMPs). TIMPs are elevated in the lungs of patients with IPF. In addition, TGF-β can markedly augment TIMP production.[20] Thus, there appears to be a loss of balance between the events mediating resolution and those mediating perpetuation of the inflammatory response, setting the stage for lung injury, tissue remodeling, and the development of irreversible pulmonary fibrosis.

KEY CONCEPTS

Pathogenesis of the Idiopathic Interstitial Pneumonias

- Although the inciting event(s) is unknown in the different diseases, a common result is a dysregulated fibroproliferative response (similar to wound healing), which leads to excessive extracellular matrix production and lung remodeling.
- A genetically determined inability to repair and re-epithelialize the denuded basement membranes adequately may be a contributing factor and may relate to the familial occurrence of some cases of idiopathic pulmonary fibrosis.
- The presence of a chronic stimulus (autoantigen), as is seen in the pneumoconioses, may result in a persistent inflammatory and immune response and lead to a failure in the normal healing process.
- The release of transforming growth factor-β following epithelial injury stimulates collagen synthesis and the prevention of apoptosis of proliferating fibroblasts in the lung, and may impair collagen degradation by inhibiting the production of metalloproteases.
- A predominant Th2 response in the lung and the absence of interferon-γ favor the development of a fibrotic response.

Diagnosis

The diagnostic evaluation of a patient with diffuse parenchymal lung disease includes a thorough history and physical examination, with particular attention to symptoms and signs that could indicate a CTD, occupational and environmental exposures, or medication and drug usage. A careful family history is also important.

The history and physical findings in IPF are nonspecific. However, extrapulmonary involvement does not occur: the presence of fever, arthralgias, myalgias, or pleuritis should suggest an alternative diagnosis. Circulating autoantibodies associated with CTD (anti-cyclic citrullinated peptide [CCP], rheumatoid factor [RF], and antinuclear antibodies [ANAs])

are present in 20% of IPF patients; however, higher autoantibody titers and any systemic signs of an underlying CTD should prompt further evaluation for underlying CTD or IPAF.[11,19]

The majority of patients with IPF have an abnormal chest radiograph at the time of presentation. Basal peripheral reticular opacities are the characteristic radiographic findings. A confident diagnosis of IPF from HRCT of the lung requires the presence of patchy, peripheral bibasilar reticular abnormalities with honeycombing.[15] The presence of extensive ground-glass opacities on HRCT should suggest an alternative diagnosis, such as DIP, hypersensitivity pneumonitis, COP, or NSIP.

A surgical lung biopsy is recommended in suspected IPF patients without a definitive HRCT appearance and who do not have contraindications to the procedure. This is especially important in patients with atypical clinical or radiographic findings, which could suggest the possibility of one of the other histologic patterns of the idiopathic interstitial pneumonias and an improved prognosis or possible treatment divergence. Biopsy may be omitted in elderly patients with cardiovascular disease,

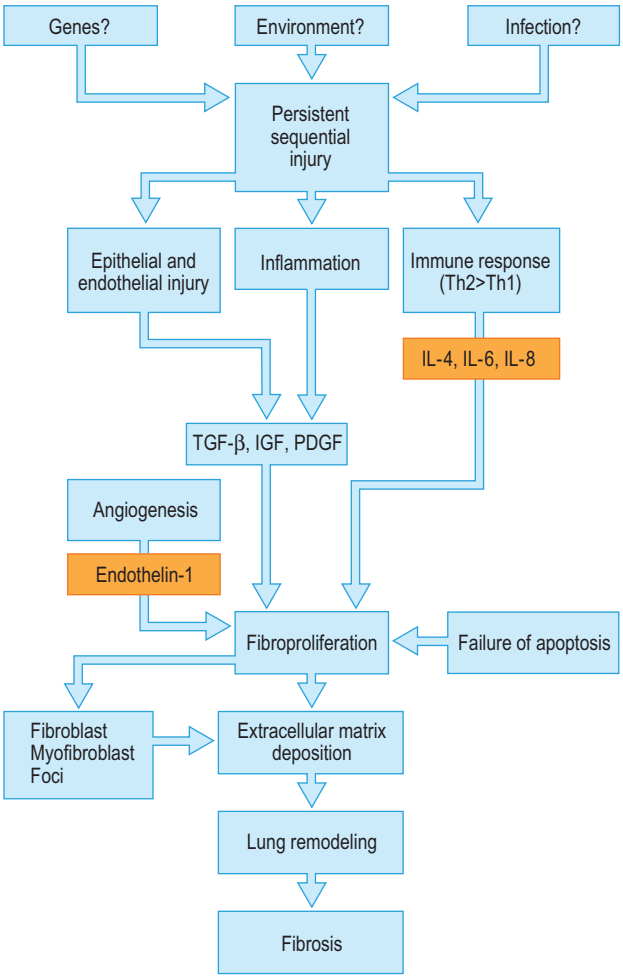

FIG. 72.4 Events Hypothesized to be Involved in the Pathogenesis of Idiopathic Pulmonary Fibrosis. The initiating event(s) leading to persistent lung injury remains poorly understood. The interaction between genetic factors, environmental exposures, and infectious agents leads to epithelial and endothelial injury, resulting in the secretion of macrophage-derived growth factors, including transforming growth factor-β *(TGF-β)*, insulin-like growth factor-1 *(IGF-1)*, and platelet-derived growth factor *(PDGF)*. This cytokine milieu stimulates fibroblast proliferation and collagen deposition. In addition, the resulting T-helper cell-2 (*Th2*) immune response stimulates extracellular matrix production and fibroblast proliferation, resulting in lung remodeling and, eventually, lung fibrosis. *IL*, Interleukin

or those with evidence of extensive honeycomb change. Video-assisted thoracoscopic (VATS) biopsy is the preferred surgical technique, as it is associated with less morbidity and a decreased hospital stay compared with open lung biopsy.

Treatment and Outcome

The usual course of IPF is relentless progression without spontaneous remission, commonly with a fatal outcome. The most common cause of death in patients with IPF is progression of the underlying disease, with two-thirds of deaths due to respiratory failure or cardiovascular complications. Other causes of death in IPF include bronchogenic carcinoma, infection, and pulmonary embolism. Recent studies in patients with biopsy-proven IPF indicate a poor prognosis (30% to 50% 5-year survival).[21] Previously, there was no evidence to support the use of any specific therapy in the management of IPF. However, clinical trials have shown decreased decline in forced vital capacity after use of either pirfenidone[22] or nintedanib.[23] Thus, for the first time, there are two Food and Drug Administration (FDA)-approved drugs for the treatment of IPF, with multiple other phase II and III clinical trials scheduled for completion in the near future. Finally, lung transplantation should be considered in patients with progressive clinical and physiologic deterioration who meet established criteria.

Acute Interstitial Pneumonia

Acute interstitial pneumonia (AIP) is a fulminant form of idiopathic interstitial pneumonia. Although it was previously thought to represent an acute phase of UIP, studies suggest it is a distinct entity.[16] However, patients with documented UIP/IPF experiencing acute exacerbations can have the pathology of AIP superimposed on UIP.[24]

Clinical Manifestations

AIP presents with the abrupt onset of dyspnea, followed by rapid progression to respiratory failure. The clinical, radiographic, physiologic, and histologic features are identical to those of the acute respiratory distress syndrome (ARDS) but without any identifiable cause. Most patients are previously healthy individuals over 40 years of age. Men and women are equally affected. A viral prodrome is common, with symptoms including fever, nonproductive cough, and dyspnea. Laboratory studies are nonspecific. Chest radiographs and HRCT show diffuse airspace opacities and ground-glass attenuation, respectively. A similar presentation may occur as the initial manifestation of a CTD.

Histopathology

AIP is characterized by diffuse interstitial fibrosis that is temporally uniform (Fig. 72.5).[25] The changes are identical to the organizing phases of diffuse alveolar damage, as seen in ARDS. Within the thickened interstitial space, there is active, diffuse fibroblast proliferation similar to the focal fibroblast foci seen in UIP. If this is progressive, honeycomb change occurs. Other features of acute lung injury, which are frequently seen in AIP, are intra-alveolar hyaline membranes.

Diagnosis

The diagnosis of AIP is based on a clinical syndrome of idiopathic ARDS and the presence of organizing diffuse alveolar damage on lung biopsy. Lung biopsy is occasionally performed to establish the diagnosis and exclude other causes of acute interstitial lung disease.

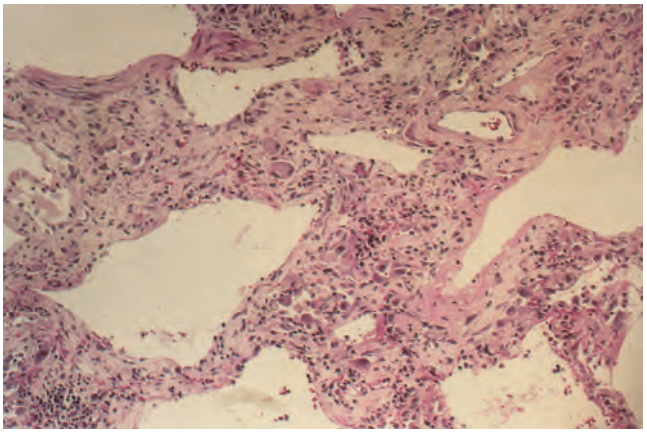

FIG. 72.5 Histopathology of Acute Interstitial Pneumonitis. Diffuse thickening of the alveolar septum with an infiltration of mononuclear cells is the characteristic abnormality. The temporal uniformity of this process is also apparent.

Treatment and Outcome

No effective therapy exists for patients with AIP. Glucocorticoids are utilized in most cases, but no survival benefit has been shown. Overall, the prognosis of patients with AIP is poor, with mortality rates ranging from 50% to 88%. Half of patients die within 6 months of disease onset. However, those who survive may have complete recovery of lung function, and AIP rarely recurs in survivors.

Desquamative Interstitial Pneumonitis

DIP represents fewer than 3% of all cases of interstitial lung disease.[26] However, it is a distinct clinicopathologic entity that differs substantially from UIP.

Clinical Manifestations

DIP affects individuals in their fourth to fifth decades of life with a male predominance. It predominantly occurs in cigarette smokers. Clinically, most individuals present with subacute onset of a dry, nonproductive cough and dyspnea. Clubbing is present in approximately 50% of DIP patients. Laboratory evaluation is usually nonspecific.

While the chest radiograph can be normal in up to 20% of symptomatic individuals, it typically shows nonspecific bibasilar ground-glass opacities. Reticulonodular interstitial infiltrates have also been reported. HRCT confirms the presence of ground-glass attenuation in the periphery of the lower lung zones (Fig. 72.6). Pulmonary function testing shows a restrictive defect with hypoxemia and a decrease in the DLCO.

Histopathology

DIP is a misnomer. It was initially thought that the intra-alveolar cells represented sloughed or desquamated alveolar epithelial cells. However, DIP is pathologically characterized by uniform, diffuse accumulation of macrophages in the alveolar space (Fig. 72.7). At low magnification, the overall appearance is one of uniformity from one field of view to the next, as opposed to the variegated appearance of UIP. In addition, there is scant interstitial inflammation, with varying degrees of fibrosis of the alveolar septum.

FIG. 72.6 Radiographic Manifestations in Desquamative Interstitial pneumonitis. High-resolution computed tomography in a patient with desquamative interstitial pneumonitis shows ground-glass attenuation in the periphery of the upper and lower lung fields.

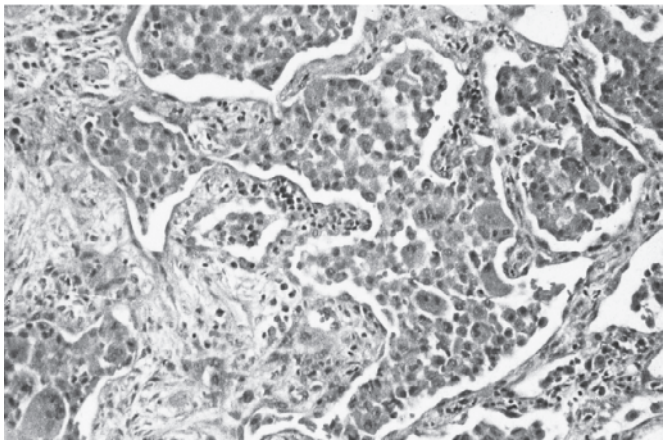

FIG. 72.7 Histopathology of Desquamative Interstitial Pneumonitis. A high-magnification photomicrograph of desquamative interstitial pneumonitis shows the uniform, diffuse accumulation of macrophages within the alveolar space, with associated thickening of the alveolar septum. These aggregates of macrophages almost completely fill the alveolar spaces.

Diagnosis

The diagnosis of DIP requires tissue confirmation of the pathologic lesion. This is important since DIP has a better prognosis and response to therapeutic intervention compared to IPF. A DIP-like pattern is frequently seen in other IIPs, as well as in pulmonary Langerhans cell histiocytosis, CTDs, and drug reactions. Thus, the diagnosis of DIP requires careful correlation of pathologic findings with clinical and radiologic findings.

Treatment and Outcome

The primary intervention in DIP is smoking cessation. Since this is a rare condition with relatively few published cases, it is unclear whether glucocorticoids alter the natural history of this disease. A mortality rate of 28% with a mean survival of 12 years has been reported, compared to a 30% to 50% 5-year survival in UIP.[21] Of note, 22% of patients improved spontaneously and 60% responded to glucocorticoid therapy. This picture is dramatically different from IPF, in which spontaneous improvement does not occur. There are, however, a significant minority of DIP patients who fail to respond to treatment and progress to respiratory failure secondary to advanced fibrosis.

Respiratory Bronchiolitis-Associated Interstitial Lung Disease

RB-ILD is a distinct clinical entity that occurs in current or former cigarette smokers. It is unclear whether RB-ILD and DIP represent different diseases or different ends on the spectrum of the same disease process.[27] DIP occurs predominantly and RB-ILD occurs exclusively in cigarette smokers, suggesting a common pathogenesis related to cigarette smoke exposure.

Clinical Manifestations

The mean age at presentation with RB-ILD is 36 years. Males are more often affected, and all individuals with RB-ILD are cigarette smokers. Symptoms include a dry, nonproductive cough and dyspnea. Clubbing is absent in RB-ILD, whereas it is frequently present in DIP. Laboratory evaluation is nonspecific.

The chest radiograph typically shows diffuse, fine reticular or nodular interstitial opacities with normal lung volumes. Additional findings include bronchial wall thickening and a prominent peribronchovascular interstitium. HRCT may reveal ground-glass opacification and emphysema.

Pulmonary function tests commonly reveal a mixed restrictive-obstructive pattern with a reduced diffusing capacity and mild hypoxemia. The residual volume may be increased with no change in other spirometry.

Histopathology

The pathology of RB-ILD is similar to DIP. However, in RB-ILD, the intra-alveolar macrophages accumulate primarily within the peribronchiolar airspaces and are associated with thickening of the alveolar septum in these areas (Fig. 72.8).

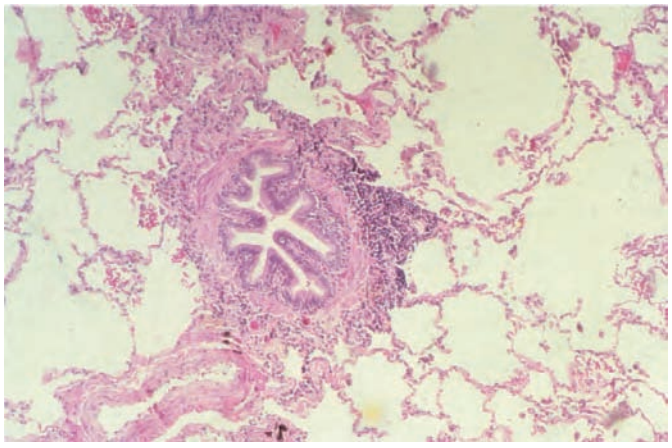

FIG. 72.8 Histopathology of Respiratory Bronchiolitis-Interstitial Lung Disease. An ectatic bronchiole with a thickened wall is shown, with a mononuclear infiltrate extending into the immediately surrounding alveoli.

The differentiation of this lesion from DIP requires sparing of distal airspaces, with the lesion confined to the peribronchiolar airspaces in RB-ILD.

Diagnosis

RB-ILD should be suspected in young individuals with a history of cigarette use who complain of cough and dyspnea with a chest radiograph or HRCT showing nodular and/or reticular interstitial opacities. The diagnosis requires tissue confirmation of the pathologic findings noted above.

Treatment and Outcome

The key therapeutic intervention in RB-ILD is cessation of smoking. The use of glucocorticoids has been associated with favorable results. At present, the clinical course and prognosis of patients with RB-ILD are unknown. In most clinical series, patients either improved or stabilized, and mortality is uncommon.[26,27]

Nonspecific Interstitial Pneumonitis

The term NSIP was first used to describe cases of interstitial pneumonia that did not demonstrate a pattern of UIP, AIP, or DIP. Currently, the term NSIP is applied to an IIP or to a similar histologic pattern that occurs in CTD, hypersensitivity pneumonitis, infection, or drug-induced lung disease. Thus, the diagnosis of NSIP should prompt investigation for a causative agent. In fact, 16% of patients in the original description of NSIP had one of the CTDs.[28]

Clinical Manifestations

Idiopathic NSIP occurs in middle-aged individuals, with a slight female predominance. A dry, nonproductive cough and exertional dyspnea are the most common symptoms, although fever is present in 25% of patients. Symptoms are usually present for 6 to 10 months prior to diagnosis. As in other IIPs, the laboratory evaluation is nonspecific.

The chest radiograph usually shows bilateral interstitial infiltrates and sometimes can be normal in a symptomatic patient. HRCT characteristically shows bilateral, patchy ground-glass attenuation indistinguishable from DIP or RB-ILD.[15]

Histopathology

NSIP is characterized by temporally uniform degrees of fibrosis and inflammation of the alveolar septum, without histopathologic features indicative of UIP, AIP, or DIP (Fig. 72.9). NSIP has been divided into three groups, depending on the presence or absence of interstitial fibrosis: interstitial lymphoplasmacytic inflammation (48% of cases); inflammation and fibrosis (38%); and fibrosis (14%). Although the changes are temporally uniform, they may be patchy with intervening areas of normal lung.

This temporal uniformity is in contrast to the variegated pattern seen in UIP. Fibroblast foci, the earliest lesion seen in UIP, are found in 20% of patients with NSIP, making the differentiation of fibrotic NSIP from UIP difficult. The key feature in this circumstance is the temporal uniformity of the lesion in NSIP.

Treatment and Outcome

Unlike patients with UIP, individuals with NSIP have a favorable prognosis. In the original description of the disease, 45% of subjects completely recovered, while another 42% remained stable or improved.[28] Only 11% of patients died, with a mean survival of 16 months. All of the individuals with an aggressive course were in the fibrotic group. Ten-year survival in the cellular group was 90%, compared to 35% in patients with the fibrotic pattern. Despite the worse prognosis of NSIP with a fibrosing pattern, this is still significantly better than the 15% survival rate at 10 years for patients with UIP.[29]

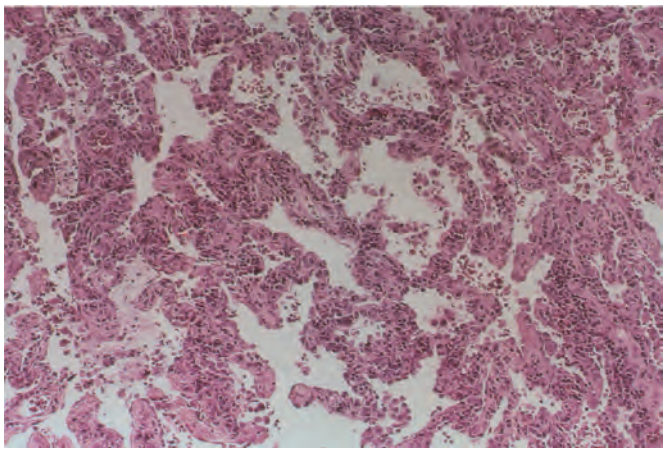

FIG. 72.9 Histopathology of Nonspecific Interstitial Pneumonitis. Low-magnification photomicrograph of cellular nonspecific interstitial pneumonitis shows diffuse uniform thickening of the alveolar septum due to the presence of a lymphoplasmacytic infiltrate.

Cryptogenic Organizing Pneumonia

Cryptogenic organizing pneumonia (COP), which was previously named idiopathic bronchiolitis obliterans organizing pneumonia (BOOP), is a specific clinicopathologic disorder of unknown etiology characterized by excessive proliferation of granulation tissue within the lumen of distal airspaces.[30] The term COP is reserved for cases demonstrating organizing pneumonia without an obvious cause, since this histologic appearance occurs in a variety of inflammatory lung disorders, including CTDs, malignancy, infections, and those caused by medications.

Clinical Manifestations

The onset of disease is usually in the fifth to sixth decades of life; men and women are equally affected. Most individuals have symptoms for less than 2 months prior to diagnosis. The initial presentation is usually with a dry, nonproductive cough and flu-like symptoms, including fever, sore throat, and malaise. This is followed by progressive dyspnea, and routine laboratory evaluation is nonspecific.

The chest radiograph shows diffuse, often patchy alveolar opacities in the setting of normal lung volumes (Fig. 72.10, A). These opacities can be migratory and usually have a peripheral distribution similar to those seen in chronic eosinophilic pneumonia. Rarer radiographic manifestations include linear or nodular interstitial opacities and honeycombing. The presence of a pleural effusion or pleural thickening should suggest an associated CTD. HRCT shows patchy airspace consolidation, especially in the lung periphery, with a lower-lung zone predominance (see Fig. 72.10, B). Other findings include ground-glass attenuation, small nodular opacities, and bronchial wall thickening.

As in other interstitial lung diseases, a restrictive ventilatory defect is the most common pulmonary function abnormality.

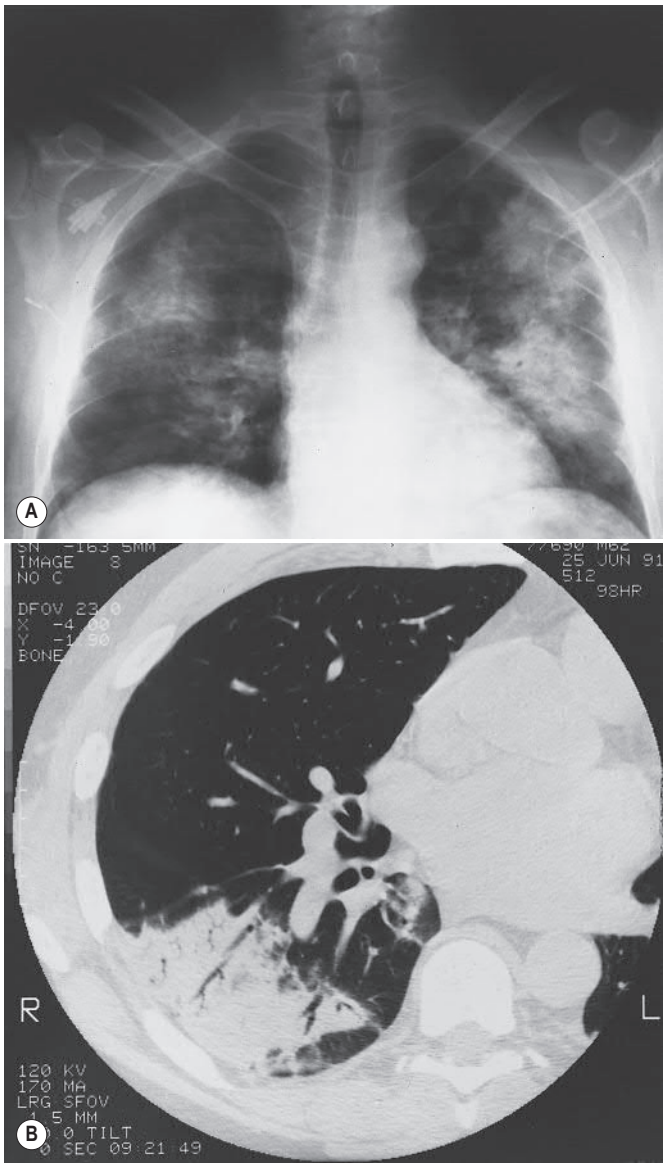

FIG. 72.10 Radiographic Findings in Cryptogenic Organizing Pneumonia. (A) Chest radiograph in a patient with cryptogenic organizing pneumonia shows bilateral patchy alveolar opacities with a peripheral distribution in the setting of normal lung volumes. (B) Chest computed tomography shows a dense right lower lung consolidation with the presence of air bronchograms.

Gas exchange abnormalities are common, and are accompanied by decreased diffusing capacity, widening of the alveolar–arterial gradient, and exercise-induced hypoxemia.

Histopathology

The histopathology of COP is characterized by excessive proliferation of granulation tissue in the small airways and alveolar ducts, with associated chronic inflammation in the alveolar walls (Fig. 72.11).[31] The intraluminal fibrotic buds (Masson bodies) consist of loose collagen-embedding fibroblasts and myofibroblasts and have a tendency to extend from one alveolus to the next, giving a characteristic "butterfly" pattern. The lesions are patchy in nature and have a uniform temporal appearance at low magnification with preservation of the underlying lung

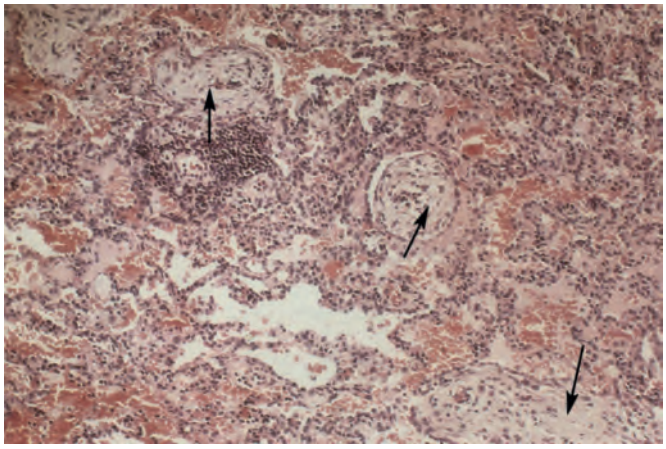

FIG. 72.11 Histopathology of Cryptogenic Organizing Pneumonia. A photomicrograph of cryptogenic organizing pneumonia shows intra-alveolar fibroblast proliferation *(arrows)* and early collagen production. In addition, thickening of the alveolar septa with a lymphoplasmacytic infiltrate consistent with cellular nonspecific interstitial pneumonitis is present.

parenchyma. COP has been described as the prototypical healing response of the lung to a variety of insults.

Diagnosis

The presence of organizing pneumonia in a lung biopsy does not necessarily represent COP since this is a diagnosis of exclusion. Organizing pneumonia is a nonspecific response to many lung injuries, and may occur in conjunction with another pathologic process or as a component of other primary pulmonary disorders, such as infections, irradiation, CTD, hypersensitivity pneumonitis, granulomatosis with polyangiitis, or chronic eosinophilic pneumonia (Table 72.3).

TABLE 72.3 Disorders Associated With Organizing Pneumonia

Secondary Organizing Pneumonia
Connective Tissue Diseases
- Systemic lupus erythematosus
- Rheumatoid arthritis
- Polymyositis/dermatomyositis
- Sjögren syndrome

Hypersensitivity Pneumonitis
Chronic Eosinophilic Pneumonia
Drug-Induced
- Gold
- Penicillamine
- Amiodarone
- Bleomycin
- Sulfa drugs

Wegener Granulomatosis
Bone marrow transplantation
Lung transplantation/rejection
Inhalational injury
Neoplasms
Lung irradiation
Virus-associated:
- Human immunodeficiency virus (HIV)
- Influenza
- Adenovirus

Treatment and Outcome

Treatment with glucocorticoids usually offers dramatic clinical and radiographic improvement within days to weeks.[30] Complete clinical, physiologic, and radiographic recovery occurs in two-thirds of cases. In the remainder, persistent disease with progression to fibrosis occurs. It is common for relapses to occur with glucocorticoid tapering, followed by improvement with reintroduction of treatment; consequently, at least 6 months of therapy is recommended. The 5-year survival in COP is 73%, compared to 5-year survival rates of 44% in patients with organizing pneumonia due to other causes (e.g., CTD), or 30% for IPF.

LUNG INVOLVEMENT IN CONNECTIVE TISSUE DISEASES

CTDs are a heterogeneous group of systemic autoimmune diseases that frequently involve the lungs. The pleuropulmonary manifestations of these diseases are diverse, affecting all parts of the respiratory tract (i.e., airways, alveoli, blood vessels, and pleura) (Table 72.4). Although pulmonary complications generally occur in patients with well-established disease, occasionally lung involvement is the first manifestation of the autoimmune disorder. This section discusses the pleuropulmonary manifestations of systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), and systemic sclerosis (SSc) (for a discussion of other manifestations in these diseases, see Chapters 52, 53, and 56).

TABLE 72.4 Pleuropulmonary Manifestations of Connective Tissue Diseases

	SLE	RA	SSc
Pulmonary hypertension	+	+	+++
Vasculitis	+	±	±
Pleural disease	+++	+++	+

Aspiration pneumonia	–	–	++
Diaphragmatic dysfunction	++	–	–
Lung nodules	–	++	–
Diffuse alveolar damage	+	±	±
Organizing pneumonia	±	+	±
UIP	+	+++	+
Capillaritis	++	+	±
LIP	+	+	+
NSIP	+	++	+

LIP, Lymphocytic interstitial pneumonitis; *NSIP*, nonspecific interstitial pneumonitis; *RA*, rheumatoid arthritis; *SLE*, systemic lupus erythematosus; *SSc*, systemic sclerosis; *UIP*, usual interstitial pneumonitis.

Systemic Lupus Erythematosus

SLE is a disease of unknown etiology, characterized by the presence of autoantibodies directed against various nuclear antigens. These autoantibodies and the resultant immune complexes mediate many of the manifestations of SLE (Chapter 52). This disease primarily affects young women (female-to-male ratio > 8:1) and may involve virtually every organ system. Pleuropulmonary involvement occurs at some point in the disease course in 38% to 89% of cases.[31] Thus, the respiratory system is affected more commonly in SLE than in any other CTD. However, infectious pneumonia remains the most common cause of pulmonary disease and death in these patients. Thus, in SLE patients presenting with a febrile illness and pulmonary infiltrates, a community-acquired or opportunistic infection must be promptly excluded.

Acute Lupus Pneumonitis

Acute lupus pneumonitis is an uncommon pulmonary manifestation of SLE, occurring in fewer than 5% of cases.[31] The clinical presentation mimics that of an infectious pneumonia with the abrupt onset of fever, cough, and dyspnea. Serum complement levels are often low, and the chest radiograph typically shows diffuse alveolar opacities. It can be accompanied by pericarditis, and often pleuritis and pleural effusion.

It can be difficult to distinguish acute lupus pneumonitis from an infectious pneumonia. BAL is recommended prior to instituting corticosteroid therapy. The histopathology varies, and includes diffuse alveolar damage, organizing pneumonia, NSIP, or a combination of these.

There are no controlled trials of therapy for acute lupus pneumonitis. Treatment includes high-dose glucocorticoids (1 to 2 mg/kg/day) with or without accompanying cytotoxic drugs, such as cyclophosphamide. Mortality rates as high as 50% have been reported in untreated cases. In patients who fail to respond to treatment, respiratory failure is the usual cause of death.

Diffuse Alveolar Hemorrhage

Diffuse alveolar hemorrhage (DAH) occurs in fewer than 5% of patients with SLE, and it represents the initial manifestation of disease in 11% to 20% of those cases.[32] However, most cases develop in individuals with well-established diagnoses of SLE, usually with pre-existing lupus nephritis.

Hemoptysis is not present in every case of DAH at presentation. Therefore, the absence of hemoptysis does not exclude the diagnosis, particularly in the setting of a falling hematocrit, diffuse pulmonary infiltrates, and progressively bloody BAL fluid. DAH in SLE is most often due to pulmonary capillaritis, but it can also be caused by diffuse alveolar damage. Immunofluorescence studies show granular deposits of immunoglobulin G (IgG) and C3 along alveolar walls, interstitium, and capillary endothelial cells.

There are no controlled trials for the treatment of alveolar hemorrhage in SLE. Glucocorticoids, cytotoxic drugs, plasmapheresis, and extracorporeal membrane oxygenation (ECMO) have been used in various combinations. The mortality rate associated with DAH and concomitant respiratory failure approaches 100% without treatment; therefore early recognition and aggressive treatment should be undertaken.

Lupus Pleuritis

The pleura are the most common site of respiratory involvement in SLE, with pleurisy and pleural effusions occurring in 50% to 80% of patients. Lupus pleuritis can be the presenting manifestation of disease, but more commonly develops in patients with established SLE and is often recurrent. The clinical manifestations include chest pain, fever, and dyspnea, and the chest radiograph typically shows bilateral pleural effusions. The pleural fluid is serous or serosanguineous and exudative in nature. Compared to effusions in RA, the glucose is higher, and the lactate dehydrogenase level is lower. The most helpful measurement is a pleural fluid ANA titer greater than 1:160. Examination of the pleura reveals infiltration with plasma cells and lymphocytes, accompanied by pleural thickening and fibrosis. Treatment with nonsteroidal anti-inflammatory drugs

and/or glucocorticoids is usually effective for relief of pleural discomfort.

Interstitial Lung Disease

The presence of ILD in SLE is uncommon, especially when compared to SSc or RA. However, minor interstitial abnormalities can be found on HRCT in approximately one-third of SLE patients despite normal physiologic testing. The significance and natural history of these subclinical findings are uncertain. The presence of anti-SSA (Ro) has been noted in approximately 80% of lupus patients with interstitial changes, and ILD is more common in those SLE patients with sclerodermatous skin changes.

The diagnosis of SLE is usually well-established in patients who develop the insidious form of ILD. The disease course is characterized by progressive dyspnea and cough; the chest radiograph shows reduced lung volumes and reticular interstitial infiltrates. A restrictive lung function pattern with reduced diffusing capacity and exercise-induced hypoxemia are typical. The histopathology of chronic interstitial disease in SLE resembles NSIP, although cases of organizing pneumonia, lymphocytic interstitial pneumonitis (LIP), and UIP have been described. Response to therapy depends on the underlying histopathology, with the UIP-like form being least responsive.

Pulmonary Vascular Disease

Although previously thought to be unusual, the development of pulmonary hypertension has been increasingly noted in SLE, with an incidence ranging from 0.5% to 17%. Pulmonary hypertension in SLE has been associated with the presence of Raynaud syndrome, serositis, digital vasculitis, and antiphospholipid antibodies.[33] Dyspnea and fatigue, despite a normal chest radiograph, is the most common presentation. The majority of SLE patients with pulmonary hypertension are female, with 3- and 5-year survival rates of 45% and 17%, respectively, which represents a worse prognosis than patients with idiopathic pulmonary hypertension. The vascular changes of SLE-associated pulmonary hypertension are similar to those seen in idiopathic pulmonary arterial hypertension (PAH) with intimal hyperplasia, smooth muscle hypertrophy, and medial thickening. Several pathologic mechanisms have been proposed for the development of pulmonary hypertension, including vasoconstriction in addition to vasculitis and thrombosis with an association with antiphospholipid and anticardiolipin antibodies. Serum endothelin levels are elevated in patients with SLE-associated pulmonary hypertension and correlate with pulmonary arterial pressures.

Pulmonary function testing shows an isolated decrease in the DLCO. Patients with SLE-associated pulmonary hypertension may respond to immunosuppressive therapy, such as azathioprine or mycophenylate mofetil, based on small studies indicating hemodynamic improvement with this approach. SLE patients treated with bosentan did not have clinical worsening and showed an improvement in 6-minute walk distance.[34] Unfortunately, despite these modest improvements with pharmacotherapy, the long-term survival of patients with SLE-associated pulmonary hypertension is poor.

Respiratory Muscle Dysfunction

The shrinking lung syndrome is due to diaphragmatic weakness as well as weakness of other respiratory muscles. This entity accounts for the findings of dyspnea without evidence of interstitial infiltrates or pulmonary vascular disease. It occurs in 25% of patients with SLE. The chest radiograph typically shows elevated diaphragms and basilar atelectasis. The pathogenesis of respiratory muscle dysfunction is unknown; however, weakness remains localized to the respiratory compartment without generalized muscle involvement, indicating specific involvement of the muscles of respiration. Glucocorticoids are generally ineffective in the treatment of this syndrome. Improvement has been noted with inhaled β-agonist and theophylline therapy. Despite a variable response to therapy, it is unusual for this manifestation of SLE to be progressive.

Rheumatoid Arthritis

RA is an autoimmune disease associated with autoantibodies directed against citrullinated antigens and characterized by the presence of a symmetric, inflammatory polyarthritis (Chapter 53). It occurs more frequently in women, with a 2:1 female-to-male ratio. Disease onset is most commonly in the fourth to fifth decades of life. Pleuropulmonary complications of RA occur more commonly in individuals with subcutaneous nodules, high titers of rheumatoid factor, anti-cyclic citrullinated proteins (anti-CCP), and more severe chronic articular involvement. Although RA itself is more common in women, the pleuropulmonary manifestations occur more commonly in men. The pleuropulmonary complications of RA are numerous, but there are also treatment-related lung toxicity and pulmonary infections related to immunosuppression, which can complicate the diagnosis of RA-related lung manifestations.

Pleuritis and Pleural Effusions

Pleural effusion in RA is common and can occur prior to the development of arthritis. Pleural disease is often discovered as an incidental finding on routine chest radiographs, but nonspecific chest pain, dyspnea, and fever are not unusual. The effusion can be unilateral or bilateral and can coexist with interstitial lung disease. Typically, the effusion is an exudate, with a glucose level usually less than 30 mg/mL. The mechanism underlying the low pleural fluid glucose is impaired membrane transport of glucose. A low pleural fluid pH is thought to occur secondary to impaired carbon dioxide exit from the pleural space. If the effusion is chronic, the cholesterol concentration can be increased, and the pleural fluid can have a milky appearance (pseudochylothorax). Cytologic examination reveals multinucleated giant cells, spindle-shaped macrophages, and necrotic debris.

Most rheumatoid effusions are small and asymptomatic, requiring no treatment. They resolve over several months without complications. The use of glucocorticoids for active articular disease hastens the resolution of the pleural process.

CLINICAL PEARLS

Lung Involvement in Rheumatoid Arthritis

- RA is more common in women, but pleuropulmonary complications occur more frequently in men.
- Factors associated with pleuropulmonary complications of RA include more severe articular involvement, subcutaneous nodules, and high levels of rheumatoid factor and antibodies to citrullinated peptides.
- Pleural effusions are the most common complication, characterized by an exudate, low glucose, and low pH.
- The differentiation of rheumatoid nodules from malignant lesions can be difficult.
- The rapid growth of a nodule should prompt aggressive investigation for a malignant cause.

Rheumatoid Nodules

Rheumatoid or necrobiotic nodules are most commonly seen in men with active articular disease, high rheumatoid factor titers, and subcutaneous nodules. Most individuals are asymptomatic and are diagnosed on routine chest radiograph. Radiographically, these nodules can be singular or multiple with an upper to mid-lung zone predominance. Cavitation occurs in approximately 50% of cases. HRCT indicates a higher frequency of nodules than previously thought. Rarely, subpleural necrobiotic nodules can erode into the pleural space, resulting in a pneumothorax with a complicating bronchopleural fistula. It can be difficult to differentiate these nodules from malignant lesions, making thoracoscopic lung biopsy necessary. Evidence on chest radiograph of rapid growth should prompt an aggressive diagnostic evaluation.

Airway Disease

Airflow limitation is a common finding in patients with RA, being present in approximately one-third of patients. The mechanism(s) responsible for airway disease is poorly understood. The interplay of cigarette smoking and RA may play a role.

A life-threatening complication of RA is upper-airway obstruction, resulting from synovitis of the cricoarytenoid joint. Common presenting complaints include a sore throat, hoarseness, and fullness in the throat. It can progress to inspiratory stridor and upper-airway obstruction. This complication occurs more commonly in women, particularly in those with advanced RA. Seventy-five percent of patients were found to have cricoarytenoid abnormalities when screening with direct or indirect laryngoscopy and computed tomography was utilized. The treatment of cricoarytenoid arthritis includes anti-inflammatory medications.

Constrictive bronchiolitis is a progressive form of obstructive lung disease that is being increasingly recognized as a complication of RA.[35] The histopathologic lesion of constrictive bronchiolitis is concentric submucosal and peribronchiolar fibrosis resulting in extrinsic compression and obliteration of the bronchiolar lumen. The typical clinical presentation is with insidious onset of cough and dyspnea, with a normal or hyperinflated chest radiograph. This complication occurs more commonly in women than in men. Pulmonary function studies show airflow limitation with hyperinflation and a reduced diffusing capacity. Inspiratory imaging on HRCT demonstrates mosaic attenuation, while expiratory imaging demonstrates corresponding areas of air trapping. Some individuals respond to high-dose glucocorticoids and cytotoxic drugs, but most patients with bronchiolitis obliterans progress to respiratory failure and require lung transplantation.

Interstitial Lung Disease

Although ILD is a common complication of RA, the incidence is difficult to determine, since different methods of detection have been employed and dissimilar populations of patients have been studied; however, recent estimates of RA-ILD are 3.2 to 6.0 cases per 100,000 people.[36] The development of ILD in relation to the onset of arthritis is variable. Most often, the ILD develops subsequent to arthritis, but, in approximately 20% of patients, the lung disease precedes the onset of arthritis. ILD in RA is associated with cigarette smoking, presence of the shared HLA-DR4 epitope, and RA-specific anti-citrullinated protein antibodies. The most important genetic risk factor for the development of ILD in RA patients appears to be the presence of the same *MUC5B* promoter polymorphism, similar to what has been observed in IPF.[13,37]

The most common histopathologic pattern of ILD in RA is UIP, followed by NSIP, LIP, and organizing pneumonia. The clinical manifestations of ILD in RA resemble those seen in idiopathic disease and include a dry, nonproductive cough and dyspnea on exertion. The chest radiograph and HRCT show increased reticular markings with a predilection for the peripheral lower-lung zones. LIP usually occurs in cases of RA complicated by Sjögren syndrome; the presence of keratoconjunctivitis sicca and xerostomia in a patient with RA and ILD should suggest this histologic subtype.

Additionally, some patterns of ILD in RA patients are believed to be related to medications used to treat the condition. The most common of these is methotrexate-induced lung disease. Methotrexate lung toxicity presents with the subacute onset of fever, cough, and dyspnea occurring 1 to 5 months after initiation of the drug. The chest radiograph shows mixed interstitial–alveolar infiltrates. Nonspecific laboratory abnormalities include leukocytosis, sometimes with mild eosinophilia, and an elevated erythrocyte sedimentation rate. In most cases, BAL reveals a lymphocytosis. Histologically, cellular NSIP is seen with areas of organizing pneumonia. Non-caseating granulomatous inflammation similar to that seen in hypersensitivity pneumonitis may also be present. The primary treatment of methotrexate-induced pneumonitis is withdrawal of methotrexate in addition to supportive care.

Unfortunately, RA-ILD typically confers a poor prognosis with high morbidity and mortality, especially in the presence of a UIP pattern. Current therapeutic strategies for RA-ILD are similar regardless of the underlying histopathologic pattern and are based on steroid-sparing therapies such as azathioprine or mycophenolate mofetil. Additionally, a recent study evaluated the use of nintedanib in a non-IPF population of progressive fibrotic ILD which included RA-ILD patients and had similar results to previous IPF trials, indicating a possible role for nintedanib in this condition.[38]

Systemic Sclerosis (Scleroderma)

SSc is characterized by excessive deposition of extracellular matrix in the skin and internal organs, and vascular involvement (Chapter 56). The degree of visceral organ involvement determines morbidity and mortality. Pulmonary involvement occurs in 70% to 100% of patients with SSc and does not correlate with the degree of extrapulmonary disease. Interstitial lung disease is the most common pulmonary manifestation of SSc. Of note, with the improved mortality associated with renal involvement in SSc, lung disease has become the most important cause of morbidity and mortality.

Interstitial Lung Disease

The incidence of ILD in SSc depends on the method of detection. Autopsy studies have reported an ILD incidence of 60% to 100% of cases, whereas studies based on chest radiographs have noted interstitial changes in 14% to 66% of cases. Cough and dyspnea on exertion are the most common symptoms. Physical examination reveals bibasilar rales. Radiographic findings include basal reticulonodular infiltrates, enlargement of pulmonary arteries, and progressive volume loss. Pulmonary function testing reveals restrictive lung disease, preservation of flow rates, and decreased diffusing capacity. A disproportionate

decrease in diffusing capacity compared to lung volume changes should suggest pulmonary hypertension, especially in individuals with limited scleroderma (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia [CREST] syndrome). The predominant histopathologic abnormality is NSIP. Rarely, LIP may complicate cases of SSc associated with Sjögren syndrome. Although the 5-year survival for SSc patients with ILD is 38% to 45%, it is better than that of patients with IPF.

Pulmonary Vascular Disease

Pulmonary hypertension is a frequent complication of SSc, occurring in approximately 30% of patients with diffuse scleroderma and in 10% to 50% of those with limited scleroderma (Chapter 56). Because it is a major cause of morbidity and mortality in systemic sclerosis, it has also become part of the diagnostic criteria for the disease.[39] Pulmonary hypertension can either be associated with interstitial fibrosis or result from involvement of small and medium-sized arteries and arterioles with smooth-muscle hyperplasia, medial hypertrophy, and intimal proliferation (plexogenic). Direct involvement of the pulmonary circulation is more common with limited scleroderma, while pulmonary hypertension in patients with diffuse scleroderma is more likely associated with ILD.

The clinical presentation is characterized by the insidious onset of fatigue and dyspnea on exertion. Physical examination and chest radiographs show signs typical of pulmonary hypertension, while a decreased diffusing capacity is seen on pulmonary function testing. Risk factors for developing SSc-associated pulmonary hypertension include limited skin involvement, duration of disease greater than 10 years, onset of SSc at older age, and severity and duration of Raynaud phenomenon.

The pathogenesis of SSc-associated pulmonary hypertension is poorly understood. Vascular changes occur at an early stage in SSc, including apoptosis, endothelial cell activation with increased expression of cell adhesion molecules, inflammatory cell recruitment, intimal proliferation, and adventitial fibrosis leading to vessel obliteration. Endothelial injury is reflected by increased levels of soluble cell adhesion molecules, disturbances of angiogenesis with increased levels of circulating vascular endothelial growth factor, and presence of angiostatic factors. It remains unclear to what extent dysregulated angiogenesis in SSc-associated pulmonary hypertension is driven by an inflammatory process or other as-yet unidentified mechanisms.

Treatment of SSc-associated pulmonary hypertension has been disappointing, with no therapy showing a significant survival benefit. Calcium channel blockers are not usually indicated for patients with SSc-associated pulmonary hypertension, although often used at lower doses for Raynaud phenomenon. Continuous intravenous epoprostenol improves exercise capacity and hemodynamics.[40] Randomized clinical trials with phosphodiesterase inhibitors, including sildenafil, showed a modest effect on exercise capacity, hemodynamic parameters, and functional class after 12 weeks of treatment. Carefully selected patients may be considered for heart–lung transplantation but are often excluded due to postoperative complications arising for SSc-related gastrointestinal reflux disease and renal dysfunction.

Sarcoidosis

Sarcoidosis is a disease of unknown etiology that occurs in individuals of all ages, sex, and ethnic backgrounds.[41] The disease can affect every compartment in the body; however, in over 90% of cases the lungs are involved. Most cases of sarcoidosis are self-limited and typically responsive to glucocorticoid-based regimens, but some patients develop a chronic form of the condition which typically necessitates a steroid-sparing treatment-based strategy.

Epidemiology

The incidence of sarcoidosis is heavily influenced by geographical factors, as well as the race of the population being studied. For instance, within an American population, African American women had a higher incidence of sarcoidosis when compared to Caucasian women (17.8 per 100,000 per year vs. 8.1 per 100,000 per year).[42] Furthermore, the incidence of sarcoidosis varies widely based on the region of the world being studied (ranging from 2.3 per 100,000 per year in Guadalupe to 11.5 per 100,000 per year in Sweden). Sarcoidosis typically affects adults in a bimodal distribution, with common peaks of diagnosis in the 20–29 and 60–69 age groups.

Pathogenesis

Despite being recognized as a distinct clinical entity for nearly 150 years, the cause of sarcoidosis remains unknown. Similar inflammatory granulomatous disorders, such as berylliosis, result in a nearly identical clinical disorder. This suggests that the underlying pathophysiology of sarcoidosis is similar to that of conditions like berylliosis, but the antigen (or antigens) leading to the phenotype of sarcoidosis remains unknown. While the environmental antigen that causes sarcoidosis is not yet known, it is clear that an environmental factor plays a causal role in the development of sarcoidosis, based on regional variation and penetrance of the disease. Environmental antigens trigger an immunologic reaction, leading to granuloma formation. Several potential causal antigens have been explored in sarcoidosis. Suspected antigens have included organic and environmental airborne exposures. For instance, since 2001, World Trade Center first responders have developed a pulmonary granulomatous disorder, similar to sarcoidosis, likely related to the inorganic and organic respiratory particle inhalation from their exposure to the debris from the site.[43] Other potential antigens in sarcoidosis have included infectious organisms such as Mycobacteria or Cutibacteria, given evidence of genetic elements from these organisms in the granulomas from patients with sarcoidosis.[44]

The hallmark immunologic feature of sarcoidosis is the accumulation of CD4 T cells in lung tissue; the BAL, CD4 T cell, and B-cell lymphopenia are common in peripheral blood. Th1 effector phenotype has expression of IFN-γ, TNF, and IL-2. CD4 T cells with a Th17 phenotype and T cells expressing both IL-17 and IFN-γ (i.e., Th17.1 cells) have been found in lung tissue and BAL fluid from patients with sarcoidosis, but whether these cells play a role in disease progression is currently unknown.[43] This inflammatory cytokine milieu ultimately drives the formation of the sarcoidosis granuloma and the clinical phenotype of this syndrome.

Genetic studies show that sarcoidosis is most strongly associated with the HLA region on chromosome 6, with *HLA-DRB1*11:01* increasing risk in both African Americans and Whites.[44] In Europeans, *DRB1*03:01* has a strong association with increased disease risk. However, this allele was found to be protective against sarcoidosis in an African American cohort.[44] Genome-wide association studies have identified associations with *ANXA11*, *NOTCH4*, and *BTNL2* (reviewed in Moller

et al.[44]). However, the role of these single-nucleotide polymorphisms in the pathogenesis of sarcoidosis remains unknown.

Clinical Manifestations

Sarcoidosis is a multisystem inflammatory disorder that can affect every organ with wide-ranging clinical impacts based on the severity of involvement and the organ system involved (Table 72.5). While every organ system is at risk for involvement with sarcoidosis, the lung is the site most commonly impacted, with over 90% of sarcoidosis cases exhibiting some degree of pulmonary involvement. The following discussion will focus primarily on the pulmonary manifestations of sarcoidosis.

Symptoms of pulmonary sarcoidosis can vary from incidental radiographic findings of bilateral hilar lymphadenopathy in asymptomatic individuals (see Fig. 72.1) to marked dyspnea leading to significant morbidity and mortality. Pulmonary function testing can vary in sarcoidosis. In asymptomatic cases or cases with only nodal involvement of sarcoidosis, there can be little to no abnormality of pulmonary physiology. However, in cases with advanced parenchymal fibrosis, there will typically be pulmonary restriction and a reduction in DLCO. Additionally, sarcoidosis can lead to pulmonary vascular disease through two mechanisms: (1) primary involvement of the pulmonary vasculature bed and (2) secondary pulmonary hypertension as a result of parenchymal fibrosis and pulmonary restriction. Therefore, pulmonary sarcoidosis can also result in out-of-proportion reductions in DLCO and morbidity due to pulmonary vascular disease. Pulmonary sarcoidosis can also display an obstructive ventilatory defect, which is often related to endobronchial involvement of sarcoidosis.

Chest radiographs in sarcoidosis have been characterized by the Scadding staging system (Fig. 72.12). This system describes five stages of lung parenchymal involvement in sarcoidosis, from Stage 0 (absence of pulmonary findings) to Stage IV (pulmonary fibrosis without nodal involvement). While the Scadding staging system remains a useful tool for prognosis, advances in imaging such as HRCT have improved our understanding of lung parenchymal involvement in sarcoidosis (Fig. 72.13, A–C).[45]

Histopathology

The pathologic hallmark of sarcoidosis is the non-caseating granuloma (Fig. 72.14).[46] Sarcoidosis granulomas are discreet and compact, consisting of a central core of epithelioid cells, macrophages, and CD4 T cells, with a peripheral localization of CD4 and CD8 T cells along with B cells. Multinucleated giant cells are scattered throughout the granuloma (see Fig. 72.14). Similar to berylliosis, granulomatous inflammation in sarcoidosis occurs along the peribronchovascular bundle.

The histologic finding of non-caseating granulomas requires a search for other potential causes of granulomatous inflammation, such as infection (e.g., mycobacteria, fungi, and parasites) or foreign material (talc), by meticulous analysis of the tissue using special stains and cultures. Typically, there is no necrosis in the granulomas of sarcoidosis; however, the finding of necrosis does not exclude the diagnosis of sarcoidosis. While sarcoidosis is a multisystem granulomatous disorder, it is rarely necessary to biopsy more than one site, as findings of granulomatous inflammation in one affected organ with clinical end-organ damage elsewhere is typically enough to secure the diagnosis in the right clinical scenario.

TABLE 72.5 Clinical Manifestations of Sarcoidosis

Organ System (% Involvement)	Clinical Features
Pulmonary (90%)	Hilar adenopathy, peribronchovascular nodularity, bronchiectasis
Ocular (5%–10%)	Anterior and posterior uveitis, optic neuritis, glaucoma, chorioretinitis
Skin (20%–30%)	Erythema nodosum, nodules and plaques, lupus pernio
Hepatic (10%)	Hepatomegaly, cirrhosis, jaundice
Cardiac (10%–15%)	Heart block, arrhythmias, cardiomegaly, sudden death
Nervous system (5%–10%)	Cranial neuropathies, mass, meningitis, seizures, obstructing hydrocephalus, small fiber neuropathy
Hematologic (30%–50%)	Anemia, lymphopenia, thrombocytopenia, splenomegaly, lymphadenopathy
Joint/muscle (10%–20%)	Arthritis, bone cysts, myopathy
Endocrine (<10%))	Hypercalcemia, hypercalciuria, diabetes insipidus, hypopituitarism
Renal (<5%)	Renal calculi, nephrocalcinosis, renal failure

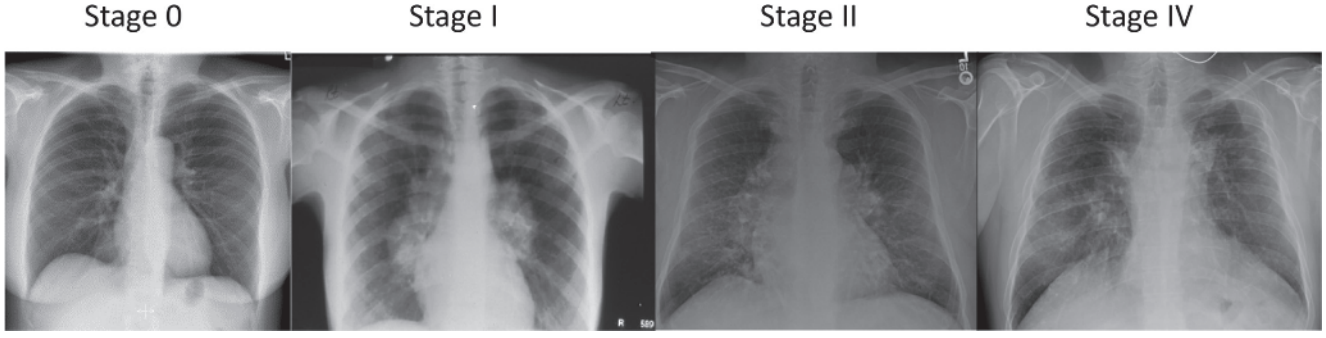

FIG. 72.12 Radiographic Staging of Sarcoidosis via the Scadding Stages. Stage 0 is a normal-appearing chest x-ray. Stage 1 has hilar lymphadenopathy in the absence of lung parenchymal infiltrates. Stage II has hilar lymphadenopathy as well as pulmonary infiltrates. Stage III has pulmonary infiltrates alone. Stage IV is notable for pulmonary fibrosis. Fifty percent of patients with sarcoidosis present at Stage I, and 75% to 80% of those have spontaneous remission.

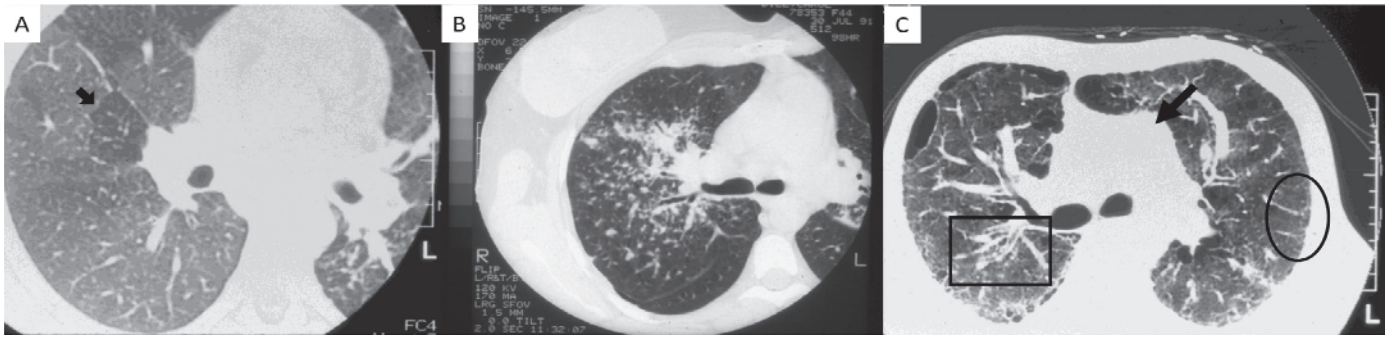

FIG. 72.13 High-Resolution Computed Tomography (HRCT) Images of Lung Involvement in Sarcoidosis. (A) HRCT showing lobular mosaicism *(arrow)* with differential air-trapping in a lobule of the lung likely reflecting airways disease from granulomatous inflammation. Tiny nodules are also present throughout the lung parenchyma in a peribronchovascular distribution. (B) HRCT image of the lung shows nodules with confluence around right hilar lymphadenopathy. These nodules and the alveolar infiltrate are perilymphatic in distribution. (C) HRCT image showing evidence of pulmonary hypertension as depicted by enlarged peripheral pulmonary arteries *(black arrow)*, peripheral reticular abnormality *(black circle)*, and areas of traction bronchiolectasis *(black square)*.

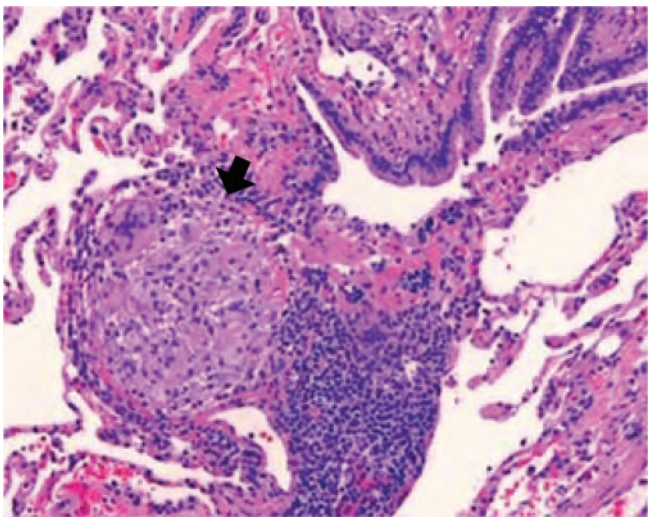

FIG. 72.14 Lung Biopsy Showing Non-Caseating Granulomatous Inflammation *(arrow)* in a Sarcoidosis Patient. The granulomas consist of a tight conglomerate of epithelioid and multinucleated-giant cells encircled by CD4 T and B lymphocytes.

Diagnosis

The diagnosis of sarcoidosis is typically made through a combination of clinical reasoning to exclude other diagnoses combined with radiographic and histologic findings consistent with sarcoidosis. While the diagnosis typically requires histopathologic confirmation of granulomatous inflammation, there are clinical scenarios where a biopsy may not be necessary. Certain clinical syndromes of sarcoidosis, such as Löfgren syndrome (e.g., erythema nodosum, arthritis, and bilateral hilar lymphadenopathy) or Heerfordt syndrome (uveoparotid fever and facial nerve palsy), rarely require a biopsy. With these exceptions, the suspected diagnosis of sarcoidosis requires tissue evaluation. In most cases, selection of the tissue site for biopsy is guided by evidence of end-organ involvement, as well as considerations for patient safety and ease of biopsy. [^{18}F]-fluorodeoxyglucose positron emission scanning (PET) can detect active sites of granulomatous inflammation that can be useful to identify alternative sites for biopsy if certain sites are deemed high risk (e.g., brain or myocardium). Given the high rate of lung involvement and advances in bronchoscopic biopsy techniques, such as endobronchial ultrasound (EBUS) and transbronchial needle aspiration (TBNA), the most common method for obtaining tissue diagnosis for sarcoidosis is via bronchoscopy. This also allows for evaluation of BAL fluid, which can aid in the evaluation of alternative diagnoses (e.g., infection or hypersensitivity pneumonitis). BAL fluid also allows for evaluation of lymphocyte populations from the distal pulmonary compartment, which can aid in the diagnosis of sarcoidosis. For instance, a high CD4:CD8 ratio (>3.5) is indicative of a CD4 T-cell alveolitis, consistent with sarcoidosis.

Serum biomarkers are not useful in isolation to diagnose sarcoidosis. Angiotensin-converting enzyme (ACE) is elevated in 40% to 50% of sarcoidosis patients and is mentioned in international guidelines as a diagnostic biomarker for sarcoidosis. However, it does not have high sensitivity or specificity, and many conditions that mimic sarcoidosis also have high ACE levels (e.g., tuberculosis, fungal infections, and thyroid disease).

Given the multisystem nature of the disease, other organs should be screened after a diagnosis of sarcoidosis is made. Screening typically includes pulmonary function testing, electrocardiogram (ECG), screening ophthalmologic exam, comprehensive metabolic panel, complete blood count, measurement of vitamin D levels, and a 24-hour urine for calcium excretion. In the presence of cardiac symptoms or an abnormal ECG, an echocardiogram and Holter monitor should be performed. If abnormalities are detected on the ECG, echocardiogram or Holter, cardiac magnetic resonance imaging (MRI), or cardiac PET may be indicated to assess for cardiac sarcoidosis. Cardiac MRI and PET have greater sensitivity for detecting patchy inflammation or scarring. Since endomyocardial biopsy has a lower sensitivity for detecting endomyocardial granulomas, the diagnosis of cardiac sarcoidosis hinges on histologic confirmation at other sites, along with cardiac imaging studies that are consistent with a diagnosis of sarcoidosis.

Treatment and Outcome

Seventy percent of cases with acute sarcoidosis experience spontaneous and lasting remission without evidence of persistent

CLINICAL PEARLS

Initial Evaluation of Patients Diagnosed With Sarcoidosis

- Chest radiograph or computed tomography
- Pulmonary function tests (spirometry, lung volumes, and diffusing capacity)
- Electrocardiogram
- Ophthalmologic evaluation
- Blood work including complete blood count, comprehensive metabolic profile, and vitamin D
- 24-hour urine for calcium excretion

disease activity. Additionally, many cases of sarcoidosis are incidental discoveries in asymptomatic patients. For most cases, careful clinical monitoring is sufficient for initial management. However, for those patients with symptomatic pulmonary sarcoidosis or evidence of end-organ damage (progressive pulmonary infiltrates, progressive loss of pulmonary function, development of pulmonary arterial hypertension), glucocorticoids should be initiated. In many cases of pulmonary sarcoidosis, glucocorticoids alone are enough to lead to remission. However, for cases of progressive, chronic sarcoidosis where long-term treatment is required, a steroid-sparing regimen should be initiated.[41]

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (HP) is a non-IgE-mediated inflammatory lung disease that results from recurrent exposure to any of a wide variety of inhaled antigenic aerosols containing organic and possibly infectious matter. Pulmonary involvement is typically diffuse and includes predominantly mononuclear inflammation of the terminal bronchioles, interstitium, and alveoli, with little involvement of the larger airways. Despite the term "extrinsic allergic alveolitis," another commonly used name for this disorder, low-grade eosinophilia, is only seen in 1% to 3% of bronchoalveolar lavage specimens and is not a consistent or characteristic feature of disease. Over time, this pattern of inflammation leads to destruction of alveoli and to irreversible pulmonary fibrosis that may be fatal.

The etiology of HP is frequently idiopathic, but many cases can be traced to exposure to organic aerosols that contain thermophilic bacteria (e.g., *Saccharopolyspora rectivirgula*) commonly found in heated water reservoirs such as room humidifiers and hay; filamentous fungi (e.g., *Aspergillus* spp.); animal proteins and fecal matter (e.g., pigeon breeder's disease); and industrial chemicals such as isocyanates. Symptoms including chest tightness, chest pain, dyspnea, and fever appear 4 to 6 hours after exposure. Removal of the offending antigen may prevent the progression to chronic, irreversible disease. Other than oxygen therapy in the setting of profound hypoxemia, there is no defined medical therapy for HP; specifically, there is no role for glucocorticoids.

The immunopathogenesis of HP is complex and not well understood. During the acute presentation, HP is thought to be initiated by an immune-complex-mediated hypersensitivity (type III), with in situ immune-complex deposition in the lung interstitium occurring as a result of the interaction of the inhaled antigen and pre-existing IgG antibodies in the alveolar spaces. Complement activation occurs and most likely contributes to the alveolitis and neutrophilia. However, a putative question remains as to why many people with precipitating antibodies to putative HP antigens (precipitins) do not develop actual parenchymal or symptomatic disease. Therefore, according to a two-hit model, antigen exposure associated with genetic or environmental promoting factors provokes an immunopathologic response, mediated by immune complexes in the acute form and by Th1 and likely Th17 T cells in subacute/chronic cases.[47] Subsequent disease stages evolve into predominant mononuclear inflammatory infiltrates consisting of lymphocytes, plasma cells, and foamy macrophages, followed by granulomas. In advanced disease, fibrosis replaces the inflammatory infiltrates.

THERAPEUTIC PRINCIPLES

Indications for Corticosteroids in Sarcoidosis

- Pulmonary involvement:
  - Moderate or severe symptomatic pulmonary disease
  - Progressive pulmonary disease
- Extrapulmonary involvement:
  - Severe ocular, cardiac, hematologic, or central nervous system disease
  - Persistent hypercalcemia
  - Posterior or anterior uveitis that is unresponsive to topical corticosteroids
  - Persistent renal dysfunction
  - Disfiguring skin lesions

CONCLUSIONS

The immunologic lung diseases comprise a diverse group of disorders ranging from idiopathic etiologies to those related to an underlying autoimmune condition. There is likely a complex interplay between the innate and adaptive arms of the immune system and the pro-fibrotic pathways that lead to the development of these various disease states. Future work should focus on better understanding this relationship and, more importantly, translating these findings to the clinical setting. The role of standard immunosuppressive approaches with the ongoing discovery of novel approaches to targeting the immune system, as well as novel anti-fibrotic therapies, will need to be determined.

ON THE HORIZON

- Our understanding of the idiopathic interstitial pneumonias and autoimmune-related interstitial lung diseases has evolved over time. With increased emphasis being placed on diagnosis due to the implications for treatment and prognosis, we are more accurately phenotyping the diseases. This has led to a better understanding of genetic associations and biologic pathways, as well as more accurate identification of risk factors for disease development and progression.
- However, there are still many areas in need of further understanding and research. In the future, determining if risk factor identification and modification can lead to primary and/or secondary prevention strategies in the treatment of immunologic lung diseases will be essential.
- Other therapies that target the immune system also need to be more carefully studied in diseases outside of idiopathic pulmonary fibrosis, including sarcoidosis.

Chronic Obstructive Pulmonary Disease and Emphysema

Tillie-Louise Hackett, Francesca Polverino, and Farrah Kheradmand

The large-scale industrial commercialization, advertisement, and addictive nature of nicotine led to the increase in smoking prevalence in the early to mid-twentieth century. In the following decades, after the surge in mass production and consumption of pre-packaged cigarettes, chronic obstructive pulmonary disease (COPD) became one of the significant causes of death in the world, a devastating legacy that until recently was not matched by progress in understanding disease pathophysiology. Observational studies of smokers in the 1960s that assessed lung function, smoking habits, and acute infection episodes ultimately established the causal link between smoking and COPD.

Historically physicians labeled smokers as "blue bloaters" when they presented with chronic cough and increased mucous production, which characterized a clinical manifestation consistent with chronic bronchitis. Alternatively, smokers were labeled as "pink puffers" when presenting with barreled chest, lung hyperinflation, and flat diaphragms consistent with the lung hyperinflation of emphysema. However, with the advent of comprehensive lung-based immune phenotyping, radiographic, and physiological studies, newer insights into smokers' different endotypes beyond the original description of "blue blotters" or "pink puffers" have emerged. Indeed, patients with chronic bronchitis can present with emphysematous lung changes, and harbor autoreactive immune cells, while the inflammatory signature in those with significant reversible airway obstruction can resemble asthmatic inflammation and is known as asthma/COPD overlap (ACO).[1]

Although most endotypes of COPD invariably result in poor oxygenation and dyspnea on exertion, clinically, they display highly variable disease progression from age-appropriate lung functional decline to rapid, unrelenting deterioration that leads to end-stage COPD and early death. Our current pharmacological interventions rely heavily on bronchodilation and exacerbation prevention, which can provide symptomatic relief but fails to reverse the underlying course of pathological changes in smokers with COPD. The small airways that offer little resistance in healthy lungs are the primary site of obstruction to airflow, as evidenced by post mortem examination of emphysematous lungs. Thereby the term "small airway disease" was introduced because smoking affected both the smaller bronchi, defined by the presence of cartilage in their walls, and the bronchioles. Some of the initial descriptions of COPD were limited to the location and patterns of cigarette-smoke-induced lung damage. However, newer advancements (e.g., imaging, molecular genetics, animal models, etc.) have provided a clearer picture of the pathophysiology of smoking-induced lung diseases, some of which will be highlighted in this chapter.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE DEFINITION AND EPIDEMIOLOGY

The umbrella term COPD is defined by the Global Initiative for Obstructive Lung Disease (GOLD) as a "common, preventable and treatable disease, characterized by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities usually caused by significant exposure to noxious particles or gases".[2] Currently, nearly 10% of the population older than 40 years (11.8% for men and 8.5% for women) are estimated to have COPD.[3] COPD is one of the few chronic diseases where the incidence continues to rise, with the estimated worldwide prevalence increasing over the last 30 years.[4] The increases in global morbidity and mortality are largely attributable to some of the most populous countries in the world (e.g., China, India, Indonesia, etc.), where greater than 50% of men smoke or are exposed to high-level particulate air pollution, complicated by recurrent respiratory infections.[2] Epidemiological studies on the prevalence and morbidity of COPD suggest that the disease burden is underestimated because of underdiagnosis, and smokers often do not seek medical help until the disease is moderately advanced. COPD poses a substantial economic burden on healthcare services globally due to a large number of affected individuals and the lack of disease-modifying therapies.

Clinical Presentation of Chronic Obstructive Pulmonary Disease

Patients with COPD experience three cardinal symptoms: (1) dyspnea at rest or upon physical activity, (2) increased sputum production, and (3) chronic cough. Clinically, the gold standard for diagnosing COPD is the detection of airflow obstruction using spirometry. The GOLD recommendations define airflow obstruction as a post-bronchodilator forced expiratory volume in 1 second (FEV_1) ratio over forced vital capacity (FVC) of less than 0.7.[2] Following a diagnosis, the severity of COPD is further categorized by the extent of FEV_1 airflow limitation (Table 73.1)

Patients with a more severe type of disease often experience exacerbations, defined as a sustained worsening of respiratory condition, from their stable state and beyond normal day-to-day variations. Exacerbations are thought to be primarily triggered by respiratory viral infections, but bacterial or fungal infections and environmental factors may also initiate these events to a lesser degree.[2] These events are acute in onset and may warrant additional treatment or hospitalization in patients with underlying COPD. Longitudinal data have shown that exacerbation

TABLE 73.1 The GOLD Classifications for the Severity of Airflow Limitation in COPD

Classification of Severity of Airflow Limitation in COPD		
GOLD Stages	**COPD Severity**	**FEV_1 (% of predicted)**
GOLD-1	Mild limitation	≥80%
GOLD-2	Moderate limitation	50–79
GOLD-3	Severe limitation	30–49
GOLD-4	Very severe limitation	<30

rates in the first year of follow-up are 0.85 per person for patients with GOLD-2, 1.34 for patients with GOLD-3, and 2.00 for patients with GOLD-4.[5] Thus, the COPD recommendations have been revised to combine COPD assessment tools incorporating spirometry, with patient-reported outcomes/symptoms and exacerbation rates.

A revised grading system has been used to identify COPD patients in four distinct classes ranging from A to D (https://goldcopd.org). In addition to using post-bronchodilator FEV_1 measurements, this more comprehensive approach adds the impact of clinical symptoms using the modified Medical Research Council (mMRC) dyspnea scale and the COPD Assessment Test (CAT). The final additional stratification uses the number of COPD exacerbations in the previous 12 months. One significant advancement of the newer system is that the A-D grading factors in features related to clinical presentations in smokers, where measurement of FEV_1 alone may not account for disease severity or prediction of the therapeutic needs of COPD subtypes (Table 73.2).[6] This more comprehensive classification scheme allows for more reliable predictions as to COPD severity.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE CLINICAL SUBPHENOTYPES

Chronic Bronchitis

Chronic bronchitis is defined as persistent cough with sputum production for at least three months over two consecutive years. Increased mucus production and secretion are attributed to mucous gland hypertrophy and bronchial epithelial goblet cell metaplasia. The Reid Index has historically been used to quantify the thickness of the mucous glands with airway wall thickness. Chronic bronchitis is associated with inflammation within the central airways (defined as larger than 4 mm in internal diameter), transformation into the mucus-producing glands, and thickening of the bronchial wall associated with extracellular matrix deposition. While most smokers will develop chronic bronchitis during their lifetime, the presence of chronic bronchitis alone does not predict the development or progression of airflow limitation. These observations suggest that the cough and sputum production that characterize chronic bronchitis can occur in parallel or independently of the disease process responsible for airflow obstruction in COPD patients.

Emphysema

Emphysema is characterized by abnormal enlargement of airspaces distal to the terminal bronchioles accompanied by the destruction of their walls and without obvious fibrosis. A more quantitative clinical noninvasive thoracic CT imaging has been used to validate radiographic correlations with regional lung function and to quantify emphysema (<−950 Hounsfield Units (HU). However, the spatial resolution of clinical CT scans, 800 to 1000 μm, does not permit analysis of the smallest conducting airways or parenchymal structures. MicroCT has been used to image tissue samples from explanted lungs from patients with very severe (GOLD-4) COPD and provided the first evidence that terminal bronchioles are destroyed in end-stage COPD, even in regions of the lung with no emphysema. Koo et al.[7] demonstrated that terminal and first-generation respiratory (e.g., transitional) airways and bronchioles are lost in lung tissue in which no emphysematous destruction is present. These findings indicate that small airways disease could represent an early pathological feature of mild and moderate COPD and that lung destruction may occur in stages. Three distinct histopathological forms of emphysema have been described based on the location of lung parenchymal loss compared to normal lung (Fig. 73.1A):

1. *Centrilobular emphysema (CLE)* is the most common form of emphysema primarily associated with cigarette smoking. CLE often develops first in the upper lobes and/or the superior segment of the lower lobes of the lung. As the disease progresses, it can be radiologically detected throughout the lung. CLE is characterized by enlargement of the centriacinar space, occurring in the proximal respiratory bronchioles, often leaving the alveolar ducts and sacs intact (Fig. 73.1B). MicroCT-based research studies that measure emphysema are only performed using human lung cadaveric tissue.
2. *Panlobular emphysema (PLE)* primarily occurs in smokers with α1-antitrypsin (A1AT) deficiency. Abnormal A1AT or complete lack of expression fails to counteract or inhibit neutrophil elastase, leading to widespread destruction of the connective tissue network, including elastin fibers. As illustrated in Fig. 73.1C, PLE is characterized by uniform dilation of the airspaces from the respiratory bronchioles to the alveoli, resulting in homogeneous destruction of the secondary lobules (acini).
3. *Paraseptal emphysema (PSE)* can present alongside lung fibrosis and can coexist with the other subtypes of emphysema. As shown in Fig. 73.1D, PSE is characterized by enlargement of the airspace at the periphery of the acini. Large paraseptal lesions or bullae favor a sub-pleural site of formation, whereas milder changes are often observed deeper within the lungs adjacent to the connective tissue septae. Patients with

TABLE 73.2 ABCD Criteria for the Severity of COPD

Classifications	Exacerbation History	mMRC/CAT score	Risk/Symptoms
A	<1 or no hospitalization	0–1/CAT<10	Low risk, fewer symptoms
B	<1 or no hospitalization	>2/CAT>10	Low risk, more symptoms
C	>2 or >1 hospitalization	0–1/CAT<10	High risk, fewer symptoms
D	>2 or >1 hospitalization	>2/CAT>10	High risk, more symptoms

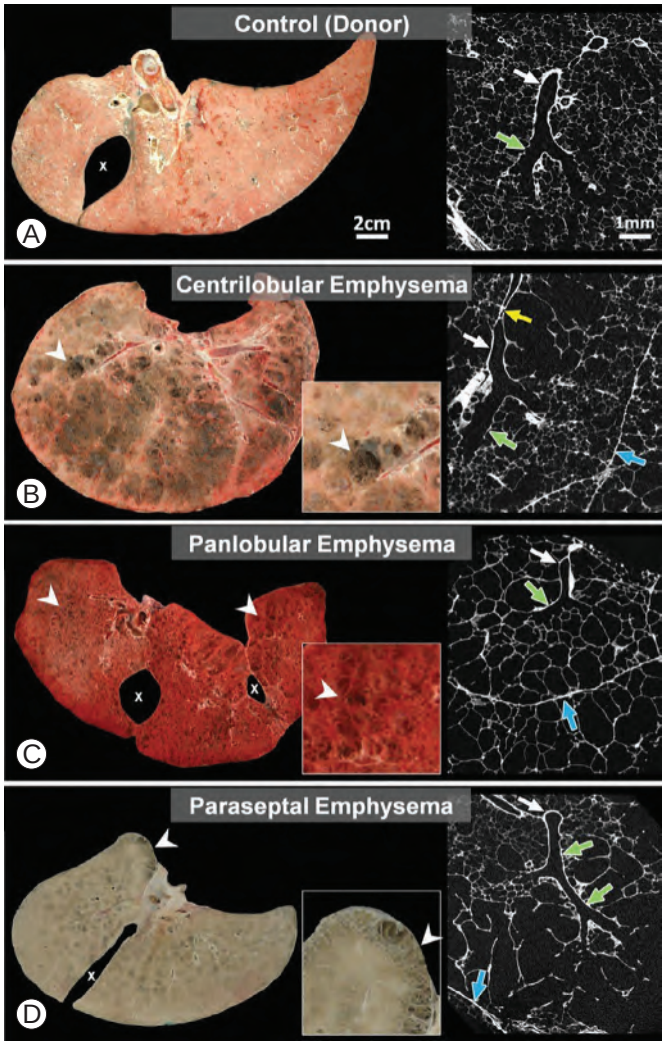

FIG. 73.1 Frozen Lung Slices and microCT Images Illustrating the Subtypes of Emphysema. (A) Normal appearance of parenchyma in the control lung slice and the microCT image shows a terminal bronchiole *(white arrow)* connected to respiratory bronchioles *(green arrow)* and intact, normal alveoli. (B) Advanced centrilobular destruction in the lung slice *(white arrows)* and microCT scan showing narrowing of the terminal bronchiole *(yellow arrow)*, dilation, and destruction of the proximal respiratory bronchioles *(green arrow)*, with sparing of the alveoli adjacent to the septa *(blue arrow)*. (C) Contrastingly, panlobular emphysema shows relatively mild destruction on the gross specimen, and the microCT scan shows uniform destruction of the alveoli proceeding up to the lobular septa *(blue arrow)*. The terminal *(white arrow)* and respiratory *(green arrow)* bronchioles appear normal. (D) paraseptal emphysema shows characteristic lesions *(arrowheads)* beneath the pleural surface in the lung slice. The microCT scan shows alveoli adjacent to the lobular septa are dilated and destroyed *(blue arrow)*, with preservation of the center lobule. The terminal *(white arrow)* and respiratory (green arrow) bronchiole appear normal. Fig. 73.1 is reproduced from a statement from the Fleischner society Lynch et al., 2015.[8]

paraseptal emphysema are typically asymptomatic, but the condition is associated with spontaneous pneumothoraces in young adults.

Chronic Bronchitis with Emphysema Features

Histological studies of explanted COPD lung tissue and airway biopsies have shown that airway remodeling and emphysema can occur in the large airways and lung parenchyma. Airway remodeling is the term used to describe structural changes within airway walls caused by inhalational injury followed by induction of chronic inflammation. Small airways show an accumulation of mucus in the lumen, which contributes to luminal obstruction. Mucus exudates may be caused by aspiration of mucus from the larger proximal bronchi or by secretion of mucins by goblet cells in the small airway epithelium itself. Inflammatory cells are recruited from the circulation to the small airways and accumulate within the airway walls and appear in inflammatory exudates within the lumen. Furthermore, with increasing disease severity, there are increased numbers of lymphoid aggregates that contain follicles[9] in the airway wall and scattered throughout the parenchyma, indicating activation of the adaptive immune system, which underlies lung destruction.[10] Each of the aforementioned pathological features shown in small airways has been consistently found in many studies and is associated with the severity of airflow obstruction in COPD.

Clinical Aspects and Diagnosis of Chronic Obstructive Pulmonary Disease

COPD is a highly heterogeneous disease; therefore, lung disease in patients may not be completely captured by the original GOLD classification or the revised ABCD description. These shortcomings in identifying COPD patients' specific characteristics have contributed to the failure to capture meaningful outcomes in multiple clinical trials. For example, it has become more evident, although not widely accepted, that a more precise measurement of lung parenchymal abnormality should include CT scanning, which can provide an exact location and quantification of lung parenchymal destruction in smokers.[11] A clear definition of the lung (airways and parenchyma) changes with or without symptoms is necessary to provide a better COPD characterization in smokers. Specifically, a chest CT can distinguish smokers who have airway disease (AD), parenchymal destruction (emphysema), or a combination of the two. Importantly, nearly 20% of patients with normal lung function tests (e.g., FEV_1 or FVC that are used for spirometric criteria in COPD diagnosis) have emphysema based on chest CT scan.[12] These findings indicate that physiological lung measurements in COPD diagnosis are insufficient for detecting smoke-induced lung pathologies. Indeed, careful examination of immune cells in the lungs has confirmed that the pathobiology of emphysema and airway disease are distinct and represent different pathogenic processes.

Obstructive and Emphysema Phenotypes

Proper identification of patients with the obstructive phenotype (e.g., a predominance of AD) is clinically relevant because patients with severe emphysema have more exacerbations and

are more likely to be hospitalized and die within three years as compared to patients with predominant AD.[13] Furthermore, from a clinical standpoint, patients with emphysema, compared with patients with AD, have an accelerated loss of lung function and enhanced loss of tissue mass in several other body compartments and show higher mortality than patients without emphysema.[14] In clinical practice, both visual and quantitative CT scans have become instrumental in the diagnosis and management of patients with COPD. Quantitative CT provides useful information regarding emphysema, airways, and air trapping and provides a means of objectively characterizing and following these pathologic processes. CT has been instrumental in showing that small airways disease/loss is evident even in low COPD stages (GOLD 1-2) and correlates with disease progression. Although microCT can measure the extent of emphysema in human lung tissue, it is exclusively used for research. However, other radiographic images, such as a high-resolution CT scan (HRCT), allow an in-depth assessment of emphysema and air trapping subphenotypes in COPD patients. In two large cohorts, (COPDgene (www.copdgene.org) and SPIROMICS (www.spiromics.org), HRCT scans were used to differentiate COPD subphenotypes. Four main subphenotypes that have emerged using radiographic studies of two large COPD cohorts are:

1. Chronic airflow obstruction defined by a low post-bronchodilator FEV_1/FVC
2. HRCT-defined emphysema (low attenuation at total lung capacity)
3. Hyperinflation or gas trapping on HRCT, defined as low attenuation of the lungs at low lung volume (functional residual capacity)
4. Airway inflammation/disease (bronchial wall thickening on HRCT; bronchiectasis).

Thus, the HRCT scan can provide more in-depth phenotyping of the lungs in patients with COPD. However, a comparison of chronic airflow obstruction versus emphysema showed striking disagreement between spirometric and HRCT-defined emphysema (regardless of disease severity),[15] further highlighting the insensitive nature of some of the commonly used diagnostic tools in COPD. HRCT scan is associated with high costs, radiation exposure, and a high incidence of false-positive findings (e.g., indeterminant pulmonary nodules). However, low-dose CT (LDC) scans could provide accurate information about lung parenchyma disease and will undoubtedly become the first-line choice in phenotyping emphysema in COPD patients.

Asthma-Chronic Obstructive Pulmonary Disease Overlap

Asthma-COPD overlap (ACO) in former or active smokers is defined by persistent airflow limitation with several clinical features usually associated with asthma (e.g., reversible obstructive airway disease) and those associated with COPD (chronic productive cough).[16] However, whether or not it represents a distinct clinical entity *per se* is still debated. A consensus statement on the clinical definition of ACO includes the following six criteria:

1. Three major (persistent airflow limitation, tobacco smoking, and previous asthma or reversibility >400 mL FEV_1), and,
2. Three minor (history of atopy or rhinitis, at least two positive bronchodilator tests, and ≥300 blood eosinophils per μL).

CT shows a higher emphysema index and a more significant upper-zone-predominant distribution of emphysema in patients with ACO than non-smokers with asthma. However, no specific pattern(s) of radiographic findings has been conclusive in the diagnosis of ACO.

Early Chronic Obstructive Pulmonary Disease

The diagnosis of "Early COPD" has been used to indicate the age of COPD onset in smokers who present with airway obstruction and are younger than 50 years of age.[17] This clinical distinction is different from detecting mild COPD in older individuals who may or may not have a progressive disease. Chronic lung conditions in young adults may begin due to prenatal or perinatal factors such as premature birth and bronchopulmonary dysplasia, or postnatal factors (e.g., environmental exposures, maternal smoke, childhood infections), which can cause persistent airflow limitation. However, little is known about those who develop COPD in their early adulthood because COPD is most often associated with smokers past the sixth or seventh decade of life. Thus, there is a critical need for improved distinction between the various phenotypes and pathophysiological mechanisms that begin in childhood and often lead to chronic airflow limitation and early diagnosis of COPD. In clinical practice, physicians rely heavily on pulmonary function tests, even though these are global measures that are not sensitive enough to detect an early obstruction and/or minor changes over time. The combination of proton MRI with hyperpolarized-gas magnetic resonance imaging (MRI) is a noninvasive imaging modality that provides multi-faceted structural and functional information, maps of gross parenchymal abnormalities, regional ventilation, alveolar-airspace size, and gas exchange abnormalities (^{129}Xe MRI). These techniques could provide a useful and safe tool to follow patients with pulmonary childhood diseases longitudinally who have a predisposition to developing fixed airflow limitation.[18]

Immunological Mechanisms of Chronic Obstructive Pulmonary Disease

Chronic inflammation is a central and well-recognized feature of the underlying lung disease pathogenesis in COPD.[2] Some of the initial studies that explored lung inflammation used immunohistochemistry (IHC) in biopsies or resected lung tissue to identify immune cell profiles in the lungs of COPD patients. The cross-sectional IHC-based examination of the lung inflammation in different stages of COPD captures one time-point in the disease pathogenesis; however, the progressive nature of COPD does not follow an exact temporal sequence marching from GOLD stage 1 to 4. Thus, the lack of longitudinal human lung tissue sampling makes it less clear whether the development of progressive disease is associated with innate immune responses that precede adaptive immune responses. Similarly, it is unclear whether small airway disease precedes emphysematous changes in COPD. Cigarette smoke can induce epigenetic reprogramming, remodeling, and hyperplasia of airway basal cells, the stem/progenitor cells that are central to pulmonary host defense, even in the absence of inflammatory cell infiltration.[19] Small airway epithelium basal/progenitor cells from smokers, with and without COPD, are limited in their ability to regenerate a fully differentiated epithelium and present abnormalities in airway epithelial junction formation. These findings support the hypothesis that decreased self-renewing cells and airway basal progenitor cells may relate to reduced lung function in smokers.

Little is known about the initial steps in the activation and recruitment of the innate and adaptive immune cells in COPD. It was initially postulated that innate immune inflammation drives the mild stages of COPD, whereas, in more advanced COPD, adaptive T and B cell responses become predominant. However, the recruitment of innate and adaptive immune responses might not be sequential. Specifically, cigarette smoke triggers pattern recognition receptors to release "danger signals" that act as ligands to Toll-like receptors, triggering the production of host-derived damage-associated molecular patterns (DAMPs) and cytokines and activating innate immune cells such as epithelial cells and macrophages. Levels of several DAMPs, including S100 proteins, defensins, and high-mobility group box-1 (HMGB1), are increased in extracellular lung fluids of COPD patients. Macrophages that are initially recruited into the lungs of smokers have dysregulated capacity to secrete proinflammatory mediators and proteases. However, they can induce oxidative stress, engulf microbes and apoptotic cells, and express surface and intracellular markers. Lung dendritic cell (DC) subsets have also emerged as critical mediators in both pathological processes from the earliest to the later stages of COPD pathogenesis. Specifically, there is strong emerging evidence that a subset of smokers develops autoimmune inflammation that is linked to the loss of tolerance to self and is driven in part by the activation of CD1a+ lung DCs. Emphysema, a major COPD subphenotype, is characterized by specific innate and adaptive immune profiles and is described below.

Evidence for Autoimmunity in Emphysema

Recent basic and translational studies have highlighted that the immunopathogenic hallmarks of emphysema are very distinct from AD. Similarly, network analysis of lung transcriptomics distinguished bronchiolitis and emphysema based on distinct molecular signatures, independent of airflow limitation severity. The pathobiology of emphysema in humans is associated with the activation of adaptive immunity, whereby antigen-specific CD4, CD8 T cells, and B cells have been identified. Studies using human lung tissue have identified extramedullary lymphoid follicle formation around the airways of active or former smokers characterized by the presence of autoreactive immune cells such as T-helper type 1 (Th1) expressing IFNγ, and Th17 cells expressing IL-17A, that correlate with emphysema severity. Specifically, emphysematous lung harbors antigen-specific Th1 and Th17 cells that secrete cytokines and chemokines, which further enhance the release of matrix metalloproteinases as compared to smokers without emphysema.

In preclinical models of cigarette smoke-induced emphysema, IL-17A, IFNγ expressing CD4 T cells (Th17 and Th1 respectively), and IFNγ expressing CD8 T cells are increased in the lungs. Preclinical studies of emphysema have shown that Th17 cells are partially responsible for the persistence of lung inflammation, as IL-17A signaling can induce and stabilize the transcripts of downstream chemokines, and mice lacking IL-17A are protected against emphysema development. Both IL-17 and IFNγ can induce proteolytic enzyme release from macrophages and neutrophils. $CD1a^+$ conventional dendritic cells (cDCs) are the primary lung antigen-presenting cells that induce Th17 cell differentiation through the action of a secreted cytokine, osteopontin (*Spp1*). To further support a role for adaptive immunity in the pathogenesis of emphysema, mice lacking IL17A or its receptor are highly protected from cigarette smoke-induced emphysema, and *Spp1* knockout mice manifest attenuated emphysema. These studies suggest redundant IL-17A induction pathways that include osteopontin but expand to other possible proinflammatory mediators. In contrast to the induction of proinflammatory mediators, a reduction in anti-inflammatory factors such as peroxisome proliferator-activated receptor gamma (PPARG/Pparg) and C1Q in lung innate immune cells (DCs, and macrophages) in humans and mice exposed to chronic smoke have been reported. In a preclinical therapeutic model of emphysema, exogenous restoration of Pparg or C1Q resulted in the attenuation of lung inflammation and emphysema. These studies provide hope that emphysema could become a treatable disease in the future by targeting specific proinflammatory pathways.[20]

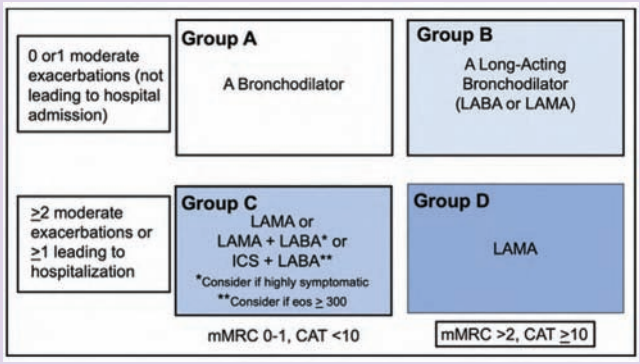
Evidence for Type 2 Inflammation in Asthma Chronic Obstructive Pulmonary Disease Overlap

Increased sputum eosinophils are present in both the stable and exacerbation phase of patients with COPD, implying the potential role of eosinophils in the pathogenesis of COPD. Eosinophilia is generally defined as greater or equal to 2% eosinophils in either blood or sputum or an absolute blood eosinophil count of 0.34×10^9 cells per liter. A subset of COPD patients present greater than 2% blood eosinophil count, which has been called "high eosinophil-COPD." Consistently in asthma and COPD, sputum eosinophilia is associated with an excellent response to corticosteroid therapy and strategies aimed to normalize sputum eosinophils to reduce exacerbation frequency and severity. Thus, the new GOLD guidelines in COPD suggest that high blood eosinophil counts (≥300 eosinophils/μL) could be used to identify patients with a greater likelihood of a beneficial response to inhaled corticosteroids (ICS). Eosinophil inflammation might be a common mechanism underlying the pathogenesis of ACO. However, eosinophils are recruited in the airway and play a key role in eradicating fungi,[21] further highlighting the need to identify mucosal fungal colonization in the airways of patients with ACO. Future studies are needed to clarify our understanding of fungal infections, eosinophil recruitment to the airway, and the consequence of eosinophil infiltrate to develop new therapies for ACO.[22]

Therapy

Evidence-based clinical guidelines for the diagnosis and management of COPD are now widely available. However, several studies on COPD have demonstrated that clinical practice may deviate significantly from guideline recommendations. The most recent clinical trials and longitudinal studies have repeatedly shown that current treatments for COPD (inhaled bronchodilators and steroids) can only relieve symptoms and reduce the frequency of exacerbations but do not improve disease outcomes over time.[23] Therefore, over 3 million COPD-related deaths occur per year worldwide.[24] To date, progress has been hampered by the heterogeneity of disease mechanisms and phenotypic expression. Perhaps more importantly, the presence of spirometrically detected airflow obstruction is not sensitive enough to detect early abnormalities in lung health or capture the endotypes and phenotypic heterogeneity of smoking-related lung disease.

TABLE 73.3 The GOLD Guidelines for Pharmacologic COPD Treatment



Abbreviations: Eos: blood eosinophil count in cells per microliter; LABA: long-acting beta-agonists; LAMA: long-acting muscarinic antagonists; ICS: inhaled corticosteroids; mMRC: modified Medical Research Council dyspnea questionnaire; CAT™: COPD Assessment Test™

Several important lifestyle changes are appropriate for all patients with COPD, including smoking cessation, avoidance of environmental pollutants, physical rehabilitation, vaccination against respiratory infections, and education about medication usage and inhaler technique. Smoking cessation can achieve a reduction in terms of all-cause mortality, even if those interventions are successful only in a minority of patients. Similarly, pulmonary rehabilitation that includes exercise, promotion of healthy behaviors, education, adherence to medication, and psychological support, has been shown to improve life quality, decrease dyspnea, decrease health care utilization and eventually reduce hospitalization and mortality of COPD.

KEY CONCEPTS

Immunopathogenesis of COPD

- Airway disease is characterized by (1) infiltration of innate and adaptive immune cells, and in particular neutrophils, monocytes/macrophages, and CD4, and CD8 T lymphocytes; (2) airway wall thickening, epithelial metaplasia, goblet cell hypertrophy, and smooth muscle hyperplasia of the walls of airways that are less than 2 mm in diameter (small airways)
- Emphysema is characterized by (1) an imbalance between protease and antiprotease activity due to chronic inflammation that can promote oxidative stress; and (2) activation of the innate (monocytes/macrophages, $CD1a^+$ DCs), and increase in adaptive immune (CD4, CD8 T, and B lymphocytes) with autoimmune features such as elastin-specific CD4 T cells, and size of B-cell-rich lymphoid follicles, and in circulating and pulmonary B-cell-secreting autoantibodies.
- Abnormal alveolarization during lung development in early life due to maternal smoking, prematurity, chronic infection, or genetic factors (e.g., A1AT) contributing to the lifetime burden of emphysema (Early COPD)
- Environmental factors. Inhalation of environmental pollution resulting from incomplete combustion of organic matter (indoor cooking with biomass fuel, industrial factory air pollution, carbon black, etc.) can promote chronic lung inflammation and emphysema.

The pharmacologic COPD treatment recommended by the current GOLD guidelines is mainly based on the symptoms and exacerbation risk summarized in Table 73.3.

Abbreviations: Eos: blood eosinophil count in cells per microliter; LABA: long-acting beta-agonists; LAMA: long-acting muscarinic antagonists; ICS: inhaled corticosteroids; mMRC: modified Medical Research Council dyspnea questionnaire; CAT™: COPD Assessment Test™.

In the 21st century, clinical management of COPD is moving towards precision-based medicine and individualized treatment approaches that incorporate multiple relevant imaging and physiological approaches to endotype patients. COPD is most often diagnosed when smokers present with shortness of breath, and changes in lung function are highly variable, thus limiting the success of most randomized phase two and three clinical trials. Therefore, future studies are needed to better classify young adults based on their underlying airway, emphysematous, and gas-exchange abnormalities identified with sensitive non-invasive technologies, such as lung MRI, and to establish earlier and patient-tailored therapies that could prevent progression and help alleviate the burden of COPD. There are exciting new goals to initiate global and multidisciplinary COPD commissions to drive new strategies for the prevention, detection, assessment, and treatment of COPD.

ON THE HORIZON

- Future studies are needed to define the clinical COPD endotypes and their circulating and pulmonary cellular signature that can benefit from future therapies targeting specific cellular pathways.
- Examples of selected clinical trials focused on interrupting key immunological pathways or repairing lungs that are registered in the clinicaltrials.gov (i.e., Dupilumab (a monoclonal antibody against IL-4 receptor), FP-025 (an MMP12 inhibitor), umbilical cord mesenchymal stem cells, Benralizumab (a monoclonal antibody against a-5 chain of the IL-5 receptor), RETHINC, etc.).
- Focused research on the importance of disease susceptibility and factors responsible for initiation and perpetuation of emphysema.
- Development of immunologically based diagnostic and prognostic strategies for obstructive and/or destructive features of smoking.
- Clinical studies that reassess the validity of the predominant use of targeted anti-inflammatory approaches.

Immunologic Ocular Disease

Michel M. Sun and Lynn K. Gordon

A broad overview of ocular inflammatory diseases, a highly diverse group of diseases of clinical and research importance, is presented in this chapter. Diagnoses that fall into this category are commonly grouped in terms of location of the primary site of inflammation in the eye: for example, the uvea or sclera. However, categorizing by location is heterogeneous in terms of causative etiology and immune pathophysiology. This chapter presents select common, clinically relevant, or scientifically interesting inflammatory diseases of the eye by anatomic location of inflammation and causative etiology where known. Some main topics of interest include the heterogeneous types of uveitis, neuro-ophthalmic immune-mediated diseases, paraneoplastic syndromes, ocular allergy, and issues in corneal transplant and transplant rejection. Absent from this chapter are topics such as orbital inflammatory diseases or immunologic factors in age-related macular degeneration (AMD). Several cutting-edge topics of active research interest, including the role of commensal microbiota in ocular immunology, cancer immunotherapy–associated ocular complications, and gene therapy, are briefly discussed.

THE OCULAR IMMUNE SYSTEM

The innate immune system of the eye includes the mechanical barriers of the eyelids, lashes, tears, and epithelium. The tear film has extensive antimicrobial properties, and contains secreted immunoglobulin A (IgA), lysozymes, lactoferrin, and peroxidases that protect the ocular surface in the absence of immune sensitization.[1] Additionally, dendritic cells (DCs) and resident macrophages in the conjunctiva and cornea produce antimicrobial substances, inflammatory cytokines, and chemokines, and act as antigen-presenting cells (APCs) of the eye. Mucosal-associated lymphoid tissue (MALT) associated with the conjunctiva and lacrimal glands are the primary locations of acquired sensitization. T cells outnumber B cells on the ocular surface, most of which are CD8 T cells in the conjunctiva, although immunoglobulin-producing B cells have been identified adjacent to lacrimal gland epithelia and contribute to the IgA component of tears.

Immune Privilege

The eye has a unique relationship with the immune system, and is one of few organs protected by immune privilege.[2] Immune privilege was originally defined as sites in the body where foreign tissue grafts can survive for extended periods of time without acute rejection, and is thought to be an evolutionary adaptation to protect indispensable tissues that have limited regeneration capacity.[2] The retina is of true central nervous system (CNS) origin and is protected by a tight blood-retina barrier, similar to that of the brain. Immune privilege of other ocular tissues is mediated by multiple anatomic, physiologic, and immunoregulatory mechanisms. Soluble immunosuppressive factors in the aqueous humor including transforming growth factor-β (TGF-β), neuropeptides such as α-melanocyte-stimulating hormone (α-MSH), vasoactive intestinal peptide (VIP), and others, and expression of immunomodulatory ligands including CD95L, TGF-β, and complement regulatory proteins contribute to ocular immune privilege.[3,4] Other unique mechanisms include low major histocompatibility complex (MHC) class I expression on the corneal endothelium, uvea, retinal pigment epithelium (RPE), and neural retina, peripheral tolerance of eye-derived antigens, and direct inhibition of T cells and preferential induction of T-regulatory (Treg) cells through both soluble and contact dependent mechanisms with ocular resident cells, including retinal glial Müller cells.[5]

The eye also employs mechanisms to actively suppress the systemic immune system response to an antigen introduced into the eye, known as anterior chamber–associated immune deviation (ACAID).[6] In animal models, antigens injected into the aqueous humor without any accompanying danger signal are taken up by APCs of the iris and ciliary body, which enter the venous circulation, bypassing the traditional lymphatic drainage. These APCs migrate through the bloodstream and can induce the formation of immunomodulatory suppressor cells in the thymus and spleen, including CD4 or CD8 Treg cells, marginal zone regulatory B cells, γδ Tregs, and invariant natural killer T cells (iNKT), which result in antigen-specific immune deviation.[6]

The eye uniquely has multiple complex layers of immune protection. However, one consequence of immune privilege is that the same mechanisms that protect the eye from immune activation may paradoxically leave the eye vulnerable to autoimmune diseases by preventing induction of peripheral tolerance.

Tolerance

Central tolerance occurs during T-cell development in the thymus where T cells are exposed to a wide cohort of self-antigens under control of the autoimmune regulator (AIRE) AIRE transcription factor.[7] T cells with high affinity for autoantigens undergo negative selection and apoptotic cell death. T cells with intermediate affinity for self-antigens may be converted to natural Treg cells to promote self-tolerance. Retinal antigens are expressed in the thymus under AIRE transcription factor control and there is detectable elimination of retina-specific T cells during negative selection in the thymus.[7] Thymic expression of ocular-specific genes is variable among individuals, and this variability may correlate with susceptibility to autoimmune uveitis and other ocular diseases. Additionally, the process of central tolerance alone is not sufficient to eliminate all autoreactive T cells.

Self-reactive T cells are further regulated in the process of peripheral tolerance, in which exposure to the cognate antigen in the absence of costimulatory signals, results in T-cell anergy or

conversion to induced Treg cells. Peripheral tolerance of ocular antigens is inefficient, as tissues of the eye are sequestered behind a blood ocular barrier with limited accessibility of unique ocular antigens. T cells that have escaped negative selection in the thymus persist in the periphery in a potentially autoreactive state due to inefficient peripheral tolerance mechanisms.[7]

INFLAMMATORY DISEASES OF THE EYE

The highly vascular nature of the uvea and prominent numbers of resident immune cells, including resident tissue macrophages, DCs, and mast cells, increases the propensity for immunologic disease when privilege is broken. As shown in experimental models of uveitis, privilege can be broken by even small numbers of activated effector T cells,[8] suggesting that the balance is very fine and can be easily tipped, leading to development of ocular inflammatory diseases.

Many systemic autoimmune diseases such as rheumatoid arthritis, sarcoidosis, inflammatory bowel disease, and systemic lupus erythematosus (SLE) develop ocular inflammatory manifestations. A wide variety of ocular involvement and clinical presentations may be seen, including uveitis, scleritis, conjunctivitis, or keratitis.[9] Ocular symptoms may also be the initial presentation of systemic autoimmune diseases, requiring physicians to have a high index of suspicion to make appropriate and timely diagnoses.

Inflammatory diseases can be loosely divided into primarily antibody-dependent or primarily cell-mediated etiologies, with most ocular diseases having contributions from both. Allergic conjunctivitis, atopic keratoconjunctivitis, vernal keratoconjunctivitis (VKC), and uveitis or scleritis associated with the joint diseases rheumatoid arthritis, juvenile idiopathic arthritis (JIA), and reactive arthritis, are believed to be predominantly driven by antibody-mediated mechanisms. Uveitis associated with sarcoidosis, Behçet disease, Vogt-Koyanagi-Harada (VKH) disease, and sympathetic ophthalmia are largely believed to be secondary to cell mediated immunity.[10] The balance between humoral and cellular immunity in these ocular inflammatory diseases frequently directs available treatment options.

Human leukocyte antigen (HLA) associations have been identified for a number of ocular inflammatory conditions. HLA-A29 carries a relative risk of 50, the highest HLA-related correlation, for developing birdshot chorioretinopathy, a form of uveitis.[11] Other associations include HLA-B27 with acute anterior uveitis and HLA-B51 with Behçet disease, among others.[12] It is commonly suggested that HLA expression in these diseases may confer a genetic susceptibility that requires additional insults, such as infection or environmental exposure, in order to result in clinical disease. HLA molecules may uniquely present disease-inducing peptides, facilitate molecular mimicry of endogenous peptides by infectious pathogens, or preferentially select disease-inducing subsets of T cells, among other proposed etiologic mechanisms (Table 74.1).[12]

UVEITIS AND INTRAOCULAR IMMUNE-MEDIATED INFLAMMATION

The uvea is a highly vascularized, middle layer of the eye composed of the iris, ciliary body, and choroid. Uveitis encompasses a spectrum of diseases resulting in inflammation of the uvea, including both infectious and immune-mediated etiologies. This chapter focuses on select non-infectious uveitis and their proposed immune mechanisms.

TABLE 74.1 Human Leukocyte Antigens Associated With Selected Ophthalmic Diseases

Disease	HLA association
Acute anterior uveitis	B27
Birdshot chorioretinopathy	A29
Behçet disease	B51
Sympathetic ophthalmia	A11, DRB1, DR4
Vogt-Koyanagi-Harada disease	DR4, DRB1
Giant cell arteritis	DR4, DRB1
Fuchs heterochromic iridocyclitis	DR53
Diabetic retinopathy	DQB1
Sjögren syndrome	DQB3, DBQ1
Mucus membrane pemphigoid	DR4, DQB1
Epidermal necrolysis	B58
Presumed ocular histoplasmosis syndrome	B7, DR2

HLA, Human leukocyte antigen.

TABLE 74.2 SUN Working Group Descriptors of Uveitis

Category	Descriptor	Comment
Onset	Sudden	
	Insidious	
Duration	Limited	≤3 months in duration
	Persistent	>3 months in duration
Course	Acute	Episode characterized by sudden onset and limited duration
	Recurrent	Repeated episodes separated by periods of inactivity without treatment ≥3 months in duration
	Chronic	Persistent uveitis with relapse in <3 months after discontinuous treatment

Jabs DA, Nussenblatt RB, Rosenbaum JT. Standardization of Uveitis Nomenclature Working G. Standardization of uveitis nomenclature for reporting clinical data. Results of the First International Workshop. *Am J Ophthalmol.* 2005;140(3):509–516.

Intraocular inflammation can be initiated by an antigen-specific or a nonspecific inflammatory response. Nonspecific ocular inflammatory responses can result from surgery, trauma, infections, and other causes of diffuse tissue damage. In contrast, antigen-specific immune responses are those directed against specific ocular antigens that are normally sequestered.[7] Frequently, development of an autoimmune response can be preceded by a viral or bacterial infection. An infectious agent may lead to initiation of an autoimmune response through molecular mimicry in which antigens on the pathogen cross-react with antigens in ocular tissue, or can induce an immune response by leading to breakdown of the blood-ocular barrier, ocular tissue destruction, and release of normally sequestered antigens.[13]

Uveitis is classified anatomically into anterior, intermediate, posterior, and panuveitis, and classified by etiology into infectious, non-infectious, and masquerade.[14] The duration and timing of inflammatory activity can be limited (3 months or less) or persistent, and disease can be acute, recurrent, or chronic (Table 74.2). Remission is defined as inactivity for 3 months or longer without treatment. Anterior chamber cell is a measure of the number of inflammatory cells in the aqueous and is a reliable indicator of inflammatory activity. A standardized grading scheme from 0 to 4+ for anterior chamber cell and flare has been defined to evaluate uveitis severity and monitor disease recovery (Tables 74.3 and 74.4). Aqueous flare is a measure of haziness of the aqueous fluid, reflecting increased protein due to breakdown of the blood-aqueous barrier. Large exudates

TABLE 74.3 SUN Working Group Grading Scheme for Anterior Chamber Cells

Grade	Cells in Field (1 × 1 mm slit beam)
0	<1
0.5+	1–5
1+	6–15
2+	16–25
3+	26–50
4+	>50

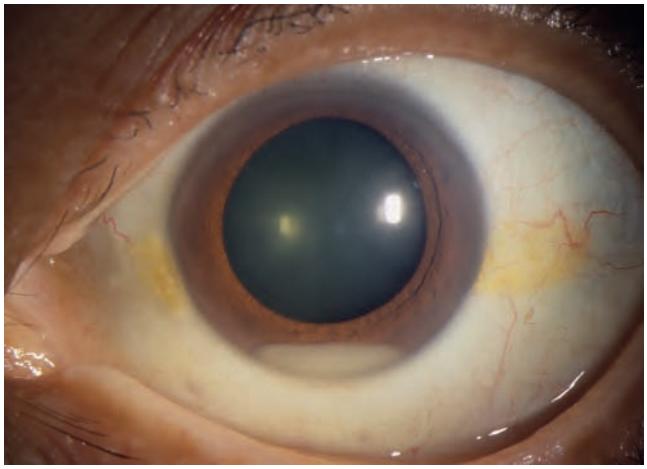

FIG 74.1 Hypopyon. A creamy white exudate rich in white blood cells produced as a result of intense intraocular inflammation. The exudate settles in the dependent aspect of the anterior chamber due to gravity.

of inflammatory white blood cells can result in layering of a purulent hypopyon in the anterior chamber and can also form deposits on the corneal endothelium known as keratic precipitates (Fig. 74.1). Other signs including iris nodules, fibrinous exudates, neovascularization, posterior synechiae, and reduced or elevated intraocular pressure, may also be observed (Figs. 74.2 and 74.3). Acute anterior uveitis is the most common presentation of uveitis. Idiopathic cases are common; however, a work-up to investigate systematic causes should be performed in cases of recurrent, severe, bilateral, or granulomatous uveitis.

Spondyloarthropathies

HLA-B27–associated seronegative spondyloarthropathies including ankylosing spondylitis, psoriatic arthritis, and reactive arthritis frequently have extra-articular manifestations. The most common ocular extra-articular finding is acute anterior uveitis, which is classically unilateral, but can recur in either eye at different times. Bilateral simultaneous involvement is rare. Up to 30% of patients with ankylosing spondylitis,[15] 20% of patients with reactive arthritis, and 10% of patients with psoriatic arthritis develop episodes of acute anterior uveitis, and less commonly may develop conjunctivitis, episcleritis, or scleritis.[16]

Common to all of these diseases is an association with HLA-B27 in rheumatoid-factor-negative joint disease. However, HLA-B27 is positive in approximately 5% of the general population, most of whom do not develop disease. The role of HLA-B27 in disease pathogenesis of the spondyloarthropathies and anterior uveitis is not fully understood. One proposed hypothesis is the arthrogenic/uveitogenic peptide hypothesis, in which HLA-B27 molecules present antigen that shares homology to those in the eye, joints, or other tissue.[17] Antigens from certain commensal gut bacteria, (*Chlamydia*) species, and numerous other organisms have been implicated, with some studies showing cross-reactivity with synovial fluid.[17] HLA-B27 heavy chains have a tendency to misfold, and an alternative hypothesis suggests that misfolding of HLA-B27

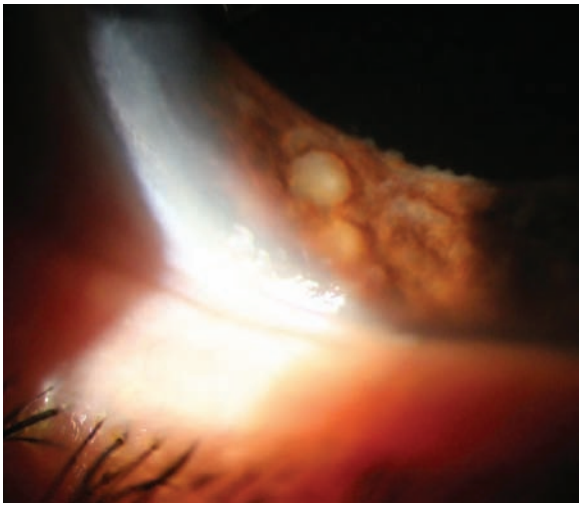

FIG 74.2 Iris Nodules. Bussaca nodules on the iris surface, which are characteristic of granulomatous uveitis. (Image courtesy of Dr. Edmund Tsui, Stein Eye Institute, David Geffen School of Medicine at UCLA.)

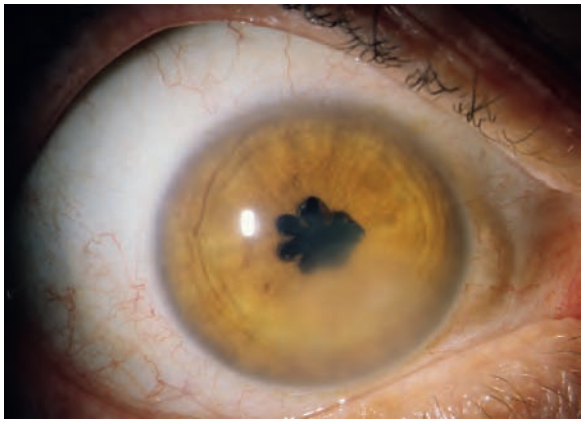

FIG 74.3 Posterior Synechiae. The irregular appearance of the pupil margin is a result of adhesions between the posterior iris and the anterior lens capsule, most commonly formed during states of inflammation. Opacification of the cornea in the inferonasal quadrant is also noted in this patient.

triggers the unfolded protein response, leading to production of proinflammatory cytokines that may play a role in mediating disease. Innate immune recognition of aberrantly folded HLA-B27 has also been proposed.

Juvenile Idiopathic Arthritis

JIA is the most common systemic cause of anterior, bilateral, non-granulomatous uveitis in children. The oligoarticular form is the most common and is also the most likely to develop uveitis. Antinuclear antibody (ANA) seropositivity and HLA-B27 positivity further increases risk of uveitis, which occurs in up to 30% of children with oligoarticular, ANA-positive JIA.[18] In most cases, arthritis is diagnosed before uveitis, and all children diagnosed with JIA should undergo routine eye screening, as the associated uveitis is typically asymptomatic and there may be no external signs of ocular disease in about 50% of affected patients. Patients rarely complain, even in acute exacerbations, making early and periodic screening critical, as undetected uveitis may lead to late complications including cataract, glaucoma, band keratopathy, and irreversible vision loss.

Pathogenesis of intraocular inflammation in JIA is unknown. Both B and T cells appear to be involved, with predominance of CD4 T cells and CD20 B cells identified in biopsy samples. The association with ANA suggests autoantibodies may be involved; however, ANAs have not been demonstrated to be pathogenic. There is a strong HLA association, with HLA-B27, HLA-DR5, and HLA-DRB1 shown to confer increased risk of uveitis, while HLA-CD1 and HLA-DQA appear protective.

Fuchs Heterochromic Iridocyclitis

Fuchs heterochromic iridocyclitis is a unilateral, chronic, low-intensity, non-granulomatous uveitis. Cellular activity in the anterior chamber is typically mild, and flare is faint. The affected eye is heterochromic due to iris stromal atrophy and, most commonly, the affected eye has a lighter iris color. Other ocular manifestations include cataracts in about 80% of patients, glaucoma in up to 59%, and, less commonly, iris nodules and iris neovascularization.

Evidence suggests that the rubella virus may be causative in this disease. Local intraocular synthesis of rubella antibodies in the aqueous humor has been identified in eyes affected by Fuchs heterochromic iridocyclitis, but not in other causes of anterior uveitis.[19,20] Rubella RNA has also been isolated from the intraocular fluid in some cases, and persistent intraocular rubella virus is thought to result in chronic low-grade inflammation in the affected eye. The incidence of Fuchs heterochromic iridocyclitis has declined significantly in patients born in the era of routine measles-mumps-rubella (MMR) vaccination, although incidence may be higher in countries with lower vaccination rates. Additional infectious associations include ocular toxoplasmosis, herpes simplex virus (HSV), and cytomegalovirus (CMV) infections.

Tubulointerstitial Nephritis and Uveitis

Tubulointerstitial nephritis and uveitis (TINU) is a rare immune-mediated disorder characterized by acute tubulointerstitial nephritis and a bilateral, non-granulomatous anterior uveitis. The disease presents most commonly in adolescent girls, with a median age of 15 years, but occurs in males with an age range from 9 to 74. Renal disease typically precedes uveitis, but uveitis can occur prior to renal disease in about 20% of cases; the severity of the renal and ocular disease appears independent.

Disease pathogenesis may involve both dysregulated cell-mediated immunity with loss of T-cell tolerance, as well as humoral immunity with autoreactive antibodies directed against renal and ocular antigens.[21] TINU patients were found to have elevated titers of anti-monomeric C-reactive protein (anti-mCRP) antibodies, targeting an acute phase reactant that deposits in the kidney and is believed to be predictive of developing subsequent uveitis.[21] One leading hypothesis is that an inciting event in the kidney stimulates an HLA class II response that targets an antigen common to the eye and kidney. This antigen could be a yet unknown native protein found in the uvea and renal interstitium, or it could directly be the mCRP acute phase reactant that deposits in both organs.

Sarcoidosis

Sarcoidosis is a chronic systemic disease characterized by non-caseating granulomatous inflammation that can affect any organ system. The disease has a high racial predilection, affecting Blacks 10 times more frequently than Caucasians. Ocular involvement is common in sarcoidosis, affecting 30% to 60% of patients, and can be the presenting symptom/sign of the disease.[22] Any ocular structure can be involved by sarcoidosis, including acute granulomatous anterior uveitis, intermediate, posterior, or panuveitis, optic nerve, or orbit. Sarcoid-associated uveitis is typically characterized by bilateral large granulomatous mutton-fat keratic precipitates, iris nodules, trabecular meshwork nodules, vitreous opacities, chorioretinal peripheral lesions, and retinal phlebitis (Fig. 74.4).

The etiology of sarcoidosis is unknown. Phagocytosis and presentation of an unidentified antigen by macrophages or DCs is thought to initiate formation of sarcoid granulomas through an exaggerated cell-mediated immune response. No single etiologic agent has been clearly implicated; however, mycobacteria, propionibacteria, vimentin, serum amyloid A, environmental exposures, and other agents have all been investigated as having potential roles in the disease pathophysiology.

Behçet Disease

Behçet disease is an autoimmune vasculitis that typically presents with recurrent aphthous oral ulcers, genital ulcers, and uveitis. The disease is more common in patients from eastern Asia, the Middle East, and the Mediterranean, and is strongly associated with HLA-B51. Ocular inflammation occurs in approximately 70% of patients and can be the presenting symptom. A bilateral, acute panuveitis with retinal vasculitis is typically observed, and usually presents with a relapsing and remitting course. The retinal vasculitis can present as a mix of arteritis and phlebitis.

Vasculitis in Behçet disease may cause severe and permanent visual disability and may involve both arterial and venous structures of any size (Fig. 74.5). The etiology is unknown, but it has been proposed to be caused by environmental or infectious triggers that induce inflammatory episodes in genetically susceptible individuals. HLA-B51 is the strongest susceptibility factor; however, other associations have been identified including Interleukin (IL)-23 and IL-10 receptor variants and endoplasmic reticulum aminopeptidase 1 (ERAP1), an enzyme involved in processing of peptides to be loaded onto the antigen-binding groove of MHC molecules.[23] One hypothesis is that ERAP1 polymorphisms may affect the specificity of peptides loaded onto HLA-B51, resulting in activation of a cytotoxic T-cell response or, alternatively, an antigen-independent innate inflammatory response caused by endoplasmic reticulum (ER) stress

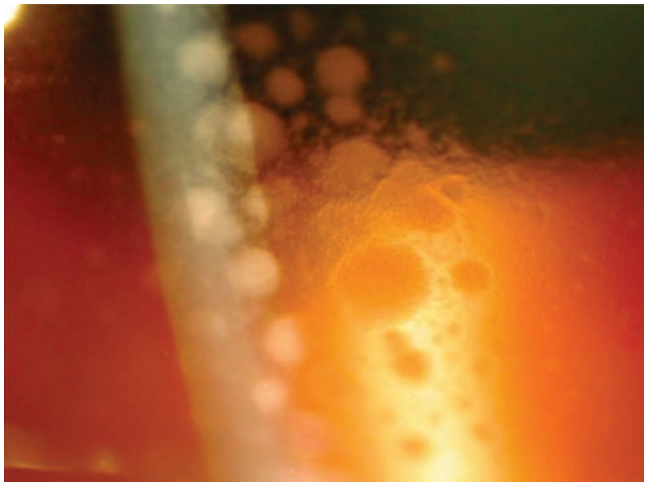

FIG 74.4 Granulomatous Keratic Precipitates. Large, greasy-appearing, yellowish-white mutton-fat keratic precipitates, which are manifestations of leukocyte aggregates adherent to the corneal endothelium. These deposits are characteristic of granulomatous uveitis. (Reproduced with permission from Keenan JD, Tessler HH, Goldstein DA. Granulomatous inflammation in juvenile idiopathic arthritis–associated uveitis. *Journal of AAPOS*. 2008(12):540–550.)

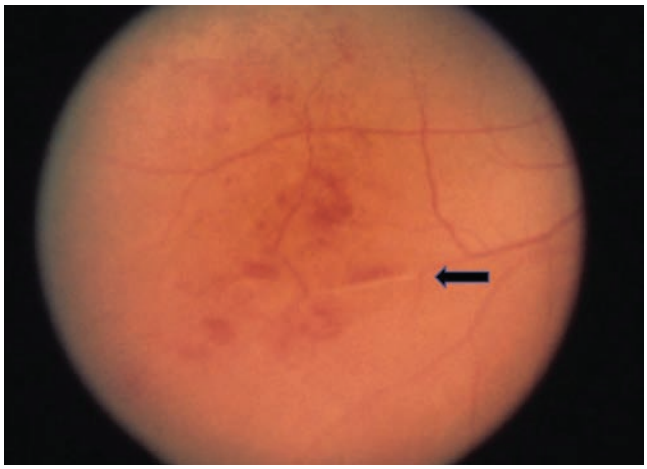

FIG 74.5 Fundus photograph showing retinal vasculitis in a patient with behçet disease. *Arrow* pointing to area of vascular sheathing and occlusion. Vascular occlusion and scattered hemorrhages are prominent.

from inappropriate matches between HLA-B51 and the available peptides.[23] Patients with Behçet disease also have exaggerated innate inflammatory responses, and other hypotheses propose that defects in sensing or processing of pathogen-associated or danger-associated molecular patterns leads to the strong nonspecific inflammatory response characteristic of Behçet disease.

Birdshot Chorioretinopathy

Birdshot chorioretinopathy is a chronic bilateral posterior uveitis predominantly seen in middle-aged Caucasian females. Classically, birdshot chorioretinopathy presents as a white, painless eye with minimal anterior segment inflammation, retinal vascular leakage, and cystoid macular edema in late stages (Fig. 74.6). Over 96% of patients are HLA-A29 positive.[24] An association with ERAP2 has also been identified, suggesting selective antigen processing and presentation on HLA-A29 may create a pathogenic immunogenic signal in this primarily T-cell-mediated disease. The disease-causing antigen is unknown; however, numerous viral antigens have been proposed with potential cross-reactivity against ocular antigens, including the retinal specific S-antigen, intraretinal-binding protein (IRBP), and a number of melanocyte-derived peptides. Increased disease risk is further conferred by specific combinations of killer-cell immunoglobulin-like receptor (KIR) genes, while other KIR genotypes are protective, emphasizing the multifactorial and polygenic nature of this disease.[25]

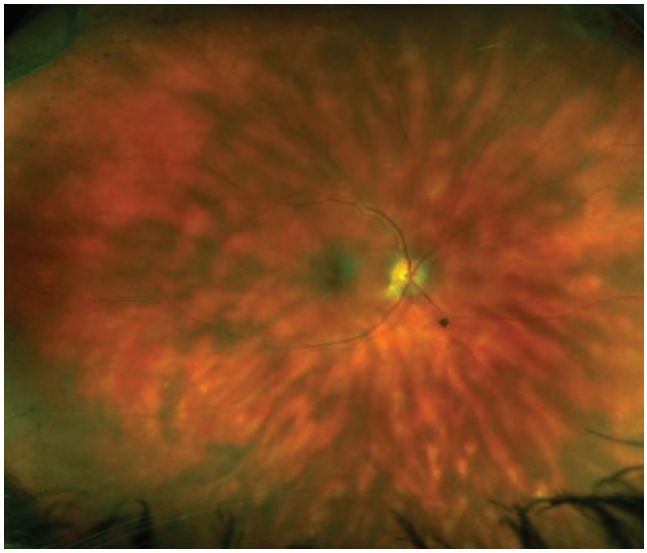

FIG 74.6 Fundus photograph showing multiple small, cream-colored fundus lesions scattered around the optic disc and radiating to the equator in a "shotgun" pattern, typical of birdshot chorioretinopathy. Vogt-Koyanagi-Harada

VKH is an immune, T-cell-mediated disease characterized by bilateral panuveitis in association with neurologic, auditory, and skin manifestations such as poliosis and vitiligo. It may be associated with an autoimmune response against melanin antigens. The associated uveitis may be granulomatous acutely with a thickened choroid, optic disc edema and hyperemia, and serous retinal detachments. Neurologic signs can include headache, cranial nerve abnormalities, cerebrospinal fluid (CSF) pleocytosis, and neck stiffness, and auditory manifestations can include tinnitus, hearing loss, and vertigo.[26,27] Patients are at high risk for complications including cataract, glaucoma, subretinal fibrosis, and choroidal neovascularization.

The incidence of VKH varies worldwide, with the disease common in Asia, the Middle East, and South America.[26] In contrast, the disease is rare in European populations.[26] HLA-DR4, HLA-DR1, HLA-DRB1, and HLA-DRw53 have all been associated with a significantly increased risk for VKH. KIR combinations on natural killer cells and cytotoxic T cells have also been implicated in conferring disease susceptibility.[28] It is hypothesized that certain combinations of HLAs and KIRs preferentially present immunogenic antigen epitopes from melanocyte-associated antigens; however, the exact antigens involved are unknown.[29] Environmental factors such as preceding viral infection, and molecular mimicry between

viral antigens and melanocyte proteins, have been hypothesized to play an inciting role.[27] VKH uveitis has also been reported to be associated with cutaneous pigmented malignant melanoma, with VKH thought to be a consequence of autoimmune reaction against melanoma in patients with good cancer immunosurveillance.[30]

Sympathetic Ophthalmia

Sympathetic ophthalmia is a rare type of bilateral granulomatous uveitis that occurs following penetrating eye trauma or eye surgery in one eye, leading to disease in the fellow eye. The pathophysiology is thought to involve a T-cell-mediated response against ocular self-antigens that are unmasked following trauma that abrogates immune privilege and tolerance mechanisms.[31] Multiple antigens, including rod photoreceptor outer segments, and RPE and choroidal melanocyte antigens, have been suggested to be causative and specific HLA associations have been made; however, the exact mechanisms remain elusive (Fig. 74.7).

The time between the inciting trauma or surgery and sympathetic ophthalmia development is typically rapid, with 80% of patients developing symptoms within 3 months, and 90% within 1 year.[31] Clinical presentation can be varied, with the exciting eye typically having photophobia, decreased vision, and mutton-fat keratic precipitates. Inflammation in the fellow eye may develop insidiously or more rapidly, and classically presents with photophobia, mild pain, epiphora, paresis of accommodation, cells and flare in the anterior chamber, mutton-fat keratic precipitates, and posterior synechiae.[32] Intraocular pressure may either be high from inflammatory cell blockage of trabecular meshwork flow or low due to ciliary body shutdown. Clinical course may have intermittent episodes of acute inflammation with highly variable outcomes. The disease is characterized by a diffuse, granulomatous, non-necrotizing inflammatory response of the entire uveal tract, with cellular infiltrates dominated by T cells. Sympathetic ophthalmia can also present with alopecia, vitiligo, poliosis, and deafness, overlapping significantly with VKH-like symptoms.

Prevention of sympathetic ophthalmia may be possible with enucleation of an injured eye within 2 weeks of the initial insult, especially in cases with little or no prognosis for recovery of useful vision. There is controversy over the benefit of enucleation once disease has begun in the sympathizing eye.

THERAPEUTIC PRINCIPLES

Current Treatment Options for Uveitis

Corticosteroids
- Topical steroids: prednisolone, dexamethasone, difluprednate, loteprednol etabonate, betamethasone, prednisolone, fluorometholone
- Long-term depot steroids: subconjunctival or sub-Tenons steroid deposit
- Intravitreal steroids: intravitreal triamcinolone acetonide, slow-release intravitreal steroid implants
- Oral: prednisone

Steroid-Sparing Agents
- Antimetabolites: azathioprine, methotrexate, mycophenolate mofetil
- T-cell inhibitors: cyclosporine, tacrolimus
- Alkylating agents: cyclophosphamide, chlorambucil
- Biologic therapy: adalimumab (FDA approved for non-infectious intermediate, posterior, and panuveitis)

Ancillary Therapy
- Cycloplegic agents: cyclopentolate, homatropine, atropine
- NSAIDs: naproxen, tolmetin

NSAIDs, Non-steroidal anti-inflammatory drugs.

Uveitis Treatment

Damage from uveitis occurs secondary to inflammatory cell infiltrates and release of inflammatory mediators that facilitate destruction of ocular tissues. The main approach to treating non-infectious ocular inflammation has been to inhibit the activity of the immune response. Topical corticosteroids are common first-choice options for anterior uveitis. Gradual tapering of the corticosteroid is initiated once the inflammation is controlled. The treatment goal is near-complete suppression of inflammation with no anterior chamber cell or flare. Common complications of topical steroids include elevation of intraocular pressure and cataract formation. Ancillary therapy including cycloplegic agents may also be used to prevent formation of posterior synechiae, break formed synechiae, or relieve ciliary muscle spasm.

For more severe cases, or cases where steroid tapering is unsuccessful, long-term depot steroid preparations can be administered via subconjunctival or sub-Tenon routes. Intravitreal triamcinolone acetonide or slow-release intravitreal steroid implants may also be considered in refractory cases. Systemic oral steroids can be used in treatment of refractory disease; however, they come with potential adverse systemic effects. Antimetabolites including azathioprine, methotrexate, and mycophenolate mofetil, T-cell inhibitors such as cyclosporine and tacrolimus, and alkylating agents such as cyclophosphamide and chlorambucil may be useful as steroid-sparing agents for patients with severe or corticosteroid-refractory disease. Newer biologic therapy has proven to be successful in cases where more conventional immunosuppressive therapy has failed, and may be particularly useful in patients with concurrent systemic symptoms. The tumor necrosis factor (TNF) inhibitor adalimumab is the first US Food and Drug Administration (FDA)-approved biologic for the treatment of non-infectious uveitis. Other agents which target inflammatory pathways, including IL-1 and IL-6 inhibitors, may have future roles in the treatment of refractory uveitis.[33]

NEURO-OPHTHALMIC IMMUNE-MEDIATED DISEASES

The eye is an extension of the CNS, and ocular symptoms can frequently manifest concurrently with or as the presenting symptom of a systemic CNS disease. Immune-mediated diseases also frequently target the optic nerve, or neuromuscular junctions (NMJs) of extraocular muscles and can have varying levels of systemic involvement. Topics of neuro-ophthalmic interest that will be presented here include optic neuritis, including the AQP4- and MOG-associated forms, giant cell arteritis (GCA), the Miller Fisher variant of Guillain-Barré syndrome (GBS), myasthenia gravis, and Lambert-Eaton myasthenic syndrome (LEMS).

Optic Neuritis

Optic neuritis, or inflammation of the optic nerve, can arise from demyelinating, autoimmune, and infectious etiologies. It classically presents with acute, unilateral, painful vision loss, with retroorbital pain typically worsening with eye movement. Patients may have visual field loss, color vision deficits, and an afferent pupillary defect. Optic neuritis is a common clinical manifestation of the demyelinating disease multiple sclerosis (MS; Chapter 66). Optic neuritis affects approximately 70% of patients with MS and

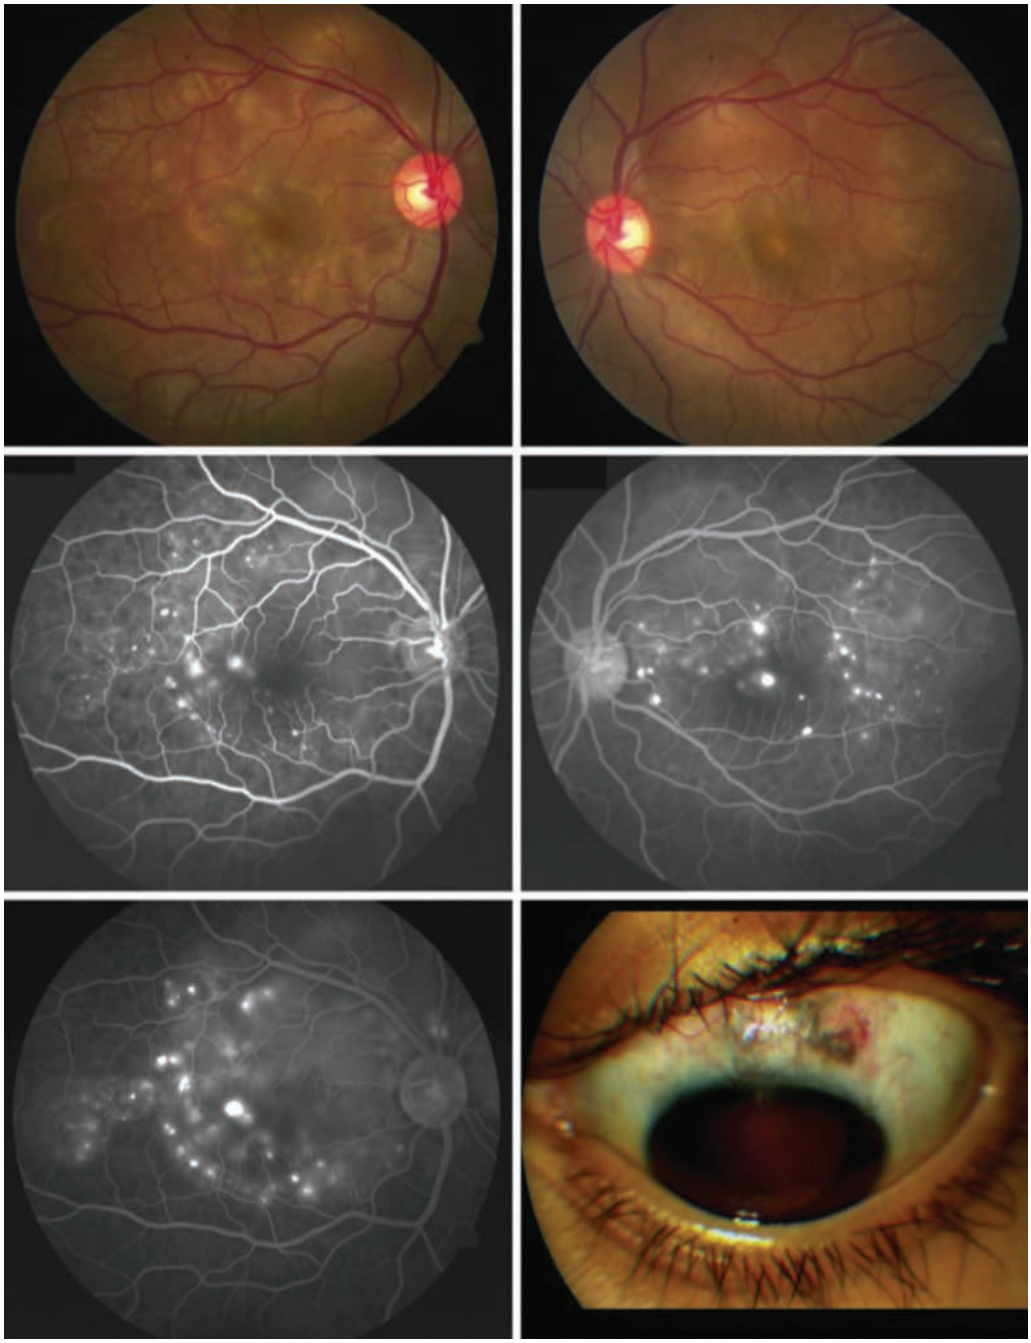

FIG 74.7 Fundus photographs and fluorescein angiography of a patient with sympathetic ophthalmia following a penetrating left eye globe injury. Foci of exudative retinal detachment are present in the posterior poles of both eyes. Fluorescein angiography demonstrating multiple areas of pin-point leakage at the level of the retinal pigment epithelium. (Reproduced with permission from Vasconcelos-Santos DV, Rao, NR. *Sympathetic Ophthalmia*. Ryan's Retina. Chapter 77 Fig. 74.5:14961–504.)

is frequently the presenting symptom of the systemic disease.[34] Magnetic resonance imaging (MRI) is required to evaluate the extent of optic nerve as well as brain involvement. The presence of a single, typical demyelinating lesion on MRI can stratify the risk of developing systemic MS in cases where optic neuritis is the initial presentation. Optic neuritis associated with MS typically results in good recovery of visual acuity, however, there is often permanent damage that is visualized using optical coherence tomography (OCT) to evaluate the retinal nerve fiber layer, as well as the thickness of the retinal ganglion cell and inner plexiform layers of the macular retina.

Two unique forms of optic neuritis have recently been identified that are defined by the presence of specific antibodies: namely, anti-aquaporin 4 (AQP4)-associated and anti-myelin oligodendrocyte glycoprotein (MOG)-associated disease. These forms present with more severe vision loss, are more commonly bilateral, and recur more frequently than typical MS-associated demyelinating optic neuritis.[35]

Neuromyelitis optica spectrum disorder (NMOSD) is an inflammatory CNS condition characterized by a variety of "core" syndromes, one of which is optic neuritis. When optic neuritis is associated with other "core" syndromes that are disseminated

in space and are associated with certain findings on MRI or the presence of antibodies against aquaporin-4 (AQP4), an abundant water channel in the CNS, then the findings meet diagnostic criteria for NMOSD.[36] AQP4 antibodies are shown to be pathologic in animal models, mediating complement activation and cytotoxic damage.[35] The AQP4 water channel is predominantly expressed on astrocytic foot processes, and NMOSD is characterized primarily by astrocytic damage, with oligodendrocyte loss and demyelination as a secondary feature.

Optic neuritis associated with antibodies against MOG is bilateral in about 40% of affected individuals. Edema of the optic disc and recurrences are both common. Optic neuritis may be isolated or may be associated with transverse myelitis or encephalitis. In contrast to AQP4-associated disease, this disease is characterized histologically by oligodendrocyte loss and demyelination in the absence of astrocytopathy.

Management of acute attacks includes high-dose intravenous corticosteroid and may require plasma exchange or intravenous immunoglobulin (IVIG). Management for relapsing disease may require long-term immunosuppressant agents.[37] Patients with NMOSD may benefit from early plasma exchange. Additionally, the complement C5 neutralizing antibody eculizumab has recently been approved by the FDA for the treatment of NMOSD. Non-FDA-approved therapies include B-cell depletion or immunosuppression.

CLINICAL PEARLS

Optic Neuritis

Multiple sclerosis–associated optic neuritis:
- Unilateral, (bilateral presentation is rare)
- Young adults, female predominance
- Acute demyelination
- Good recovery of visual acuity

Neuromyelitis optica spectrum disorder (NMOSD):
- Associated with anti-aquaporin-4 (AQP4) antibodies
- Predominantly astrocyte damage
- Older adults, female predominance
- May have severe visual acuity loss
- 20% bilateral
- Recurrences common
- Poor visual outcome

Myelin oligodendrocyte glycoprotein (MOG)-associated optic neuritis:
- Associated with anti-myelin oligodendrocyte glycoprotein (MOG) antibodies
- Predominantly oligodendrocyte loss and demyelination
- Pediatric and adult, no sex predilection
- 40% bilateral
- May have severe visual acuity loss
- Recurrences common
- Most with optic disc edema
- Good visual outcome

Giant Cell Arteritis

GCA is an autoinflammatory granulomatous disease primarily targeting medium-and large-sized arteries, with DCs, T cells, and macrophages identified as the main drivers of the inflammatory response. Abnormal activation of vascular DCs recruits other immune cells to the vessel wall through the vasa vasorum, a normally immune-protected tissue microenvironment.[38] T cells and large multinucleated giant cells derived from activated macrophages are found in granulomatous infiltrates in affected arterial walls. A reactive vascular injury response can cause endothelial cell damage, intimal hyperplasia, vessel lumen occlusion, and subsequent tissue ischemia that leads to the major clinical complications of GCA. Age is the greatest risk factor for GCA, and likely contributes to the immune and vascular system dysfunction seen in this disease. Most patients with GCA appear to have systemic inflammation, with elevated acute phase markers including erythrocyte sedimentation rate and C-reactive protein.[38] Evidence suggests that circulating blood monocytes and macrophages in GCA patients may be in an abnormally activated state, producing proinflammatory cytokines, including IL-1β and IL-6.[39] The disease also has an association with HLA-DR4, which is commonly associated with other autoimmune diseases such as rheumatoid arthritis.

Clinical presentation of the disease includes headache, jaw or tongue claudication, new neck pain, scalp pain, fatigue, and weight loss. Involvement of the aorta can lead to aneurysm, aortic dissection and rupture. Vasculitis and occlusion of the vessels supplying the eye and optic nerve can lead to arteritic anterior ischemic optic neuropathy (AAION) due to ischemic damage to the optic nerve. AAION classically presents with acute loss of vision in one eye with severe optic disc edema and a relative afferent pupillary defect. Permanent occlusion may be preceded by episodes of transient vision loss or double vision, and if untreated, the risk to the fellow eye is high. GCA is an ophthalmologic emergency and can progress quickly to permanent vision loss.

Diagnosis of GCA is histologic, with temporal artery biopsy showing intimal thickening, internal elastic lamina fragmentation, and chronic inflammatory infiltrate with giant cells. Due to the high risk of vision loss in the fellow eye, early aggressive treatment is recommended prior to biopsy. The gold standard of therapy is high-dose glucocorticoids, and the IL-6 inhibitor tocilizumab is used in select patients as a steroid-sparing agent.

Miller Fisher Variant of Guillain-Barré Syndrome

Miller Fisher syndrome (MFS) is a rare, acute demyelinating peripheral polyneuropathy variant of GBS, occurring in about 5% of cases. Clinically the presenting symptoms include an infectious prodrome followed by diplopia, ptosis, ophthalmoplegia, supranuclear palsies and facial palsies, ataxia, and areflexia. Presence of anti-GQ1b antibodies with a CSF albuminocytologic dissociation is suggestive of MFS. Electromyography (EMG) and nerve conduction studies can also be supportive. The pathologic antibody is targeted against sialylated glycosphingolipids located in neuronal and glial plasma membranes and neuromuscular junctions (NMJs).[40] High concentrations of the GQ1b ganglioside are found in the oculomotor nerve, trochlear nerve, and abducens nerve, explaining the relationship with ophthalmoplegia in this subtype of the disease (Fig. 74.8). Viral or bacterial organisms, including *Campylobacter jejuni*, have been found to contain lipopolysaccharides that are antigenically identical to those on human gangliosides, supporting molecular mimicry as the method of immune sensitization and disease initiation. Treatment includes IVIG, plasmapheresis, and supportive care, with a good overall prognosis.

Myasthenia Gravis

Myasthenia gravis is characterized by autoantibodies against postsynaptic acetylcholine receptors (AChRs) on skeletal muscle leading to dysfunction at the NMJ. Functionally, this leads to impaired signal transduction at the NMJ, resulting in muscle weakness and

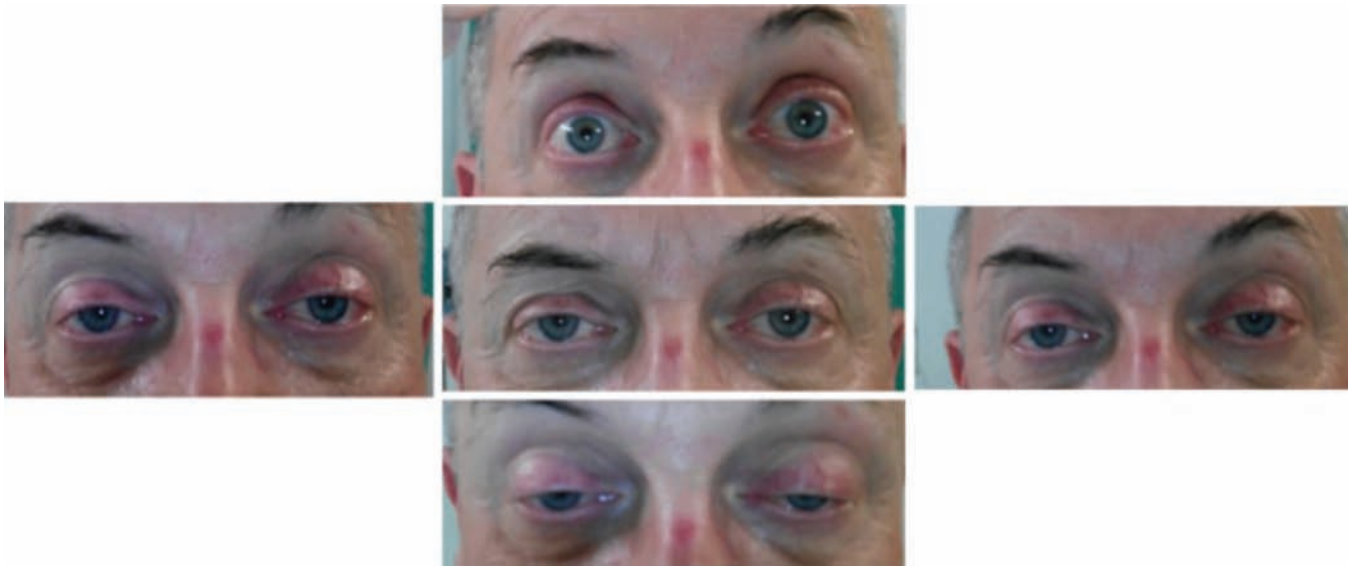

FIG 74.8 Extraocular Motility in a Patient with the Miller Fisher Variant of Guillain-Barré syndrome. There is mild right ptosis and ophthalmoplegia, with decreased movement in all fields of gaze. (Reproduced with permission from Pellegrini F, Prosdocimo G, Barton JJS. *Survey of Ophthalmology*. 2016;61:248–254. See Fig. 74.2.)

fatigability.[41] Typical ocular symptoms include ptosis and diplopia with fatigability of extraocular muscles that worsens with sustained muscle use and improves with cold, rest, and sleep. It can present localized to the palpebral and extraocular muscles, or occur in conjunction with systemic symptoms including difficulty swallowing, change in voice, shortness of breath, and weakness of the extremities. Ocular manifestations are commonly the initial presentation of generalized myasthenia gravis, with most patients developing systemic symptoms within 2 years.[42]

Serologic tests for disease-causing circulating antibodies against nicotinic AChRs are diagnostic; however, many patients are seronegative with no detectable antibodies.[43] Antibodies against other NMJ proteins including anti-muscle-specific tyrosine kinase (MuSK) and low-density lipoprotein (LDL)-related receptor-related protein 4 (LRP4) have also been reported and may be causative in some AChR seronegative cases. Electromyography is diagnostic and may be important in establishing the diagnosis in seronegative patients. Single-fiber EMG, the diagnostic "gold standard," shows characteristic muscle fiber jitter. Repetitive nerve stimulation shows a decrement in the muscle action potential, in contrast to the paraneoplastic mimicker Lambert-Eaton syndrome, which is characterized by increase in amplitude with repetitive nerve stimulation.

Treatment includes acetylcholinesterase inhibitors, most commonly pyridostigmine, for symptomatic management of generalized disease, but may be ineffective for ocular manifestations. Immunosuppressive drugs including glucocorticoids and steroid-sparing agents such as azathioprine and mycophenolate mofetil may be required for treatment of generalized disease. Chest computed tomography (CT) imaging should be obtained in every patient to assess for presence of a thymoma, which, if present, would require thymectomy.[41]

PARANEOPLASTIC SYNDROMES

Paraneoplastic syndromes are those that arise secondary to immune responses against a remote tumor, resulting in autoimmune responses against normal tissue. In some diseases, specific causative antibodies or target antigens have been identified. Seropositivity and a history of known malignancy may suggest the presence of a paraneoplastic syndrome; however, the ophthalmic consequences of these paraneoplastic syndromes are varied in presentation and may precede a cancer diagnosis by months to years, adding to the diagnostic difficulty of this group of diseases.[44] This section describes cancer-associated retinopathy (CAR) and melanoma-associated retinopathy (MAR), the most common paraneoplastic retinopathies, as well as LEMS, a common mimicker of myasthenia gravis. However, other paraneoplastic syndromes have been identified, including bilateral diffuse uveal melanocytic proliferation (BDUMP), polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder and skin changes (POEMS), paraneoplastic optic neuropathy, and opsoclonus-myoclonus, but are not be discussed here. Myasthenia gravis, discussed in the prior section, can result from a primary autoimmune condition, or rarely a paraneoplastic syndrome associated with thymoma or thymic hyperplasia.

Lambert-Eaton Myasthenic Syndrome

LEMS is mediated by antibodies targeting presynaptic P-Q voltage-gated calcium channels at the NMJ, causing a decrease in voltage-gated calcium expression at the synapse, subsequent decrease in calcium internalization, and ultimately decreased release of acetylcholine at the NMJ. Clinical symptoms can be similar to those seen in myasthenia gravis and include proximal muscle weakness, autonomic dysfunction, and hyporeflexia or areflexia. Ocular symptoms include diplopia and a milder ptosis that may, in contrast to myasthenia gravis, decrease with prolonged upgaze. Other features that distinguish LEMS from myasthenia gravis include an improvement in strength or tendon reflexes after muscle use or exercise, and EMG that shows a low-amplitude compound muscle action potential that increases in amplitude with high-frequency repetitive nerve simulation or after maximal muscle contraction.[44]

LEMS is strongly associated with small cell lung cancer, and patients with suspected LEMS are recommended to undergo chest CT imaging first to identify a causative tumor. Treatment of the underlying malignancy can often greatly improve neurologic

symptoms. Other treatment options include amifampridine, a voltage-dependent potassium channel blocker, pyridostigmine, corticosteroids, IVIG, or plasma exchange.

Autoimmune Retinopathies

Autoimmune retinopathies are rare ophthalmic disorders characterized by autoantibodies against retinal proteins leading to progressive visual loss. Anti-retinal antibodies can be paraneoplastic and occur in the setting of an underlying malignancy, with CAR and melanoma-associated retinopathy (MAR) being the most common classic retinal-based paraneoplastic syndromes.

CAR is the most prevalent paraneoplastic retinopathy and is most often associated with underlying small cell lung carcinoma, followed by gynecologic and breast malignancies. Vision loss is typically painless, progressive, and bilateral, and can occur before a systemic malignancy is diagnosed in up to 50% of cases. Molecular mimicry is proposed as the causative mechanism, with tumor cells expressing antigenic epitopes that cross-react with retinal photoreceptors or other retinal antigens. Numerous retinal antigens have been identified, including recoverin, α-enolase, transducin, arrestin, photoreceptor cell-specific nuclear receptor, and multiple others.[45] Recoverin is expressed and functional in many tumors, and anti-recoverin antibodies may have tumor-suppressing effects,[46] suggesting anti-tumor immunosurveillance may be at the cost of retinal autoimmunity in these patients.

MAR typically presents following diagnosis of the primary cutaneous melanoma with a latency of 2 to 19 years and can frequently be a harbinger of non-ocular metastasis.[45] MAR is hypothesized to result from autoantibodies against postsynaptic receptors of the depolarizing ON bipolar cells, disrupting rod photoreceptor transmission, and mediating rod-predominant dysfunction. A wide variety of retinal antigen targets have been implicated, emphasizing the immunologic heterogeneity associated with these paraneoplastic disorders. Rare cases of melanoma patients developing an unusual paraneoplastic vitelliform maculopathy have also been reported, including one patient with circulating autoantibodies against bestrophin,[47] and another with antibodies against an RPE peroxidase.[48]

Treatment for CAR and MAR involves long-term immunosuppression with corticosteroids, with possible benefit from plasmapheresis and IVIG to decrease circulating anti-retinal antibodies. Overall prognosis is poor, with rapid vision loss, and treatment of the underlying malignancy does not appear to improve vision.

EXTRAOCULAR IMMUNE-MEDIATED INFLAMMATION

Ocular Allergy

Allergic conjunctivitis is extremely common and often underdiagnosed and undertreated. It is a type I hypersensitivity, IgE-mediated reaction to a specific allergen, and can be seasonal due to airborne pollens or perennial due to year-round allergens. Activation of mast cells increases histamine, tryptase, prostaglandins, and leukotrienes in tears, as well as activation of vascular endothelial cells to secrete chemokines and adhesion molecules for inflammatory cell recruitment, leading to inflammation in the conjunctival mucosa.[49] Ocular symptoms include conjunctival hyperemia, acute chemosis, and itching. Management includes avoidance of the allergen when possible, topical antihistamines or mast cell stabilizers, topical non-steroidal anti-inflammatory drugs (NSAIDs), or mild topical steroids.

VKC is a nonspecific hyperreactivity reaction mediated by Th2 lymphocytes. It is more common during the spring and summer months in warm climates and is thought to be due to nonspecific stimuli such as wind, dust, and sunlight, rather than airborne allergens. Skin tests and serum IgE tests against common seasonal allergens are often nonreactive. VKC often involves a chronic ocular surface inflammation with increased eosinophils, neutrophils, mononuclear cells, mast cells, and lymphocytes. The formation of giant papillae filled with inflammatory cells and edema on the upper tarsal conjunctiva is a characteristic finding. The cornea can become involved with development of a punctate keratitis that may lead to central scarring and declining vision (Fig. 74.9). Horner-Trantas dots, consisting of clumps of necrotic eosinophils, are a characteristic finding in the active phase of the disease.[49] VKC is more common in children and typically resolves by age 20. Management includes topical antihistamines or mast cell stabilizers, topical steroids, supratarsal injection of steroids, or topical cyclosporine.

Atopic keratoconjunctivitis is a chronic ocular inflammatory disease, considered to be the ocular counterpart to atopic dermatitis. It involves both type I and type IV hypersensitivity with chronic IgE-mediated mast cell degranulation as well as altered T-cell-mediated immunity. Over 30% of patients have a history of atopic dermatitis or other systemic atopy. Patients typically present with chronic papillary conjunctivitis without seasonal variation and eczematous lesions on the eyelids (Fig. 74.10). The presence of giant papillae or Horner-Trantas dots may be variable. Anterior shield-like atopic cataracts may also develop. More severe manifestations can include neovascularization, limbal stem cell deficiency, and corneal opacification. Treatment includes the topical options for VKC but may also require adding systemic therapy for chronic management.

KEY CONCEPTS

Ocular Allergy

Allergic Conjunctivitis
- Type I hypersensitivity—IgE-mediated activation of mast cells
- Reaction to specific seasonal or perennial allergen

Vernal Keratoconjunctivitis
- Nonspecific hyperreactivity with chronic ocular surface inflammation
- Reaction against nonspecific stimuli: for example, wind, dust, sunlight
- Giant papillae on upper tarsal conjunctiva
- Horner-Trantas dots of necrotic eosinophils

Atopic Keratoconjunctivitis
- Type I and type IV hypersensitivity—IgE-mediated activation of mast cells with altered T-cell immunity
- Associated with history of atopic dermatitis and systemic atopy
- Chronic papillary conjunctivitis

Sjögren Syndrome

Sjögren syndrome is a chronic autoimmune disease characterized by a T-cell-mediated destruction of exocrine glands. Classic symptoms include dry eye and dry mouth from progressive damage to the lacrimal and salivary glands. Sjögren syndrome has a 9:1 female to male predominance. It can present as a primary disease or in association with a systemic connective tissue disease, commonly rheumatoid arthritis. Diagnosis of Sjögren syndrome requires the presence of ocular symptoms, including keratoconjunctivitis sicca, and ocular surface damage from dryness of the

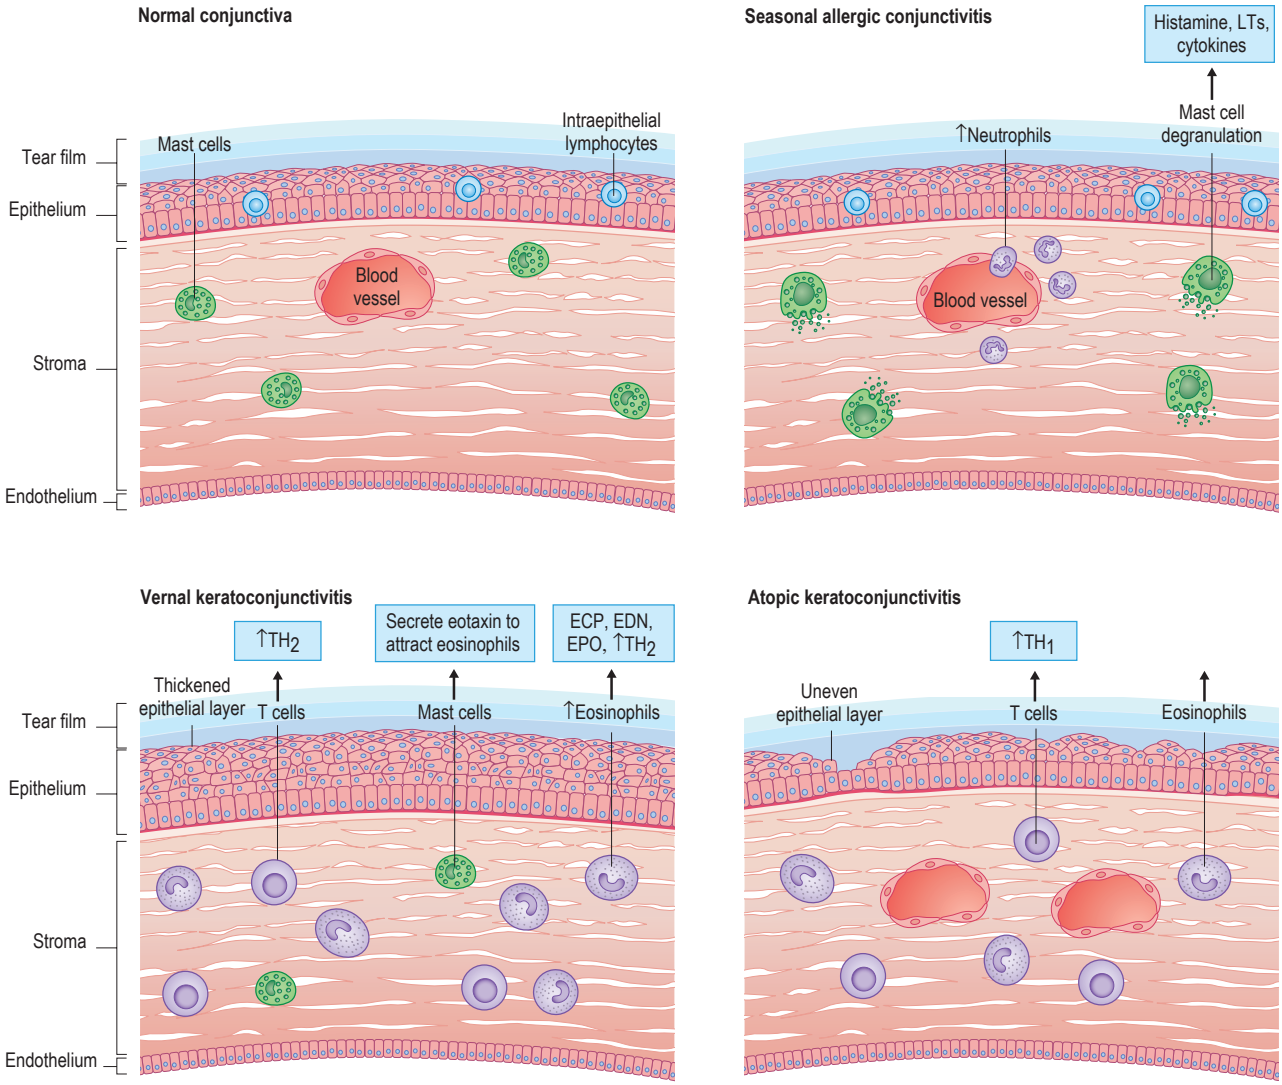

FIG 74.9 A schematic diagram of a cross-section of conjunctival tissue, showing the cell processes involved in normal vs sac- vs vkc- vs akc- affected tissues. *AKC*, Atopic keratoconjunctivitis; *ECP*, eosinophil cationic protein; *EDN*, eosinophil-derived neurotoxin; *EPO*, eosinophil peroxidase; *SAC*, seasonal allergic conjunctivitis; *VKC*, vernal keratoconjunctivitis.

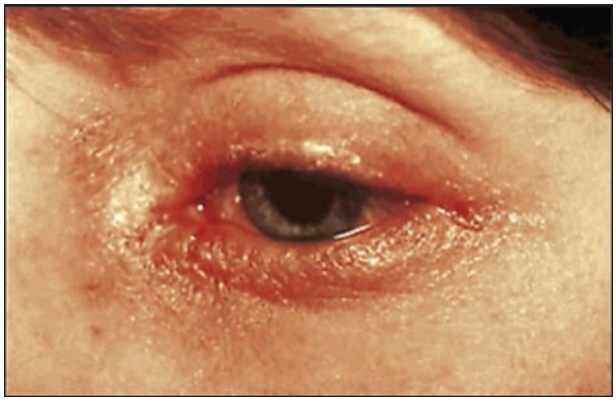

FIG 74.10 Allergic Keratoconjunctivitis (AKC). Patient with AKC demonstrating conjunctival injection, increased lacrimation, and erythematous, thickened eyelids. Patients typically have a personal history of atopy, including allergies, atopic dermatitis, eczema, or other atopic conditions. (Reproduced with permission from Conjunctivitis. Elsevier Point of Care 2019. Copyright Elsevier BV. All rights reserved.)

conjunctiva and cornea. The disease can also have optic nerve involvement.

Patients are typically seropositive for anti-SSA (Ro) or anti-SSB (La) and may also be rheumatoid factor or ANA positive.[50] Histopathology classically shows focal lymphocytic sialoadenitis. Extra-glandular manifestations are common and include polyarticular arthralgias or synovitis, gastrointestinal motility problems related to decreased salivary flow, autoimmune pancreatitis, celiac disease, chronic cough due to desiccation of the upper airways, interstitial lung disease, recurrent respiratory infections due to impaired mucociliary clearance, anemia of chronic disease, leukopenia, and lymphopenia. Approximately 5% of patients will develop non-Hodgkin B-cell lymphoma, most often presenting in the parotid gland, or other hematologic malignancy.[50]

Management strategies for the dry eye associated with Sjögren syndrome include tear substitutes, nighttime gels and ointments, topical cyclosporine, topical steroid drops, punctal occlusion, and autologous serum tears. More severe cases may require systemic anti-inflammatory medication or tarsorrhaphy (surgical closure of part of the eyelids).

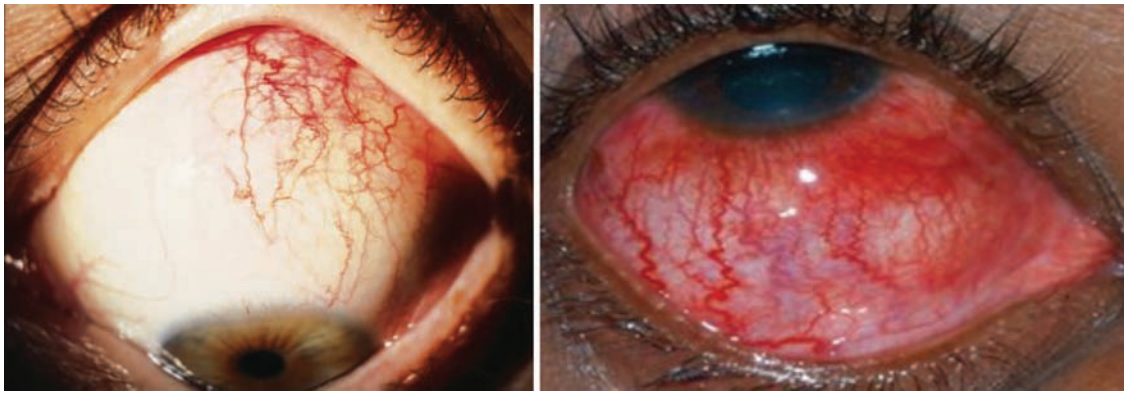

FIG 74.11 Episcleritis and Scleritis. Episcleritis with sectoral vascular dilatation of conjunctival and superficial episcleral vessels. Markle JG, Deenick EK, (Left) Cornea, 4e. Scleritis with inflammation of the sclera and deeper scleral vessels and notable violaceous hue. A discrete, raised scleral nodule is also present near the limbus at the 5 o'clock position. (Right) Scleritis is frequently associated with rheumatoid arthritis and other collagen-vascular diseases. (Reproduced with permission from Galoir A, Thorne, JE. Scleritis and peripheral ulcerative keratitis. *Rheumatic Disease Clinics of North America*. 2007; 33: Fig. 74.4.)

Episcleritis and Scleritis

Episcleritis is a mild, self-limiting inflammation of the episcleral tissue, and a common cause of red eye. Vascular congestion of the superficial episcleral plexus is typically sectoral, but may also present diffusely. The nodular form will have a discrete, elevated area of inflamed tissue (Fig. 74.11). The episclera and Tenon capsule are infiltrated with inflammatory cells on histopathologic analysis. Episcleral vessels will blanch with phenylephrine, differentiating this from a deeper scleritis. Management includes NSAIDs and a brief course of mild topical steroids. Most cases are idiopathic, but autoimmune work-up may be indicated for recurrent cases.

Scleritis is a deeper immune-mediated vasculitis of the sclera that can result in scleral thinning and perforation in severe cases. Patients present with severe pain, deep hyperemia with violaceous hue that does not blanch with phenylephrine, and scleral edema. Autoimmune work-up for systemic conditions should be pursued, with one-third of patients with diffuse or nodular anterior scleritis and two-thirds of patients with necrotizing anterior scleritis having an underlying systemic autoimmune disease, most commonly rheumatoid arthritis, lupus, spondyloarthropathies, and vasculitides such as granulomatosis with polyangiitis and polyarteritis nodosa.[51] Histopathology can show either a non-granulomatous or granulomatous process with or without associated scleral necrosis. Management includes high-dose oral NSAIDs, oral steroids, and systemic immunosuppression. Surgical intervention may be needed for scleral perforation or excessive scleral thinning.

CORNEAL TRANSPLANT AND TRANSPLANT REJECTION

The cornea was the first successfully transplanted solid tissue and remains the most commonly transplanted tissue worldwide. Corneal transplants are the only solid organ that is not typically HLA matched. Additionally, patients are not routinely cross-matched for the presence of HLA-specific antibodies. Despite this, graft survival is overall excellent due to the healthy cornea's lack of blood and lymphatic flow and unique immune privilege.

Corneal graft survival is inversely related to the degree of host corneal bed vascularity, presence of inflammation, and number of antigen-presenting Langerhans cells in the cornea.[52] Data from corneal transplant registries have shown that transplant survival for penetrating keratoplasty is primarily dependent on the indication for surgery, with 10-year graft survival rates ranging from 89% for keratoconus, 73% for Fuchs corneal dystrophy, 70% for non-herpetic corneal scars, 60% for herpetic corneal scars, and 40% for pseudophakic and aphakic corneal edema.[53] Eyes that failed one corneal transplant and required a regraft showed the lowest graft survival rate of 37% after 10 years.[53] Notably, the diagnoses with the best transplant outcomes such as keratoconus and Fuchs corneal dystrophy present with the least vascularization, while regrafts typically occur in vascularized corneal beds, with consequently lower graft survival.

Immune-mediated rejection in solid organ transplants is typically characterized as hyperacute, acute, or chronic. Hyperacute rejection mediated by alloantibodies against ABO blood group or HLA antigens does not occur in corneal transplantation. The presence of alloantibodies against a graft, for example in a patient undergoing regraft after a graft failure, can exacerbate and accelerate rejection, but alloantibodies alone are not believed to be capable of hyperacutely rejecting corneal grafts.[52] Acute rejection is initiated by host recognition of alloantigens, is both antibody and cell mediated, and manifests in days to months. Acute rejection events can occur and are typically managed with medical immunosuppression. Chronic rejection develops slowly over months or years, is largely cell mediated with T-cell and macrophage involvement and is the major source of corneal allograft failure.

Rejection of the graft epithelial layer is typically asymptomatic, as donor epithelium is replaced by host epithelium derived from the corneal limbus. Destruction of the epithelium can immunize the host against the donor but does not greatly affect graft survival.[54] Stromal rejection is relatively common, but easily treated by intensive use of topical corticosteroid drops, and rarely leads to endothelial rejection. Immune-mediated endothelial rejection is the most serious and frequently leads to corneal graft failure. Human endothelial cells are nonreplicative, and their loss is irreversible. Endothelial cell density below a critical level results in chronic corneal edema due to inability to maintain a clear dehydrated state. Endothelial cell loss due to

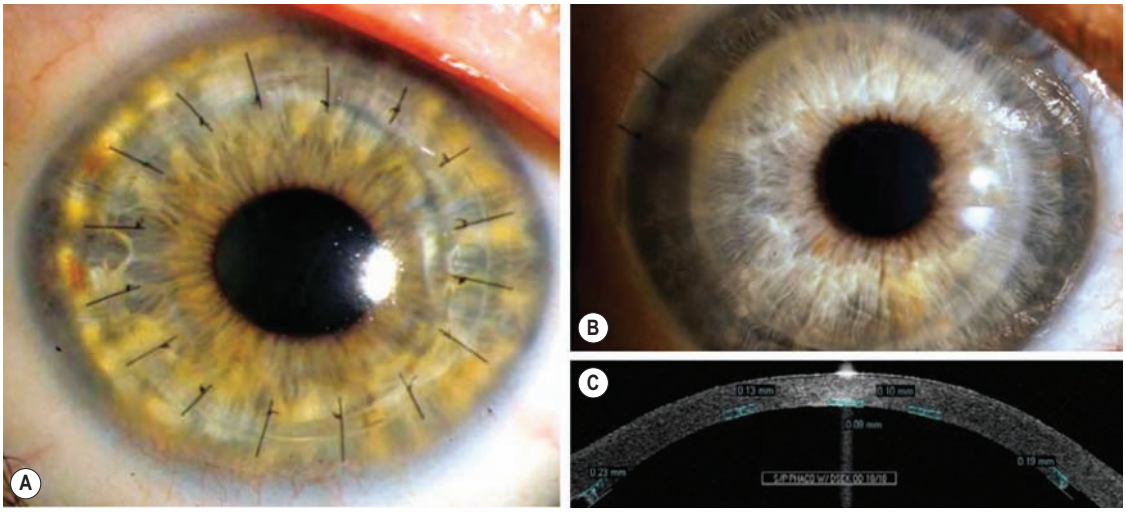

FIG 74.12 External Photograph of Cornea. (A) After a penetrating keratoplasty with interrupted sutures. (B) After Descemet's stripping automated endothelial keratoplasty. Corneal transplantation. *Lancet*. 2012;379: 1749–1761. Copyright © 2012 Elsevier Ltd.)

recurrent acute rejection events or chronic cell-mediated rejection can eventually lead to end-stage graft failure. Donor endothelial cells can also fail by non-immune-mediated pathways. Endothelial cell density rapidly falls during ex vivo storage, and graft endothelial cells have accelerated rate of loss even in the absence of overt rejection.[54] Donor endothelial cells after penetrating keratoplasty have been measured to have a half-life of approximately 21 years, over 10-fold less than anticipated for normal aging cell loss.[55] Progressive endothelial cell death over time can thus result in late graft failure decades after transplant. Other cases of transplant failure can occur due to recurrence of disease, most commonly for infectious disorders such as herpetic and fungal keratitis, or failure to heal in anesthetic corneas.

Although HLA matching of corneal transplants has been generally assumed to be unnecessary, extensive studies do show a reduction in rejection in both high-risk and normal-risk recipients who are HLA matched.[52] Additionally, pre-transplant cross-matching to screen for HLA-specific antibodies may be of benefit in high-risk or retransplant patients. However, the value of routine HLA matching for corneal transplants is controversial, given the cost and complexity of matching, delay in surgical treatment, high success rates in the absence of matching, and availability and success of immunomodulatory agents and biologics for the prophylaxis and treatment of corneal graft rejection.

Newer forms of lamellar transplantation surgery in which only specific layers of the cornea are removed and transplanted to address individual diseases have gained favor over traditional full-thickness penetrating keratoplasty.[56] Rejection rates for these selective lamellar keratoplasty techniques have the potential to be lower than for traditional penetrating keratoplasty; however, long-term follow up will define the success of the newer surgical techniques. Corneal transplantation remains the most successful type of organ transplantation, with long-term graft survival rates in non-matched corneal transplant patients even higher than rates seen in HLA-matched transplants of other solid organs (Fig. 74.12).

KEY CONCEPTS

Corneal Transplant

Factors mediating corneal transplant graft survival:
- Indication for surgery
- Host corneal bed vascularity
- Presence of inflammation
- Number of antigen-presenting Langerhans cells in cornea
- Prior graft failure

Indications with high corneal graft survival:
- Keratoconus
- Fuchs corneal dystrophy
- Other endothelial and stromal dystrophies
- Non-herpetic corneal scars

Indications with low corneal graft survival:
- Herpetic corneal scars
- Chemical burns
- Corneal regraft for previous transplant failure

EMERGING TOPICS IN IMMUNOLOGIC OCULAR DISEASES

Commensal Microbiota in Ocular Immunology

The role of the microbiome has been traditionally focused on its role in gastrointestinal diseases; however, increasing evidence suggests that gut commensals affect all aspects of immune homeostasis and have many effects in distant tissues, including those of the eye.[57] There is evidence that gut microbiota can trigger development of uveitis. Studies in the R161H mouse model of spontaneous T-cell-driven uveitis show that depletion of the gut microbiota by broad-spectrum antibiotics or rearing in germ-free conditions attenuates disease, and disease development was associated with increased populations of Th17 cells in the intestinal lamina propria.[58] Prevailing hypotheses include the idea that retina-specific T cells may be primed in the gut, possibly though an unidentified commensal antigen mimic of

retinal antigens. Bacteria-rich intestinal contents can activate R161H T cells in vitro and transfer of these activated cells can confer disease to naïve wild-type mice, supporting an antigenic mimicry hypothesis.[58] Alternatively, microbial products and metabolites may provide adjuvant innate signals that modify the host response toward developing uveitis. An activation step in the periphery is likely important for autoimmune ocular diseases, as antigens in a healthy eye are sequestered, requiring T cells to be activated to breach the blood-retinal barrier. Microbial exposure may be an important causative or modulatory factor in the initiation and severity of uveitis in some models. However, commensals are not the only disease trigger, as R161H mice will develop uveitis with reduced disease scores over time, even in germ-free conditions. Additionally, the AIRE$^{-/-}$ mouse model develops spontaneous autoimmune uveitis that is not dependent on the presence of commensal microbiota.[59] The relationship of the commensal microbiome to ocular disease is likely complex, and further research is needed. However, the possibility of modulating the gut microbiota through antibiotics, probiotics, prebiotics, or fecal transplants as a therapeutic approach in the treatment of uveitis and other autoimmune diseases is intriguing and warrants further exploration.

Cancer Immunotherapy-Associated Ocular Complications

A revolution is taking place not only in the treatment of autoimmune diseases with increasing development of biologics but also in the field of cancer therapy with the advent of cancer immunotherapy drugs. We are now in an era where we are able to harness the natural power of the immune system to detect and eliminate transformed cells. Cancer immunotherapy acts by enhancing immune function to amplify antitumor response and aid in eradication of existing cancers and metastases. However, the side effects seen with immunotherapy drugs reflect this immune enhancement and disruption of self-tolerance, resulting in high rates of autoimmune toxicity. Autoimmune-related side effects are common and can affect almost any organ, including causing both uveitis and neuro-ophthalmic complications of the eye. The study of immune-related adverse events (irAEs) and their management is a critical area of immunotherapeutic research, as the development of autoimmune-related toxicity frequently limits the use of these otherwise effective cancer therapeutics.

There are currently several distinct classes of immunotherapeutic drugs, including antitumor vaccination, cellular immunotherapy, cytokine therapy, and monoclonal antibody-based therapies. Uveitis associated with anti-CTLA-4 and anti-PD-1/PD-L1 checkpoint inhibitor use has been well documented.[60] Other ophthalmic complications have recently been recognized, ranging from optic neuritis, myasthenia gravis–like presentations, and muscle/orbit involvement. This illustrates the vast range of ocular presentations that may result from immunotherapy treatment, and highlights the fact that management of patients on complex immunotherapeutic regimens will require a multidisciplinary approach.

Gene Therapy

The eye is an ideal location to pioneer advancements in gene therapy. The eye is uniquely immune privileged, yet has easy access for surgical delivery with subretinal, intravitreal, and other minimally invasive available intraocular routes of administration. The highly compartmentalized nature of the eye and separation from the rest of the body by the blood-brain barrier also minimizes concerns for off-target effects. The use of gene therapy to permanently correct monoallelic genetic disorders has been an elusive goal, until recently. Voretigene neparvovec (Luxturna, Spark Therapeutics) was approved by the US FDA in 2017 as the first in vivo gene replacement therapy. It is designed as an AAV2 vector containing a functional copy of human RPE65 cDNA with a modified Kozak sequence, administered subretinally, and is the first and only treatment of Leber congenital amaurosis, an autosomal recessive RPE65-mediated inherited retinal disease that causes progressive blindness.[61] This targeted gene therapy resulted in significant visual improvement which is maximal by 30 days after administration and durable for at least 4 years with continued ongoing observation.[62]

The early success of voretigene neparvovec provides tremendous encouragement to the field of gene therapy and future treatments of diseases such as Stargardt macular degeneration, X-linked retinoschisis, choroideremia, Leber hereditary optic neuropathy, and others. The introduction of CRISPR gene editing has further opened new possibilities in this field. We expect additional rapid advancements, and we anticipate that ophthalmology will continue to play a leading role due to the unique location and immune environment of the eye.

ON THE HORIZON

Topics of research interest:
- Immune mechanisms in degenerative diseases, including age-related macular degeneration (AMD)
- Role of commensal microbiota in ocular immunology

Development of new drugs and new therapeutics:
- Biologics: TNF inhibitors, IL-1 inhibitors, IL-6 inhibitors, etc.
- Gene therapy for ocular disease

Investigation of new diseases:
- Checkpoint-inhibitor-associated uveitis and neuro-ophthalmologic complications

SUMMARY

Multiple mechanisms have evolved to protect vision, including the blood-retinal barrier, immune privilege, and tolerance mechanisms to safeguard the eye from immune cell infiltration. However, this special immune status of the eye can paradoxically leave it vulnerable in states of autoimmunity and disease, as eye antigens are normally sequestered and not available during the development of induced Tregs that mediate peripheral tolerance. Immune diseases of the eye can affect any ocular tissue, and as such are highly varied in etiology and presentation. Frequently, these ocular diseases present in the setting of a broader systemic autoimmune disease or in the setting of general autoimmune susceptibility. Many MHC associations have been identified, and some putative targets or initiating factors have been proposed for some diseases. However, the targets for most autoimmune ocular diseases, preceding infectious triggers, and other risk factors are still not well defined and require further study. We expect that there will be many cutting-edge developments in the field of ocular immunology in the coming years, with resolution of many of these unanswered questions.

Immunologic Diseases of the Gastrointestinal Tract

Peter J. Mannon

GASTRITIS

Gastritis is a histological term that differs from normal gastric mucosa (Fig. 75.1, A). It describes stomach inflammation resulting from toxic exposures, infection, idiopathic inflammation, and autoimmunity. Although symptoms tend to be very nonspecific, the etiology and treatment of gastritis can be extremely specific, particularly for *Helicobacter pylori* infection, which has important implications for outcomes and natural history.

Atrophic Gastritis/Pernicious Anemia

The most classic autoimmune disease of the gastrointestinal (GI) tract is atrophic gastritis (AG) characterized by loss of acid-producing parietal cells, anti-intrinsic factor, and anti-parietal cell autoantibodies, and an association with autoimmune thyroiditis, vitiligo, and type 1 diabetes.[1] The resulting loss of acid production interferes with inorganic iron absorption, causes hypergastrinemia and enterochromaffin cell hyperplasia, and B_{12} deficiency ("pernicious anemia [PA]"). Despite the age-old stereotype of the AG/PA patient as an older Caucasian woman (there is a female preponderance 2:1), 25% of cases are diagnosed below age 50 years, and disease does occur in African and Asian ethnicities. The detection of both anti-intrinsic factor and anti-parietal cell serum antibodies has 73% sensitivity and 100% specificity for PA.[2] Murine models show that immunity to H^+-K^+-ATPase (the parietal cell membrane protein that secretes H ions into the gastric lumen) results in AG.[3] Although potentially pathogenic H^+-K^+-ATPase–responsive CD4 T cells can be isolated from the gastric mucosa of patients with AG, it remains unclear how these cells arise, but observations implicate a role for *H. pylori* infection (>80% of patients with AG have antibodies to *H. pylori*).[4] Antral inflammation (up to 92%) and mucosal atrophy (up to 30%) together with histological evidence of *H. pylori* infection (up to 30%) occur in AG, with antigastric antibodies present in up to 65% of patients with *H. pylori* infection (and none in noninfected patients with gastritis).[5]

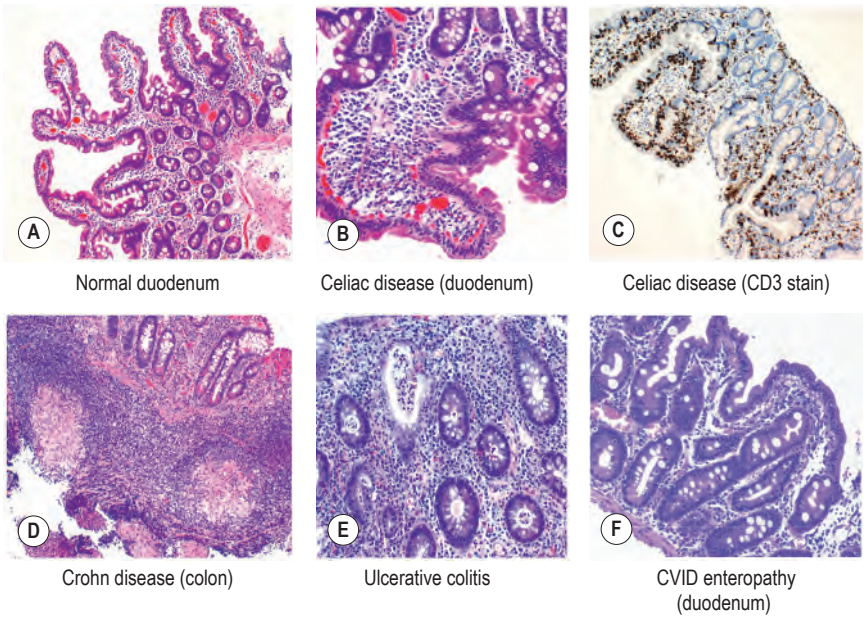

FIG. 75.1 Gastrointestinal Histology in Health and Immune-Mediated Disease. (A) Normal duodenal histology. (B) Celiac disease with blunted villus, increased plasma cell infiltrate, increased intraepithelial lymphocytes. (C) CD3 staining in celiac disease showing increased intraepithelial lymphocytes. (D) Crohn colitis showing mucosa expanded with lymphoplasmacytic infiltrate and two granulomata. (E) Ulcerative colitis showing crypt dropout, cryptitis, crypt abscess, and lymphoplasmacytic infiltrate. (F) Common variable immunodeficiency *(CVID)* enteropathy showing villus blunting, increased intraepithelial lymphocytes, and epithelial apoptosis. (Photomicrographs courtesy of Dr. Leona Council, Department of Pathology, University of Alabama at Birmingham, Birmingham, Alabama, USA.)

The diagnosis of AG/PA relies on the combination of laboratory, serological, and histological data.[6] AG itself does present a risk of cancer (neuroendocrine cell and adenocarcinoma) and guidelines are still in development as to surveillance.[7]

Helicobacter pylori Gastritis

H. pylori infection of the gastric mucosa is the leading cause of peptic ulcer disease and is a World Health Organization (WHO)-designated class I carcinogen for gastric carcinoma. Primary infection is largely acquired in childhood, and poor sanitation enhances fecal/gastro-oral transmission. Although acute infection can cause abdominal pain and dyspepsia, there is little clinical recognition of acute infection. The burden of *H. pylori* ensues from chronic infection of the stomach; *H. pylori* is uniquely adapted to the acidic environment of the stomach through its ability to metabolize urea to acid-buffering ammonia that allows prolonged asymptomatic colonization.

The ability of *H. pylori* to confer risk of peptic ulcer disease in 15% of chronically infected persons has been linked to *H. pylori* infection inhibition of local bicarbonate secretion by the gastric epithelium which enhances permeability to damaging hydrogen ions. In addition, expression of cytotoxins (vacuolating cytotoxin, VacA) and pro-inflammatory virulence factors, such as CagA, may contribute to pathogenesis.

The development of peptic ulcer disease and adenocarcinoma caused by chronic *H. pylori* infection correlates with the anatomical distribution of inflammation. When *H. pylori* chronic gastritis affects the antrum predominantly, there is an association with duodenal ulcers, increased serum gastrin levels and excess acid production, and no gastric mucosal atrophy.[8] However, when *H. pylori* affects the body and the antrum in a confluent or patchy manner, intestinal metaplasia develops, oxyntic mucosa atrophies, and acid production decreases; this type of *H. pylori* chronic gastritis is associated with gastric ulcerations and increased risk for adenocarcinoma and mucosa-associated lymphoreticular tissue (MALT) B-cell lymphoma. Although eradication of *H. pylori* may reverse the mucosal atrophy and restore acid production at this stage, mucosal restoration occurs only in a minority of patients and does not necessarily reverse the intestinal metaplasia.[4] Histologically, this form of AG is differentiated from primary autoimmune AG (above) by the presence of *H. pylori* organisms in the specimen (and concurrent involvement of the antrum). Specific immunohistochemical methods for detecting *H. pylori* are required when organisms are not seen on hematoxylin and eosin staining, when intestinal metaplasia occurs widely (*H. pylori* does not colonize intestinal metaplasia heavily), or when confirming *H. pylori* eradication after antibiotic treatment.[9] Immune mechanisms contribute to the persistence of *H. pylori* infection in the stomach, including pro-regulatory effects of local interleukin-10 (IL-10) production, increased regulatory T cells (Tregs) in the gastric mucosa, and increased antigen-presenting cell (APC) phagocytosis of apoptotic cells.[10–12] Establishing the diagnosis of active *H. pylori* infection is essential in the setting of active gastroduodenal ulcer disease, gastric MALT lymphoma, and, in highly endemic areas such as Central America, dyspepsia symptoms alone (upper abdominal pain, bloating, early satiety, and nausea). Active disease is diagnosed with endoscopic biopsy, which has high sensitivity and specificity, while simultaneously assessing peptic and malignant complications. Noninvasive testing for *H. pylori* infection includes serum antibody detection (best used in highly endemic areas to predict active infection), urea breath testing (limited by expense and possible false-positive results), and fecal antigen testing (which has potential advantages in the setting of intestinal metaplasia and after antibiotic treatment).

Once *H. pylori* infection is diagnosed, there are many effective eradication therapies that need to be tailored to patients' drug tolerance and allergy history as well as local antibiotic resistance patterns. In general, a 14-day course with a proton pump inhibitor (PPI; histamine 2 [H_2] blockers may be substituted) and two antibiotics (clarithromycin with amoxicillin or metronidazole) is recommended as first-line treatment.[13] Alternative regimens, including bismuth or sequential therapy, may be needed in cases of antibiotic resistance. Eradication of infection can be confirmed by either invasive or noninvasive (but not serum antibody) methods. In addition to the cure of recurrent gastroduodenal ulcer disease, eradication of *H. pylori* can cause regression of gastric MALT lymphoma in a majority of coinfected patients.[14]

KEY CONCEPTS

Gastritis

- Atrophic gastritis (AG) results from immune-mediated loss of the acid-producing cells of the gastric body. AG is associated with anti-parietal cell antibodies, an intact antral gastric mucosa, and no evidence of *Helicobacter pylori* infection.
- However, *H. pylori* infection has been linked to atrophic gastritis via increased rates of anti-*H. pylori* antibodies in AG patients and gastric mucosal CD4 T cells with cross-reactivity to H^+-K^+-ATPase and *H. pylori* antigens.
- *H. pylori* infection of the stomach is chronic because of metabolic and immune adaptations by the pathogen that allow persistence in the acidic gastric environment.
- *H. pylori* infection is a leading cause of peptic ulcer disease and a World Health Organization (WHO) class I carcinogen because of its link to gastric adenocarcinoma.

ON THE HORIZON

Gastritis

- Development of a *Helicobacter pylori* eradication treatment with affordable global implementation without significant adverse effects or antibiotic resistance that work to enhance current regimens or replace them (e.g., vaccines).

CELIAC DISEASE

Celiac disease is the most prevalent (0.5% to 1% of the general population) immune-mediated disease of the human GI tract.[15] Gluten-derived peptides not only disrupt the tight junction complex (via CXCR3-stimulated release of zonulin) but also gluten peptide–specific T cells drive specific autoantibody formation and an inflammatory response that leads to small intestinal villus atrophy and malabsorption caused by subsequent intestinal surface injury. The identification of the specific gluten peptide-presenting human leukocyte antigen (HLA) molecules (DQ2 and DQ8) and the gluten peptide cognate ligands that activate the T cells has advanced the understanding of the pathophysiology and genetics of celiac disease, driving the development of innovative therapies.[16]

Presentation

The classic clinical presentation of celiac disease—chronic diarrhea, weight loss, and abdominal bloating—results from defective nutrient absorption by the small intestine as a result

of inflammatory injury. However, adult patients with celiac disease are more likely to present with complications of nutrient deficiency (anemia, osteoporosis, sarcopenia) without overt GI complaints. Celiac disease can also present with an associated skin eruption (dermatitis herpetiformis), cerebellar ataxia, infertility and miscarriage, and chronic fatigue, and can be associated with autoimmune disorders, such as type 1 diabetes and thyroiditis, Addison disease, Sjögren syndrome, autoimmune hepatitis, and primary biliary cirrhosis.[15] The high frequency of nonspecific GI symptoms, such as abdominal pain and constipation, which are reported in over one-fifth of newly diagnosed subjects, complicates targeted screening. The variations of celiac disease presentation reflect several features: *(i)* the dose effect of celiac disease risk alleles on severity; *(ii)* the development of celiac disease involves additional genetic and environmental factors as well as the required HLA background; *(iii)* celiac disease activity depends on the quantity and quality of gluten exposure; and *(iv)* celiac disease effects are proportionate to the inflammatory activity and the extent of involved bowel. The concept of a vast subclinical celiac disease prevalence has led to an "iceberg model," where the visible tip is the group with symptomatic GI disease and the characteristic gut mucosal lesion, and below the surface are those with subclinical disease (no overt symptoms but gut mucosal lesions) and latent disease (no symptoms or mucosal lesions but possibly positive serology against a background of HLA genetic susceptibility).

The key to diagnosing celiac disease is simply to consider it in the differential diagnosis of classic gut malabsorption as well as subtle manifestations of malabsorption (e.g., unexplained iron deficiency anemia). Conversely, the differential diagnosis of villus blunting or intraepithelial lymphocytosis (without positive serologies) includes small-intestinal bacterial overgrowth, tropical sprue, autoimmune enteropathy, common variable immunodeficiency (CVID) enteropathy, and *H. pylori* gastritis, emphasizing that celiac disease is also not solely a histological diagnosis.

Immune Pathophysiology

Celiac disease results from the activation of T cells by gluten peptide–major histocompatibility complex (MHC) complexes on APCs in the lamina propria of the gut (primarily the small intestine). Dietary gluten, largely from wheat, barley, and rye, exists in polymeric (glutenin) and monomeric (gliadin) form and is incompletely digested to small peptides by gut luminal enzymes because of their high glutamine and proline content.[17] These large gluten peptides cross the zonulin-disrupted epithelial barrier and bind to specific HLA-DQ2 or -DQ8 molecules (tissue transglutaminase [TTG] can deamidate gluten peptides, resulting in negatively charged gluten peptides with increased affinity for the HLA binding site). Gut microbes also can affect the immunogenicity of gluten peptides via their own proteolytic enzymes but a specific celiac disease dysbiotic signature has not been defined.[18,19] The gluten peptide-activated T cells produce proinflammatory cytokines interferon-γ (IFN-γ), interleukin-18 (IL-18), and IL-21. The activated T cells also induce B-cell maturation to plasma cells, producing antibodies to gluten peptides as well as to TTG. The reason for TTG being targeted for autoantibody production is unknown.

Observed in animal models, the activated T cells are not required, but are sufficient to induce the epithelial damage and villus blunting. The characteristic villus atrophy is induced by gut APC- and epithelial cell–produced IL-15, enhancing CD8 T-cell infiltration into the epithelium where intraepithelial T lymphocytes (IELs) with upregulated NKG2D receptors, interacting with Major histocompatibility complex (MHC) class I chain-related protein A (MICA) and B upregulated on epithelial cells, induce cysteinyl leukotrienes that drive IEL cytotoxicity.[20]

Beyond the HLA associations with disease, genome-wide association studies (GWAS) have linked over 30 disease susceptibility loci with non-HLA regions such as the polymorphism in *lnc13*, a long noncoding RNA, which affects its binding with a heterogeneous nuclear ribonucleoprotein to undo its repression of other genes, including inflammatory mediators.[21]

Diagnosis

Celiac disease patients can present with both suggestive symptoms and signs (weight loss, chronic diarrhea) as well as in atypical ways, such as with specific micronutrient deficiencies or unexplained hyperamylasemia or hypertransaminasemia. Initial tests include measuring serum immunoglobulin A (IgA) antibodies against TTG and endomysial proteins, which have an estimated specificity/sensitivity of 95%/95% and 100%/>90%, respectively. Total serum IgA level must be made at the same time to prevent false–negative results; however, in the setting of IgA deficiency (there is an association with celiac disease), elevated IgG anti–TTG or anti-deamidated gliadin levels and identification of celiac disease susceptibility HLA genes can help determine the risk and presence of disease.[15]

An important part of celiac diagnosis is biopsy of the upper small intestine mucosa (see Fig. 75.1, B and C); typically three to four endoscopic biopsy specimens are obtained from both the duodenal bulb and the distal duodenum. Although the absolute requirement for histological diagnosis of celiac disease may be debated (and cannot be used alone because of lack of specificity), it remains important for several reasons: *(i)* the serological markers should only be used as a screening test, identifying which patients are at highest risk for the disease and appropriate for biopsy confirmation; *(ii)* even in people with HLA DQ-2 or DQ-8 backgrounds, only a minority of persons will develop symptomatic celiac disease, so the evaluation of atypical presentations especially will require histological examination; and *(iii)* because the treatment can be life altering, it is essential to make a definitive diagnosis.

Treatment

The treatment of celiac disease is avoidance of gluten, specifically foods containing wheat, barley, and rye. Successful gluten avoidance should first resolve symptoms and clinical lab abnormalities (iron deficiency, for instance). Follow-up endoscopy to assess response to therapy should be done only after 6 to 12 months of a strict gluten-free diet (GFD), although full recovery of the villus mucosa may take several years. There are no accurate biomarkers to monitor adherence to a GFD, although one indication may be a fall in the pretreatment level IgA anti-TTG serum antibodies; therefore, follow-up endoscopy with biopsy is needed to document restoration of the villus architecture.

About 5% of patients with celiac disease do not respond to a GFD. Ensuring a strict adherence to a GFD is important to identify the reasons for nonresponse, whether through inadvertent gluten exposure or whether the inflammation is truly refractory to a strict GFD. One group of patients with the so-called refractory celiac disease with polyclonal IEL populations may respond to corticosteroids and immunosuppressant treatment; another group with monoclonal IELs do not respond to such treatment and are at increased risk of lymphoma.[22]

The majority of patients with celiac disease respond positively to a GFD with return of normal gut absorption. However, ongoing inflammation is associated with risk of small-bowel lymphoma, so ensuring adherence to a GFD and documenting mucosal healing can affect the natural history of this disease. Finally, since first-degree relatives are at increased risk of celiac disease, patients should be advised of recommended serum antibody screening of these family members.

KEY CONCEPTS

Celiac Disease

- Patients with celiac disease present more often with complications of malabsorption than chronic diarrhea and weight loss.
- Human leukocyte antigen (HLA)-DQ2 or -DQ8 alleles are necessary but not sufficient for celiac disease to develop, as they are present in more persons unaffected by celiac disease.
- Immunoglobulin A (IgA) antibodies to tissue transglutaminase and endomysial proteins should be used for screening only (not diagnosis) and should be measured along with total IgA for validity.
- The goals of gluten-free diet treatment are relief of symptoms, reversal of malabsorption, and restoration of villi.

ON THE HORIZON

Celiac Disease

Discovery of additional genetic and environmental factors (beyond gluten) that strongly confer risk for celiac disease in the setting of human leukocyte antigen (HLA)-DQ2 and -DQ8 alleles leading to strategies to eliminate that risk and prevent disease.

- Novel treatment approaches to modify gluten to nonimmunogenic forms, anti-IL-15 strategies that interrupt the inflammatory cascade of events, and even vaccines to downregulate responses to gluten peptides or that induce tolerance to gliadin.
- Identification of specific celiac disease–relevant components of the microbiome that influence the expression of disease.

CROHN DISEASE

Crohn disease is a chronic idiopathic inflammation of the gut characterized by transmural involvement of the bowel wall (mucosa, muscle layer, and serosa) (see Fig. 75.1, D). Although often referred to as "terminal ileitis," the majority of patients with Crohn disease have colonic inflammation in addition or solely. Crohn disease typically runs a chronic, relapsing course often complicated by bowel obstruction as a result of fibrous strictures and by abscesses and fistulae caused by extension of inflammation beyond the bowel wall. Most Crohn patients will require surgical treatment at rates up to 70% after 20 years' disease duration. Crohn disease is treated with broad antiinflammatory drugs (corticosteroids and immunosuppressants) as well as antibodies targeting tumor necrosis factor (TNF-α), L-12/IL-23 p40, and the integrin molecules α_4 and $\alpha_4\beta_7$.

Crohn disease is thought to result from a dysregulated immune response to gut microbes. Despite evidence for genetic disease heritability, it is clear that the complex interactions of environmental exposures (including the gut microbiome and its metabolome), innate and adaptive immune dysfunction, and complex genetic and epigenetic features all contribute to disease causation and expression.[23]

Presentation

Patients with Crohn disease most often come to medical attention because of abdominal pain, altered bowel habits, and rectal bleeding. Abdominal pain may indicate bowel obstruction (especially if the pain is postprandial), an inflamed viscus, or a penetrating complication, such as an abscess or fistula. Diarrhea is related to malabsorption and dysmotility secondary to the effects of inflammatory cytokines on gut function. Diarrhea can also result from noninflammatory mechanisms like bile salt wasting or small intestinal bacterial overgrowth (SIBO). Conversely, constipation in Crohn disease can be a sign of stricturing of the bowel. Rectal bleeding results from mucosal friability and ulceration. In addition, fever, unexplained weight loss, fatigue, anemia, and failure to thrive (in children) can accompany the GI complaints or even be the primary presentation. Extraintestinal manifestations of Crohn disease include arthritis, uveitis, inflammatory skin lesions (pyoderma gangrenosum and erythema nodosum), and stomatitis. The arthritis can affect the axial (spine and pelvis) and articular skeleton, with the latter more often mirroring the activity of the gut disease. The joint complaints range from usual arthralgias to frank synovitis with swelling and tenderness (without erosive joint destruction). The uveitis most commonly occurs as episcleritis and iritis. Many of these lesions will subside with effective therapy aimed at the gut, but they can also have independent courses that require site-targeted treatment.

The incidence of Crohn disease and ulcerative colitis (UC) in Western populations has been estimated to be 5 to 15 cases/100,000 person-years.[24] Ashkenazi Jewish heritage confers increased Crohn risk in Caucasians, whereas African Americans seem to have rates similar to those of non-Jewish Caucasians, and Hispanics and Asians have much lower rates. There is a genetic risk with up to 10-fold increased rates of inflammatory bowel disease (IBD) in relatives of patients with Crohn disease and a 30% concordance rate in monozygotic twin pairs. The typical patient is diagnosed in his or her second or third decade, and there is no significant gender preference. The only environmental exposure that has been repeatedly linked to risk of Crohn disease has been tobacco use.

The majority (up to 70%) of Crohn patients experience a remitting and relapsing course, but some have chronically active symptoms refractory to medication. There are several phenotypes of disease. These include inflammatory disease (manifesting primarily as intestinal edema and ulceration), fibrostenotic disease (luminal narrowing by fibrous strictures dominate with symptoms of painful obstruction), and fistulizing disease (inflammatory tracts between the bowel and other intestines, the bladder, vagina, skin, and other structures). Although the majority of patients have inflammatory disease at the time of diagnosis, over time this phenotype changes so that after 20 years of disease duration, up to 70% and 18% of patients with Crohn disease report penetrating and fibrostenotic complications, respectively, often leading to surgery.[25]

Immune Pathophysiology

The current paradigm of Crohn disease pathogenesis is a dysregulated immune response to gut commensal microbial components (antigens and pathogen-associated molecular patterns). Initial rodent colitis models showed a predominant T-helper-cell-1 (Th1) inflammation, where the colitis could be blocked or reversed by treatment with anti–IL-12 antibodies. Roles for IL-23 and IL-17 in Crohn disease were later supported

by the IL-10–deficient mouse model of spontaneous colitis and the cell transfer model of induced colitis, where colitogenic naïve $CD4^+CD45RB^{high}$ T cells from wild-type mice are infused into T-cell–deficient mice.[26,27] IL-12 (p35/p40 dimer), IL-23 (p19/p40 dimer), IFN-γ, and IL-17 are significantly elevated in Crohn disease, but it is not known which cytokines play a more important role in specific patients. The first and most widely used biological in IBD targets TNF-α, which itself is a more downstream cytokine in the inflammatory cascade. The anti–IFN-γ monoclonal antibody (mAb) fontolizumab showed no clinical efficacy in Crohn disease (but did decrease C-reactive protein [CRP] level).[28] However, anti–IL-12/IL-23 p40 subunit mAbs targeting the Th1 and Th17 pathways resulted in clinical improvement that led to the use of ustekinumab for Crohn disease.[29,30] Currently, agents targeting IL-23 alone (anti-p19 antibodies) are being evaluated for efficacy in IBD. Unexpectedly, antibodies targeting IL-17A alone (secukinumab) or the IL-17AR receptor subunit (transducing IL-17A, IL-17E, and IL-17F intracellular signals) either did not show clinical improvement (and was associated with increased fungal infections) or even induced clinical deterioration (the anti–IL-17AR antibody).[31]

To date, it is estimated from multiple genome polymorphism studies that more than 200 IBD susceptibility loci exist, most associated with risk of both Crohn disease and UC.[32] However, it is estimated that all the loci together could account for no more than 15% of overall IBD risk. While most of these genetic risk loci are in noncoding regions of genes thought to modulate gene expression, the actual genes implicated have roles in the immune response, cell trafficking, and epithelial integrity, providing biological plausibility for their involvement in IBD. Several examples stand out. *(i)* The *NOD2* gene encodes an intracellular protein that binds muramyl dipeptide (MDP), a component of the bacterial cell wall TLR2 ligand peptidoglycan. Disease-associated mutations in the MDP-sensing leucine-rich repeat domain of *NOD2* are associated with defective activation of nuclear factor (NF)-κB. *(ii)* The *ATG16L1* autophagy gene is important for the metabolism of autologous cell proteins as well as intracellular microbes. Expression of the Crohn disease–associated Thr300Ala polymorphic *ATG16L1* sequence in a colon cancer cell line showed in vitro inhibition of packaging of intracellular *Salmonella* into autophagosomes, supporting the hypothesis that this mutation could lead to impaired clearance of microbes and chronic inflammation.[33] *(iii)* A polymorphism in the coding region of the IL-23 receptor gene (Arg381Gln) found in 14% of healthy controls is associated with protection from Crohn disease (less so UC) and is associated with decreased Th17 cascade effector cells.[34]

The key role of the commensal microbiota in gut immune homeostasis was established by the observations that germ-free mouse models are largely protected from experimental IBD. A number of studies show a dysbiosis compared with the healthy gut microbiota.[35] This change in the microbiota in IBD has been characterized as a loss of microbial community diversity, reversal of the Bacteroidetes-to-Firmicutes phyla ratio with reduction in Firmicutes, and metabolic and community changes associated with activity of disease.[36] The roles of antibiotics, probiotics, prebiotics/diet, or actively changing the microbiota through fecal transplant have not been clarified sufficiently to employ these strategies as conventional treatments in Crohn disease.

Diagnosis

The diagnosis of Crohn disease relies on radiographic, endoscopic, and histological examinations. In general, a combination of colonoscopy (with ileal examination) and small-bowel imaging (barium small-bowel follow-through, computed tomography [CT] or magnetic resonance enterography, or capsule video endoscopy) is usually sufficient to demonstrate active inflammatory disease of the colon and small bowel. Observed mucosal ulceration and friability in a patchy distribution separated by unaffected mucosa ("skip areas") are the endoscopic hallmarks of Crohn disease. Diagnostic imaging showing patchy bowel wall thickening, mucosal hyperemia, luminal narrowing (stricturing), and penetrating complications of the bowel wall, such as fistulae and abscesses, all suggest Crohn disease. Histologically, although the appearance of noncaseating granulomata is highly supportive of a diagnosis of Crohn disease, in practice, they are not often detected by endoscopic biopsy, particularly in adults. More often, evidence of chronic inflammation, such as architectural crypt distortion and basal lymphoplasmacytosis, help to differentiate the inflammation from an acute, self-limiting colitis or enteritis. Other findings, such as fecal leukocytes or elevated fecal calprotectin, may indicate an inflammatory colitis but are not specific for diagnosis of a chronic idiopathic IBD, such as Crohn disease or UC. In the setting of suggestive imaging or endoscopy appearances of colitis, the measurement of certain serum antibodies can further support the diagnosis of Crohn disease and even help differentiate it from UC, but they should not be used by themselves as diagnostic tests.[37] It has been shown that up to 68% of patients with Crohn disease are seropositive for antibodies targeting microbial antigens, such as anti–*Saccharomyces cerevisiae* antibody (up to 16% of patients with UC are seropositive). Additional antimicrobial antibodies, such as anti-OmpC, anti-I2, anti-flagellin 3, X, and CBir, also develop in Crohn disease. Crohn disease may need to be differentiated from other similarly presenting conditions, including UC, chronic ischemic colitis, infectious enteritis/colitis (amebiasis, *Yersinia enterocolitica* infection, *Mycobacterium tuberculosis* infection), intestinal lymphoma, celiac disease, diverticula-associated colitis, and radiation- and nonsteroidal antiinflammatory drug (NSAID)–induced enteropathy.

Treatment

The treatment of Crohn disease includes medical and surgical approaches. Since there is no cure for Crohn disease, the principles of therapy are to first make sure that symptoms are secondary to the underlying idiopathic inflammation and not caused by infectious or noninflammatory factors, such as coexisting irritable bowel syndrome (IBS). The goal is to induce quick remission of symptoms and establish therapy to maintain the remission with aggressive initial therapy commensurate with the extent and activity of the disease. Current management continues to evolve as new drugs, patient disease risk assessment, and treatment goals are introduced into therapeutic decision making.[38] For instance, limited anatomic extent of gut disease with little clinical impact could be treated with episodic corticosteroids and mesalamine (for colonic disease); however, for more advanced disease with more symptoms, inflammatory burden and even complications, initial therapy with biological medicines such as anti-TNF-α drugs (with or without immunosuppressants like thiopurines or methotrexate depending of disease severity) could be used; for patients with contraindications, intolerances,

prior anti-TNF-α exposure, or risk mitigation considerations, then anti-p40 or anti-integrin ($\alpha_4\beta_7$) agents could be used. Typically, maintenance therapy with the same agent used to achieve remission is needed. Continuous assessment of response (symptoms, biomarkers, mucosal healing) and use of therapeutic drug monitoring can optimize successful long-term treatment outcomes.

Surgery is required in cases of complications, such as bleeding, pain/obstruction, and fistulae that are refractory to medical therapy. Surgery typically involves resection limited to inflamed segments of small intestine and colon but small strictures can be treated in situ by stricturoplasty. In addition, surgery is required for treatment of intestinal adenocarcinoma, which also complicates the chronic inflammation of the bowel. There is a high incidence of endoscopic and symptomatic recurrence of inflammation by 2 years after surgery, and anti-TNF-α agents can successfully prevent this. Strategies to identify patients who would benefit from early postoperative drug prophylaxis are being developed.[39]

KEY CONCEPTS

Crohn Disease

- Crohn disease affects the full thickness of the bowel wall, resulting in fistulae and abscesses in 70% of patients by 20 years' disease duration.
- Crohn disease is a chronic, relapsing inflammation of the bowel, and up to 80% of patients will require surgical treatment at some point.
- Over 200 genetic loci are associated with disease risk, but several coding region polymorphisms, including *NOD2* and *ATG16L1*, highlight a role for dysfunctional innate immune responses.

ULCERATIVE COLITIS

UC also involves chronic idiopathic inflammation of the gut, but this is limited to the mucosal layer of the colon (see Fig. 75.1, E). UC can involve the rectum alone (ulcerative proctitis), the distal transverse colon to rectum (left-sided colitis), or the entire colon (pancolitis). Without the transmural inflammation of Crohn disease, penetrating complications, such as fistulae and abscesses, generally don't complicate UC. Oral and topical (per rectum) mesalamine preparations are most often used to treat UC, although patients also may require corticosteroids, immunosuppressants, and biological agents to induce and maintain remission. Unlike Crohn disease, total colectomy eliminates the disease. However, there can be ongoing complications of the surgery such as ostomy dysfunction or pouchitis if an ileal pouch–anal anastomosis is performed. Over 40% of patients with UC require surgery to treat medically refractory symptoms or development of dysplasia over their lifetime.[40]

Presentation

UC has rectal inflammation (proctitis) as its primary location but can extend to involve the whole colon. Bloody loose stool (including nocturnal) and abdominal pain are common symptoms along with proctitis-specific complaints of rectal urgency and incomplete evacuation. As in Crohn disease, fever, unexplained weight loss, fatigue, and anemia can accompany the GI complaints or be the primary presentation. Extraintestinal manifestations may include arthritis, uveitis, inflammatory skin lesions, and stomatitis. An interesting genetic connection exists between UC and HLA-B27–positive spondyloarthropathy (see Chapter 58), with 60% of patients with ankylosing spondylitis showing inflammation on colonoscopy. UC is also closely associated with primary sclerosing cholangitis (PSC; see Chapter 76); up to 3% of UC patients develop PSC, and up to 75% of all patients with PSC have UC.[41]

UC incidence is up to 20 to 25 cases per 100,000 person-years; the diagnosis of UC is typically made in the second or the third decade without significant gender preference.[42] Approximately 6% to 15% of first-degree relatives of patients with UC have a history of UC, but in general, the genetic contribution to risk is lower than in Crohn disease. There is a higher incidence of UC in European and North American populations compared with that in Asian and Latin American countries, but newly industrialized countries are increasing in incidence.[24] The only environmental exposures linked to risk of UC are the protective effect of tobacco exposure and appendectomy in the first decade of life.

The natural history of UC shows that most patients experience a remitting and relapsing course (60%), although some have prolonged remission after one episode of disease (20%), and others have chronically active symptoms refractory to medical remission (20%). Chronic inflammatory UC (and Crohn colitis) is accompanied by an increased incidence of colorectal cancer, so much so that recurring colonoscopic surveillance for dysplasia with biopsy is recommended starting 8 to 10 years after diagnosis.[43] Total colectomy is performed to treat refractory symptoms or in certain instances of detected dysplasia.

Immune Pathophysiology

UC was originally characterized as a Th2-like disease because of the increased IL-5 and IL-13 production in inflamed gut tissue seen in an animal model of UC, oxazolone-induced colitis, as well as from patient specimens.[44] In this model, mucosal natural killer T (NKT) cells produced the excess IL-13 and the colitis was reversed by immunoneutralizing anti–IL-13. When translated to humans, patients with UC were found to have high capacity for IL-13 production, also by type II NKT cells. IL-13 is a biologically plausible effector cytokine in UC injury because it disrupts the epithelial tight junction by upregulating claudin-2 and has a direct toxic effect on human gut epithelial cells in vitro.[45] However, results from a clinical trial using an anti–IL-13 antibody in UC did not show significant treatment efficacy.[46]

Data from genetic susceptibility studies in UC have provided less-compelling examples of disease-specific mechanisms compared with those in Crohn disease, but there are associations with HLA class II genes distinct from Crohn disease and loci associated with genes involved in epithelial barrier function, such as *GNA12* for tight junction formation, *CDH* for epithelial cadherin-1, *LAMB1* for the laminin constituent of basement membranes, and the ubiquitin ligase gene *RNF186*.[47,48] When specifically assaying epithelial cells (vs. whole tissue) for epigenetic markers associated with genomic risk loci, there is an enhanced association supporting the epithelium as a primary target for dysfunction in UC.[49,50]

Diagnosis

The diagnosis of UC is made by colonoscopy to show the confluent extent of the inflammation from the rectum to points proximal (ileal intubation can confirm that the inflammation is limited to the colon) and biopsy, which should contain histological features of chronic inflammation, including crypt distortion, crypt dropout, and lymphoplasmacytosis. The presence

of acute inflammatory features alone (polymorphonuclear cells, crypt abscess, and cryptitis) may also be seen but, when in isolation, these features suggest other etiologies, such as acute infectious, drug-induced, ischemia, and toxic exposures. Although no blood test can be used to diagnose UC, the presence of high-titer perinuclear antineutrophil cytoplasmic antibodies (pANCAs) can be seen in up to 70% of patients with UC; this information can help differentiate chronic indeterminate colitis when coupled with anti-*Saccharomyces cerevisiae* mannan antibodies (ASCAs; see above). At all times, acute infections from enteric pathogens, including *Clostridium difficile*, should also be excluded, as these may also occur during active IBD treatment and mimic exacerbation of disease (evaluation for cytomegalovirus [CMV] infection should be performed in the setting of UC seemingly refractory to immunosuppressants). Once a diagnosis is established, elevations in transaminases or alkaline phosphatase should prompt an evaluation for PSC (imaging by magnetic resonance or endoscopic cholangiopancreatography).

Treatment

Treatment is tailored to the extent and activity of disease.[51] Mild to moderate proctitis can respond to topical corticosteroids or mesalamine alone (enemas and/or suppositories). Most often with more extensive colonic involvement, oral mesalamine is required, which can be useful for induction and maintenance of remission. In moderate to severe disease, corticosteroids may be required to induce rapid responses and early introduction of anti–TNF-α, anti-p40 or anti-integrin agents are used to induce fairly rapid clinical responses and remission and may also be used as maintenance therapy. Janus kinase (JAK) inhibitors may be used if there is no response to the biologicals. Severe disease may require hospitalization for high-dose intravenous steroids followed by anti-TNF or cyclosporine if no response.

Mesalamine-based drugs are a cornerstone of therapy in UC and are generally included in most ongoing UC medical regimens. Whether use of mesalamine even in quiescent disease confers chemoprotection from developing dysplasia is still being debated, but because of their generally low adverse event rate and high tolerance, long-term use is a reasonable choice.

As discussed, surgery has a definite role in treating medically refractory disease or addressing dysplasia discovered by surveillance colonoscopy (dysplasia surveillance is done every 1 to 2 years after 8 to 10 years of disease by taking four-quadrant biopsy specimens every 10 cm). After total colectomy, options include an ileal pouch–anal anastomosis or a permanent end ileostomy. However, even the pouch can become chronically inflamed; generally, antibiotic responsive, this inflammation can also become refractory and require steroid, immunosuppressant, or biological therapy and even pouch removal.

KEY CONCEPTS

Ulcerative Colitis

- Ulcerative colitis (UC) is a chronic, relapsing inflammation of the colon that is limited to the mucosa and is not transmural.
- Many medical treatments for UC (including anti-TNF-α, anti-p40 or anti-integrin biologicals) overlap with Crohn disease, but total colectomy is typically reserved for UC when surgery is required for complicated or refractory disease.
- Although less strongly associated with genetic inheritance compared with Crohn disease, several UC susceptibility loci have been identified and are associated with epithelial barrier function.

ON THE HORIZON

Inflammatory Bowel Disease

- Improvement in detection of dysplasia using molecular techniques to better understand the incidence, natural history, prevention of, and role of inflammation-induced somatic mutations in inflammatory bowel disease (IBD)-related colonic epithelial neoplasia.
- Defining biomarkers that identify genotype–phenotype linkages that predict responses to highly targeted therapies like monoclonal antibodies.
- Determining whether the dysbiosis in IBD is a cause or effect and how manipulation of the microbiome can influence inflammation and response to treatment.

OTHER IDIOPATHIC INFLAMMATORY BOWEL DISEASES

Microscopic Colitis

Microscopic colitis is an increasingly recognized clinical condition that links chronic watery diarrhea with intraepithelial lymphocytosis (lymphocytic colitis) or with increased subepithelial collagen deposition (collagenous colitis). It differs from Crohn disease and UC by lacking endoscopic mucosal damage or evidence of histological features of chronic inflammation (no architectural crypt distortion, basal lymphoplasmacytosis, or loss of goblet cells). However, it causes significant morbidity and may require chronic immunosuppression for treatment. Although its etiology is unknown, there are associations with autoimmune conditions as well as with certain drug exposures.[52]

The hallmark symptom of microscopic colitis is poorly tolerated chronic, copious, watery, nonbloody diarrhea that can cause fatigue, arthralgias, and weight loss. Microscopic colitis typically begins in the sixth and seventh decades with a female predominance and is associated with a history of autoimmunity, especially thyroid disease, rheumatoid arthritis, and CREST (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) syndrome and even celiac disease.[53] Although celiac-like villus blunting may be seen in less than 10% of patients with microscopic colitis, celiac serologies will not be positive, indicating that classic gluten enteropathy is not playing a role.

There is no current information on the immune mechanism of microscopic colitis. Activated NF-κB, increased nitric oxide and prostaglandin production have been measured and have been linked to the diarrhea. Excessive transforming growth factor (TGF)-β has also been measured in collagenous colitis, consistent with its role in collagen production and fibrosis. Concomitant medications associated with microscopic colitis include H_2 blockers, PPIs, selective serotonin reuptake inhibitors, ticlopidine, and NSAIDs.

The diagnosis of microscopic colitis relies on histology. The sine qua non for microscopic colitis is increased numbers of intraepithelial lymphocytes (>20 lymphocytes/100 epithelial cells) on colonic mucosal biopsy. This can be accompanied by a chronic inflammatory infiltrate in the lamina propria and, less often, a limited appearance of neutrophils (especially cryptitis), the latter finding suggesting that the etiology of the microscopic colitis may actually be related to an injurious drug effect, such as NSAID exposure. In collagenous colitis, a prominent subepithelial collagen band ≥10 μm is seen in addition to the intraepithelial lymphocytosis.

The general treatment approach to the patient with microscopic colitis begins with eliminating suspect concomitant medications, such as NSAIDs. Coexisting celiac disease should be considered, where appropriate, and addressed with gluten withdrawal. Medical therapies can begin with antidiarrheals (loperamide, diphenoxylate/atropine), a trial of cholestyramine (bile salt malabsorption has been hypothesized to play a role in microscopic colitis), and even a course of mesalamine. Bismuth subsalicylate has been reported to benefit a minority of patients with microscopic colitis; in patients with initially severe symptoms or who are refractory to these first treatments, short-term corticosteroids have been very effective. In particular, limited courses of oral budesonide 9 mg taken once per day has reliably improved diarrhea and induced remission, a result supported by placebo-controlled studies.[54] However, balancing long-term relief of symptoms with side effects of corticosteroid use in relapsing or steroid-dependent disease has led to possible use of steroid-sparing immunosuppressive medications, such as azathioprine and methotrexate, for long-term maintenance. Reports of anti–TNF-α drugs for refractory microscopic colitis have been published.[55] Occasionally, patients may need colectomy and ileostomy to manage refractory symptoms or drug intolerance.

Eosinophilic Esophagitis

Eosinophilic esophagitis (EoE) is a more recently recognized disease defined by symptomatic idiopathic eosinophilic inflammation of the esophagus in the absence of other known causes, especially chronic gastroesophageal reflux disease (GERD). Although its etiopathology is unclear, there are gene associations (*FLG* for epithelial barrier effects and *eotaxin-3* and *TSLP* for immune response effects), and data from animal models and human disease have implicated central roles for loss of tolerance to food antigens involving Th2 cytokines IL-5 and IL-13. EoE is being recognized with increasing frequency against a background of increased incidence of inflammatory allergic diseases.

EoE has an incidence rate of 0.1 to 0.2 cases/10,000 persons/year, has a male predominance (up to 70%), and peak incidence in neonates to 3 year olds. Symptoms include failure to thrive and feeding difficulty in infants (e.g., food refusal, limited variety diet, prolonged feeding times) and abdominal pain and vomiting in older children and adolescents. In adults, the primary symptom is typically intermittent dysphagia, with the first presentation possibly being an acute food impaction in the esophagus. Adult patients may report GERD symptoms that do not respond to adequate acid-suppression therapy. Patients report a high rate (>50%) of atopy (rhinoconjunctivitis, wheezing, or family history of atopy) as well as food allergies (including positive skin prick test, allergen-specific IgE test, or anaphylactic response to a dietary allergen).[56] There is also an association of esophageal disease (strictures or EoE) in the parents of up to 10% of patients.

The diagnosis of EoE requires endoscopic biopsy of the esophagus since increased eosinophils in the esophageal epithelium must be measured. The endoscopic appearance of the esophagus can show multiple thin rings ("feline esophagus"), with linear longitudinal furrows and whitish papules that represent eosinophilic microabscesses at the surface of the squamous epithelium. Biopsies show an infiltrate of eosinophils in the epithelium of at least 15 to 20 eosinophils/high-power field (hpf).[57] These often concentrate just under the epithelial surface and also form microabscesses in groups of ≥4 eosinophils (systemic eosinophilia can be seen in over 70% of patients with EoE). It is important to take at least three biopsy specimens, since involvement may be variable and patchy; in addition, it is advisable to take biopsy specimens from the distal and mid-to-upper esophagus (to help differentiate changes seen in GERD that can be limited to the distal esophagus) and specimens from the gastric and duodenal mucosae (to show that the eosinophilic infiltration is limited to the esophagus and does not represent a diffuse process, such as that found in eosinophilic gastroenteritis or hypereosinophilic syndrome). However, the introduction of the EoE diagnostic panel, a set of 94 differentially expressed genes in the esophageal mucosa of EoE patients, may possibly supplant histological examination as a way to follow response to therapy and stratify risk for recurrent disease as a way to monitor treatment.[58]

In terms of GERD, it is important to make sure that any excessive acid reflux is treated and controlled; persistent symptoms (and persistent biopsy abnormalities) may prompt a 24-hour ambulatory pH study of the distal esophagus to ensure that the acid-suppression treatment results in a normal acid-contact time. In fact, there seems to be a form of EoE that, while seeming to be without excess exposure to gastric acid, does, in fact, respond well to proton pump inhibitor (PPI) treatment; this may be attributed to the non–acid-suppressive effects of a drug, such as omeprazole, that can suppress eotaxin-3 secretion from squamous mucosae.[59] Multiple types of esophageal dysmotility, often reversible with treatment, have been described in EoE, contributing more to dysphagia than to strictures.

The pathogenesis of EoE seems to be linked to environmental and food allergen hypersensitivity. Given a familial association of EoE, atopy, and food allergy, a genetic component may be contributing to disease susceptibility. Several candidate disease susceptibility gene/gene loci in EoE include the 3′ untranslated region of eotaxin (*CCL26*), the TGF-β_1 promoter, a filaggrin (*FLG*) exon, and a thymic stromal lymphopoietin (*TSLP*) intron and TSLP receptor (*CRLF2*) exon. These associations are biologically plausible, since eotaxin is excessively expressed in EoE mucosa, filaggrin is a structural skin protein that helps maintain barrier function (and is downregulated by IL-13), and TSLP has been shown to stimulate IL-13 production by innate helper cells in the lamina propria. Moreover, the inflammation in EoE is characterized by increased IL-13 and IL-5 production; animal models of aeroallergen induction of an EoE-like lesion is blocked in both IL-13–deficient and signal transducer and activator of transcription 6 (STAT6)–deficient (an intracellular molecule important for IL-13 receptor α_1 signaling) animals. These data suggest that IL-13 secretion induces production of eotaxin from epithelial cells, which, together with IL-5, drives the local eosinophilic infiltration. Finally, the association with food allergy has led to successful therapy of EoE by using strict elimination diets (sometimes informed by skin testing) or even the use of elemental diet tube feedings.

Given the strong association with food allergies, elimination of foods commonly associated with IgE-mediated responses may be restricted first. Lack of improvement in symptoms would lead to a trial of amino acid–based elemental liquid diet necessitating nasogastric (or later percutaneous gastrostomy) placement, but despite its high efficacy, this approach can be uncomfortable, impractical, and expensive. If this dietary approach is successful, then after several weeks, individual foods may be added back every 5 to 7 days. For patients not responding to dietary therapy or with no identifiable dietary

allergens, corticosteroid treatment has been used successfully. Both systemic oral and swallowed topical corticosteroids (e.g., fluticasone propionate metered dose inhalers) for 4 to 6 weeks have been shown to relieve symptoms and resolve histological inflammation; one or the other may be more or less effective based on body weight, dose, steroid resistance, or severity of the EoE. However, relapse rates are high over the year following a course of steroids, which might suggest a trial of azathioprine or 6-mercaptopurine. Lastly, endoscopic therapy to treat strictures using dilation may incur higher risk of mucosal tears so that conservative treatment (smaller dilators, assessment for tears during the procedure before proceeding further) is encouraged.

GASTROINTESTINAL COMPLICATIONS OF PRIMARY IMMUNODEFICIENCIES

Certain primary immunodeficiency diseases increase the risk for GI complications. These complications fall into three main categories: infectious, idiopathic inflammatory/autoimmune, and neoplastic. CVID and chronic granulomatous disease (CGD) have some of the most frequent and significant gut manifestations, and these are discussed in detail below. However, a variety of inherited conditions of broad lymphocyte or innate immune cell dysfunction can also lead to gut disease. The study of monogenic diseases that are associated with inflammatory diseases of the gut have come to the attention of investigators, as they may be models for the mechanisms that could contribute to the pathophysiology of more genetically complex conditions, such as Crohn disease and UC.[60]

Common Variable Immunodeficiency

CVID is a syndrome of hypogammaglobulinemia (low levels of IgG and IgA and/or IgM) accompanied by recurrent sinopulmonary infections (see Chapter 33). Patients have no isohemagglutinins and cannot mount an adequate antibody response to T cell-dependent and -independent vaccine antigens. In general, Ig replacement therapy improves the sinopulmonary infection rate but does not affect other complications, such as autoimmune and gastrointestinal. Case series of patients with CVID have shown that up to 60% of patients experience GI symptoms and that endoscopic and histological abnormalities can occur in the majority of patients with CVID.[61] When considering the differential diagnostic possibilities for the GI complications of CVID, it is helpful to separate them into infectious, immune-mediated, and neoplastic processes. Among the infectious agents, *Giardia lamblia*, nontyphoidal *Salmonella*, and *Campylobacter jejuni* are frequently seen, but *Cryptosporidium* may also be found, and *C. difficile* and viral agents (CMV) may be encountered. In addition to the higher rate of gastric *H. pylori* infection, small-intestinal bacterial overgrowth is present in up to 30% of patients with CVID. The immune-mediated GI complications of CVID include idiopathic enteropathy (villous atrophy, increased intraepithelial lymphocytes/microscopic colitis, nodular lymphoid hyperplasia) seen in less than 15% of patients (see Fig. 75.1, F), manifesting as severe malabsorption (see below) and, even more rare, macroscopic ulcerating disease resembling UC or Crohn disease. CVID-associated autoimmune disease involving the GI tract also includes type II gastritis that can lead to achlorhydria and vitamin B_{12} deficiency ("pernicious anemia") and even autoimmune hepatitis and primary biliary cirrhosis. Increased rates of intestinal lymphoma and gastric adenocarcinoma (related to achlorhydric autoimmune gastritis) have been found.[62]

Presentation

The most common symptom of GI complications in CVID is episodic diarrhea that can progress to chronic diarrhea, regardless of the etiology. Weight loss and evidence of vitamin or mineral deficiencies may occur, with underlying maldigestion or malabsorption. In addition, abdominal pain related to splenomegaly (with or without portal hypertension) or ascites (portal hypertension secondary to hepatic nodular regenerative hyperplasia) can occur. Fever, together with intestinal obstruction and GI bleeding, may indicate the development of small-bowel lymphoma. Patients with CVID may report increased frequency of GERD symptoms as well as dyspepsia, but these complaints are nonspecific and have been difficult to link with immune defects or autoimmune complications.

Immune Pathophysiology

It is not clear if lack of Igs alone causes susceptibility to gut infections and inflammation because patients with X-linked agammaglobulinemia infrequently develop overt GI disease (they lack B cells but have functionally intact T-cell populations). Even persons with selective IgA deficiency have little in the way of GI disease, including infections, though CVID enteropathy risk may be higher in patients with very low tissue IgA levels.[63] The T-cell dysfunction that often accompanies CVID likely contributes substantially to susceptibility to GI disease.

In terms of an increased GI infection risk, autoimmune gastritis-induced achlorhydria could increase small-bowel exposure to swallowed commensals and pathogens escaping this innate gastric barrier to infection. Mucosal nodular lymphoid hyperplasia, characterized by disorganized secondary lymphoid nodules with poorly formed germinal centers, is likely related to the inability of B cells to undergo class switching when presented with antigen in situ. Last, CVID enteropathy is characterized clinically by severe malabsorption and histologically by blunted villi and increased intraepithelial lymphocytes, and epithelial apoptosis is associated with excess Th1 cytokine secretion (IL-12 and IFN-γ).[64] It remains unknown why this inflammatory lesion occurs in the first place, but a recent report implicates chronic norovirus infection as a possible etiology.[65]

Diagnosis

The work-up of GI complications of CVID often takes place as symptoms are usually first episodic but may eventually turn into chronic, progressive complaints. The key to successful diagnosis is the initial search for treatable infectious causes. This requires stool assay and culture for bacterial (especially *Campylobacter*) and protozoal pathogens as well as stool polymerase chain reaction (PCR) for norovirus RNA. In addition, hydrogen breath testing can help detect SIBO to provide another antibiotic-responsive etiology of the symptoms.

Negative results for infectious causes require endoscopy for biopsy of the proximal small intestine and colon. Routine histology will detect the features of enteropathy, including blunted villi and increased IELs, which are often interpreted as celiac disease. Unlike celiac disease, there usually is a lack of plasma cell infiltrate and crypt hyperplasia, as well as a preserved brush border and goblet cells, and there is often an increase in epithelial cell apoptosis, particularly in the colon.[66] If the diagnosis of

celiac disease must be considered, then genetic testing for celiac susceptibility HLA alleles should be performed; the absence of combinations of A and B alleles for HLA-DQ2 or -DQ8 that confer risk will rule this out. However, even if celiac disease gene alleles are detected, it still does not indicate that this is a gluten-driven celiac disease lesion but will require a trial of GFD nonetheless. The functional significance of any histological lesion in the small intestine can be evaluated by a measure of steatorrhea (fecal fat excretion) and small-bowel absorption (D-xylose absorption test), values that can be used to track improvement following treatments.

Treatment

None of the GI complications of CVID is treated by IgG replacement (initial treatment might alleviate GI symptoms, it does not treat overt gut inflammation and ulcers). Patients with any bacterial or protozoal pathogens should be treated with a recommended course of conventional antibiotics, including those positive for the *C. difficile* toxin. SIBO should be treated, and recurrent SIBO may need cycling antibiotic regimens. Norovirus infection responds unreliably to ribavirin.

The treatment of the idiopathic enteropathy is very challenging. Although this seems to be a late complication in a subset of patients, it has a high mortality.[67] In the early stages, it may be responsive to a short course of oral corticosteroids, either prednisone or budesonide. Case reports attest to the efficacy of infliximab and anti-p40 antibodies are being tested in clinical trials. It is possible that immunosuppressants may be used to control the inflammatory response underlying the small-bowel mucosal damage, but this should only be done in a closely observed clinical setting, with monitoring for infections. At all times, the patient's nutritional status should be maintained, initially using the oral route but administering parenteral nutrition to complement oral nutrition and when oral feedings are not adequately absorbed and exacerbating the diarrhea.

Portal hypertension may complicate CVID, typically from the nodular regenerative hyperplasia of the liver though little fibrosis occurs. It needs to be clarified in individual patients with splenomegaly (≈20%) that portal hypertension is not caused by excessive splenic vein flow associated with splenomegaly (induced by antibody-mediated autoimmune cytopenias) that might be ameliorated by splenectomy. In any scenario, the management of such late complications requires an especially experienced team of internists, surgeons, and nutritionists.

KEY CONCEPTS

Common Variable Immunodeficiency

- The majority of gastrointestinal (GI) complications of common variable immunodeficiency (CVID) are infectious and generally do not respond to intravenous or subcutaneous immunoglobulin (IV/SCIG) therapy (compared with sinopulmonary suppurative infections).
- CVID enteropathy is a rare immune-mediated complication of CVID that also does not respond to IV/SCIG.
- CVID enteropathy is often confused with celiac disease because of similar villus damage on biopsy, but additional features (lack of plasma cells, increased epithelial apoptosis, absence of celiac gene risk alleles) can help differentiate them.
- CVID enteropathy has no established therapy though judicious use of short courses of oral steroids or conventional immunosuppression may relieve the malabsorption and diarrhea temporarily.

Chronic Granulomatous Disease

CGD results from defects in the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex that impair the ability of phagocytic cells to produce the reactive oxygen species required to kill bacteria and fungi within intracellular phagolysosomes (see Chapter 39). Patients with CGD have recurrent infections of the skin, lungs, liver, and bone, and nearly half develop gut inflammatory complications affecting areas anywhere from the mouth to the anus. Interestingly, the frequency of GI disease in CGD is higher in the X-linked $gp91^{phox}$ defect, but a recently described $p40^{phox}$ defect occurred in a young male patient who presented with granulomatous colitis alone.[68]

Presentation

GI symptoms (abdominal pain and diarrhea, with or without rectal bleeding) usually begin in the first decade of life, sometimes preceding the diagnosis of CGD. Although infectious diarrhea (especially *Salmonella* spp. and *C. difficile*) occurs in CGD, an idiopathic CGD-associated IBD also develops. In the mouth, granulomatous stomatitis and dental abscesses cause pain and difficulty eating; in the esophagus, dysphagia, chest pain, and vomiting may result from luminal narrowing or dysmotility related to granulomatous inflammation and fibrosis; in the stomach, loss of motility caused by thickened walls and smaller volume leads to vomiting, epigastric pain, and weight loss as a result of feeding difficulty; and in the small and large intestines, diarrhea (including protein-losing enteropathy), bowel obstruction (large granulomata compromising the size of the lumen), rectal bleeding, and tenesmus may result from active colitis/enteritis with mucosal ulceration, anal fissures, and perianal abscesses. In addition, because of the transmural nature of the granulomatous inflammation, penetrating complications, such as fistulae and abscesses, can occur. Feeding difficulties and the chronic inflammatory state itself predispose to growth delay that often affects pediatric patients with CGD.

Hepatic abscesses represent another frequent complication in CGD, occurring in up to 45% of patients.[69] These patients present with fever as well as abdominal pain, fatigue, and, less often, abdominal tenderness and hepatomegaly. The erythrocyte sedimentation rate (ESR) and the alkaline phosphatase level are elevated in half the affected individuals. However, a high level of suspicion, especially in the setting of fever with or without abdominal pain, should instigate a search for hepatic abscesses.

Immune Pathophysiology

Given the defects in ability to kill intracellular bacteria and fungi, pathogens, and possibly commensals alike, it is thought that the excessive granulomatous response is caused by delayed antigenic clearance or persistent infection. In this way, granulomata continue to multiply and grow while other inflammatory pathways that normally deal with the microbes or are induced by cytokines are activated. The end results of granulomatous inflammation are most evident in tissues rich in macrophages and reticuloendothelial cells, such as the gut lamina propria, liver, lymph nodes, and spleen.

Diagnosis

The symptoms and signs will dictate the initial diagnostic examinations. For diarrheal complaints, stool culture and examination for *C. difficile* toxin are required; in the setting of hypoalbuminemia, fractional fecal excretion of α_1-antitrypsin can detect

protein-losing enteropathy (>50 mg/24 hour) as a result of either diffuse mucosal inflammation or lymphangiectasia. For complaints of dysphagia, vomiting, or epigastric pain, upper endoscopy can help document macroscopic and microscopic involvement with granulomatous inflammation. Radiological studies using oral contrast can detect a narrowed lumen, stricturing, and motility and mucosal abnormalities of the esophagus and stomach but cannot provide histological confirmation. However, radiological imaging studies may be the primary diagnostic tools to evaluate obstructive symptoms from the small intestine, including barium small-bowel studies and CT or magnetic resonance enterography. CT and MR can show penetrating complications such as fistulization. Finally, to evaluate lower abdominal and perianal pain and rectal bleeding, anoscopy, colonoscopy, and pelvic CT or magnetic resonance imaging (MRI) will help diagnose granulomatous inflammation of the colon and its complications, including perirectal and perianal abscesses. In the case of hepatic abscess detection (generally 1 to 6 cm), CT, MRI, and ultrasonography have similar sensitivity (≈60%). Active abscesses appear to be solid, hypoechoic lesions on ultrasonography or postcontrast ring–enhancing lesions on CT and MRI.

The GI histological diagnosis hinges on the presence of noncaseating granulomata, both gross and microscopic. These granulomata are often seen against a background of acute inflammation (acute focal colitis, crypt abscesses, cryptitis) as well as chronic inflammation (lymphocytic infiltrate, Paneth cell metaplasia in the colon) that can be mild to severe. The histological picture may resemble Crohn disease except that the granulomata of CGD are well defined, often large collections of epithelioid histiocytes that can expand the mucosa (and even deform the overlying epithelium to make it look flattened in the case of the villous mucosa of the small intestine). Like Crohn disease, the inflammation can affect the three layers of the gut wall, but unlike in Crohn disease, CGD biopsy specimens also show prominent lipid-laden macrophages that have periodic acid-Schiff (PAS)–positive cytoplasmic granules.

Treatment

Current clinical practice for CGD includes using prophylactic antimicrobials to prevent infections, typically trimethoprim-sulfamethoxazole for bacterial and itraconazole for fungal infections. Some clinicians also use IFN-γ (subcutaneous, three-times-weekly dosing) to prevent infections, although this is not a universal practice. Obviously, discovery of infectious etiologies of diarrhea should be treated appropriately.

Once infections are ruled out and granulomatous inflammation of the GI tract is established, with or without complications, such as stricturing of the bowel, treatment with corticosteroids is indicated; beginning doses up to 1 mg/kg/day tapering over 12 to 20 weeks to maintenance doses of 2.5 to 5 mg every other day has been reported to induce rapid alleviation of symptoms. Use of sulfasalazine for colitis may have limited benefit in some patients. Isolated reports of successful use of cyclosporine and infliximab have indicated that these agents are best reserved for refractory cases because of the potential for infectious side effects. Similarly both granulocyte colony-stimulating factor (G-CSF) and granulocyte–macrophage colony-stimulating factor (GM-CSF) have been used with therapeutic benefit in GI complications of CGD because of their success in the granulomatous colitis of glycogen-1-β storage disease.[70] Although there are no data to suggest that IFN-γ worsens established disease, it also may not prevent it as greater than 40% of one cohort developed GI manifestations of granulomatous inflammation after starting it; in contrast, isolated reports have attributed alleviation of GI inflammation to IFN-γ. IL-1 receptor blockade, based on preclinical efficacy data in CGD, may offer limited success.[71]

Finally, it cannot be overstated that surgical drainage of complicating abscesses and resection of fibrotic or refractory strictures needs to be pursued, when indicated. Although there can be considerable postoperative complications because of ongoing fistula formation and wound breakdown, these problems may be managed by administration of corticosteroids. In addition, judicious use of endoscopic therapy to dilate narrowed esophageal or pyloric regions is an option for symptomatic strictures.

Treatment of hepatic abscesses has been shown to be amenable to nonsurgical management by adding corticosteroids to the antibiotic regimen. Empiric antibiotic coverage (at least to cover the most frequent isolate, *Staphylococcus aureus*) is generally appropriate although percutaneous aspiration of hepatic abscesses may be needed as well.[72]

KEY CONCEPTS

Chronic Granulomatous Disease

- Half of patients with chronic granulomatous disease (CGD) develop gastrointestinal (GI) involvement with granulomatous inflammation.
- Symptoms are caused by both obstructive complications of stricture formation and mucosal inflammation.
- A resemblance to Crohn disease is suggested by granulomatous inflammation, transmural bowel involvement, and underlying innate immune defect, but unlike in Crohn disease, there are also prominent skin and lung infections and periodic acid-Schiff–positive lipid-laden macrophages in the lamina propria.
- Complicated hepatic abscesses require collaborative medical and surgical intervention.

Gastrointestinal Complications Occurring in Other Primary Immunodeficiency States

Severe combined immunodeficiency (SCID) covers a wide phenotype of low-to-absent T cells, NK cells, and dysfunctional B cells reflecting the mechanisms of the genetic defect (see Chapter 32). Recurrent infectious diarrhea and thrush are typical GI conditions before a diagnosis of SCID is made in newborns and neonates. After allogeneic hematopoietic stem cell transplantation (HSCT), GI graft-versus-host disease (GvHD) is also a possibility. For many of the monogenic immunodeficiency diseases that confer susceptibility to GI inflammation, the success of HSCT to correct the secondary effect on the GI tract will depend entirely on whether the gene defect affects the myeloid or lymphoid cells primarily. If the gut stromal or epithelial cells also depend on normal function of the defective gene, then bone marrow transplantation will not likely relieve the GI effects.

The rare X-linked recessive Wiskott-Aldrich syndrome (*WAS*) (see Chapter 34) results from *WAS* gene mutations, a signaling protein largely restricted to hematopoietic cells, and leads to a syndrome of eczema, thrombocytopenia, and infections related to combined immunodeficiency (impaired antibody responses and T-cell function). A vexing aspect of the gut complication in this immunodeficiency is that patients may develop a noninfectious colitis resembling UC (confluent mucosal inflammation with ulceration, crypt abscesses, and no granulomata) with the bleeding exacerbated

by the thrombocytopenia.[73] Patients may respond to mesalamine drugs but use of steroids and immunosuppressives must be done cautiously because of increasing the infection risk. Successful bone marrow transplantation can treat the colitis as well.

Very early-onset IBD is a severe intestinal inflammation from rare mutations that affect IL-10 or its receptor. Patients present with colitis within weeks of birth that has features of Crohn disease. Diagnosis is made by genetic testing as well as by assay of peripheral blood mononuclear cells for absence of IL-10 production or absent IL-10 signaling demonstrated by decreased/absent induction of phospho-STAT3 following the addition of IL-10. X-linked lymphoproliferative syndrome 2 (*XIAP* deficiency) can present with very early-onset fistulizing perianal disease in up to 20% of patients.[74] The only cure is with HSCT.

The hyper-IgM syndrome (type 1) (see Chapter 33) is an X-linked condition resulting from mutations in CD40 ligand leading to defective antibody class switching (hence high [or normal] IgM with low IgA and IgG) and NK- and T-cell cytotoxicity. *Cryptosporidium* infectious diarrhea is seen, and sclerosing cholangitis, cirrhosis, and neoplasms of the hepatobiliary system complicate the course in teenagers and young adults. Rarely, noninfectious colitis has been reported. HSCT, preferably done before chronic complications occur, is the only approach with a potential for cure. IPEX (immune dysfunction/polyendocrinopathy/enteropathy/X-linked) syndrome is interesting in that it results from a defect in FOXP3 expression and function, thereby inhibiting the generation of Tregs (see Chapter 13). There is a lack of immune regulation, and enhanced responses, including autoimmunity, occur. The gut mucosa is a major site affected by inflammation, and this complication presents with a watery, sometimes bloody, diarrhea and malabsorption. Biopsies show villus blunting and atrophy in the small bowel and increased intraepithelial lymphocytes, lamina propria infiltration with T cells, eosinophils, and neutrophils elsewhere in the gut. Treatment requires HSCT, but the gut disease may be managed temporarily with corticosteroids and immunosuppressants.

Of note, colitis is a major side effect of the so-called checkpoint inhibitors that remove the regulation of the immune response in order to foster an anti-tumor T-cell response. Antibodies to cytotoxic T-lymphocyte antigen-4 (CTLA-4) and programmed cell death 1 (PD-1) can induce a colitis that can have penetrating ulcers; this unexpected side effect points to the importance of gut mucosal regulatory mechanisms for maintaining immune homeostasis.

ON THE HORIZON

Primary Immunodeficiency Diseases

Translation of monogenic immunodeficiency disease mechanisms, especially in very-early-onset inflammatory bowel disease (IBD), into knowledge of pathophysiology (genetic and acquired) of Crohn disease and ulcerative colitis for novel drug development.

Inflammatory Hepatobiliary Diseases

Benedetta Terziroli Beretta-Piccoli, Carlo Selmi, Michael P. Manns, and M. Eric Gershwin

Inflammatory hepatobiliary disease refers to chronic autoimmune diseases with predominant hepatic or biliary manifestations, without evidence of infectious diseases. Based on the target tissue, we can distinguish autoimmune hepatitis (AIH), targeting hepatocytes, from primary biliary cholangitis (PBC) and primary sclerosing cholangitis (PSC), both targeting the biliary tract. Cirrhosis and eventually liver failure are the common evolution of inflammatory hepatobiliary diseases, regardless of the target tissue, despite pathogenesis and therapeutics varying in between the spectrum of inflammatory hepatobiliary diseases.[1,2] In this chapter we aim to elucidate the main characteristics of AIH, PBC, and PSC, with particular interest for the clinical manifestations, pathogenesis, autoantibodies, and therapeutic options.

Immunoglobulin G4 (IgG4)-mediated cholangitis is a more recently reported clinical entity belonging to the group of immune-mediated hepatobiliary disorders, and will therefore also be briefly discussed in the present chapter.

AUTOIMMUNE HEPATITIS

Definition

AIH is defined as a chronic, inflammatory liver disease of unknown etiology, affecting all ages and races, and is characterized by female preponderance, elevated serum transaminase and immunoglobulin G levels, positive circulating autoantibodies, interface hepatitis at liver histology, and a swift response to corticosteroid treatment. If untreated, the disease invariably progresses over time to cirrhosis and eventually liver failure: the reported 5- and 10-year survival rates without treatment are 50% and 10%, respectively.[3]

Two types of AIH are distinguished based on the autoimmune serological profile: AIH type 1 is characterized by positive anti-nuclear (ANA) and/or anti-smooth muscle (SMA) antibodies, and AIH type 2 by anti-liver kidney microsomal type 1 (LKM1) and/or anti-liver cytosol (LC1) type 1 antibodies. Type 1 AIH can affect people of any age and sex, accounting for two-thirds of juvenile AIH cases. Type 2 AIH primarily affects young children and adolescents/young adults; onset later in life is virtually absent.

Epidemiology

Albeit an accurate estimate of AIH incidence and prevalence is not available, AIH type 1 incidence is supposed to be between 1.1 and 3 per 100,000 person-years in adults and between 0.23 and 0.83 in children, and AIH-1 prevalence between 16.9 and 35.9 in adults (being highest in Alaska) and 11.6 in children.[2,4] Therefore, AIH meets the definition of a rare disease.

AIH has a female preponderance, with a male:female ratio of 1:4, and a two-peak incidence during adolescence and at 30 to 45 years of age.[2] Type 2 AIH, which typically affects children and adolescents, is much rarer than type 1 AIH—the precise incidence and prevalence being largely unknown.

Risk Factors and Pathophysiology

Although the AIH etiology remains unknown, it results from the immune-mediated destruction of hepatocytes.[5] Both genetics and environmental risk factors contribute to the development of the disease. Susceptibility to AIH is strongly influenced by the large and highly polymorphic human leukocyte antigen (HLA) class II region (Chapter 5), whose protein products play a key role in the presentation of antigenic peptides to T cells.[5] There is a geographical variability of HLA alleles associated to AIH, DR3 (*DRB1*0301*), and DR4 (*DRB1*0401*) being found in 70% of AIH patients in Europe and North America, whereas *DRB1*0405* and *DRB1*0404* confer AIH susceptibility in populations living in Argentina, Mexico, and Japan. Of note, both *DRB1*0301* and *DRB1*0401* alleles code for the hexameric amino acid sequence LLEQKR at positions 67 to 72, whereby *DRB1*0405* and *DRB1*0404* allele encode a very similar hexameric sequence with arginine instead of lysine at position 7, suggesting that this sequence with a basic amino acid at position 71 is critical to confer susceptibility to AIH.[6]

Interestingly, *DRB1*0401* was found to be protective in juvenile AIH, whereas *DRB1*0301* is a risk allele also in children and adolescents.[6] Type 2 AIH is linked to possession of the *DRB1*0701* and *DRB1*0301* alleles. Moreover, HLA alleles have been linked to AIH clinical manifestations, as well as autoimmune serology, response to treatment, and prognosis.

Environmental factors have also been linked to AIH development, whereby the best investigated mechanism is molecular mimicry, a process leading to exaggerated immune response against self-components with structural homology to foreign antigens.[7] Supporting this hypothesis, it has been demonstrated that the hepatitis C virus (HCV) shares high amino acid sequence homology with the cytochrome P4502D6, which is the auto-antigenic target of anti-LKM1, and that up to 10% of HCV patients are seropositive for anti-LKM1. Nonviral environmental factors include medications, in particular antibiotics (nitrofurantoin and minocycline), statins, anti-tumor necrosis factor-α (TNF-α) agents (adalimumab and infliximab) and herbal remedies; however, the disease is different from classical AIH, and usually does not require long-term immunosuppressive treatment.

Therefore, a careful history on drug and herbal remedies intake is essential in patients presenting with suspected AIH.[8]

From an immunological standpoint, liver damage is initiated by the presentation of an autoantigenic peptide to a naïve CD4 T cell, which, depending on the cytokine milieu, will differentiate into a Th1, Th2, or Th17 cell (Chapters 10 and 11). These effector cells initiate a cascade of immune reactions: (a) Th1 cells secrete mainly interleukin (IL)-2 and interferon (IFN)-γ; IFN-γ is considered the main orchestrator of tissue damage since it stimulates CD8 cells, enhances the expression of HLA class I, induces the expression of HLA class II molecules on hepatocytes, and activates monocytes/macrophages, which in turn release IL-1 and TNF; (b) Th2 cells produce IL-4, IL-10, and IL-13, cytokines that induce the maturation of B cells into plasma cells, with consequent production of autoantibodies; (c) Th17 cells, which arise in the presence of transforming growth factor (TGF)-β and IL-6, produce IL-17, IL-21, IL-22, TNF, and chemokine ligand (CCL)-20.[2] Th17 cells, which play a central role in PBC, are being evaluated also in AIH as an increased number of Th17 cells have been reported in the peripheral blood and liver of patients with AIH compared to healthy controls.[1,9]

In healthy individuals, regulatory T cells (Treg), constituting 5% to 10% of peripheral CD4 T cells, are key players in limiting the ability of physiologically present autoreactive T cells to cause tissue damage. In AIH, Treg are numerically and functionally impaired, particularly during active disease phases. Therefore, therapeutic approaches aiming at restoring the number and the function of Treg are under investigation.

Clinical Presentation and Biochemical Features

While the majority of adult AIH patients present with mild, unspecific or no symptoms, an acute icteric hepatitis associated with hypergammaglobulinemia is the initial presentation in 20% to 30% of cases. Rarely, patients present with a complication of portal hypertension, and, very rarely, with acute liver failure.[10] Acute presentation is more frequent in children compared to adults.[2]

Some 20% of AIH patients have concomitant extrahepatic autoimmune diseases: therefore, presenting symptoms may be attributable to these diseases, which include, among others, Hashimoto thyroiditis, rheumatoid arthritis, lupus erythematosus, inflammatory bowel disease (IBD), alopecia, and psoriasis.[2,11]

Blood tests usually show marked elevation of aminotransferases; γ-glutamyl transferase is also frequently elevated, whereas alkaline phosphatase is generally normal in adults, but in children it is elevated due to bone growth. Direct bilirubin ranges from normal to markedly elevated with jaundice. Furthermore, serum globulins, particularly of the γ type, are commonly increased in AIH cases regardless of the histological stage.

At the time of diagnosis, approximately 30% of adult and pediatric patients have histological evidence of cirrhosis; however, when appropriately treated, only a small number of patients develop cirrhosis during follow-up if biochemical remission is achieved.[2,12,13] Cirrhosis at presentation is probably not associated with worse outcomes.[2,12] The occurrence of hepatocellular carcinoma (HCC) in patients with AIH is a rare event and only develops in long-standing cirrhosis.

The clinical course of AIH without treatment is burdened by high mortality, with 5- and 10-year survival rates estimated as 50% and 10%, respectively, but the use of corticosteroids has dramatically improved the course of the disease with a 10-year survival rate exceeding 90%.[8] The complications associated with AIH are similar to those of other progressive liver diseases as chronic hepatitis can evolve to cirrhosis and ultimately to HCC despite the use of immunosuppressive therapy, particularly if biochemical remission is not achieved.

Serum Autoantibodies

Serum autoantibodies are a key feature of AIH, being positive in up to 95% of the patients if tested according to international, dedicated guidelines issued in 2004 to overcome the lack of standardization (Table 76.1).[2,14] According to these guidelines, liver-relevant autoantibodies should be tested, at a screening level, by indirect immunofluorescence on triple rodent tissue: this methodology allows for the simultaneous detection of ANA, SMA, anti-LKM1, anti-LC1 and anti-mitochondrial antibody (AMA). The positivity cut-off is ≥1:40 in adults, while in children even lower titers are of clinical significance: that is, ≥1:20 for ANA and SMA, and ≥1:10 for anti-LKM1 and anti-LC1. ANA-positive sera should be further tested on HEp2 cells, allowing the detection of the nuclear pattern. Anti-neutrophil cytoplasmic antibody (ANCA) should be tested using human fixed neutrophils as an indirect immunofluorescence substrate. Autoantibody for which the target antigen has been identified are increasingly tested by molecular-based assays. The initial screening for liver-relevant autoantibodies should include, besides immunofluorescence on triple rodent tissue, a molecular-based assay for anti-soluble liver antigen (SLA), whose AIH specificity is as high as 98.9%, despite a relatively low sensitivity of about 30%.[2]

ANA in AIH patients most frequently produces a homogeneous pattern in immunofluorescence on HEp cells.[15] However, ANA is not specific for AIH, being not uncommon in patients with viral or other autoimmune liver diseases, with systemic/extrahepatic diseases, as well as in as many as 15% of healthy subjects, especially in older age groups.[16] Moreover, ANA positivity, immunofluorescence pattern, or titer does not reflect different AIH phenotypes and they cannot predict the disease's natural history.

Serum SMA is an autoantibody reacting with different proteins (actin, tubulin, vimentin, desmin, cytokeratins) of the cytoskeletal components. Its presence lacks AIH specificity, being detected in the serum of patients with other hepatic and extrahepatic autoimmune diseases, such as PSC or celiac disease, and in non-autoimmune liver diseases, including viral hepatitis C and E, and non-alcoholic steatohepatitis. However, when detected at high titers (>1:80), SMA is considered a sensitive marker for AIH-1, being found in up to 85% of cases.[15] In addition, the staining pattern in indirect immunofluorescence on rodent kidney tissue is of diagnostic help: staining of glomerula and tubuli, besides vessels, is more frequently observed in sera of AIH than non-AIH cases.[15]

Autoantibody against LKM1 is the serological hallmark of AIH-2. In indirect immunofluorescence on triple rodent tissue, it stains the proximal, larger renal tubuli and the hepatocellular cytoplasm, sparing stomach tissue. The 50-kDa autoantigen was identified as the cytochrome P450 2D6 (CYP2D6). Anti-LKM1 is detected also in serum of up to 13% of patients with chronic HCV infection, sharing target epitopes of CYP2D6 with the anti-LKM1 detected in AIH-2.[15] Importantly, anti-LKM1 titers correlate with disease activity of AIH-1, and should be used to monitor patients. The pathogenic role of anti-LKM-1 is still debated, despite the development of AIH-2 animal models following immunization with human CYP2D6 or with adenoviruses

TABLE 76.1 Most Relevant Features of Liver-Relevant Autoantibodies

Specificity	Known Antigenic Targets	Methods of Detection	Frequency	Diagnostic Role	Other Associated Liver Diseases	Comments
ANA	Homogeneous, speckled, nucleolar pattern: Chromatin, histones, cyclin A, ribonucleoproteins, double-/single-stranded DNA, SSA, SSB, Scl70, Smith Rim-like/membranous pattern: gp210, nucleoporin p62, lamin B receptor Multiple nuclear dots pattern: Sp100, promyelocytic leukemia protein, Sp140, small ubiquitin-related modifiers Centromeric pattern: CENP-A, CENP-B, CENP-C, CENP-D, CENP-E, CENP-F	IIF	AIH-1 and ASC: 75% PBC: 10%–65% PSC: 8%–77%	AIH: concomitant SMA confers 99% diagnostic specificity PBC: Rim-like/membranous and multiple nuclear dots patterns virtually diagnostic; Anti-centromere rarely present in isolation PSC: may suggest AIH overlap	Viral hepatitis DILI NAFLD Wilson disease HCC	AIH: Homogeneous pattern in ~75% of patients Speckled or nucleolar pattern in ~25% of patients PBC: Rim-like/membranous and, multiple nuclear dots associated with worse outcomes Anti-centromere associated with portal hypertensive phenotype
SMA	Filamentous actin Vimentin Desmin	IIF	AIH-1: 85% ASC: 75% PSC: up to 83% PBC: unknown	VG and VGT IIF patterns specific for AIH-1 Concomitant SMA: 99% diagnostic specificity	DILI NAFLD Viral hepatitis Wilson disease	V pattern in 20% of type 1 AIH patients Titers correlate with disease activity
Anti-actin antibody	Actin	Molecular-based assays	AIH-1: 60%	Specific for AIH-1 at high titers	DILI NAFLD Viral hepatitis Wilson disease	Sensitivity and specificity depend on the cut-off point. Less specific for AIH than the VG/VGT IIF pattern
Anti-LKM1	Epitopes of CYP2D6	IIF Molecular-based assays	AIH-2: up to 90%	Specific for AIH-2 in absence of hepatitis C	Hepatitis C	Titers correlate with disease activity Post-transplant reappearance predicts AIH-2 recurrence Atypical anti-LKM1 associated with de novo AIH
Anti-LC1	Formiminotransferase cyclodeaminase	IIF Molecular-based assays	AIH-2: 60%	Specific for AIH-2 in absence of hepatitis C	Hepatitis C	Only serological marker in 10%–30% of AIH-2 cases Titers correlate with disease activity
Anti-SLA	*O*-Phosphoseryl-tRNA (Sec) selenium transferase	Molecular-based assays	AIH-1 and AIH-2: up to 58% ASC: up to 41%	Highly specific for AIH. Low disease sensitivity when tested with commercial solid phase assays	Extremely rare in hepatitis C	Associated with worse outcomes
pANNA	Beta-tubulin isotype 5; HMG1; HMG2; other unknown autoantigens	IIF	AIH-1: 40%–96% PSC: 26%–94% ASC: up to 74%	Specific for AIH-1, PSC and IBD		May be the only serological marker in AIH-1 Absent in type II AIH IBD and sclerosing cholangitis must be excluded in pANNA-positive patients
AMA	E2 subunits lipoyl domains of PDC, OGDC and BCOADC, E3 binding protein of PDC	IIF Molecular-based assays	PBC: up to 95%	Highly specific of PBC	Acute liver failure PBC/AIH overlap	Predicts PBC if detected in absence of liver disease May be associated with histological PBC changes even in absence of biochemical cholestasis

delivering human CYP2D6 to hepatocytes. Finally, two other types of anti-LKM, giving slightly different staining patterns in indirect immunofluorescence, have been described in patients with ticrynafen-associated hepatitis (anti-LKM2, directed against CYP2C9) and in 19% of patients with type 2 AIH (anti-LKM3, directed against UGT1A), either alone or in combination with LKM1 antibodies. Anti-LKM3 is also detected in 13% of patients with chronic hepatitis delta infection. Its clinical use is hampered by detection only on primate or humane substrates.

Anti-soluble liver antigen (SLA) antibody is detectable by immunoblot and enzyme-linked immunosorbent assay, but not by immunofluorescence, and is directed against different epitopes of a UGA tRNA suppressor. Serum anti-SLA is occasionally found in patients with AIH who are negative for ANA, SMA, or anti-LKM and is cumulatively detected in 10% to 30% of cases of AIH-1 and -2. However, the assays used in clinical laboratories have low sensitivity; if tested by radioligand assays, which preserve conformational epitopes, anti-SLA are positive in 58% of AIH-1 and AIH-2, and in 41% of children with autoimmune sclerosing cholangitis (ASC).[15] Anti-SLA is the only autoantibody disease-specific autoantibody, having a specificity as high as 98.9%.[2] Its presence is also associated with a more aggressive disease course.

The anti-LC1 antibody is detected by indirect immunofluorescence in sera of up to 30% of patients with type 2 AIH and much less frequently in chronic hepatitis C. Importantly, however, anti-LC1 is the only detectable serological marker in 10% of AIH-2 cases. The LC1 autoantigen is the liver formiminotransferase cyclodeaminase, an enzyme involved in folate metabolism. Serum anti-LC1 antibody titer correlates with AIH-2 activity, and should be used to monitor patients.

Antibodies to neutrophil cytoplasmic antigens (ANCA) can be detected by indirect immunofluorescence on human neutrophil substrate, giving either A perinuclear (pANCA) or a cytoplasmic (cANCA) pattern. pANCA are frequently detected in sera from AIH-1 patients, although they give an atypical staining pattern; as opposed to pANCA, which give a cytoplasmic pattern on ethanol-fixed neutrophils, the perinuclear pattern of atypical pANCA is unaffected by the method of fixation. As a consequence, they are also known as perinuclear anti-neutrophil nuclear antibody (pANNA) or nuclear anti-neutrophil antibody (NANA). ANCA are absent in AIH-2, and are frequently detected also in PSC and IBD.

Histology

The role of liver histology in the diagnosis of AIH remains critical and all suspect cases should undergo a liver biopsy. In fact, although no typical feature can be sufficient to prove the diagnosis, histology remains the gold standard for grading and staging, and to rule out coexisting conditions, including overlap with PBC. Typical findings include portal hepatitis with mononuclear cell infiltrate and interface hepatitis (Fig. 76.1). Fibrosis is frequently observed; bridging or multiacinar necrosis indicates severe disease requiring prompt therapy. Importantly, the presence of granulomas, bile duct damage, or iron or copper accumulation should not be overlooked since these signs point towards alternative diagnoses. On the other hand, steatosis is a nonspecific and frequent finding that does not rule out AIH.[9]

Diagnostic Criteria

There is no single diagnostic test for AIH; therefore, diagnosis is based upon several indicative clinical, serological, biochemical, and histological findings. It is critical to exclude alternative causes of liver injury, particularly viral hepatitis. The International Autoimmune Hepatitis Group (IAIHG) has established, and subsequently simplified for clinical use, a set of diagnostic criteria with high sensitivity and specificity for the diagnosis (Table 76.2). Factors taken into account by the simplified scoring system include serum autoantibodies, liver histology, and exclusion of viral hepatitis.[17]

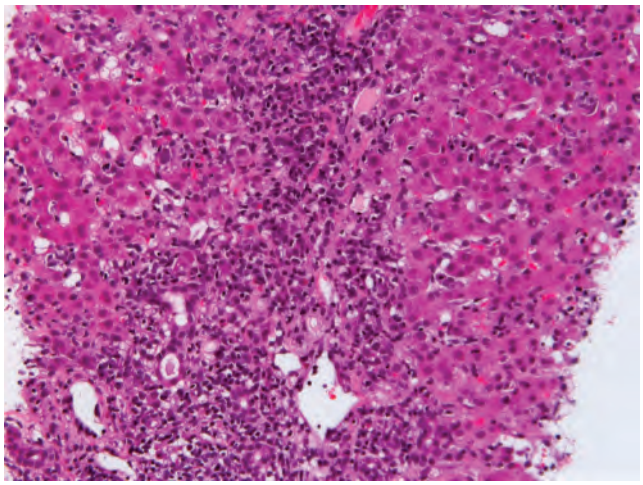

FIG. 76.1 Typical histological findings of autoimmune hepatitis showing marked lymphoplasmacellular infiltration of the portal tract with interface hepatitis. (Courtesy of Elisabetta Merlo.)

Therapy

Treatment of AIH aims at completely suppressing the hepatic inflammatory activity, which correlates with biochemical remission, defined as complete normalization of transaminase and IgG levels: patients achieving biochemical remission very rarely have histological progression.[18] Induction of remission is based on corticosteroids, in particular prednisone, while maintenance of remission is based on azathioprine, with or without low-dose prednisone, tailored to the individual risk–benefit profile. The initial prednisone dose is 0.5 to 1 mg/kg/day, but lower doses can be given in mild disease, and up to 100 mg/day intravenously should be used in case of severe disease. Steroids should be reduced at weekly intervals, under close monitoring of transaminase levels. A decrease in transaminase levels is almost universally achieved within 2 to 3 weeks; lack of response requires reconsideration of the diagnosis.[2] Once transaminase and bilirubin levels improve, azathioprine should be started, gradually reaching the dose of 1 to 2 mg/kg/day. Therapy should be maintained for at least 3 years, and an attempt of gradual withdrawal should be made only after stable biochemical remission. Relapses following therapy discontinuation are common since <20% of patients remain in sustained remission off treatment. Close monitoring of patients is required long term.

Mycophenolate mofetil is the drug of choice in case of azathioprine intolerance, with a reported response rate of 60% to 80%; however, it should be used with caution in fertile women due to its teratogenicity.

In case of insufficient response to initial treatment, azathioprine metabolites should be checked to assess both adherence and pharmacodynamics. Mycophenolate mofetil is rarely effective in patients not responding to azathioprine, and cyclosporin A or tacrolimus should be preferred in this situation. Infliximab and rituximab are reserved for very difficult patients and should be used only by specialized centers. Liver transplantation is the ultimate treatment for AIH patients presenting with acute liver failure not responding to steroids, or who

TABLE 76.2 Revised Diagnostic Scoring System Proposed by the International Autoimmune Hepatitis Study Group

Criteria	Points
Sex:	
Male	+2
Female	0
Ratio of ALP vs. AST/ALT:	
>3.0	+3
1.5–2.0	+2
1.0–1.5	+1
<1.0	0
Autoantibodies (ANA, SMA, LKM1) titer:	
>1:80	+3
1:80	+2
1:40	+1
<1:40	0
AMA:	
Positive	−4
Negative	0
Seropositivity for other autoantibodies	+2
Viral hepatitis markers:	
Negative	+3
Positive	−3
History of drug use:	
Yes	−4
No	+1
Average alcohol consumption (g/day):	
<25	+2
>60	−2
Presence of genetic factors (HLA, DR3, or DR4)	+1
Presence of other autoimmune disorders	+2
Liver histology:	
Interface hepatitis	+3
Predominant lymphocytic infiltrate	+1
Rosetting of liver cells	+1
None of the above	−5
Biliary changes	−3
Other changes	−3
Response to therapy:	
Complete	+2
Relapse	+3

A score >15 or >17 indicates a definite diagnosis of AIH pre- or post-treatment, respectively. Scores between 10–15 and 12–17 indicate a probable diagnosis, pre- or post-therapy, respectively.
ALP, Alkaline Phosphatase; *ALT*, alanine aminotransferase; *AST*, aspartate aminotransferase; *AMA*, Anti-mitochondrial autoantibodies; *ANA*, anti-nuclear; *DR3*, no expaned form; *DR4*, no expaned form; *HLA*, human leukocyte antigen; *LKM1*, anti-liver–kidney microsomal antibodies; *SMA*, anti-smooth-muscle antibodies.

progress to end-stage liver disease despite treatment (10% to 20% of the cases). Although liver transplantation for AIH is very successful, it should be noted that AIH may recur after transplant in up to 30% of the cases, rarely requiring a second transplant. Patients with AIH undergoing liver transplant have overall 5- and 10-year survival rates of 90% and 75%, respectively.

KEY CONCEPTS

- Autoimmune hepatitis (AIH) is a chronic inflammatory liver disease associated with high morbidity and mortality, especially due to the development of cirrhosis and liver failure.
- Autoantibodies represent a key diagnostic feature of AIH; the definition of an AIH subset is based on serum autoantibodies.
- Liver biopsy is mandatory to diagnose AIH, as histology remains the gold standard for grading and staging, and to rule out concomitant liver diseases.

CLINICAL PEARLS

- Serum transaminase levels can spontaneously improve in untreated autoimmune hepatitis (AIH): this should not delay treatment
- If autoantibodies are tested according to dedicated recommendations, up to 95% of AIH patients are positive for at least one autoantibody
- In children, overlap with sclerosing cholangitis is frequent, and magnetic resonance cholangiopancreatography should be part of the diagnostic work-up

THERAPEUTIC PRINCIPLES

- Corticosteroids represent the cornerstone of remission induction: they should be rapidly tapered under close monitoring of transaminase levels in order to minimalize side effects.
- Long-term maintenance therapy is based on azathioprine, or mycophenolate mofetil in intolerant patients.
- Dosage of steroids and azathioprine should be carefully tailored to the individual patient, taking into account disease severity, comorbidities, and side effects.
- Liver transplantation is very successful; however, autoimmune hepatitis may recur after transplant.

PRIMARY BILIARY CHOLANGITIS

Definition

PBC is defined as a chronic autoimmune attack to intrahepatic biliary epithelial cells. It is characterized by a striking female preponderance, biochemical cholestasis, pruritus, positive AMA, and progression to cirrhosis if left untreated.[1] PBC is absent in children, and the average age at diagnosis is within the 5th and 6th decade of life.

Nomenclature

In 2014, the term primary biliary cirrhosis has shifted towards PBC to correct the inaccuracy and remove the cirrhosis stigma as well the misunderstanding, disadvantages, and discriminations emanating from this misnomer for patients. This change was necessary after the dramatically improved PBC diagnosis, treatment, and prognosis, thanks to widely available AMA testing, and early treatment initiation with ursodeoxycholic acid (UDCA). Nowadays, two out of three PBC patients treated with UDCA have an expected survival equal to the general population, and only a minority will ever develop cirrhosis.[19]

Epidemiology

PBC is considered a rare disease: prevalence reported in Europe, North America, Australia, and Asia ranges from 19 to 402 cases per million inhabitants; incidence varies between 3.3 and 58 cases per million inhabitants per year.[20,21] Overall, the reported incidence and prevalence have increased in recent years, potentially due to more widely available AMA testing and increased awareness among clinicians, leading to diagnosis of mild, asymptomatic cases; however, a true increase in disease frequency cannot be excluded.

Pathogenesis

As in many autoimmune diseases, genetics, epigenetic, and environmental factors interact to lead to PBC, whose precise pathogenesis, however, remains elusive.

Genetic factors play a predominant role in PBC susceptibility, as suggested by the fact that the disease is more frequent in

relatives of affected individuals, and the term "familial PBC" has been coined to indicate families that have more than one case. In our experience, 6% of cases have a first-degree relative that is also affected, while AMA may be positive in first-degree relatives and offspring of patients with PBC without any sign of disease, thus indirectly suggesting the existence of a strong genetic predisposition.[1,21,22] Importantly, the concordance rate observed among monozygotic twins for PBC is 63%, which is among the highest reported in autoimmunity.[21] As for other autoimmune disorders, genetic factors are not limited to a single gene but are complex multi-gene traits.[21] HLA alleles have been identified by case-control studies, and later confirmed by a genome-wide association study, as the strongest link with PBC susceptibility.[21] Interestingly, PBC is associated with not only the HLA *DRB1*08* allele but also two protective alleles, *HLA DRB1*11* and *DRB1*13*. A wide array of non-HLA risk loci has also been identified, and, although the identified loci are different across studies, they involve the same immunological pathways, particularly antigen presentation and production of interleukin-12, and T- and B-cell activation.

In spite of these observations, genetic susceptibility alone is insufficient to explain the PBC pathogenesis. Other factors, including epigenetics and exposure to environmental factors, have been shown to play a key role in increasing the susceptibility to PBC. Urinary tract and vaginal infections are more frequent in PBC than in controls, with *Escherichia coli* being the main etiological agent. The mechanism linking infections and autoimmune biliary tract damage is probably molecular mimicry. Xenobiotics are foreign compounds, which may trigger an autoimmune response to self-proteins as they modify their molecular structures or complex to self- or nonself-proteins to generate neoantigens. In this view, our group has demonstrated that xenobiotic modification of the E2 subunit of the pyruvate dehydrogenase (PDC-E2) inner lipoyl domain can lead to loss of tolerance in genetically susceptible hosts.[23]

Epigenetic modifications could represent the link between genetic and environmental factors influencing the onset and evolution of PBC. For instance, DNA hypermethylation of a number of immunological genes on chromosome X has been identified in studies of discordant monozygotic twins and sister pairs, and decreased methylation of the CD40 ligand gene on chromosome X has been shown to correlate with serum IgM elevation, a typical feature of PBC. In addition, higher X chromosome monosomy has been demonstrated in PBC patients.[21] Differential expression of a wide range of micro-RNAs (mi-RNAs) in PBC compared to controls has also been reported, suggesting their potential role as novel biomarkers (Chapter 19). Moreover, a functional role of miRNA has robustly been demonstrated in PBC: upregulation of miR-506 correlates with decreased expression of the anion exchanger 2 protein—the main protein involved in biliary bicarbonate secretion. The bicarbonate-rich layer on the canalicular cholangiocyte membrane, named biliary bicarbonate umbrella, is crucial in protecting cholangiocytes from toxic bile acids, which in protonated form, can invade cells, leading to apoptosis and exposure of intracellular antigens, triggering an autoimmune attack. This cascade of events raises the fundamental question as to whether the disrupted biliary homeostasis in PBC is the cause or the consequence of the autoimmune attack. This question has to be addressed by future research.[1]

Diagnosis, Clinical Features, and Prognosis

The diagnosis of PBC is based on the presence of two out of three internationally accepted criteria: that is, detectable serum AMA (titer >1:40), increased cholestasis enzymes (i.e., alkaline phosphatase) for longer than 6 months, and a compatible or diagnostic liver histology.[24] Serum IgM is typically elevated in PBC cases, with no correlation with AMA titers or levels of other Ig subtypes.

Symptoms of PBC in the early phases, affecting more than half of the patients, are mainly fatigue and pruritus, while physical findings may include skin hyperpigmentation, hepatosplenomegaly, and xanthelasmas. Late-stage symptoms are those of all types of cirrhosis, including ascites, jaundice, hepatic encephalopathy, and upper digestive bleeding. However, portal hypertension may appear earlier in the disease course as compared to non-cholestatic diseases, owing to a pre-sinusoidal component; treatment of PBC-associated portal hypertension is not different from other chronic liver diseases. Fatigue is a nonspecific symptom affecting 70% of PBC patients, often overlooked, particularly in middle-aged women. The severity of fatigue is independent of the stage of PBC. Pruritus is more frequent in advanced-stage PBC, but may long precede jaundice onset, and typically worsens at night, following contact with wool, or in warm climates. Since both fatigue and pruritus are subjective, it is very important to collect information directly from patients, in a quantitative manner, in the form of "patient-reported outcomes." Dedicated, PBC-specific tools such as the PBC-40 questionnaire, are available, but must be validated locally.[1] Osteopenia and osteoporosis are more frequent in PBC patients when comparing to sex- and age-matched healthy individuals: therefore, screening with bone mineral density at diagnosis and during follow-up is advisable in all patients, as well as calcium and vitamin D supplementation, if needed. Hyperlipidemia affects up to 80% of patients with PBC. However, it is not accompanied by a proportionally increased incidence of cardiovascular events or atherosclerosis. This assumption has recently been challenged, and therefore clinicians should carefully evaluate cardiovascular risk of PBC patients.[24]

Extrahepatic Autoimmune diseases frequently overlap with PBC, most commonly Sjögren syndrome, Raynaud phenomenon, autoimmune thyroid disease, scleroderma, and systemic lupus erythematosus, while the prevalence of rheumatoid arthritis does not differ from controls.

Similarly to other types of cirrhosis, end-stage PBC can be complicated by the occurrence of hepatocellular carcinoma (HCC) and patients should be admitted to a surveillance program with ultrasound every 6 months.

The progression of PBC varies widely, and risk factors for a more aggressive course have been identified, including male sex, younger age at diagnosis, PBC-specific ANA positivity, lack of biochemical UDCA response (see below), and advanced fibrosis at diagnosis. An important message for patients is that UDCA initiation at an early disease stage is accompanied by 10-year survival rates similar to the general population.[1]

Serum Autoantibodies

AMA are highly specific for PBC and can be detected in up to 95% of patients when sensitive diagnostic methodologies based on recombinant antigens are used.[1] However, the gold standard method to detect AMA in clinical settings is still indirect immunofluorescence, because it allows the simultaneous detection of all liver-relevant autoantibodies, except anti-SLA. AMA is directed against components of the 2-oxoacid dehydrogenase family of enzymes within the mitochondrial respiratory chain, most frequently the E2- and E3-binding protein components of

the PDC and the E2 components of the 2-oxo-glutarate dehydrogenase and branched-chain 2-oxo acid dehydrogenase complexes. In all three antigens, epitopes contain the motif DKA, with lipoic acid covalently bound to the lysine (K) residue: lipoic acid is the immunodominant AMA epitope.[1] The pathogenic role of AMA is debatable, since no clinical correlation can be found and animal models developing serum AMA do not develop PBC-like liver lesions. Importantly, AMA may be present in the absence of biochemical cholestasis: in this setting, a liver biopsy may reveal PBC-compatible histology; in the absence of a liver biopsy or when histology is normal, patients deserve close follow-up, since clinically apparent disease develops over time in the majority of cases.[1]

Autoantibodies other than AMA can be found in the majority of PBC patients. ANA is present in 50% of PBC patients, the most common indirect immunofluorescence patterns on HEp2 cells being the "nuclear rim" and the "multiple nuclear dots" patterns. The target antigens of the nuclear rim pattern are gp210 and nucleoporin 62 (both within the nuclear pore complex of the nuclear envelope), whereas the multiple nuclear dots pattern corresponds mainly to antibodies against Sp100, promyelocytic leukemia protein, sp140, and small ubiquitin-like modifiers.[15] These two patterns are PBC specific, having the same diagnostic value as AMA: that is, being diagnostic of PBC when associated with a cholestatic biochemical profile. Therefore, the laboratory should always report the immunofluorescence pattern of ANA, and the clinician should be aware of the disease specificity of these two patterns. ANA-positive patients are more frequently AMA negative, possibly because of the lack of a masking effect of this latter antibody in indirect immunofluorescence. The pathogenic role of ANA in PBC remains to be investigated, although cross-sectional and longitudinal data demonstrate an association between PBC-specific ANA positivity, particularly the rim-like pattern, and a worse prognosis.[25] Finally, anti-centromere antibody, another ANA subtype, is typically detected in PBC patients with coexisting limited systemic sclerosis; very rarely, this serological specificity may be the only autoantibody in PBC.

Histology

PBC is characterized histologically by chronic non-suppurative destructive cholangitis, with bile duct loss (ductopenia) and granulomatous inflammation (Fig. 76.2). It is important to be aware that interface hepatitis, the typical histological finding of AIH, is universally detected in untreated PBC.

PBC histology has classically been assessed by two staging systems: by Scheuer in 1967, and Ludwig in 1978. They both recognize four stages, according to portal/periportal inflammation, ductular reaction, and fibrosis. A more recent staging system proposed by Nakanuma in 2010 includes three features more specific for PBC and correlating with disease progression.[1]

Therapy

The pharmacological treatment of PBC is based on drugs impacting the bile acid physiology, since immune-based therapies have failed to show effectiveness, despite the autoimmune basis of the disease, highlighting the key pathogenetic role of altered biliary homeostasis in PBC. UDCA is the first-line treatment, and is the only drug with a demonstrated beneficial effect on long-term transplant-free and overall survival.[24,25] The recommended dose is 13 to 15 mg/kg body weight/day. UDCA is a natural, non-toxic secondary bile acid, forming 1% to 3% of the bile acids pool in human bile. This percentage is increased to 40% in subjects treated with therapeutic UDCA doses.[26] One probable mechanism of UDCA action is therefore decreased bile toxicity; additional effects include stimulation of biliary bicarbonate secretion, immunomodulation, and antiinflammatory and anti-apoptotic effects.[1] UDCA is a safe drug; the only side effect is increased stool frequency. It should not be discontinued even during pregnancy and breast-feeding. The aim of UDCA treatment is biochemical response, defined according to different criteria based on bilirubin and alkaline phosphatase serum levels after 6, 12, or 24 months of UDCA treatment.[25] Patients achieving a biochemical response have better clinical outcomes and transplant-free survival. These criteria use thresholds of biochemical tests allowing dichotomization of patients in low- or high-risk groups for liver transplantation or death.[25] More recently, the GLOBE score and the UK-PBC score, which provide a continuous risk stratification, have been demonstrated to have excellent sensitivity and specificity for predicting

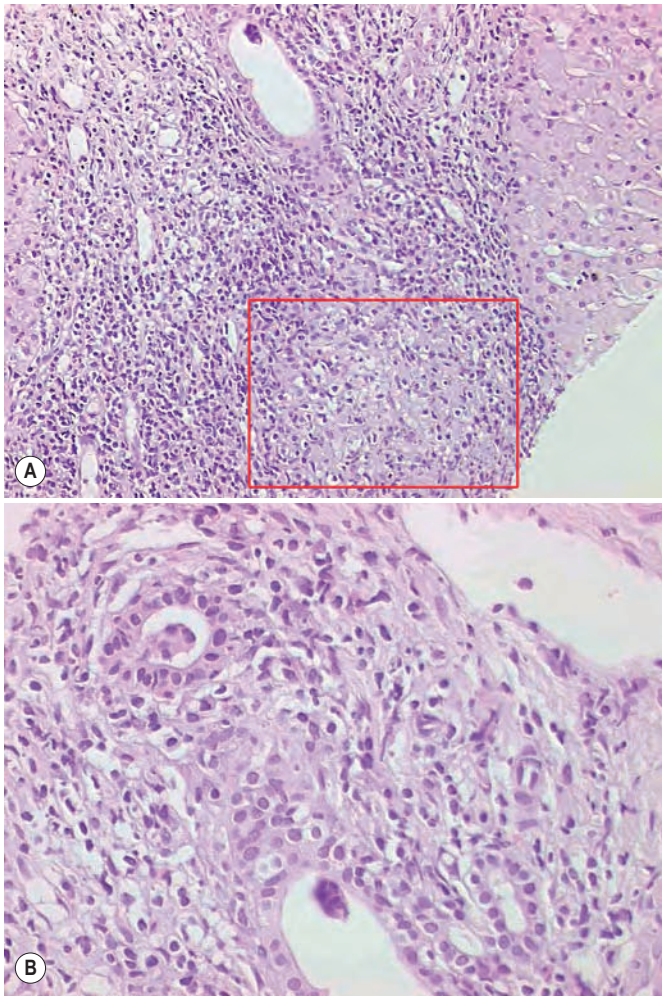

FIG. 76.2 Histological findings in early stages of primary biliary cholangitis: that is, non-suppurative destructive cholangitis (hematoxylin and eosin staining). (A) Mixed lymphocytic and plasma cell periductular inflammation with bile duct infiltration and granulomatous reaction *(square)*. (Magnification × 200.) (B) Detail of bile duct disruption with lymphocytic and plasmacellular periductular and intraepithelial infiltration. (Magnification × 200.)

transplant-free survival up to 15 years.[24] Recently, the GLOBAL PBC study group has refined the biochemical criteria associated with better outcomes, showing that bilirubin level <0.6 × upper limit of normal (ULN) and normal alkaline phosphatase level at 1 year are best in predicting the risk for liver transplantation or death.[27]

Of note, UDCA treatment has a beneficial impact on long-term survival even in patients without biochemical response, and should therefore be given lifelong to every PBC patient, with the exception of the rare patients who prove to be UDCA-intolerant.

Obeticholic acid (OCA), a synthetic analogue of the natural chenodeoxycholic acid, was approved in 2016 as second-line treatment for PBC patients with insufficient UDCA response or intolerance. OCA is an agonist of the nuclear receptor called farnesoid-X receptor (FXR); nuclear receptors are ligand-activated transcription factors that control transcription of a wide range of proteins involved in the immune system and metabolism. OCA is the first-in-class FXR agonist and has been shown to decrease bile acid synthesis and promote choleresis, although the precise downstream effects of FXR agonism in humans remain to be elucidated. OCA is associated with pruritus, which hampers its use in PBC patients already suffering from this symptom. In addition, dose reduction is needed in patients with advanced liver disease, and recent data suggest an increased risk of gallstones in patients treated with OCA. Newer FXR agonists, so-called nonsteroidal agonists, are being tested in PBC, and are expected to have fewer side effects.

Targeting the nuclear receptors known as peroxisome proliferator-activated receptors (PPARs) impacts bile acid synthesis and detoxification, and biliary phospholipid secretion. PPAR agonists include fenofibrate and bezafibrate, which have been on the market since the early 1970s to treat hyperlipidemia. Both drugs have been shown to improve biochemical cholestasis in PBC in small trials; these data have recently been confirmed in a large, placebo-controlled trial of bezafibrate as second-line treatment for PBC,[28] with a positive effect also on pruritus and hyperlipidemia. Of note, the primary endpoint of this trial was complete normalization of alkaline phosphatase, bilirubin, aminotransferases, albumin, and prothrombin index after 24 months. Efficacy on hard endpoints and long-term safety still need to be investigated. Importantly, fibrates use in PBC remains off-label.

Liver transplantation is the ultimate treatment for end-stage PBC, with survival rates of 92% and 85% at 1 and 5 years after transplant, respectively. Recurrence is common but rarely impacts on graft or patient survival; it is prevented by cyclosporine and UDCA.

KEY CONCEPTS

- Primary biliary cholangitis (PBC) is a chronic autoimmune cholestatic disease affecting more frequently women in the 5th–6th decades of life.
- Genetics play a strong role in PBC pathogenesis, as suggested by the familiar recurrence and the high concordance in monozygotic twins.
- Anti-mitochondrial antibodies (AMAs) are highly specific for PBC, and can be detected in nearly 100% of patients.
- Anti-nuclear antibody (ANA) giving a multiple nuclear dot or a nuclear rim staining pattern on HEp2 cells are PBC-specific, being of high diagnostic value in AMA-negative patients.

CLINICAL PEARLS

- Fatigue and pruritus represent the most frequently observed symptoms that may be disabling for patients.
- Primary biliary cholangitis (PBC) can be frequently associated with other autoimmune diseases: that is, Sjögren syndrome and systemic sclerosis.
- Clinically significant portal hypertension may occur in pre-cirrhotic stages.
- Osteopenia and osteoporosis are frequently observed in PBC patients.

THERAPEUTIC PRINCIPLES

- Ursodeoxycholic acid (UDCA; 13–15 mg/kg) is the cornerstone therapy for primary biliary cholangitis, improving long-term survival in all patients.
- Obeticholic acid improves biochemical cholestasis in patients intolerant to UDCA or with insufficient response; pruritus is a major safety issue of this drug.
- Fibrates, particularly bezafibrate, have been shown to be highly effective in improving cholestasis and pruritus in patients intolerant to UDCA or with insufficient response; data on long-term safety and efficacy are still lacking.

PRIMARY SCLEROSING CHOLANGITIS

Definition

PSC is a rare progressive cholestatic liver disease of unknown etiology characterized by inflammation, fibrosis, and destruction of intra- and extrahepatic bile ducts, by a strong association with inflammatory bowel disease (IBD), by male preponderance, and by high risk of cholangiocarcinoma and colorectal cancer.[29] It should be distinguished from sclerosing cholangitis related to other identifiable causes. Small-duct PSC, affecting 6% to 16% of PSC patients, is characterized by biochemical cholestasis and PSC typical histology but normal cholangiography. It has a more benign course but may progress to classical PSC over time.

Autoimmune sclerosing cholangitis is a pediatric nosological condition representing overlap of AIH with bile duct disease.[13] Its relationship with adult PSC is still debated.[13]

Epidemiology

The reported yearly incidence in Caucasians of PSC ranges between 0.91 and 1.3 per 100,000 inhabitants.[29] Its prevalence is approximately 10 to 15/100,000 in Northern Europe and the USA.[24] There is a North-South gradient, with 10 to 100 times lower prevalence in Southern Europe and Asia.

At variance from the vast majority of autoimmune diseases, PSC is more commonly diagnosed in men, with a female-to-male ratio estimated as 1:2, and generally between 30 and 40 years. However, recent data show a similar PSC prevalence in males and females, with a more benign course in females, suggesting underdiagnosis in asymptomatic female patients. Approximately 60% to 80% of Caucasian patients with PSC have coexisting IBD, most often ulcerative colitis.[29] Reported PSC prevalence in IBD patients varies between 5% and 7.5%.

Pathogenesis

The etiopathogenesis of PSC is unknown, despite evidence that (auto)immune-mediated mechanisms play a role, as suggested by the frequent association with IBD and other autoimmune

diseases, the presence of serum autoantibodies, and the reported HLA susceptibility associations. PSC autoantigens are unknown. Genetics play a role in determining PSC susceptibility; family studies have demonstrated that the PSC prevalence among first-degree relatives is 100 times higher compared to the unrelated population. The most significant PSC genetic risk factor is represented by HLA variations, suggesting a prominent role of adaptive immunity: positive associations have been reported with *HLA-B*08:01*, *HLA-DRB1*03:01, HLA-DRB1*13:01, HLA-DQA1*01:03*, and *HLA-DQA1*01:01*. The haplotypes *HLA-DRB1*04, DQB1*03:02,* and *HLA-DRB1*07:01* and *DQB1*03:03* confer protection.

Environmental factors contribute to PSC pathogenesis, although no definitive causal agent has been identified so far.[30] The close association with IBD suggests that the gut microbiome plays a pathogenic role in PSC. An altered microbiome has been reported in PSC, affecting not only the colon but also the oral cavity, the duodenum, and the bile.[31] An increased biliary concentration of toxic components, such as taurolithocholic acid, has also been observed in PSC patients, potentially due to abnormal bile acid microbial metabolism.[31]

Clinical Features and Diagnosis

The typical PSC patient is a 30- to 40-year-old male with IBD and elevated serum alkaline phosphatase and γ-glutamyltransferase serum levels. Of note, PSC may develop even after colectomy for IBD. In a subgroup of patients, IBD presents after the diagnosis of PSC, even after liver transplantation.

The diagnosis is based on typical magnetic resonance cholangiopancreatography (MRCP) bile duct changes; MRCP has been shown to have similar sensitivity and specificity as endoscopic retrograde cholangiopancreatography. The latter procedure should be performed only if an intervention is required. Typical MRCP findings are irregular bile ducts with a beading appearance due to multiple short strictures affecting most commonly both intrahepatic and extrahepatic bile ducts. However, singular intrahepatic involvement or, more rarely, isolated extrahepatic involvement are also encountered (Fig. 76.3). Liver biopsy is not part of the standard diagnostic work-up, but remains the key diagnostic procedure to diagnose small-duct PSC and overlap with AIH.

ANA and SMA are frequently positive in PSC patients; their presence requires exclusion of AIH overlap. Atypical pANCA are detected in serum of up to 94% of PSC patients; however, they lack disease specificity (as they are present also in IBD and AIH) and prognostic significance.

The histological hallmark of PSC is concentric, periductal, so-called onion-skin fibrosis (Fig. 76.4), which may be absent in early disease, though some degree of bile-duct damage is usually identified.

The genotype and phenotype of IBD associated with PSC is distinct from IBD without PSC, as it is characterized by pancolitis, backwash ileitis, and rectal sparing. An upper endoscopy and colonoscopy are recommended in every newly diagnosed PSC patient without known IBD, irrespective of gastrointestinal symptoms.

PSC symptoms are generally nonspecific and include right-upper-quadrant abdominal pain, jaundice, weight loss, pruritus, and fatigue; 40% to 50% of patients are asymptomatic at the time of diagnosis. At more advanced stages, symptoms include those of all types of decompensated cirrhosis or neoplasia; however, similarly to PBC, clinically significant portal hypertension may occur in pre-cirrhotic stages.

PSC is a progressive disease, leading to cirrhosis and liver failure in the vast majority of patients. However, mortality is mainly

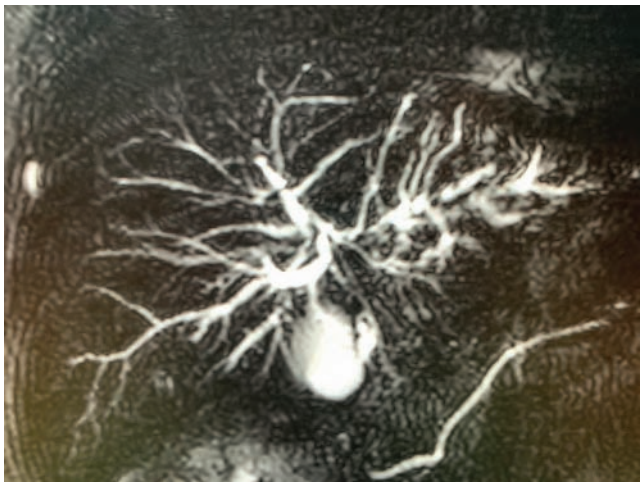

FIG. 76.3 Magnetic resonance cholangiopancreatography of intrahepatic biliary tree (sequence SENSE shimming (SSH), repetition time (TR) 5100, echo time (TE) 740, flip angle 90) showing intrahepatic bile ducts with marked caliber irregularities specially in the left liver lobe with narrowing and dilatation. FIG. 76.4 Histological Findings in Primary Sclerosing Cholangitis. (A) Early disease and periductular fibrosis. (Magnification × 200, hematoxylin and eosin staining.) (B) Advanced disease with cirrhosis and bile duct substitution by fibrous scar *(square)*. (Magnification × 200, Masson staining.)

due to cholangiocarcinoma and colorectal cancer. Cholangiocarcinoma occurs in 20% of patients after a disease duration of 30 years, leading to the proposal of considering PSC as a pre-malignant condition. Cholangiocarcinoma should always be excluded in PSC patients with rapid deterioration. The diagnosis is often difficult in the early stages, since radiological distinction between malignancy and inflammatory/fibrotic lesions is inaccurate. Brush cytology may be of use, with variable sensitivity depending on lesion accessibility, as well as operator and pathologist experience. Cholangiocarcinoma surveillance with annual MRCP and contrast-enhanced liver magnetic resonance imaging coupled with serum CA19-9 is generally performed, despite the absence of evidence for survival advantage.

Annual colonoscopic surveillance of colorectal cancer is recommended in patients with concomitant IBD.

Therapy

There is no approved pharmaceutical therapy of PSC, since no drug has been demonstrated to have a beneficial effect on disease progression and survival.

UDCA at a dose of 10 to 20 mg/kg is widely prescribed based on a beneficial impact on biochemical cholestasis and decreased bile toxicity. High-dose UDCA (28 to 30 mg/kg/day) should be avoided since a high-quality study demonstrated a significant increase in clinical endpoints.

Endoscopic measures are indicated to treat bile duct strictures associated with worsening of symptoms and cholestasis, or bacterial cholangitis. Some studies have shown improved survival of patients undergoing endoscopic treatment of clinically significant strictures. Brush sampling should always be performed for cholangiocarcinoma surveillance.

Finally, PSC represents an important indication for liver transplantation since patients are commonly younger compared to other autoimmune liver diseases. Recurrence of disease is common and affects 20% to 40% of transplanted patients during prolonged follow-up.

KEY CONCEPTS

- Primary sclerosing cholangitis (PSC) is a rare, chronic autoimmune cholestatic disease that can affect all tracts of the biliary tree, including the extrahepatic bile ducts.
- PSC has a striking association with inflammatory bowel disease.
- PSC can be regarded as a pre-malignant condition, being complicated by cholangiocarcinoma in 20% of patients over a 30-year disease course.

CLINICAL RELEVANCE

- Primary sclerosing cholangitis (PSC) affects all ages.
- Diagnosis is based on the typical appearance of magnetic resonance cholangiopancreatography.
- Secondary forms of sclerosing cholangitis must be ruled out.
- Autoimmune sclerosing cholangitis is a pediatric clinical entity representing overlap of autoimmune hepatitis with sclerosing cholangitis.
- Small duct PSC is diagnosed in the presence of typical histology and normal imaging.

THERAPEUTIC PRINCIPLES

- Ursodeoxycholic acid (UDCA; 10–20 mg/kg) is widely prescribed, and is associated with improvement of biochemical cholestasis, without evidence of improved survival.
- Endoscopic procedures are indicated to treat stenosis.
- Primary sclerosing cholangitis represents an important indication for liver transplantation, despite disease recurrence in almost half of the cases.

OVERLAP/VARIANT SYNDROMES

A subgroup of PBC and PSC patients develop clinical, serological, histological, and radiological features of AIH and are classified as variant syndromes. This nomenclature has been proposed as being more appropriate compared to overlap syndromes, since the latter implies coexistence of different diseases in the same patient, while these patients should be considered as PBC or PBC with AIH manifestations.[32] In a minority of cases, AIH predates bile duct disease. Histology plays a central diagnostic role of the variant syndromes.

Treatment is empiric, and based on adding AIH treatment on top of UDCA in PBC and PSC patients, or, conversely, on adding UDCA in AIH patients with cholestatic features.

IMMUNOGLOBULIN 4-RELATED SCLEROSING CHOLANGITIS

IgG4-related sclerosing cholangitis is the bile tract manifestation of IgG4-related diseases and is characterized by inflammation and fibrosis leading to progressive stenosis and destruction of the bile ducts.[33] The condition affects more commonly males in their 60s. The clinical features include jaundice, pruritus, and biochemical cholestasis. Elevated serum IgG4 is found in up to 85% of the cases; the diagnosis can be aided by the IgG4/IgG1 ratio determined by polymerase chain reaction, since high serum IgG4 is present in 10% to 20% of PSC patients.[33,34] MRCP shows segmental or diffuse stenosis of the intra- and/or extrahepatic bile ducts with thickened walls. Typical histological findings include storiform fibrosis, lymphoplasmacytic infiltration, and obliterative phlebitis. Treatment is based on corticosteroids, which induce a remarkable improvement in clinical and biochemical manifestations, and should be started at the dosage of 0.6 mg/kg/day of prednisolone for 2 to 4 weeks, gradually tapered in 2 to 3 months. Long-term outcomes are excellent, despite 20% of relapse after corticosteroid discontinuation.

ON THE HORIZON

- Novel, more targeted therapeutic approaches are needed for autoimmune hepatitis, possibly including Treg adoptive therapy and low-dose interleukin (IL)-2. A better knowledge of the immunodominant epitopes could lead to the establishment of peptide immunotherapy.
- It should be possible to identify high-risk primary biliary cholangitis patients at diagnosis with novel biomarkers. Novel therapeutic approaches may include not only a combination of FXR+PPAR agonists and anti-IL-17 agents but also stage-specific treatments.
- The relationship of primary sclerosing cholangitis (PSC) with the pediatric condition known as autoimmune sclerosing cholangitis deserves further investigation and may lead to a better understanding of the PSC pathophysiology.

Lymphoid Leukemias

Sarah Elitzur, Shai Izraeli, Dina Ben-Yehuda, and Moshe E. Gatt

Leukemias are a group of hematologic malignant clonal diseases arising in bone marrow that present with differing clinical and laboratory features. The focus of this chapter is on acute lymphoblastic leukemia (ALL), which is the most common leukemia of lymphoid precursors, and on chronic lymphocytic leukemia (CLL), which is the most common leukemia of mature lymphoid cells in adults. A special emphasis is given to immunologic aspects of both diseases.

ACUTE LYMPHOBLASTIC LEUKEMIA

ALL manifests with the clonal proliferation and accumulation of malignant lymphoid progenitors. ALL can be viewed as a developmental disease of the lymphoid system because it often arises as a "developmental accident" during normal fetal lymphopoiesis. Studies of chromosomal translocations in ALL cells have identified key genes involved in normal lymphopoiesis and hematopoiesis. Conversely, basic studies of the development of the immune system and the immune receptors have provided important tools for the diagnosis and management of ALL. These achievements in basic and clinical research have led to the remarkable transformation of ALL from a uniformly fatal disease several decades ago to a disease that is curable in more than 85% of children. However, adults remain a challenge.[1]

Epidemiology and Etiology

ALL is the most common malignancy of childhood. In contrast, ALL accounts for less than 20% of leukemias in adults. In developed countries, the incidence of ALL peaks at 2 to 5 years of age. The low age peak is characteristic of affluent societies.[2]

Most ALLs are sporadic, with less than 5% associated with hereditary or constitutional syndromes. For example, children with Down syndrome have approximately 20-fold increased risk of ALL. Other disorders associated with increased risk are rare inherited genomic instability syndromes, such as ataxia-telangiectasia, Bloom, and Li-Fraumeni syndromes. Similarly, ALL is more common in patients with other congenital immunodeficiencies, such as X-linked agammaglobulinemia, immunoglobulin A (IgA) deficiency, and common variable immunodeficiency (CVID). Some cases of CVID associated with leukemia are caused by germline mutations in *IKZF1*, which encodes the lymphoid transcription factor Ikaros.[3] Germline mutations in additional hematopoietic and B-cell developmental genes, such as *ETV6, RUNX1*, and *PAX5*, also predispose to ALL.[4]

Studies of leukemia in identical twins have shed light on the etiology of childhood ALL. Although ALL is not hereditary, there is markedly increased risk of leukemias in identical twins. If leukemia occurs in one identical twin, the other twin generally has a 10% to 20% chance of developing the disease. This phenomenon has promoted the hypothesis that at least two genetic hits are required for the development of ALL[2] (Fig. 77.1). The first occurs during fetal lymphopoiesis and results in clonal proliferation of a preleukemic clone. Intrauterine metastasis of such a preleukemic clone from one twin to the other via their shared placental circulation is responsible for the concordant leukemia. Additional genetic hits in the preleukemic cells occur after birth and are required for the development of full-blown leukemia. The initial findings in identical twins with leukemia have been extended to sporadic ALL; in at least 70% of patients, the preleukemic clone can be detected molecularly in the neonatal blood samples collected after birth (known as Guthrie cards). More recently, careful molecular analysis of the cord blood of normal infants has demonstrated that the occurrence of a preleukemic clone carrying a leukemia-defining chromosomal translocation is relatively common. However, only 1% of children born with such a preleukemic clone will develop leukemia, implying the impracticality of a molecular screen for the early diagnosis of childhood ALL.

KEY CONCEPTS

Environmental Factors in the Epidemiology of Childhood Acute Lymphoblastic Leukemia (ALL): Roles for Infection and Immunity?

"Common" B-cell precursor ALL at the preschool age is the most common type of ALL in the suburban regions of affluent countries. The causes for this phenomenon are unknown. A popular hypothesis suggests a modified immune response to delayed infections during infancy.

The causes of the relatively rare postnatal leukemogenic genetic hits are unknown. Although environmental agents such as ionizing radiation and chemical mutagens have been implicated in the induction of ALL, almost all cases lack discernible etiologic factors. Because the risk of B-cell precursor ALL during early childhood is markedly increased by higher socioeconomic status and a suburban style of living in which the exposure of children to infectious pathogens is typically delayed beyond the neonatal period, Greaves hypothesized that many childhood cases are the consequence of an abnormally late immunologic response to common infections. One proposed mechanism is that growth inhibitory factors, such as interferon or transforming growth factor-β (TGF-β), secreted during this immune response provide a survival advantage to a preleukemic clone, setting the stage for additional leukemogenic mutations. A more direct suggestion for the involvement of infection (or the response to infection) in the pathogenesis of ALL has been provided; PAX5 heterozygous mice developed preB-cell ALL only after exposure to common mouse pathogens.[5]

Immunologic and Molecular Classification of ALL

Immunologic Classification

The subtypes of ALL are usually identified by their immunophenotype, which tends to resemble the lymphoid developmental stage in which the leukemic cell was arrested (Table 77.1).

B-Cell Precursor Leukemias

B-cell precursor ALLs are the most common childhood leukemias. **ProB-cell ALL** is characterized by expression of CD19 and CD34 without CD10. This is the most common leukemia of infants, which contains rearrangements of the *MLL*(*KMT2A*) gene on chromosome 11q23. It is associated with a poor outcome. Leukemic blast cells of **early preB-cell ALL** resemble normal B-lymphoid cell precursors. They express CD19, CD22, and CD79a. CD10 and terminal deoxynucleotidyl transferase (TdT) are detectable in 90% of cases. CD34 is detected in greater than 75% of cases. Early preB-cell ALL is the most prevalent type of ALL and is thus often called "common ALL."

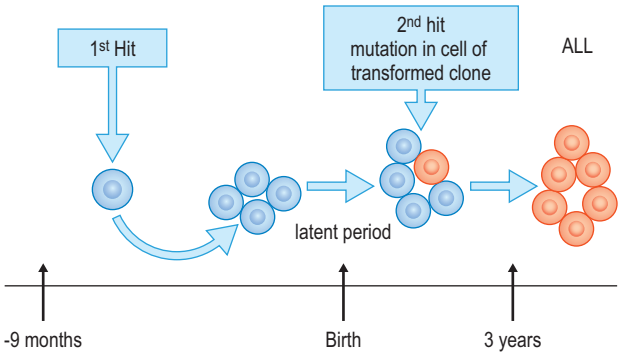

FIG. 77.1 A Model for the Development of Childhood Acute Lymphoblastic Leukemia (ALL). The first acquired genomic hit (e.g., chromosomal translocation or change in chromosomal copy number) occur during fetal hematopoiesis and results in clonal proliferation of a preleukemic clone. This event is common occurring in up to 1:20 children. Additional genetic aberrations occurring after birth are required for the development of ALL. These events are rare and are estimated to occur in approximately 1% of the children born with a preleukemic clone [Greaves, 2006 #1482].[5]

CLINICAL PEARLS

Mature Versus Precursor B-Cell Acute Lymphoblastic Leukemia

- Because the treatment of mature B-cell leukemia (the leukemic form of Burkitt lymphoma) is vastly different from the treatment of B-cell precursor ALL, it is critical to distinguish between the two.
- Burkitt leukemia is characterized by mature B-cell phenotype and by the presence of chromosomal translocations involving the *cMyc* gene (see Chapter 78).

Mature B-cell ALL is the leukemic form of Burkitt lymphoma (see Chapter 78). Because treatment is dramatically different from that for B-cell precursor ALL, this subtype must be specifically ruled out as part of the immunophenotypic evaluation of ALL. Mature B-cell ALL cells express surface Ig μ heavy chains in association with either κ or λ light chains.

T-Cell ALL

In affluent countries, T-ALL occurs in 10% to 15% of children with ALL. It is more prevalent in nonaffluent countries, probably as a reflection of a lower incidence of the common B-lineage early childhood peak. T-ALL is also more common in adults.

T-cell ALL cells express surface CD7 and cytoplasmic CD3 (cCD3) antigens on their surface; more than 90% of T lymphoblasts express CD2, CD5, and TdT. T-cell receptor (TCR) proteins are heterogeneously expressed in T-lineage ALL. In approximately two-thirds of cases, membrane CD3 and TCR proteins are absent. In half these cases, however, TCR proteins (TCRβ, TCRα, or both) are present in the cytoplasm. When membrane CD3 and TCR chains are expressed, the αβ form of the TCR predominates. Only a minority of cases express TCR γδ proteins.

A genetically and immunophenotypically distinct form of T-ALL originating from early T-cell precursors (ETPs) has been recognized. It is characterized by low or absent CD1a and CD5 coupled with the expression of at least one myeloid marker.[6]

Genetic and Molecular Classification

Virtually every leukemic cell contains acquired alterations in multiple genes. These alterations often manifested by gross numeric or structural aberrations that frequently define a specific clinical subtype of ALL. Common and/or clinically significant genetic aberrations that are typically found in ALL are summarized in Table 77.2.

TABLE 77.1 Immunophenotypic Classification of Acute Lymphoblastic Leukemia

	Leukocyte Antigen Expression (% of Cases Positive)										Frequency (%)	
Subtype	CD19	cCD22	CD79a	CD10	CD7	CD2	cCD3	clg μ	slg μ	slg κ/λ	Children	Adults
Pre-preB	100	>95[a]	>95	0	0	0	0	0	0	0	5	10
Early preB	100	>95[a]	>95	95	5	<5	0	0	0	0	60–65	50–55
PreB	100	100[a]	100	>95	0	0	0	100	0	0	20–25	10
Transitional preB	100	100[a]	100	50	0	0	0	100	100	0	1–3	?
B	100	100[a]	100	50	0	0	0	>95	>95	>95	2–3	4
PreT	<5	0	0–20	45	100	0	100	0	0	0	1	5

c, Cytoplasmic; *clg μ*, cytoplasmic immunoglobulin μ chain; *slg κ/λ*, surface immunoglobulin κ or λ chains; *slg μ*, surface immunoglobulin μ chain.
[a]Detectable on the cell-surface membrane in some cases.

TABLE 77.2 Frequencies of Major, Clinically Important Genetic Aberrations in Childhood and Adult Acute Lymphoblastic Leukemia

Genetic Aberration	Children	Adults
B-Cell Lineage		
Hyperdiploidy (>50 Chromosomes)	30%	9%
Hypodiploid (<45 chromosomes)	1%	2%
Amplified 21q	2%	2%
TEL-AML1 (t12;21)	25%	3%
MLL rearrangements	9%	13%
BCR-ABL	4%	33%
E2A-PBX1	5%	4%
"Ph like" including CRLF2	8%	25%
MYC rearrangements	2%	5%
T-Cell Lineage		
Notch1 mutations	60%	70%
TAL1 (SCL) cluster	58%	33%
HOX11 (TLX1) cluster	3%	33%
HOX11L2 (TLX3) cluster	20%	5%
LYL1 cluster	12%	37%
MLL-ENL	2%	2%
NUP214-ABL	6% (?)	

Numeric Chromosomal Aberrations

Deviation from the normal chromosomal modal number is called *aneuploidy* and is the most common chromosomal aberration in cancer. **High hyperdiploid ALL** (Fig. 77.2A), containing 50 to 60 chromosomes, is the most common type of B-lineage ALL in children and is associated with approximately 90% cure rate. Typically there is an excess of specific chromosomes, most commonly chromosomes 6, 10, 14, 17, 18, 21, and X. **Hypodiploid ALL** (see Fig. 77.2B), which contains less than 45 chromosomes, is much rarer and is associated with a very poor prognosis.

Structural Genetic Aberrations

Chromosomal translocations can be divided into two general subtypes. The first results from a translocation of an oncogene into the proximity of a strong regulatory region, resulting in its marked overexpression. Often these translocations are mediated by the V(D) J recombination machinery (see Chapter 4) and can be therefore viewed as an unfortunate developmental "accident" caused by the physiologic lymphocyte-specific genomic instability that is necessary for the creation of the diversity required to recognize novel antigens. Examples of these translocations include the activation of the *MYC* oncogene by t(8;14) translocation in Burkitt lymphoma and of the *SCL* (*TAL1*) gene by t(1;14) or by rearrangement with the *STIL* gene on chromosome 1p32 in T-cell ALL. The second type of translocation creates a novel fusion protein consisting of the genes that participate in the chromosomal translocation. The mechanisms that underlie these translocations remain unclear. Most of the translocations characteristic of B-cell precursor ALL are of this type, for example the *t*(12; 21) fusing of the *TEL* (*ETV6*) gene on chromosome 12 with the *AML1* (*RUNX1*) gene on chromosome 21.

Amplification and deletion of a small chromosomal region is another type of structural aberration that is often detected in leukemias. For example, deletions of the *INK4A* locus or *PAX5* are commonly detected in T- and B-cell precursor ALLs, respectively.

Oncogenic-activating mutations in ALL are reported with an increasing frequency. For example, the Notch pathway, which plays a role in T-cell development, is activated by acquired mutations in more than 60% of T-ALL.

Many of the genes modified by chromosomal translocations, amplification, deletions, or point mutations function in normal lymphoid or hematopoietic development (Table 77.3). The acquired aberrations promote malignant transformation by either overexpression or dysregulated expression (in the wrong cell or in the wrong developmental stage) of the developmental gene. For example, loss-of-function mutations in the IL7Rα receptor cause $T^{-}B^{+}NK^{+}$ severe combined immunodeficiency (see Chapter 34), and activating mutations are found in 10% of T-cell ALL.[7] Conversely, the acquired genetic aberration may block the normal developmental function of the involved gene(s). Good examples are genomic deletions or inactivating mutations in B-cell differentiation genes, such as *PAX5, EBF*, or *IKZF1*, detected in approximately 50% of B-lineage ALLs.

Molecular Subtypes of Clinical Relevance

(See Table 77.2.)

B-Lineage ALL

Hyperdiploid ALL and *TEL/AML1* gene translocation comprise the majority of "common ALL" leukemias typical of young children and are rare in adults with ALL. Both are associated with an extremely good prognosis. In contrast, the much less common hypodiploidy (less than 45 chromosomes) and the intrachromosomal amplification of chromosome 21 (iAMP21) are associated with a poor prognosis. The *MLL(KMT2A)* gene located on chromosome 11q23 is involved in fusion translocations with more than 80 different partner genes. The most common translocation in ALL fuses the *MLL* with the *AF4* gene on chromosome 4. It is characteristic of infant leukemia and is associated with a poor prognosis.

Another aberration with a poor prognosis is the B-cell receptor (BCR)-ABL1 fusion protein created by the *t*(9;22) "Philadelphia chromosome." Its frequency is low in children (3% to 5%) and much higher in adults (at least 25%). Outcome of patients with Philadelphia-ALL has dramatically improved after the addition of tyrosine kinase inhibitors to chemotherapeutic treatment.

A novel subgroup of ALLs has been termed "Philadelphia-like ALL" because of a gene expression profile that is similar to BCR-ABL1, while lacking the classic fusion sequence.[8,9] These leukemias are characterized by activation of either the ABL or the JAK kinase pathway and are caused by many types of fusion genes or aberrantly expressed receptors, such as ABL1 and ABL2, PDGFRB, CSF1R, EPOR, JAK2, and CRLF2. Their proper diagnosis is important because of the potential therapeutic effect of kinase inhibition.

Deletions of the *IKZF1* gene, encoding the B-cell transcriptional factor Ikaros, are common in both Philadelphia and in Philadelphia-like ALL and are associated with poor prognosis.

T-Lineage ALL

Although multiple genetic and molecular subtypes of T-cell ALL have been recently described, their clinical significance is presently unclear, except ETP-ALL, which has been associated with poor prognosis. Most of the genetic aberrations in T-cell ALL result in the abnormal expression of transcription factors. Examples include SCL (TAL1), which forms a complex with

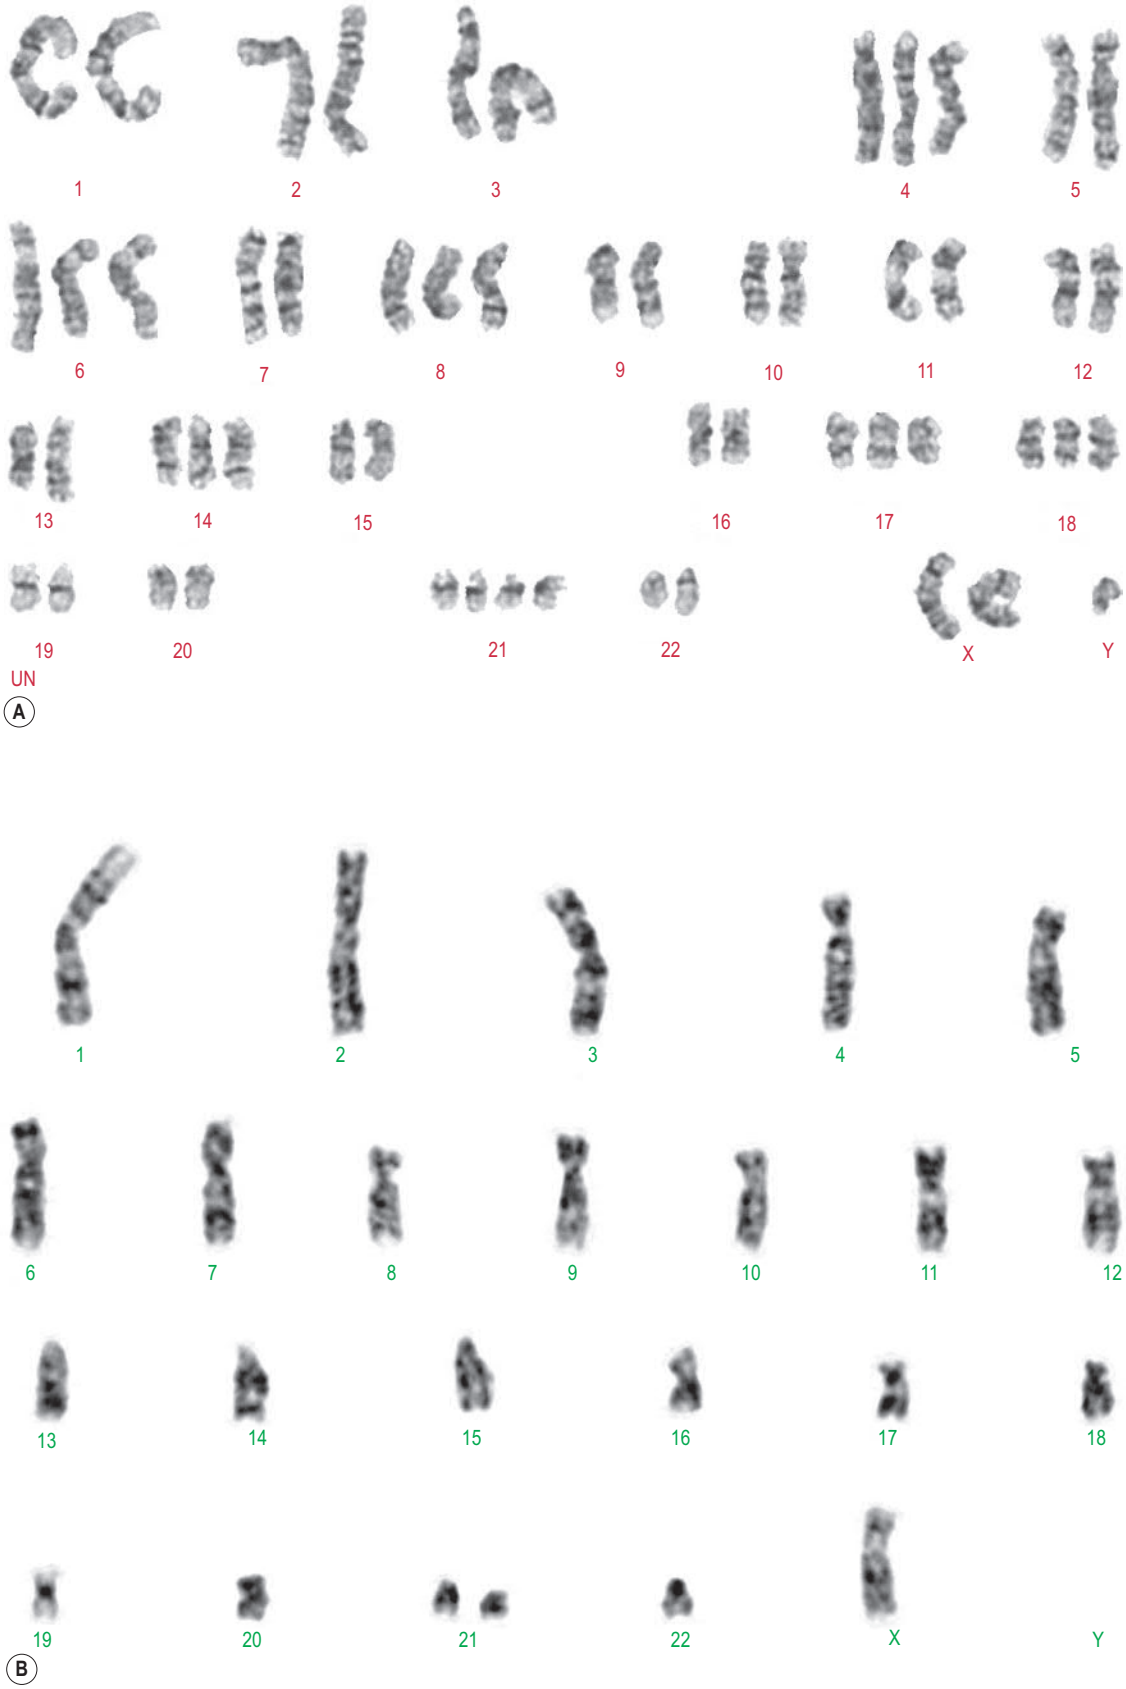

FIG. 77.2 Continued

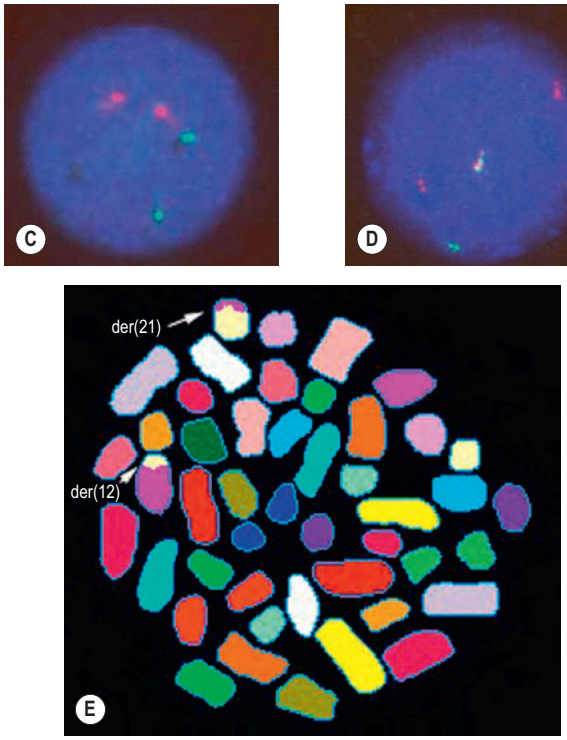

FIG. 77.2 Chromosomal Aberrations in Acute Lymphoblastic Leukemia (ALL). (A) A typical karyotype of hyperdiploid ALL. (B) A hypodiploid karyotype (pictures courtesy of B. Stark and D. Betts). Panels (C) and (D) display interphase fluorescence in situ hybridization with probes to the AML1 (RUNX1) gene on chromosome 21 *(red)* and to the TEL (ETV6) gene on chromosome 12 (green). (C) normal cell and (D) leukemic cell with fusion TEL-AML1 translocation *(arrow)*. Panel E display the same translocation on metaphase chromosomes using a molecular cytogenetics technique called Spectral Karyotyping *(arrows)*. Classical cytogenetics analysis often misses this translocation. (Courtesy of L. Trakhtenbrot).

TABLE 77.3 Example of Hematopoietic Genes Involved in the Pathogenesis of Leukemia

Gene(s) Names	Normal Hematopoietic Development	Leukemic Involvement
SCL (TAL1)	Hemangioblast specification Erythropoiesis and megakaryopoiesis	T-ALL
LMO1/2	Similar to SCL	T-cell ALL
NOTCH1	T lymphocytes	T-cell ALL
HOX11	Spleen	T-cell ALL
E2A	T and B lymphocytes	BCP-ALL
PAX5	B lymphocytes	BCP-ALL, B-NHL
SLP-65	B lymphocytes	BCP-ALL
TEL	Bone marrow hematopoietic stem cells	BCP-ALL, T-cell ALL rarely myeloid malignancies
RUNX1 (AML1, CBFA2)	Definite hematopoiesis Megakaryopoiesis and T lymphocytes	BCP-ALL, AML (M0-M1) Hereditary FPD/AML
CBFB	Same as RUNX1	AML (M4e)
C/EBP 1-3	Myeloid cells	AML (M1, M2)
PU.1	Myeloid and lymphoid stem cells	AML
GATA1	Erythropoiesis, megakaryopoiesis, and mast cells	AML (M7) associated with trisomy 21
FLT3	Hematopoiesis and lymphopoiesis	AML and ALL
MLL	Hematopoiesis stem cells	AML and ALL
IL7R	T lymphocytes	ALL

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; BCP-*ALL*, B-cell precursor acute lymphoblastic leukemia; B-*NHL*, B-cell non-Hodgkin lymphoma; *FPD*, familial platelet disorder; *T-ALL*, T-cell acute lymphoblastic leukemia

LMO1 or LMO2, HOX11L2 (TLX3) or HOX11 (TLX1), LYL1, and MYB. Other abnormalities include MLL-ENL fusion and amplification of the *ABL* oncogene. Cooperating mutations are activating mutations in NOTCH1 or interleukin-7R (IL-7R) and inactivating mutations in the E3 ligase FBW7 or the phosphatase PTEN. In several treatment protocols, T-cell ALL was considered to have a less favorable prognosis compared with B-cell precursor ALL, but outcome has improved considerably following therapy intensification through the past decades.

Clinical Features

The clinical signs and symptoms of leukemia relate to the replacement of bone marrow cells by leukemic blasts and to the infiltration of extramedullary sites. Pallor, fatigue, petechiae, bleeding, or fever may be caused by cytopenias. Bone pain and arthralgias, the onset of a limp and refusal to walk, and even frank arthritis are not uncommon. The musculoskeletal symptoms are sometimes confused with osteomyelitis or juvenile rheumatoid arthritis, which may delay diagnosis. Splenomegaly, hepatomegaly and lymphadenopathy are also common at presentation. Uncommonly, central nervous system (CNS) involvement may present as headache or cranial nerve palsies. Overt testicular leukemia manifests as painless testicular enlargement. Mediastinal involvement, common in T-cell ALL, may cause dyspnea and superior vena cava syndrome.

Clinical laboratory findings often include anemia and thrombocytopenia. Approximately 20% of children present with leukocyte counts greater than 50,000/μL. Importantly,

approximately 40% of children have leukocyte counts of less than 10,000/μL, and leukemic blasts may or may not be seen on peripheral smears. Therefore the diagnosis of leukemia may occasionally be missed in routine automated blood count. Elevated serum lactate dehydrogenase activity, hyperuricemia, and hyperphosphatemia are common in patients with a large leukemic cell burden.

The diagnosis of ALL is established by bone marrow examination. The normal bone marrow contains less than 5% blasts. A minimum of 25% lymphoblasts on differential examination of the bone marrow aspirate is necessary for the diagnosis of ALL. Most children with ALL have a hypercellular marrow with blasts constituting 60% to 100% of the nucleated cells.

Although overt CNS leukemia is relatively rare, submicroscopic CNS involvement is present at diagnosis in at least half the patients in the absence of any neurologic symptoms. Thus CNS-directed therapy is routinely included in ALL therapy.

CLINICAL PEARLS

Acute Lymphoblastic Leukemia and Rheumatoid Disorders

- ALL can mimic juvenile idiopathic arthritis (JIA; see Chapter 54) and other musculoskeletal disorders.
- Because leukemic blasts may be absent from the peripheral blood, bone marrow examination should be considered in any child with JIA, especially prior to commencing steroid therapy.

As many as 10% of children with ALL are first evaluated at pediatric rheumatology clinics. Fever, arthralgias, arthritis, or a limp accompanied by anemia, mild splenomegaly, and lymphadenopathy frequently can be confused with juvenile idiopathic arthritis (see Chapter 54) or osteomyelitis. These patients may be treated with antibiotics and antiinflammatory agents for several weeks to months before the diagnosis of ALL is finally made. Bone marrow examination should be seriously considered in such patients.

Special Diagnostic Tests

The classification and risk stratification of patients in clinical ALL trials are based on detailed immunophenotyping and genotyping analysis.[10] Classical cytogenetics by karyotyping may be performed to determine the chromosomal complement of the leukemic cells (see Fig. 77.2). In addition, clinically relevant structural and numeric chromosomal aberrations can be detected with the use of commercially available fluorescence *in situ* hybridization (FISH) probes (see Fig. 77.2). Sequencing-based assays that use DNA or RNA of sets of genes accurately detect mutations and rearrangements.

The elucidation of the human genome and the invention of the genomic technologies are in the process of revolutionizing the diagnostics of leukemias. New methodologies of next generation sequencing (NGS) are likely to transform both our understanding of leukemia biology and the diagnostic approach. Routine use of NGS mutation panels and copy number genomic arrays is likely to replace routine cytogenetic analysis in the near future.

Principles of Therapy[1]

ALL therapy consists several treatment phases. Typical remission-induction regimens include a glucocorticoid (prednisone or dexamethasone), vincristine, asparaginase, optional use of an anthracycline, and intrathecal chemotherapy. Rates of complete remission (CR) currently range from 97% to 99% in children and from 75% to 90% in adults. However, remission is not cure, and relapses will occur in the absence of additional therapy. Following remission, treatment includes several months of intensive combination chemotherapy, designed to consolidate remission and prevent systemic and CNS relapses. Repeated courses of methotrexate are an integral part of contemporary ALL therapy. Delayed intensification, or reinduction, is a subsequent phase of therapy that uses therapeutic agents similar to those administered during induction. Patients then receive prolonged low-intensity maintenance therapy with daily mercaptopurine and weekly methotrexate.

CNS-directed therapy is an integral part of ALL treatment. Cranial irradiation has dramatically improved cure rates among patients with ALL but is associated with significant deleterious long-term effects, including neurocognitive effects, endocrinopathies, and an increased risk of secondary CNS tumors. Consequently, CNS irradiation has been limited to smaller patient subgroups over time. Intrathecal chemotherapy and administration of methotrexate remain cornerstones of CNS prophylaxis. It is highly recommended that children and adults with ALL be treated in specialized centers as part of prospective clinical prospective studies. These clinical trials have led to the dramatic improvement in outcome that has been achieved over the past several decades. Optimal supportive care is required to mitigate the life-threatening toxicities of leukemia and its treatment.

Allogeneic hematopoietic stem cell transplantation (allo-HSCT) is generally reserved for relapsed or refractory leukemia and for patients with a very-high-risk leukemia that demonstrates a slow response to therapy or is highly likely to relapse.

Prognostic Factors

Modern therapy for ALL is based on adjustment of the intensity of therapy to the risk assessment of the relapse hazard (Table 77.4). Several clinical parameters of prognostic significance have been described, mainly age at diagnosis and leukocyte count. In children, age at presentation between 1 to 9 years and a leukocyte count less than 50×10^9/L are favorable prognostic factors. Females fare somewhat better than males. The prognostic significance of the major genetic aberrations has been described earlier.

TABLE 77.4 Major Prognostic Factors in Acute Lymphoblastic Leukemia[a]

Prognostic Factor	Good Prognosis	Worse Prognosis
Age at diagnosis	Age 1 year to <10 years (children)	<1 year; >10 year (children) >60 years (adult)
Peripheral blood WBC	<50,000 cells/μL	>100,000 cells/μL
Response to therapy	Early response to therapy Negative MRD at the end of induction	Slow response to therapy. High MRD
Genetic abnormalities	Hyperdiploidy (>50 chr.); *TEL/AML1 (ETV6/RUNX1)*	*BCR/ABL MLL/AF4* Hypodiploidy <45 chr.

chr., Chromosomes; *MRD*, minimal residual disease; *WBC*, white blood cells.
[a]The most important prognostic factor is the *treatment protocol*. Thus the prognostic significance of various clinical and laboratory variables may differ between protocols. Here, the significant parameters common to most studies are listed.

The most significant prognostic factor is the initial response to therapy. Rapid clearance of leukemic cells from blood or bone marrow confers a favorable prognosis. The level of minimal residual disease (MRD) after the induction of clinical remission has emerged as a powerful tool for gauging treatment response and predicting outcome.

Where Immunology Meets Oncology—Minimal Residual Disease

Modern treatment protocols have led to morphologic CR in the majority of patients, which is defined as less than 5% blasts in bone marrow examination. If treatment is discontinued at that stage, in most patients the disease will eventually relapse. Prospective clinical studies have shown that ALL should be treated for at least 2 years. These facts indicate that at the completion of remission induction not all clonogenic malignant lymphoblasts have been destroyed, even though most of the patients are in clinical and morphologic remission. Indeed, by this criterion, patients may have as many as 10^{10} undetectable neoplastic cells when in remission. Because, by definition, leukemic cells must constitute at least 1% to 5% of the nucleated cells in bone marrow to be detected by microscopic examination, morphologic examination is clearly inadequate for evaluation of the quality of remission in patients with ALL. Therefore more sensitive techniques for the detection of rare leukemic cells are required. This is the rationale behind the incorporation of modern techniques of MRD detection into treatment protocols of childhood ALL.

During the past two decades, two general methodologies have been developed for the sensitive detection of submicroscopic residual leukemic cells. These methodologies could not have been developed without elucidation of the scientific basis of the developmental phenotype of immune cells (see Chapters 7 and 9) and of the elaborate process of Ig gene rearrangements (see Chapter 4).

The most widely studied DNA-based MRD methodology is based on the identification of clonospecific rearrangements of Ig genes or TCRs (Ig/TCR-PCR).[11] This approach exploits the physiologic process of somatic rearrangement of Ig and TCR gene loci that occurs during the early differentiation of B cells and T cells. Thus any single T or B lymphocyte carries a unique rearrangement that is not shared by any other lymphoid cell. Because leukemia is clonal (i.e., it originates from one lymphoid cell), all of the leukemic cells of a particular person carry the same Ig and/or TCR rearrangements. Because leukemic cells are genetically unstable, they often (>90% of the cases) carry multiple rearrangements, a fact that facilitates the usefulness of using these rearrangements as a clonal marker for MRD detection. The major advantages of this technique are the exquisite sensitivity (at least 10^{-5}), reliability, reproducibility, and its applicability to greater than 90% of children with ALL. The application of NGS techniques lowers the costs and complexity of this approach.

Current strategies for flow cytometric detection of MRD rely on combinations of leukocyte markers that do not normally occur in cells of the peripheral blood and bone marrow. Such leukemia-associated phenotypes can be identified by multiple color staining techniques (Fig. 77.3). Flow cytometric analysis of these immunophenotypes allows the detection of one leukemic cell among 10^{-4} or more normal cells. The advantages of flow cytometry for MRD detection are adequate

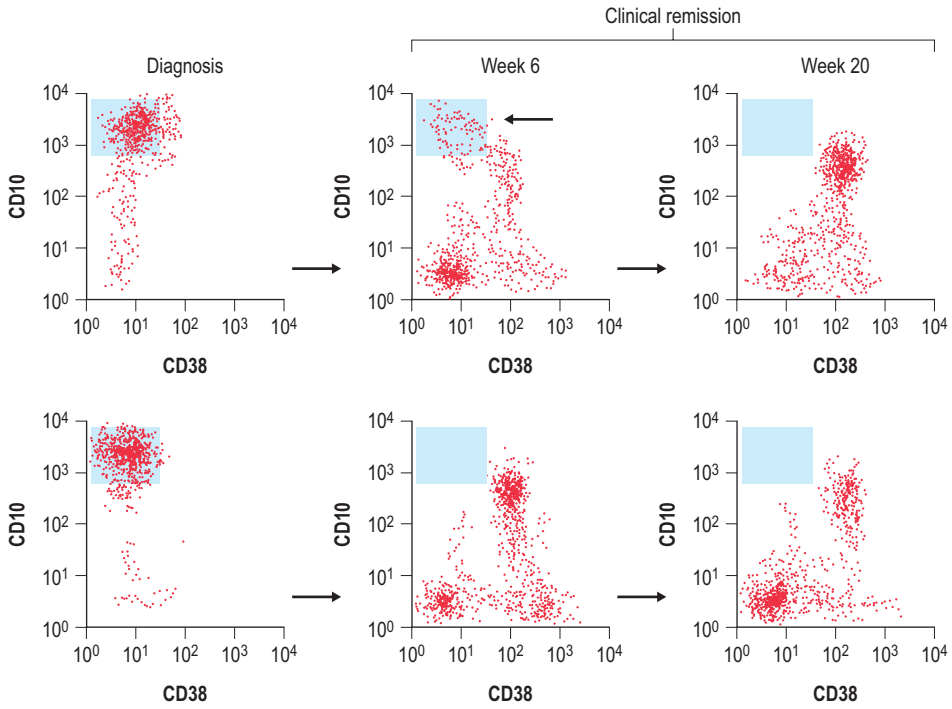

FIG. 77.3 Different Kinetics of Leukemia Cytoreduction Revealed by Minimal Residual Disease (MRD) Studies with Flow Cytometry. The left panels illustrate the leukemia-specific immunophenotype ($CD10^+$, $CD38^-$) determined at diagnosis in two children with acute lymphoblastic leukemia. This phenotype is not found in normal bone marrow. Bone marrow samples were collected during clinical remission from both patients. In one patient *(top panels)*, 0.04% of mononuclear cells expressed the leukemia-specific phenotype at week 6. MRD was undetectable by week 20. In the other patient *(bottom panels)*, a profound remission (MRD <0.01%) was achieved by week 6 and maintained at week 20.

sensitivity, and the presence of immunophenotyping facilities in most major centers that facilitate timely performance of the analysis on fresh cells at a reasonable cost.

Many ALL clinical studies have revealed strikingly similar results. Rapid clearance of leukemic blasts to less than 10^{-4} cells within the first 2 to 4 weeks of therapy is detected in approximately 40% of children with ALL and is associated with an extremely good prognosis. Conversely, the presence of greater than 0.1% blasts after 2 or 3 months of therapy defines a very-high-risk group. A prospective study involving 3184 children with ALL confirmed the strength of PCR MRD over genetic classification as a prognostic marker.[12] Currently, MRD studies have been incorporated into most treatment protocols. Patients with high MRD are stratified into a high-risk arm and receive more intensive chemotherapy.

Course and Prognosis

Current survival rates are approximately 90%. Between 15% to 20% of children will relapse. Cure rates after relapse are significantly lower. Prognostic factors include time to relapse (shorter time is worse), immunophenotype (T-cell immunophenotype is worse), and site of relapse (bone marrow disease is associated with a worse prognosis than extramedullary disease). MRD following relapse treatment is also a significant prognostic factor. Although some relapses can be treated with chemotherapy alone, many ultimately require HSCT. Genomic analysis has discovered marked subclonal heterogeneity in ALL.[13] Most of the relapses apparently arise from a minor subclone present at diagnosis. The identification and specific targeting of these resistant cells is a major future challenge.

Treatment Sequelae

Treatment-related mortality during induction and later, following remission, occurs in 2% to 4% of children with ALL, mostly of infectious causes. As cure rates improve, treatment-related mortality accounts for a higher percentage of total deaths. Certain subgroups are at higher risk for chemotherapy-associated death, such as infants, adolescents and young adults, patients with certain genetic predisposition syndromes, and those who receive more intensive therapy.

Many survivors of childhood ALL do not develop significant long-term effects. Factors that determine a child's risk for late effects include the type of treatment administered, age at leukemia treatment, and various host pharmacogenomic factors. A significant late effect of contemporary therapy is osteonecrosis, which occurs in 5% to 10% of patients, more commonly in adolescents and females. Osteonecrosis may be severely debilitating. It often involves major joints and may lead to joint collapse, requiring total joint replacement. Other long-term effects include obesity and the metabolic syndrome, secondary malignancies, neurocognitive impairments and, rarely, cardiotoxicity. Long-term follow-up to monitor for possible late effects is essential. Improvements in treatment have resulted in minimizing certain adverse effects, but further research is needed concerning the long-term effects of contemporary therapy.[14]

Where Immunology Meets Oncology—Immunotherapy of B-linage acute lymphoblastic leukemia (B-cell precursor ALL)

Despite tremendous progress, ALL remains a significant cause of childhood cancer-related mortality, due to both disease relapse and treatment-related toxicity. Acute adverse effects of chemotherapy may be life-threatening, and long-term side effects often impair survivors' quality of life. Treatment outcomes are still unsatisfactory for certain patient subgroups, such as infants, adolescents, young adults, and those with unfavorable genomic alterations. Survival rates in patients with relapsed or refractory ALL remain poor, especially in patients with early bone marrow relapse, in patients with multiple relapses, and in those who relapse after prior allo-HSCT. Certain subgroups, such as patients with Philadelphia ALL or those with "Ph-like" ALL, may benefit from molecularly targeted agents, but the majority lack a suitable target. This led to the introduction of novel immune-based therapies into the treatment of relapsed/refractory ALL (Fig. 77.4). These modalities gained US Food and Drug Administration (FDA) approval after demonstrating improved remission rates compared with chemotherapy or showing long-term benefits compared with historical controls.

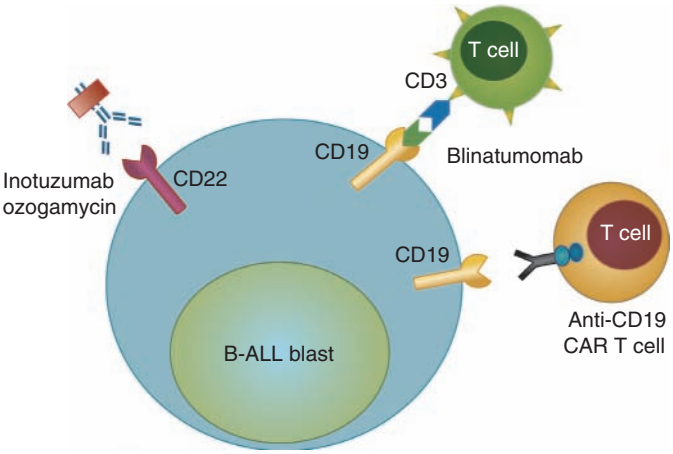

FIG. 77.4 Immunotherapy in B-ALL. Immunotherapeutic approaches include the anti-CD22 antibody-drug conjugate inotuzumab ozogamicin, the bispecific T-cell engager anti-CD19 antibody blinatumomab and chimeric antigen receptor T cells.

Inotuzumab Ozogamicin

CD22 is expressed on more than 90% of B-ALL cells and therefore serves as an attractive target for immunotherapy. Inotuzumab is a monoclonal antibody to CD22 linked to calicheamicin, a cytotoxic agent. Upon binding to CD22, the complex is rapidly internalized. Calicheamicin is released in the acidic environment of the lysosomes, with subsequent DNA damage and cell death. In adults with relapsed/refractory B-ALL, treatment with inotuzumab resulted in higher rates of remission and MRD negativity and better overall survival and quality of life, compared with chemotherapy.[15]

Inotuzumab has been shown to be effective also in combination with chemotherapeutic agents. Inotuzumab has been shown to be safe and effective in the pediatric population.

Higher rates of hepatotoxicity have been reported following inotuzumab therapy, mainly due to the development of sinusoidal obstruction syndrome in patients who subsequently underwent HSCT.

Blinatumomab

Blinatumomab is a bispecific T-cell engager (BiTE) construct designed to direct cytotoxic T cells towards CD19, an early B-lineage restricted antigen expressed on almost all leukemic cells in patients with B-ALL. Blinatumomab consists of two

connected single-chain variable antibody fragments: one binds to CD19 expressed on B cells, and the other to the TCR/CD3 complex, thus forming an immunologic complex which triggers apoptosis of the CD19-positive leukemia cell. Blinatumomab therapy has resulted in significantly higher remission rates compared with standard-of-care chemotherapy in adult ALL patients, along with significantly longer overall survival.[16] Single agent blinatumomab effectively eradicated MRD, leading to improved survival in responders compared with MRD nonresponders. Blinatumomab is safe and effective in the pediatric population. In pediatric patients in first ALL relapse, blinatumomab proved superior to intensive chemotherapy. Patients who received blinatumomab were more likely to attain MRD negativity and to proceed to HSCT, with considerably less toxicity and an improved event-free survival.

Following the success of blinatumomab treatment in the relapsed/refractory B-ALL setting, current pediatric clinical trials (e.g., the international AIEOP-BFM ALL 2017 study, *NCT03643276*) are incorporating blinatumomab into the first line treatment of B-ALL treatment, as an alternative to highly intensive and toxic chemotherapy for high-risk subgroups, and in addition to conventional chemotherapy for medium-risk patients, in an effort to reduce relapse rates.

Chimeric Antigen Receptor T Cells

Chimeric antigen receptor T cells (CARs) are a form of adoptive immunotherapy designed to modify T cells to recognize specific proteins expressed by cancer cells. Most CAR products use autologous T cells, which are harvested by leukapheresis and then reengineered to contain a receptor protein that combines antigen-binding and T-cell activating functions. CARs are then expanded for clinical use and infused back to the patient. Upon binding the target cell, the linked T-cell signaling domain activates the cytotoxic machinery, subsequently causing the death of the antigen-expressing cell. Most CARs developed for clinical trials include a primary CD3-ζ signaling domain and a CD28 or 4-1BB secondary costimulatory domain. The majority of CARs designed for clinical development have targeted the B-cell associated CD19 surface antigen and were used in B-cell malignancies, including B-cell leukemias and lymphomas in adults and children. Dramatic clinical responses and high remission rates have been observed as a result of CAR therapy of B-ALL.[17]

Unique and significant toxicities are associated with blinatumomab and CAR therapy, mainly cytokine release storm after cytotoxic T-cell activation, which can be life threatening, and neurotoxicity of varying severity. Hypogammaglobulinemia develops as a result of B-cell aplasia, and monitoring of immunoglobulin levels is recommended.

Current and future advances in immunotherapy have the potential to transform childhood ALL treatment. Yet growing experience with these treatment modalities has revealed that several mechanisms of resistance may arise. Major causes of treatment failure are loss of T-cell persistence following CAR therapy and loss of target-antigen expression on leukemic cells. Further research will reveal the precise role of these agents in pediatric ALL therapy and strategies will need to be developed to overcome these obstacles.

Future Perspectives

The high cure rates in patients with ALL (nearly 90% of children; 40% of adults) attest to the steady progress that has been made in treating this disease. A further increase in cure rates will require efforts to maximize the efficacy and minimize the toxicity of current therapy. Advanced genomic technologies carry the promise of discovering the full spectrum of leukemogenic pathways and the identification of targets for new therapies. An exciting development is the advent of immunotherapy. The role of immunotherapy in the treatment of both newly diagnosed and relapsed patients with ALL will be more precisely defined in the near future.

ON THE HORIZON

Translational Research of Acute Lymphoblastic Leukemia

- Whole genomic analyses will discover all leukemia genetic abnormalities, enabling further personalization of treatment.
- Novel therapies targeting specific leukemia-associated abnormalities will be implemented.
- Immunotherapy utilizing antibodies directed against lymphoid antigens and conjugated either to toxins or to T-cell engaging molecules or modified T cells will be routinely implemented in the treatment of ALL.

CHRONIC LYMPHOCYTIC LEUKEMIA

CLL is an often-indolent lymphoproliferative neoplasm of mature peripheral circulating B cells. It is the most common leukemia in adults living in countries in the Western hemisphere. CLL originates from a clonal lymphoid evolved mature stem cell that can be identified by its distinct B-cell Ig gene rearrangement. Both clinically and at the molecular level, it is a heterogeneous disease. Some patients have an indolent course, whereas other have a more rapid and aggressive disease. During its progression, CLL may be associated with significant immune deficiencies and autoimmune phenomena that can complicate its course and treatment. These abnormalities may be profound and thus alter the nature of the disease. They are attributed to the clonal nature of its B-cell origin. Less than 5% of patients have T-cell CLL. Understanding the molecular pathways involving BCR moieties enables focusing of novel and targeted chemoimmunotherapy.

Epidemiology

The extensive use of automated peripheral blood lymphocyte counts has increased the rate of diagnosis of asymptomatic patients with CLL. The incidence rate of CLL increases logarithmically from age 35 years, with a median age at the time of diagnosis of 65 years. There is a male predilection, and the disease appears to have geographic and ethnic variations in incidence. In the United States, CLL is uncommon in people of Asian descent. Because many of these patients may never require tissue diagnosis or inpatient treatment, cases among them are not likely to be recorded in a tumor registry, thus making the true annual incidence of the disease higher than previously thought (6.8 per 100,000 population).[18] With sensitive techniques, a monoclonal population of B lymphocytes that is indistinguishable in immunophenotype from CLL cells may be found in the blood of 3.5% of persons older than 40 years of age.[19]

The presence of B lymphocytes less than 5000/μL showing clonality is defined as monoclonal B-lymphocytosis (MBL). MBL is an indolent disorder that may progress to frank CLL at a rate of 1% to 2% per year, and almost all patients with CLL

begin with MBL. This state is divided into low or high MBL (less than or greater than 500/μL clonal lymphocytes in the peripheral blood, respectively). Low MBL is more abundant and rarely progresses to frank CLL, whereas high MBL may progress at the aforementioned rate. Some patients with MBL will experience autoimmune phenomena, as later described for CLL. However, the importance of the MBL clone is not fully understood and does not necessarily imply a future progression to CLL.[20]

The etiology of CLL is still unknown. However, as with other forms of malignancy, there is increasing evidence for the role of inherited factors in its development. Family surveys show a genetic predisposition in first-degree relatives, who also demonstrate increased susceptibility to other lymphoproliferative disorders, including other lymphomas.[21] Anticipation, the phenomenon of earlier onset, and a more severe phenotype in successive generations have been reported in families of patients with CLL.

Pathogenesis and the Biology of Leukemic Lymphocytes

CLL is now viewed as two related entities, both of which originate from B lymphocytes but differ in their activation state and in the maturation state of the cellular subgroup.[19.]

Normal B lymphocytes mature in bone marrow (see Chapter 7). In the process, they undergo rearrangement of Ig V(D)J gene segments to create the code for an Ig molecule that serves as the BCR for antigen (see Chapter 4). When an antigen of adequate affinity engages the receptor, the cell enters a germinal center located in a lymphoid follicle. There, as a centroblast, it rapidly divides and the V domains of its Ig undergo somatic hypermutation. Cells with receptors that have enhanced antigen-binding affinity proliferate in the presence of the antigen, whereas centrocytes with receptors that no longer bind the antigen (or bind autoantigens) are normally eliminated. Once the centrocytes are selected, they become plasma or memory B cells (Fig. 77.5).

The sequence and structure of Igs expressed by CLL cells from various patients have been found to be similar, suggesting a common pathogenetic antigen, such as an autoantigen-provoking clonal expansion. These findings suggest that antigenic stimulus plays a role in the promotion of CLL proliferation.

CLL may originate from a clone with few or no V domain mutations or from a more mature clone where these domains are hypermutated. These differences in the extent of V domain mutation suggest differing entities with two different developmental histories. Both originate from antigen-stimulated mature B lymphocytes. However, in the CLL with mutated Ig V domains, the proliferating B cell may have traversed the germinal centers, whereas in CLL with unmutated Ig V domains, the malignant B cell may derive from a naïve, pre–germinal center B cell.

The mutational status of the V domains strongly correlates with prognosis in that patients with an unmutated clone have a much worse prognosis compared with patients with mutated clones. These patients may differ also in their association with specific genetic aberrations. The 11q22-23 (the ataxia-telangiectasia mutated gene) or 17p13 (the *p53* gene) deletions are associated with poor outcome and with an unmutated V domain profile.

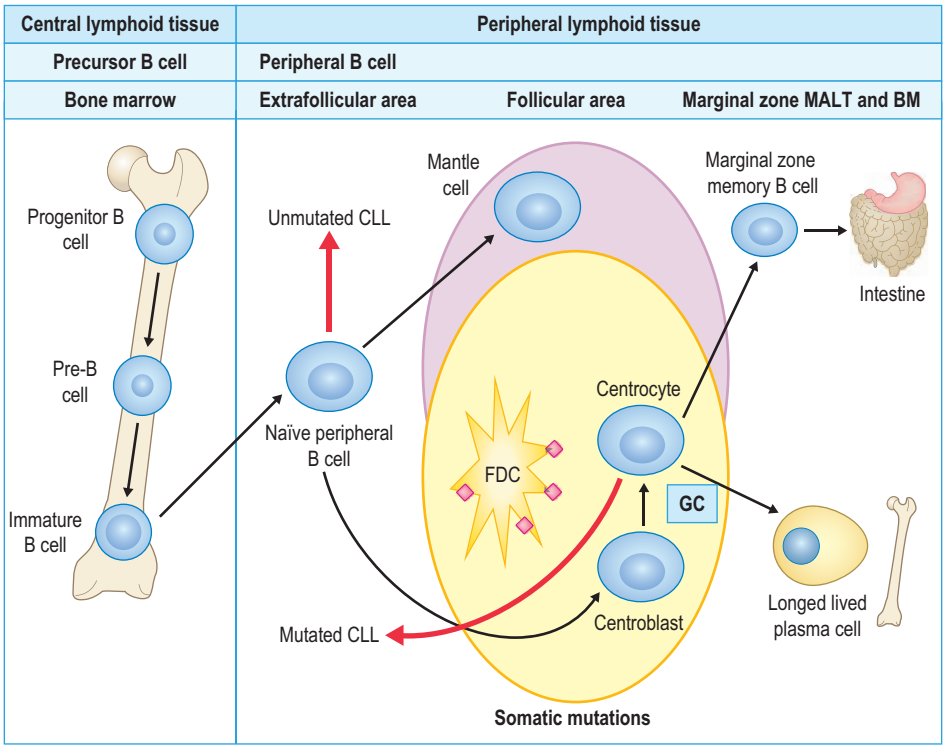

FIG. 77.5 **B-Cell Lymphoproliferative Disorders.** These diseases are related to different stages of normal B cell development. Maturation starts at the bone marrow. The more mature cells exit to the peripheral blood but do not experience the somatic hypermutation in the germinal center (GC), hence giving rise to the unmutated CLL form. When the B cells mature and differentiate within the GC into the hypermutated centrocytes, they will pathologically become the mutated form of CLL. Other forms of B cell neoplasms may arise at other stages. Earlier, as pro- and pre-B cells to give rise to acute lymphoblastic leukemia; intermediate stages to mantle zone lymphoma; late and more mature stages to marginal zone lymphoma and plasma cell–derived multiple myeloma.

These genes regulate apoptosis and resistance to chemotherapy. The 13q14 deletion or a normal karyotype is associated with a mutated profile and better prognosis. These chromosomal aberrations have independent prognostic significance (unrelated to the mutational status).

Surface membrane antigens typically found on B-cell CLL cells include CD19, CD21, and CD23. Expression of membrane IgM, IgD, and CD79b is reduced and is thus consistent with a phenotype matching that of mature, activated B lymphocytes. The pathologic features of biopsy specimens of lymph nodes are those of a small lymphocytic lymphoma (SLL).[19] The co-expression of CD5, a T cell–associated antigen, is a phenotypic characteristic and part of the disease defining criteria. $CD5^+$ B cells can be found in the peripheral blood of normal adults, suggesting that specific subsets of $CD5^+$ B cells from the mantle zone may be the normal counterparts of B-cell CLL. The low expression of the BCR is the hallmark of CLL cells and contributes to impairments in the activation of the cell following BCR stimulation.

BCR signaling in CLL has been extensively studied and has shed considerable light on the pathogenesis of the disease, thus aiding in the design of targeted therapies. The BCR is a multimeric complex containing the antigen-specific surface Ig and the two membrane-bound signal transduction elements CD79A and CD79B. Binding of antigen to the BCR induces activation of upstream kinases, which, in turn, activate other kinases by means of their cytoplasmic moieties, including SYK and the Src kinase. These kinases further activate the Bruton tyrosine kinase (BTK), PI3K, and other downstream pathways, including phospholipase C gamma 2 (PLC-γ2), calcium signaling, protein kinase C (PKC), nuclear factor (NF)-κB signaling, mitogen-activated protein kinases (MAPKs), and nuclear transcription.[22] The upstream kinases BTK and PI3K are currently targeted by specific agents, and other kinases and pathways are being explored for novel therapies (Fig. 77.6).

The CD38 surface molecule supports B-cell interactions and differentiation. Under certain circumstances, CD38 also augments signaling of BCR, delivering signals that regulate the apoptosis of B cells. Expression of CD38 correlates with expression of unmutated V domains and suggests a bad prognosis. Another molecule that influences the BCR is the ζ-associated protein 70 (ZAP70). High levels of this receptor associated protein tyrosine kinase (usually found in T and natural killer [NK] cells but not in normal B cells) are detected in the majority of unmutated CLLs and correlate with a poor prognosis (Fig. 77.7).

The microenvironment may play a role in the pathogenesis of CLL. Interactions with stromal cells rescue CLL cells from apoptosis *in vitro*. Activated T cells support the growth of CLL cells; cytokines, such as IL-4 and vascular endothelial growth factor (VEGF), and chemokines, such as CXCL12, support the expansion of CLL clones. When compared with blood-derived cells, expression profiling of CLL cells in the patient's lymph nodes showed BCR and nuclear factor (NF)-κB activation promoting cell proliferation, thus indicating the strong effects of the tumor microenvironment.[22] Mesenchymal stromal cells are also commonly found in secondary lymphatic tissues of patients with CLL. There they provide survival and migration signals to CLL cells, as well as protection from apoptosis and modulation of antigen presentation.[22,23] Endothelial cell and follicular dendritic cells (FDCs) may also play a role.

Interaction with and evasion from the normal immune system has been shown to be of significance.[22] The number of circulating T cells, oligoclonal in both the CD4 and the CD8 compartments, is increased. The function of these T cells is impaired, and they express exhaustion markers, including programmed death protein 1 (PD-1), at higher levels. Accordingly, CLL cells express high levels of PD-1 ligand (PD-L1). In addition, NK cells have reduced effector activities[22] that are associated with low expression levels of the activating receptors NK-cell p30-related protein (NKp30) and NK group 2 member D (NKG2D). Together, these findings provide an explanation for ability of CLL cells to evade immune-mediated destruction.

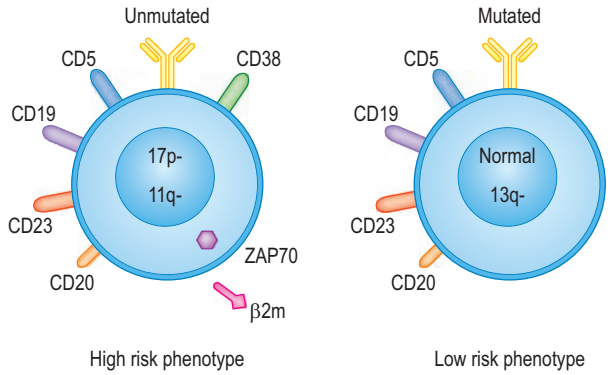

FIG. 77.6 Risk Markers and Stratification in Chronic Lymphocytic Leukemia (CLL). CLL is one disease with two different entities. It commonly expresses the B-cell surface antigens CD19 and CD23, low CD20, with the co-expression of the pan T-cell antigen CD5. The unmutated genotype correlates to worse prognosis, featuring positive CD38 surface antigen, intracellular ZAP 70, chromosomal aberrations as 17p– and 11q–, and high levels of soluble β2-microglobulin. This as opposed to the better prognosis associated with the mutated form of CLL, lacking these phenotypic features, and no chromosomal aberrations or the 13q–.

CLL has been classically characterized by the accumulation of mature B cells that evade apoptosis, with high levels of the BCL2 antiapoptotic protein. Contradicting this dogma is the measurement of CLL kinetics that has shown CLL cells to proliferate at a high dynamic rate of up to 1% of the clone per day.[24] In addition, proliferation-related genes (e.g., *c-MYC* and *E2F1*) have been found to be upregulated, especially in the unmutated CLLs.[23] This finding suggests that CLL is not solely an accumulative disease but also has a proliferative element.

Clinical Features of CLL

CLINICAL PEARLS

Chronic Lymphocytic Leukemia: Clinical Manifestations

- Absolute blood lymphocytosis >5000 /mm^3 sustained over a period of 4 weeks (to exclude transient lymphocytosis related conditions as viral infections)
- At least 30% lymphocytes in a normocellular or hypercellular marrow
- Phenotypically monoclonal lymphocytes that express mature B-cell markers (e.g., CD19) and CD5
- Morphologically mature-appearing lymphocytes
- Most patients have some degree of lymphadenopathy on physical examination
- Progression and the need for treatment depend on lymphocyte doubling time, bulky symptomatic disease, anemia, thrombocytopenia, autoimmune phenomena

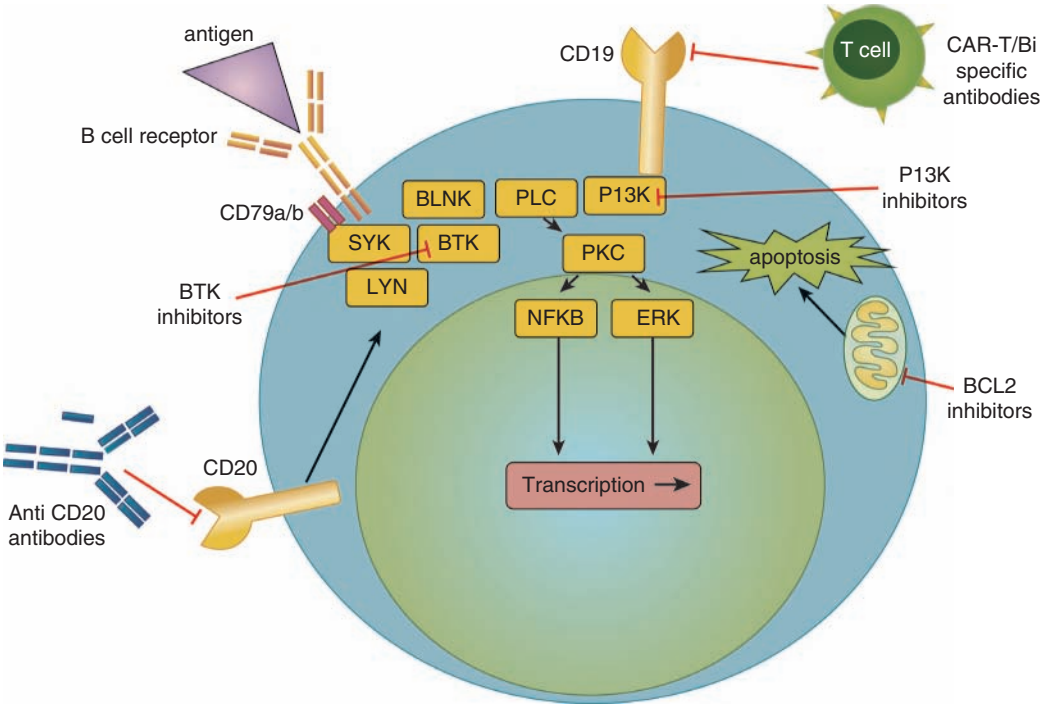

FIG. 77.7 Chronic Lymphocytic Leukemia (CLL) Signaling and Targeted Therapy. B-cell receptor (BCR) signaling in CLL has been extensively studied and helps the design of targeted therapies. Antigen binding by the BCR induces the formation of a signaling complex that is initiated by the cytoplasmic tails of CD79A and CD79B, further recruiting spleen tyrosine kinase, which is followed by the activation of B cell linker protein, phospholipase Cγ2, and Bruton tyrosine kinase (BTK). Inhibition of BTK by tyrosine kinase inhibitor ibrutininb and second-generation acalabrutinib and zanubrutinib interferes with this signaling and causes cell death. The tyrosine-protein kinase LYN also directly phosphorylates BTK. BCR signaling via the PI3K pathway is promoted further, and the positive BCR co-receptor CD19 contributes to the activation of the PI3K pathway and to the induction of survival. CD19 is also the target of new antibodies and the main target of activated chimeric antigen receptor T cells. Further downstream signaling of the pathway are responses of protein kinase C, the RAS-MAPK pathway, and nuclear factor-κB. The signaling response induces transcription. Other activators of cellular activity of survival like CD20, which is inhibited by first- (rituximab, ofatumumab) and second- (obinutuzumab) generation anti-CD20 antibodies. Promotion of apoptotic pathways are done via the BCL2 inhibitor venetoclax.

The clinical diagnosis of CLL requires an absolute lymphocytosis with a threshold of greater than 5000×10^9/L mature-appearing lymphocytes in the blood smear, persistence of the lymphocytosis for greater than 4 weeks, and a distinct immunophenotype (as described earlier). Approximately a quarter of patients with CLL are asymptomatic at diagnosis. The clinical characteristics at presentation include lymphadenopathy (87%), splenomegaly (54%), hepatomegaly (14%), high white blood cell (WBC) count, anemia, and thrombocytopenia (20%). Very high WBC counts are rare but may develop along the course of the disease. Hyperleukocytosis, which causes leukostasis and necessitates emergency treatment, is extremely rare. Other organs that are involved include other lymphoid tissues and rarely solid organs or skin.

A prognostic evaluation of the patient with CLL begins with study of the patient's blood and bone marrow. Lymph node biopsy is not necessary but, if performed, may reveal the diagnosis of SLL, which is considered a different manifestation of the same disease. The differential diagnosis includes other low-grade lymphoproliferative disorders, such as a leukemic phase of lymphoma and mantle cell lymphoma (usually negative for CD23); hairy cell leukemia (CD5 and CD21 negative and CD103 and CD25 positive); T-cell leukemia (other T-cell markers, such as CD3, CD4, and CD7); and prolymphocytic leukemia (PLL), which is distinguished by morphologically immature-appearing cells and the presence of FMC7 and CD79b on the cell surface. T-cell CLL is rare (<5%).

The oldest staging systems of CLL risk stratification rely on measurement of disease bulk as reported by Rai[25] and Binet[26,27] (Table 77.5). These staging systems are very useful for identifying patients who will need treatment at the time of diagnosis, but not for predicting who will subsequently need treatment. Approximately 33% of patients never require treatment and have a long survival. In another third, an initial indolent phase is followed by disease progression. The remaining third of patients exhibit an aggressive disease at the onset and need immediate treatment.

The most powerful predictors for rapid and aggressive progression are the mutational status of the V domains and chromosomal abnormalities, as described earlier (see Fig. 77.7; see Table 77.5). In contrast to genomic aberrations and serum markers, such as CD38, the mutational profile has the advantage of remaining constant during disease evolution. NGS has identified new genetic markers that have altered prognosis for patients with CLL.[27] *TP53, ATM, NOTCH1*, and *SF3B1* mutations indicate a worse prognosis.

TABLE 77.5 Major Factors Associated With Prognosis of Chronic Lymphocytic Leukemia (CLL)[4–7,9,30,31,33,34]

	Definition	Median Survival (Years)	Used in Clinical Practice
Rai stage 0	Leukocytosis	12.5	Yes
1	Leukocytosis and lymphadenopathy	8.4	
2	Lymphocytosis plus hepatosplenomegaly	6.9	
3	Lymphocytosis plus anemia (<11 g/dL)	1.5	
4	Lymphocytosis plus thrombocytopenia (<100 000 × 10^9/L)	1.5	
Binet	Leukocytosis and lymphadenopathy	Age-matched	Yes
Stage A	Lymphadenopathy of more than two involved areas	7	
Stage B	Anemia or thrombocytopenia	2	
Stage C			
β_2 microglobulin	Normal	9.7	Yes
	Elevated	4.5	
CD 38	>30%	2.9 to <10 years	Yes
Early-stage CLL	<30%	9 to >26 years	
Chromosomal aberrations (FISH analysis)	17p–	2.7	Sometimes
	11q–	6.5	
	Trisomy 12	9.5	
	Normal karyotype	9.3	
	13q–	11.1	
Zeta-associated protein 70 (ZAP-70)	>20%	7.5	If available
Early-stage CLL	<20%	Not reached	
Mutational status	Unmutated	5.7 to <9.9 years	If available
	Mutated	10.2 to >24 years	

FISH, Fluorescence in situ hybridization.

Treatment

THERAPEUTIC PRINCIPLES

Chronic Lymphocytic Leukemia Is Incurable, but It Is Possible to Ameliorate Symptoms

- High rates of complete remissions and encouraging survival curves for high-risk patients
- Watch and wait approach in the case of asymptomatic patients with early-stage CLL
- Supportive care (immunoglobulins, blood supplements and erythropoietin, treatment of infections)
- Steroids with or without chemotherapy, especially for autoimmune phenomena
- Conventional chemotherapy (alkylating agents, such as chlorambucil and cyclophosphamide; purine analogues, such as fludarabine and cladribine; other lymphoma regimens; bendamustine)
- Targeted therapy with or without chemotherapy (i.e., rituximab, ofatumumab, obinutuzumab (all anti-CD20 antibodies) and alemtuzumab (anti-CD52 antibody)
- B-cell receptor pathway inhibitors—BTK (ibrutinib), PI3K-d (idelalisib), and BCL2 antagonists (venetoclax)
- Allogeneic (mostly with reduced intensity) stem cell transplantation

Because CLL remains an incurable tumor, treatment may be delayed and the patient monitored until becoming symptomatic (see Table 77.4). Indications for therapeutic intervention include the development of symptoms, a worsening anemia and/or thrombocytopenia, autoimmune cytopenias, progressive splenomegaly, progressive lymphadenopathy, or a lymphocyte doubling time of 6 months or less. No prospective data yet exist to support the early treatment of asymptomatic patients with adverse prognostic features. However, this group warrants close monitoring.

Conventional chemotherapy was the mainstay of treatment. Novel targeted therapy gradually replaces this approach to the verge of "chemo-free" treatment paradigm.[28] Chlorambucil, alone or combined with corticosteroids, has been the most commonly used drug. It is advantageous in relieving symptoms, even in advanced disease. However, several randomized controlled trials have failed to demonstrate improved survival, and hardly any patient achieves CR. Purine analogues (most commonly fludarabine) with or without cyclophosphamide have been shown to induce higher response rates, with some patients achieving CR. Bendamustine is a novel agent that contains both alkylating properties and a purine-like benzimidazole ring. It has been shown to be effective in CLL and less toxic than the fludarabine and cyclophosphamide combination.[29]

The anti-CD20 mAb rituximab as a single agent has shown limited efficacy in CLL, possibly because of the weak receptor expression on CLL cells. However, in combination with chemotherapy, particularly with fludarabine and cyclophosphamide or bendamustine,[29] and to other novel targeted agents,[28] discussed later, it appears to act synergistically and to achieve high rates of response, including molecular CR and prolongation of disease-free and overall survival. A newer fully human mAb targeting CD20 (ofatumumab) has a very potent effect as a single agent in both rituximab-naïve and rituximab-treated patients. It targets a different epitope on the CD20 antigen. A second-generation anti-CD20 antibody, obinutuzumab, was added to chlorambucil and to venetoclax, a BCL2 inhibitor

(discussed later) in the treatment of the older adult population. When compared with chlorambucil, alone or in combination with rituximab and chlorambucil, obinutuzumab was shown to be superior and relatively safer.[28,29] Other invetigational agents showing efficacy include lenalidomide (an immune modulator related to thalidomide), albeit with an interestingly initial flair-up phenomenon of disease-enlarged lymph nodes.

A major breakthrough in treatment was achieved through drugs targeting the BCR pathway. A BTK inhibitor, ibrutinib, has shown an impressive progression-free survival in relapsing patients and as first line treatment, especially for patients with resistant or high-risk 17p-deleted CLL. It is currently considered as standard of care especially for high-risk patients. Interestingly, at treatment initiation, it causes a steep rise in peripheral blood lymphocyte counts, most likely due to translocation of nodal lymphocytes to the blood. This is actually correlated to a better and prolonged response.[28,30] Currently, second-generation BTK inhibitors such as acalabrutinib and zanubrutinib with fewer side effects are being tested.[28,30,31] In combination with rituximab, another pathway inhibitor, the PI3Kδ inhibitor idelalisib had an efficacy superior to rituximab alone in frail, older patients who were relapsing. However, it has been linked to severe toxicities, and second-generation kinases such as duvelisib and copanlisib are expected to be used.[28,30,31]

Furthermore, clinical trials with small molecules targeting BCL2, venetoclax, have shown deep and sustained responses, both in the upfront first line and in the relapsed refractory patients. Combined with anti-CD20 obinutuzumab and rituximab it allows the possibility to stop treatment after 12 to 24 months of therapy.

However, resistance due to specific mechanisms (e.g., BTK, PLCg2, and BCL2 mutations) is emerging, indicating the need to develop time-limited combinations and novel agents combinations.[28,30,31] In addition, under investigation are various novel agents targeting other surface molecules (CD23, CD79b, and other CD20 inhibitors), pathway inhibitors (SYK, PI3K, second-generation BTK, and others), and immune-checkpoint inhibitors. Some immunologic novel approaches include expanded autoreactive activated T cells (Chimeric antigen receptor [CAR] T-cells), which is showing promise. Unfortunately, the majority of patients with CLL do not attain durable responses.[31,32]

Allo-HSCT is the only curative treatment for CLL. Allo-HSCT relies on myeloablative doses of chemoradiotherapy, which makes the treatment unacceptably risky for the majority of patients with CLL. In nonmyeloablative, or reduced-intensity, approaches, rates of engraftment are similar to fully ablative conditioning regimens but with lower rates of early toxicity. Early evidence suggests that the graft-versus-leukemia (GvL) effect is present. Patients with deletion 17p (p53 involvement) with an extremely poor prognosis are physically fit candidates for allo-HSCT,[28,29] even as newer agents (i.e., BTK inhibitors, PI3K inhibitors, and BCL2 inhibitors) are showing high efficacy in this high-risk population. Studies involving autologous transplantation and high-dose chemotherapy for CLL have a limited survival advantage.

With treatment advances, the overall survival of patients with CLL has improved across the globe as a result of targeted therapy, even in high-risk and in patients with relapsed and refractory CLL. Thus classic prognostication (as presented in Table 77.5) is becoming less accurate as treatment improves.

Immunologic Aspects of CLL

CLINICAL PEARLS

Chronic Lymphocytic Leukemia: Immunologic Manifestations

- Panhypogammaglobulinemia
- A monoclonal immunoglobulin peak, usually of the immunoglobulin M type
- Downregulation of T-cell function and aberrant cytokine production
- Defects in the complement system
- High risk of recurrent infections—encapsulated bacteria and opportunistic infections
- Autoimmune-associated phenomena:
  - Autoimmune hemolytic anemia
  - Autoimmune thrombocytopenia
  - Pure red cell aplasia and autoimmune neutropenia
  - Other autoimmune disorders (myositis, vasculitis, pemphigus vulgaris, acquired angioedema, glomerulonephritis)

CLL is characterized by multiple immune deficiencies and autoimmune phenomena. It is reasonable to hypothesize that immune incompetence and autoimmunity are two sides of the same coin.

The Pathophysiologic Rationale

CLL cells secrete TGF-β, which is a potent inhibitor of B-cell proliferation. They also release high levels of circulating IL-2 receptor, which downregulates the T-helper (Th) cell function. Unlike normal cells, activated B cells, both B-cell CLL cells and anergic normal B cells, fail to present soluble antigen and alloantigens. Moreover, the T cells in patients with CLL often demonstrate profound abnormalities of their antigen receptor (TCR) repertoire and appear dysfunctional in terms of cytokine secretion.[33] This cytokine imbalance may be the cause of upregulation of the BCL-2 antiapoptotic activity. T-cell dysfunction could also explain the higher incidence of autoimmune complications, such as autoimmune hemolytic anemia (AIHA), among patients receiving purine analogues therapy, which induces T-cell depletion. Certain T-cell subsets appear to prevent the development of autoreactive B cells. When these are absent (e.g., after treatment with purine analogues), autoreactive B-cell clones may easily emerge and expand.

Immunologic Deficiencies

Patients with CLL are extremely sensitive to a number of infectious agents. A monoclonal Ig peak, usually of the IgM type, is found in 5% of patients with CLL, and a small amount of a monoclonal component can be identified in the serum or urine of 60% of patients. Hypogammaglobulinemia occurs in at least 60% of B-cell CLL cases and may include all three classes (IgG, IgA, and IgM). The pathogenesis of hypogammaglobulinemia in B-cell CLL is poorly understood because this phenomenon is rare in other B-cell malignancies except multiple myeloma. Low Ig levels correlate with recurrent infections of encapsulated organisms. In patients who receive intravenous immunoglobulin (IVIG), there is a decrease in the incidence of major bacterial infections.

Infections are a major cause of morbidity and mortality in patients with CLL. Impaired humoral and cellular immunities, defects in the complement systems, and variable neutropenia, depending on marrow infiltrates, all contribute to the high rate

of infections. Opportunistic infections are initially uncommon as the result of the relative preservation of cellular immunity early in the disease. Infection risk increases following purine analogue therapy because of the side effects of myelosuppression and marked lymphopenia with T-cell depletion. The addition of rituximab, the anti–B cell marker CD20 antibody, to nucleoside analogue-based therapy does not appear to increase the risk of early or late infections but may increase the rate of neutropenia. Active immunization with vaccines is hampered by the patient's inability to generate or retain a long and significant immune response. The advances in therapy with newer agents show high efficacy (i.e., BTK inhibitors, PI3K inhibitors, and BCL2 inhibitors) but also more atypical bacterial, fungal, and protozoal infections.[31]

Autoimmune Phenomena

Autoimmune-associated features are common in CLL. These manifestations primarily affect hematopoietic cells. For example, the most common known cause of AIHA is CLL.[34] Positive result of direct antiglobulin test (direct Coomb test) has been reported to be as high as in 7% to 35% of patients with CLL, and AIHA itself occurs in 10% to 25% of patients during the course of their disease, twice as often in patients with unmutated genes as in those with mutated ones. Autoantibodies against red blood cells (RBCs) are warm-reactive polyclonal IgG. They are not secreted by the malignant clone but rather by normal B cells.[34] Cold agglutinins are rare. AIHA is thought to arise from the imbalance among lymphocyte subsets, contributed to by therapy, resulting in the emergence of the autoimmune clone. It is usually observed in advanced stages of the disease, correlates with a poor prognosis, and has a close relationship with the activity of the CLL. After therapy, the autoimmune antibodies may remit in 70% of the treated patients.

Idiopathic thrombocytopenic purpura (ITP) is observed in approximately 2% to 3% of cases and presents as increased megakaryocytes in bone marrow. It should be distinguished from immune thrombocytopenia induced by marrow infiltration, which is very common (in up to 50% of patients at presentation).[34] Two-thirds of patients with CLL-associated ITP also have AIHA (Evan syndrome). Pure red cell aplasia (PRCA) and autoantibodies against neutrophils are only rarely observed but are part of the CLL-related autoimmunity repertoire. Interestingly, the addition of cyclophosphamide represses the emergence of fludarabine-induced AIHA, but the latter may also be seen with other chemotherapies (i.e., bendamustine).[35] Autoimmune phenomena in patients treated with purine analogues (mostly fludarabine-related) are of a more severe nature.

Other rare entities are reported as paraneoplastic autoimmune disorders with connective tissue disease manifestations, such as polymyositis, dermatopolymyositis, and focal myositis or as vasculitis, pemphigus vulgaris, and acquired angioedema. These autoimmune disorders are related to T-cell dysfunction and may be associated with purine analogue treatment. Paraneoplastic pemphigus also occurs in patients with CLL and may be triggered by chemotherapy and radiotherapy. Glomerulonephritis and nephrotic syndrome are seldom reported but, when present, are related to different mechanisms, such as cryoglobulins and antineutrophil cytoplasmic antibodies (ANCAs).

Therapy of autoimmune phenomena includes high-dose steroids and disease control.[34] In patients refractory to or relapsing after steroid therapy, more aggressive treatment is warranted. High-dose Igs offers transient amelioration in some patients. Splenectomy or splenic irradiation, cytotoxic agents, or cyclosporine may represent valid rescue approaches. In cases where AIHA has been triggered by fludarabine, further exposure is hazardous. Rituximab may be an alternative agent for the treatment CLL-associated autoimmune diseases, including rare autoimmune phenomena, such as pemphigus and PRCA.

In line with the introduction of novel agents, the possible role of these drugs in inducing or exacerbating autoimmune phenomena and, on the other hand, of treating them still needs to be elucidated and with most is anecdotally reported.[36] PI3K inhibitors may cause various autoimmune complications and therefore theoretically may cause or exacerbate these in CLL. Although some reports connect ibrutinib with autoimmune complications, most evidence supports its efficacy in treating or at least improving such autoimmune complications.

Other Malignancies

Second malignancies (hematologic and solid tumors) are not uncommon in CLL. The most common hematologic malignancy is the Richter transformation to diffuse large B-cell lymphoma, which occurs in approximately 5% of patients, as well as other high-grade lymphoproliferative diseases. Dermatologic tumors, such as basal cell carcinoma, are the most frequent of the solid tumors encountered in patients with CLL, and these malignancies are more likely to be locally aggressive and metastatic.[29] The pathogenesis of these second cancers is not fully understood, and although disease-related genetic factors (i.e., 17p deletion, notch mutation) are a major determinant, it is probably multifactorial and includes Epstein-Barr virus (EBV) infection and BCR configuration to respond to multiple autoantigens and immune/inflammatory stimuli present in the microenvironment.[29,37]

CONCLUSIONS

CLL is a common indolent lymphoid neoplasm with a wide clinical heterogeneity. It is suspected and diagnosed more commonly because of routine blood tests. Diagnosis is made with simple immunophenotyping. Cytogenetics and molecular diagnostic techniques are needed to determine the prognosis. The complications of CLL appear to be unique to this neoplasm and are part of a failing immune system with T-cell and B-cell dysregulation causing both deficiencies and predisposing patients to recurrent infections and autoimmune diseases. New molecular and protein markers are key to the current novel effective targeted therapies approach for the treatment of these patients.

Lymphomas

Stefania Pittaluga, Ivo M.B. Francischetti, Joo Y. Song, and Elaine S. Jaffe

The classification of malignant lymphomas continues to undergo revision based on insights gained through the application of immunologic and molecular techniques as well as the application of these discoveries to individualized therapeutic approaches. Early classifications were based on morphologic characteristics of the neoplastic elements; however, with increasing knowledge of the complexity of the immune system, a more functional approach was sought. Differentiation schemes provided a useful starting point for understanding lymphomas (Fig. 78.1). High-throughput genomic studies have been applied to lymphomas to define their molecular signatures with the aim of improving the understanding of oncogenic pathways and their clinical implications. These studies have led to new prognostic and diagnostic tools associated with the emergence of more targeted therapies.[1]

KEY CONCEPTS

Lymphoma

- Classification consists of a list of individual disease entities defined by morphologic, immunophenotypic, genetic, and clinical features.
- Neoplastic cells are linked to the postulated normal counterpart, when possible.
- Histologic grade should be applied within individual diseases.
- Clinical factors for individual patients, as measured by the International Prognostic Index (IPI) and gene expression profiling, are useful in predicting clinical outcome.

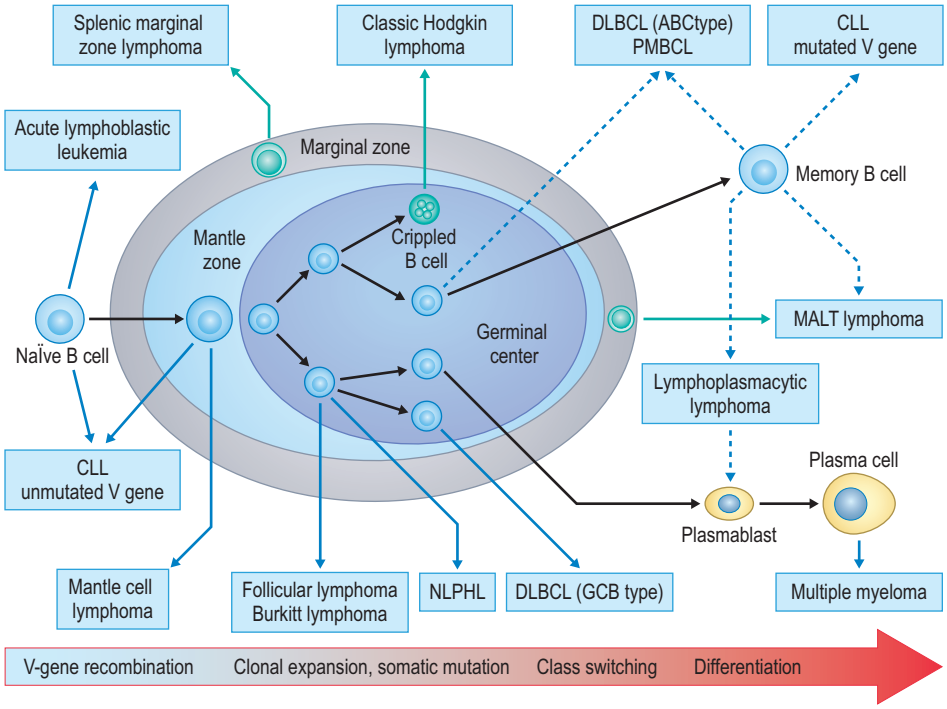

FIG. 78.1 Normal B-Cell Differentiation in Relation to a Secondary B Follicle, Mutational Stages of the Immunoglobulin Genes, and Cellular Counterparts for B-Cell Lymphomas. Simplified version of B-cell development indicates points at which V-gene recombination, clonal expansion, and somatic mutations occur in relation to a secondary B follicle. B-cell lymphomas are related to different stages of B-cell differentiation and function. *ABC type*, Activated B-cell-like type; *CLL*, chronic lymphocytic leukemia/lymphoma; *DLBCL*, diffuse large B-cell lymphoma; *GCB type*, germinal center B-cell–like type; *MALT lymphoma*, marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT) type; *NLPHL*, nodular lymphocyte-predominant Hodgkin lymphoma; *PMBCL*, primary mediastinal B-cell lymphoma.

The guiding principles of the World Health Organization (WHO) classification of neoplasms of the hematopoietic and lymphoid tissues were published in 2001 and updated in 2008 and 2016.[2] These classifications identified individual diseases based on an integration of morphologic, immunophenotypic, genetic, and clinical features. The application of gene expression profiling (GEP) in lymphomas has generated distinct molecular "signatures" for a variety of disease entities, either corresponding more closely to different stages of lymphoid differentiation or offering insights into mechanisms of neoplastic transformation. The advent of whole-genome sequencing contributes additional insights into pathogenetic mechanisms. A latest revision of the WHO classification of lymphoid neoplasms (Table 78.1) was published clarifying the diagnosis of lesions at the very early stages of lymphomagenesis, refining diagnostic criteria for some entities, and detailing the expanding genetic/molecular landscape of numerous lymphoid neoplasms and their clinical correlates.[3]

TABLE 78.1 WHO Classification of Tumors of Hematopoietic and Lymphoid Tissues (2016)

B-Cell Neoplasm

Precursor B-cell lymphoblastic leukemia/lymphoma
- B-lymphoblastic leukemia/lymphoma, not otherwise specified
- B-lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities

Mature B-Cell Neoplasm

Chronic lymphocytic leukemia/small lymphocytic lymphoma
Monoclonal B-cell lymphocytosis[a]
B-cell prolymphocytic leukemia
Splenic B-cell marginal zone lymphoma
Hairy cell leukemia
Splenic B-cell lymphoma/leukemia, unclassifiable
- *Splenic diffuse red pulp small B-cell lymphoma*
- *Hairy cell leukemia-variant*

Lymphoplasmacytic lymphoma
Waldenström macroglobulinemia
Monoclonal gammopathy of undetermined significance (MGUS), IgM[a]
μ heavy-chain disease
γ heavy-chain disease
α heavy-chain disease
Monoclonal gammopathy of undetermined significance (MGUS), IgG/A[a]
Plasma cell myeloma
Solitary plasmacytoma of bone
Extraosseous plasmacytoma
Monoclonal immunoglobulin deposition diseases[a]
Extranodal marginal zone lymphoma of mucosa-associated lymphoreticular tissue (MALT) lymphoma
Nodal marginal zone lymphoma
- Pediatric nodal marginal zone lymphoma

Follicular lymphoma
- In situ follicular neoplasia[a]
- Duodenal-type follicular lymphoma[a]
- Pediatric-type follicular lymphoma[a]
- *Large B-cell lymphoma with IRF4 rearrangement*[a]
- Primary cutaneous follicle-center lymphoma

Mantle cell lymphoma
- In situ *mantle cell neoplasia*[a]

Diffuse large B-cell lymphoma (DLBCL), NOS
- Germinal-center B-cell type[a]
- Activated B-cell type[a]

T-cell/histiocyte-rich large B-cell lymphoma
Primary DLBCL of the central nervous system
Primary cutaneous DLBCL, leg type
EBV+ DLBCL, NOS[a]
EBV+ mucocutaneous ulcer[a]
DLBCL associated with chronic inflammation
Lymphomatoid granulomatosis
Primary mediastinal (thymic) large B-cell lymphoma
Intravascular large B-cell lymphoma
ALK positive large B-cell lymphoma
Plasmablastic lymphoma
Primary effusion lymphoma
HHV-8–positive DLBCL, NOS[a]
Burkitt lymphoma
Burkitt-like lymphoma with 11q aberration[a]
High-grade B-cell lymphoma, with MYC and BCL2 and/or BCL6 rearrangements[a]
B-cell lymphoma unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classic Hodgkin lymphoma

T-Cell Neoplasm

Precursor T-cell lymphoblastic leukemia/lymphoma

Mature T-Cell and NK-Cell Neoplasms

T-cell prolymphocytic leukemia
T-cell large granular lymphocytic leukemia
Chronic lymphoproliferative disorder of NK cells
Aggressive NK leukemia
Systemic EBV+ T-cell lymphoma of childhood[a]
Hydroa vacciniforme-like lymphoproliferative disorder[a]
Adult T-cell leukemia/lymphoma
Extranodal NK/T-cell lymphoma, nasal type
Enteropathy-associated T-cell lymphoma
Monomorphic epitheliotropic intestinal T-cell lymphoma[a]
Indolent T-cell lymphoproliferative disorder of the GI tract[a]
Hepatosplenic T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Mycosis fungoides
Sézary syndrome
Primary cutaneous CD30+ positive T-cell lymphoproliferative disorders
- Primary cutaneous anaplastic large-cell lymphoma
- Lymphomatoid papulosis

Primary cutaneous γ/δ T-cell lymphoma
Primary cutaneous CD8 positive aggressive epidermotropic cytotoxic T-cell lymphoma
Primary cutaneous acral CD8+ T-cell lymphoma[a]
Primary cutaneous CD4-positive small/medium T-cell lymphoproliferative disorder[a]
Peripheral T-cell lymphoma, NOS
Angioimmunoblastic T-cell lymphoma
Follicular T-cell lymphoma[a]
Nodal peripheral T-cell lymphoma with T_{FH} phenotype[a]
Anaplastic large-cell lymphoma, ALK positive
Anaplastic large-cell lymphoma, ALK negative[a]
Breast implant-associated anaplastic large-cell lymphoma[a]

Hodgkin Lymphoma

Nodular lymphocyte predominant Hodgkin lymphoma
Classic Hodgkin lymphoma
Nodular sclerosis Hodgkin lymphoma
Lymphocyte-rich classic Hodgkin lymphoma
Mixed cellularity classic Hodgkin lymphoma
Lymphocyte-depleted classic Hodgkin lymphoma

EBV, Epstein-Barr virus; *GI*, gastrointestinal; *HHV*, human herpes virus; *NK*, natural killer; *NOS*, not otherwise specified; *WHO*, World Health Organization.
[a]Refers to changes from the 2008 classification.
Note: More common entities are underlined. Provisional entities in italics.
From Swerdlow SH, Campo E, Harris NL, et al. *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues*. Lyon, France: International Agency for Research on Cancer; 2017.

This chapter focuses on the classification of neoplasms derived from mature B cells, T cells, and natural killer (NK) cells, with emphasis on malignant lymphomas. Special attention is devoted to the impact of clinical features (e.g., age and anatomic site) on disease definition and a greater appreciation of early events in neoplastic transformation. These early lesions can sometimes be detected in otherwise healthy individuals, a situation that may or may not progress to overt lymphoma or leukemia. These early entities appear to carry fewer genetic aberrations compared with the conventional forms of the disease, which perhaps explains their indolent clinical behavior.[4]

CLINICAL PEARLS

Indolent Lymphomas

- Natural history: survival measured in years.
- Least sensitive to therapy.
- Good response to low-dose oral alkylating agents, radiotherapy, and steroids, but not curable.
- Higher response rate and complete remission with combination of standard chemotherapy and anti-CD20 monoclonal antibody.
- Gene expression profiling can help identify patients who might benefit from high-dose chemotherapy and autologous stem cell transplantation, a potentially curative modality.

MATURE B-CELL NEOPLASMS

KEY CONCEPTS

Somatic Mutation in Relation to Normal B-Cell Development

- *Premutational stage:* circulating naïve B cells (immunoglobulin [Ig]M$^+$/D$^+$) before antigen exposure
- *Stage of somatic mutation, clonal expansion, and isotype switch:* at the germinal center
- *Postmutational stage:* selected B cells move to the periphery (post–germinal center), to the recirculating pool (memory B cells), or undergo terminal differentiation (plasma cells)

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphoma (LPL) is a disease of adult life, usually presenting with generalized lymphadenopathy, constitutional symptoms, and splenomegaly.

Histologically, it consists of a diffuse proliferation of small lymphocytes (many with plasmacytoid features) and plasma cells, with or without immunoglobulin (Ig)-filled intranuclear inclusions (Dutcher bodies). An increased number of mast cells and iron-laden macrophages can be seen. Although many B-cell neoplasms occasionally show maturation to plasmacytoid or plasma cells with cytoplasmic Ig, the term LPL should be restricted to tumors lacking features of other well-defined entities, such as chronic lymphocytic leukemia (CLL) or mantle cell lymphoma (MCL), which occasionally can manifest plasmacytoid differentiation. Many but not all patients with LPL have clinical evidence of Waldenström macroglobulinemia (WM), based on the detection of an IgM monoclonal gammopathy of any concentration and associated with bone marrow involvement by LPL (Chapter 79).

In LPL, cells have surface and cytoplasmic Ig, usually IgM (but usually lacking IgD), and express B cell–associated antigens (CD19, CD20, CD22, CD79a). They are generally negative for CD5 and cyclin D1, distinguishing LPL from CLL and MCL, respectively. CD25, CD10, or CD11c may be weakly expressed in some cases. The postulated normal counterpart is thought to be a postfollicular medullary cord B cell, based, in part, on the presence of somatic mutations in the Ig heavy-chain and light-chain variable region genes.

The identification of *MYD88* L265P mutation (found in approximately 90% of WM cases) is a reliable marker supporting a diagnosis of LPL.[5] This mutation is also found in a significant proportion of IgM, but not IgG or IgA, monoclonal gammopathy of undetermined significance (MGUS) cases (Chapter 79). Cases with the *CXCR4^{WHIM}* mutations exhibit a resistance to ibrutinib.

Mantle Cell Lymphoma

MCL usually presents in adults (median age 62; variable male predominance) with advanced-stage disease—involving lymph nodes, Waldeyer ring lymphoid tissue, spleen, bone marrow, and peripheral blood. Gastrointestinal (GI) tract involvement is common, often associated with lymphomatous polyposis. Retrospective studies have shown a poor prognosis (median survival 3 to 5 years), with a high relapse rate following initial remission. MCL is composed of small lymphoid cells with slightly irregular nuclear contours, finely clumped chromatin, and scant cytoplasm. Specifically, blastoid and pleomorphic variants have been associated with a more aggressive clinical course. The postulated normal counterpart is a CD5$^+$ "naïve" surface IgM$^+$ and surface IgD$^+$ B cell, found in peripheral blood and the mantles of reactive follicles.

MCL is characterized by t(11;14)(q13;q32)—involving cyclin D1 (*CCND1*) and the *IGH* genes; an overexpression of *CCND1* is believed to be essential in the pathogenesis. Rare variants negative for *CCND1* but with similar immunomorphology and GEP have also been identified.[6] Half of the *CCND1* expression/rearrangement-negative forms have *CCND2* translocations, often with *IGK* or *IGL* as a partner locus.[7] SOX11 is overexpressed in most *CCND1*-positive and *CCND1*-negative cases.[8] Additional alterations involving other cell cycle regulatory proteins (RB, p53, CDK inhibitors) have been described in the more aggressive forms of MCL.

In situ mantle cell neoplasia (ISMCN) (previously "in situ" MCL) represents a clonal proliferation of cyclin D1–positive cells restricted to the inner mantle cuffs in an otherwise reactive lymph node/lymphoid tissue and is usually an incidental finding. Some cases will eventually progress to overt MCL[2]; however, the risk of progression is difficult to ascertain because the number of reported cases is small. The more recently identified non-nodal variant is characterized by a leukemic phase without nodal disease but often long-standing splenomegaly. These cases develop from IgHV-mutated SOX11-negative B cells, carry t(11;14) with few additional chromosomal abnormalities, and lack expression of SOX11.[9]

The proliferation rate based on Ki67 positivity has been considered of prognostic relevance. More recently, GEP using genes involved in cell cycle progression and DNA synthesis has identified a proliferation signature that defines different prognostic groups and shows some correlation with cytologic subtype such as the blastoid variant.[10]

The treatment approach for newly diagnosed patients with MCL depends on their eligibility for stem cell transplantation (SCT). The incorporation of rituximab into chemotherapeutic regimens has become standard of care. The application of the Bruton tyrosine kinase (BTK) inhibitors might change treatment paradigms by obviating the need for transplantation in

younger patients and chemotherapy in older patients. Patients with the non-nodal variant do not appear to require aggressive chemotherapy.[9]

Follicular Lymphoma

Follicular lymphoma (FL) is the most common subtype of non-Hodgkin lymphoma (NHL) in the United States and accounts for approximately 45% of all newly diagnosed cases. It has a peak incidence in the fifth and sixth decades and is rare younger than the age of 20 years, and both sexes are equally affected. Most patients have stage 3 or 4 disease at diagnosis with generalized lymphadenopathy and bone marrow involvement. Approximately 10% of patients have circulating malignant cells.

FL is composed of varying proportions of follicle center–type cells, centrocytes, and centroblasts, representing the proliferative component. According to the WHO classification, all low-grade FL are combined into a single category, grade 1/2—with an overall predominance of centrocytes and fewer than 15 centroblasts per high-power field (hpf). Grade 3 (with >15 centroblasts/hpf) is further subdivided into 3A and 3B, based on the presence or absence of background centrocytes. FL represents the neoplastic counterpart of the reactive germinal center cells; intraclonal heterogeneity with high numbers of somatic and ongoing Ig mutations can be detected in the neoplastic cells, as in the normal counterparts. Biologically, grade 3B is more closely related to diffuse large B-cell lymphoma (DLBCL) compared with FL.

The vast majority of FL (approximately 90%) is associated with a t(14;18) involving rearrangement of the *BCL2* gene. This translocation appears to result in constitutive expression of BCL2 protein, inhibiting apoptosis in lymphoid cells. The cells of FL accumulate and are at risk for secondary mutations, which may be associated with histologic progression. It is thought that the *BCL2* translocation occurs at a very early stage of B-cell development, during Ig gene rearrangement. Mutations in *BCL2* can lead to loss of BCL2 protein in the presence of the translocation; fluorescence in situ hybridization (FISH) studies for t(14;18) in these cases are informative. Grade 3B FL is less commonly associated with *BCL2* translocation and carries genetic aberrations more commonly seen in DLBCL. The neoplastic cells in FL have a mature B-cell phenotype with expression of the B-cell antigens (CD19, CD20, and CD22). Surface Ig is positive, most commonly with IgM expression, but IgG or IgA can also be seen in many cases. CD10 and BCL6 are positive, but CD5 is usually negative. Mutation analysis of FL has shown recurrent mutations in genes involved in epigenetic regulation and chromatin modification. Transformation of FL to DLBCL is a common event, and, although there is no unique mutation to predict transformation, genes commonly mutated include *TP53*, *EZH2*, *MYC*, *CCND3, MLL3*, and *CARD11*.[11]

FL is indolent but is still incurable with available therapeutic modalities. The occurrence of *BCL2* translocation at a very early stage of B-cell development might contribute to the difficulty in eradicating the neoplastic clone with chemotherapy. Clinical parameters have been used to develop prognostic indexes (e.g., the Follicular Lymphoma International Prognostic Index). Recently, much has also been learned about the mutational landscape of FL. Mutations in *CREBBP, MLL2*, and *EZH2* have been shown as extremely common early events and may be potential therapeutic targets.[12] The natural history of the disease is associated with histologic progression in cellular composition and pattern (Fig. 78.2).

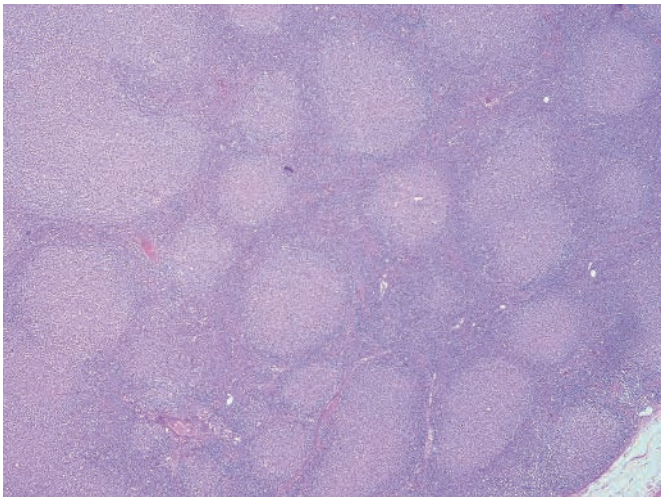

FIG. 78.2 Follicular Lymphoma. The neoplastic follicles are similar in size and are partially surrounded by lymphoid cuffs. In contrast to reactive germinal centers, they lack polarization and tingible body macrophages ("starry-sky pattern").

The 2008 WHO classification had recognized variants of FL: namely, *pediatric FL, GI tract FL*, and other *extranodal FL*. Pediatric-type FL (now a definite entity in the 2016 WHO classification) is more common in males and presents as localized nodal disease. It typically has an expansile serpiginous pattern, with relatively monotonous, medium-sized, blastoid cellular composition. *BCL2, BCL6*, and *MYC* rearrangements are lacking. Complete remissions may be obtained with either surgical excision or local radiation therapy. Some studies have raised the possibility that pediatric-type FL might be a "benign clonal proliferation with low malignant potential."[13,14] A recent study showed that pediatric-type FL had a low genetic complexity with frequent mutations in *TNFRSF14* and *MAP2K1*, the latter leading to ERK pathway activation. Of note, mutations commonly seen in adult FL such as *EZH2* and other histone-modifying genes were not seen or rare.[15]

The WHO classification recognizes "FL in situ" (now termed *in situ follicular neoplasia* [ISFN]) as a distinctive lesion. It should be distinguished from partial involvement of FL. ISFN shows involvement of germinal centers by CD10 and BCL2-positive cells carrying t(14;18) in an otherwise reactive lymph node, which is typically an incidental finding. Patients have a very low risk of progression, but ISFN may be detected in association with other forms of B-cell lymphoma, necessitating additional clinical assessment.[16] Fewer chromosomal abnormalities are noted in IFSN in comparison with partial or overt FL.[17] Patients lacking evidence of FL at staging have a low risk of developing the disease; this phenomenon appears to represent the tissue counterpart of circulating clonal B cells carrying t(14;18) as detected in healthy individuals. A higher level of circulating t(14;18)-positive lymphocytes ($>10^{-4}$ of total cells) indicates a higher risk for FL.

The 2016 WHO classification recognizes GI tract FL as duodenal-type FL because these can also be seen elsewhere in the GI tract and have features overlapping with ISFN and extranodal mucosa-associated lymphoid tissue (MALT) lymphoma.[17] These present as small mucosal polyps or nodules, and most cases are discovered incidentally on endoscopy. The lesions are usually low grade and have an indolent clinical course, and most

patients have been managed without therapy. Local recurrences in the intestine may occur but spread beyond the small intestine is rare.

Mucosa-Associated Lymphoid Tissue Lymphoma

Most lymphomas of marginal zone derivation present in extranodal sites and are part of the spectrum of MALT lymphomas. MALT lymphomas occur most frequently in the stomach, lung, thyroid gland, salivary gland, and lacrimal gland. Other less common sites of involvement include the orbit, breast, conjunctiva, bladder, kidney, and thymus. MALT lymphomas are characterized by a heterogeneous cellular composition, including centrocyte-like cells, monocytoid B cells, small lymphocytes, and plasma cells. In most cases, large transformed cells are uncommon, but reactive germinal centers are nearly always present. Historically, the distinction from reactive lesions has been problematic. Clonality can be established based on light-chain restriction or molecular studies. Follicular colonization by the neoplastic cells can simulate FL. The clinical course is usually quite indolent, but MALT lymphomas tend to relapse in other MALT-associated sites. MALT lymphomas of the salivary gland, thyroid gland, and mediastinum (thymus) are usually associated with a history of autoimmune diseases, predominantly Sjögren syndrome.

MALT lymphomas have several recurring cytogenetic abnormalities, including t(11;18)(q21;q21), t(1;14)(p22;q32), t(14;18)(q32;q21), t(3;14)(q27;q32), and t(3;14)(p14.1;q32); these abnormalities are observed with variable frequency, often depending on the anatomic site.[18] Although several genes are involved in these translocations, at least three of them—t(11;18), t(1;14), and t(14;18)—share a common pathway, leading to the activation of nuclear factor κB (NF-κB). By genome-wide DNA profiling integrated with GEP, differences were detected among the three main types of marginal zone lymphoma (MZL) (MALT, nodal and splenic), lending support to the current WHO classification that separates these three entities.[19] The translocation t(11;18)(q21;q21) is associated exclusively with low-grade extranodal MALT and is not detected in cases with concurrent low-grade and high-grade tumors, or in primary extranodal large-cell lymphomas—raising doubts whether these primary extranodal lymphomas are, in fact, related to low-grade MALT. The term *extranodal marginal zone lymphoma* of MALT type applies only to low-grade MALT; the term *high-grade MALT* should not be used for extranodal large B-cell lymphomas in a MALT site.

There is a strong association between chronic infection with *Helicobacter pylori* and gastric MALT lymphoma. Other infectious agents have been described in MALT lymphomas involving skin *(Borrelia burgdorferi)*, ocular adnexae *(Chlamydia psittaci)*, and the small intestine *(Campylobacter jejuni);* however, a causal relationship has not yet been demonstrated. Chronic antigenic stimulation is critical to both the development of MALT lymphoma and the maintenance of the neoplastic state. Indeed, in some cases lacking these genetic aberrations, eradication of *H. pylori* by antibiotic therapy has led to the spontaneous remission of gastric MALT lymphoma. MALT lymphomas are positive for B cell–associated antigens but are usually negative for CD5 and CD10. BCL6 and CD10 are helpful markers to identify residual reactive germinal-center cells, especially in cases of follicular colonization. The putative cell of origin of MZL is a post–germinal-center memory B cell.

Nodal Marginal Zone Lymphoma

Nodal marginal zone lymphoma (NMZL), a primary nodal disease, is phenotypically similar to other MZL, extranodal or splenic types. Adult patients often present with bone marrow involvement and tend to have a more aggressive clinical course than those with extranodal MALT. The neoplastic proliferation is mostly composed of small to medium-sized B cells, often with pale cytoplasm and the immunophenotype is $CD20^+$, $CD5^-$, $CD10^-$, with variable IgD expression. Plasmacytoid differentiation may be present, and, in lymph nodes, follicular colonization can be seen.

Splenic Marginal Zone Lymphoma

Splenic marginal zone lymphomas (SMZLs) present in adults and have a slight female gender predilection, usually with splenomegaly but without peripheral lymphadenopathy. Most patients have bone marrow involvement with modest lymphocytosis. Some evidence of plasmacytoid differentiation and the presence of a low-level M ptotein may also be seen. The course is reportedly indolent, and splenectomy may be followed by a prolonged remission.

Histologically, the spleen shows expansion of the white pulp with a characteristic biphasic pattern—central zone of small lymphocytes surrounded by a peripheral zone of larger cells resembling marginal zone cells while an intact mantle is not present. The abundant pale cytoplasm evident in tissue sections may also be seen in peripheral blood smears, and the cytologic features may be mistaken for those of hairy cell leukemia. The phenotype resembles other marginal zone B-cell lymphomas with a more frequent IgD expression.

CLINICAL PEARLS

Aggressive Lymphomas

- Natural history: survival measured in months.
- Successful therapy can be achieved with combination chemotherapy.
- Relapses from chemotherapy-induced remission may be cured with high-dose chemotherapy with hematopoietic support.
- In addition to the International Prognostic Index (IPI), gene expression profiling can be useful in predicting prognosis and survival of individual patients.

Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

DLBCL, not otherwise specified (DLBCL, NOS) is one of the more common subtypes of NHL, representing up to 40% of cases. This diagnosis is used for both primary DLBCL as well as for cases involving transformation from a low-grade lymphoma. It may be nodal or involve extranodal sites, including bone, skin, thyroid gland, GI tract, and lungs.

DLBCL, NOS is composed of large transformed lymphoid cells with nuclei at least twice the size of a small lymphocyte (Fig. 78.3). The nuclei generally have vesicular chromatin, prominent nucleoli, and basophilic cytoplasm—resembling either centroblasts or immunoblasts, albeit with an overall greater cellular pleomorphism.

In terms of morphology and phenotype, DLBCL is one of the most heterogeneous categories in the WHO classification; currently, several morphologic variants as well as specific subtypes are recognized.[2] There has been a great interest in identifying DLBCL features that might be prognostically relevant. To address

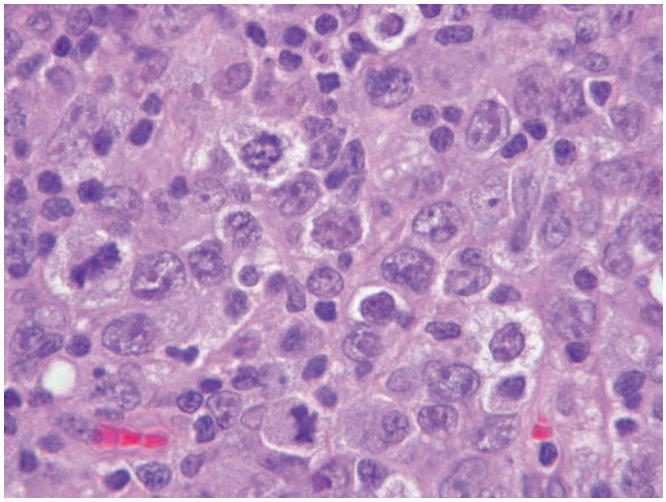

FIG. 78.3 Diffuse Large B-Cell Lymphoma. The neoplastic cells have large round to oval nuclei with vesicular chromatin and multiple eosinophilic nucleoli. Numerous mitoses are also present.

issues traditionally not resolved by morphologic or immunophenotypic features, DLBCL was among the first lymphomas to be analyzed by GEP. Based on the differential expression of a large set of genes by GEP, *germinal center B cell–like* (GCB) group and *activated B cell–like* (ABC) group have been identified,[20] in addition to the previously recognized *primary mediastinal (thymic) large B-cell lymphoma* (PMBCL). GCB DLBCLs express a set of genes that are associated with normal germinal center B cells, whereas ABC DLBCLs show downregulation of these genes and share similarities with post–germinal center B cells.

The t(14;18) translocation involving *BCL2* and Ig heavy-chain gene has been detected in the GCB subtype but not in the other subtypes. Previous studies have shown reduced disease-free survival in DLBCL cases with BCL2 overexpression, irrespective of the translocation. Although no absolute correlation between morphology and GEP has been established, the majority of DLBCLs with centroblastic morphology fall into the GCB subtype, whereas those with immunoblastic morphology usually correlate with the ABC subtype.

DLBCL has an aggressive natural history but generally responds well to chemotherapy. The complete remission rate with modern regimens is 75% to 80%. Currently, with R-CHOP (rituximab–cyclophosphamide, doxorubicin, vincristine, and prednisone) regimen, the 10-year progression-free and overall survival rates for older patients with advanced-stage DLBCL are 36.5% and 43.5%, respectively.[21]

Immunophenotype-based algorithms using CD10/BCL6 positivity for GCB and MUM1/IRF4 expression for the ABC subtype have been proposed as surrogates for GEP; in addition, BCL2 and IPI are also informative to stratify the DLBCL cases. ABC DLBCLs show constitutively activated NF-κB and mutations in the B-cell receptor (BCR) signaling pathway with poorer overall survival when compared with GCB DLBCL using R-CHOP. The addition of BTK inhibitors has improved the survival in those with ABC DLBCL since these drugs target the BCR signaling pathway. Because of the therapeutic impact, it has been recommended that these two subtypes be identified, on the basis of either immunophenotype-based algorithms or GEP.

T-cell/histiocyte–rich large B-cell lymphoma (THRLBCL) is a distinct clinicopathologic entity, rather than a morphologic variant. THRLBCL tends to occur in younger patients compared with other DLBCL, NOS, and often presents with advanced stage and bone marrow involvement with an aggressive clinical behavior.

The WHO classification recognizes that lymphomas arising from certain anatomic sites may have distinctive clinical and biologic features. Among these are *primary DLBCL of the central nervous system* (CNS) and *primary cutaneous DLBCL, leg type*. Primary DLBCL of the CNS with some distinctive GEP features shares some similarities with DLBCL arising in other immune-privileged sites, such as the testis. These lymphomas typically show biallelic *CDKN2A* loss and *MYD88* mutations and have frequent copy number gains in 9p24.1 *(PD-L1* and *PD-L2)* contributing to immune evasion of the tumor cells.[22] Primary cutaneous DLBCL, leg type, has a GEP resembling the ABC subtype of DLBCL, presents most often in older females, and generally has an aggressive clinical course.

A recently described provisional entity usually manifests a follicular growth pattern but may have diffuse areas. This lesion, termed *large B-cell lymphoma with IRF4 rearrangement* is common in children or young adults, typically involves the Waldeyer ring and/or the cervical lymph nodes. These cases show strong IRF4/MUM1 expression, usually with BCL6 and a high proliferative fraction, and are considered more aggressive than other pediatric-type FL; however, when treated, they show good response.[23,24]

Primary Mediastinal Large B-Cell Lymphoma

PMBCL has a distinct constellation of clinical and morphologic features. PMBCL shows marked female predominance in adolescents and young adults. It presents with a rapidly growing anterior mediastinal mass with frequent superior vena cava syndrome and/or airway obstruction. Nodal involvement is uncommon at presentation and at relapse. Frequent extranodal sites of involvement, particularly at relapse, include the liver, kidneys, adrenal glands, ovaries, the GI tract, and the CNS. The treatment approach includes aggressive systemic chemotherapy plus rituximab, along with radiation therapy used in some centers. A relatively abundant pale cytoplasm with distinct cytoplasmic membrane and fine compartmentalizing sclerosis are characteristic. The tumor appears to be derived from medullary B cells within the thymus gland. These cells express CD20 and CD79a but not surface Ig. CD23 is frequently positive, and MUM-1/IRF4 coexpression is also common. A unique signature was identified by GEP in PMBCL that shared similarities with Hodgkin lymphoma (HL) cell lines, including constitutive activation of the NF-κB and recurrent gains and amplification of c-Rel.[25]

The 2008 WHO classification included borderline categories, one of which manifests features intermediate between DLBCL, especially PMBCL and classic Hodgkin lymphoma (CHL) "gray zone lymphomas."[26] A close relationship between PMBCL and CHL has been supported by GEP.[25]

Gray zone lymphomas are more common in males than females, present with bulky mediastinal masses, and appear to have a more aggressive clinical course compared with either PMBCL or CHL. Previously, methylation profiling showed a signature distinct from both CHL and PMBCL.[27] GEP of gray zone lymphomas in comparison with CHL and PMBCL shows that they are distinct from the other entities with downregulation of the B-cell program and higher NF-κB as compared with PMBCL.[28] However, as shown by FISH studies, gray zone lymphomas, PMBCL, and CHL all share a number of common cytogenetic aberrations, including gains at 2p16.1 (*REL/BCL11A*

locus), 9p24.1 *(JAK2/PDL2)*, and rearrangements of 16p13.13 *(CIITA)*. DA-EPOCH R has been effective in both PMBL and DLBCL; however, the therapeutic approach is not clear, although combined modality therapy appears to be beneficial.[29]

Virally Associated B-Cell Lymphoproliferative Disorders

Epstein-Barr virus (EBV)-positive B-cell lymphoproliferations show a range in cytologic features and clinical behavior. In the revised WHO 2016 classification, *EBV-positive DLBCL, NOS*[3] has now replaced a previous provisional entity "*EBV-positive DLBCL of the elderly*" in the 2008 WHO classification because it may occur in younger patients with a broader morphologic spectrum and better survival[30,31] as a consequence of decreased immune surveillance. In this entity, both nodal and extranodal sites may be involved. Large transformed neoplastic cells often show immunoblast and/or Hodgkin/Reed-Sternberg (HRS)-like cell features, in a background consisting of interspersed small lymphocytes, histiocytes, and epithelioid cells. In other cases, a monomorphic pattern is present. (Fig. 78.4)

These should be distinguished from EBV-associated atypical hyperplasia and lesions associated with iatrogenic or age-related immunosuppression, as well as those typified by an isolated and circumscribed cutaneous or mucosal presentation, with an indolent behavior and a self-limiting clinical course as *EBV-positive mucocutaneous ulcer* (new provisional entity).[32] Lesions are most common in the oral mucosa, skin, and GI tract. Ulcerated surfaces have an underlying polymorphic infiltrate with large transformed cells resembling immunoblasts and HRS-like cells (Fig. 78.5). Patients rarely present with lymphadenopathy or systemic symptoms.

Lymphomatoid granulomatosis is an EBV-positive B-cell lymphoproliferative disorder (LPD) associated with an inflammatory background rich in T cells. The lung is nearly always involved; in addition, skin, kidneys, the liver, and the brain are frequently affected.[33] *DLBCL associated with chronic inflammation* are EBV-driven large B-cell proliferations encountered in diverse clinical settings, usually associated with a confined anatomical space and a background of chronic inflammation. These cases appear to have a good prognosis if successfully resected.

Human herpes virus-8/Kaposi sarcoma herpes virus (HHV-8/KSHV)-associated LPDs are also documented. These include *primary effusion lymphoma* (PEL), *multicentric Castleman disease* (MCD), and lymphomas arising in the context of MCD. The cells of PEL are usually coinfected with EBV, and the disease is most often diagnosed in the setting of human immunodeficiency virus (HIV) infection and immunosuppression. Although pleural or peritoneal effusions are most common, extracavitary PEL can present as a tumor mass, usually in extranodal sites. PEL has a phenotype resembling terminally differentiated B cells (*i.e.*, plasmablastic).

Two other lymphomas with a plasmablastic phenotype are *plasmablastic lymphoma* (PBL) and *anaplastic lymphoma kinase (ALK)-positive large B-cell lymphoma*. PBL is usually positive for EBV, most often extranodal, and is associated with immunosuppression from either HIV infection or advanced age. Recent studies have identified a high incidence of *MYC* translocation in PBL.[34] ALK-positive large B-cell lymphomas show overexpression of ALK, usually as a consequence of translocation. They mainly affect older individuals but can occur at any age.

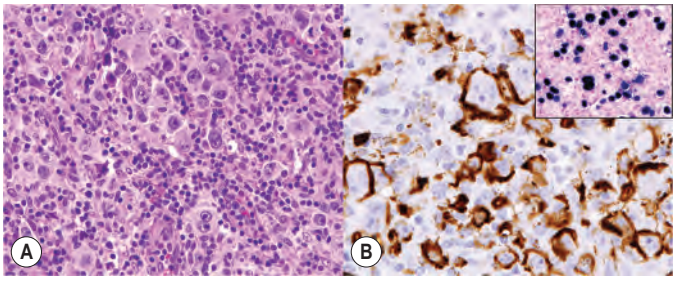

FIG. 78.4 Epstein-Barr virus (EBV)-positive diffuse large B-cell lymphoma, NOS. (A) There is a polymorphous population with scattered large atypical cells. (B) The large cells are positive for CD20 (variable) and EBV by in situ hybridization with EBER (*inset*).

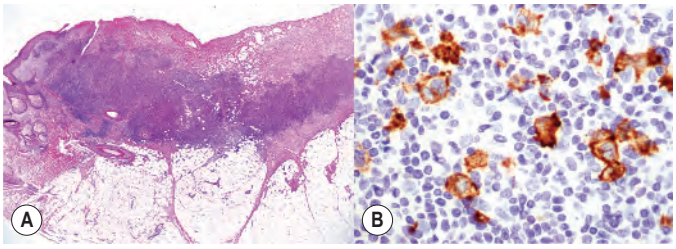

FIG. 78.5 Mucocutaneous Ulcer. (A) Low-power magnification shows an ulcerated surface with a dense lymphoid infiltrate underneath. (B) Higher magnification shows a dense polymorphic infiltrate with histiocytes and large atypical cells resembling immunoblasts and Hodgkin/Reed-Sternberg–like cells that are positive for CD30.

CLINICAL PEARLS

Highly Aggressive Lymphomas

- More common in children
- Natural history similar to acute leukemia
- Successful treatment includes high-dose chemotherapy (induction, consolidation, and maintenance phases) with central nervous system prophylaxis

Burkitt Lymphoma

Burkitt lymphoma (BL) occurs most commonly in children and accounts for up to one-third of all pediatric lymphomas in the United States. Three clinical variants of BL are recognized—endemic, sporadic, and immunodeficiency associated. The endemic cases are seen in equatorial Africa (African BL) in malaria-endemic regions and mostly involve the jaw and other facial structures. In non–malaria-endemic regions, such as the United States, extranodal sites are frequent, including the ileocecal region, ovaries, kidneys, or breasts. Bone marrow involvement is a poor prognostic feature.

EBV has been shown to be a cofactor for the development of BL and shows varying degrees of positivity in the variant subtypes. BL is one of the more common tumors associated with HIV. It can present at any time during the clinical course, including the initial acquired immunodeficiency syndrome (AIDS)-defining illness. GEP data have supported a common pathogenetic mechanism in cases of HIV infection and endemic malaria–related immunosuppression.

Cytologically, BL shows monomorphic medium-sized cells with round nuclei, multiple (2 to 5) basophilic nucleoli, and moderately abundant deeply basophilic cytoplasm. Cytoplasmic lipid vacuoles reflecting a high proliferation rate and apoptosis are frequent. It is the most rapidly growing of all lymphomas, with 100% of the cells in cell cycle at any time. The characteristic

"starry sky" pattern of BL is a manifestation of the numerous benign macrophages that have ingested karyorrhectic or apoptotic tumor cells. BL has a mature B-cell phenotype, expressing CD19, CD20, CD22, CD79a, and monoclonal surface Ig that is nearly always IgM. CD10 is positive in almost all cases, whereas CD5, CD23, and BCL2 are consistently absent.

The pathogenesis of BL is related to the *MYC* oncogene translocations seen in virtually 100% of cases. The *MYC* translocation is considered a primary event and often is the sole karyotypic abnormality detected. This is in contrast to other aggressive lymphomas, in which the *MYC* translocation occurs as a secondary event in a more complex karyotype.[35] Most of the translocations involve the *IGH* gene on chromosome 14 and, less commonly, the light-chain genes on chromosomes 2 and 22. Mutations in the transcription factor *TCF3* or its negative regulator *ID3* are present in approximately 70% of sporadic and immunodeficiency-related BL and 40% of endemic cases.

A subset with chromosome 11q alterations has a new provisional entity "*Burkitt-like lymphoma with 11q aberration*" in the revised classification. The malignant cells resemble BL morphologically, largely phenotypically, and by GEP, but lack *MYC* translocations.[36]

High-Grade B-Cell Lymphoma With *MYC* and *BCL2* and/or *BCL6* Rearrangements

This category attempts to unify aggressive lymphomas carrying rearrangements of *MYC*, as well as *BCL2* or *BCL6*, so-called double- or triple-hit lymphoma.[2] These cases can resemble DLBCL, NOS or have features intermediate between DLBCL and BL (Fig. 78.6). Cases of FL and B lymphoblastic lymphoma that have these rearrangements should be excluded. A less well-defined group is high-grade B-cell lymphoma, NOS. Some of these cases have blastoid morphology, but unifying features are lacking.

T-CELL AND NK-CELL NEOPLASMS

Overview of the Classification of T-Cell Neoplasms

*Peripheral T-cell lymphoma*s (PTCLs) are uncommon, representing fewer than 10% of all NHLs. The classification of PTCL has always been controversial. The genetic landscape of many entities has only recently been defined, and immunophenotypic markers are less specific for apparently distinct disease entities. For these reasons, the WHO classification relied, to a considerable extent, on clinical presentation to subdivide these tumors.[2]

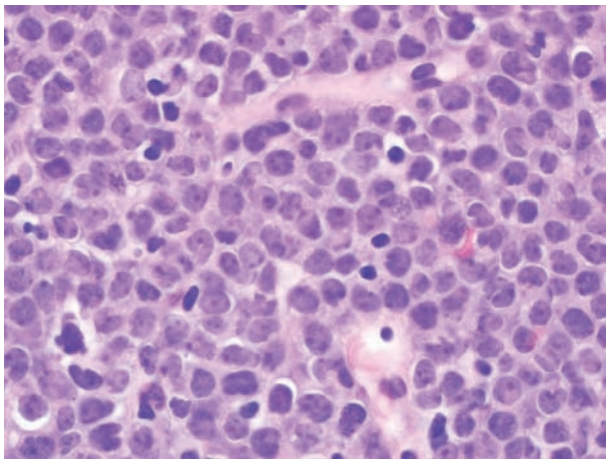

FIG. 78.6 Triple-Hit Lymphoma. A case of high grade B-cell lymphoma with *MYC, BCL2,* and *BCL6* translocations. The tumor cells are monotonous and medium in size with dispersed chromatin and small nucleoli.

Extranodal Natural Killer/T-Cell Lymphoma, Nasal Type

Extranodal NK/T-cell lymphoma, nasal type, is a distinct clinicopathologic entity highly associated with EBV. It affects adults (median age 50 years), and the most common clinical presentation is a destructive nasal or midline facial lesion. Palatal destruction, orbital swelling, and edema can be prominent. NK/T-cell lymphomas have been reported in other extranodal sites, including skin, soft tissue, testes, the upper respiratory tract, and the GI tract. It is much more common in Asians and indigenous populations of the Americas than in those of European background, and this indicates that genetic factors play a role in the pathogenesis of these lymphomas.

Extranodal NK/T-cell lymphoma, nasal type, is characterized by a broad cytologic spectrum. Although the cells express some T cell–associated antigens, most commonly CD2, other T-cell markers, such as surface CD3, are usually absent. Cytoplasmic CD3 is positive, but most cases lack clonal T-cell gene rearrangement. In favor of an NK-cell origin, the cells are nearly always CD56 positive, although CD16 and CD57 are usually negative. EBV is invariably positive as shown by in situ hybridization.

The clinical features and treatment response of non–nasal-type extranodal NK/T-cell lymphoma are different from of those of nasal presentation of this lymphoma in that the addition of radiotherapy in early-stage nasal cases may offer a survival benefit.[37] A hemophagocytic syndrome is a common clinical complication and adversely affects survival. Emerging oncogenic pathways have been identified by GEP.

There are other EBV$^+$ T-cell and NK-cell proliferations seen mainly in Asian children and in indigenous populations from Central and South Americas and Mexico. These show a broad range of clinical manifestations from indolent, localized forms involving skin, such as *hydroa vacciniforme-like lymphoproliferative disorder* (name changed from lymphoma) and *mosquito bite allergy*, the latter usually being derived from NK cells, to *systemic EBV$^+$ T-cell lymphoma* (name changed from lymphoproliferative disease),[3] which is a more systemic form characterized by fever, hepatosplenomegaly and lymphadenopathy with or without cutaneous manifestations[38] and a fulminant clinical course, and hemophagocytic lymphohistiocytosis (HLH). The neoplastic cells are usually positive for CD2, CD3, CD8, TIA-1, and Epstein-Barr virus-encoded small RNA (EBER) and negative for CD56 and most commonly infiltrate the liver, spleen, skin, lung, and lymph nodes (Fig. 78.7).

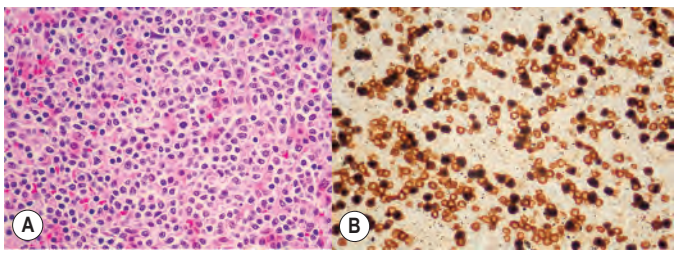

FIG. 78.7 Systemic Epstein-Barr Virus–Positive T-Cell Lymphoma of Childhood. (A) Spleen infiltration by cytologically atypical T cells that are (B) positive for CD3 and EBER-ISH double-staining.

Nodal T-Cell Lymphoma With T_{FH} Phenotype: Angioimmunoblastic T-Cell Lymphoma

Recently angioimmunoblastic T-cell lymphoma (AITL) has been grouped under an umbrella category "nodal T-cell lymphoma with T follicular helper cell (T_{FH}) phenotype" to highlight a spectrum of nodal lymphomas with T_{FH} phenotype, including follicular T-cell lymphoma and other nodal PTCLs with a T_{FH} phenotype, in addition to AITL.[3]

AITL presents in adults with generalized lymphadenopathy and prominent systemic symptoms, including fever, weight loss, and skin rash. Polyclonal hypergammaglobulinemia is usually seen.

Histologically, the nodal architecture is generally effaced, but peripheral sinuses are often open or dilated. Proliferation of high endothelial venules (HEVs) is often prominent. Follicles are regressed, but a proliferation of dendritic cells (DCs) often abutting HEVs is typically seen. The atypical lymphoid cells have clear cytoplasm and are admixed with small lymphocytes, immunoblasts, plasma cells, and histiocytes, with or without eosinophils. A relationship to T_{FH} has been confirmed by GEP. The atypical T cells are usually positive for CD4, CD10, CXCL-13, and PD-1, a phenotype characteristic of T_{FH}. In keeping with an established derivation from T_{FH}, B-cell proliferation, including marked polyclonal plasmacytosis, is often seen. In some cases, the plasma cells may be monoclonal. Background EBV^+ B cells are almost constant, and progression to EBV^+ B-cell lymphoma may occur. The exact role of EBV in AILT is uncertain; however, plausible theories include expansion resulting from decreased immune surveillance. The majority of cases shows clonal rearrangements of T-cell receptor (TCR) genes. Patients may initially respond to steroids or mild cytotoxic chemotherapy, but progression usually occurs. More aggressive combination chemotherapeutic regimens have led to a higher remission rate, but patients are prone to secondary infectious complications. The median survival is usually less than 5 years. Recurrent mutations include epigenetic modifiers *TET2, IDH2, DNMT3A*, and *RHOA*. Moreover, fusion genes encoding a CTLA4-CD28 and *ITK-SYK* have been reported in a significant proportion of PTCL, NOS cases with a T_{FH} phenotype including AITL.

Peripheral T-Cell Lymphoma, Not Otherwise Specified

PTCL, not otherwise specified (PTCL, NOS) is a diagnosis of exclusion with most cases being nodal in origin. PTCLs are characterized by cytologic and phenotypical heterogeneity. Cases have a mature T-cell phenotype and express one of the major subset antigens, with CD4 expression seen more frequently than CD8. These are not clonal markers, and antigen expression can change over time. Loss of one of the pan-T-cell antigens (CD3, CD5, CD2, or CD7) is seen in two-thirds of cases, with loss of CD7 being most frequent.

Recently, GEP has shown a global signature close to one of activated T lymphocytes and has identified at least three subtypes characterized by overexpression of *GATA3, TBX21*, and cytotoxic genes associated with differences in clinical behavior and response to therapy. The clinical course is generally aggressive, especially with a high proliferation signature and a lower response rate than that seen for aggressive B-cell lymphomas. A recent study investigating genomic copy number changes revealed that loss or mutation of genes in the *CDKN2A/B-TP53* and PTEN-PI3K pathways are a feature of *GATA3* expressing PTCL-NOS while co-occurring gains/amplifications of *STAT3* and *MYC* also occur in this subgroup. On the other hand, PTCL-NOS expressing *TBX21* showed mutations of genes regulating DNA methylation.[39,40]

Anaplastic Large-Cell Lymphoma

Anaplastic large-cell lymphoma (ALCL) is most common in children and young adults, with male predominance. Nodal presentations are most common; however, a variety of extranodal sites can be involved.

ALCL is characterized by pleomorphic or monomorphic cells that have a propensity to invade lymphoid sinuses. The cells of classic ALCL have large, often lobulated nuclei with small basophilic nucleoli. In some cases, the nuclei may be round. The cytoplasm is usually abundant and amphophilic and has distinct cytoplasmic borders, with a prominent Golgi region. The expression of the CD30 antigen is a hallmark of this disease (Fig. 78.8). However, CD30 expression is not specific for ALCL and may also be seen in other forms of malignant lymphoma, including CHL. ALCL-ALK^+ is associated with a characteristic chromosomal translocation, t(2;5)(p23;q35), involving the *ALK* and *NPM* genes, respectively. A variety of other *ALK* partners has been identified, and monoclonal antibodies to the ALK protein have been able to identify tumor cells regardless of the underlying translocation. Staining of both the nucleus and cytoplasm is found in cases with the classic *NPM:ALK*; cases with variant translocations show only cytoplasmic staining.

Immunohistochemistry is indispensable in the correct diagnosis of ALCL. The prominent Golgi region usually shows intense staining for CD30 and epithelial membrane antigen (EMA). The cells exhibit an aberrant phenotype with loss of many T cell–associated antigens. Both CD3 and CD45RO, the most widely used pan-T-cell markers, are negative in greater than 50% of cases, while CD2 and CD4 are positive in the majority, whereas CD8 is usually negative. ALCL cells, despite the $CD4^+/CD8^-$ phenotype, often express the cytotoxic-associated antigens TIA-1, granzyme B, and perforin. In addition, clusterin is generally present in ALCL and represents another useful diagnostic marker. Molecular studies in most cases demonstrate TCR rearrangement, confirming a T-cell origin.

Improved criteria now exist for the recognition of ALK-negative ALCL as a separate entity. It occurs in an older age group compared with the ALK-positive cases. Recently, a unique form of ALK-negative ALCL arising in association with breast implants has been identified[41] with a median interval from time of implant to lymphoma of approximately 10 years. Confinement of the neoplastic cells to the seroma fluid without capsule invasion portends a favorable prognosis.

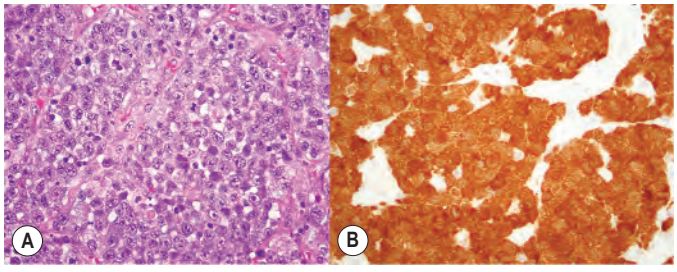

FIG. 78.8 Anaplastic Large-Cell Lymphoma, ALK-Positive. (A) The cells have large, lobulated nuclei with small basophilic nucleoli. The cytoplasm is usually abundant and amphophilic and has distinct cytoplasmic borders, and a prominent Golgi region is generally present. (B) ALK-1 expression is a hallmark of this disease.

GEP studies have shown that ALK-negative ALCLs have a signature close to that of ALK-positive counterparts but distinct from other NK/T-cell lymphomas. Genetic studies have shown convergent mutations and kinase fusions leading to constitutive activation of the JAK/STAT3 pathway. The overall survival and disease-free survival are significantly better in ALK-positive cases than in ALK-negative cases. Clinical or prognostic variations exist in ALK-negative ALCLs—a subset with rearrangements at the *DUSP22* and *IFR4* locus on 6p25 has a superior prognosis, whereas a small subset with *TP63* rearrangements is very aggressive.[42] Loss of *PRDM1 (BLIMP1)* and/or *TP53* has also been associated with poor outcome.

Primary Cutaneous Anaplastic Large-Cell Lymphoma

Primary cutaneous ALCL (pcALCL) is closely related to lymphomatoid papulosis (LyP) and differs at the clinical, immunophenotypic, and molecular levels from the systemic form. Indeed, LyP and cutaneous ALCL represent a histologic or clinical continuum of $CD30^+$ cutaneous lymphoproliferative diseases. Small lesions are likely to regress, whereas patients with large tumor masses may develop disseminated disease with lymph node involvement—a period of observation is usually warranted before the institution of any chemotherapy for isolated lesions. Most patients with primary cutaneous ALCL have multiple skin lesions, but it is a more indolent disease compared with other T-cell lymphomas of the skin. Cutaneous ALCL is $CD30^+$ but is usually ALK and EMA negative and also lacks the t(2;5) translocation. Most cases of pcALCL have clonally rearranged TCR genes and approximately 28% of cases harbor translocations involving *DUSP22*.

LyP is characterized by a chronic course of recurrent, self-healing papulonecrotic or nodular skin lesions. The histologic picture of LyP is variable and may resemble different types of CD30-positive CTCLs. Appreciation of these variants is important as they can mimic aggressive T-cell lymphoma histologically but clinically are similar to other forms of LyP.

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma (SPTCL) usually presents with subcutaneous nodules primarily affecting the extremities. In some cases, the infiltrate may appear deceptively benign, mimicking lobular panniculitis. The neoplastic cells are CD8 cytotoxic α/β T cells (perforin, granzyme B, and TIA-1 positive), while EBV is negative. Some PTCL of γ/δ T-cell derivation may show similar features but differ from SPTCL in their clinical behavior (more aggressive) and histologic pattern because they are often not confined to the subcutis. Some patients have a history of autoimmune disease, and, in particular, the differential diagnosis of SPTCL with lupus profundus panniculitis can be challenging. Unlike SPTCL, lupus panniculitis usually contains abundant plasma cells, a mixture of CD4 and CD8 cells, and a relative increase of γ/δ T cells and plasmacytoid DCs.

A loss-of-function germline mutation altering TIM-3 was identified in up to 60% of SPTCL, and this TIM-3 deficiency leads to uncontrolled immune activation.[43] Patients present with fever, pancytopenia, hepatosplenomegaly, and HLH. HLH is most readily diagnosed in bone marrow aspirate smears, where histiocytes containing erythrocytes, platelets, and other blood elements may be observed.

Primary Cutaneous γ/δ T-Cell Lymphoma

Primary cutaneous γ/δ T-cell lymphomas are clinically aggressive tumors that can present with involvement of the subcutis and the dermis with or without epidermal infiltration. A hemophagocytic syndrome may be seen and is more common than in SPTCL. Skin is the most common presenting site; however, similar lymphomas of γ/δ T-cell origin can present in other extranodal sites, including the GI tract and lungs. The cells have a cytotoxic phenotype and express cytotoxic molecules and, like normal γ/δ T cells, lack CD5. CD8 may be positive but more often is negative (in which case the T cells are negative for both CD4 and CD8) (Fig. 78.9) while most cases express CD56. Few cutaneous T-cell lymphomas appear to be TCR silent (negative for both TCR-β and TCR-γ) but share the same aggressive clinical behavior.

Mycosis Fungoides and Sézary Syndrome

Mycosis fungoides (MF) and Sézary syndrome (SS) are closely related and often considered together from a clinical and biologic standpoint but are now regarded as separate diseases. Both are primary cutaneous T-cell malignancies derived from mature skin homing CD4 T cells. Epidermotropism is the hallmark of MF; infiltration of the epidermis produces characteristic Pautrier microabscesses. The cutaneous lesions are categorized as patches, plaques, and tumors, based on the extent of the infiltrate, and, clinically, SS is more aggressive than MF. A γ/δ indolent variant of MF has also been described. SS presents with exfoliative erythroderma and circulating cerebriform lymphocytes known as *Sézary cells*.

Intestinal T-cell Lymphoma

Enteropathy-associated T-cell lymphoma (EATL) is highly associated with celiac disease on a worldwide basis. This disease occurs in adults; the majority has either overt or clinically silent gluten-sensitive enteropathy (Chapter 75). Ulcerative jejunitis may precede the development of overt EATL and may share a common clonal T-cell population as with the subsequent lymphoma. The small bowel usually shows ulceration with frequent perforation, which may or may not be accompanied by a mass. EATL shows a cytologic composition of variably sized or polymorphic atypical lymphoid cells. The adjacent small bowel usually shows villous atrophy associated with celiac disease. The neoplastic cells are $CD3^+$, $CD7^+$ T cells that also express the homing receptor CD103. Anaplastic cells strongly positive for CD30 can be present. The cells express cytotoxic molecules, a feature shared by nearly all extranodal T-cell lymphomas. The majority belong to the α/β TCR subset, whereas only a minority expresses the γ/δ TCR. Other PTCLs can present with intestinal disease, including EBV^+ extranodal T/NK-cell lymphomas and γ/δ T-cell lymphomas, and should be distinguished from EATL. The clinical course of EATL is aggressive.

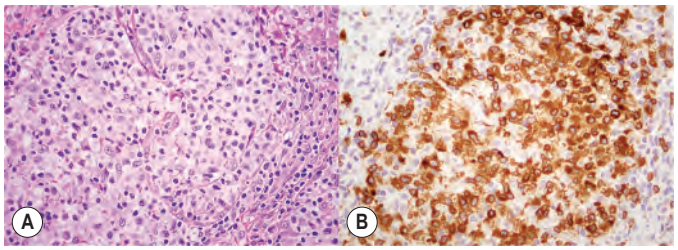

FIG. 78.9 Primary Cutaneous γ/δ T-Cell Lymphoma. (A) The lesions usually involve the dermal and subcutaneous tissue and are composed of atypical cells with irregular nuclear contours. (B) They have a γ/δ phenotype highlighted by the T-cell receptor δ immunostain.

The disease previously known as *EATL type II* has been now been formally designated as *monomorphic epitheliotropic intestinal T-cell lymphoma* (MEITL); it shows no association with celiac disease and therefore is the form most often seen in Asian and Hispanic populations. Unlike classic EATL, MEITL is monomorphic, usually positive for CD8, CD56, and MATK (Fig. 78.10). *STAT5B* and *SETD2* mutations are common in MEITL cases, many of which are of γ/δ T-cell origin.[44]

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma (HSTCL) shows a marked male gender predominance, and most patients are young adults. The clinical presentation is that of marked hepatosplenomegaly in the absence of lymphadenopathy.

The liver and the spleen show marked sinusoidal infiltration, with sparing of both portal triads and white pulp, respectively. The homing pattern manifested by the malignant cells is similar to that of normal γ/δ T cells, which also populate the sinusoidal areas of the spleen. The neoplastic cells have a phenotype that resembles normal γ/δ T cells, usually expressing neither CD4 nor CD8 while CD56 is often positive. The cells are positive for the cytotoxic protein TIA-1 but are not activated and generally lack granzyme B and perforin. In situ hybridization for EBV is negative. The recognition of the atypical cells in bone marrow is greatly aided by immunohistochemical stains for CD3 showing a sinusoidal pattern of infiltration.

Isochromosome 7 is a consistent cytogenetic abnormality, usually seen in conjunction with trisomy 8. Rare cases derived from α/β T cells but with similar morphologic and biologic features can be seen. Recurrent mutations of *STAT5B*, and less often, *STAT3* and *PIK3CD*, are seen in HSTCL of γ/δ origin.[45] Clinically, HSTCL is aggressive, and, although patients may respond initially to chemotherapy, relapse occurs frequently. The median survival is less than 3 years. Allogeneic bone marrow transplantation is required for sustained remission.

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATLL) is a distinct form of T-cell lymphoma associated with the retrovirus human T-lymphotropic virus-1 (HTLV-1). The highest number of cases is seen in southwestern Japan and the Caribbean basin. The disease has a long latency, and affected individuals are usually exposed to the virus very early in life. The virus may be transmitted in breast milk and through exposure to blood or blood products. The cumulative incidence of ATLL is estimated to be 2.5% among HTLV-1 carriers. The virus is clonally integrated into tumor DNA. Different clinical variants of ATLL, including the acute, lymphomatous, chronic, and smoldering types, have been recognized. Cutaneous involvement is seen in the majority of patients.

Peripheral blood involvement is very common, often without bone marrow disease. The atypical cells are often markedly polylobated and have been referred to as "flower" cells. The cells have a characteristic phenotype that resembles T regulatory cells (Tregs)—$CD3^+$, $CD4^+$, and $CD25^+$—but FOXP3 is expressed only in a minority of tumor cells. The function of the tumor cells as Tregs may correlate with the associated immunodeficiency.

Somatic gain of function *CCR4* mutations have been implicated in the pathogenesis of ATLL.[46]

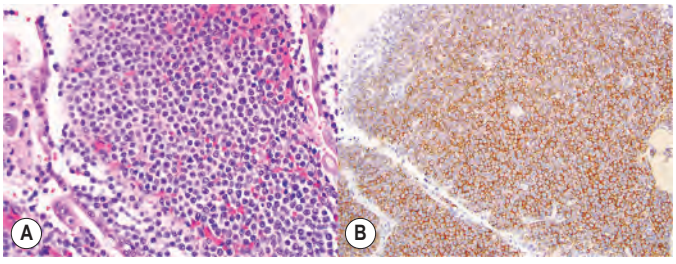

FIG. 78.10 Monomorphic Epitheliotropic Intestinal T-Cell Lymphoma. (A) Monomorphic population of medium-sized cells in the submucosa of the intestine with dispersed chromatin and indistinct nucleoli. (B) The cells are positive with CD56.

CLINICAL PEARLS

Hodgkin Lymphoma

- B-cell lineage established in nearly all cases
- Reed-Sternberg cell, the hallmark of the disease, represents a "crippled" germinal center B cell
- Nodular lymphocyte-predominant Hodgkin lymphoma considered a related but distinct entity
- Eighty percent of patients are curable with current therapy
- Stage of disease guides the choice of therapy; even patients with advanced-stage disease may be cured
- Late complications from treatment include acute leukemia (associated with alkylating agents with extended-field radiation therapy), second solid tumors (radiation therapy), and premature atherosclerotic coronary artery disease (radiation therapy)
- Cause of death in the first 5–10 years is mainly Hodgkin lymphoma; after 10 years, mainly secondary malignant tumors

HODGKIN LYMPHOMAS

HL and NHL have long been regarded as distinct disease entities on the basis of their differences in pathology, phenotype, clinical features, and response to therapy. It is now accepted that the malignant cell of HL is an altered B cell. Thus the current preferred term is *Hodgkin lymphoma*, rather than *Hodgkin disease*, reflecting current knowledge regarding the nature of the cell of origin. Despite the close histogenetic relationship with NHL, these disorders are still treated with different modalities.

Classic Hodgkin Lymphoma

The diagnosis of CHL depends on the identification of HRS cells in an appropriate inflammatory background composed of small T lymphocytes, plasma cells, histiocytes, and granulocytes (often eosinophils). All cases of CHL share certain immunophenotypic and genotypic features. The phenotype is $CD30^+$, $CD15^{+/-}$, $CD45^-$, and EMA^-. Expression of B cell–associated antigens is seen in up to 75% of cases; however, when present, CD20 staining is usually weaker or more variable than that seen in normal B cells, and PAX5 is dimly expressed. Ig and TCR genes are usually germline because of the paucity of tumor cells in the inflammatory background; however, microdissection can enable amplification for clonal rearrangement of the Ig genes by polymerase chain reaction (PCR). In addition, the presence of somatic mutations indicates transit through the germinal center.

Classic Hodgkin Lymphoma, Nodular Sclerosis

This variant of HL, classic Hodgkin lymphoma, nodular sclerosis (CHLNS) is most commonly seen in adolescents and young adults but can occur at any age. It is more common in females

than males, the mediastinum is commonly involved, and stage and bulk of disease have prognostic importance.

The tumor has at least a partially nodular pattern, with fibrous bands separating the nodules in most cases. The characteristic cell is the "lacunar-type" Reed-Sternberg (RS) cell, which may be very numerous. Classic RS cells are usually also present. The background contains lymphocytes, histiocytes, plasma cells, eosinophils, and neutrophils. Grading (I and II) is based on the proportion of the tumor cells and the presence of necrosis but is considered optional. The immunophenotype and genotype are characteristic of CHL. However, EBV is infrequently positive, seen in less than 15% of cases.

CHLNS is often curable; however, in long-term survivors, the risk of secondary malignancies is increased, especially in those receiving both chemotherapy and radiation. CHLNS of the mediastinum is thought to be closely related to PMBCL, and both types of tumors can be seen in the same patient, either as composite malignancy or sequentially.

Classic Hodgkin Lymphoma, Mixed Cellularity

Classic Hodgkin lymphoma, mixed cellularity (CHLMC) is predominantly seen in male adults. A bimodal age distribution, with peaks in young children and later in older adults can be present. Both CHLMC and the lymphocyte-depleted form (see later) can be associated with underlying HIV infection. The infiltrate is diffuse without band-forming sclerosis, although fine interstitial fibrosis may be present (Fig. 78.11). HRS cells are of the classic type. It is often EBV positive, seen in up to 75% of cases. The stage is often advanced at diagnosis. The clinical course is moderately aggressive but is often curable.

Classic Hodgkin Lymphoma, Lymphocyte Depletion

Classic Hodgkin lymphoma, lymphocyte depletion (CHLLD) is the least common variant of CHL and is most common in older people, in HIV-positive individuals, and in populations of nonindustrialized countries. It frequently presents with abdominal lymphadenopathy, and spleen, liver, and bone marrow involvement but without peripheral adenopathy. The infiltrate is diffuse and often appears hypocellular because of the presence of diffuse fibrosis and necrosis. The immunophenotype is characteristic of CHL. Because the histologic differential diagnosis often includes B- or T-large-cell lymphoma or ALCL, immunohistochemistry should be performed in most cases. EBV is positive in the majority of cases, and the stage is usually advanced at diagnosis.

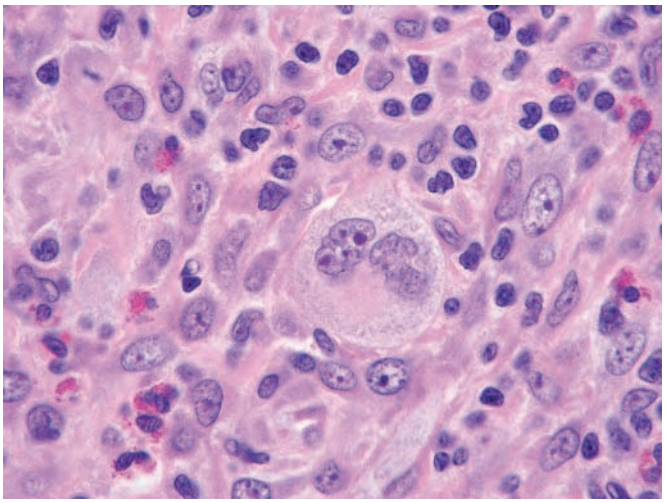

FIG. 78.11 Classic Hodgkin Lymphoma, Mixed Cellularity Subtype. A classic Reed-Sternberg cell is shown in a mixed inflammatory background with eosinophils, plasma cells, histiocytes, and small lymphocytes.

Classic Hodgkin Lymphoma, Lymphocyte-Rich

Classic Hodgkin lymphoma, lymphocyte-rich (CHLLR) may be nodular or diffuse and contains relatively infrequent classic HRS cells. Eosinophils and plasma cells are rare. In the nodular form, the HRS cells are seen at the periphery of B cell–rich nodules, mainly in the marginal zone. CHLLR has some features that are intermediate between other CHL and nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL).[47] Immunophenotypically, the neoplastic cells resemble classic HRS cells, but morphologic distinction from LP cells may be difficult in some cases. Thus, in the past, many cases were misdiagnosed as NLPHL. However, patients usually present with localized disease and tend to be older than patients with NLPHL. The genetic features are similar to other variants of CHL.

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

NLPHL is considered a distinct entity. Although it resembles other types of HL in having a minority of putative neoplastic cells in a background of benign inflammatory cells, it differs morphologically, immunophenotypically, and clinically from CHL.

NLPHL occurs at all ages but is more common in adult males. It usually involves peripheral lymph nodes with sparing of the mediastinum and is localized at diagnosis, although rarely it may be disseminated. NLPHL usually has a nodular growth pattern, with or without diffuse areas. The number of infiltrating reactive T cells is variable, and various patterns have been described on the basis of the cellular composition and growth pattern.[48] The atypical cells have vesicular, polylobated nuclei and small nucleoli. These had been called *lymphocytic and/or histiocytic (L&H) cells*, or "popcorn" cells, but the term *lymphocyte-predominant (LP) cell* is currently preferred. LP cells differ from classic HRS cells. The background is composed predominantly of lymphocytes with or without clusters of epithelioid histiocytes. Plasma cells are infrequent; eosinophils and neutrophils are also rare. The atypical cells are $CD45^+$, positive for B cell–associated antigens (CD19, CD20, CD22, CD79a), $CDw75^+$, $EMA^{+/-}$ $CD15^-$, $CD30^{-/+}$, and usually sIg^-. Small lymphocytes in the nodules are predominantly B cells with a mantle zone phenotype. However, numerous T cells are present, with $CD279^+$ T cells "rosetting" the LP cells. The proportion of T cells tends to increase over time in sequential biopsies. A prominent follicular DC meshwork is present within the nodules. LP cells, when microdissected, have shown to have clonally rearranged Ig genes with evidence of somatic hypermutation.

Survival for localized cases with or without treatment is long. However, cases with variant histology are more likely to have advanced-stage disease with a higher relapse rate. Moreover, patients with advanced-stage disease respond poorly to HL regimens, such as Adriamycin (doxorubicin), bleomycin, vinblastine, dacarbazine (ABVD), and benefit from treatment for aggressive B-cell lymphoma.[49]

ON THE HORIZON

- In recent years, there has been a greater appreciation of early events in lymphoid neoplasia.
- These early lesions in some ways can be considered equivalent to benign neoplasms in the epithelial system.
- These are clonal proliferations of B or T cells that carry genetic aberrations associated with specific forms of lymphoid neoplasia: chronic lymphocytic leukemia, multiple myeloma, follicular lymphoma, mantle cell lymphoma.
- Examples include monoclonal gammopathy of undetermined significance, monoclonal B lymphocytosis, in situ mantle cell neoplasia, in situ follicular neoplasia, lymphomatoid papulosis, patch stage of mycosis fungoides.
- Early lesions appear to lack the secondary and tertiary "hits" seen in lymphoid neoplasms that are clinically significant, and most patients have a very low risk of clinical progression.
- Current focus is to define the precise genetic features that distinguish early lesions from lymphoma, assess the risk of clinical progression, and determine their clinical management.

Monoclonal Gammopathies

Angela Dispenzieri

The monoclonal gammopathies include a spectrum of disorders involving an over-proliferation of plasma cells or B cells that have the ability to secrete monoclonal proteins into the serum or the urine. Some of these disorders are overt malignancies, characterized by significant overgrowth of malignant cells in the bone marrow, and in the instance of Waldenström macroglobulinemia (WM) in lymph nodes; others are premalignant conditions that are asymptomatic; and yet others create pathology through deposition and or humoral-mediated mechanisms.

DIAGNOSING A MONOCLONAL GAMMOPATHY

As will be discussed throughout this chapter, there are different pathways by which each of the clinical diagnoses are made, but basic common elements to the diagnosis of monoclonal gammopathies rely on the detection of a monoclonal protein and bone marrow evaluation. Monoclonal proteins are defined as proteins that have restricted migration on an electrophoretic gel (Fig. 79.1, A). The clonality has historically been established by immunoelectrophoresis (see Fig. 79.1, B) or immunosubstraction and most recently by mass spectrometry (see Fig. 79.1, C). An expansive repertoire of plasma cells will make a diverse population of immunoglobulins, but clonal expansion of secretory plasma cells in the bone marrow space will result in overproduction of a single (monoclonal) immunoglobulin (Ig), which in turn may be seen on protein electrophoresis of the blood (serum protein electrophoresis [SPEP]) and/or urine as a restricted band, which has been called an M component, an M protein, or an M spike. "M" in this context refers to "monoclonal." The isotype of this Ig is then clarified by immunologic techniques, demonstrating whether the heavy chain is present or not, and if present whether it is IgG, IgA, IgM, IgD, or IgE. The same methodology provides information about whether the light chain is kappa or lambda. The level (quantity) of the M protein typically has been determined by the area under the curve on the electrophoretic pattern.

Nephelometry, which measures light scatter, contributes to the assessment of the quantity of serum immunoglobulins. However, there is imperfect correlation between the M protein calculated by SPEP and nephelometry, due to technical issues. First, quantitative immunoglobulins by nephelometry measure both monoclonal and polyclonal immunoglobulins, thereby overestimating the size of small M proteins in the context of polyclonal activation of plasma cells (e.g., infection, autoimmune disease, liver disease). Second, the SPEP can underestimate the size of M proteins when they migrate in the middle of the beta-region. Third, the SPEP can underestimate the size of very large M proteins due to dye saturation.

The nephelometric test measuring serum immunoglobulin free light chain (FLC) has proven to be most useful, particularly in the context of immunoglobulin light-chain (AL) amyloidosis and also in myeloma when much of the secreted immunoglobulin is light chain without an accompanying heavy chain. Measuring ***total*** immunoglobulin light chains by nephelometry is typically not a constructive exercise because even in diseases in which large amounts of immunoglobulin free (or unbound) light chains are made, these quantities are orders of magnitude lower than that of the overall total circulating immunoglobulin levels. Therefore the measurement of total light chains merely provides the amount of intact immunoglobulins with that particular light chain, and the unbound or FLCs are a rounding error. In contrast, the reagents specifically designed to detect FLCs do not detect light chains bound to heavy chains. These tests revolutionized physicians' ability to follow patients with AL amyloidosis and have been useful for the diagnosis, risk assessment, and monitoring of many other monoclonal gammopathies.

The newest technology for identifying and monitoring monoclonal proteins is mass spectrometry, a technique penned as miRAMM (monoclonal immunoglobulin rapid accurate mass measurement).[1] This methodology can be carried out on a liquid chromatography–coupled electrospray ionization time of flight (TOF)-based mass spectrometer or on a simpler, less-expensive tabletop matrix-assisted laser desorption/ionization (MALDI)-TOF mass spectrometer, the latter of which is penned MASS-FIX. miRAMM identifies the M protein from the accurate molecular mass of the light chain. The advantages to this methodology are multiple. First, it provides greater sensitivity and specificity than does immunoelectrophoresis. Second, it can distinguish therapeutic monoclonal antibodies from a patient's own monoclonal protein by differences in mass. Third, the methodology is quicker and requires less technical time to generate the result.

The other test that is essential for evaluating most of the monoclonal gammopathies is a bone marrow aspiration for morphologic assessment, flow cytometry, and genetic analysis (most often fluorescence in situ hybridization [FISH]). In addition to the bone marrow aspiration, a biopsy is typically done for a better morphologic appraisal.

KEY CONCEPTS

1. Low-abundance monoclonal proteins are found in monoclonal gammopathy of unknown significance (MGUS) and merely warrant patient observation
2. A monoclonal gammopathy with clinical findings often signals a malignant condition including multiple myeloma, Waldenström macroglobulinemia, or AL amyloidosis that requires specific therapy
3. Monoclonal proteins are also observed in patients with smoldering multiple myeloma or smoldering Waldenström macroglobulinemia
4. Low-level monoclonal proteins also can be associated with a number of serious conditions, known as monoclonal gammopathy of clinical significance (MGCS), that often warrant plasma cell–directed therapy

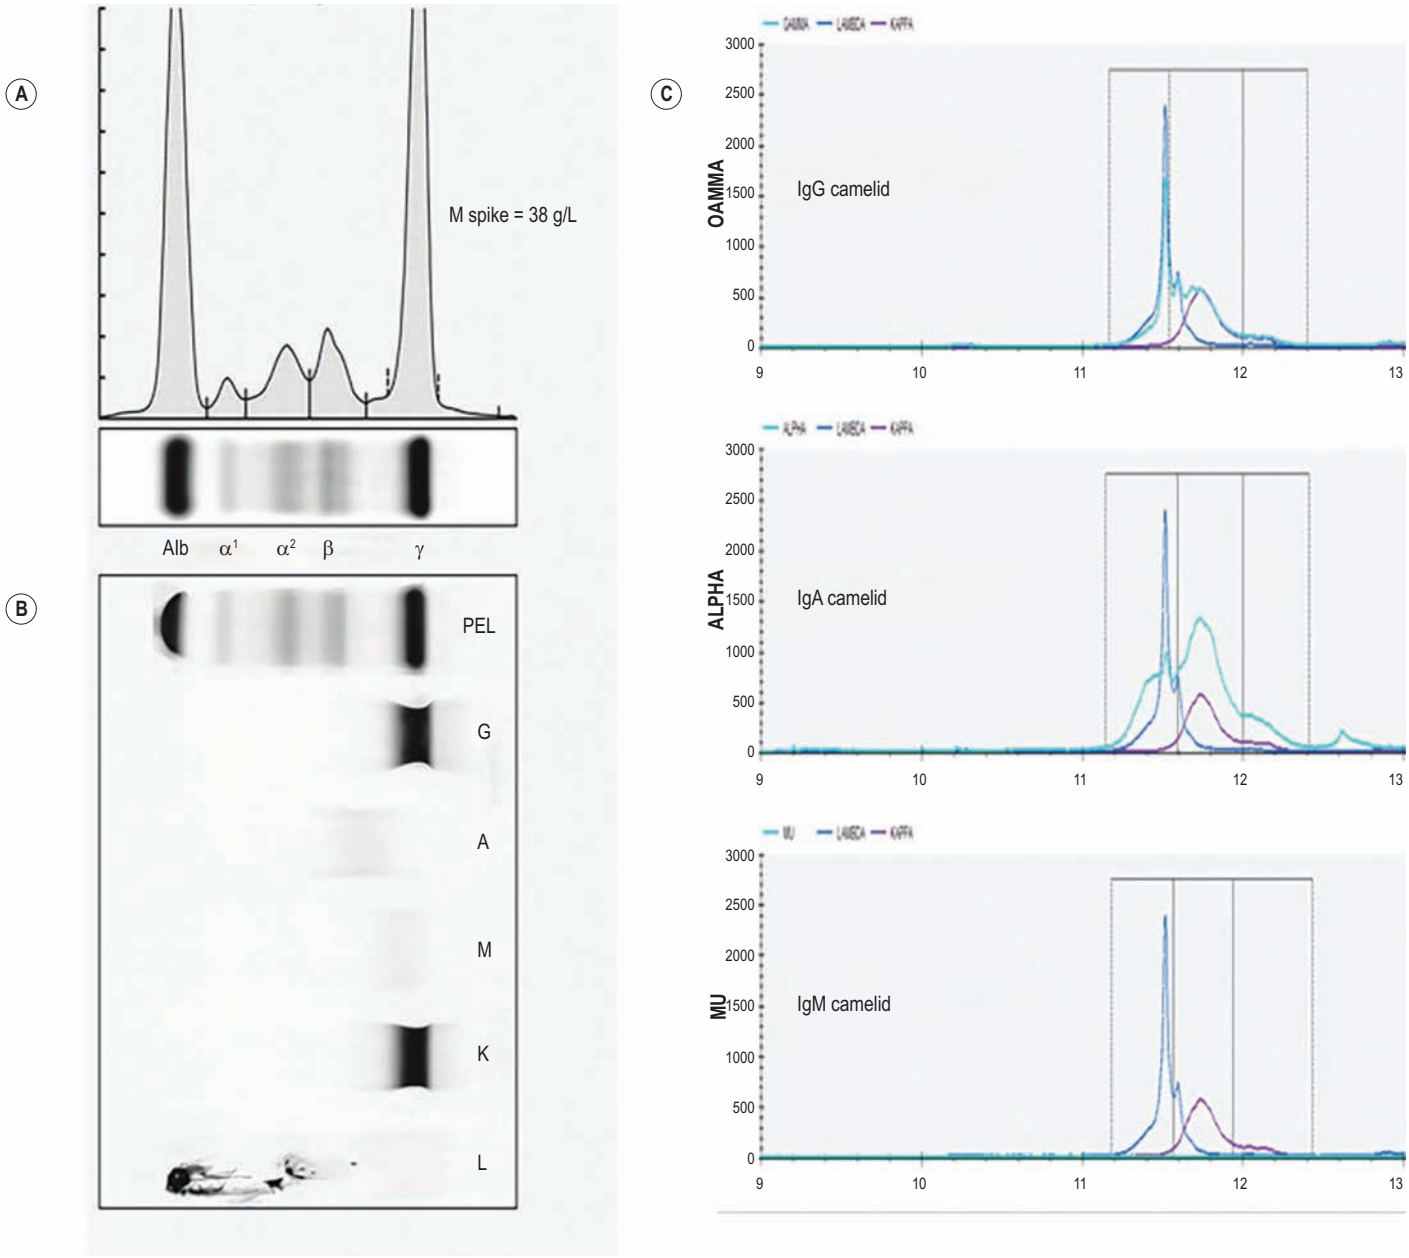

FIG. 79.1 Selected Techniques for Identifying Monoclonal Proteins. (A) Protein electrophoresis in a patient with multiple myeloma. (B) Immunoelectrophoresis in an immunoglobulin G (IgG) lambda patient. (C) MASS-FIX in a different immunoglobulin G (IgG) lambda patient. (C) Blue, purple, and turquoise represent lambda, kappa, and specified heavy chain camelids, respectively.

CLINICAL RELEVANCE

Accurate diagnosis is essential for each monoclonal gammopathy to determine whether observation or directed therapy is the appropriate management strategy.

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Monoclonal gammopathy of undetermined significance (MGUS) is a term coined by Kyle in 1978 to account for the observation that patients found with small monoclonal proteins on electrophoresis without multiple myeloma (MM) or WM had a condition that could progress to these malignancies over time. These small proteins that persisted as such for years without end-organ damage attributable to the plasma cell disorder progressed at a rate of approximately 1% per year to myeloma and related disorders.

Epidemiology

MGUS is the most common plasma cell proliferative disorder, with a prevalence of approximately 4% among adults 50 years or older.[2] Rates are higher in men than women, increase with increasing age, are more than twofold more common in African Americans than Whites, and twofold to threefold more common in first-degree relatives of individuals with MGUS or MM. The annual incidence of MGUS in males is estimated to be 120/100,000 at age 50 and rises to 530/100,000 at age 90 years. The rates for women are 60/100,000

TABLE 79.1 Definition of Plasma Cell Dyscrasia

	M Protein	BM Clonal Cells	Other
MGUS (all required)			
Non-IgM (IgA, IgG, IgD, or IgE)	Serum <3 g/dL	PC <10%[a]	No CRAB attributable
IgM	Serum <3 g/dL	LP <10%	No CRAB attributable
Light chain	Abn FLC ratio due to elevation of one of the FLCs. No heavy chain Urine M protein <0.5/24 h	PC <10%	No anemia, hyperviscosity, adenopathy, organomegaly attributable
SMM (either M protein or BM criteria met)	Serum (IgA, IgG, IgD, or IgE) ≥3 g/dL or urine M protein ≥ 0.5/24 h	PC 10%–60%	No CRAB attributable
SWM (all criteria required)	Serum (IgM) ≥3 g/dL or urine M protein ≥ 0.5/24 h	LP ≥10%[b]	No anemia, hyperviscosity, adenopathy, organomegaly attributable
Multiple myeloma[c] (any criteria met)	Serum (IgA, IgG, IgD, or IgE) ≥3 g/dL Urine M protein ≥ 0.5/24 h	PC ≥10%[d]	CRAB attributable, >1 focal lesion on MRI, FLC ratio ≥100 with involved FLC also ≥100, or BMPC ≥60%
Waldenström macroglobulinemia (all required)	Serum IgM protein	LP ≥10%[b]	Anemia, hyperviscosity, adenopathy, or organomegaly attributable
Solitary plasmacytoma	Any	No clonal BM PC	Biopsy proven solitary lesion of bone or soft tissue with clonal PC
Solitary plasmacytoma with minimal marrow involvement	Any	PC <10%	Normal skeletal survey and MRI (or CT) of spine and pelvis (except for the primary solitary lesion) No CRAB attributable

[a]Bone marrow can be deferred in patients with low-risk MGUS.
[b]Phenotype (e.g., surface IgM$^+$, CD5$^{+/-}$, CD10$^-$, CD19$^+$, CD20$^+$, CD23$^-$) that satisfactorily excludes other lymphoproliferative disorders including chronic lymphocytic leukemia and mantle cell lymphoma.
[c]Plasma cell leukemia diagnosis is made if more than 20% plasma cells in periphery and a circulating absolute plasma cell count of 2×10^9/L.
[d]Few plasma cells may be present if biopsy proven bony or extramedullary plasmacytoma.
BM, Bone marrow; *CRAB*, hypercalcemia, renal dysfunction, anemia, bone lesions; *CT*, computed tomography; *FLC*, free light chain; *Ig*, immunoglobulin; *LP*, lymphoplasmacytic infiltrate; *MGUS*, monoclonal gammopathy of undetermined significance; *MRI*, magnetic resonance imaging; *PC*, plasma cells; *SMM*, smoldering multiple myeloma; *SWM*, smoldering Waldenström macroglobulinemia.

at age 50, and 370/100,000 at age 90. The fact that the increased prevalence of MGUS with increasing age is not just related to accumulation of new cases but due to an actual increase in incidence suggests that an age-related cumulative damage model is at play in the pathogenesis of MGUS.

Clinical Presentation and Diagnosis

By definition (Table 79.1), individuals with MGUS are asymptomatic in terms of their plasma cell disorder, and it typically represents an incidental finding. A monoclonal protein may be found when an individual is found to have a high total serum protein or high erythrocyte sedimentation rate on routine blood work or when the patient has some indeterminant symptomatology, and a SPEP is performed as part of the evaluation. In this latter scenario, a patient may have symptoms and signs, but when the evaluation is complete, none of these are attributed to the monoclonal gammopathy. To exclude other diagnoses, an extensive review of symptoms looking for symptoms referable to monoclonal gammopathy of clinical significance (MGCS), MM, AL amyloidosis, etc., is required. In terms of testing, in addition to the SPEP and immunofixation which had already been done to diagnose the monoclonal gammopathy, the individual should have a complete blood count, a serum calcium, serum creatinine, alkaline phosphatase, spot urine looking for excess urinary protein, and serum FLC assay. The FLC assay is essential for MGUS prognostication. If there are cardiac symptoms, an N-Terminal proB-type natriuretic peptide (NT-proBNP) blood test should also be done as an initial screen for AL amyloidosis cardiomyopathy. A bone marrow is not necessary if the patient has low-risk MGUS and is potentially elective if the patient has low-intermediate–risk MGUS (see later).

Differential Diagnosis

The differential diagnosis for MGUS is as listed earlier. The monoclonal protein could be part of a malignant disease, a deposition disease, or a humoral-mediated disease (see later).

Management and Prognosis

Once the diagnosis is of MGUS is established, follow-up in 3 to 6 months is important to exclude the possibility that the patient was on his or her initial trajectory toward a malignant disorder. Once again, an extensive review of systems and the same blood work done at diagnosis minus the immunoelectrophoresis and the bone marrow should be performed. If the results are stable, follow-up can be based on the MGUS risk assessment.[3] Patients are assigned a point for each of the following factors: immunoglobulin M (IgM) or IgA isotype; abnormal FLC ratio; and M protein greater than 1.5 g/dL. A score of zero is deemed low-risk MGUS, and these patients have a 0.5%/year risk of progression to MM or related disorders. A score of 1 is low-intermediate risk, and these patients have a 1% per year risk for progression; 2 is intermediate risk with a 1.5% per year risk for progression; and a score of 3 is high-risk MGUS with a risk of 2% per year for progression. Overall risk is considerably lower if one accounts for competing risk of death in this generally elderly population. Other risk factors for progression include suppression of uninvolved immunoglobulins, higher bone marrow plasmacytosis, and increased percent aberrant phenotype plasma cells in the marrow.

After stability has been demonstrated, it is quite reasonable to do no additional follow-up in the low-risk MGUS population and annual follow-up for the remaining groups and/or additional special follow-up if there are symptoms worrisome for progression.

SMOLDERING MULTIPLE MYELOMA

As shown in Table 79.1, smoldering multiple myeloma (SMM) is another asymptomatic condition. Patients who clinically look like MGUS, but who have either an M protein or plasmacytosis beyond what is allowable for MGUS, are designated SMM. These patients have a significantly higher rate of progression to MM and related disorders. SMM is not a true biologic entity but rather a gray zone between MGUS and MM. Genetic studies of bone marrow plasma cells from SMM patients and MM patients are indistinguishable.

Epidemiology

SMM accounts for approximately 15% of all cases of newly diagnosed myeloma. There are no epidemiologic studies defining SMM prevalence.

Clinical Presentation and Diagnosis

Like MGUS, SMM is an incidental finding. Individuals with SMM by definition should not have anemia, renal dysfunction, hypercalcemia, bone disease, or plasmacytosis more than 60%. Evaluation for these patients is similar to that of MGUS patients, but bone radiographs—preferably a computed tomography (CT) skeletal survey, or magnetic resonance imaging (MRI)—should also be performed to exclude bone involvement.

Differential Diagnosis

The differential diagnosis is active MM, AL amyloidosis, and the other MGCS.

Management and Prognosis

Progression of SMM, based on a study of 276 patients with SMM, was 10% per year for the first 5 years, 5% per year for the next 3 years, and then 1% to 2% per year thereafter.[4] This pattern of progression in which there is a plateau after 10 years is consistent with the heterogeneous nature of SMM; in the first 10 years, the subset of patients with early MM declare themselves with symptomatic disease, while after 10 years, the remaining cohort of patients is identical to MGUS in biology and clinical behavior. A subset of patients can remain free of progression for several years.[5]

Risk factors for progression include level of the M protein, extent of abnormal FLC ratio, uninvolved immunoglobulin suppression, circulating plasma cells evaluated by flow cytometry, extent of aberrant bone marrow plasmacytosis and overall bone marrow plasmacytosis, proliferative rate of bone marrow plasma cells, and cytogenetic changes. Patients with t(4;14) and deletion 17p have the highest risk of progression, and patients with no FISH abnormalities are at lowest risk.

Patients with SMM are generally observed with serial follow-up blood tests and radiographs, the former of which are done quarterly and the latter typically every year.

The exception to the aforementioned observation strategy should be followed for those patients who are classified as having high-risk SMM defined by having two or three of the following risk factors: bone marrow plasma cells greater than 20%; M protein greater than 2 g/dL; and FLC ratio greater than 20.[6] Patients with high-risk SMM have a median time to MM progression of 29 months as compared with patients with none or one risk factors, who have a progression to MM of 110 and 68 months, respectively. Two randomized trials have demonstrated improved progression-free survival (PFS) for the high-risk population when treated with lenalidomide or lenalidomide and dexamethasone therapy. In addition, therapy trials showed improvement in overall survival.[7,8] There is controversy as to whether these patients be recategorized as active myeloma and treated as such, with ongoing trials underway to address this question.

MULTIPLE MYELOMA

MM is a neoplastic plasma cell dyscrasia (PCD) characterized by CRAB: (1) hypercalcemia; (2) renal insufficiency; (3) anemia; and (4) bone lesions and/or bone pain (Fig. 79.2). According to the World Health Organization (WHO) classification system, there is only one category for MM.[9]

Epidemiology

With the exception of MGUS, MM is the most common PCD, with an incidence of approximately 1 per 10,000 per year in the United States.[10] The 2018 annual estimate in the United States for new cases of MM is 30,770 and for deaths is 12,770. The age-adjusted rates in the United States show an incidence among African Americans that is approximately twofold higher than Whites and the incidence in men is approximately 1.6-fold that of women. The median age at diagnosis is 69 years. Since the turn of the century, 5-year survival rates in ethnic groups noted have equalized. Epidemiologic risk factors for MM include radiation, chronic antigenic stimulation, obesity, and low socioeconomic status.

Clinical Presentation and Diagnosis

The diagnosis is made according to criteria shown in Table 79.1, and one of the most important distinctions is whether the disorder is SMM or active MM requiring treatment. Anemia, bone disease, hypercalcemia, and renal dysfunction are the hallmarks of MM resulting in a typical clinical presentation of fatigue and/or bone pain. Due to suppression of uninvolved immunoglobulin production, patients with MM are at higher risk for infection. In addition, hyperviscosity occurs rarely and may be a cause for increased bleeding.

Essential testing at the time of diagnosis includes: SPEP and urine protein electrophoresis with isotype monoclonal protein using one of the methods discussed previously; complete blood count; calcium; creatinine; serum albumin (found on SPEP); lactate dehydrogenase. In addition, a bone marrow biopsy with FISH, looking for IgH translocations (t(11;14), t(4;14), t(14;16), t(14;20)), evidence of hyperdiploidy (focusing on odd chromosomes), copy number of 1q+, and deletions

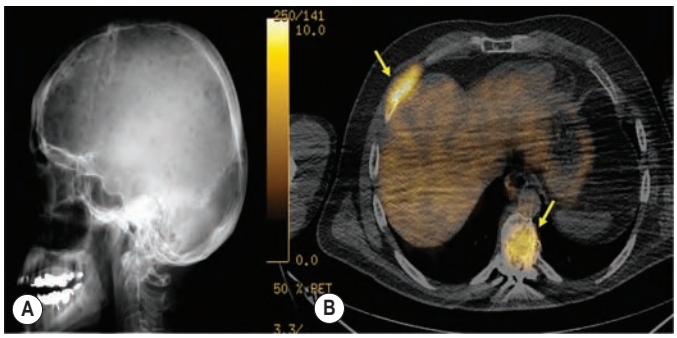

FIG. 79.2 Lytic Lesions in Multiple Myeloma. (A) Lytic lesions in skull. (B) ^{18}Fluorodeoxyglucose positron emission tomography/computed tomography demonstrating two avid lytic lesions in right rib and vertebra. *Yellow arrows* refer to lesions.

(chromosome 13, 17p, 1p).[11] Additional testing such as gene expression profiling and flow cytometry looking for plasma cell phenotype and proliferative rate may also be done.

Two-thirds of myeloma patients have a monoclonal kappa clone. Approximately 1% of patients with MM have nonsecretory disease and have no detectable circulating or urinary monoclonal proteins. The Ig isotype has been reported to be IgG, IgA, IgD, and light chain only in 52%, 20%, 2%, and 16% of cases, respectively. No individual bone marrow finding is pathognomonic for a malignant plasma cell process other than plasmacytosis of greater than 60%; the bone marrow diagnosis of MM relies on percentage of clonal bone marrow plasma cells, with 10% accepted as a cutoff to move a patient from MGUS to SMM or MM. However, a clinical diagnosis of MM can be made with fewer bone marrow plasma cells if CRAB or a myeloma-defining event is present.

Differential Diagnosis

The differential diagnosis is SMM, MGUS, AL amyloidosis, MGCS, solitary plasmacytoma, POEMS (polyradiculoneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes) syndrome, plasma cell leukemia (PCL), and diseases that can cause reactive plasmacytosis with resultant polyclonal hypergammaglobulinemia (e.g., chronic infection and autoimmune diseases). Because a very small minority of MM cases (≤1%) can have an IgM monoclonal protein, it is unusual to confuse MM with WM.

Management and Prognosis

The management involves aggressive supportive care and treatments directed at killing the myeloma cells. The complications of hypercalcemia and/or renal failure at presentation require aggressive treatment using hydration, occasionally with plasmapheresis, calcium-lowering agents, and urgent chemotherapy. There is an expanding repertoire of therapies for patients with myeloma. The two most important considerations are fitness (which often correlates with age) and genetic risk. Many will consider a pathway that includes autologous stem cell transplant (ASCT) in fit patients younger than age 75; alternate, effective strategies exist for less fit patients. In general, allogeneic stem cell transplant is not considered a standard therapy.

The mainstays of chemotherapy include the following different classes of drugs. Proteasome inhibitors include bortezomib, carfilzomib, and ixazomib. Immune modulators include thalidomide, lenalidomide, and pomalidomide. Alkylators include melphalan and cyclophosphamide. Corticosteroids include dexamethasone, prednisone, and methylprednisolone. Monoclonal antibodies include daratumumab, elotuzumab, and isatuximab. The most commonly used induction (first-line therapy) involves a combination of an immune modulator, a proteasome inhibitor, and a corticosteroid (e.g., bortezomib, lenalidomide, and dexamethasone). This highly effective regimen can be continued for approximately 4 months in those patients headed for ASCT as part of their first-line treatment and for approximately 6 months in those patients who are not ASCT candidates. In this latter group, maintenance with the single agent lenalidomide (or sometimes with dexamethasone) is continued for a minimum of 2 years but often indefinitely. For those patients intended for early transplant, their stem cells are collected before receiving myeloablative melphalan, followed by infusion of their stem cells. Maintenance with lenalidomide is then started around day 100 and continued for a minimum of 2 years to indefinitely.[12] With these strategies, the vast majority—upwards of 75%—of patients achieve a very good partial response or better. Durations of response vary depending on risk, but with these strategies, median PFS is 3 years in the non-ASCT group and more than 4 years in the ASCT group. Alternate induction regimens gaining popularity include combinations of an immune modulator drug, daratumumab, and a corticosteroid.

Relapsing patients have a number of therapeutic options including combinations of the drugs already mentioned, as well as innovative clinical trial strategies including check-point inhibitors, antibody-drug conjugates, chimeric antigen receptor T-cell (CAR-T) therapies and bi-specific T-cell engagers (BITE). Most commonly targeted antigens include B-cell maturation antigen (BCMA) and CD38.[13] The drug venetoclax, which blocks the antiapoptotic B-cell lymphoma-2 (BCL-2) protein, has shown efficacy in myeloma patients with the t(11;14) as a single agent but also in combination with bortezomib. This drug is US Food and Drug Administration (FDA) approved for other hematologic malignancies. The check-point inhibitor strategy had initially looked promising in conjunction with immune modulator drugs at the level of response, but randomized trials showed higher mortality using check-point inhibitors, stalling these initiatives. GSK2857916 (belantamab mafodotin), an antibody-drug conjugate against BCMA studied in multiply refractory myeloma, has yielded 60% response rates with a PFS of nearly 8 months. The most common adverse events were thrombocytopenia and corneal events. There are multiple CAR-T therapies in clinical trials. The products with the most experience in the United States include the bb2121 CAR-T (idecaptagene cicleucel), which targets BCMA.

There are many prognostic factors recognized in myeloma, but the most universally used are based on the International Staging System (ISS) and the Revised ISS (R-ISS).[11] The ISS is a simple system that incorporates the baseline serum albumin and beta-2 microglobulin. In 2015 FISH (t(4;14), t(14;16), or deletion 17p) and serum lactate dehydrogenase (LDH) was added to the ISS to further stage patients.

PLASMA CELL LEUKEMIA

PCL is a rare form of PCD. By definition, there are more than 20% plasma cells in the peripheral blood with an absolute plasma cell count of more than 2×10^9/L. Some authors accept the diagnosis with only one of these criteria. Less rigorous cutoffs have been considered to establish the diagnosis of PCL. The presentation may be primary, de novo, or secondary, evolving from an existing case of myeloma as part of the terminal phase of the disease. The morphology and immunophenotype of the plasma cells in PCL are indistinguishable from that of myeloma, but CD56 is more frequently found to be expressed on myeloma cells and CD20 on PCL cells.

Epidemiology

Between 2% and 4% of malignant PCD cases are PCL, and 60% to 70% of these cases are primary. The incidence of PCL in a Danish registry was 1.2 cases per million persons.[14]

Clinical Presentation and Diagnosis

As compared with patients with myeloma, primary PCL patients tend to be younger and sicker and have higher rates of light chain–only disease, high LDH, 17p deletion, and extramedullary disease.

The diagnostic work-up is similar to that of myeloma, but a positron emission tomography (PET)/CT may be warranted to enable better assessment for extramedullary disease.

Differential Diagnosis

Myeloma or severe infection is in the differential diagnosis. Because high levels of circulating polyclonal plasma cells can be seen in severe infections and serum sickness, establishing clonality of the plasma cells is important.

Management and Prognosis

The prognosis of primary PCL is worse than that of MM. In contrast, the survival of patients with secondary PCL is universally dismal. The most optimistic median survival rates are approximately 3 years, but those are in patients who lived long enough to make it to stem cell transplantation. Most other studies/reports estimate median survival of 1.5 to 2 years for patients with primary PCL. There is no clear guidance on what the most effective therapies are, but immune modulator drug (IMiD)-proteasome inhibitor (PI) combinations have yielded good response rates, as have complex multidrug regimens including conventional chemotherapy. Consolidation with ASCT should be done if feasible, and all patients should have maintenance therapy. So far, there are no data to support allogeneic stem cell transplant over ASCT in PCL. There is an anecdotal report of a patient with relapsed primary t(11;14)-PCL who was treated with venetoclax monotherapy and who enjoyed remission for more than 9 months.[15]

PLASMACYTOMA

Solitary plasmacytomas come in two varieties: (1) bone (SPB) and (2) extramedullary spaces (SEP).[16] In the old literature there was an overcall of SPB because immunohistochemistry of the bone marrow was not always done and imaging was primitive by current standards. Many of these older cases diagnosed as SPB were early myeloma with either low levels of MM in the marrow or multiple other bone lesions that were below the level of detection using imaging of the period. This yielded a falsely high rate of progression for true plasmacytoma of bone. Definitions were also not standardized in that some reports allowed for a patient to be diagnosed with SPB even if they had documented clonal plasma cells found on a random bone marrow biopsy. The International Myeloma Working Group developed more restricted diagnostic criteria and allowed for a new category called plasmacytoma of bone with minimal marrow involvement (see Table 79.1). In contrast, cases of SEP have increased over the decades, with better imaging and biopsy techniques, but this diagnosis still remains a rare entity.

Epidemiology

Good epidemiologic studies are lacking, but SPB and SEP account for approximately 2% to 5% of malignant PCD treated at large referral centers.

Clinical Presentation and Diagnosis

Criteria for diagnoses are shown in Table 79.1. For SPB, there is a male predominance and the median age of patients is 55 years. The axial skeleton is more often affected, and pain is the usual presentation. SPB can sometimes be associated with POEMS syndrome (see later). The presenting symptoms of SPE align with the location of the mass, with approximately 80% involving the oronasopharynx and paranasal sinuses, while other sites of involvement include the gastrointestinal tract, lung, liver, lymph nodes, skin, and central nervous system. Careful staging should be done akin to the evaluation performed for patients with MM, but PET/CT or whole-body MRI is required to exclude additional disease. Careful evaluation of the random bone marrow biopsy for clonal disease is also required.

Differential Diagnosis

The SPB differential diagnosis includes MM and POEMS syndrome. For SEP, reactive plasmacytosis, plasma cell granuloma, and immunoblastic lymphoma should be excluded. Some cases of SEP may represent marginal zone B-cell lymphoma that has undergone plasmacytic differentiation.

Management and Prognosis

These are potentially curable diseases. For SPB the most commonly used therapy is radiation, 40 to 50 Gy. Surgery should be reserved for patients with mechanical instability. For SEP, treatment options include surgery or radiation, whereas adjuvant chemotherapy is not recommended.[16] Many risk factors for progression have been identified, including size of the lesion, a nonvertebral presentation, abnormal FLC ratio, nonsecretory disease, and depression of immunoglobulins at presentation. Local progression is rare (<10%), and the risk for progression to myeloma appears to be less common for patients with SEP than SPB, with 10% progressing to myeloma within 3 years.

IMMUNOGLOBULIN LIGHT-CHAIN AMYLOIDOSIS

AL amyloidosis (formerly called primary amyloidosis) is a complex plasma cell disorder that impacts patients through immunoglobulin deposition in vital organs in the form of amyloid fibrils. These 8- to 10-nm fibrils have a beta pleated sheet structure and are highly insoluble.[17] Some immunoglobulin light chains are more prone to form amyloid, including the light chains from IGVL-6 gene; light-chain glycosylation may also be a risk factor for amyloid formation. Currently it is unknown why AL amyloid is formed.

There are two types of AL amyloidosis: a localized form and a systemic form. The former refers to the condition with little to no circulating clonal immunoglobulin and the amyloid deposits occur at the site of the cells producing the clonal protein. In systemic AL, there is circulating clonal immunoglobulin—most often in the form of an FLC—and the amyloid deposition is distant from the immunoglobulin-producing cells that reside in the bone marrow.

Epidemiology

There are limited data on the epidemiology of AL amyloidosis. The rates of the disease rise with increasing age, with the reported median in the 70 s. There is a male predominance ranging from 54% to 70%, and there are no identified risk factors for AL amyloidosis other than a preexisting monoclonal gammopathy. The incidence of AL has been estimated to be approximately 10.8 to 15.2 cases per million.

Clinical Presentation and Diagnosis

Systemic AL amyloidosis is an insidious disease that often goes undiagnosed for a year or longer. Approximately 70% have cardiac and/or renal involvement, and 15% have liver and/or 15% nerve involvement. Patients will have symptoms referable to these organ systems, including dyspnea, fluid retention, light-headedness, dysesthesias, and fatigue. Other symptoms may include periorbital purpura and jaw claudication (due to

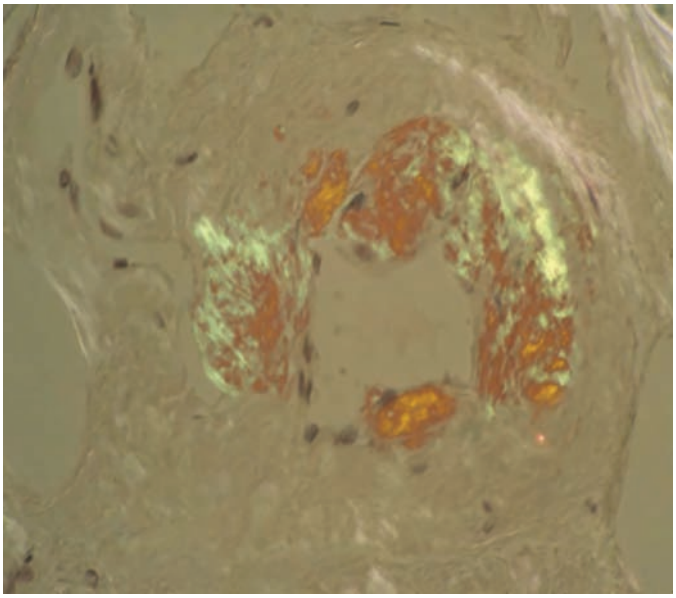

FIG. 79.3 Congo Red Stain of a Bone Marrow. Positive Congo red stain (1000×) under polarized light demonstrating apple green birefringence.

microvascular disease), macroglossia, vocal hoarseness, diarrhea, constipation, early satiety, hematochezia, weight loss, and carpal tunnel syndrome.

In contrast, localized AL amyloidosis occurs in one of the following systems: the respiratory tract, the genitourinary tract, the skin, the gastrointestinal tract, or the lymphatics. Symptoms are associated with the involved organ systems.

The diagnosis of AL amyloidosis is a tissue diagnosis. Biopsy of the affected organ in localized AL amyloidosis is required to make that diagnosis, but for systemic AL amyloidosis, surrogate tissues can provide a diagnosis in the right clinical situation. The fat aspirate is positive for AL amyloidosis in approximately 85% of cases demonstrating Congo red positivity and apple green birefringence on polarized light (Fig. 79.3). The application of mass spectrometry typing showing either kappa or lambda light chains is sufficient to make the diagnosis of systemic AL amyloidosis. In such a patient, the presence of an enlarged, stiff heart is presumed to be associated with AL amyloid deposition in the tissue without the need for an endomyocardial biopsy.

Differential Diagnosis

The differential diagnosis for AL amyloidosis is MGUS, SMM, MM, light-chain deposition disease, and other types of amyloidosis. Not all amyloid is AL amyloidosis, with more than 30 proteins having been found to cause disease in humans. Once amyloidosis is identified on a biopsy, the causative protein must be typed to distinguish the type of amyloid present. A tissue mass spectrometry approach is preferable, but in some instances other techniques can be used. The importance of typing cannot be overemphasized, because the therapeutic strategy is different for patients with AL amyloidosis compared with other acquired or inherited forms of amyloidosis.

Management and Prognosis

Patients are staged using simple blood tests: troponin, NT-proBNP, and immunoglobulin FLCs. The Mayo 2012 staging system assigns those patients with none of these markers elevated Stage I, with one elevated Stage II, with two elevated Stage III, and all three elevated Stage IV. Patients with Stage IV disease have very poor overall survival, whereas patients with Stage I disease have median survival of more than 6 years.

The mainstay of therapy for patients with AL amyloidosis is plasma cell–directed chemotherapy. The same drugs used to treat myeloma are used to treat AL amyloidosis, although often at slightly different doses and schedules. Patients with AL amyloidosis have more side effects due to their compromised organs. The flip side is that, because approximately half of patients with AL amyloidosis have such a low plasma cell burden, they often respond faster and more completely than myeloma patients and also have a longer time to progression. Daratumumab, a therapeutic monoclonal antibody directed against CD38, is especially active in patients with AL amyloidosis,[18] and anecdotal evidence shows great promise for venetoclax,[19] a BCl-2 inhibitor, in the 50% of AL patients whose plasma cells harbor the t(11:14) translocation. However, for patients with AL amyloidosis, therapy is a race against time because these patients can die if their disease is too advanced at diagnosis, due to organ dysfunction (most commonly cardiac) before (and even after) they achieve an effective hematologic response.

To date, there are no proven therapies that are effective in increasing removal of amyloid from tissues. Neod-001, a therapeutic antibody, was thought to be promising, but its development was terminated when a phase III trial did not demonstrate efficacy. There is one antiamyloid antibody, Cael-01, that is currently being tested in clinical trials. The antibiotic doxycycline disrupts amyloid fibrils in vitro, and there are some clinical data that suggest it may reduce mortality.

WALDENSTRÖM MACROGLOBULINEMIA AND SMOLDERING WALDENSTRÖM MACROGLOBULINEMIA

WM is a rare hematologic malignancy characterized by accumulation of malignant IgM-secreting lymphoplasmacytic lymphoma cells in the bone marrow and lymph nodes.[20] *MYD88* L256P is the somatic point mutation that is found in more than 90% of patients with WM. Those patients without the mutation appear to be at higher risk of transformation to diffuse large B-cell lymphoma. Approximately 30% to 40% of patients have mutations in *CXCR4*, and these patients typically have higher serum IgM levels and lower rates of lymphadenopathy and hepatosplenomegaly. The clonal lymphoplasmacytic cells express CD19, CD20, CD22, and CD79a (lymphoid population) and CD38 on the plasmacytic population.

Epidemiology

The age-adjusted incidence for males and females is approximate 0.9 and 0.3 per 100,000 person-years, respectively.[21] The median age at presentation is 69 years. It is more common in Whites than African Americans, and there is a familial predisposition.

Clinical Presentation and Diagnosis

Most symptomatic patients present with anemia and fatigue and less often with symptoms and signs of hyperviscosity. A large proportion of patients are diagnosed when they are asymptomatic, and these patients are referred to as smoldering WM.

Differential Diagnosis

The differential diagnosis is smoldering WM, IgM MGUS, AL amyloidosis, cryoglobulinemia, Schnitzler syndrome, other lymphomas, and IgM myeloma.

Management and Prognosis

The International Prognostic Staging System for WM includes age plus serum albumin, lactate dehydrogenase, and beta-2 microglobulin levels. The median diseases specific survival is approximately 10 years. The size of the M protein spike and the degree of anemia are also prognostic.

For patients who are symptomatic (e.g., bulky disease or the presence of cytopenias), either bendamustine and rituximab or ibrutinib with or without rituximab are the mainstays of first-line therapy. If the patient has symptomatic hyperviscosity, plasmapheresis is indicated followed by the therapy noted earlier. For the elderly or less symptomatic patients, single-agent rituximab with or without an alkylator can be tried, but more often these patients are given bendamustine and rituximab as well. In contrast, patients with smoldering WM are observed.

MONOCLONAL GAMMOPATHY OF CLINICAL SIGNIFICANCE

MGCS was coined after the expression monoclonal gammopathy of renal significance (MGRS, see later).[22,23] It became increasingly apparent that a diagnosis was required for a patient with a small B-cell clone and low-level monoclonal protein who was presenting with serious and even life-threatening disease. Under these circumstances, diagnosing these patients with MGUS was inappropriate. In addition, some of these patients satisfied the definition for SMM or smoldering WM but did not require treatment directed at their clone because they did not have the classic end-organ damage that defines active MM or WM. Although nearly half of AL amyloidosis cases could be called MGCS, the expert community decided that AL amyloidosis is discrete and complex enough to stand on its own as a separate diagnosis. The MGCS can be broken down into different systems that are affected, the most common of which are kidney, nerve, and skin (Table 79.2). There is overlap because some of these rare disorders can have a more systemic, multiorgan presentation and/or course.

Monoclonal Gammopathy of Renal Significance

This was the first consensus of monoclonal gammopathies of clinical significance. There have been multiple iterations since the first publication by Leung et al. in 2012.[24] Fig. 79.4 demonstrates the spectrum of diagnoses based on location and type of deposits. All of these diagnoses are made by the renal pathologist.

With the exception of C3 glomerulopathy with monoclonal gammopathy and thrombotic microangiopathy, all other MGRS are broken into either "nonorganized" or "organized" monoclonal immunoglobulin deposits. The nonorganized includes two disease entities: monoclonal immunoglobulin deposition disease (see later), and proliferative glomerulonephritis with monoclonal immunoglobulin deposits (PGNMID). In contrast, the organized deposits can be further broken down into fibrillar deposits, which include AL amyloidosis (previously discussed) and monoclonal fibrillary glomerulonephritis (GN); and microtubular, which includes immunotactoid GN and cryoglobulinemia GN. Finally, there is the subcategory of inclusions or crystalline deposits, which includes light-chain proximal tubulopathy, crystal storing histiocytosis, and cryocrystalglobulin GN.

This classification allows for a uniform vocabulary among nephrologists, renal pathologists, and hematologists such that diagnostic algorithms can be constructed, and natural history and therapeutic interventions can be analyzed. As an example, careful study has clarified that patients with MGCS-associated fibrillary GN, immunotactoid GN, and PGNMID, who receive renal allografts, commonly have disease recurrence in the allograft. This is less commonly seen in patients with AL amyloidosis. Which diseases best respond to which plasma cell–directed therapies remains a work in progress. The most data exist on light-chain deposition disease, so that topic is described next. Cryoglobulinemia is discussed under dermatologic MGCS. An extensive review of MGRS was published by Leung and colleagues.[24]

Light-Chain Deposition Disease

Light-chain deposition disease shares similarities with AL amyloidosis in that both are immunoglobulin deposition diseases. Both can rarely involve immunoglobulin heavy chains as well. Light-chain deposition disease is less common than AL amyloidosis, is more often due to a kappa-restricted light chain (IGKV4), and presents with impaired creatinine clearance. This disease primarily

TABLE 79.2 Summary of Disease Characteristics of Selected Monoclonal Gammopathies of Clinical Significance

AL, Immunoglobulin light chain; *DADS-M PN*, distal, acquired demyelinating, symmetric, neuropathy with M protein; *MGRS*, monoclonal gammopathy of renal significance; *MGCS*, monoclonal gammopathy of clinical significance; *POEMS*, polyradiculoneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes; *TEMPI*, telangiectasias; elevated erythropoietin and erythrocytosis; monoclonal gammopathy; perinephric fluid collections; and intrapulmonary shunting.

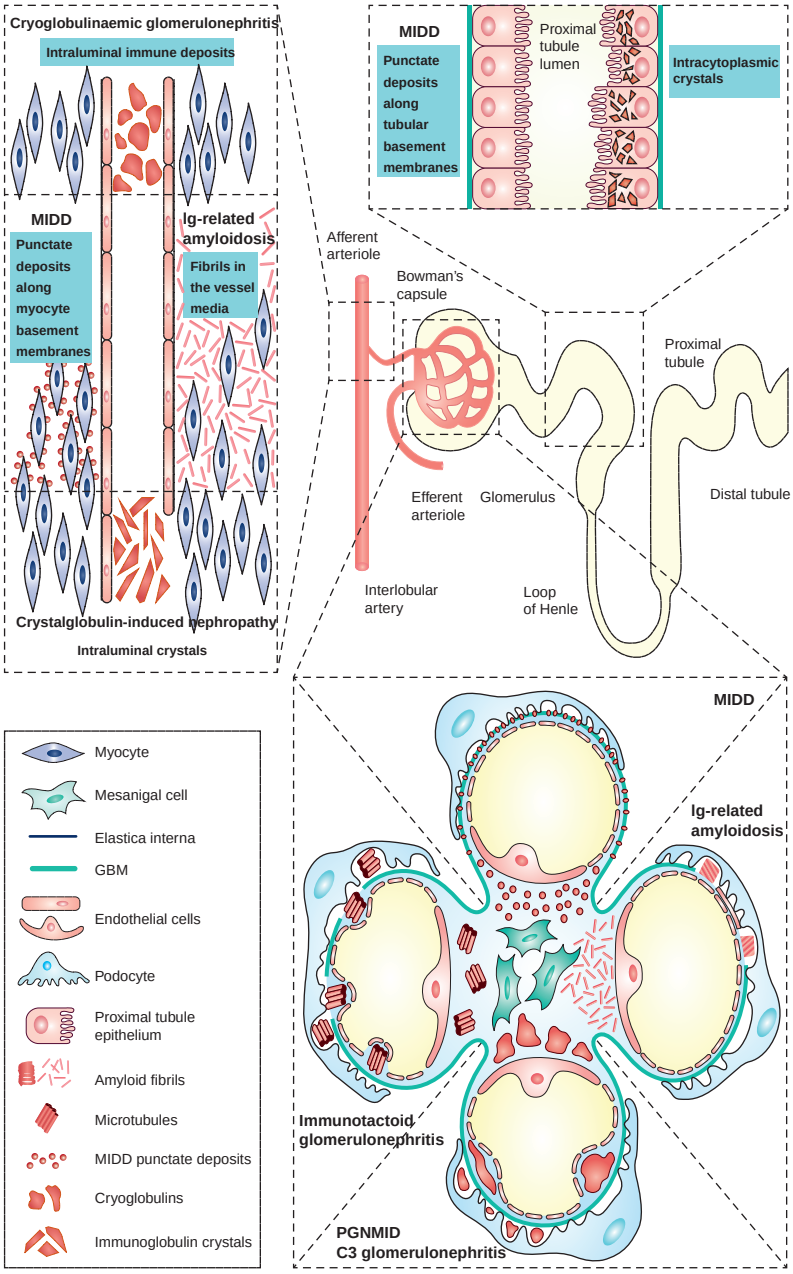

FIG. 79.4 Monoclonal Gammopathy of Renal Significance. Monoclonal gammopathy of renal significance (MGRS)-associated lesions can involve one or more renal compartments. In immunotactoid glomerulonephritis, C3 glomerulopathy, and proliferative glomerulonephritis with monoclonal immunoglobulin deposits (*PGNMIDs*), MGRS-associated lesions involve only the glomeruli, whereas in light-chain proximal tubulopathy (LCPT), MGRS-associated lesions involve only the proximal tubules. MGRS-associated lesions in cryoglobulinemic glomerulonephritis mainly involve the glomeruli but can occasionally affect blood vessels in the form of intravascular cryoglobulin thrombi or endovasculitis. Immunoglobulin *(Ig)*-related amyloidosis and monoclonal immunoglobulin deposition disease (*MIDD*) usually affect all renal compartments, including glomeruli, vessels, and the tubulointerstitium. MGRS-associated lesions can involve one or more renal compartments. In immunotactoid glomerulonephritis, C3 glomerulopathy, and PGNMIDs, MGRS-associated lesions involve only the glomeruli, whereas in LCPT, MGRS-associated lesions involve only the proximal tubules. MGRS-associated lesions in cryoglobulinemic glomerulonephritis mainly involve the glomeruli but can occasionally affect blood vessels in the form of intravascular cryoglobulin thrombi or endovasculitis. Immunoglobulin-related amyloidosis and MIDD usually affect all renal compartments, including glomeruli, vessels, and the tubulointerstitium. *GBM,* Glomerular basement membrane. (Redrawn with permission from Leung, N., Bridoux F, Batuman V, et al. The evaluation of monoclonal gammopathy of renal significance: a consensus report of the International Kidney and Monoclonal Gammopathy Research Group. *Nat Rev Nephrol.* 2019;15[1]:45–59.)

affects the kidneys but can occasionally affect other organs. As in the case of AL amyloidosis, glycosylation may be a risk factor for the disease.[25] Also like AL amyloidosis, the median plasmacytosis in the bone marrow is approximately 10%, making half with myeloma and the other half with a bone marrow that would appear to be MGUS (now classified as MGRS).

On immunofluorescence of the kidney biopsy, linear deposits of the involved monoclonal immunoglobulin are seen along

tubular and glomerular basement membranes. On electron microscopy, these deposits have a granular appearance.

Treatment is similar to that of patients with AL amyloidosis, and prognosis tends to be better because it is extraordinarily unusual for patients with light-chain deposition disease to have cardiac involvement, which is the major determinant of poor outcomes in patients with AL amyloidosis.

Monoclonal Gammopathy of Neurologic Significance

The three most common monoclonal gammopathies that have neurologic significance are POEMS syndrome, cryoglobulinemia, and AL amyloidosis (see Table 79.2). The neuropathy associated with cryoglobulinemia and AL amyloidosis is not discussed here because these diseases are covered in other sections, but suffice it to say that the former is more often an axonal neuropathy due to vasculitis and the latter a small-fiber neuropathy, which can eventually become axonal. Distal, acquired demyelinating, symmetric neuropathy with M protein (DADS-M), previously known as MGUS-associated neuropathy, is an entity that probably has significance only among patients with IgM monoclonal proteins. Scleromyxedema can sometimes cause neuropathy. Finally, there is a condition called sporadic late-onset nemaline myopathy, which is not a neuropathy but causes severe motor issues as will be discussed.

POEMS Syndrome

POEMS syndrome is the acronym for polyradiculoneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes.[26] It is a rare condition with a prevalence of 3 per million people in Japan. Median age at presentation is in the 50s, and there are slightly more men than woman affected. Symptoms and signs refer to the acronym as well as features covered by the other acronym associated with this syndrome, PEST (papilledema, extravascular volume overload, sclerotic bone lesions, thrombocytosis, and erythrocytosis). Other findings not covered by either of the acronyms are elevated vascular endothelial growth factor, pulmonary hypertension, reduced diffusion capacity of lungs for carbon monoxide (DLCO), and arterial and venous thromboembolism. The dominant symptom in this disease is a progressive length-dependent ascending sensorimotor peripheral neuropathy. Diagnostic criteria are shown in Table 79.3.

The most significant risk factors in this disease are age, pleural effusion, reduced estimated glomerular filtration rate (eGFR), and pulmonary hypertension. Coexisting Castleman disease also is an adverse risk factor as is lack of complete hematologic response. ASCT is a favored therapy, but lenalidomide and dexamethasone are also active. Data are emerging with proteasome inhibitors and daratumumab. Overall survival in patients with POEMS syndrome is excellent with plasma cell–directed therapy, with estimated 10-year survivorship at 79%.

Distal, Acquired Demyelinating, Symmetric Neuropathy With M Protein

The IgM monoclonal gammopathy accounts for approximately 60% of neuropathies associated with monoclonal gammopathy.[27] Pathologic studies in WM and IgM DADS-M have identified demyelination and widened myelin lamellae with IgM deposits detected in the widened lamellae of myelin fibers and myelin debris contained in Schwann cells and macrophages. These M proteins may bind to myelin-associated glycoprotein (MAG) or other gangliosides. However, anti-MAG antibodies are not specific for peripheral neuropathy, and reduction in anti-MAG antibody titers with rituximab or other anti-CD20 antibodies has not correlated with clinical improvement.

Patients are more often male and in their 50s to 80s. They present with a distal, demyelinating symmetric neuropathy, with sensory ataxia the most common finding. The diagnosis is one of exclusion. Even in the presence of a monoclonal gammopathy, other explanations including inherited neuropathies, diabetes, alcoholism, and drugs should be ruled out, as should POEMS syndrome and AL amyloidosis. Anti-MAG antibodies can be ordered, but as mentioned, these are not specific. Treatments include intravenous immunoglobulin (IVIG) and rituximab.

TABLE 79.3 Criteria for the Diagnosis of POEMS Syndrome[a]

Mandatory major criteria	1. Polyneuropathy (typically demyelinating) 2. Monoclonal plasma cell-proliferative disorder (almost always lambda)
Other major criteria (one required)	3. Castleman disease[a] 4. Sclerotic bone lesions 5. Vascular endothelial growth factor elevation
Minor criteria	6. Organomegaly (splenomegaly, hepatomegaly, or lymphadenopathy) 7. Extravascular volume overload (edema, pleural effusion, or ascites) 8. Endocrinopathy (adrenal, thyroid,[b] pituitary, gonadal, parathyroid, pancreatic[b]) 9. Skin changes (hyperpigmentation, hypertrichosis, glomeruloid hemangiomata, plethora, acrocyanosis, flushing, white nails) 10. Papilledema 11. Thrombocytosis/polycythemia[c]
Other symptoms and signs	Clubbing, weight loss, hyperhidrosis, pulmonary hypertension/restrictive lung disease, thrombotic diatheses, diarrhea, low vitamin B_{12} values

[a]There is a Castleman disease variant of POEMS syndrome that occurs *without* evidence of a clonal plasma cell disorder that is not accounted for in this table. This entity should be considered separately.
[b]Because of the high prevalence of diabetes mellitus and thyroid abnormalities, this diagnosis alone is not sufficient to meet this minor criterion.
[c]Approximately 50% of patients will have bone marrow changes that distinguish it from a typical monoclonal gammopathy of undetermined significance (MGUS) or myeloma bone marrow.[36] Anemia and/or thrombocytopenia are distinctively unusual in this syndrome unless Castleman disease is present.
The diagnosis of POEMS syndrome is confirmed when both of the mandatory major criteria, one of the three other major criteria, and one of the six minor criteria are present.
POEMS, Polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes.

Sporadic Late-Onset Nemaline Myopathy

Sporadic late-onset nemaline myopathy (SLONM) is a rare muscle disease that can be associated with a monoclonal protein or human immunodeficiency virus (HIV) infection. On biopsy, muscle fibers accumulate nemaline rods, with no associated inflammation. Patients present with predominantly proximal or axial muscle weakness, including respiratory muscle weakness.[28] Treatment strategies include IVIG and plasma cell–directed therapies, including ASCT.

Monoclonal Gammopathy of Dermatologic Significance

These conditions include Schnitzler syndrome, scleromyxedema, necrobiotic xanthogranuloma (NXG), TEMPI (telangiectasias; elevated erythropoietin and erythrocytosis; monoclonal gammopathy; perinephric fluid collections; and intrapulmonary shunting) syndrome, cryoglobulinemia, capillary leak syndrome, and POEMS syndrome (Table 79.4). This last entity is described

earlier, but these patients have skin findings including hyperpigmentation, hypertrichosis, thickening, rubor, and white nails.

Schnitzler Syndrome

Schnitzler syndrome is a condition that is characterized primarily by chronic urticaria and the presence of an IgM monoclonal gammopathy. It was described in 1972 by the French dermatologist Liliane Schnitzler and is currently classified as an autoinflammatory disorder. Interleukin (IL)-1β plays a critical role in in the disease, with aberrant NLRP3 inflammasome signaling and cytokine pathway dysregulation having been identified. Schnitzler syndrome can rarely be associated with an IgG monoclonal gammopathy. Other features and diagnostic criteria are shown in Table 79.4.[29] Although the presence of a dermal neutrophilic infiltrate on skin biopsy became a minor criterion with the Strasbourg revision, such a biopsy finding is nonspecific, and its relative importance in the diagnostic criteria has been questioned. Therapy with the anti–IL-1 monoclonal antibody anikinra and newer anti–IL-1 monoclonal antibodies (rilonacept and canakinumab) are effective.

Scleromyxedema

Scleromyxedema affects the skin primarily but can also affect other systems. It is characterized by generalized papular and sclerodermoid cutaneous eruptions and is typically associated with an IgG monoclonal gammopathy. Aside from cutaneous involvement, extracutaneous involvement can include the nervous system, joints, gastrointestinal system, and heart. The infiltrates are composed of mucin. The mechanism associated with a PCD and its monoclonal protein–inducing fibroblast proliferation remains unknown but is gradually emerging through skin transcriptome analyses and the study of peripheral blood immune cells. Transforming growth factor β (TGF-β) is overexpressed as well as other proteins, including collagen 1a and several interferon-inducible proteins.[30,31] Diagnostic criteria are shown in Table 79.5.

The two mainstays of treatment in this disease are IVIG and plasma cell–directed therapy. In one study, baseline levels of peripheral blood Tc17 cells ($CD8^+CCR\gamma^+CXCR3^+CCR4^-$) correlated with extent of skin involvement and decreased after IVIG therapy. RNA analysis of skin tissue before and after treatment revealed a decrease in gene expression of TGF-β–induced cytokines and several interferon-inducible proteins.[30] The combination of IVIG, dexamethasone, and either lenalidomide or bortezomib seems to be effective therapy in the majority of patients.[31] IVIG is considered first-line therapy, with plasma cell–directed therapy added if no response or more severe disease.

Necrobiotic Xanthogranuloma

NXG is a non-Langerhans cell histiocytosis typically associated with monoclonal proteins attributable to PCD or lymphoproliferative disorders (LPDs).[32] It was first described by Kossard and Winkelmann in 1980. The classic presentation is yellow to orange papules, plaques, and/or nodules involving the eyelids. Cutaneous lesions may also be found on other places of the face, the trunk, and the extremities. NXG plaques can occasionally be pruritic and also painful, especially if they ulcerate. Extracutaneous involvement includes the eye, heart, gastrointestinal tract, liver, and lung but is relatively rare.

On biopsy, palisading granulomas are found with nonclonal lymphoplasmacytic infiltrates and zones of necrobiosis. Cholesterol clefts and large bizarre foreign body giant cells are also classic. The pathogenesis of the disease is unknown, but it has been speculated that there is a monoclonal protein–lipoprotein interaction. Diagnostic criteria have been proposed (Table 79.6).

TABLE 79.4 Strasbourg Diagnostic Criteria of Schnitzler Syndrome

Obligate Criteria
1. Chronic urticarial rash and
2. Monoclonal immunoglobulin M (IgM) or IgG

Minor Criteria
1. Recurrent fever[a]
2. Objective findings of abnormal bone remodeling with or without bone pain[b]
3. A neutrophilic dermal infiltrate on skin biopsy[c]
4. Leukocytosis and/or elevated C-reactive protein (CRP)[d]

Definite Diagnosis
If IgM, both obligate criteria AND at least 2 minor criteria
If IgG both obligate criteria AND 3 minor criteria

Probable Diagnosis
If IgM, both obligate criteria AND 1 minor criteria
If IgG, both obligate criteria AND 2 minor criteria

[a]Must be greater than 38°C, and otherwise unexplained. Occurs usually—but not obligatory—together with the skin rash.
[b]As assessed by bone scintigraphy, magnetic resonance imaging (MRI), or elevation of bone alkaline phosphatase.
[c]Corresponds usually to the entity described as "neutrophilic urticarial dermatosis"; absence of fibrinoid necrosis; and significant dermal edema.
[d]Neutrophils greater than 10,000/mm^3 and/or C-reactive protein *(CRP)* greater than 30 mg/L.
From Simon, A., Asli, B., Braun-Falco, M., et al. Schnitzler's syndrome: diagnosis, treatment, and follow-up. *Allergy.* 2013;68:562–568.

TABLE 79.5 Rongioletti Diagnostic Criteria for Scleromyxedema

1. Generalized papular and sclerodermoid eruption
2. Evidence of monoclonal gammopathy
3. Microscopic triad associating dermal mucin deposition, thickened collagen, and fibroblast proliferation or an interstitial granuloma annulare–like pattern
4. Absence of thyroid disease

From Rongioletti, F., Merlo, G., Carli, C., et al. Histopathologic characteristics of scleromyxedema: A study of a series of 34 cases. *J Am Acad Dermatol.* 2016;74:1194–1199.

TABLE 79.6 Proposed Diagnostic Criteria for Necrobiotic Xanthogranuloma[a]

Major Criteria
1. Cutaneous papules, plaques, and/or nodules, most often yellow or orange in color
2. Histopathologic features demonstrating palisading granulomas with lymphoplasmacytic infiltrate and zones of necrobiosis. Characteristic features that are variably present include cholesterol clefts and/or giant cells (Touton or foreign body)

Minor Criteria
1. Paraproteinemia, most often IgG-κ, plasma-cell dyscrasia, and/or other associated lymphoproliferative disorder
2. Periorbital distribution of cutaneous lesions

[a]Both major criteria and at least 1 minor criterion are required for diagnosis, applicable only in the absence of foreign body, infection, or other identifiable cause.
From Nelson, C.A., Zhong, C.S., Hashemi, D.A., et al. A Multicenter Cross-Sectional Study and Systematic Review of Necrobiotic Xanthogranuloma With Proposed Diagnostic Criteria. *JAMA Dermatol.* 2020;156(3):270–279.

The leading differential diagnosis is necrobiosis lipoidica, which is a necrotizing skin condition that most often occurs in patients with diabetes mellitus but can also occur in patients with rheumatoid arthritis.

Treatment with IVIG is one of the most promising therapies, but limited success has also been reported with plasma cell–directed therapies, intralesional triamcinolone, and antimalarials.

Cryoglobulinemia

Cryoglobulinemia is a multisystem disease that can affect almost any organ system. It is discussed under dermatologic conditions because cutaneous manifestations are almost always present (see Table 79.2). A cryoglobulin is an immunoglobulin that precipitates at a low temperature but that can dissolve upon warming. The Brouet classification divides cryoglobulins into three types: type I, a monoclonal protein; type II, polyclonal immunoglobulins that form immune complexes with one or more monoclonal immunoglobulins; and type III polyclonal immunoglobulins. Type I cryoglobulins are most often IgM followed by IgG. Type II cryoglobulins are typically IgM with rheumatoid factor activity that binds to the Fc of the IgGs, which are themselves bound to antigen—most often hepatitis C viral antigens. Type I cryoglobulins arise from PCD or LPDs. In contrast, type II and type III cryoglobulins may be related to PCDs or LPDs but are more often due to infections, particularly hepatitis C, or connective tissue disorders.

Manifestations are quite variable, as is the severity of disease. This is in part due to the immunoglobulin level and biophysical characteristics (see Table 79.2). Type I cryoglobulins more often cause occlusive symptoms due to occlusion of capillary lumina, whereas vasculitis is uncommon.[33] Low complement levels and rheumatoid factor are rare. Patients report cold-induced skin symptoms, including purpura, livedo, and cold urticaria. Ulceration can occur. Fewer than one-third of patients will have renal involvement, but as many as 50% may have peripheral neuropathy. In contrast, in type II/III cryoglobulinemia or mixed cryoglobulinemia, small vessel vasculitis is the major mechanism driving morbidity. Skin symptoms including purpura occur in the vast majority of patients; arthralgia is also very common, as is peripheral neuropathy followed by renal involvement.

Treatment for cryoglobulinemia is based on the underlying cause. For those driven by PCD or LPD, clone-directed therapy is appropriate. For patients with HCV, which comprises approximately 70% to 90% of these cases, treating the underlying hepatitis is most appropriate. Sustained virologic responses can be achieved in greater than 50% of these patients. For patients not responding to antiviral therapy, rituximab and other immunosuppressants can play an important role in treating the vasculitis. Plasmapheresis can be used in patients with severe end-organ damage and/or refractory disease. Other disease modifiers including corticosteroids and cyclophosphamide can also play a role in therapy. For disease driven by autoimmunity, rituximab and corticosteroids are the best first-line option.

TEMPI Syndrome

TEMPI syndrome is a rare (22 reported cases as of December 2019) acquired disorder characterized by the features that comprise the acronym: telangiectasias; elevated erythropoietin and erythrocytosis; monoclonal gammopathy; perinephric fluid collections; and intrapulmonary shunting.[34] The underlying pathophysiology is not understood, but it is clear that plasma cell–directed therapy reverses the clinical manifestations.

TABLE 79.7 Proposed Diagnostic Criteria for TEMPI Syndrome

Major
1. Telangiectasias
2. Elevated erythropoietin and erythrocytosis
3. Monoclonal gammopathy

Minor
1. Perinephric fluid
2. Intrapulmonary shunting

Other
1. Venous thrombosis

Patients most often present with telangiectasias involving the face and upper body and erythrocytosis (see Table 79.2). Unlike the erythrocytosis of polycythemia rubra vera and of POEMS syndrome, patients with TEMPI syndrome have a high erythropoietin. Patients develop progressive hypoxia, but the underlying pulmonary shunting is not evident on high-resolution chest CT and is best demonstrated by ^{99m}Tc macro-aggregated albumin scintigraphy. The perinephric fluid collections have the same electrolyte composition as serum. Proposed diagnostic criteria are shown in Table 79.7. Unlike POEMS syndrome, there is no bias in clonality for lambda-restricted clones and there are no features of a myeloproliferative neoplasm.

Plasma cell–directed therapy appears to be useful, specifically bortezomib, daratumumab, lenalidomide, and high-dose melphalan. All of the features can improve upon achievement of a complete hematologic response.

Idiopathic Systemic Capillary Leak Syndrome (Clarkson Disease)

This devastating disease was described by Dr. Bayard Clarkson in 1960. Systemic capillary leak syndrome (SCLS) is characterized by capillary leak resulting in sudden-onset shock and anasarca caused by plasma extravasation (up to 70% of total plasma volume). The diagnostic triad is composed of the "3 Hs," hypotension, hemoconcentration, and hypoalbuminemia, which occur in the absence of secondary causes. Sixty-eight percent of adult cases of SCLS have monoclonal proteins, most commonly IgG kappa. There is no clear pathologic role for the monoclonal protein in this disorder, other than its presence in the majority of cases. A recent review provides the current understanding of the disease mechanism(s) associated with the vascular endothelial hyperpermeability in SCLS.[35]

The differential diagnosis for an acute attack includes sepsis, anaphylaxis, and hereditary angioedema. Treatment at the time

ON THE HORIZON

- Innovative diagnostics will emerge that more precisely differentiate the various forms of monoclonal gammopathies
- Novel immunotherapies are in clinical trials to treat multiple myeloma
- New approaches to therapy should eventually prove to be helpful for managing AL amyloidosis and the spectrum of the monoclonal gammopathy of clinical significance (MGCS)
- The MGCS represent a group of disorders whose pathogenic mechanisms will be unraveled in the future

of an acute attack is supportive with fluid resuscitation until the flare subsides, which typically occurs over the course of days. Empiric prophylaxis with IVIG is recommended based on the demonstration of fewer attacks with this therapy.

Immune Responses to Solid Tumors and Immune Checkpoint Therapy

Satya Das, Justin M. Balko, and Douglas B. Johnson

Harnessing the immune response to target cancer has been a long-standing and elusive goal of cancer researchers. Several early advances suggested that such an approach was possible, including Coley toxins (heat-killed Serratia directly injected into tumors), cytokine therapy (specifically high-dose interleukin-2 in melanoma and renal cell carcinoma), and hematologic stem cell transplants (for certain hematologic malignancies). Despite these proof-of-concept applications, most cancer patients lack benefit to any type of immune therapy.

Several discordant threads characterized cancer immunology research over past decades. First, the concept of cancer immune surveillance suggested that the immune system was able to suppress and eliminate nascent cancers. However, even "true believers" in this concept readily admitted that established tumors seemed unimpeded by this immune surveillance. Second, a variety of immune suppressive mechanisms were identified in tumor cells, ranging from loss of antigen-presentation machinery (e.g., loss of major-histocompatibility complex [MHC] class I) to immunosuppressive subpopulations (e.g., regulatory T cells and myeloid derived suppressor cells) to promotion of immunosuppressive factors in the tumor microenvironment (e.g., hypoxia, indolamine dioxygenase). Overcoming this gauntlet of negative regulators was thought to be a daunting challenge. Third, repeated disappointing and thoroughly negative results of numerous tumor vaccine and cytokine studies further dampened enthusiasm for immunotherapy approaches.

Still, glimmers of hope remained and convinced a dedicated group of researchers to continue searching for methods to harness the immune system to elicit effective antitumor responses. It remained clear that many, if not all, tumors harbored immunologically distinct molecular features from host tissue, including somatic mutations, cancer-testis antigens, and differentiation antigens. Furthermore, many tumors were obviously infiltrated by immune cells, suggesting that these antigens might be driving an immune response. In addition, while most vaccine studies were negative, correlative data suggested that patients were mounting an immune response, and occasionally clinical evidence of antitumor and immune activation occurred, including tumor shrinkage and development of vitiligo. Other clinical hints remained, including the durable complete responses generated by high-dose interleukin-2 (IL-2) in 5% to 8% of metastatic melanoma and renal cell carcinoma patients. Other labor intensive, cellular therapy approaches also showed promise, with phase II studies of tumor-infiltrating lymphocytes showing response rates as high as 50%. Still, the ability to routinely unlock effective antitumor immune responses remains limited.

IMMUNE CHECKPOINTS

T lymphocytes constitute a major portion of adaptive immunity. Expression of a unique T-cell receptor (TCR) is a hallmark of T cells and represents the mechanism by which they can identify pathogens and cancerous tissue. During development, each T cell obtains a unique TCR—composed of an alpha (α) and beta (β) chain arising from two independent genes—through a process called TCR V(D)J gene rearrangement (see Chapter 4). Positive and negative selection of immature T cells occurs in the thymus, ensuring that each uniquely generated TCR combination can recognize an antigen with low affinity, while not completely activating against self-antigens. Breaks or failures in this process are one of the mechanisms at play in the generation of autoimmunity.

Each unique TCR, expressed in a single T-cell clone, can bind to a cognate antigen bound to a MHC on the surface of a cell. The interaction of a TCR with its MHC-antigen complex (present on the antigen-presenting cell; signal 1) together with the binding of T-cell CD28 receptor with a co-stimulatory ligand (also present on the antigen presenting cell; signal 2) can prime T cells and prepare them for functional activation. Following this initial activation, the primed T cell can activate and eliminate other MHC-antigen-presenting cells in the absence of signal 2 through a variety of cytotoxic mechanisms, or in the case of CD4 T helper cells, secrete critical supportive cytokines required for effective adaptive immune function (Fig. 80.1).

Potent and sustained inflammation has the potential to hyperactivate T cells, expanding T-cell clones with weak affinity for self-antigens. As such, development of self-reactivity in the form of autoimmunity can be a negative downstream consequence. Thus, several safety mechanisms are programmed into the activation of adaptive immunity that aid in limiting or thwarting chronic inflammation and sustained T-cell activity, called immune checkpoints. Immune checkpoints are often induced by signaling cascades parallel or even identical to those potentiating inflammation and cytotoxic activity or are present on regulatory cells that are recruited at later stages to a site of chronic inflammation. The expression of immune checkpoints and their binding to their cognate ligands negatively regulate T-cell function.

CTLA-4

CTLA-4 was identified in 1987 by the laboratory of Pierre Golstein and was later found by the same group as having highly similar structure to CD28 (responsible for "signal 2").

However, its function as an immune checkpoint was not described until 5 years later by the laboratory of Jeffrey Bluestone, who found that a soluble CTLA-4 molecule could inhibit T-cell function. Eventually it was understood that CTLA-4 functioned by competing with CD28 for co-stimulation, resulting in suppression of priming of new T-cell clones against antigen (Fig. 80.2). James Allison later applied this principle to cancer biology, demonstrating that inhibition of the CTLA-4 signal through anti-CTLA-4 antibodies could potentiate antitumor immunity, paving the way for an entire class of therapeutic molecules in cancer treatment.[1]

While there was initial skepticism about this approach clinically, eventually a clinical trial of anti-CTLA-4 was initiated. Among 14 patients treated prior to 2003 with the agent that became ipilimumab (MDX-010), three patients experienced objective responses. This agent also was associated with a novel set of autoimmune toxicities, including colitis, hypophysitis, hepatitis, dermatitis, and others, which are discussed in depth subsequently. Several phase II studies were conducted as well, demonstrating an approximately 10% to 20% response rate in advanced melanoma and suggesting that responses were durable in nature.

The responses from these studies set the stage for two randomized phase III studies in patients with advanced or metastatic melanoma, a cancer-type with no approved therapies that had demonstrated improved survival in the metastatic setting. The first was a randomized phase III study comparing ipilim-

KEY CONCEPTS

Box A: CTLA-4 Inhibition in Cancer

- Anti-CTLA-4 antibodies are associated with relatively modest activity in most cancers, although it was the first class of agents to improve overall survival in melanoma.
- Ipilimumab demonstrated key proof of principle features of immune-checkpoint inhibitor response, including atypical responses (including growth before shrinkage), durability, and novel toxicity profiles.
- The role of ipilimumab moving forward is largely as combination therapy.

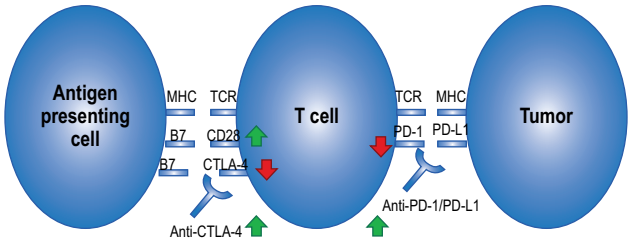

FIG. 80.2 Simplified schematic of mechanism of action of immune-checkpoint inhibitors; anti-CTLA-4 is highlighted on the left, anti-PD-1/PD-L1 on the right. *MHC*, Major histocompatibility complex; *TCR*, T-cell receptor.

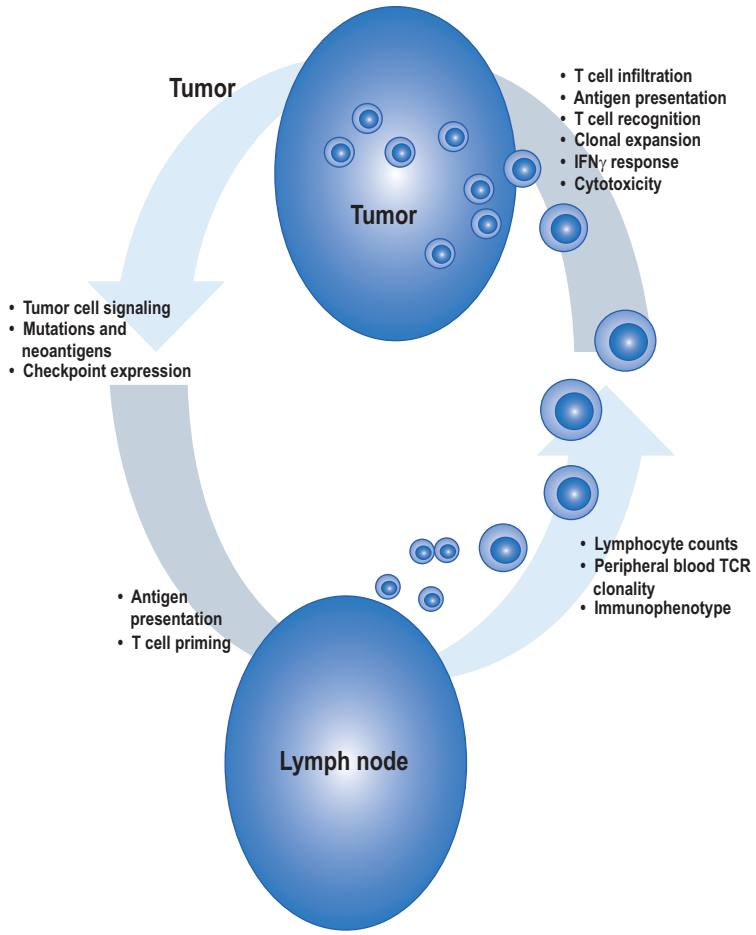

FIG. 80.1 Necessary components for generating an antitumor response against cancer. *IFN γ*, Interferon-γ; *TCR*, T-cell receptor.

umab with a gp100 vaccine and the combination in 676 patients who had already received other treatments (chemotherapy or high-dose IL-2). Both ipilimumab containing arms improved overall survival (OS) compared with chemotherapy (median survivals of approximately 10 months vs. 6 months). The second was a randomized phase III study comparing ipilimumab (given at a higher dose: 10 mg/kg) and dacarbazine (850 mg/m2) versus dacarbazine alone in patients without prior treatment. The combination arm was also associated with improved survival (median 11.2 months vs. 9.1 months), although the combination was also associated with substantially high rates of liver toxicity. These studies ultimately led to the approval of ipilimumab (at the dose of 3 mg/kg for a maximum of four doses) for metastatic melanoma.[2] A subsequent study showed that ipilimumab 10 mg/kg improved OS compared with 3 mg/kg, albeit at the cost of increased toxicities. These data show that both the efficacy and toxicity of ipilimumab appears to be dose dependent. Currently, 3 mg/kg is the approved and widely used dose of ipilimumab for metastatic melanoma.

Subsequent studies have shown that ipilimumab responses are quite distinct from chemotherapy in many cases. Similar to the experience with IL-2, many responding patients experience long-lasting benefit, with responses now lasting more than 10 years.[3] Distinct from IL-2, often partial responses or even stable disease were quite persistent. For patients who respond but later relapse, retreatment with an additional course of ipilimumab may be effective. The phenomenon of "pseudoprogression" was also identified with ipilimumab. At times, the first scan obtained after starting treatment would demonstrate increased tumor size, and patients would be considered as having progressed (Fig. 80.3). However, subsequent scans showed tumor shrinkage, and biopsies of these "progressing" lesions showed substantial immune cell infiltration. Thus, patients occasionally (5% to 10% of the time) experience tumor growth prior to shrinkage when assessed early. Accordingly, obtaining follow-up imaging for patients on ipilimumab is deferred until about 12 weeks on therapy to decrease (but not eliminate) the chances of observing this phenomenon. Novel methods of quantitating responses were generated to allow the possibility of pseudoprogression (immune-related response criteria; IRRC and immune RECIST).[4] Of note, even among patients without pseudoprogression, responses were usually relatively slow in onset and rarely occurred in patients with rapidly progressing disease.

Ipilimumab was also tested in the adjuvant setting in high-risk stage III melanoma patients who had disease that was resected. Compared with placebo, ipilimumab improved OS (hazard ratio 0.75). However, this setting and dose (10 mg/kg) was associated with high rates of severe toxicity (greater than 50% events requiring steroids and greater than 1% treatment-related deaths). Although this regimen was approved and briefly considered a standard of care, it has been supplanted by anti-PD-1 antibody therapy.

Despite the efficacy of ipilimumab in some melanoma patients, most (more than 80%) failed to respond. Moreover, relatively limited activity was observed in other cancers, including negative studies in lung and prostate cancer, suggesting that other immune targets would be needed to more fully generate an effective immune response. Thus, anti-CTLA-4 as a single agent remains primarily useful in demonstrating the potential of immune-checkpoint inhibitors to produce durable antitumor responses.

Anti-Programmed Death-1/Programmed Death-L1

The second immune-checkpoint pathway to be discovered was that of the programmed death-1 (PD-1)/programmed-death-ligand-1 interaction.

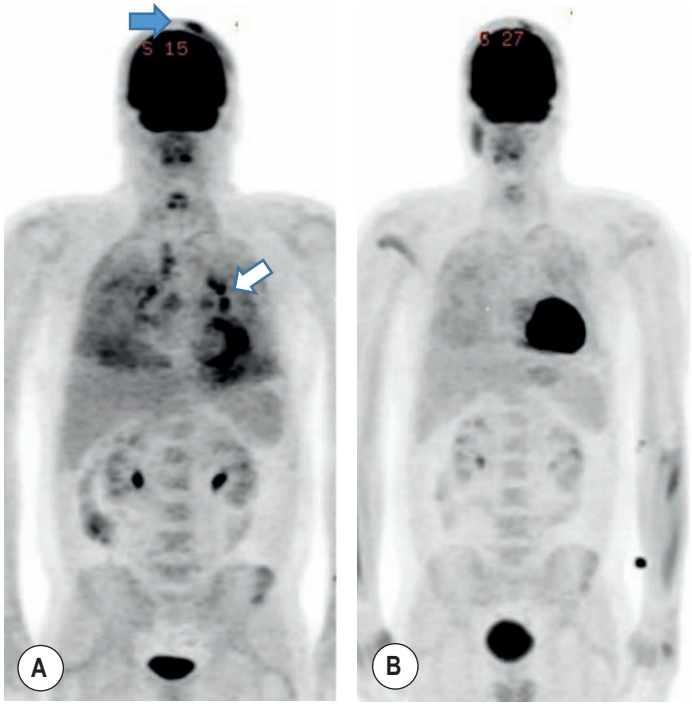

FIG. 80.3 Schematic showing pseudoprogression. Baseline scans (not shown) revealed no metastatic disease outside subcutaneous metastases in the scalp. 3-month scans *(left)*, showed increased scalp lesion *(blue arrow)* and enlarged hilar and mediastinal lymph nodes (white arrow). Biopsy of both lesions showed inflammation and no tumor cells. These lesions resolved on next imaging *(right)*.

KEY CONCEPTS

Box B: Anti-PD-1/PD-L1 Monotherapy in Cancer

- Anti-PD-1/PD-L1 antibodies are now approved in 17 different cancers, producing often durable responses in ~10% to 80% of treated patients, depending on the cancer.
- The greatest clinical activity is seen in tumors with high rates of somatic mutations, T-cell infiltration, and PD-L1 expression, which include Hodgkin lymphoma, skin cancers, and renal cell carcinoma.
- Many other solid tumors, including urothelial, lung, head and neck, and hepatocellular carcinomas have response rates in the range of 15%–20%
- Within most individual tumor types, PD-L1 expression on tumor or infiltrating immune cells correlates with higher response rates and superior clinical outcomes.

The PD-1 gene and gene-product were initially identified in the laboratory of Tasuku Honjo. The expression of PD-1 was found to be induced on T lymphocytes following activation. Upon binding of its ligand PD-L1, also identified by the Honjo and Gordon Freeman laboratories, negative signals are transmitted to the T cell, forcing it into a state of temporary, and eventually terminal, exhaustion (see Fig. 80.2). In *in vitro* and *in vivo* preclinical models, blockade of this axis using either PD-1 or PD-L1 blocking antibodies demonstrated therapeutic potential for modulating T-cell responses.[5]

Importantly, although PD-L1 may be expressed by numerous tumor types in the setting of inflammation and interferon production, as well as in mediated tolerogenic states (e.g., by the placenta during pregnancy), it is particularly highly expressed in the tumor microenvironment. Thus, one might predict that responses generated by blocking the PD-1/PD-L1 axis might be more tumor-specific than blocking the CTLA-4 axis.

Indeed, early preclinical work using murine-tumor models overexpressing PD-L1, or using knockout mice lacking the PD-L1 or PD-1 gene, demonstrated suppressive effects on tumor growth in a variety of settings. Later, more elaborate studies showed that these effects were driven by a renewal of activated T cells in the microenvironment that could elicit tumor control or even elimination. In contrast to the CTLA-4 axis which is largely thought to hold greatest activity in lymphoid tissue (e.g., tumor-draining lymph nodes and spleen), the PD-1/L1 pathway was primarily functioning as a peripheral tolerance mechanism at the site of inflammation, in this case the tumor microenvironment. These differing mechanisms of action suggested not only therapeutic potential of PD-1/L1 blockade in cancer, but also potential for combinatorial activity between the two pathways.

Anti-Programmed Death-1 in Melanoma

In view of the success of IL-2, tumor-infiltrating lymphocytes, and ipilimumab in melanoma, melanoma was a logical starting point for anti-PD-1/PD-L1 antibody trials. Early phase I data suggested response rates of greater than 30% in previously treated patients, exceeding that observed with ipilimumab. Importantly, toxicities were also less frequent than with CTLA-4 blockade, with high-grade events in 10% to 20% and requiring discontinuation in less than 5% of cases. Responses also occurred more rapidly and with lower incidence of pseudoprogression (Table 80.1 for list of FDA-approved indications for anti-PD-1 agents in cancer).

These data set the stage for several phase III trials of both nivolumab and pembrolizumab, which are briefly summarized. Patients treated with anti-PD-1 antibodies experienced statistically significant improvements in OS (median of about 24 months in initial trials), progression-free survival (PFS) (median 6 to 8 months), and objective-response rates (35% to 45%) compared with either ipilimumab or chemotherapy (depending on several different trials). Subsequent analyses have shown a 5-year survival of 44% for patients without prior treatment, with a 29% 5-year PFS.[6] Largely equivalent efficacy and toxicity profiles were observed with both pembrolizumab and nivolumab at various doses and schedules. Both agents are thought to have largely dose-independent effects and are now approved at a variety of doses and schedules.

Anti-PD-1 agents were also tested as adjuvant therapy in two phase III studies of patients with high risk, resected stage III-IV melanoma. Pembrolizumab, compared with placebo, and nivolumab, compared with ipilimumab, were both associated with superior relapse-free survival in these patients (hazard ratios 0.57 and 0.65, respectively). These agents are now standards of care for patients with high-risk, resected stage III-IV disease, and were the first anti-PD-1 agents successfully tested as adjuvant therapy.[7]

Anti-Programmed Death-1/Programmed Death-L1 in Lung Cancer

As the leading cause of cancer-related mortality, developing improved treatments in non-small-cell lung cancer (NSCLC) as well as SCLC have been major priorities. Intriguing responses were observed in initial phase I studies of nivolumab (approximately 20%), setting the stage for future studies. As second-line treatment, nivolumab was associated with improved OS compared with docetaxel (median 12.2 vs. 9.4 months in non-squamous NSCLC) in patients who previously received platinum-containing chemotherapy. Subsequently, in the first-line, pembrolizumab improved OS compared with chemotherapy in patients with NSCLC with PD-L1 expression greater than 1% (hazard ratio 0.81).[8] Nearly all the benefit, however, was in the patients with PD-L1 expression greater than 50% (median 20 months vs. 12 months). Of note, patients harboring epidermal growth factor receptor (EGFR) mutations and anaplastic lymphoma kinase gene (ALK) translocations were largely excluded from these trials, as these molecular subsets appear to have much lower rates of benefit from anti-PD-1 therapy. Thus, appropriate, molecularly-selected patients with NSCLC may receive chemotherapy-free front-line regimens. Along with chemo-immunotherapy combinations, (see Chemotherapy-containing regimens section), pembrolizumab (front-line, PD-L1$^+$) and nivolumab (second-line, irrespective of PD-L1 expression) are standard care regimens. Importantly, response rates and clinical outcomes appear largely similar in squamous vs. non-squamous NSCLC.

Although stage IV NSCLC is the largest contributor to lung cancer mortality, patients with unresectable stage III NSCLC also have very poor outcomes, with long-term cure rates of less than 15%. One phase III study assessed durvalumab (anti-PD-L1) compared with placebo following completion of chemotherapy and radiation and found prolonged survival (median 28.3 months vs. 16.2 months, hazard ratio 0.53). Importantly, pneumonitis (which can occur with both radiation and anti-PD-1/PD-L1) occurred in 4.8% of patients (compared with 2.6% of placebo-treated patients).[9] Adjuvant and neoadjuvant (e.g., treatment initiated prior to surgery) studies are ongoing for earlier stage (I and II) lung cancer.

TABLE 80.1 FDA-Approved Indications for Anti-PD-1 Antibody Monotherapy in Metastatic/Unresectable Malignancies

Drug	Disease Indication	Phase of Study [NCT Number]	Response Rate [95% CI]	Median Overall Survival (mon)
Nivolumab	First-line melanoma	Phase III [NCT01844505]	45% [39.1%–50.3%]	36.9
Pembrolizumab	First-line melanoma	Phase III [NCT01866319]	42% [38.1%–46.5%]	32.7
Nivolumab	Second-line NSCLC	Phase III (squamous) [NCT01642004] Phase III (non-squamous) [NCT01673867]	20% [14%–28%] (squamous) and 19% [15%–24%] (non-squamous)	9.2 (squamous) and 12.2 (non-squamous)
Pembrolizumab	First-line NSCLC (PD-L1 ≥ 50%)	Phase III [NCT02142738]	44.8% [36.8%–53%]	30
Nivolumab	Third-line SCLC	Phase I/II [NCT01928394]	12% [6.5%–19.5%]	4.4
Nivolumab	Second-line RCC	Phase III [NCT01668784]	25% [not mentioned]	25
Nivolumab	Second-line UCC	Phase II [NCT02387996]	19.6% [15.0%–24.9%]	8.74
Pembrolizumab	Second-line UCC	Phase III [NCT02256436]	21.2% [16.4%–26.5%]	10.3
Pembrolizumab	First-line Merkel cell carcinoma	Phase II [NCT02267603]	56% [41.3%–70%]	NR
Pembrolizumab	Any refractory MSI-H tumor	Phase II [NCT01876511]	53% [42%–64%]	NR
Cemiplimab	Cutaneous SCC not amenable to local resection	Phase I [NCT02383212] and [NCT02760498]	47% [34%–61%]	NR
Nivolumab	Later-line MSI-H CRC	Phase II [NCT02060188]	31.1% [20.8%–42.9%]	NR
Pembrolizumab	Later-line MSI-H CRC	Phase II [NCT02460198]	33% [21%–46%]	31.4
Pembrolizumab	Third-line (PD-L1 ≥ 1%) gastric and gej adenocarcinoma	Phase II [NCT02335411]	22.7% [13.8%–33.8%]	NA
Nivolumab	HCC	Phase I/II [NCT01658878]	20% [15%–26%]	NR
Nivolumab	Second-line head and neck SCC	Phase III [NCT02105636]	13.3% [9.3%–18.3%]	7.5
Pembrolizumab	Second-line head and neck SCC	Phase III [NCT02252042]	14.6% [10.4%–19.6%]	8.4
Pembrolizumab	First-line head and neck SCC (PD-L1 ≥ 1%)	Phase III [NCT02358031]	19% [not mentioned]	12.3
Nivolumab	Relapsed/refractory cHL	Phase II [NCT02181738]	69% [63%–75%]	NR
Pembrolizumab	Relapsed/refractory cHL	Phase Ib [NCT01953692]	65% [48%–79%]	NR
Pembrolizumab	Relapsed/refractory PMBCL	Phase II [NCT02576990]	45% [32%–60%]	NR
Pembrolizumab	Second-line (PD-L1 ≥ 1%) cervical carcinoma	Phase II [NCT02628067]	14.6% [7.8%–24.1%]	11

cHL, Classical Hodgkin lymphoma; *CRC*, colorectal cancer; *GEJ*, gastroesophageal junction; *mon*, months; *MSI-H*, microsatellite instability-high; *NA*, not available; *NR*, not reached; *NSCLC*, non-small cell lung cancer; *PMBCL*, primary mediastinal B-cell lymphoma; *RCC*, renal cell carcinoma; *SCC*, squamous cell carcinoma; *SCC*, squamous cell carcinoma; *SCLC*, small cell lung cancer; *UCC*, urothelial carcinoma.

SCLC remains one of the more aggressive cancers and has very poor outlook despite high initial response rates to chemotherapy. In previously treated patients, nivolumab demonstrated a response rate of 10% to 12% in initial studies, leading to emergency FDA approval of nivolumab as third-line therapy for SCLC. However, subsequent confirmatory studies failed to confirm these early promising findings, leading to withdrawal of FDA approval of nivolumab for SCLC. Mesothelioma is another treatment-refractory malignancy with poor long-term survival, particularly after failure of front-line platinum-based chemotherapy. Several small studies with pembrolizumab or nivolumab demonstrated responses in the range of 20% to 40% in patients progressing on chemotherapy.

Anti-Programmed Death-1/Programmed Death-L1 in Renal Cell Carcinoma

Along with melanoma, renal-cell carcinoma (RCC) has been classically considered among the most responsive tumors to immune therapy, including to IL-2 and interferon. Distinct from both melanoma and NSCLC, which both have a high tumor-mutation burden (a metric correlated with response to treatment, see Biomarkers section), RCC has a low/intermediate mutation burden. On the other hand, it is one of the more T-cell inflamed tumors (perhaps due to endogenous retroviral sequences which generate an immune response), which may partially explain the more immune responsive nature of this disease. Although responses to ipilimumab were infrequent, the phase I study of nivolumab demonstrated responses in 29% of previously treated RCC patients. This led to a phase III trial of nivolumab vs. everolimus in patients previously treated with anti-angiogenic therapy, which resulted in improved OS (median 25 months vs. 19.6 months, hazard ratio 0.73), with a response rate of 25%.[10] Although monotherapy remains an option, the major impact of immune therapy in RCC has been in combination regimens, both with anti-angiogenic agents and with combination ipilimumab and nivolumab (see Combination Regimens section).

Anti-Programmed Death-1/Programmed Death-L1 in Urothelial Carcinoma

Historically, urothelial carcinoma has been associated with dismal outcomes in patients who fail or are ineligible for platinum-doublet chemotherapy. Multiple randomized phase III studies, however, have now demonstrated improved OS in patients progressing on chemotherapy, showing approximately 3-month improvement in median OS and response rates in the range of 15% to 20%.[11] Five agents (nivolumab, pembrolizumab, atezolizumab, avelumab, and durvalumab) are all approved in this setting. Two phase III studies were also conducted in patients who were ineligible for first-line cisplatin-based chemotherapy. Notably, atezolizumab was not associated with improved OS compared with investigator's choice chemotherapy (although improvements were observed in PD-L1$^+$ tumors) (Table 80.2 for list of FDA approved anti-PD-L1 agents). Pembrolizumab was associated with improved OS in the front-line setting, however.

Anti-Programmed Death-1/Programmed Death-L1 in Skin Cancers

Although melanoma is the most frequently metastatic skin cancer requiring systemic therapy, Merkel-cell carcinoma (MCC), cutaneous-squamous-cell carcinoma (cuSCC), and basal-cell carcinoma may also present with locally advanced or metastatic disease. All of these tumors, with the exception of the MCCs, which are polyoma-virus associated, have extensive ultraviolet DNA damage signatures and high mutation burdens.

MCC is a neuroendocrine tumor with poor outcomes, particularly after failure of platinum-based chemotherapy. Pembrolizumab was tested as front-line therapy and was associated with a 56% response and nearly 50% 2-year PFS. Outcomes were similar in viral-positive vs. negative tumors. Avelumab (anti-PD-L1) was tested in previously treated patients and was associated with a 33% response rate; subsequent data showed a 62% response rate in untreated patients. Thus, these agents are now FDA approved and standard of care for advanced or unresectable MCC.

cuSCC is usually resectable but may occasionally present as metastatic or locally advanced disease. Cemiplimab (anti-PD-1) was associated with an approximately 50% response rate and is now an approved standard-of-care agent for this disease. Similarly, basal-cell carcinoma may require systemic therapy occasionally. Several case reports and small studies have reported responses in this disease, and phase II studies are ongoing.

Anti-PD-1/PD-L1 in GI Malignancies

Anti-PD-1 and anti-PD-L1 monotherapy has been trialed across GI malignancies, with relatively few successes.[12] The several instances where monotherapy has been effective include microsatellite-instability-high (MSI-H) colorectal adenocarcinoma, MSI-H refractory non-colorectal gastrointestinal malignancies, hepatocellular carcinoma (HCC), and gastric/gastroesophageal junction (GEJ) adenocarcinoma. In the nivolumab monotherapy cohort of the phase II Checkmate-142 trial, 74 later-line MSI-H colorectal cancer patients (54.1% with 3 or more prior lines of therapy) treated with the anti-PD-1 antibody experienced a 31.1% (20.8% to 42.9%) response rate. Median duration of response was not yet reached at the time of reporting, at which time all responding patients were alive. Median PFS and OS have not yet been reached for the cohort. In the phase II Keynote-164 trial, 63 MSI-H CRC patients (median two prior lines of treatment) were treated with pembrolizumab. The response rate was 32% with a median PFS of 4.1 months and a median OS that was not reached. Median duration of response was not reached with a duration of response of 6 months or more in 75% of responding patients.

In the landmark study[13] that led to pembrolizumab's tissue agnostic approval for refractory solid tumors, 53.4% of patients (46) had tumors of non-colorectal cancer origin. Of these patients, 58.6% (27) had GI origin primaries. Response rate in the non-colorectal cancer patients was 54% (39% to 69%). Median OS and PFS have not been reached in the study patients, with a 2-year OS rate of 64%.

Pembrolizumab garnered accelerated approval in third-line gastric/GEJ adenocarcinoma patients with tumor PD-L1 expression (CPS of 1 or greater) based on findings from the Keynote-059 study.[14] In the pembrolizumab monotherapy cohort of the phase II trial, 259 patients were treated with the anti-PD-1 antibody. Response rate in the entire cohort was 11.6% with a median duration of response of 8.4 months. Response rate in patients with PD-L1 positive tumors (CPS of 1 or greater) was 15.5% with a median response duration of 16.3 months. Specifically, in third-line PD-L1 positive patients, response rate was 22.7%.

The phase III Keynote-062 study explored pembrolizumab monotherapy versus platinum-doublet chemotherapy in treatment naive metastatic gastric/GEJ adenocarcinoma patients with PD-L1 positive (CPS of 1 or greater) tumors.[15] Patients treated with pembrolizumab demonstrated non-inferiority for OS when compared to patients treated with chemotherapy. In the MSI-H subgroup (33 patients), patients treated with pembrolizumab demonstrated markedly improved overall survival compared to patients treated with chemotherapy (12-month overall survival of 79% compared to 49%).

Nivolumab was tested in HCC patients (both with and without viral hepatitis) who had progressed on sorafenib or were intolerant of the agent in the Checkmate-040 study. In this

TABLE 80.2 FDA-Approved Indications for Anti-PD-L1 Antibody Monotherapy

Drug	Disease Indication	Phase of Study [NCT Number]	Response Rate [95% CI]	Median OS (mon)
Durvalumab	Unresectable stage III NSCLC, post-consolidation CCR	Phase III [NCT02125461]	30.0% [25.8%–34.5%]	28.3
Avelumab	Platinum-refractory UCC	Phase Ib [NCT01772004]	17% [11%–24%]	6.5
Durvalumab	Platinum-refractory UCC	Phase I/II [NCT01693562]	31% [17.6%–47.1%]	NR
Avelumab	Stage IV Merkel cell carcinoma	Phase II [NCT02155647]	62.1% [42.3%–79.3%]	NR

CCR, Concurrent chemoradiation; *mon*, months; *NSCLC*, non-small cell lung cancer; *UCC*, urothelial carcinoma.

multi-cohort phase I/II trial,[16] 262 patients with Child-Pugh A or Child-Pugh B7 liver function were treated with the anti-PD-1 drug. The response rate in treated patients was 20% (15% to 26%) and median duration of response was 9.9 months. The 9-month OS rate was 74% (67% to 79%). The results from this study granted nivolumab accelerated approval in the post-sorafenib setting in HCC patients.

Pembrolizumab was also tested in HCC patients in the single-arm phase II study Keynote-224. In this study, 104 patients with Child-Pugh A liver function received the anti-PD-1 agent. The response rate in treated patients was 17% and median OS was 12.9 months (9.7 to 15.5 months). The drug gained accelerated approval in second-line HCC patients based on findings from this study. In the confirmatory phase III study Keynote-240 of pembrolizumab versus best supportive care in HCC patients whose disease had progressed on sorafenib, pembrolizumab improved OS (HR 0.78; one-sided $P = 0.024$) and PFS (HR 0.78; one-sided $P = 0.021$) although neither of these endpoints met prespecified significance.[17]

Anti-Programmed Death-1/Programmed Death-L1 in Head and Neck Tumors

Nivolumab was initially tested in the second-line setting post-progression on platinum chemotherapy in recurrent squamous cell carcinoma of the head and neck (HNSCC).[18] Patients were randomized to nivolumab or physicians choice of chemotherapy (methotrexate, cetuximab, docetaxel). OS was longer in patients receiving the anti-PD-1 agent (HR 0.7, 97.7% CI 0.51 to 0.73; 1-year survival 36% vs. 16.6%). Nivolumab was FDA approved based on findings from the study. Pembrolizumab also obtained accelerated approval in recurrent head and neck SCC based on findings from the Keynote-012 study. In this phase 1b expansion cohort, 192 patients were treated with the anti-PD-1 agent. Of these patients 24% (47) received the checkpoint inhibitor in the second-line setting. In the entire cohort of treated patients, response rate was 18%. Similar response rates (17% and 15%) were reported between patients whose disease had progressed on prior platinum chemotherapy or patients whose disease had progressed on platinum chemotherapy plus cetuximab. Median duration of response was not reached and median OS was 8 months. The findings from this study were confirmed in the subsequent confirmatory phase III study Keynote-040. In this 495-patient study, first-line platinum progressive patients with HNSCC were randomized to pembrolizumab or standard-of-care chemotherapy. A statistically significant difference in median OS was observed in the immunotherapy treated patients (HR 0.8, 95% CI 0.65 to 0.98; 1-year survival 37% vs. 26.5%).

A portion of the Keynote-048 study tested pembrolizumab monotherapy versus cetuximab, platinum and fluorouracil triplet chemotherapy in the first-line setting for metastatic HNSCC. In patients with tumors with PD-L1 expression (CPS of 1 or greater) or PD-L1 high expression (CPS of 20 or greater), pembrolizumab was associated with a statistically significant improvement in OS (HR 0.78, 95% CI 0.64 to 0.96 [CPS $\geq$ 1] and HR 0.61, 95% CI, 0.45 to 0.83 [CPS $\geq$ 20]). These findings led to the FDA approval for pembrolizumab in first-line metastatic HNSCC patients with tumors expressing PD-L1.

Anti-Programmed Death-1/Programmed Death-L1 in Lymphoma

Nivolumab was tested in relapsed/refractory classical Hodgkin lymphoma (cHL) patients in the multi-cohort Checkmate-205 study.[19] Most patients had disease that had progressed after autologous stem cell transplant and brentuximab vedotin and had received a median of five prior lines of therapy. The response rate with nivolumab was 65% with a median duration of response of 8.7 months. Nivolumab was granted accelerated approval in patients with disease that had relapsed post-autologous transplant and post-transplant brentuximab vedotin. In the longer term follow up from the study, response rate was 65% to 73% in each cohort, median duration of response was 16.6 months, and median PFS was 14.7 months.

Pembrolizumab was trialed in relapsed/refractory cHL patients in a cohort of the phase 1b Keynote-013 trial. In this cohort, 31 cHL patients, the majority of whom had received prior autologous stem cell transplant (71%) and failed brentuximab vedotin, were treated with the anti-PD-1 agent. Response rate in treated patients was 65% with 16% of patients achieving complete responses. PFS rates at 1-year were 46%. Findings from this cohort led to the phase II Keynote-087 trial. This was a 210-patient study where most enrolled patients had progressed after autologous stem cell transplant (ASCT; 61.4%), brentuximab vedotin (71.4%), and received a median of four prior treatments. Response rate was 69%, median duration of response was not reached, and median OS was not reached in all treated patients. The 9-month OS in study patients was 96%. Pembrolizumab received accelerated approval in cHL patients who had disease that was refractory to three or more prior therapies.

Another cohort of the Keynote-13 trial explored pembrolizumab in non-Hodgkin lymphoma patients (primary mediastinal B-cell lymphoma [PMBCL] specifically). In this cohort, 18 patients received the anti-PD-1 agent. Of treated patients, 61% had received three or more lines of prior treatment and 33% had been pre-treated with ASCT. Response rate in treated patients was 41% and median duration of response was not reached. The subsequent Keynote-170 trial was a single arm phase II trial of relapsed refractory PMBCL patients. Among 53 patients whose data were reported, response rate was 45% (11% complete response) and median duration of response was not reached. Based on these data, the FDA granted accelerated approval to pembrolizumab in PMBCL patients with refractory disease or those with disease that had relapsed after two or more prior lines of therapy.

Anti-Programmed Death-1/Programmed Death-L1 in Cervical Carcinoma

Pembrolizumab was tested in patients with recurrent or metastatic cervical cancer in a cohort of the phase II basket Keynote-158 trial.[20] In this cohort, 98 patients were treated with the anti-PD-1 therapy; of these patients, 83.6% had PD-L1 positive tumors (CPS of 1 or greater) and 65.3% were treated with two or more lines of prior therapy. Across all patients, the response rate was 12.2% (6.5% to 20.4%). However, no responses were seen in patients without PD-L1 expression. Median duration of response was not reached in treated patients. Median OS was 9.4 months (7.7 to 13.1 months) and 11 months (9.1 to 14.1 months) in the entire population and patients with PD-L1 positive tumors, respectively. Based on data from this study, the FDA granted accelerated approval to pembrolizumab in patients with PD-L1-positive cervical cancer that had progressed on chemotherapy. Although nivolumab has also demonstrated anti-tumor efficacy against progressive cervical cancer in the Checkmate-358 trial, the FDA has not yet provided a decision with regard to approval for the agent in this disease space.

KEY CONCEPTS

Box C: Combination Checkpoint Blockade

- Combined PD-1/CTLA-4 blockade has demonstrated additive or synergistic activity in several cancer types, although at a cost of increased toxicity
- Anti-PD-1 plus chemotherapy has demonstrated improved survival in several cancers, including NSCLC, HNSCC, and TNBC, although the durability of the responses is unclear at this time.
- Kinase inhibitors, such as VEGF or BRAF/MEK inhibitors, also appear to provide improved efficacy in combination with anti-PD-1 antibodies.
- Numerous clinical trials testing a wide variety of combinations are underway in this rapidly evolving field.

Immunotherapy Combinations

Despite the success of anti-CTLA-4 and anti-PD-1/PD-L1 monotherapies, most cancer patients still fail to benefit from treatment. One potential method to extend the benefit of immune checkpoint inhibitors (ICIs) is to combine them with other immune, targeted chemotherapies.

The development of combination regimens that include ICI has rapidly expanded, and a comprehensive characterization of each regimen is beyond the scope of this chapter. Thus, we will primarily focus on approved regimens and highlight a few regimens that may be cornerstones of therapy in the future (Table 80.3 for list of approved combination therapies).

Immune-Immune Combinations

The most obvious combination regimen was the first approved: combined PD-1 and CTLA-4 blockade. Pre-clinical and mechanistic data suggested that the immune activation induced by each agent was non-overlapping and potentially synergistic. Further, patients who failed one class of therapy often responded to the other class following progression. Thus, after initial promising responses were observed in metastatic melanoma in phase I/II studies, a phase III study comparing nivolumab, ipilimumab, and the combination was conducted in metastatic melanoma patients. Study metrics were superior in both nivolumab containing arms, particularly in the combination for response rate (58%, 45%, and 19% for nivolumab/ipilimumab, nivolumab, and ipilimumab, respectively), PFS (median 11.5, 6.9, and 2.9 months, respectively), and OS (median not reached at 60 months, 36.9 months, and 19.9 months). The difference in OS between the combination and nivolumab was not statistically significant, although of potential clinical significance (HR 0.83, 95% CI 0.67 to 1.03; 5-year survival 52% vs. 44%), and the trial was not powered to find a difference in these arms. The increased efficacy was accompanied by increased toxicity (59% vs. 23% for high-grade toxicities).[6]

Ipilimumab and nivolumab have also improved demonstrated efficacy in other cancers. Among patients with intermediate or poor risk metastatic RCC, ipilimumab and nivolumab was superior to sunitinib in terms of OS (median not reached vs. 26.6 months, HR 0.66) and response rate (42% vs. 29%). Thus, ipilimumab and nivolumab is now a standard of care for frontline, metastatic RCC.[21]

Similarly, in NSCLC, ipilimumab and nivolumab improved outcomes for patients compared with cytotoxic chemotherapy. In untreated patients, ipilimumab and nivolumab was superior to platinum-based chemotherapy in both PD-L1$^+$ patients (median OS 17.1 months vs. 14.9 months) with a more pronounced improvement in PD-L1$^-$ patients (median OS 17.2 months vs. 12.2 months).[22] Thus, one emerging paradigm in chemotherapy-free regimens is to treat patients with PD-L1$^+$ tumors with pembrolizumab monotherapy, and patients with PD-L1$^-$ with ipilimumab and nivolumab.

TABLE 80.3 FDA-Approved Indications for Immune Checkpoint Inhibitor Combinations in Metastatic/Unresectable Malignancies

ICI Drug	Partner Drug(s)	Disease Indication	Phase of Study [NCT Number]	Response Rate [95% CI]	Median OS (Mon)
Nivolumab	Ipilimumab	First-Line Melanoma	III [NCT01844505]	57.6% [52.0%–63.2%]	NR
Nivolumab	Ipilimumab	Later-Line MSI-H CRC	II [NCT02060188]	58% [49%–67%]	NR
Nivolumab	Ipilimumab	First-Line Poor to Intermediate-Risk RCC	III [NCT02231749]	42% [37%–47%]	NR
Atezolizumab	Carboplatin and Etoposide	First-Line Extensive-Stage SCLC	III [NCT02763579]	60.2% [53.1%–67%]	12.3
Pembrolizumab	Axitinib	First-Line RCC	III [NCT02853331]	59.3% [54.5%–63.9%]	NR
Avelumab	Axitinib	First-Line RCC	III [NCT02684006]	51.4% [46.6%–56.1%]	NR
Pembrolizumab	Carboplatin and Pemetrexed	First-Line NSCLC Adenocarcinoma	III [NCT02578680]	47.6% [42.6%–52.5%]	NR
Pembrolizumab	Carboplatin and Nab-Paclitaxel/Paclitaxel	First-Line NSCLC Squamous	III [NCT02775435]	57.9% [51.9%–63.8%]	15.9
Atezolizumab	Carboplatin and Nab-Paclitaxel	First-Line NSCLC Adenocarcinoma	III [NCT02367781]	49·2% [44.5%–54·0%]	18.6
Atezolizumab	Carboplatin, Paclitaxel and Bevacizumab	First-Line NSCLC Adenocarcinoma	III [NCT02366143]	63.5% [58.2%–68.5%]	19.2
Atezolizumab	Nab-Paclitaxel	First-Line PD-L1 (≥ 1%) TNBC	III [NCT02425891]	NA	25
Pembrolizumab	Platinum and 5-FU	First-Line Head and Neck SCC	III [NCT02358031]	36% [NA]	13
Pembrolizumab	Lenvatinib	Second-Line Endometrial Cancer	II [NCT02501096]	39.6% [26.5%–54.0%]	NA

CRC, Colorectal cancer; *ICI*, immune-checkpoint inhibitor; *mon*, months; *MSI-H*, microsatellite instability-high; *NA*, not available; *NR*, not reached; *NSCLC*, non-small cell lung cancer; *RCC*, renal cell carcinoma; *SCLC*, small cell lung cancer; *TNBC*, triple-negative breast cancer.

Other cancers have also demonstrated benefit from this combination, including MSI-H colorectal cancer (response rate 55%; 24-month OS rate 74%), SCLC (response rate 22%, compared with 11.6% with nivolumab), and urothelial bladder cancer (26% to 38%). Of note, the dose of ipilimumab appears important in determining the rate of high-grade toxicities. In renal, colorectal, and lung cancer studies, ipilimumab is usually given at 1 mg/kg, compared with the 3 mg/kg dose in melanoma studies. The lower dose seems to result in 10% to 20% fewer patients experiencing high-grade toxicities (approximately 30% vs. 40% to 50%), although with both regimens approximately 1% of patients experience fatal toxicities.[23]

Other immune/immune combinations are being developed. A host of other alternative immune checkpoints, such as LAG-3, TIM-3, VISTA, B7-H3, and others have been discovered to have broadly similar roles as PD-1 or PD-L1 in suppressing T-cell function.[24] Early data for PD-1/LAG-3 blockade have shown promise in metastatic melanoma, including in anti-PD-1 progressors. T-cell co-stimulators also are thought to have great promise, as "the other side of the coin" from immune checkpoints. Inhibitors of IDO, which has many common properties to the immune checkpoints, have also been tested in combination with PD-1 blockade. Despite the anticipated promise, a phase III study of epicadostat plus pembrolizumab versus pembrolizumab alone in metastatic melanoma was negative for all prespecified endpoints. Agonist antibodies against OX40, 4-1BB activate T cells in preclinical data (both *in vitro* and *in vivo*) and produce antitumor responses. However, these agents seem to lack efficacy in early clinical trials.

Immune Checkpoint/Cytokine Combinations

The relative efficacy of IL-2 has spurred attempts to produce less toxic reformulations. Bempegaldesleukin is a pegylated recombinant IL-2 that has shown preliminary signs of efficacy with manageable toxicity (minimal hypotension and cytokine release) in combination with nivolumab in melanoma, RCC, NSCLC, and urothelial cancer. Larger studies are currently ongoing.[25] Pegilodecakin (pegylated IL-10) promoted proliferation, expansion, and reversal of exhaustion of CD8 T cells in preclinical models. Early data have suggested that pegilodecakin, in combination with pembrolizumab or nivolumab, has activity in NSCLC and RCC (greater than 40% response rates in approximately 30 patients each). This agent is associated with cytopenias rather than classical immune toxicities.[26]

Immune Checkpoint/Intratumoral Injection Combinations

Intratumoral injections have a long history in immune-oncology, dating back to Coley toxins.[27] Melanoma, with frequent cutaneous, subcutaneous, and palpable lymph node metastases, has been a particularly fertile ground for testing these agents and led to the first approved oncolytic virus. Talimogene laherparepvec (T-VEC) is a modified herpes simplex virus type one with neurovirulence components removed and the GM-CSF promoter inserted, which leads to durable responses in 15% to 25% of melanoma patients. Early phase studies have showed excellent response rates in combination with either pembrolizumab (approximately 60%) or ipilimumab (approximately 40%); a phase III study of pembrolizumab plus T-VEC versus pembrolizumab alone has completed accrual. Other oncolytic viruses are currently being developed with several early ongoing studies involving combinations of these agents with anti-PD-1/PD-L1 antibodies.

Toll-like receptor agonists also may synergize with immune checkpoint inhibitors by activating innate immunity, specifically through stimulating type 1 interferons and promoting dendritic cell maturity and activation. Early data combining TLR7/8 agonists with pembrolizumab have demonstrated response rates as high as 60% in phase II studies. Early data combining ipilimumab with a TLR9 agonist (tilsotolimod) have shown 30% to 40% response rates in patients refractory to anti-PD-1 antibodies.

Immune Checkpoint/Chemotherapy Combinations

On the surface, the idea of combining chemotherapy (and its frequent attendant steroid premedications) with ICI appears counterproductive. Specifically, one would suppose that myelosuppressive and lympholytic agents would counteract T-cell activation/reinvigoration mediated by checkpoint inhibitors. Nonetheless, there was some preclinical rationale for this approach. First, cell-death mediated by chemotherapy could augment an antitumor immune response by releasing additional immunogenic peptides or neoantigens, and by inducing immunogenic cell death (with resulting T cells and additional immune cell recruitment). Second, chemotherapy depletes protumor immune-cell populations, including myeloid-derived suppressor cells and regulatory T cells, thus potentially tipping the balance toward antitumor immunity.

Initial phase II studies in NSCLC demonstrated superior response rates for pembrolizumab and carboplatin plus pemetrexed compared with chemotherapy alone (55% vs. 29%) with only modestly increased toxicities.[28] This led to two phase III studies; pembrolizumab plus chemotherapy improved outcomes in both squamous and non-squamous NSCLC irrespective of PD-L1 status compared with chemotherapy alone. In squamous NSCLC (using carboplatin plus paclitaxel as a backbone), the triplet was associated with improved overall survival (median 15.9 months vs. 11.3 months, HR 0.64), PFS (median 6.4 months vs. 4.8 months, HR 0.56), and response rate (57.9% vs. 38.4%). In non-squamous NSCLC (using pemetrexed and platinum-based drug as chemotherapy backbone), the combination improved outcomes compared with chemotherapy for OS (12-month survival 69.2% vs. 49.4%, HR 0.49), PFS (median 8.8 months vs. 4.9 months, HR 0.52), and response rate (47.6% vs. 18.9%). In both trials, toxicities were only minimally increased with the combination. Atezolizumab, in combination with carboplatin and nab-paclitaxel, was also associated with superior OS (median 18.6 months vs. 13.9 months, HR 0.79) and PFS (median 7 months vs. 5.5 months, HR 0.64) compared with chemotherapy alone. A quadruplet combination (atezolizumab, bevacizumab, carboplatin, and paclitaxel) was also superior to bevacizumab and chemotherapy (median OS 19.2 months vs. 14.7 months, HR 0.78; median PFS 8.3 months vs. 6.8 months, HR 0.62). In addition, in SCLC, atezolizumab plus chemotherapy improved survival (median 12.3 months vs. 10.3 months, HR 0.7) and PFS (median 5.2 months vs. 4.3 months, HR 0.77) compared with chemotherapy alone. Similarly, durvalumab plus chemotherapy was associated with improved OS and PFS compared with chemotherapy alone in SCLC.[29]

Other cancers have demonstrated mixed outcomes when immune checkpoint inhibitors have been combined with chemotherapy. In untreated, metastatic, PD-L1$^+$, triple-negative breast cancer, atezolizumab plus nab-paclitaxel improved PFS

(median 7.5 months vs. 5 months, HR 0.62), and OS (median 25 months vs. 15.5 months, HR 0.62) compared with nab-paclitaxel alone in a phase III trial. In the intention-to-treat analysis (not restricted to PD-L1$^+$ tumors), there was also a trend toward improved survival (median OS 21.3 months vs. 17.6 months, HR 0.84, $P = 0.08$).[30] In another portion of previously described Keynote-048 trial, pembrolizumab plus platinum doublet chemotherapy was compared against cetuximab, cisplatin, and fluorouracil in patients with SCC of the head and neck. In the total population, patients treated with pembrolizumab plus platinum chemotherapy demonstrated improved overall survival compared to patients treated with chemotherapy plus cetuximab (HR 0.77, 95% CI 0.63 to 0.93), in addition to demonstrating improved overall survival in patients with CPS of 1 or greater and CPS of 20 or greater tumors.

The superiority analysis of the Keynote-062 trial, where treatment-naïve gastric/GEJ adenocarcinoma patients with tumor CPS of 1 or greater were treated with either pembrolizumab plus platinum doublet chemotherapy or platinum doublet chemotherapy, failed to demonstrate any survival difference between the two arms (HR 0.85, 95% CI 0.7 to 1.03). No OS difference was seen between the patient groups even in patients with tumors with CPS of 10 or greater (HR 0.85, 0.62 to 1.17). Furthermore, the grade 3/4 treatment-related toxicities were significantly greater in the combination arm than in the chemotherapy arm. Additional trials are ongoing in multiple cancer types with anti-PD-1/PD-L1 plus chemotherapy.

Immune Checkpoint/Targeted Therapy Combinations

Although "targeted therapy" is a broad category that encompasses widely divergent treatments, we will focus here on antibodies or small molecules targeting mutated proteins or cell-surface molecules harbored on or within the cancer cell. The rationale for this approach is similar to that of chemotherapy, in that an effective targeted therapy may induce cell death and potentially immune infiltration, thus potentially promoting an antitumor immune response.

The first approved immune/targeted combinations are in RCC.[31] After early data suggested that axitinib and anti-PD-1/PD-L1 treatments were tolerable and had high response rates, a phase III trial comparing pembrolizumab and axitinib with sunitinib was conducted in patients with untreated metastatic RCC. The combination arm was associated with improved survival (12-month OS 89.9% vs. 78.3%, HR 0.53) and PFS (median 15.1 months vs. 11.1 months, HR 0.69). Toxicities were slightly augmented (high-grade 75.8% vs. 70.6%), although only approximately 10% of patients had to discontinue both drugs. Similarly, avelumab and axitinib were associated with improved PFS compared with sunitinib, although no OS benefit was observed. Both combinations are now approved and are commonly used options for metastatic RCC.

Among the first attempts to combine immune and targeted agents was a small study of ipilimumab and vemurafenib for BRAF mutant melanoma.[32] This combination was associated with unacceptable hepatotoxicity. While dabrafenib and ipilimumab was more tolerable, a triplet combination of ipilimumab, dabrafenib, and trametinib was associated with several colon perforations among the first few patients treated. Several studies have now tested combinations of BRAF and MEK inhibitors and anti-PD-1 or PD-L1 agents. These studies have suggested at least additive efficacy with manageable toxicity and have led to several phase III studies of BRAF/MEK/PD-1 or PD-L1 inhibition.

Endometrial cancer has been associated with responses to immune-checkpoint inhibitors, especially in the subset of patients with MSI-H tumors. However, a recent phase II study of pembrolizumab plus lenvatinib demonstrated response rates in 38% of MSI-low patients, leading to approval in metastatic endometrial cancer with at least one prior therapy. In HCC, the anti-PD-L1 agent atezolizumab has been combined with bevacizumab in treatment-naïve patients with advanced disease. In an initial phase 1b study, 26 patients were treated with the study combination. Among 21 patients evaluable for response, the response rate was 63% (all partial responses). These findings led to the first-line randomized phase III IMbrave150 trial where patients received atezolizumab plus bevacizumab or sorafenib. A recent press release suggests the combination arm demonstrated improved PFS and OS compared to sorafenib. Although the final data are pending, this will likely establish atezolizumab plus bevacizumab as the new first-line standard-of-care in advanced HCC patients. Many other immune/targeted combinations are currently being evaluated in clinical trials, including combinations with PARP inhibitors, EGFR inhibitors, and many others.

Biomarkers of Response

ICI are not effective in all cancer patients with advanced disease. A significant need exists to better identify the patients who are more likely to respond to these agents. Thus far, efforts to identify biomarkers of response have focused primarily on tissue-based biomarkers such as PD-L1, MSI-H, and tumor mutational burden (TMB) (Fig. 80.4).

Emerging areas of interest include cell-free DNA-based biomarkers and on-treatment biomarkers including immune-related adverse events (IRAEs).

Programmed Death-L1 as a Biomarker

Across current approvals for ICI, PD-L1 expression has been found to be predictive of response in only 28.9% percent of cases.[33] Among the other cases, PD-L1 expression has largely been found not to be predictive. Further complicating the issue is that different PD-L1 thresholds, PD-L1 assays and cells upon which PD-L1 is measured have been utilized in different disease sites. In gastric/GEJ adenocarcinoma and cervical cancer patients with metastatic disease, PD-L1 expression threshold of 1% or greater on tumor cells plus immune cells (by IHC 22C3) is sufficient for patients to be treated with pembrolizumab. In patients with treatment naïve metastatic NSCLC, a PD-L1 expression threshold of 50% or greater on tumor cells (by IHC

KEY CONCEPTS

Box D: Biomarkers of Response and Toxicity

- Predicting which patients will respond to treatment remains a key challenge.
- Certain clinical parameters correlate with response, including low disease burden, lung and lymph node (vs. liver and brain) involvement, and good performance status.
- Molecular correlates of response include PD-L1 expression on tumor cells or infiltrating macrophages, high tumor mutation burden, tumor cell expression of MHC class II, and T-cell infiltration
- While these factors may be clinically useful and may help with treatment prioritization in some circumstances, more reliable biomarkers are needed to improve prediction capacity.

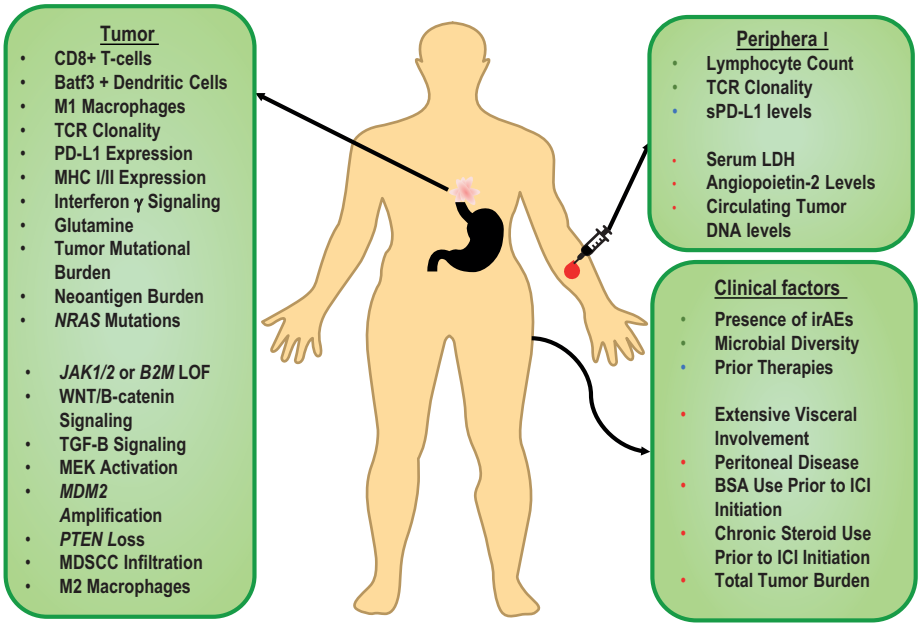

FIG. 80.4 Candidate biomarkers for response to immune-checkpoint inhibitors. *ICI*, Immune-checkpoint inhibitor; *irAEs*, immune-related adverse events; *MHC*, major-histocompatibility complex; *TCR*, T-cell receptor; *TGF-B*, transcription factor beta; *MDSCC*, myeloid-derived suppressor cell; *LDH*, lactate dehydrogenase; *BSA*, body surface area.

22C3) has been identified for the cutoff for first-line pembrolizumab therapy. In patients with cisplatin-ineligible bladder cancer, a PD-L1 expression threshold of 5% or greater on immune cells (by SP142) was used to garner approval for atezolizumab. The inter-assay and inter-disease variability make PD-L1 an inconsistent biomarker.

Microsatellite-Instability as a Biomarker

MSI-H status is perhaps the most predictive existing biomarker for ICI response. MSI-H tumors display aberrant mismatch repair, which results in spontaneous mutations; the propagation of these mutations during DNA replication leads to subsequent expression of numerous neoantigens. The volume of neoantigen expression of these tumors allows for more ready immune recognition. In the seminal publications that garnered pembrolizumab a tissue-agnostic approval across refractory advanced malignancies, the response rate in MSI-H non-colorectal cancer patients was 34.3% with a median OS of 23.5 months (95% CI, 2.4 to 4.9 months). In MSI-H colorectal cancer, ORR was 32% with a median OS not reached. Response rates with combination PD-1 and CTLA-4 blockade are even higher than with anti-PD-1 inhibitors in MSI-H colorectal cancer, although it remains to be seen whether mature OS data will also be different.[12,13]

Tumor Mutational Burden as a Biomarker

TMB is a proxy for neoantigen expression and the principle for elevated TMB predicting response to immune-checkpoint inhibitors mirrors the mechanism by which MSI-H status is thought to influence immune-therapy response. In the original study highlighting the pooled benefit of pembrolizumab in refractory MSI-H tumors in 2015, TMB was significantly associated with progression-free survival and non-statistically associated with overall survival. In a 2017 NEJM Letter to the Editor, investigators examined the relationship between TMB and response rate to anti-PD-1 or anti-PD-L1 agents in studies in 27 tumor types and found a correlation coefficient of 0.74 ($P < 0.001$).[34] Although data suggest that TMB is associated with anti-PD-1 or anti-PD-L1 response, defining an appropriate TMB cut-off and consistent means of measurement has been more problematic. In different tumor types, different TMB thresholds suggest successful prediction of checkpoint-inhibitor response. In NSCLC, this threshold has been thought to be 10 mutations/MB whereas in MSI-H colorectal cancer, this threshold may be 37 mutations/MB. Other publications suggest rather than looking at TMB by a single value across tumor types, using the top 20% of TMB values for individual cancer types can perhaps serve as a better threshold for predicting response.[35] TMB can be quantified through next-generation sequencing (NGS) based panels or through whole exome sequencing, though in clinical practice, NGS is more readily utilized. A limitation between NGS assays is the variation in number of genes sequenced by each assay and the lack of a standard conversion of TMB estimates between them. Thus, although higher TMB is suggestive of immune-checkpoint inhibitor responsiveness, the optimal means of measuring and standardizing TMB remain to be determined.[36]

Other Biomarkers

Other less prevalent biomarkers of immune-checkpoint inhibitor response include mutations in the genes encoding DNA polymerases epsilon (*POLE*) and delta 1 (*POLD1*). The polymerases play essential roles in proofreading during DNA replication, and mutations in them can lead to a hypermutated molecular phenotype. In an analysis of outcomes in patients treated with immune-checkpoint inhibitors, patients with *POLE/POLD1* mutations demonstrated significantly improved OS compared to patients without the genotype (median OS 34 months vs. 18 months, $P = 0.004$).[37] On multivariate regression, when tumor histology and MSI status were adjusted, *POLE/POLD1* mutations independently identified patients who benefit from checkpoint inhibitors.

Tumor-infiltrating lymphocytes have also been explored as a possible predictive biomarker for immune-checkpoint inhibitor response. In melanoma, an immune cell infiltrate score

(Immunoscore) from primary tumor specimens of patients who later developed metastatic disease and were treated with either anti-PD-1 or anti-CTLA-4 antibodies was assessed with checkpoint inhibitor treatment response. Among 22 patients who had primary resection specimens available, 59% had Immunoscore high tumors, while 41% had Immunoscore low tumors. Patients with Immunoscore high tumors exhibited a 5-year OS of 59.8% compared to 11.1% in patients with Immunoscore low tumors ($P = 0.024$). The predictive potential of tumor-infiltrating lymphocytes continues to be explored across other disease sites.

Toxicities from Immune-Checkpoint Inhibitors

Immune checkpoints, including PD-1, PD-L1, and CTLA-4, are key regulators of immune tolerance in the physiologic state, and thus restrain autoreactive T cells to prevent autoimmunity. When these molecules are inhibited, self-reactive T cells may be unleashed and produce inflammation. Essentially any organ system can be affected, but skin, colon, lungs, liver, and thyroid are most commonly involved. It remains unknown why particular toxicities affect individual patients. Potential triggers include: (1) shared antigens between tumor and host tissue (or perhaps mutations generating epitopes with high degrees of homology to host epitopes), (2) smoldering inflammation present in a particular organ prior to treatment (due to viral or autoimmune causes), (3) cytokine imbalances, (4) environmental exposures triggering inflammation, and (5) antibody deposition on particular organs (as has been suggested with anti-CTLA-4 hypophysitis).

The incidence of severe adverse events is approximately 20% with anti-PD-1/PD-L1 monotherapy and 50% with combination PD-1/CTLA-4 blockade; lower-grade events occur in additional patients.

Management consists of three components. First, ICIs should be discontinued (either permanently or temporarily). However, the lengthy half-lives, and still longer pharmacodynamic effects of checkpoint inhibitors, will continue to provoke further inflammation. Thus, additional immune suppression is needed for severe events. Second, glucocorticoid treatment (prednisone 1 to 2 mg/kg or equivalent) will mitigate lymphocyte-mediated inflammation. Thus far, studies have suggested that high-dose steroids do not compromise cancer-specific outcomes; however, conclusively demonstrating any effect on the cancer is challenging. One study did suggest that low-dose steroids were associated with better outcomes in patients with hypophysitis, a condition that generally does not require high-dose steroids. Toxicities that do not respond to steroids may improve with other immunosuppressants, including infliximab for colitis and mycophenolate mofetil for hepatitis. Third, disease-specific supportive management, including electrolyte and fluid replacement for colitis, oxygen supplementation for pneumonitis, and hormone replacement for endocrinopathies, may be necessary.[38] Although toxicities are usually manageable with these algorithms, between 0.35% (with anti-PD-1/PD-L1 monotherapy) and 1.2% (with combination therapy) of treated patients experience fatal toxicities.[23] While some fatalities likely stem from delays in obtaining optimal care, others are from fulminant events refractory to immunosuppression. In addition, patients with skin, joint, nerve, endocrine, and lung effects may ultimately evolve to more chronic toxicities. Most events (other than endocrinopathies), however, resolve with appropriate management. Although a full review of immune-mediated toxicities is beyond the scope of this chapter, we will review four clinically relevant toxicities that offer a window into the nature of autoimmunity generated by these agents.

KEY CONCEPTS

Box E: Toxicities of Immune-Checkpoint Inhibitors

- Clinically severe immune-related toxicities occur in 10%–20% of patients receiving anti-PD-1, and up to 50% of those with combined PD-1/CTLA-4 blockade
- These autoimmune-like phenomena may affect any organ, most commonly the skin, thyroid, colon, lungs, liver, and joints.
- Rarer events may involve the heart, brain, peripheral nervous system, and hematologic system, and may cause morbidity and mortality.
- The treatment of severe toxicities involves treatment cessation, high-dose corticosteroids, and supportive management.

Colitis

The most common serious toxicity, particularly among anti-CTLA-4 treated patients, is colitis. Although some similarities to inflammatory bowel disease exist, this entity tends to arise after several doses of therapy and is characterized by diarrhea, with much less frequent bloody stools or abdominal pain. Biopsies demonstrate infiltrating lymphocytes and neutrophils. Specific strains of microbial flora and IL-6 imbalance have been correlated with onset of colitis but have not been confirmed in larger series. Untreated colitis may lead to perforation, but this complication is usually steroid responsive. Infliximab, vedolizumab, or event fecal transplant may be effective in steroid-refractory settings.[39]

Myocarditis

Although uncommon (up to 1% to 3% with combination ipilimumab/nivolumab), clinically severe myocarditis may have fatality rates as high as 50% (Fig. 80.5). This toxicity tends to occur in the first month of therapy, frequently co-occurs with skeletal muscle inflammation (myositis) and a myasthenia-gravis-like condition, and presents with often fulminant arrhythmias.[40] The early onset and severe nature suggest that pre-existing cardiac inflammation may be the cause of this entity. Indeed, studies have suggested that shared high-frequency T-cell clones are common to both heart, skeletal muscle, and tumor. High-dose steroids may be effective but worsening and death are still common even with prompt treatment. Case reports of resolution with abatacept (CTLA-4 fusion protein) and alemtuzumab (anti-CD52) have been published, thus suggesting potentially effective rescue approaches.

Pneumonitis

Lung inflammation occurs in 3% to 5% of patients treated with anti-PD-1 agents, although subsequent series suggest up to 20% of lung cancer patients may experience pneumonitis.[41] Various radiographic appearances are possible, including interstitial thickening, groundglass opacities, and organizing pneumonia (see Fig. 80.5). Bronchoscopic evaluation reveals CD4 T cells with central memory differentiation and type 1 polarization and increased expression of IL-1B. Although pneumonitis typically improves with steroids, refractory cases causing respiratory failure do occur.

Hypophysitis

Inflammation of the pituitary gland, or hypophysitis, is a medical condition almost exclusively linked with anti-CTLA-4 therapy, which occurs in up to 10% of patients receiving combination PD-1/CTLA-4 blockade. Preclinical and correlative studies have suggested that CTLA-4 is expressed in the pituitary, particularly

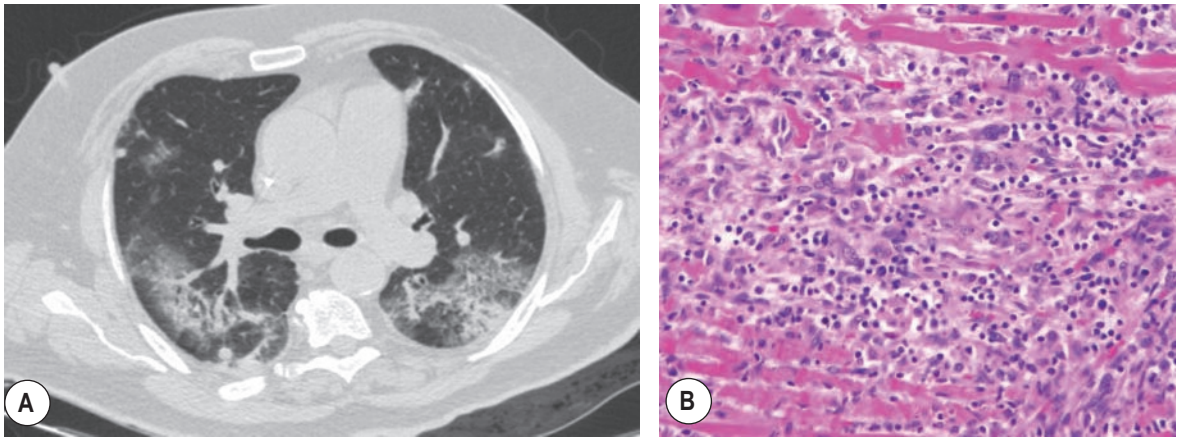

FIG. 80.5 Cross-sectional imaging showing interstitial opacities in a patient with anti-PD-1 associated pneumonitis (A). Myocardial biopsy showing extensive immune cell infiltration into myocardium in a patient with ICI-associated myocarditis (B).

on thyrotropin- and prolactin-secreting cells. With therapy, the drug is deposited on these cells, thus inducing ADCC and complement deposition similar to a type II hypersensitivity. As with other endocrine toxicities, patients may continue ICI therapy uninterrupted since the toxicity is largely irreversible due to the inflammation-induced "burnout" of all hormone-producing cells. Patients usually require lifelong glucocorticoid replacement and usually thyroid replacement.[39]

Specific Safety Considerations

Interestingly, several populations were excluded from clinical trials due to concern for either heightened immune activation and toxicity (e.g., those with pre-existing autoimmune disease or organ transplant), decreased immune function (HIV/AIDS, chronic steroid use, poor performance status), or difficulty identifying toxicities (e.g., pre-existing organ dysfunction).[42] Patients with pre-existing autoimmune disease seem to have somewhat higher risk of autoimmune adverse events, but these are manageable and associated with similar anticancer response rates as unselected patients. Patients with HIV/AIDS seem to have similar toxicity and response compared with unselected patients as well. Those with pre-existing steroid use or poor performance status have low response rates to treatment, which may reflect compromised immune function. However, these patients may respond to treatment and should not be excluded from treatment without a thoughtful consideration of risks and benefits. One near absolute contraindication to therapy is a pre-existing solid organ transplant; patients have what appears to be greater than 50% risk of graft failure with anti-PD-1 treatment. Pregnancy is also considered a very high-risk consideration, as PD-L1 is highly expressed on the placenta, and likely mediates immune exclusion from the developing fetus. Somewhat surprisingly, several case reports of healthy full-term births with excellent maternal and fetal outcomes have been reported in patients receiving anti-PD-1 treatment during pregnancy.

CAR T-Cell Therapy

Cliona M. Rooney

The ability of T cells to eliminate tumors was clear from early bone marrow transplants (BMTs) in 1965, when T-cell depletion to prevent graft versus host disease (GVHD) revealed that T cells also mediated a graft versus leukemia effect. The potential of adoptively transferred T cells to eliminate tumors was later demonstrated by the use of *in vitro* expanded tumor-infiltrating lymphocytes (TILs), demonstrating that contrary to earlier beliefs, T cells could be tumor specific. These studies led to the identification and validation first of tumor specific antigens and later of neoantigens derived from mutations.[1] However, tumor-specific T cells circulate with low frequency, and are difficult to selectively expand for therapy, especially when tumor biopsies are not available to provide a concentrated source of tumor-specific T cells. Hence, the idea to genetically modify T cells with tumor antigen-specific receptors arose. Although recombinant T-cell receptors (TCRs) have been cloned and used for tumor immunotherapy with some success, TCRs are MHC restricted and therefore must be customized to the HLA phenotype of each individual. Antibodies, by contrast, recognize unprocessed antigens and can target any tumor expressing the antigen of interest on its cell surface. Hence chimeric antigen receptors (CARs), in which antibody variable regions linked to TCR signaling domains were developed. CARs can render any T cell tumor-specific, regardless of its native TCR specificity and without the constraints of HLA restriction.

KEY CONCEPTS

Capacity of T Cells to Eliminate Tumors

- T cells
  - Eliminate tumors with high specificity and low toxicity
  - Migrate to tumor sites
  - Immense capacity to expand and persist long-term
- Any T cell can be rendered tumor-specific by expression of a chimeric antigen receptor transge

The first CARs combined the variable heavy (V_H) and light (V_L) domains of antibodies with the constant (C)α and Cβ domains of the TCR, making a two-chain CAR. The following year, Gideon Gross and Zelig Eshhar published the CAR design that is most common today.[2] In this design, the V_H and V_L antibody domains were linked in a single chain and combined with the zeta chain of the TCR to generate a cytotoxic CAR (Fig. 81.1A). Over the ensuing 30 years, CARs have been extensively modified and optimized, producing second and third generation CARs that include costimulatory endodomains that trigger proliferation and cytokine secretion, as well as tumor-cell killing (see Fig. 81.1B).[3] Of note, each CAR T cell also expresses its own TCR (Fig. 81.1C). Polyclonally activated CAR T cells comprise T cells with tens of thousands of different TCRs, the specificities of which are usually unknown. The specificity of a TCR may profoundly affect the function of the CAR if, for example, it is specific for an infecting virus.

In 2013, CAR T cells were labeled "the breakthrough of the year" by Science magazine after CAR T cells targeting CD19 produced spectacular clinical activity in patients with B-cell acute lymphocytic leukemia (ALL).[4,5] In 2017, the FDA approved CD19.CARs for the treatment of B-ALL and diffuse large B-cell lymphoma (DLBCL). CARs targeting other malignancies have been less successful, and CAR T-cell therapies face many challenges as investigators seek to increase potency without increasing toxicity. It is clear that anti-tumor efficacy requires extensive expansion of CAR T cells after infusion, migration to tumor sites, resistance to the many inhibitory cytokines and ligands encountered within the tumor microenvironment (TME), functional persistence despite a general lack of positive signals, and means to overcome heterogeneity of tumor antigen expression. These challenges will be discussed below. We will not discuss potential tumor target antigens since these have been described extensively in other reviews.[6]

KEY CONCEPTS

Tumors Develop by Avoiding the Immune Response

Tumors

- Downregulate major histocompatibility complex (MHC) molecules and target antigens
- Lack costimulatory ligands and cytokines
- Recruit inhibitory cells that express inhibitory ligands and cytokines
- High metabolism competes with T cells for glucose and amino acids
- Tumor-specific T cells are rendered anergic at the tumor site

CAR STRUCTURE

T-cell activation and proliferation requires at least three signals. The first is provided by ligation of the TCR (or CAR), the second by engagement of costimulatory receptors on T cells by complementary ligands expressed by professional antigen presenting cells (pAPCs), and the third by cytokines, produced by T cells and pAPCs. Lack of signals 2 and/or 3 can result in T-cell anergy or tolerance, and neither signal is present in most TMEs.

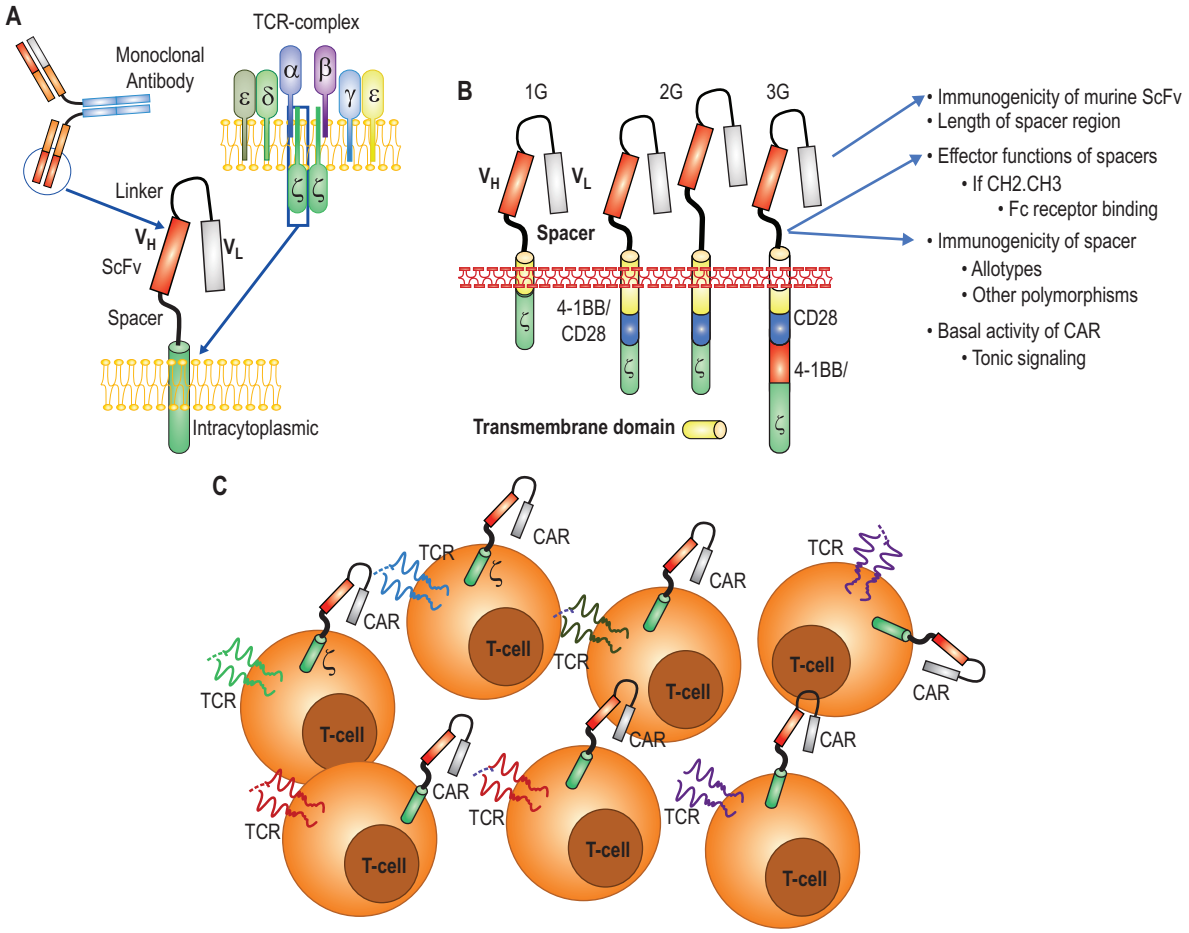

FIG. 81.1 Chimeric Antigen Receptor *(CAR)* Structure. (A) A CAR comprises an extracellular antigen-binding domain, separated by a spacer from a transmembrane domain and the intracellular ζ chain of the T-cell receptor *(TCR)*. The antigen-binding region usually combines the variable domains of the heavy and light chains of an antibody into a single-chain variable fragment *(ScFv)*. The spacer is often derived from the constant CH2 and/or CH3 regions of an antibody. The transmembrane domain shown here derives from the ζ chain. As can be seen, the structure of the CAR is very different from the structure of the TCR and, although the CAR can form a functional immune synapse, its signaling is likely to be very different from that of the TCR. (B) CAR variants. Each component of a CAR has almost infinite variants. The extracellular antigen-binding domain may be a ligand for a tumor antigen or an ScFv. The spacer may be long or short, flexible or rigid, to allow access to the cognate epitope on the targeted antigen and production of a functional immune synapse. The transmembrane domain can be substituted to improve CAR function, and may derive from the costimulatory molecule or the spacer. One or more endodomain from costimulatory molecules may be placed between the transmembrane domain and the TCR ζ chain. (C) CAR-modified T cells have dual specificity for the antigens targeted by the TCR and the CAR. There may be hundreds of thousands or more different TCRs (clonotypes) within a population of CD3 and CD28 antibody-activated CAR T cells, depending on the starting number of T cells transduced. Different TCR sequences are indicated by colors.

Inherent Problems of the Chimeric Antigen Receptor (CAR) Molecule. Most CAR ScFvs are derived from murine antibodies that are immunogenic, and may cause immune elimination. Humanization of the framework or the use of phage display libraries of human antibodies can solve this problem. Many spacers are derived from antibody constant regions that may be polymorphic, and pre-existing antibodies to constant region allotypes may limit CAR T-cell persistence. Constant regions may also bind to Fc receptors on myeloid cells, resulting in activation leading to CRS or apoptosis. The length of the spacer is important, as it determines antigen binding and may affect the avidity of the CAR. Finally, antigen-independent CAR signaling may induce T-cell differentiation and exhaustion, particularly if CARs dimerize at the cell surface or recognize T-cell antigens. *TCR*, T-cell receptor.

The first generation (1 G) of CARs combines an antigen-binding domain, usually from an antibody (but sometimes from a natural ligand), with the cytotoxic zeta chain of the TCR via a transmembrane domain and a hinge or spacer to facilitate antigen binding (see Fig. 81.1B). 1 G CAR T cells can kill tumor cells, but do not proliferate or produce cytokines in response to CAR ligation and, as a result, have been ineffective in clinical studies despite the infusion of massive T-cell numbers. Second generation (2 G) CARs include costimulatory endodomains, usually from CD28 or 4-1BB, that mediate cytokine production and proliferation and, as a result, show enhanced expansion and persistence. However, second generation CARs induce insufficient cytokines for sustained autonomous proliferation. Their true potential for both expansion and clinical efficacy is observed only when they are infused after lymphodepleting

(LD) regimens,[6, 7] most commonly cytoxan and fludarabine, that liberate the homeostatic cytokines IL7 and IL15, which maintain normal T- and B-cell numbers in the circulation.[8] After LD, these cytokines are available to infused CAR T cells, dramatically increasing their *in vivo* expansion and clinical efficacy. However, endogenous hematopoietic cells usually recover within a few weeks, reducing the availability of IL7 and IL15, so that CAR T-cell expansion peaks at one or 2 weeks, often followed by rapid decline in numbers.

The CAR is a non-physiological molecule that may present problems for its host T cell. The choice of costimulatory endodomain has been the subject of many preclinical studies. The CD28 endodomain produces more rapid effector functions than the 4-1BB domain, but the latter promotes longer T-cell persistence. Third generation CARs attempt to combine the benefits of both, and some studies indicated some clinical benefit.[7] The transmembrane and spacer domains also affect CAR function, and each single-chain variable fragment (ScFv) must be tested in different CAR backbones to optimize its function. Other factors that can limit the function and persistence of a CAR include its ability to engage the antigen and form a robust synapse with the tumor. This is affected by the avidity of the CAR for its antigen, as well as the length and rigidity of the spacer. Spacer domains that are derived from IgG CH2.CH3 domains may express allotypic antigens bound by pre-existing antibodies and may bind Fc receptors on NK cells and macrophages, resulting in activation or apoptosis of either partner. Other components of the CAR are immunogenic, such as the murine ScFv. The tendency of some CARs to dimerize, particularly if highly expressed, results in tonic signaling that can lead to T-cell differentiation and exhaustion (see Fig. 81.1B).[9] Finally, spatial and temporal differences in signaling through the TCR and the CAR are likely to affect the long-term function of CAR T cells.

Our strategy for optimizing a new ScFv is first to assess its ability to support T-cell proliferation, to kill tumor cells specifically, and to produce cytokines in response to the targeted antigen. Second, we measure the ability of the CAR to support continued T-cell proliferation and killing after repeated challenge with fresh tumor cells. Finally, the CAR is tested for its ability to eliminate tumors in murine xenograft models. Parallel experiments in which either the tumor or the T cells are labeled with bioluminescent dyes, such a luciferase, allow serial measurement of tumor responses, while bioluminescent T cells provide information of T-cell migration, expansion, and persistence, and may give an indication of tumor activity. However, preclinical models used for CAR optimization cannot predict the best outcome in patients, and even humanized mouse models cannot recreate the complex TME.

CAR T-CELL TOXICITY

Cytokine release syndrome (CRS) and immune effector cell-associated neurotoxicity syndrome (ICANs). The efficacy of CAR T cells comes at a cost. CRS is the major common severe toxicity that accompanies the logarithmic CAR T-cell expansion seen in patients with a high tumor burden and who have received LD chemotherapy. The cytokines responsible for CRS are produced not from the expanding T cells, but from macrophages that are likely activated by cytokines like GM-CSF, TNFα and IFNγ produced by activated T cells, as well as by costimulatory interactions through CD40 and CD40 ligand. Macrophage activation syndrome is often observed. CRS can be ameliorated by antibodies to IL6 (tocilizumab) and steroids. Initially, there was concern that blocking IL6 too early would inhibit the anti-tumor activity of the CAR T cells, but this has proved not to be the case; CRS is now considered an expected and manageable toxicity. ICANs is a heterogeneous group of neurotoxicities that sometimes follows CRS but does not respond to tocilizumab. Preclinical models of CRS and neurotoxicity suggested that the IL1 receptor α antagonist, anakinra, could block both CRS and neurotoxicity.[10] IL1Rα acts upstream of IL6, and anakinra blocks the production of both cytokines from macrophages. When used preemptively, this did not inhibit the anti-tumor activity of CD19.CARs. In a small clinical study at MD Anderson, anakinra alleviated ICANS in 4 of 6 patients who had received a CD19.BBz CAR for relapsed or refractory large B-cell lymphoma. It was suggested that earlier administration would likely produce better responses.[11] Several clinical trials are currently evaluating anakinra as a treatment for CRS and ICANs.

Despite the possibility of preventing CRS and ICANs, there are extensive efforts to prevent their occurrence. Ying *et al*. altered the structure of a clinically effective CD19-BBz CAR so that it produced lower levels of cytokines and proliferated less in response to CAR ligation, while retaining killing activity.[12] The authors treated 25 patients with relapsed or refractory lymphoma using escalating doses of T cells expressing the modified CAR. Six of the 11 patients on the highest dose levels receiving 2 to 4×10^8 cells achieved complete responses (CRs), two had partial responses (PRs), none of the 25 patients infused had greater than grade 1 CRS, and none had neurotoxicity.

On-target, off-tumor toxicity. Finding an antigen that is expressed on tumors but not on normal tissues is not easy. Several studies have instead targeted antigens that are overexpressed on tumor cells, hoping that normal antigen-positive tissues will escape recognition, as can be the case for therapeutic antibodies. Patients can survive complete loss of normal $CD19^+$ B cells, often with gamma globulin supplementation, and although B cells recover as CD19.CAR levels decrease, this may take more than 2 years. Other CAR target tissues are not so forgiving; fatalities have occurred in patients receiving CARs targeting HER2neu, EGFR variant 3, and carbonic anhydrase IX (CAIX).[13] A patient receiving a high dose of HER2.CAR T cells for metastatic colon cancer at the NCI experienced rapid pulmonary edema 15 minutes after infusion, progressing to multiorgan failure and death. This was considered a result of cytokine storm induced by CAR T-cell recognition of low levels of HER2 on normal lung tissue. At our center, patients with glioblastoma multiforme (GBM) and osteosarcoma received T cells expressing a HER2.28ζ CAR with a different ScFv without experiencing toxicities, but also without major clinical efficacy.[6] None of these patients received preinfusion LD, which seems to be essential for effective CAR T-cell therapy. In a follow-up phase I trial (NCT00902044), this group infused T cells modified with the same HER2.CAR after LD, and reported one CR for over 20 months in a child with metastatic rhabdomyosarcoma who received seven doses of HER2.CAR T cells.[14] This patient experienced grade 1 CRS after each of the three infusions that were preceded by LD, but no pulmonary or cardiac toxicity despite the presence of CAR T cells in the circulation for over 200 days.

Many preclinical strategies to overcome on-target, off-tumor toxicity have been described, including dialing down CAR T-cell avidity (so that only antigens overexpressed on tumor cells are recognized), or using Boolean gating, in which "and" "or" "not" gates are used to allow tumor-cell killing only when a predetermined pattern of antigens is present.[13] In such strategies, the T cell expresses two or more receptors for antigens differentially expressed on tumors and normal tissues. A cytotoxic CAR might recognize and kill target cells only in the absence of second antigen present on a healthy cell that would deliver the inhibitory signal via an inhibitory CAR. In a second strategy, a 1 G CAR is combined with a non-cytotoxic costimulatory CAR that delivers signal 2 so that the dual CAR T-cell proliferation occurs only if a tumor-specific combination of antigens is present. Many of these strategies rely on cis expression of antigens, and it is not clear if co-inhibition by local or distant healthy cells could prevent tumor-cell killing. Roybal's group designed a synthetic notch receptor that on ligation of an extracellular antigen-binding domain by an antigen in the TME, cleavage of the notch transmembrane domain releases a synthetic intracellular transcription factor to trigger expression of genes designed to enhance the anti-tumor activity of the CAR T cells.[15]

As the potency of CAR T cells is increased genetically, suicide genes that can be activated rapidly become increasingly important.[15] Suicide genes were first evaluated for the treatment of GVHD mediated by allogeneic donor T cells after hematopoietic stem cell transplantation (HSCT). Among the first was the herpes simplex thymidine kinase (*TK*) gene that could convert a nontoxic prodrug (ganciclovir) into a toxic metabolite. The problems with the viral TK enzyme are, first, that it is immunogenic, leading to unwanted immune elimination of transgenic T-cells, and second, that it precludes the use of ganciclovir as an antiviral agent. To solve these problems, we developed an inducible human caspase 9 (icasp9), in which the native dimerization domain of human caspase 9 was replaced by a modified human FK binding domain that binds with high affinity to a small molecule chemical inducer of dimerization. Administration of the dimerizer led to rapid elimination of icasp9-expressing T cells both in preclinical models and in HSCT recipients who had received icasp9-modified donor T cells to enhance immune reconstitution. The dimerizer was infused in patients who developed GVHD, resulting in a 90% decrease of transduced cells within 30 minutes and an additional one log depletion in 24 hours. Symptoms of GVHD resolved within 24 to 48 hours, and did not recur.[16]

ANTIGEN LOSS AND HETEROGENEITY

The heterogeneity of the targeted antigen expression and CAR T-cell-driven antigen loss are major challenges when a single epitope in a single antigen is targeted. Unless the antigen and indeed the epitope are crucial for tumor survival, they may easily be downregulated, and antigen loss variants can be selected in the face of CAR T-cell killing. CD19 expression is essential for B-cell survival and is expressed on all resting and activated normal and malignant B cells during all phases of development, until it is downregulated on plasma cells. As a result, 70% to 90% of patients with relapsed or refractory B-cell acute lymphoblastic leukemia (B-ALL) enter CR in response to CD19.CAR T cells. Although 30% to 60% of these patients will relapse, only 10% to 20% relapse with CD19-negative disease. Interestingly, a significant proportion of these are associated with myeloid lineage switch.

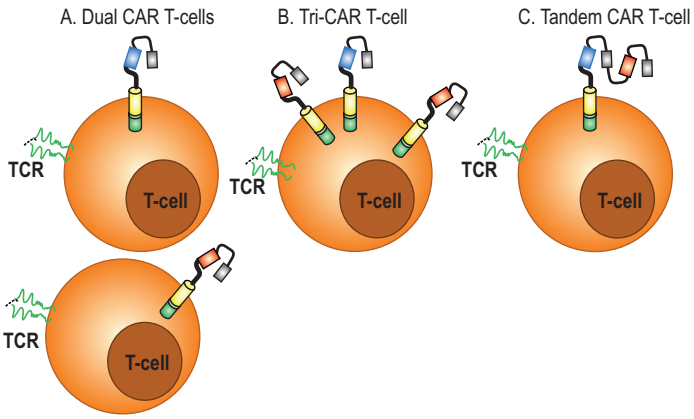

FIG. 81.2 Overcoming Tumor Heterogeneity. (A) Multiple populations of T cells, each expressing a different chimeric antigen receptor *(CAR)*, can be infused to limit antigen heterogeneity or antigen loss. This strategy is limited only by the expense of the clinical grade vectors. (B) Shows a Tri-CAR T cell that recognizes three different tumor antigens. This strategy can also increase the avidity of a weak CAR for antigens expressed at low levels. If expressed from different vectors, this strategy may be challenged by FDA limits on vector copy number. This can be overcome in (C), in which two ScFvs are linked in series in the same molecule. Tandem CARs must be designed based on biophysical properties to allow two different antigens to be targeted by a single molecule. *TCR*, T-cell receptor.

Few CAR target antigens are as stable or homogeneously expressed as CD19, and the outgrowth of antigen-negative tumor cells after CAR T-cell treatment has been shown repeatedly in preclinical tumor models. To overcome this problem, investigators have combined CARs with different specificities, expressed on the same or different T-cell populations in separate or single vectors. In innovative strategies, ScFvs have been combined with linkers to generate tandem CARs in single molecules that have proved effective in increasing the avidity of the CAR for tumors expressing low levels of antigens (Fig. 81.2). Hegde *et al.* showed that a tandem CAR with specificity for both HER2 and IL13Rα2 could engage both target antigens and produced greater control of GBM in xenograft models than T cells expressing both HER2.CAR and IL13Rα2.CAR. The same group[17] showed that while HER2, IL13 receptor α2, and ephrin-A2 were differentially expressed on primary GBM samples, a tricistronic vector encoding CARs specific for each of the three antigens was able to target most of the cells in primary tumors and showed improved tumor control in xenograft models, compared to mono-or bi-specific CAR T cells.[18]

TARGETING HEMATOLOGIC MALIGNANCIES

CAR T cells targeting B-cell malignancies have so far surpassed other CAR T cells in efficacy, likely in part because B cells are professional antigen-presenting cells that express costimulatory molecules and cytokines that help CAR T-cell persistence and expansion, and in part because they share the B-cell lymphoid niche. Although costimulatory molecules are not expressed by all B-cell tumors, they are expressed by normal B cells in lymphoid tissues and may be upregulated on tumor cells exposed to cytokines, such as IFNγ, TNFα, and GM-CSF, that are produced by

CAR T cells on ligation of the CAR. T cells naturally circulate in lymphoid tissues in which B-cell tumors are located, and therefore are more likely to access tumor tissues; lymphoid tissues provide a supportive niche for T-cell expansion. CD19.CARs have shown outstanding success for the treatment of B-ALL, B-cell lymphoma, and chronic lymphocytic leukemia, while BCMA. CARs for the treatment of multiple myeloma are also promising, producing tumor responses in up to 85% of patients including CRs in 45%.[19] CD30.CARs have also been highly effective for B-cell lymphoma, and sequential trials at our institution clearly demonstrate the added value of lymphodepletion.[7]

T-cell and myeloid-cell malignancies are more challenging, as neither population is dispensable. Most antigens expressed on T-cell malignancies are also expressed on healthy T cells, so it is often difficult even to grow the CAR.T cells. Gomes-Silva *et al.* overcame this problem by knocking out CD7 on CD7.CAR T-cells to prevent fratricide, allowing CD7.CAR T cells to target both T-cell malignancies and AML.[20] In contrast, CD5.CAR- and CD30.CAR T cells solved this problem for themselves. CD5 is downregulated on CD5 CAR T cells and CD30 is masked in *cis* by the CD30.CAR. However, without a suicide strategy, CARs targeting normal T cells may be limited to use as a bridge to transplant, which can be vital for patients who do not respond to standard therapies and hence are not eligible for HSCT. CD30 expression, in contrast, is limited to activated T cells; CD30.CAR T cells have been safe and effective for both T- and B-cell malignancies, notably without an increase in viral infections.[21] However, this might be because CD30.CAR T cells peaked at one week after infusion, and by 8 weeks represented less than 0.1% of circulating PBMCs.

CARs targeting AML antigens like CD123, CD33, and CLL1 are currently in clinical trials at multiple centers throughout the world. However, most are also expressed on healthy myeloid cells or their progenitors, so again are used as a bridge to transplant, combined with suicide switches, or even with hematopoietic stem cells knocked out for the target antigen. AML also suffers from heterogeneous antigen expression, and multitargeted CARs will likely be required to sustain remissions.

SOLID TUMORS AND THEIR IMMUNOSUPPRESSIVE MICROENVIRONMENT

CAR T cells have had less success for the treatment of solid tumors. Access to solid tumors, in contrast with hematologic malignancies, requires T cells to extravasate into non-lymphoid tissues, which, in the absence of specific chemokine signaling, is slow. CAR T cells arriving at the tumor site are often found outside the tumor core, likely blocked by the multiple inhibitory components of the TME, which includes suppressive myeloid cells, T regulatory cells, and tumor associated fibroblasts (Fig. 81.3). Within the tumor core, T cells are subject to suppressive ligands such as PD-L1, galectin 9, ceacam 1, cytokines such as TGF-β and IL-10, and metabolic inhibitors like arginase 1 and indoleamine dioxygenase (IDO), while costimulatory ligands and growth-promoting cytokines are lacking. Clinical trials targeting solid tumors have been disappointing, but PRs and rare CRs lend promise to their potential. It is now accepted that effective CAR T cells will require concomitant strategies to counter the suppressive TME. Many such strategies have been evaluated preclinically and are making their way to the clinic. These strategies include additional genetic modifications of the CAR T cells and combination with monoclonal antibodies, small molecules that inhibit suppressive myeloid cells, and oncolytic viruses.

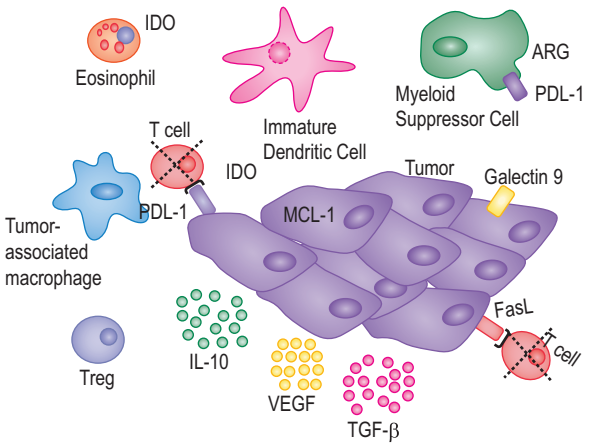

FIG. 81.3 Suppressive Components of the Tumor Microenvironment. This figure shows just some of the immunosuppressive components that promote tumor growth and metastasis, increase angiogenesis, and inhibit the infiltration and function of tumor-specific T cells. Targeting just one of these inhibitory factors may be insufficient to relieve T-cell inhibition, and inhibitors that interfere with multiple factors may be required. Multiple factors may be tackled at once, for example, by eliminating suppressive myeloid cells that exert multiple inhibitory actions. *IDO*, Indoleamine dioxygenase; *IL*, interleukin; *TGF*, transforming growth factor beta, *VEGF*, vascular endothelial growth factor.

KEY CONCEPTS

Suppressive Cells of the Tumor Microenvironment

- T regulatory cells
- Suppressive myeloid cells
  - Tumor-associated macrophages, myeloid suppressor cells, immature dendritic cells
- Express inhibitory and cytotoxic ligands
  - PD1, galactin 9, CD48, CD122, CD155, RCAS1, Fas ligand
- Produce metabolic inhibitors
  - Indoleamine dioxygenase, ARG1, adenosine, lactic acid, hypoxia

COMBATING THE TME BY GENE MODIFICATION OF CAR T CELLS

Multiple strategies to improve CAR T-cell proliferation after infusion, homing to, and functional persistence at the tumor site have been evaluated preclinically; several are in clinical trials. Homing of CAR T cells to the tumor site can be improved by co-expression of transgenic receptors for chemokines expressed within the TME, either by tumor cells or by tumor stroma. Maintaining CAR T-cell persistence after the effects of lymphodepletion have waned may be achieved by the systemic administration of cytokines, but since these have dose-limiting toxicities, several trials are evaluating CAR T cells producing cytokines either constitutively or in response to CAR ligation. To prevent excessive production of transgenic cytokines and their use by unwanted cell types, such as Tregs, constitutively active cytokine receptors can be expressed in CAR T cells (Fig. 81.4C).

TGFβ, produced by many tumors and by immunosuppressive tumor components, is an important homeostatic cytokine that potently inhibits T cells. We expressed a dominant-negative

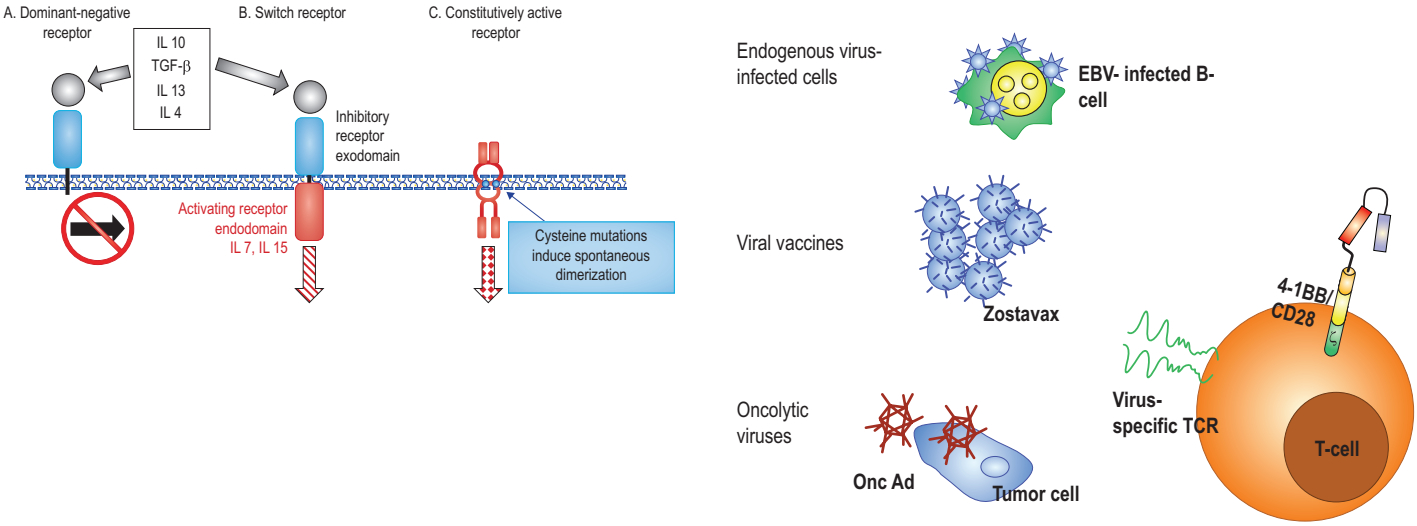

FIG. 81.4 Enhancing Chimeric Antigen Receptor (CAR) T-Cell Signaling. (A) A dominant-negative receptor for an inhibitory ligand in which the intracellular signaling domain is deleted, so the cell is not inhibited on ligand binding. In (B), the extracellular domain of an inhibitory receptor is linked to an intracellular signaling domain of an activating receptor, so activating signal can convert the inhibitory signal into a stimulatory signal. Both receptors can bind their ligand and deplete it from the environment. (C) A cysteine mutation in the transmembrane domain of the IL7 receptor leads to constitutive IL7 receptor signaling, leading to Jak1-STAT5 signaling and supporting cytokine-independent T-cell proliferation. In (D), CARs can be introduced into virus-specific T cells so that additional signaling can be induced via the virus-specific TCR. Viruses potently stimulate both adaptive and innate immunity via pattern recognition receptors on infected cells and innate responders. Hence, CAR virus-specific T cell (VST) stimulation may be provided by endogenous viruses such as EBV, viral vaccines such as the live-attenuated VZV vaccine, zostavax, or oncolytic viruses, such as adenoviruses that can also recruit CAR VSTs to the infected tumor site. *IL*, Interleukin; *TCR*, T-cell receptor.

KEY CONCEPTS

Gene Modifications to Improve CAR T-Cell Function and Persistence

- Growth-promoting cytokines or constitutive cytokine receptors
- Dominant-negative or switch receptors for inhibitory ligands
- Multiple chimeric antigen receptors to avoid antigen heterogeneity and downregulation
- Immune modulatory payloads, such as mini-antibodies to checkpoints or IL12
- Suicide strategies

TGFβ receptor (TGFβDNR) on EBV-specific T-cells (EBVSTs) and showed they were resistant to TGFβ *in vitro* and in preclinical tumor models (see Fig. 81.4A). The removal of a homeostatic mechanism from T cells was a safety concern since TGFβ knockout mice developed T-cell leukemia. However, these leukemias were restricted to IL2-independent pre-thymic T cells and the DNR was not oncogenic in mature post-thymic T cells. Indeed, TGFβDNR-EBVSTs were safe and produced CRs in patients with multiply relapsed or refractory EBV-positive lymphoma and could be detected in patients for up to 5 years.[15] Since then, the TGFβDNR has been used safely in HER2.CAR T cells, melanoma-specific TILs, and HPV-specific T cells. Clearly, there are multiple checkpoints for T-cell proliferation; removing a single one is likely to be safe and worth testing in patients with few, if any, other options. Switch receptors take this concept one step further and combine the extracellular domain for inhibitory cytokines, such as TGF-β, with the intracellular signaling domains of activating cytokines, such as IL-7 to convert an inhibitory signal into an activating signal (see Fig. 81.4B).[6] Other strategies use CAR T cells to deliver immune modulating payloads such as mini-antibodies targeting checkpoint molecules.

Sitkovsky's group has long been a proponent of targeting hypoxia and adenosine in the TME.[22] Hypoxia in the TME drives the expression of the ectoenzymes CD39, that converts extracellular ATP and ADP into AMP, while CD73 produces adenosine from AMP. Adenosine activates A2 adenosine receptors (A2AR) on T cells, activating cyclic AMP and inhibiting T-cell-receptor signaling. Several groups have demonstrated the antitumor activity of A2R antagonists on their own and in combination with other immune modulators such as checkpoint inhibitors.

KEY CONCEPTS

Combination Strategies to Improve CAR T Cells

- Molecules that eliminate suppressive myeloid cells
  - All-trans retinoic acid, Rank ligand inhibitors, bisphosphonates
- Epigenetics molecules that upregulate tumor antigens
  - Histone deacetylase inhibitor (HDAC) inhibitors, methylation inhibitors
- Oncolytic viruses that debulk tumor and produce immunomodulatory transgenes
- Checkpoint inhibitors to disable the suppressive tumor microenvironment.

THE DIFFERENTIATION STATE AND SUBSET ORIGIN OF THE INFUSED T CELLS IS IMPORTANT

Generation of CAR T cells usually involves stimulating T cells with CD3 and CCD28 antibodies, followed by transduction with vectors expressing the CAR of interest, then expansion with cytokines until sufficient T cells for the patient dose, quality control (QC) testing for eligibility, and other analyses have been obtained. Within these parameters, there are multiple variables in addition to the structure and specificity of the CAR: the source of T cells may be peripheral blood or apheresis units that may be processed into PBMCs, purified $CD3^+$ T cells, or more defined subsets. The vector may lentiviral, retroviral, or transposon and the media used may include fetal bovine serum, human serum, human platelet lysate, or serum-free formulations, containing a range of cytokines and sometimes incorporating drugs such as Akt inhibitors or IL21 to inhibit T-cell differentiation. T cells may be expanded for just a few days or for up to 2 weeks in culture ware ranging from 24 well plates, to G-Rex flasks, the Wave bioreactor, or the Prodigy. Finally, cells may be infused fresh or after cryopreservation. The relative benefits of most of these variables have not been directly compared in clinical trials, and preclinical *in vitro* or *in vivo* studies may have limited value. The commonly held theory is that the least differentiated T-cell phenotype is desirable, and that cells must proliferate and kill tumor cells over multiple *in vitro* stimulations and be effective in murine xenograft models.

It has been suggested in preclinical studies that CD19 .BB. CAR T cells with a defined T-cell subset composition of 50% central memory (cm)-derived $CD8^+$ T cells plus 50% $CD4^+$ T cells from unseparated T cells had better preclinical antitumor activity than other subset combinations. This combination was later studied in a clinical trial for adult patients with heavily pretreated NHL,[23] with half of patients receiving the CD19.BB.CAR after cytoxan and fludarabine preconditioning achieving CR. However, this study did not determine if this subset combination was more effective than unseparated subsets. To identify the characteristics of T cells with the greatest persistence and expansion after infusion, this group compared $CD8^+$ T-cell clonotypes in the infusion product with the cells detected in patient blood at different times after infusion using single cell RNA seq. T cells in the infusion product fell into four groups associated with T-cell activation, effector function, metabolism, and cell cycle, and clonotypes that persisted fell into all four groups, but most commonly derived from groups with enhanced cell cycle and effector functions. The efficacy of memory-enriched CAR T cells is currently under evaluation in several clinical trials for B-cell malignancies and brain tumors, some in combination with PD-L1 blockade (NCT02706405).

We have evaluated CARs in virus-specific T cells (VSTs) that derive from the T-cell memory compartment. We hypothesized that CAR VSTs could be boosted *in vivo* by endogenous viruses, such as EBV, viral vaccines such as VZV, or oncolytic viruses (see Fig. 81.4D), and that if infused after HSCT, they could protect against both viral infections and leukemic relapse. An intrapatient comparison of a first generation GD2.CAR expressed in EBVSTs or CD3-activated T-cells (ATCs) showed that GD2. CAR-EBVSTs circulated with higher frequency in the 6 weeks after infusion than GD2.CAR ATCs and produced CRs in 3 of 11 patients. However, neither population (CAR EBVSTs or CAR ATCs) expanded after infusion and persistence even at low levels of either population correlated positively with time to progression. We also used CD19.28.CAR T cells specific for CMV, adenovirus, and EBV (CD19.CAR-VSTs) as adjuvant therapy after HSCT for children with high risk B-ALL.[24] Patients did not receive lymphodepletion, were not lymphopenic at the time of infusion, and had circulating normal B cells. Virus reactivation correlated with much greater expansion of CAR-VSTs and loss of normal B cells, showing that viruses can expand CAR T cells via the TCR. This study also showed that in the absence of lymphodepletion, normal B cells were unable to induce substantial CD19. CAR.T-cell expansion.

INTRAPATIENT COMPARATIVE STUDIES CAN BEST IDENTIFY OPTIMAL CAR T CELLS

There are many different CAR structures and manufacturing strategies, and it remains unclear which is the best. Intra-patient comparisons, in which CAR T cells are introduced into the same patient environment, provide powerful means to compare post-infusion expansion and persistence. In addition to comparing GD2.CAR EBVSTs with GD2.CAR ATCs within patients, our group compared first (1 G) and second generation (2 G) CD19. CARs, and then 2 G with 3 G CD19.CARs. Each patient received two cell products simultaneously, and the relative expansion of each could be compared using quantitative PCR. As expected, the 2 G CD19.CARs expanded to a greater degree than 1 G CD19.CARs in patients with B-cell lymphoma, as measured by quantitative PCR of PBMCs. Although none of the six patients had CRs, the cells were infused without prior lymphodepletion. In the second study, 3 G CARs infused after lymphodepletion expanded to a greater degree than 2 G CARs, and persisted for longer, although both peaked at 2 weeks after infusion.[7] Three of 11 patients with disease at the time of infusion had CRs and three had PRs. While powerful, these studies cannot determine precisely which product had the greatest clinical benefit, since T-cell expansion and persistence within the tumor site and lymphoid tissues could not be measured and may not be accurately reflected by the cells detected in the circulation. Hence, there is a great need for improved *in vivo* imaging and biopsy analyses.

OFF-THE-SHELF CAR T CELLS

The generation of autologous CAR T cells for every patient is an expensive and lengthy process, and patients cannot always wait the 4 months usually required to generate and QC test their product. Furthermore, individual CAR T-cell products cannot be standardized, and many fail the product eligibility criteria. Allogeneic off-the-shelf CAR T cells can be generated in bulk to treat multiple patients in the shortest possible time frame. Unfortunately, alloreactive T cells in the infusion product may cause GVHD, while host alloreactive T cells can rapidly eliminate the infused cells. Despite this problem, partially HLA-matched, allogeneic VSTs have been almost as effective as stem cell donor-derived VSTS at controlling viral infections after HSCT, without causing GVHD. However, graft rejection is far more likely in fully immunocompetent hosts, and investigators have used gene-editing approaches to solve both problems. To prevent GVHD, they have deleted the TCR, and to prevent rejection, they have prevented the cell surface expression of HLA class I and II molecules. Since HLA-negative T cells are sensitive to NK-cell killing, NK-cell-inhibitory molecules such as HLA E must also be expressed. However, NK-cell-inhibitory

receptors are heterogenous, and HLA E may not block all NK cells. Our group has evaluated alternative strategies such as allodefense receptors (ADRs), which comprise CARs that recognize molecules upregulated on activated T- and NK-cells. Co-expression of an ADR of CD19.CAR T cells has proved effective in humanized xenograft models.[25] We are also evaluating VSTs as hosts for ADRs, since allogeneic VSTs with their more limited array of TCRs have not caused GVHD in multiple clinical trials.

SUMMARY

CAR T cells hold great promise as a therapy with high tumor specificity that causes few, if any, long-term toxicities. If their anti-tumor efficacy in the immunosuppressive TME can be improved, CAR T cells would be infinitely preferable to most standard chemoradiotherapies and surgery. To achieve this goal, combination strategies that enhance the potency of CAR T cells and reverse the immunosuppressive TME will likely be required. Finally, an affordable and feasible model to bring cellular immunotherapies into clinical practice is required.

Immunoglobulin Therapy: Replacement and Immunomodulation

Mark Ballow

Over 70 years ago, a cold ethanol fraction of plasma that contained an enriched fraction of gammaglobulin was used intramuscularly as passive immunotherapy for the treatment and protection of infectious pathogens and subsequently as antibody replacement therapy for patients with primary immune deficiency diseases (PIDDs). This Cohn ethanol plasma fraction of immunoglobulin G (IgG) remained the principal form of therapy until 1981 when an intravenous (IV) preparation (i.e., intravenous immunoglobulin [IVIG]) became available. Subsequently, a Swiss physician observed that thrombocytopenia resolved when patients with immune deficiency were treated with IVIG. This observation led to the use of IVIG in patients with autoimmune idiopathic thrombocytopenic purpura (ITP), and an expansion on the use of IVIG as immunomodulatory therapy in several US Food and Drug Administration (FDA) approved autoimmune disorders (Table 82.1). Most IVIG preparations are derived from plasma by the Cohn ethanol fractionation method or the Cohn-Oncley modification. IVIG products are modified to prevent the formation of IgG aggregates and to make IVIG suitable for the IV route. Excipients, such as sugars (maltose or D-sorbitol) or amino acids (glycine or L-proline), stabilize the IgG molecules from aggregation. Cold ethanol fractionation, as the first step in plasma processing, inactivates human immunodeficiency virus (HIV). Treatment with low pH, solvent and detergent, pasteurization or nanofiltration/depth filtration in combination, depending on the Ig product, is used as further five to seven steps for viral inactivation and removal. Commercial lots of IVIG are derived from approximately 15,000 donors (not to exceed 60,000 donors according to the FDA and the Plasma Protein Therapeutics Association). Each lot must contain adequate levels of antibody to measles. These products may vary slightly among manufacturers and from lot to lot; however, they are generally comparable with regard to clinical efficacy, but perhaps not tolerability. The newer Ig formulations are iso-osmolar, low-sodium, and low-IgA liquid products. The characteristics of IVIG preparations available in the United States are reviewed elsewhere (*Immune Deficiency Foundation. Immunoglobin Products. Available at: https://primaryimmune.org/about-primary-immunodeficiencies-treatments/immunoglobulin-products [Accessed on March 23, 2020]*).

TABLE 82.1 FDA-Approved Indications for Intravenous Immunoglobulin

- Primary humoral immunodeficiency disease, as replacement therapy.
- Immune thrombocytopenic purpura, to prevent severe and/or control bleeding
- Children with HIV/AIDS and recurrent infections, to prevent serious bacterial infections
- B-cell chronic lymphocytic leukemia with recurrent infections and humoral immune deficiency, to prevent bacterial infection
- Kawasaki disease, to prevent coronary artery aneurysms
- Bone marrow transplantation, to decrease risk of infection, interstitial pneumonia, and graft-versus-host disease in the first 100 days after transplantation
- Chronic inflammatory demyelinating polyneuropathy, to improve neuromuscular impairment and for maintenance therapy to prevent relapse
- Multifocal motor neuropathy, to improve neuromuscular impairment and maintenance therapy to prevent relapse

AIDS, Acquired immunodeficiency syndrome; *FDA*, US Food and Drug Administration; *HIV*, human immunodeficiency virus.

KEY CONCEPTS

Properties of Intravenous Immunoglobulin and Subcutaneous Immunoglobulin

- Plasma fractionation (first step) by cold ethanol/Cohn-Oncley modification (fraction II)
- >98% IgG; >90% monomeric IgG
- Traces of other immunoglobulins (i.e., IgA and IgM) and serum proteins
- Addition of sugar or amino acids, stabilizes IgG from aggregation
- Multiple viral inactivation/removal steps:
  - Cold ethanol fraction
  - Chromatography
  - Solvent/detergent treatment
  - Caprylate fractionation
  - Nanofiltration
  - Depth filtration
  - Pasteurization
- Intact Fc receptor important for biological function:
  - Opsonization and phagocytosis
  - Complement activation
  - Antibody-dependent cytotoxicity
- Normal half-life comparable to serum IgG
- Normal proportion of IgG subclasses
- Broad spectrum of antibodies to bacterial and viral agents

In this chapter, the application of IVIG as replacement therapy in patients with primary immune deficiency (PID) and the potential mechanisms of action of Ig therapy in the treatment of autoimmune and inflammatory diseases are reviewed. For more information on the use of Ig therapy in specific diseases, the reader is referred to an evidence-based review of the topic elsewhere.[1]

REPLACEMENT THERAPY WITH INTRAVENOUS IMMUNOGLOBULIN

Several studies have shown that pulmonary abnormalities are the most important factors associated with morbidity and mortality in patients with PIDs. The number of infections, days on antibiotic therapy, days missed from school or at work, and hospitalized days may not be sufficient indicators of adequate treatment. Therefore the improvement or maintenance of pulmonary function is an important measure of the success of therapy. Orange et al.[2] examined the impact of serum IgG trough levels on pneumonia incidence in patients with PIDDs receiving replacement IVIG therapy in a meta-analysis of published clinical studies. The results of their analysis showed that trough IgG levels increased by 121 mg/dL for every 100 mg/kg increase in dose, which resulted in a decrease in pneumonia incidence by 27%. There was a strong correlation between increasing trough IgG levels and a decrease in pneumonia. Clinicians should choose a "biological" trough level for the serum IgG related to the patient's clinical course (i.e., frequency of infections) instead of arbitrarily choosing a trough value of ≥500 mg/dL. A longitudinal study of patients with common variable immune deficiency (CVID) and X-linked agammaglobulinemia with a follow-up of 22 years showed that the dose of IVIG needed to keep a patient free of infection varied among patients, emphasizing that the goal of replacement therapy should be improvement of clinical outcome, not a specific IgG trough level.

The overall consensus among clinical immunologists is that an IVIG dose of 400 to 600 mg/kg/month is a good *starting point*. Catabolism of infused Ig varies among individuals. The rate of elimination of IgG may be higher during a period of active infection. For persons with a higher catabolism of infused IgG or more frequent infections, infusions every 3 weeks with smaller doses may be more efficacious. In the final analysis, trough levels are only a general guide, and the clinical well-being of the patient is a more important parameter. Clearly, with higher trough levels, the incidence of pneumonia and comorbid conditions (e.g., bronchiectasis and meningoencephalitis) is reduced. Pulmonary abnormalities are among the most frequent comorbid conditions associated with morbidity and mortality in patients with antibody immunodeficiencies. Periodic pulmonary function testing and careful use of high-resolution chest computed tomography should be used to monitor pulmonary function and anatomy.

For replacement therapy in patients with PID, all brands of IVIG are probably equivalent for efficacy, although there are differences in viral inactivation processes (see *Immune Deficiency Foundation. Immunoglobin Products. Available at: https://primaryimmune.org/about-primary-immunodeficiencies-treatments/immunoglobulin-products [Accessed on March 23, 2020]*). The choice of brands may be dependent on the hospital, payor, or home care formulary; the distributor availability and cost; and, most importantly, patient tolerability. The dose, manufacturer, and lot number should be recorded for each infusion to facilitate review procedures for adverse events or other consequences. It is crucial to record all side effects that occur during the infusion. It is also recommended that liver and renal functions be monitored once or twice a year. Changes in weight or growth in children or changes in clinical response or adverse events may necessitate a more frequent laboratory evaluation. More frequent serum IgG levels may be necessary for patients on home therapy, especially for those receiving subcutaneous immunoglobulin (SCIG) products to evaluate compliance.

In patients with active infection, especially patients with CVID, the initial (first) dose can be halved (i.e., 200 to 300 mg/kg) and the dose repeated 2 weeks later to achieve a full dose. To minimize cost and inconvenience, self-administration and home treatment have been used successfully. For home therapy, patients need to be selected carefully. Infusions should be done only in the presence of a responsible adult who is ready to provide assistance. Home treatment has been reported to be as effective as hospital treatment in terms of the frequency of infections, days missed from school or work, antibiotics used, and Ig level achieved. Patients receiving home treatment should be seen regularly (i.e., approximately every 6 months) to monitor clinical status, liver function, and serum IgG level.

The first description on the use of the subcutaneous (SC) route for Ig replacement therapy was published in 1980. It was reported to be safe, well tolerated, and effective in achieving adequate serum IgG levels. In a multicenter study of patients with hypogammaglobulinemia receiving SC infusions at home, a significant reduction in adverse systemic reactions with SC administratiown, compared with the intramuscular (IM) or IV administration, was observed. Anaphylactoid reactions did not occur. Studies have shown enhancements in quality-of-life measurements.[3] Local tissue reactions occur with SCIG infusions, including swelling, soreness, redness, induration, local heat, itching, and bruising. There are advantages and disadvantages for each of the routes of administration of replacement Ig therapy.

SCIG is a suitable alternative to IVIG and may present certain opportunities for optimizing care for patients with PIDD at home. SCIG is an excellent alternative to IVIG for those patients unable to tolerate the IV route of Ig replacement due to systemic side effects with IVIG administration. SCIG also leads to higher serum IgG steady-state levels and may eliminate the wear-off effects of IVIG replacement therapy.

KEY CONCEPTS

Treatment of Patients With Primary Immune Deficiency With Intravenous Immunoglobulin

- Starting dose 400–600 mg/kg every 4 weeks.
- Maintain a serum IgG trough level or steady-state serum IgG level that keeps the patient free of infections (i.e., biological trough level).
- Recent studies indicate that most patients may require a trough or steady-state level of 750–850 mg/dL.
- Higher trough levels (>800 mg/dL) may be necessary to prevent chronic pulmonary disease and enteroviral meningoencephalitis.
- Subcutaneous immunoglobulin (SCIG) offers an advantage in achieving higher steady-state plasma IgG levels.
- It may take ≥3 months to achieve a steady state after a change in dose.
- Monitor serum blood urea nitrogen (BUN) and creatinine and perform liver function tests every 12 months.
- Keep a log of dose, manufacturer, lot number, and reactions for each infusion. Reactions from IVIG are commonly due to rate of infusion, change of product, concurrent infections or inflammation or other preexisting conditions (migraine headaches).
- For patients with rate-related adverse side effects consider pretreatment with:
  - Acetaminophen
  - Diphenhydramine
  - Nonsteroidal antiinflammatory drugs (NSAIDs)
  - Corticosteroids
- Consider alternate administration of SCIG in patients with frequent systemic adverse reactions to IVIG.

CLINICAL PEARLS

Comparison of Routes of Administration of Immunoglobulin Therapy in Patients With Primary Immune Deficiency

Intravenous Route

Advantages

- Can achieve rapid plasma levels.
- Can use this route in patients with bleeding disorders.
- Can give large volumes per infusion allowing intermittent dosing (every 21–28 days).

Disadvantages

- Requires venous access and trained personnel in most situations.
- Interrupts patient's schedule for 3–5-h period.
- Often needs patient to come to a hospital or infusion center for treatment.
- May have more frequent systemic side effects in some patients than subcutaneous (SC) route.
- Large shift in immunoglobulin (Ig) levels during dosing may cause adverse effects at or just after peak and during low troughs, e.g., "wear-off" effects.

Subcutaneous Route

Advantages

- Avoids need for Intravenous (IV) access for patients with poor venous access.
- Eliminates trough levels
- Achieves a stable serum level of IgG
- May eliminate 3rd–4th week fatigue ("wear off" effect) prior to next infusion.
- Has fewer systemic adverse effects than IV route.
- Provides more flexibility for patient's (and/or parent's) schedule
- Convenient for those living at a distance from infusion center or hospital
- Helpful for young adults going to college.

Disadvantages

- Requires frequent dosing due to relatively small volume per infusion.
- Has common minor local reactions at the site of infusion.
- Depends on patient reliability.
- May require multiple infusion sites.
- Some equipment is complex, with need for an infusion pump, sterile technique.
- Loss of dexterity in the elderly may make it difficult to set up equipment and/or draw Ig out of bottles.

SCIG products are 10%, 16.5%, or 20% formulations, the former being similar in composition to IVIG products. The calculated dose for SC administration is generally 100 to 150 mg/kg weekly. Depending on the weight or body mass of the patient and the concentration of the SCIG (i.e., 10% or 20%), infusions may have to be given more frequently than every 7 days. Pharmacokinetics studies in clinical trials have suggested that upward adjustments by 37% of the IVIG dose may be needed to achieve comparable bioavailability, defined as the area under the serum concentration curve (AUC). This adjustment in dosing between IVIG and SCIG has not been mandated by European regulatory agencies, and in the United States some clinical immunologists select dosing based on optimization for prevention of infections, as noted above for the IVIG dosing. The SCIG schedule should be started 1 week after the last dose of IVIG, or in a new patient loaded with four or six doses of SCIG. Before home treatment, patients need to be instructed on the correct technique, observed to apply it under close supervision, and educated about the recognition of possible side effects. SCIG infusion is safer, better tolerated, and preferred by some patients. More detailed information about SCIG administration has been published by Wasserman.[4] Studies in Europe and Canada have shown that healthcare costs of SCIG therapy are lower compared with IVIG. It should be considered as an alternative, especially in those patients with systemic adverse reactions from IV administration. Another method for the administration of Ig by the subcutaneous route has been approved and has been referred to as *facilitated SC infusion*.[5] In this approach, human recombinant hyaluronidase is used to enhance the volume of 10% liquid Ig that can be infused into the SC space, allowing for monthly doses of Ig to be administered in one or two sites. The hyaluronidase depolymerizes the hyaluronan temporarily, allowing the Ig greater access to the lymphatics of the SC space and facilitating the absorption of Ig. This method of administration of 10% Ig has been shown in pharmacokinetic studies to result in bioavailability of 93% of the IVIG dose and thus does not require an upward adjustment factor in calculating the dose of Ig replacement.

ADVERSE EVENTS ASSOCIATED WITH INTRAVENOUS IMMUNOGLOBULIN THERAPY

Rate-Related Adverse Events

Typical rate-related adverse reactions with IVIG include tachycardia, dyspnea, chest tightness, back pain, arthralgia, myalgia, hypertension or hypotension, headache, pruritus, rash, and low-grade fever. Mild to moderate reactions occur in 5% to 15% of infusions; severe reactions occur in less than 1% of patients. Reactions may be delayed and occur several hours after the infusion. Of course, in patients with autoimmune disorders, reaction rates are higher with higher IgG doses. Patients with more profound immunodeficiency or patients with active infections also tend to have more severe reactions. Other factors that contribute to adverse reactions include change of IVIG products, concomitant infections, higher concentrations or lyophilized products, and rapid infusion rates (reviewed in the report by Stiehm).[6] The cause of the reactions is thought to be related to the anticomplementary activity of IgG aggregates in the IVIG in which immune complexes form between infused antibodies and antigens of infectious agents in the patient. The other possible mechanism is that the formation of oligomeric or polymeric IgG complexes that interact with Fc receptors and triggers the release of inflammatory mediators. These rate-related reactions occur less frequently with the newer IVIG products that are liquid and iso-osmolar. Headaches are the most frequent symptom associated with IVIG infusions, occurring in 5% to 20% of infusions and one-third of patients. Slowing the infusion rate or discontinuing therapy until symptoms subside may diminish the reaction. Pretreatment with nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen (10–15 mg/kg/dose in a child), diphenhydramine (1 mg/kg/dose in a child; 25–50 mg 12 years and older), and/or hydrocortisone (6 mg/kg/dose, maximum 100 mg) 1 hour before the infusion may prevent adverse reactions. Oral hydration prior to the infusion is often helpful. Switching IgG products may also lead to adverse events in 15% to 18% of patients and is discouraged. Persistence of side effects with IVIG infusions despite rate changes, premedication, or even product changes should be a consideration for switching to SCIG.

Central Nervous System–Related Adverse Events

Aseptic meningitis has been reported as one of the complications of IVIG, especially with large doses and rapid infusions, and in the treatment of patients with autoimmune disease.

CLINICAL PEARLS

Adverse Events Associated With Immunoglobulin Therapy

Rate-Related
- Infusion site erythema, swelling, pain, itching
- Headache
- Myalgia, back pain, arthralgia
- Malaise, fatigue
- Chills, fever
- Pruritus
- Rash, urticaria
- Nausea, vomiting
- Tachycardia
- Dyspnea, chest pain, or tightness
- Hypotension
- Hypertension

Central Nervous System
- Severe headaches
- Trigger migraine headaches
- Aseptic meningitis*

Renal
- Azotemia
- Renal failure

Thromboembolic Events[a]
- Thrombosis, cerebral infarction
- Myocardial infarction
- Pulmonary embolism

Anaphylaxis From Anti-Immunoglobulin E Antibodies to Immunoglobulin A

Other (Isolated Reports)
- Cardiac rhythm abnormalities
- Coagulopathy
- Serum sickness
- Hemolysis, related to alloantibodies to blood type A/B
- Cryoglobulinemia
- Neutropenia
- Alopecia
- Uveitis
- Noninfectious hepatitis
- Progressive neurodegeneration

*See text for predisposing risk factors

[a]See Clinical Pearls Risk Factors for Adverse Events box.

Interestingly, this rarely occurs in subjects with immunodeficiencies. Symptoms, including headache, stiff neck, and photophobia, usually develop within 24 hours after completion of the infusion and may last 3 to 5 days. Spinal fluid pleocytosis occurs in most patients. Long-term complications are minimal. The etiology of aseptic meningitis is unclear, but migraine headache has been reported as a risk factor and may be associated with recurrence despite the use of different IVIG preparations and slower rates of infusion.

Renal Adverse Events

Acute renal failure is a rare but a significant complication of IVIG treatment and has been associated in the past with products containing sucrose. Histopathological findings of acute tubular necrosis, vacuolar degeneration, and osmotic nephrosis were suggestive of osmotic injury to the proximal renal tubules. Most patients (95%) had received large doses for treatment of autoimmune diseases. The majority of the cases were treated successfully with conservative therapy, but deaths were reported in 17 patients, all of whom had serious underlying conditions. Most cases of this adverse event were associated with IVIG products containing sucrose as a stabilizer. Risk factors for this adverse reaction include pre-existing renal insufficiency, diabetes mellitus, dehydration, patient age less than 65 years, sepsis, paraproteinemia, and concomitant use of nephrotoxic agents. Newer IVIG products are using alternative stabilizers (e.g., amino acids) instead of sucrose; currently there are no Ig products in the United States that contain sucrose.

CLINICAL PEARLS

Risk Factors for Adverse Events

- Infusion issues:
  - Prior history of an infusion reaction with an immunoglobulin (Ig) product
  - First infusion in a patient with active infection or inflammation
  - Changing Ig products
  - Rapid infusion and/or large dose
- Patient factors:
  - Preexisting renal insufficiency
  - Prior history of thrombotic event
  - Autoimmune disorder
  - Diabetes mellitus
  - Older age
  - Hyperlipidemia or elevated cholesterol
  - Dehydration with volume depletion
  - Hypercoagulable state
  - Indwelling catheters
  - Paraproteinemia or other causes of hyper-viscosity
  - Cardiac or peripheral vascular disorders
  - Estrogen use
  - Smoking

Thromboembolic Events

This adverse effect was observed mainly in patients receiving large doses of IVIG for autoimmune diseases, although there had been reported cases in patients with PIDD. Patients with elevated serum viscosity (e.g., cryoglobulinemia, hypergammaglobulinemia, and hypercholesterolemia) are at risk for developing a critical increase in serum viscosity with IVIG, especially high doses that predispose them to thromboembolic events, such as myocardial infarction, stroke, deep vein thrombosis, or pulmonary embolism. Recently, a contaminating procoagulant factor (e.g., factor XIa) has been implicated in these thromboembolic events. Patients at risk are older (>65 years), on multiple drugs, and have comorbidities, such as diabetes or hypertension. Patients at risk should be well hydrated, IVIG should be administered at lower rates, and products with low sodium and an osmolality in the physiological range should be selected. Ig manufacturers have taken steps to remove or reduce procoagulant activity from their products.

Transfusion Reaction Caused by Antibodies Against Immunoglobulin A

True anaphylaxis is rare in patients with selective IgA deficiency and CVID who develop IgE antibodies to IgA after treatment with Ig; this adverse event appears to be much less frequent than originally thought. In various studies 10% to 22% of patients with CVID have IgG antibodies to IgA, but there is no correlation between the presence of these antibodies and adverse reactions. Patients with anti-IgA antibodies who have had reactions to IVIG have tolerated SCIG.[7]

Hemolysis Caused by Isoagglutinins (Anti-A and Anti-B Antibodies) in the Immunoglobulin Products

Hemolysis following the administration of Ig products is uncommon and occurs in approximately 1.6% of patients and more commonly in patients receiving large doses of Ig, e.g. autoimmune diseases. It usually does not lead to clinical adverse effects; however, if extensive, it can cause renal failure. IVIG infusion–associated hemolysis occurs from 12 hours to 10 days after the first infusion. Patients with blood type A or AB are particularly at risk. Labs include Coombs' positivity, decreases in the hemoglobin and haptoglobin levels, increase in lactate dehydrogenase, and increases in bilirubin and reticulocyte counts.[8] Currently, isoagglutinins levels in Ig products have a limit of ≤1:64 by regulatory agencies. Additional manufacturing processes have been added by some manufacturers to reduce the level of isoagglutinins in their Ig products.

Other Adverse Reactions

A number of other adverse reactions have been reported in association with IVIG infusions, as noted in Clinical Pearls 2. These side effects are usually less common and are discussed in more detail elsewhere.[6,8]

Summary: Immunoglobulin Replacement in Treatment of Immune Deficiency

Ig replacement is the mainstay of treatment for primary humoral immune deficiency. The goal of treatment is to provide a broad spectrum of antibodies to prevent infections and chronic long-term comorbid conditions such as chronic lung disease. The usual dose is 400 to 600 mg/kg/month, but this may vary among individuals, and some patients may require higher doses. A serum trough level above 500 mg/dL has been shown to be effective in the prevention of severe bacterial infections. However, recent studies have suggested that even higher doses (e.g., a "biological" trough level and achieving trough levels of IgG in the range of 750 to 900 mg/dL) may be desirable.[9] Ig can be given intramuscularly, intravenously, or subcutaneously. SCIG administration has been proven to be safe and is a good choice in some patients, especially those experiencing side effects of administration by the IV route. Generally, Ig replacement therapy is considered safe in the majority of patients. Side effects are usually mild and treatable with premedication. Good manufacturing practices, improved screening of plasma donors, testing of the source plasma, and additional viral inactivation and removal steps have made Ig a better and safer plasma-derived product. To optimize the care of patients with PIDDs, the Immune Deficiency Foundation has a helpful chart to facilitate the discussion between the patient and the healthcare provider (Table 82.2).

TABLE 82.2 Immunoglobulin Replacement Treatment Options

	Intravenous Immunoglobulin	Subcutaneous Immunoglobulin	Hyaluronidase-Facilitated Immunoglobulin
Who?	Indicated for adult and pediatric patients with PI	Indicated for adult and pediatric patients with PI	Indicated for adult patients with PI
How?	Usually administered by a nurse	Self-administered	Either self-administered or given by a nurse
Where does it go?	Infused directly into the bloodstream through a vein	Infused or injected under the skin into the subcutaneous tissues of the arms, belly, outer buttock or the thighs	Infused under the skin into the subcutaneous tissues of the belly, outer buttock or the thighs
When?	Usually given every 3–4 weeks	Can be given on a flexible schedule from daily to every 2 weeks	Can be given every 3–4 weeks
How long?	Can take 2–6 h to infuse	Can take 5 min to 2 h to infuse or inject	Can take 1–2 h to infuse
Where is it given?	Can be infused at home, in a hospital or an outpatient infusion center depending on insurance and patient preference	Usually administered in a home setting after the patient is trained to be independent	Can be infused at home or in an outpatient infusion center depending on insurance and patient preference
Side effects?	Patients can have side effects that are often related to the rate of infusion and can be treated and prevented with other medications, given before or after the treatment	Skin can be red and irritated at the site of injections. This often improves with each injection	Skin can be red and irritated at the site of injections. This often improves with each injection. The volume per injection is larger than standard subcutaneous (under the skin) injection, so the volume is more visible under the skin, and may take 48–72 h to totally absorb

MECHANISMS OF ACTION OF IMMUNOGLOBULIN THERAPY IN AUTOIMMUNE AND INFLAMMATORY DISEASES

Although we still do not understand *all* the mechanisms by which IVIG has immunomodulatory effects, knowledge of the actions of IVIG in these diseases will allow for definition of appropriate indications and schedules of administration of IVIG and the design of a new generation of IVIG products that are better able to target the immune perturbations in autoimmune and inflammatory processes. Furthermore, additional multicenter placebo-controlled clinical trials are needed to confirm clinical efficacy. A more detailed discussion of the evidence-based treatment of autoimmune and inflammatory disorders can be found elsewhere.[1] This chapter does not review the indications for IVIG therapy in these disorders; the reader is directed to other works, including comprehensive reviews and practice-based guidelines, for more details about the various indications for IVIG therapy in autoimmune and inflammatory

disorders. This section adresses the possible mechanisms of actions of Ig therapy; more than one mechanism may be important in the immune modulation of these autoimmune disorders.

KEY CONCEPTS

Mechanisms of Action of Intravenous Immunoglobulin in Autoimmune and Inflammatory Diseases

- Blockade of Fc receptors on macrophages of the reticuloendothelial system of liver and spleen.
- Restoration of idiotypic/anti-idiotypic network.
- Suppression or neutralization of cytokines by specific antibodies in the intravenous immunoglobulin (IVIG); augmenting immune modulating cytokines, e.g. interleukin (IL)-1RA, IL-10.
- Block the binding of adhesion molecules on leukocytes to vascular endothelium.
- Inhibition of complement deposition and formation of the C5b-C9 membrane-attack complex on endomysial capillaries in dermatomyositis, and interaction with effector fragments C3b and C4b of the complement cascade.
- Neutralization of microbial toxins (superantigens).
- Inhibit Fas-mediated keratinocyte apoptosis by anti-Fas antibodies (toxic epidermal necrolysis).
- Induction of apoptosis with anti-Fas antibodies at high concentrations of IVIG.
- Neutrophil apoptosis by anti-Siglec-9 antibodies in IVIG.
- IVIG saturation of FcRn receptors to accelerate degradation of IgG autoantibodies.
- Induction of inhibitory FcγRIIb receptors on effector macrophages by the binding of sialylated IgG to DC-SIGN on antigen-presenting cells via IL-33 induction of IL-4 by basophils.
- B-cell modulation through the IL-22 receptor, FcγRIIB receptor, and neuralization of BAFF cytokine (e.g., B cell–activating factor [BAFF]).
- Inhibition of T-cell proliferative responses.
- Expansion and/or activation of a population of regulatory T cells (Tregs) by enhancement of the cyclooxygenase 2 (COX-2) pathway and increasing prostaglandin E_2 (PGE_2) from dendritic cells (DCs).
- Inhibition of leukocyte recruitment into inflammatory tissues by inhibiting selectin and integrin binding.
- Downregulation of the T-helper 17 (Th17) pathway.
- Modulation of DC function through C-type lectin receptors (DCLRs): the DC-specific intercellular adhesion molecule-grabbing nonintegrin (DC-SIGN; spleen) and DCLR (lung and lymph nodes).

Blockade of Fc Receptors of the Reticuloendothelial System

ITP results from accelerated platelet destruction attributable to an immunological process resulting in bleeding that may be life threatening. Studies have shown that IVIG leads to the rapid reversal of the thrombocytopenia in ITP. Autoantibody-opsonized platelets are destroyed in the spleen and the liver by FcγR-mediated phagocytic clearance. One of the first mechanisms proposed was that IVIG blocks the FcγRs on monocytes, macrophages, and the cells of the reticuloendothelial systems to reduce immune mediated destruction of antibody-coated platelets.

Interactions of Idiotype and Anti-Idiotype as Immune Modulation

Idiotype–anti-idiotype interactions between antiplatelet glycoprotein IIb (GPIIb)/IIIa autoantibodies and IVIG may be another mechanism by which IVIG could affect autoantibody production and effector function in ITP and may be playing a role in the long-term immune effects in ITP. IVIG contains anti-idiotypic antibodies to a number of disease-associated autoantibodies including anti-DNA, anti-factor VIII, antineutrophil cytoplasmic antibody (ANCA) autoantibodies, antithyroid autoantibodies, acetylcholine receptor, and others. A proposed mechanism of action of IVIG in ANCA-positive vasculitis is binding or neutralization of the ANCA autoantibodies by anti-idiotypic antibodies in IVIG. Studies have shown that IVIG contains antibodies with idiotypic specificities that can bind and neutralize potentially pathogenic autoantibodies in autoimmune neurological diseases, such as Guillain-Barré syndrome (GBS), chronic inflammatory demyelinating polyneuropathy (CIDP), and myasthenia gravis (MG). Anti-idiotypic antibodies in IVIG directed against idiotopes on the anti-GM_1 Ig molecule block the binding of the anti-GM_1 antibodies to its target antigen. Support for a similar mechanism in acquired factor VIII deficiency comes from the fact that IgG or $F(ab')_2$ fragments in IVIG preparations are capable of binding to autoantibodies to factor VIII. Thus the anti-idiotypic antibodies in IVIG may be beneficial by restoring the idiotypic control network in these autoimmune diseases.

The Role of the FcRn Receptor on Immune Modulation

The FcRn receptor (neonatal Fc receptor) was identified as the receptor responsible for protecting IgG from catabolism in the endocytic vesicles of the endosome, and this explains the relatively long half-life of this plasma protein. IVIG may accelerate the catabolism of IgG autoantibodies by saturating these protective receptors in direct proportion to the relative concentration of exogenous plasma levels of IgG from IVIG.[10] In a rat model of immune thrombocytopenia IVIG enhanced the clearance of antiplatelet antibodies in a dose-dependent manner by saturation of the FcRn receptor. Approximately 50% of the overall effect of IVIG in ITP may be attributed to IVIG-mediated acceleration of the elimination of antiplatelet antibodies by the FcRn saturation mechanism. In FcRn knock-out mice, IVIG failed to increase the clearance of antiplatelet antibodies. Although very little data are available in human autoimmune disease to support this mechanism, recent developments of monoclonal antibodies to the FcRn receptor and high-affinity FcRn binding engineered Fc fragments are now in clinical trials.[11]

KEY CONCEPTS

Proposed Mechanisms of Action of Intravenous Immunoglobulin in Autoimmune Idiopathic Thrombocytopenic Purpura

- Fc receptor blockade of reticuloendothelial system.
- Fcγ receptor downregulation.
- Idiotype–anti-idiotype interaction between antiplatelet GPIIb/IIa autoantibodies and the anti-idiotypic antibodies in intravenous immunoglobulin.
- Activation of inhibitory receptor FcγRIIB.
- Saturation of FcRn receptor to accelerate the catabolism of antiplatelet autoantibodies.

Modulation of Immunoregulatory Function Through the Fc Receptor

The FcγRIIB receptor provides an inhibitory signal to cells through a pathway mediated by an immunoregulatory tyrosine-based inhibition motif (ITIM). Studies have shown that IVIG stimulates these inhibitory FcγRIIB receptors found on a variety of cell types,

including macrophages, B cells, and a subpopulation of T cells. Samuelsson et al.[12] using a murine model of ITP, showed that the administration of IVIG prevented platelet destruction by a pathogenic monoclonal autoantibody. Protection was associated with the induction of the expression of FcγRIIB receptors on splenic macrophages. This inhibitory FcγRIIB receptor was required for the protection of the animals against the monoclonal autoantibody, since disruption of the receptor by either genetic deletion or a blocking monoclonal antibody (mAb) reversed the therapeutic effects of IVIG. Kaneko et al.[13] showed that the inhibitory properties of IVIG were linked to the sialylation of the glycan component of the Fc fragment. The important glycan moiety in the IgG molecule is located at the asparagine (Asn^{297}) site in the second domain of the constant region. The sialylated fraction accounts for approximately 10% of the total IgG. Using a K/BxN serum-induced arthritis model in mice, Kaneko et al.[13] showed that IVIG at 1 g/kg inhibited the inflammatory arthritic process. De-glycosylated or neuraminidase-treated IVIGs were unable to inhibit this inflammation. IVIG enriched for the sialylated glycan moiety had comparable inhibitory effects on the inflammatory process at only 10% of the dose used with intact IVIG. This inhibitory activity was dependent on FcγRIIB expression on effector macrophages. An engineered recombinant/sialylated human IgG1 Fc protein had a 35-fold enhanced immune-modulating activity compared with native IVIG. A splenic marginal zone macrophage expressing the C-type lectin receptor (i.e., SIGN-R1) was required for the anti-inflammatory activity of IVIG in concert with its ability to bind to sialylated Fc domains. The interaction between sialylated IgG Fc and SIGN-R1 led to the upregulation of the inhibitory FcγRIIB receptor on effector cells. DC-SIGN (dendritic cell [DC]-specific intercellular adhesion molecule-grabbing nonintegrin), the human orthologue of SIGN-R1, may have a comparable role in the anti-inflammatory effects of IgG Fc fragment on human macrophages and DCs. Anthony et al.[14] presented data in their murine model that this immune-modulating pathway may be mediated by the production of interleukin-33 (IL-33) by DCs, which, in turn, produces IL-4 from basophils, leading to the increased expression of the FcγRIIB receptor on effector macrophages. Others, however, have questioned whether this pathway of immune modulation is important in humans.[15,16] Studies by von Maddur et al.[17] showed that basophil expansion did not occur with IVIG treatment of patients with autoimmune disease, and that IVIG did not induce IL-33 production by DC-SIGN$^+$ APC in humans. Furthermore, the effects of IVIG on the activations of DC-SIGN$^+$ human cells were independent of IgG-Fc sialylation.[15] Nevertheless, these exciting studies define, at least in mice, an important mechanism by which IVIG modulates immune processes mediated through sialylated Fc on the IgG molecule and the receptors on DCs and effector macrophages (i.e., SIGN-R1 and FcγRIIB) involved in this antiinflammatory process.

Neutralizing Antibody Activity in Intravenous Immunoglobulin Against Bacterial Toxins

Kawasaki syndrome (KS), an acute multisystem disease of unknown etiology, primarily affects infants and young children. Although KS occurs worldwide in children of all racial groups, it is most prevalent in Japan and in children of Japanese ancestry. Although the acute illness is generally self-limiting, coronary artery abnormalities related to a generalized inflammation and immune activation of small and medium-sized blood vessels develop in up to 25% of untreated patients. Although the etiology remains unknown, the clinical features and laboratory findings suggest an infectious or post-infectious process. The administration of high-dose IVIG, together with aspirin, is the standard of care in the treatment of KS.

KS is associated with marked activation of T cells, monocytes, and macrophages. On the basis of immunological and clinical features of KS overlapping with those of bacterial toxic shock-like syndrome, studies were carried out to determine if KS is associated with exposure to a superantigen, such as a bacterial toxin. Acute KS is associated with marked immune activation and increased circulating cytokine levels. Some of these cytokines elicit proinflammatory and prothrombotic responses by inducing the expression of leukocyte adhesion molecules, which localize inflammatory cells to vascular endothelial cells. The expression of endothelial–leukocyte adhesion molecules has been demonstrated in acute KS, and its downregulation correlates with favorable response to IVIG treatment. The magnitude and persistence of proinflammatory cytokine synthesis have been reported to constitute a risk for the development of coronary artery abnormalities.

IVIG has been shown to contain high titers of specific antibodies inhibitory to the activation of T cells by staphylococcal and streptococcal superantigens. These findings may account for the observation that treatment of acute KS with IVIG results in a marked reduction of macrophage and T-cell activation. In this regard, the efficacy of IVIG in suppressing the immune activation associated with KS and, more importantly, its ability to prevent the development of coronary artery abnormalities in this illness may relate to the neutralizing antibody activity of IVIG against these bacterial toxins. Toxin neutralization is unlikely to be the only beneficial effect of IVIG in KS. Blocking or neutralizing cytokines by the anti-cytokine antibodies in IVIG may modulate the local inflammatory responses of blood vessels in KS by modifying leukocyte adhesion after increasing the expression of cell-surface determinants on vascular endothelial cells.

IVIG may have therapeutic value in the treatment of patients with toxic shock syndrome secondary to *Staphylococcus aureus* or *Streptococcus pyogenes* exotoxins. In an open study by the Canadian Streptococcal Study Group IVIG appeared to be beneficial in patients with streptococcal toxic shock syndrome. In a meta-analysis of IVIG treatment of neonatal sepsis, there was a six-fold decrease in mortality. IVIG inhibits *Staphylococcus* exotoxin-induced T-cell activation and contains antibodies against exotoxins responsible for toxic shock syndrome. Great variations in neutralizing activity against streptococcal pyrogenic exotoxins can be found in different brands and even among different lots of IVIG. However, these findings suggest that it is possible to select an IVIG preparation that contains high levels of neutralizing activity against a wide variety of group A streptococcal superantigens, which could be used in the treatment of streptococcal toxic shock syndrome. The neutralizing capacity of IVIG against these bacterial superantigens is important because of their potential to stimulate the production of proinflammatory cytokines that lead to clinical disease. A number of in vitro studies have shown that IVIG can inhibit the production of, or bind to and neutralize, a number of cytokines and growth factors from various cell types.[18,19] Thus IVIG may exert its antiinflammatory effects in many different types of inflammatory diseases by interrupting or modifying a number of different steps in the inflammatory cascade, from the inhibition of effector cell function to reduction in cytokine-induced endothelial cell activation, or the "neutralization" of proinflammatory cytokines.

Modulation of Adhesion Molecules on Endothelial Cells and Antibodies in Intravenous Immunoglobulin to Cell-Surface Receptors

IVIG contains a number of natural autoantibodies that may have immune-modulating activities (e.g., antibodies to CD4, major histocompatibility complex [MHC] class I molecules, cytokines, adhesion molecules, and Siglec molecules on leukocytes and other cell-surface molecules). The "natural" antibodies in IVIG have also been shown to bind to a number of plasma and tissue proteins, including B cell–activating factor (BAFF), granulocyte macrophage–colony-stimulating factor (GM-CSF), liver antigens, and beta-amyloid peptide.[19] The binding of native IgG can be significantly increased by mild denaturing conditions (e.g., mild pH treatment and cold ethanol precipitation used during the manufacturing of IVIG).

IVIG contains specific antibodies to a 10-peptide sequence, including the RGD (Arg-Gly-ASP) motif that is expressed in adhesion molecules on a variety of cell surfaces. Most integrins bind to this RGD sequence. IVIG can inhibit leukocyte recruitment into inflammatory tissues by inhibiting selectin and integrin binding. In a mouse model of sickle cell vaso-occlusive crisis, IVIG was shown to inhibit neutrophil adhesion to the vascular endothelium, resulting in an increase in capillary blood flow and reversal of the vessel occlusion.[20] IVIG could modulate this cytokine-mediated endothelial cell activation by neutralizing the effects of the cytokines, inhibiting endothelial cell responses to the cytokines, or inhibiting the production of cytokines and growth factors. These mechanisms of IVIG may be playing an important role in preventing coronary artery abnormalities in patients with KS.

Toxic epidermal necrolysis (TEN) and Stevens-Johnson syndrome (SJS) are severe drug-induced skin diseases. TEN results in apoptotic epidermal cell death, in which there is separation of large areas of the skin at the epidermal junction, producing the appearance of scalded skin. Keratinocyte apoptosis that precedes epidermal detachment is an early event in TEN. A number of drugs, including sulfonamides, anticonvulsants, and NSAIDs, can cause TEN and SJS. The mortality rate can be as high as 30%. Viard et al.[21] studied serum samples from patients with TEN and found that the sera of these patients had very high levels of soluble Fas ligand (sFasL). Keratinocytes normally express the death receptor Fas. The keratinocytes of patients with TEN also express very high levels of active Fas ligand. In in vitro studies, IVIG completely inhibited Fas-mediated keratinocyte apoptosis. This effect was related to the presence of naturally occurring Fas-blocking antibodies in IVIG, which inhibit Fas-mediated keratinocyte cell death. In a large multicenter retrospective study, early infusion of high-dose IVIG (mean total dose 2.7 g/kg) was well tolerated and effective in improving the survival of patients with TEN.

Modulation of Complement Effector Function

The principal inflammatory mechanism in dermatomyositis (DM) is complement (C)-dependent microangiopathy with activation of C3 and deposition of the complement C5b-9 membrane attack complex (MAC) on the endomysial capillaries. In patients with DM who were treated with IVIG, C3 deposition was reduced with corresponding decreases in complement expression on endomysial capillaries. IVIG prevents the uptake of complement components and formation of the MAC on the endomysial capillaries in the muscle tissues of patients with DM. Consequently, IVIG allowed neovascularization to occur with reversal of the ischemic process, resulting in muscle tissue healing. This effect of IVIG on complement deposition may be relevant to other autoimmune neurological diseases, such MG, GBS, and CIDP, in which a complement may be playing a role in the tissue damage.[22] IVIG may also protect the brain against acute ischemic injury mediated by a complement.[23]

Effects of Immunoglobulin on the Regulatory T-Cell Pathways

In a mouse model of multiple sclerosis (MS), IVIG has been shown to expand and enhance the function of $FoxP3^+$ regulatory T cells (Tregs) while inhibiting the differentiation of T-helper 17 (Th17) and Th1 cells. This protective effect of IVIG was lost in mice that were depleted of Tregs.[24] These changes were independent of FcγRIIB and the Fc domain, since $F(ab')_2$ fragments led to similar changes in Th17 cells, Tregs, and clinical efficacy in this experimental allergic encephalomyelitis (EAE) model. De-sialylated IVIG had the same immune-modulating effects as "native" IVIG.[25] Investigations by Trinath et al.[26] suggested that the mechanism by which IVIG induces Tregs was the enhancement of the cyclo-oxygenase 2 (COX-2) pathway via increased expression of prostaglandin E_2 (PGE_2) from human DCs.

IVIG therapy in an ovalbumin (OVA)-sensitized mouse model of asthma markedly attenuates lung inflammation, decreased bronchial hyperresponsiveness to methacholine, and suppressed the Th2 pathway.[27] The draining pulmonary lymph nodes of IVIG-treated mice showed a significant increase in $CD4^+CD25^+FoxP3^+$ Treg cells. IVIG-primed DCs on adoptive transfer to OVA-sensitized and challenged mice abrogated airway hyperresponsiveness and induced Tregs cells. In their model system, Massoud et al.[28] reported that sialylated IgG bound to a novel C-type lectin receptor (i.e., dendritic cell immunoreceptor [DCIR]) led to the induction of Tregs cells. Thus, a number of studies have demonstrated the importance of the induction of $FoxP3^+$ Tregs by IVIG in modulating the autoimmune/anti-inflammatory process. In contrast, Ig therapy in this murine model downregulated the Th-17 pathway. The effects of IVIG on Th17 cells are not due to neutralization of the Th17 cytokines but mediated through STAT3.[29] In patients with KS and GBS, clinical improvement with IVIG therapy correlated with increased number and function of Tregs.[30] B cells also express the inhibitory FcγRIIB receptor. Of note, observations in patients with CIDP treated with high-dose IVIG demonstrated upregulation of the FcγRIIB receptor on peripheral blood B cells and monocytes.[31] IVIG also inhibits IL4/CD40-, Toll-like receptor (TLR)-, and B-cell receptor (BCR)-mediated activation of B cells. IVIG contains antibodies to BAFF, an important regulatory cytokine for B-cell survival. IVIG treatment of patients with CIDP decreased elevated serum levels of BAFF.

Effects of Intravenous Immunoglobulin on B Cells

The effects of IVIG on B cells is mainly mediated through interaction with the CD22 receptor, a receptor belonging to the Siglec superfamily. The CD22 receptor is important in modulating signaling thresholds for B-cell activation. Sialylated IgG binds to CD22 on B cells to affect B-cell inhibition through several BCR signaling pathways.

Summary: Intravenous Immunoglobulin in Treatment of Autoimmune and Inflammatory Diseases

Clearly, IVIG (IgG) has a number of immune-modulating effects and has been found to be an effective treatment for a wide spectrum of autoimmune and inflammatory diseases.[19] At present, IVIG is FDA approved for only a few autoimmune and inflammatory diseases. In autoantibody-mediated disease, the Fc domain appears to be the important IgG moiety that leads to immune modulation. The importance of sialylation of the Fc fragment remains controversial, as do the mediators involved (e.g., IL-33 and IL-4). Differences in animal models, IVIG source, route and timing of the administration of the IVIG, mouse strain, and other variables may account for the differences in the experimental observations of laboratories. In T-cell-mediated animal models of disease, such as EAE, there is strong evidence that there is upregulation of Tregs and inhibition of the Th17 pathway. These effects may be mediated by the F(ab′)2 portion of the IgG molecule, and not the Fc domain. Furthermore, there is also controversy over the receptor on antigen-presenting cells (APCs), such as macrophages and DCs, which are involved in the immune-modulating process mediated by IVIG. In certain animal models, the SIGN-R1 (or in humans DC-SIGN) is important, and in other models (e.g., murine asthma), a novel C-type lectin receptor (DCIR) appears to be important. These differences undoubtedly relate to the disease model. Two studies have demonstrated the importance of the PGE_2 pathway on IVIG-induced immune modulation mediated by the F(ab′)2 portion of the IgG molecule. These observations may point to the possibility of alternative treatment regimens that employ the selective increase in PGE_2 in certain autoimmune or inflammatory disorders to increase Tregs and inhibit the production of certain cytokines. Further clarification in human disease models using in vitro human cells is important. These mechanisms are not mutually exclusive, and probably more than one mechanism is playing a role in the efficacy of Ig therapy in an autoimmune disease process. A better understanding of the pathogenic mechanisms involved in these diseases will undoubtedly lead to a more effective therapy with IVIG and more specific, modified forms of this biological product.

ON THE HORIZON

Translational Research Opportunities Related to Immunoglobulin Therapy

- Elucidation of mechanism(s) of action will lead to more precise bioengineered molecular products to treat autoimmune and inflammatory diseases.
- Clarification of the mechanisms of action of intravenous immunoglobulin (IVIG) in autoimmune and inflammatory diseases should lead to better understanding of the pathobiology of these diseases.
- Enhanced product purification with further identification of the minor components (e.g., procoagulant factors, isohemagglutinins) in Ig products that may contribute to adverse reactions should lead to improved manufacturing processes and improved product tolerability and safety for patients.
- Development of innovative approaches to the delivery of Ig products, such as pre-filled syringes, to patients will enhance safety and compliance.

Glucocorticoids

Anthony J. Frew[†] *and David B. Corry*

Glucocorticoids are among the most commonly prescribed drugs and are used for a wide range of medical conditions.[1] More than 60 years after their introduction into clinical practice, they remain the most important and most frequently used class of antiinflammatory drug, and their use continues to increase especially with the introduction of intranasal glucocorticoids that do not require prescription. Community survey data suggest that 1.2% to 3% of the general population and up to 7% of the elderly are taking oral glucocorticoids.[2,3] Between 56% and 68% of patients with rheumatoid arthritis (RA) are more or less continuously treated with glucocorticoids.[4] Although glucocorticoids are relatively inexpensive, total market volume is about US$10 billion per year.[2] Glucocorticoids are widely used because they are the most effective (and cost-effective) antiinflammatory and immunomodulatory drugs available. However, glucocorticoids can cause serious adverse effects, especially when used incorrectly.

MECHANISMS OF ACTION

The way in which glucocorticoids are used in different clinical conditions is essentially empirical, as there is only limited evidence to support current practice in specific clinical settings.[4] In general, glucocorticoid dosages are increased in parallel with the clinical activity and severity of the disease under treatment. The rationale for this approach is that higher dosages increase glucocorticoid receptor saturation in a dose-dependent manner (Table 83.1), which intensifies the therapeutically relevant, *genomic* actions of glucocorticoids. Moreover, with increasing dosages, additional and qualitatively different, *nonspecific, nongenomic* actions of glucocorticoids come into play (see Table 83.1).

KEY CONCEPTS

Characteristics Applying to Genomic Actions

- Physiologically relevant
- Therapeutically effective at all dosages, even very small ones (low-dose therapy).
- Slow; significant changes in the regulator protein concentrations are not seen within less than 30 min because of the time required for cGCR activation/translocation, transcription, and translation effects.
- The GC-induced synthesis of regulator proteins can be prevented by inhibitors of transcription (e.g., actinomycin D) or translation (e.g., cycloheximide).

Genomic Actions of Glucocorticoids

The antiinflammatory and immunomodulatory effects of glucocorticoids (GCs) are mainly mediated by genomic mechanisms (Figs. 83.1 and 83.2). Their lipophilic structure and low molecular mass allow GCs to pass easily through the cell membrane and bind to cytosolic glucocorticoid receptors (cGCRs). Ultimately this either induces the synthesis of regulatory proteins ("*transactivation*") or inhibits their synthesis ("*transrepression*").[5] Between 10 and 100 genes per cell are directly regulated by glucocorticoids but many other genes are regulated indirectly, through interaction with transcription factors and co-activators (see below).[6] It has been estimated that glucocorticoids influence the transcription of approximately 1% of the entire genome.

Structure of the Cytosolic Glucocorticoid Receptor

The unactivated cGCR (cGCRα) is a 94 kDa protein held in the cytoplasm as a multiprotein complex, consisting of several heat shock proteins (hsp), including hsp90, hsp70, hsp56, and hsp40 (chaperones) (Fig. 83.3). The cGCR interacts with immunophilins, p23. and several kinases of the mitogen-activated protein kinase (MAPK) signaling system, including Src, which also act as molecular (co)chaperones (see Figs. 83.1 and 83.3).[1,7] The general function of molecular (co)chaperones is to bind and stabilize proteins at intermediate stages of folding, assembling, translocation, and degradation. With regard to cGCR, they also regulate cellular signaling, which includes (1) stabilizing a high-affinity conformational state of cGCR; (2) opening the glucocorticoid binding cleft to access by glucocorticoids; and (3) stabilizing the binding of GCR to the promoter.[1]

The first step in assembling the multiprotein cytosolic complex is ATP- and hsp40(YDJ-1)-dependent formation of a cGCR-hsp70 complex that primes the receptor for subsequent ATP-dependent activation by hsp90, Hop, and p23.[5] The glucocorticoid receptor consists of different domains with distinct functions: an N-terminal domain, a DNA-binding domain (DBD), and a ligand-binding domain (LBD) (see Fig. 83.3). The N-terminal domain harbors transactivation functions, especially within the "τ1" region. The zinc finger motif, a sequence common to many DNA-interacting proteins, is found twice within the DBD. The LBD consists of 12 α helices, several of which help form a hydrophobic ligand-binding pocket.[6] The cGCR contains another major transactivation region ("τ2") that can interact with the above-mentioned cofactors (see Fig. 83.3). Following GC/cGCR binding, the hsp90 molecules and other molecular chaperones are rapidly shed. This allows translocation into the cell nucleus, where the GC/cGCR complex binds as a homodimer to consensus palindromic DNA sites (GC-responsive elements [GREs]).[7]

Translocation Into the Nucleus

Nuclear translocation of the GC/cGCR complex occurs within 20 minutes. This may be caused by hormone-directed

[†] Deceased.

TABLE 83.1 Current Knowledge on the Relationship Between Clinical Glucocorticoid Dosing and Cellular Glucocorticoid Actions

Terminology (mg Prednisone Equivalent per Day)	Clinical Application	Genomic Actions (Receptor Saturation)	Unspecific Nongenomic Actions	cGCR-Mediated Nongenomic Actions
Low dose (≤7.5)	Maintenance therapy for many rheumatic diseases	+ (< 50%)	–	?
Medium dose (>7.5–≤ 30)	Initially given in primary chronic rheumatic diseases	++ (> 50–<100%)	(+)	(+)
High dose (>30–≤100)	Initially given in subacute rheumatic diseases	++ (+) (almost 100%)	+	+
Very high dose (>100 mg)	Initially given in acute and/or potentially life-threatening exacerbations of rheumatic diseases	+++ ([almost] 100%)	++	+ (+?)
Pulse therapy (≥250 mg for 1 or a few days)	Particularly severe and/or potentially life-threatening forms of rheumaticdiseases	+++ (100%)	+++	+ (++?)

cGCR, Glucocorticoid receptor.

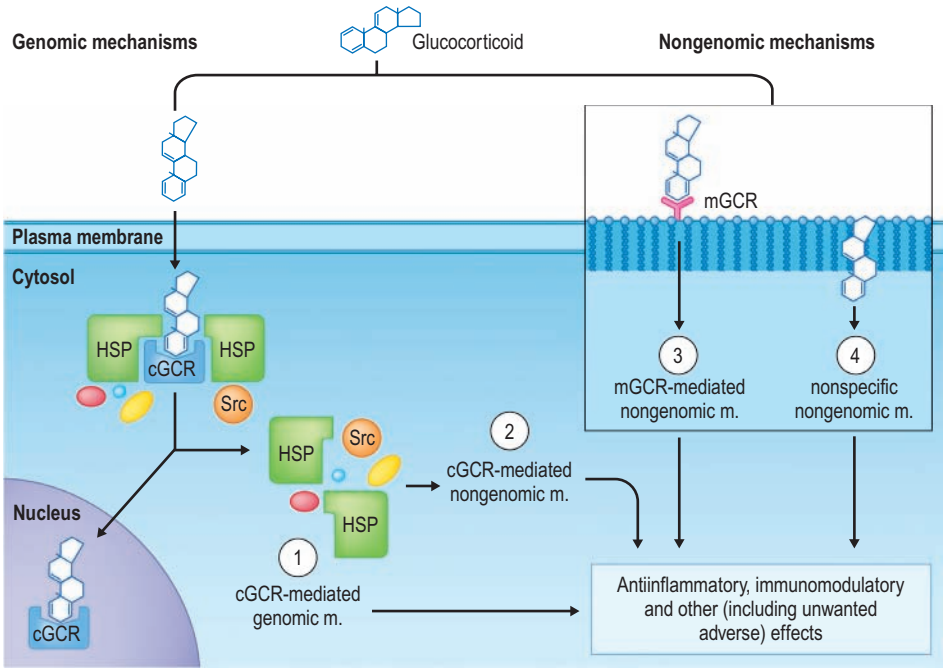

FIG. 83.1 Mechanisms of the Cellular Action of Glucocorticoids. As lipophilic substances, glucocorticoids pass very easily through the cell membrane into the cell, where they bind to ubiquitously expressed cytosolic glucocorticoid receptor *(cGCR)*. This is followed by either the classic cGCR-mediated genomic effects *(1)* or by cGCR-mediated nongenomic effects *(2)* Moreover, the glucocorticoid is very likely to interact with cell membranes, either specifically via membrane-bound glucocorticoid receptor *(mGCR) (3)* or via nonspecific interactions with cell membranes *(4)*. *HSP, heat shock protein.* (From Buttgereit F, Straub RH, Wehling M, Burmester GR. Glucocorticoids in the treatment of rheumatic diseases. An update on mechanisms of action. *Arthritis Rheum.* 2004;50:3408–3417.)

recruitment of an immunophilin (FKBP51, FKBP52, or CyP-40) or the protein phosphatase PP5 and dynein to the GCR.[7] Depending on the target gene, transcription is then either activated (*transactivation* via positive GRE) or inhibited (*transrepression* via negative GRE) (see Fig. 83.2, A and B).

Interactions With Transcription Factors

As well as the interactions of GC/cGCR complexes with GREs, a further important genomic mechanism of GC action is the interaction of activated cGCR monomers with transcription factors. Accordingly, although the GC/cGCR complex does not inhibit their synthesis, it modulates the activity of AP-1 (activator protein-1), NF-κB (nuclear factor-kappa B) and NF-AT (nuclear factor for activated T cells). This leads to inhibition of nuclear translocation and/or function of these transcription factors, and hence to inhibition of expression of many immunoregulatory and inflammatory cytokines. Possible mechanisms include:[8]

- Synthesis of IκB (a specific inhibitor of NF-κB) induced through GC/cGCR complex–GRE interaction (see Fig. 83.2, A).
- Protein–protein interaction of the GC/cGCR complex with transcription factors through binding to their subunits (see Fig. 83.2, C), which prevents their DNA binding.
- Competition for nuclear co-activators between the GC/cGCR complex and transcription factors (see Fig. 83.2, D).

Inhibition of transcription factor function and the resultant inhibition of protein expression are referred to as *transrepression*. Numerous genes are regulated by this mechanism. Many adverse effects of GC are caused by *transactivation* (induced synthesis of regulator proteins), whereas most antiinflammatory effects are mediated by *transrepression* (inhibited synthesis of regulator proteins). This differential molecular regulation underlies current drug-discovery programs aimed at developing dissociated cGCR-ligands.[9]

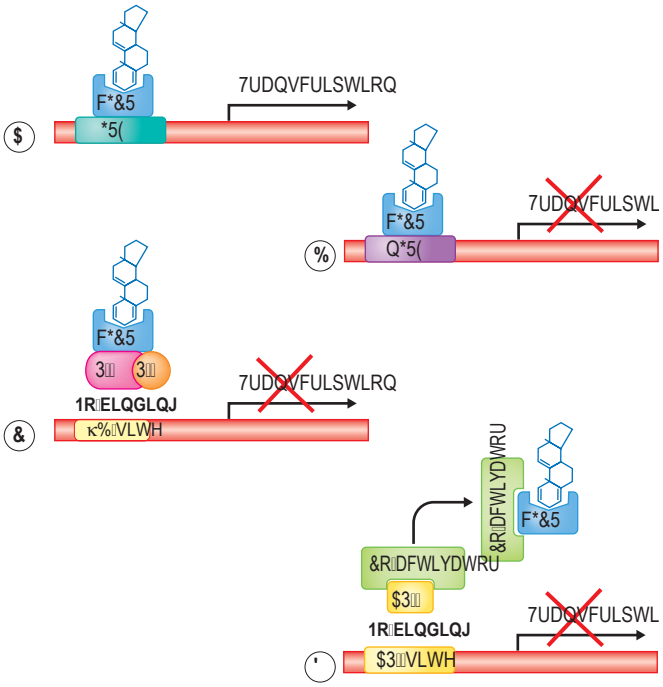

FIG. 83.2 (A–D) **Genomic Mechanisms of Glucocorticoids.** (A–D) The different mechanisms by which the activated glucocorticoid receptor complex leads to the induction or to the inhibition of transcription and finally translation/synthesis of specific regulator proteins. Details are given in the text. *cGCR*, Cytosolic glucocorticoid receptors; *GRE*, glucocorticoid-responsive elements. (From Buttgereit F, Straub RH, Wehling M, Burmester GR. Glucocorticoids in the treatment of rheumatic diseases. An update on mechanisms of action. *Arthritis Rheum.* 2004;50:3408–3417.)

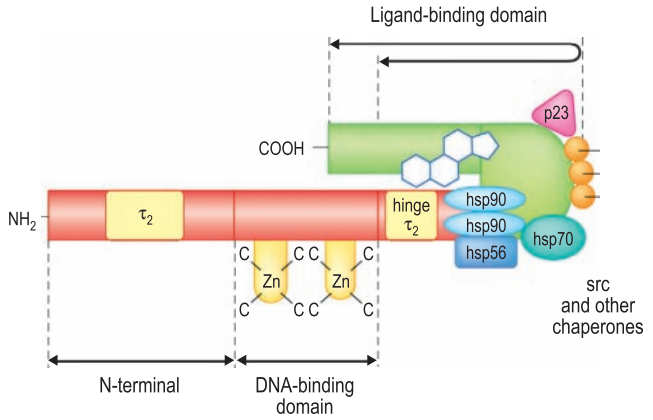

FIG. 83.3 **Structure of the Cytosolic Glucocorticoid Receptor (cGCR).** The unactivated (unligated) cGCR is a 94 kDa protein retained in the cytoplasm as a multiprotein complex consisting of several heat shock proteins *(hsp)*, including hsp90, hsp70, hsp56, and hsp40 (chaperones). Furthermore, the cGCR interacts with immunophilins, p23, and several kinases of the mitogen-activated protein kinase (MAPK) signaling system, including Src, which also act as molecular (co-)chaperones. An important function of molecular (co)chaperones is to stabilize a specific conformational state of the GC which binds ligand with high affinity (see text). The receptor protein itself consists of different domains: an N-terminal, a DNA-binding domain (DBD), and a ligand-binding domain (LBD). The N-terminal domain harbors transactivation functions, especially within the so-called τ1 region. Another major transactivation region is τ2, which can interact with the above-mentioned cofactors. (From Buttgereit F, Straub RH, Wehling M, Burmester GR. Glucocorticoids in the treatment of rheumatic diseases. An update on mechanisms of action. *Arthritis Rheum.* 2004;50:3408–3417.)

The Cytosolic Glucocorticoid Receptor β Isoform

The cGCRβ isoform is an alternative splicing variant of cGCRα that does not bind GC or activate gene expression. This isoform is thought to function as a negative inhibitor of cGCRα and it may play a role in the clinical phenomenon of GC-resistance. cGCRβ lacks the GC-binding domain, which is needed for activation, and as it does not undergo ligand-dependent downregulation, it has a longer half-life than the active form (cGCRα). It is thought that the likely mechanism of the dominant negative activity of cGCRβ is through the formation of inactive heterodimers with cGCRα.[8]

Post-Transcriptional and Post-Translational Mechanisms

Glucocorticoids also act through post-transcriptional and post-translational mechanisms, including reduction of the half-life of cytokine mRNA and downregulation of GCR, via reduced mRNA levels and reduced stability of the GCR protein.

KEY CONCEPTS

Glucocorticoid Effects on Immune Cells

- Inhibit leukocyte traffic and access of leukocytes to the site of inflammation.
- Interfere with functions of leukocytes, fibroblasts, and endothelial cells.
- Suppress the production and actions of humoral factors involved in the inflammatory process.

Glucocorticoid Receptor Resistance

Several different mechanisms may explain the clinical finding of GCR resistance, among them alterations in the number, binding affinity, or phosphorylation status of GCR. Other possible explanations are polymorphic changes and/or overexpression of (co-)chaperones, increased expression of inflammatory transcription factors, overexpression of the GCRβ isoform, the multidrug resistance pump, and altered mGCR expression.[10]

Nongenomic Actions of Glucocorticoids

Some regulatory effects of glucocorticoids occur within seconds or minutes. These are too rapid to result from genomic actions, and therefore must be due to *nongenomic* mechanisms of action. Three different rapid nongenomic actions of glucocorticoids have been described.

Cytosolic Glucocorticoid Receptor–Mediated Nongenomic Actions

Dexamethasone can rapidly inhibit epidermal growth factor-stimulated $cPLA_2$ (cytosolic phospholipase A_2) activation with subsequent arachidonic acid release.[11] This effect is thought to be mediated by occupation of cGCR, rather than changes in gene transcription, as the observed effect is RU486-sensitive (i.e., glucocorticoid receptor dependent) but actinomycin-insensitive (i.e., transcription independent). Chaperones or co-chaperones of the multiprotein complex may act as signaling

components to mediate this effect. Following glucocorticoid binding, the cGCR is released from this complex to mediate classic genomic actions. However, there is also a rapid release of Src and other (co-)chaperones of the multiprotein complex, which may cause rapid inhibition of arachidonic acid release. Similarly, dexamethasone has been reported to have cardiovascular protective effects which are neither genomic (because they occurred too quickly and were actinomycin insensitive) nor nonspecific-nongenomic effects (because they occurred at a very low concentration (100 nM)).[12] These may involve binding of glucocorticoids to the cGCR, leading to nontranscriptional activation of phosphatidylinositol 3-kinase, protein kinase Akt, and endothelial nitric oxide synthase.

Nonspecific Nongenomic Actions

Glucocorticoids are sometimes administered at very high doses. Systemic daily dosages greater than 100 mg prednisone equivalent are regarded as "very high dose." "Pulse therapy" is the daily administration of ≥250 mg prednisone equivalent for one or a few consecutive days[13] (see Table 83.1). At a daily dose of 100 mg prednisone equivalent, almost all cGCR are completely saturated, which implies that specificity (i.e., the exclusivity of receptor-mediated effects) is lost. Nonspecific nongenomic actions occur in the form of physicochemical interactions with biological membranes, which probably contribute to the therapeutic effect.[4] Intercalation of glucocorticoid molecules into cell membranes is thought to alter cell function by influencing cation transport and increasing mitochondrial proton leak. The resulting inhibition of calcium and sodium cycling across the plasma membrane of immune cells is thought to contribute to rapid immunosuppression and to reduced inflammation.

Such high GC doses are only used in a few clinical specialties, and this practice has been criticized by endocrinologists and pharmacologists. Unfortunately, there are no randomized controlled trials of high-dose glucocorticoid therapy, but it is often used with clinical success in acute exacerbations of life-threatening diseases and various clinical conditions resistant to other therapies. For example, pulsed intravenous (IV) methylprednisolone is effective in the treatment of systemic lupus erythematosus (SLE) and rapidly immunosuppresses patients with organ- and/or life-threatening manifestations of SLE. However, the standard regime (1 g/day for 3 consecutive days) is associated with significant risks of infection, and lower doses may be just as effective.[14]

High-dose glucocorticoids are also often used in immune thrombocytopenia associated with SLE, although comparative studies are lacking[15] It has been calculated that, in situations like these, the concentrations achieved in vivo are high enough (around 10^{-5} mol/L) to cause immediate nonspecific nongenomic effects on immune cells.[4] Intraarticular injections also bring high concentrations of glucocorticoids into contact with inflammatory cells, although it is difficult to assess locally achieved concentrations because crystal suspensions are most often used.

Specific Nongenomic Actions

Glucocorticoids can also induce specific nongenomic actions, mediated through membrane-bound glucocorticoid receptors (mGCRs). The existence and function of membrane-bound receptors have been demonstrated for various steroids (including mineralocorticoids, gonadal hormones, vitamin D, and thyroid hormones).[4,16] Small numbers of mGCRs can be demonstrated by immunofluorescence on human peripheral blood mononuclear cells (monocytes and B cells) obtained from healthy controls.[16] The monoclonal antibody used to detect mGCR also recognizes cGCR, suggesting that mGCRs are probably variants of cGCRs produced by differential splicing or promoter switching. Immunostimulation with lipopolysaccharide increases the percentage of $mGCR^+$ monocytes and this can be prevented by inhibiting the secretory pathway with brefeldin A. This suggests that mGCRs are actively upregulated and transported through the cell following immunostimulation. These in vitro findings are consistent with observations that the frequency of $mGCR^+$ monocytes is increased in patients with rheumatic disorders and is positively correlated with disease activity in RA.[16] It remains unclear whether mGCRs are involved in pathogenesis. Alternatively, and perhaps they may more likely, cause negative feedback regulation.

GLUCOCORTICOID EFFECTS ON IMMUNE CELLS

Through the above mechanisms, glucocorticoids mediate a wide range of antiinflammatory and immunomodulatory effects, with virtually all primary and secondary immune cells affected to some extent (Table 83.2).[8]

KEY CONCEPTS

Definition of Conventional Terms for Glucocorticoid Dosages

Low dose	≤7.5 mg prednisone equivalent per day
Medium dose	>7.5 mg, but ≤30 mg prednisone equivalent per day
High dose	>30 mg, but ≤100 mg prednisone equivalent per day
Very high dose	>100 mg prednisone equivalent per day
Pulse therapy	≥250 mg prednisone equivalent per day for 1 or a few days

TABLE 83.2 Important Effects of Glucocorticoids on Primary and Secondary Immune Cells

Monocytes/Macrophages
- ↓ number of circulating cells (↓ myelopoiesis, ↓ release)
- ↓ expression of MHC class II molecules and Fc receptors
- ↓ synthesis of proinflammatory cytokines (e.g., IL-2, IL-6, TNF-α) and prostaglandins

T Cells
- ↓ number of circulating cells (redistribution effects)
- ↓ production and action of IL-2 (most important)

Granulocytes
- ↓ number of eosinophil and basophil granulocytes
- ↑ number of circulating neutrophils

Endothelial Cells
- ↓ vessel permeability
- ↓ expression of adhesion molecules
- ↓ production of IL-1 and prostaglandins

Fibroblasts
- ↓ proliferation
- ↓ production of fibronectin and prostaglandins

IL, Interleukin; *MHC*, major histocompatibility complex; *TNF-α*, tumor necrosis factor alpha.

From Buttgereit F, Saag K, Cutolo M, et al. The molecular basis for the effectiveness, toxicity, and resistance to glucocorticoids: focus on the treatment of rheumatoid arthritis. *Scand J Rheumatol.* 2005;34:14–21, with permission.

THE ROLE OF ENDOGENOUS GLUCOCORTICOIDS IN INFLAMMATORY ARTHRITIS

Exogenous (therapeutic) and endogenous (physiological) glucocorticoids differ in several respects. The most important differences are in their relative mineralocorticoid and glucocorticoid (anti-inflammatory) activities. Exogenous and endogenous glucocorticoids also differ in their pharmacological characteristics, such plasma kinetics, metabolism, biological half-life, lipophilicity, drug-receptor interactions, and nongenomic potencies.[17]

The actions of exogenous glucocorticoids as described above are well established. In contrast, we know relatively little about the role of endogenous glucocorticoids in arthritis. While glucocorticoid actions on target tissues are thought to be determined by glucocorticoid plasma concentrations and the tissue-specific density of glucocorticoid receptors, it seems that endogenous glucocorticoids are subject to extensive pre-receptor metabolism. Within target cells or tissues, glucocorticoid action depends not only on plasma hormone levels, receptor expression, and receptor-effector coupling but also on local glucocorticoid metabolism. Specifically, 11β-hydroxysteroid dehydrogenases appear to govern access of glucocorticoids to their cognate receptors by changing the balance between active and inactive glucocorticoids within the cell (reviewed in Buttgerit *et al.*[17]). Thus, the predominant reductase activity of 11β-hydroxysteroid dehydrogenase *type 1* (11βHSD1) catalyzes the formation of bioactive cortisol from inactive cortisone (in humans) and corticosterone from 11-dehydrocorticosterone (in rodents). This $NADP^+(H)$-dependent enzyme is present in many tissues and usually increases the intracellular availability of active glucocorticoids. In contrast, 11β-hydroxysteroid dehydrogenase *type 2* (11βHSD2) only possesses dehydrogenase activity: it inactivates active glucocorticoids and therefore decreases the intracellular concentration of bioactive glucocorticoids.

Proinflammatory cytokines such as interleukin-1β (IL-1β) and tumor necrosis factor alpha (TNF-α) stimulate 11βHSD1 and downregulate 11βHSD2 expression. Hence, specific proinflammatory cytokines can modulate local intracellular glucocorticoid metabolism, which may affect their own proinflammatory effects. More recently, substantial glucocorticoid metabolism has been shown in joints since TNF-α and IL-1β induce 11βHSD1 activity in primary cultures of synovial fibroblasts isolated from synovial tissue biopsies from rheumatoid arthritis (RA) patients.[18]

In a rodent model of immune-mediated arthritis, targeted disruption of glucocorticoid signaling in osteoblasts attenuates joint inflammation and cartilage destruction.[19] These results suggest that, under the control of endogenous glucocorticoids, osteoblasts modulate immune-mediated inflammatory responses, and, as a consequence, inflammation-induced cartilage damage and bone integrity. These findings are supported by recent evidence suggesting that the effects of glucocorticoids follow a dose–response curve with permissive or even stimulatory effects at physiological concentrations, and suppressive effects at pharmacological concentrations.[18]

THERAPEUTIC USE

A wide range of GC molecules are available for clinical use: the common basic structure has been modified to improve their usefulness in various clinical applications (Fig. 83.4). Despite their widespread use, the designation of GC treatment regimens is often imprecise. Recommendations for a standardized nomenclature for GC therapy are summarized below.[13]

Terminology

Although the term "*steroids*" is widely used to describe this class of drugs, it is too broad, as it simply describes chemical compounds characterized by a common multiple-ring structure (including cholesterol, vitamin D, and sex hormones). Similarly, the terms "*corticosteroids*" or "*corticoids*" are not sufficiently precise, as the adrenal cortex synthesizes not only glucocorticoids but also mineralocorticoids and androgens. For these reasons, the terms "*glucocorticoid*" or "*glucocorticosteroid*" are preferred, but "*glucocorticoid*" is the more widely used term.

When describing the use of glucocorticoids, it is necessary to define the drug, the dosage, the route of administration, and the timing, frequency, and duration of treatment.

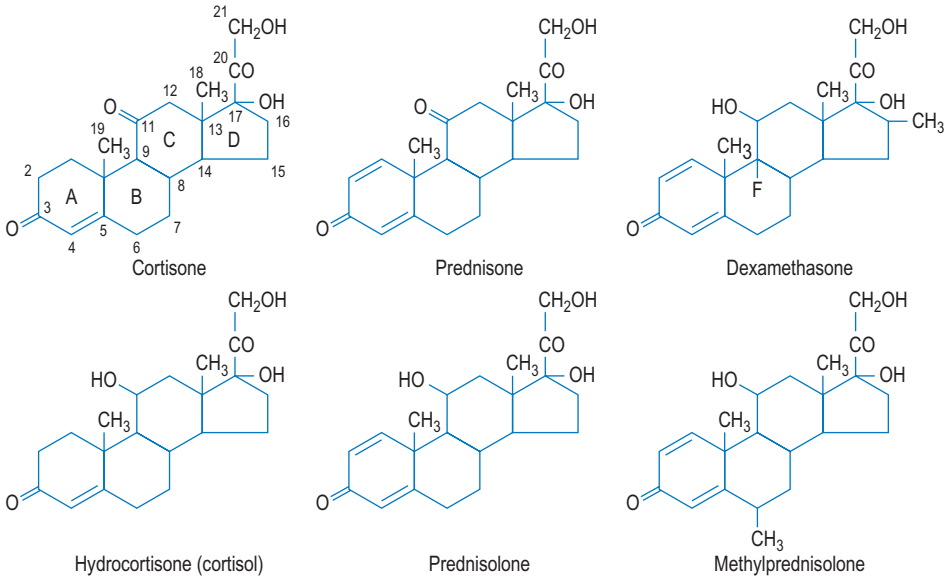

FIG. 83.4 Molecular Structures of Cortisone and Commonly Used Glucocorticoids. Carbon and ring nomenclature is indicated on the cortisone molecule.

TABLE 83.3 Drug Potencies of Selected Glucocorticoids

Cortisol	1 (per definition)
Prednyliden	3.5
Predniso(lo)ne	4.0
Methylprednisolone	5.0
Dexamethasone	25
Betamethasone	25

Drug potencies describe the potency of the respective drug to produce classical genomic (antiinflammatory) effects relative to cortisol. These potencies provide the basis for calculating equivalent dosages.
Data from Lipworth BJ. Therapeutic implications of non-genomic glucocorticoid activity. *Lancet.* 2000;356:87–89.

Different glucocorticoid drugs have different potencies and they differ in their ability to produce the distinct therapeutic effects discussed above. Drug potencies are usually described by the equivalent dosages (relative potencies) to produce classic genomic effects (Table 83.3). These values have been used for decades, although the experimental and clinical evidence for their precise relative potency is weak. In practice, relative potencies are useful as a general therapeutic guideline in daily clinical practice, as long as they are not used dogmatically. It has therefore been suggested that we should continue to use relative potencies until more exact data are available, and that doses of different glucocorticoids should be expressed in terms of "prednisone equivalent": that is, doses of different glucocorticoids are expressed as equivalent to milligrams of prednisone (or prednisolone, as the potency of prednisone is equal to that of prednisolone).

However, recent data indicate that the concept of equivalent dosages is only valid for doses less than 100 mg prednisone equivalent, because nongenomic effects come into play at higher doses. This reason is important because the relative potencies of different glucocorticoids to produce these nongenomic effects are completely different from their classic genomic effects (see Table 83.3). For example, methylprednisolone is used for pulse therapy of exacerbations of immunologically mediated disorders. Prednisolone and methylprednisolone have similar genomic potency, but when used for high-dose therapy the nonspecific nongenomic effect of methylprednisolone is more than three times stronger. This may explain the apparent superiority of high-dose methylprednisolone. In contrast, betamethasone has very low nongenomic potency, which may be why this drug is considered less effective systemically, even though it has the same genomic potency as dexamethasone. In summary, the clinical usage of different glucocorticoids is clearly determined by the magnitude of their clinical efficacy, but another important factor in selecting which one to use is their nongenomic potency.

GLUCOCORTICOID TREATMENT REGIMENS: GENERAL ASPECTS

For many decades there has been confusion surrounding the terms used to describe dosage (very low, low, mild, mild to moderate, moderate, high, very high, ultra-high, and mega) and by loose usage of terms such as "low-dose therapy," "high-dose therapy," and "pulse therapy." A 2002 consensus statement has clarified this situation, partly to achieve scientific consistency and partly to recognize that glucocorticoid actions are strongly dose-dependent, both quantitatively and qualitatively. The following standardized nomenclature for glucocorticoid dosages and glucocorticoid treatment regimens is now recommended.[13]

Low Dose

Treatment with doses of up to 7.5 mg prednisone equivalent per day is considered low-dose glucocorticoid therapy because these doses occupy less than 50% of the receptors. Such courses are frequently used for maintenance therapy; and have relatively few adverse effects (such as osteoporosis). As there may be relative hypocortisolism in chronic inflammatory conditions such as RA and polymyalgia rheumatica, low-dose glucocorticoids act in part as replacement therapy for reduced adrenal glucocorticoid production.

Medium Dose

Glucocorticoid doses of more than 7.5 mg but less than 30 mg prednisone equivalent per day are considered to be medium-dose therapy because they lead to a significantly higher receptor engagement between 50% and less than 100%. These doses are effective in modulating disease activity in various rheumatic diseases but may have considerable and dose-dependent adverse effects if given for longer periods.

High Dose

Treatment with doses of more than 30 mg and up to 100 mg of prednisone equivalent per day is considered high-dose therapy because these doses significantly increase receptor saturation, in a dose-dependent manner. At approximately 100 mg prednisone equivalent per day, receptor saturation is almost complete and it is likely that genomic glucocorticoid effects are fully exerted (see Table 83.1). High-dose therapy can be successfully given as initial treatment for subacute diseases such as non-life-threatening exacerbations or visceral complications of RA or other connective tissue diseases but cannot be administered long term, because of the danger of severe adverse effects.

Very High Dose

Doses above 100 mg of prednisone equivalent per day are considered "very high." At this level, there is virtually 100% saturation of cytosolic receptors, so any further increase in dose may affect the pharmacodynamics (e.g., receptor off-loading and re-occupancy), receptor synthesis, and expression. At these doses nongenomic effects may deliver additional therapeutic benefit, although it remains unclear whether these effects have any direct therapeutic relevance. Experimental data suggest that these differential effects come increasingly into play above ~100 mg/day (see Table 83.1). Doses of greater than 100 mg of prednisone equivalent per day are frequently (and successfully) given as initial treatment for acute or life-threatening exacerbations of connective tissue diseases, vasculitis, and RA. These doses cannot be administered long term because of their severe adverse effects.

Pulse Therapy

Pulse therapy involves administration of ≥250 mg prednisone equivalent per day (usually IV) for a short period of time

(typically 1 to 5 days, rarely longer). At such high doses, the nongenomic potencies of glucocorticoids come into play. It is likely that these explain the success of very high doses and pulse therapy in acute exacerbations of immunologically mediated diseases. The immediate effects of very high doses may be additive to the genomic effects mediated by cytosolic GC receptors. These additional effects may make a crucial contribution to the therapeutic effect by helping to terminate acute exacerbations. Circumstances where very high doses or pulse therapy can be successful include acute episodes or particularly severe forms of rheumatic diseases such as systemic lupus erythematosus, vasculitis, polymyositis, and RA (see below).

Alternate-Day Regimens

Alternate-day regimens were introduced for long-term oral GC therapy with the aim of minimizing undesirable adverse effects, such as suppression of the hypothalamo-pituitary–adrenal (HPA) axis. Instead of daily dosing, a single dose is administered every other morning, usually in a dose equivalent to, or somewhat higher than, twice the usual daily dose. The idea behind this regimen is to allow the HPA axis to remain active by exposing the body to exogenous GC on alternate days instead of suppressing it every day. This strategy only works if the HPA axis is still active, and, unfortunately, patients often experience breakthrough symptoms on the second day of treatment. Alternate-day regimens are used rarely these days except in patients with juvenile idiopathic arthritis, in whom alternate-day glucocorticoid regimens cause less inhibition of body growth.

Glucocorticoid Withdrawal Regimens

Because of their significant adverse effects, GCs are usually reduced or stopped as soon as the disease is under control. This needs to be done carefully in order to avoid a relapse in disease activity and to permit recovery of adrenal function. There are no controlled comparative studies to support a specific regimen for weaning patients off GCs, as this process needs to be adjusted according to disease activity, dose/duration of therapy, and clinical response. When patients with rheumatoid arthritis are treated with up to 10 mg/day of prednisone, the daily dose can be reduced by 2.5 mg every month until 5 mg/day is reached. Thereafter, doses can often be reduced by 1 mg per month. When higher doses have been used, a reduction by 5 mg every 1 to 2 weeks down to 20 mg/day is often well tolerated, followed by further reductions of 1 to 2.5 mg/day every 2 to 3 weeks. Addition of immunomodulatory drugs such as methotrexate and azathioprine may allow further dose reductions. Short courses of GC for conditions such as asthma may be ceased without tapering if the total treatment course was less than 14 days in duration. With longer periods of treatment, the dose should be reduced gradually to allow the HPA axis to recover, but the rate of reduction is usually quicker than for rheumatological conditions.

Glucocorticoids in Rheumatoid Arthritis: An Example

Glucocorticoids are crucially important in the management of rheumatoid arthritis and are used in various dosages at different disease stages. RA is therefore a useful example to discuss GC therapy in more detail.

Low-Dose Maintenance Therapy

In early RA, GC in doses less than 10 mg are highly effective for relieving symptoms in patients with active arthritis. Many patients are functionally dependent on this low-dose therapy and continue it long term.[20] Improvement has been documented in all clinical parameters, including pain scales, joint scores, morning stiffness, and fatigue, but also in acute inflammatory markers such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). After 6 months of therapy the beneficial effects of GC seem to diminish, but if therapy is then tapered and stopped, patients often experience an exacerbation of symptoms within a few months.

The disease-modifying properties of GC were first described in 1995, in a 2-year trial of 7.5 mg prednisolone in patients with RA of short/intermediate disease duration who also were treated with nonsteroidal antiinflammatory drugs (NSAIDs) (95%) and disease-modifying antirheumatic drugs (DMARDs) (71%). Presently, GC are considered to have disease-modifying properties in early RA, but it is less clear whether they inhibit the progression of erosions in RA of longer duration. A meta-analysis of 15 studies that included 1414 patients concluded that GC given in addition to standard therapy can substantially reduce the rate of erosion progression in RA.[21] Another meta-analysis of 70 randomized placebo- or drug-controlled studies found similar effects of DMARDs, glucocorticoids, and biologicals on radiographic progression in RA.[22]

Glucocorticoid Pulse Therapy

GC pulse therapy is used to treat some serious complications of RA and to induce remission in active disease: for example, when initiating second-line antirheumatic treatment. Pulse therapy with methylprednisolone 1 g/day, dexamethasone 200 mg/day, or equivalent, given intravenously for 1 to 3 days, was effective in most studies with a beneficial effect that generally lasts for about 6 weeks, albeit with large variations. This means it is not sensible to apply pulse therapy in active RA, unless the therapeutic strategy is changed (e.g., DMARD treatment introduced to maintain the remission induced by pulse therapy).

Intraarticular Glucocorticoid Injections

Intraarticular injections with GC are often used in RA. The benefit achieved varies according to several factors, such as the joint treated (size, weight-bearing, or non-weight-bearing), inflammatory activity, the volume of synovial fluid in the joint, whether or not synovial fluid was aspirated before the injection, the choice and dose of GC preparation, injection technique, and whether the joint is rested after the injection.[23] In order to prevent GC-induced joint damage, it is recommended that intraarticular GC injections

KEY CONCEPTS

Glucocorticoid Therapy in Rheumatoid Arthritis

The risk–benefit ratio of low-dose GC has been shifted in the last few years:

- GCs can now be considered as disease-modifying antirheumatic drugs, especially in early RA.
- Adverse effects of low-dose GCs are less abundant and less severe than previously suggested, and some (e.g., osteoporosis) can be well managed.
- The goal of antirheumatic treatment in early RA is to induce remission of disease by aggressive management: GCs are part of this aggressive strategy.

should not be repeated more often than once every 3 to 4 weeks, and no more than 3 to 4 times a year in a weight-bearing joint.

Adverse Effects

Studies of GC toxicity tend to be retrospective and observational. This can make it difficult to differentiate unfavorable outcomes attributable to GCs from those occurring due to the underlying disease or other comorbidities. Furthermore, there is a strong selection bias for GC use, as physicians are more inclined to use them in patients with more severe disease. Frequent, but less serious adverse effects (such as skin thinning, Cushingoid appearance) may be of great concern to patients, whereas more debilitating toxicities such as osteoporosis, cataracts, and GC-induced hypertension may initially go unrecognized or be asymptomatic. Interpretation of toxicity data is further confounded by the use of GCs at variable points in the disease course, limited data defining "threshold" doses for particular adverse events, and the fact that toxicity reports cover a heterogeneous group of GC-treated diseases.

Compared to other antirheumatic agents, GCs have a low incidence of short-term symptomatic toxicity and patients rarely discontinue therapy for these reasons. Despite over 60 years of use, we still lack robust data on the longer-term toxicities of glucocorticoids from large randomized controlled trials with long-term follow-up. The commonest GC toxicities are summarized below.

Some progress has been made by formulating recommendations on which adverse effects of glucocorticoid treatment should be monitored in rheumatoid arthritis, how to monitor them, and how often.[24] Two levels of monitoring GC adverse events have been proposed. (1) For routine clinical practice, details are given on how to identify adverse events in a systematic and practical way. This should result in preventive and therapeutic measures in order to minimize the risks of glucocorticoid therapy. (2) For clinical trials, recommendations have been made on how to accurately assess the frequency and severity of a wider range of adverse events.[25]

Osteoporosis

Glucocorticoid-induced osteoporosis (GIOP) is the most important potential complication of prolonged GC therapy. Chronic GC treatment results in rapid and profound reductions in bone mineral density, with most bone loss occurring during the first 6 to 12 months of treatment.[9]

GIOP initially affects trabecular bone, but cortical bone is also affected with more chronic use, at sites such as the femoral neck. Precisely how GCs affect bone remains obscure. GCs decrease calcium absorption, increase renal calcium loss, diminish sex and growth hormone production, induce muscle wasting, and modulate RANKL/OPG, NF-κB, and AP-1 signaling in bone.[9] All of these changes lead to enhanced osteoclast function and life span, and hence to increased bone resorption. Consequently, markers of bone resorption are often increased in patients treated with GCs.[9] However, reduced bone formation due to reduced osteoblast function is likely to be a more important effect of GCs on skeletal health. Oral doses of prednisone as low as 2.5 mg/day have been shown to suppress serum osteocalcin, a marker of bone formation. Histologically, mean wall thickness is reduced, reflecting the reduced amount of bone replaced in each remodeling unit. In vitro, osteoblasts and their precursors are highly GC responsive. Here, the predominant effect is to promote osteoprogenitor proliferation, lineage commitment, and osteoblast differentiation, resulting in the formation of bone nodules of increased size and numbers. However, GCs also inhibit type I collagen expression, and reduce pre-osteoblastic replication. Finally, GCs promote apoptosis of osteoblasts and osteocytes. The inhibitory effects of GCs on bone formation may be partly due to downregulation of insulin-like growth factor-1 (IGF-1) expression by osteoblasts. Fortunately, we now have effective strategies for the prevention and treatment of GC-induced osteoporosis, using calcium, vitamin D, and specific osteotropic agents such as bisphosphonates or parathyroid hormone.

Osteonecrosis

Osteonecrosis has long been considered an important consequence of high-dose glucocorticoid use. In a Japanese study of femoral head osteonecrosis, 35% cases were related to GC treatment. Higher average dose may be a more important predictor of avascular necrosis of bone than cumulative dose. Osteonecrosis is particularly noted in SLE, but rarely occurs in RA patients receiving low-dose therapy, affecting less than 3% of patients. Osteonecrosis rarely occurs in SLE patients on prednisone doses less than 20 mg/day.

Myopathy

As with osteonecrosis, GC-induced myopathy is rare in patients receiving low-dose glucocorticoids. In small studies, myopathy appears more closely associated with fluorinated GC preparations such as triamcinolone than with prednisone. Notably, myopathy has been reported after only 3 months' treatment with triamcinolone 8 mg/day. In general, myopathy attributable to prednisone only occurs after higher doses and longer durations of treatment.

Cardiovascular Adverse Effects

Glucocorticoid-induced hypertension seems to be, at least in part, mediated via fluid retention (as a result of mineralocorticoid effects); it is dose related and less likely with medium- or low-dose therapy. Individual variation in susceptibility and other factors, such as the starting level of blood pressure, dietary salt intake, functional renal mass, associated diseases, and drug therapy may also play a role.

Another troublesome potential toxicity of low-dose GCs is the development of premature atherosclerotic vascular disease. This has proven difficult to investigate: studies evaluating the effects of GCs on lipids and atherosclerosis in RA patients have yielded mixed results, with some studies suggesting that GCs may actually reverse unfavorable lipid changes. At present, there is no evidence of a strong association between low-dose glucocorticoids and cardiovascular disease in RA, even though atherosclerotic vascular disease is known to be accelerated in patients with Cushing disease. Systemic GC use during pregnancy may also have epigenetic effects, leading to adult hypertension in the next generation.[26]

Dermatological Adverse Effects

Skin thinning and ecchymoses are common adverse events with glucocorticoids, even at low doses. Cutaneous atrophy results from catabolic effects of GC on keratinocytes and fibroblasts. Purpura and easy bruising in GC-treated patients are probably due to decreased vascular structural integrity. A Cushingoid appearance is very troubling to patients but is uncommon

at doses below the physiuological range. One study reported facial fullness ("moon facies") in 13% of patients receiving 4 to 12 mg triamcinolone for up to 60 days. These adverse effects are observed in over 5% of patients exposed to ≥5 mg prednisone equivalent for ≥1 year. The incidence of iatrogenic Cushing syndrome is dose-dependent and generally becomes evident after greater than 1 month of GC therapy. Alternate-day therapy may reduce the incidence, although there are only limited data supporting this concept. Glucocorticoid acne, hirsutism, and striae are other undesirable dermatological effects that occur even with lower doses.[27]

Gastrointestinal Adverse Effects

Glucocorticoids are considerably less toxic to the upper gastrointestinal (GI) tract than NSAIDs. If GCs independently increase the risk of GI events (e.g., gastritis, ulceration, bleeding), the effect is slight, with estimated relative risks varying from 1.1 (not significant) to 1.5 (marginally significant). There have also been anecdotal reports of intestinal rupture, diverticular perforation, and pancreatitis attributed to low-dose GCs. Glucocorticoids are frequently used concurrently with NSAIDs in RA, and meta-analyses confirm that the combination of the two drugs synergistically increases the risk of adverse GI events. In a large-scale study based on the UK General Practice Research Database, the risk of upper GI complications was 1.8 times higher for GC users than for nonusers (95% confidence interval [CI], 1.3 to 2.4). The risk tended to be greater for higher GC doses, but the dose gradient was not statistically significant. The risk was greater than 12 times higher for those taking both glucocorticoids and NSAIDs than for those not using either. No studies have yet looked at the GI effects of combining GCs with cyclooxygenase-2 (COX-2)-selective NSAIDs.[27]

Infectious Diseases

Medium- to high-dose GC therapy may increase the risk of serious infections leading to hospitalization or surgery, particularly when administered for prolonged periods of time. However, there is no evidence that infection rates are increased in patients on doses of prednisone below 10 mg/day or cumulative doses below 700 mg. In those taking higher doses, the risk of infection appears to be lessened with alternate-day therapy.

In GC-treated patients, physicians should be aware of the risk of infections with typical and atypical organisms, recognizing that GCs may blunt the classic clinical features and delay diagnosis. *Pneumocystis jiroveci* infections can occur with doses as low as 16 mg/day of prednisone for 8 weeks.[28] Herpes zoster is also more common in RA patients treated with immunosuppressive agents.[24] However, it is difficult to separate the independent effects of GC use from those of other commonly used antirheumatic agents, such as methotrexate and anti-TNF-α agents. At present, the independent role of GCs in facilitating herpes zoster infection in patients with RA remains uncertain.

Other Adverse Effects

Adverse effects on the hypothalamo–pituitary axis and on glucose metabolism are reviewed elsewhere, together with neuropsychiatric and ophthalmological adverse effects.[24,27,29]

TIMING OF GLUCOCORTICOID ADMINISTRATION MATTERS

In patients with rheumatoid arthritis, major symptoms such as pain, inflammation and stiffness vary across the day, usually with the highest severity in the morning hours. These symptoms are preceded by elevated levels of proinflammatory cytokines. Based upon these considerations it has been proposed that altering the timing of glucocorticoid administration may help to optimize RA therapy.[17]

NEW GLUCOCORTICOID RECEPTOR LIGANDS ON THE HORIZON

The various mechanisms of GC action provide interesting opportunities for developing optimized GCs and GC-receptor ligands.

Selective Glucocorticoid Receptor Agonists

The genomic component mechanisms of transactivation and transrepression offer the opportunity to develop GC-receptor ligands that predominantly cause transrepression rather than transactivation. This concept is based on the proposition that the antiinflammatory properties of GCs are mostly due to repression of AP-1- and NF-κB-stimulated synthesis of inflammatory mediators, whereas their adverse effects are associated with transactivation of genes involved in metabolic processes. Investigators have therefore sought novel GCR ligands with high transrepression activity but low effect on transactivation. One such compound, A276575, exhibits a high affinity for the GCR and potently represses IL-1α-induced IL-6 production, similar to dexamethasone. However, unlike dexamethasone, A276575 induces little aromatase activity. Other novel nonsteroidal GCR ligands are being developed that possess high repression activities against inflammatory mediator production but have lower transactivation activities than traditional GCs. Substances that cause a receptor conformation preferring a GCR/protein interaction as opposed to a GCR/DNA-binding-dependent mechanism are called selective glucocorticoid receptor agonists (SEGRAs) or "dissociated glucocorticoids." The SEGRA concept has, however, recently been challenged by studying a mouse knock-in strain with a dimerization-deficient GCR, which demonstrated that some inflammatory processes can be suppressed by glucocorticoids while others cannot.[30] Also, these mice exhibited classical adverse effects of glucocorticoids such as glucocorticoid-induced osteoporosis. Thus, depending on the process being treated, SEGRAs could be therapeutically more effective or less effective; moreover, not all adverse effects of glucocorticoid therapy may be reduced.[30,31] Nevertheless, from the clinical perspective it is disappointing that the sound underlying theory and the promising initial data have not led yet to a therapeutic breakthrough. As of now, it remains uncertain whether SEGRAs will become relevant in clinical practice.

Long-Circulating Liposomal Glucocorticoids

The antiinflammatory efficacy of GCs can be improved by the additional benefits of nongenomic actions at high GC concentrations. This has led to the use of long-circulating liposomal GCs in experimental models. In rats with experimental autoimmune encephalitis, GC-containing liposomes accumulate at sites of inflammation, reaching concentrations greater than

10^{-5} mol/L for ≥18 hours. These liposomes may be therapeutically superior to conventional intravenous high-dose GC therapy, as evidenced by their successful use in rats with adjuvant-induced arthritis. A single injection of 10 mg/kg liposomal prednisolone phosphate resulted in complete remission of the inflammatory response for almost a week. In contrast, the same dose of unencapsulated prednisolone phosphate did not reduce inflammation, and had only a slight effect after repeated daily injections. It may be that preferential delivery of GC to the site of inflammation leads to very high GC concentrations at the inflamed joint, but lower plasma concentrations, with a consequent lower rate of adverse effects. These are very promising developments which exploit the broad spectrum of therapeutically relevant genomic and nongenomic GC actions at the site of inflammation.[32]

In conclusion, glucocorticoids are extremely valuable antiinflammatory agents with a range of actions that are useful in the management of inflammatory conditions, including arthritis and asthma. Recent research on GCs has highlighted the effects of cytosolic GCRs on intracellular signaling, transcription processes, and gene expression. Exploration of membrane-bound glucocorticoid receptors, dose–effect relationships, and the timing of glucocorticoid administration have stimulated intensive research activity aimed at improving the efficacy:risk ratio. Modified-release prednisone has already been approved for the treatment of rheumatoid arthritis and the associated morning stiffness. Further clinical developments seem likely to follow, such as new GCR ligands and liposome encapsulation, with a view to improving the risk–benefit ratio of GC therapy and the well-being of patients.

ON THE HORIZON

- Selective glucocorticoid receptor agonists (SEGRAs)
- Modified-release steroids
- Liposomal encapsulation
- Optimized combinations with biologicals

Immunomodulating Drugs

Gideon P. Smith and Edwin S.L. Chan

Excitement over biologic agents and their capacity to regulate immunological reactions that significantly impact immunologically mediated diseases, such as rheumatoid arthritis (RA) and inflammatory bowel disease (IBD), have overshadowed the older, small-molecule therapeutic agents. Nonetheless, when tested head-to-head, some small-molecule agents (most notably methotrexate) have proven to be almost as effective as biologics; moreover, combining small-molecule therapies with biological agents generally leads to significantly better outcomes than the use of either agent alone.[1] Given this synergy, and the fact that they are often much more cost-effective, it is likely that small-molecule immunomodulatory drugs will continue to be used. Here, we review the most widely accepted and commonly used immunomodulators currently available.

METHOTREXATE

Methotrexate (Fig. 84.1) was employed in the treatment of RA as early as 1951, but its popularity with regard to RA did not come until the 1980s. Over the years, extensive experience with its use in inflammatory diseases as diverse as RA (Chapter 53), psoriasis (Chapter 64), and IBD (Chapter 75) has taught us a great deal about its safety, efficacy, and toxicity, as well as its anti-inflammatory mechanisms of action. In this respect, methotrexate, much as corticosteroids, can be justly regarded as a cornerstone of immunomodulatory therapy.

Pharmacokinetics of Methotrexate

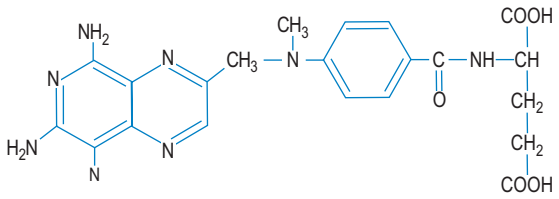
As an anti-inflammatory agent, methotrexate is administered at low doses (usually 10 to 25 mg/week) once weekly, usually orally, but it can also be given subcutaneously or intramuscularly. At these doses, oral bioavailability is high (60% to 70%), and although transporters are responsible for its absorption from the gastrointestinal (GI) tract, saturation effect does not occur. A small portion of methotrexate is metabolized by hydroxylation into 7-hydroxymethotrexate. Both compounds have a serum half-life of no more than 8 hours. The much longer anti-inflammatory action, which allows for once-weekly dosing, must therefore be mediated by other longer-lasting metabolites, such as polyglutamates. Excretion occurs principally via the urinary tract, but also via the biliary tract. Therefore renal function is an important consideration in methotrexate dosing, and any medication that impairs glomerular filtration may also potentiate methotrexate's effectiveness and toxicity.[2]

Mechanisms of Action for Methotrexate

As an analogue of folic acid, methotrexate is an inhibitor of purine and pyrimidine synthesis and thereby suppresses cellular proliferation (Table 84.1). These actions are dependent on inhibition of dihydrofolate reductase; hence toxicities arising from high-dose methotrexate therapy can be treated with folic acid derivatives, such as leucovorin. However, folic or folinic acid, which are often given in conjunction with methotrexate in inflammatory diseases to reduce the incidence of mucositis and bone marrow suppression, does little to inhibit its anti-inflammatory efficacy. Decreases in purine and pyrimidine concentrations in the serum have been observed following a single dose of methotrexate, along with a decreased proliferation of antigen-stimulated lymphocytes. However, these changes are transient and insufficient to explain the anti-inflammatory effects of once-weekly dosing. This, as well as the low doses of methotrexate required to produce an anti-inflammatory effect, suggests that the anti-inflammatory actions are mediated via different mechanisms.

One alternate mechanism is that methotrexate blocks intracellular transmethylation reactions and inhibits the production of *S*-adenosylmethionine. Since *S*-adenosylmethionine is necessary for the formation of the toxic polyamine metabolites spermine and spermidine, their accumulation at the inflammatory site is prevented. This inhibition of transmethylation is associated with an impairment of monocyte and lymphocyte function and thus potentially the synthesis of reactive oxygen species. However, diminution of transmethylation by the use of the *S*-adenosylhomocysteine hydrolase inhibitor, deaza-adenosine, has failed to produce any beneficial clinical effects in RA.

Methotrexate and its long-acting polyglutamate metabolites also exert anti-inflammatory effects by releasing the endogenous autocoid adenosine.[3] As potent inhibitors of the enzyme 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase, methotrexate polyglutamates promote the accumulation of AICAR in tissues. Since AICAR inhibits catabolizing enzymes for both adenosine and adenosine monophosphate (AMP), which can be dephosphorylated to adenosine, the net effect is intracellular and extracellular increases in adenosine levels. These metabolic pathways are pharmacologically relevant since aminoimidazole carboxamide and adenosine have been shown to be increased in urine following low-dose methotrexate treatment in patients with psoriasis.[4] Adenosine causes diminution of neutrophil accumulation, adhesion, phagocytosis, and generation of reactive oxygen species, inhibition of adhesion molecule expression, suppression of pro-inflammatory cytokines, and induction of anti-inflammatory cytokines, as well as modulation of macrophage and endothelial function.[2] Indeed, blockade of adenosine receptors reversed the anti-inflammatory effects of methotrexate in animal models. It



Methotrexate

FIG. 84.1 Methotrexate—Chemical Structure.

TABLE 84.1 Methotrexate: Mechanisms of Action

Suggested Mechanism	Rationale
Folate antagonism	Prevents purine and pyrimidine synthesis required for the proliferation of actively dividing immune cells, such as lymphocytes
Inhibition of spermine and spermidine production	Reduces formation of polyamines harmful to tissues
Alteration of cellular redox state	Reversible inhibition of lymphocyte and macrophage functions
Release of adenosine	Generation of a potent endogenous anti-inflammatory mediator through inhibition of catabolism of both adenosine and adenosine monophosphate

has also been suggested that caffeine, itself a nonselective antagonist of adenosine receptors, may both reduce the effectiveness of methotrexate in RA and protect against the development of cirrhosis of the liver, a major side effect of methotrexate.[5]

THERAPEUTIC PEARLS

Methotrexate

- Proven safety profile
- Concomitant administration of folic acid advisable
- Anti-inflammatory effects may be reduced by heavy use of caffeine
- Hepatotoxicity a rare but real concern
- Teratogenic

Risk of hepatotoxicity increased with:

- Alcohol use
- Hepatitis
- Diabetes
- Obesity
- Alpha-1-antitrypsin deficiency

Adverse Effects

Over decades, methotrexate has proven to be one of the safest disease-modifying antirheumatic drugs (DMARDs). Serious side effects such as cirrhosis are much less common than previously thought (Table 84.2). The use of folic acid has decreased the occurrence of mucosal and GI side effects, without limiting its anti-inflammatory activity, and cytopenias are managed adequately with regular blood counts. Although side effects, such as nausea and vomiting, may resolve spontaneously or respond to dose reduction or folic acid supplementation, mild

transaminasemia has rarely necessitated discontinuation of the medication. The risk of serious hepatotoxicity over 5 years of use is likely to be less than 1 in every 1000 patients with RA but may be more common in psoriasis patients. Risk factors, such as alcohol consumption, hepatitis B and C, diabetes, obesity, and alpha-1-antitrypsin deficiency, identify patients more likely to develop a methotrexate-induced hepatic injury. However, other serious side effects, such as pneumonitis, may be overlooked, since early symptoms (mild cough or shortness of breath) are often ignored and no serologic screen exists. Early identification allows for prompt discontinuation. The risk of developing solid tumors is debated, since the risk of malignancies is intrinsic to some of the conditions, such as RA, for which methotrexate is used. It is likely the risk of drug-induced malignancy in some patients is real since reports have documented tumor regression following discontinuation of methotrexate. But the risk remains extremely small.

SULFASALAZINE

Sulfasalazine (Fig. 84.2) was originally introduced in the late 1930s for the treatment of RA but is now used in a wide range of inflammatory diseases, in particular, IBD and the seronegative arthritides. It consists of a derivative of anti-inflammatory salicylic acid, 5-amino-salicylic acid, and the antimicrobial sulfapyridine. These two moieties are joined together by an azo bond. Which component is responsible for the drug's anti-inflammatory actions is unclear, but it appears to vary according to disease state. For instance, in IBD, 5-amino-salicylic acid is likely the main active component, as it is poorly absorbed following metabolism by intestinal flora. In inflammatory arthritides, sulfapyridine is likely to play a more important role, as it is relatively well absorbed and has a bioavailability in the region of 60%. Since acetylation is the principal route of the metabolism of sulfapyridine following absorption, acetylator status is a major determinant of the plasma half-life. Similarly, slow acetylators are more liable to develop side effects.

Mechanisms of Action for Sulfasalazine

Sulfasalazine has several immunomodulatory effects. Lymphocyte proliferation is suppressed *in vitro* and involves both B-cell and T-cell populations. *In vivo*, a decrease in activated

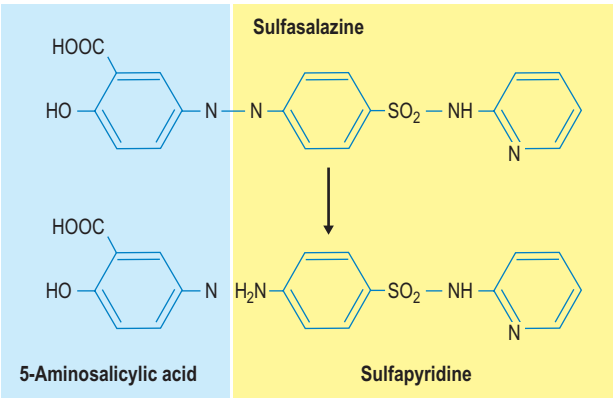

FIG. 84.2 Sulfasalazine—Chemical Structure.

lymphocytes in the peripheral blood is also seen. Tumor necrosis factor (TNF) production is suppressed, and receptor binding is inhibited. Sulfasalazine also inhibits activation of the transcription factor, nuclear factor (NF)-κB. Like methotrexate, sulfasalazine inhibits AICAR transformylase and thus promotes the accumulation of adenosine and its anti-inflammatory actions via the adenosine A_{2A} receptor. Indeed, treatment of animals with an adenosine A_{2A} receptor antagonist reversed sulfasalazine's reduction of leukocyte accumulation in an air-pouch model of inflammation.

KEY CONCEPT

Sulfasalazine: Mechanism of Action

- Suppresses the proliferation of lymphocytes
- Suppresses proinflammatory cytokine production
- Inhibits activation of nuclear factor (NF)-κB
- Promotes adenosine accumulation

Adverse Effects

In a large series, a quarter of those treated over 11 years stopped treatment because of toxicity.[6] Most toxicities occurred early and were both trivial and resolved following therapy withdrawal. Most common are nausea, vomiting, anorexia, and rash. Serious cutaneous reactions, such as toxic epidermal necrosis, are rare. Transaminasemia and drug-induced hepatitis can occur. Blood dyscrasias with megaloblastic anemia, neutropenia, aplastic anemia, and myelodysplastic syndrome may arise. Neurological adverse effects include headache and dizziness or, more seriously, peripheral neuropathy, Guillain-Barré syndrome, or transverse myelitis. Sulfasalazine should be avoided in patients with sulfa allergy, and glucose-6-phosphate dehydrogenase (G6PD). Deficiency screening should be performed before prescribing.

AZATHIOPRINE

Azathioprine, an imidazolyl derivative of 6-mercaptopurine (Fig. 84.3), has been widely used in RA and IBD as well as in solid organ transplantations. Cleavage into 6-mercaptopurine and the imidazole moiety occurs rapidly within erythrocytes, both enzymatically by glutathione transferase and nonenzymatically. Several enzymes (Table 84.3) participate in the metabolism of

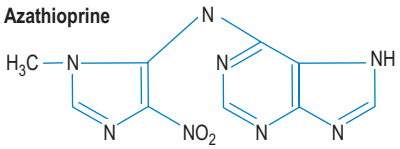

FIG. 84.3 Azathioprine—Chemical Structure.

TABLE 84.3 Principal Enzymes Involved in the Metabolism of Azathioprine

Enzyme	Action
Glutathione transferase	Cleaves azathioprine into 6-mercaptopurine and imidazole moieties
Thiopurine methyltransferase	Metabolism of 6-mercaptopurine
Xanthine oxidase	Conversion of 6-mercaptopurine to 6-thiouric acid

6-mercaptopurine into active and inactive compounds. One of these, thiopurine methyltransferase, is associated with genetic polymorphisms; inherited changes in its activity may impact patient response to azathioprine. Xanthine oxidase inactivates 6-mercaptopurine by converting it to 6-thiouric acid. Since this occurs mainly in the liver, toxicity from azathioprine therapy is a danger in enzyme deficiency states, as a result of disease or the use of drugs, such as allopurinol.

Proposed Mechanisms of Action for Azathioprine

The immunomodulatory mechanism of azathioprine remains unclear. As purine analogues, the active metabolites interfere with the salvage pathway and *de novo* synthesis of purines, and they are incorporated into RNA and DNA. The proliferation of T and B lymphocytes is inhibited, and the function of natural killer (NK) cells is suppressed without any change in cell numbers. The production of antibodies is also suppressed, although it is not known which of these effects predominate *in vivo*. Cellular responses to chemoattractants are altered, and the production of cytokines, such as interleukin-6 (IL-6), is also affected.

Adverse Effects

Azathioprine is generally well tolerated. The most common side effects are mild and affect the GI system. Pancreatitis can occur as an idiosyncratic reaction. Hepatotoxicity and cholestasis are not uncommon, and hepatic peliosis and nodular regenerative hyperplasia occur rarely. There have been reports of possible heightened risk for non-Hodgkin lymphoma, but because of the rarity of these events, no definite link has been established. Bone marrow suppression and opportunistic infections pose far greater threats.

CYCLOPHOSPHAMIDE

Alkylating agents were used in the treatment of inflammatory diseases after promising reports on using nitrogen mustard in RA. Cyclophosphamide (Fig. 84.4) is metabolized to produce the alkylating agent phosphoramide mustard as well as acrolein, which, although inactive, results in the hemorrhagic cystitis

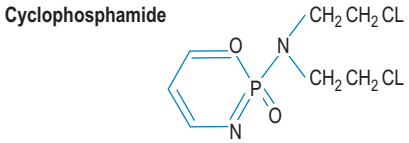

FIG. 84.4 Cyclophosphamide—Chemical Structure.

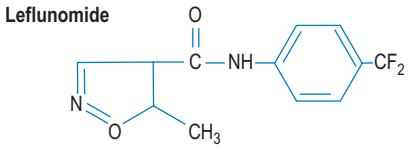

FIG. 84.5 Leflunomide—Chemical Structure.

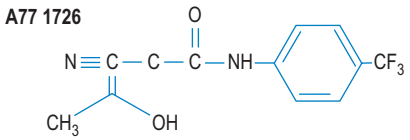

FIG. 84.6 A77 1726—Chemical Structure.

associated with cyclophosphamide. Cyclophosphamide can be given intravenously, but bioavailability following oral administration is high (>75%). Toxicity has severely limited its use in inflammatory diseases, although its contribution to the management of lupus nephritis cannot be denied. The alkylating actions occur at guanine residues (principally on DNA, but also on RNA) resulting in cross-linkable strands and disruption of transcription and translation.

Mechanisms of Action of Cyclophosphamide

This alkylating process has immunomodulating effects on resting and actively dividing cells. The numbers of circulating CD4 T lymphocytes and, to a lesser extent, CD8 T lymphocytes are reduced, thus reducing the CD4/CD8 ratio. Despite an apparent increase in immunoglobulin-secreting cells, B-cell function is suppressed, and overall immunoglobulin synthesis is reduced.

Adverse Effects

The best-known toxicity is hemorrhagic cystitis. Since this occurs more frequently following oral dosing, this route of administration is rarely used. This may relate to continuous exposure of the bladder to acrolein, so the acrolein-neutralizing agent 2-mercaptoethane sulfonate (Mesna) is used prophylactically along with copious hydration. Hemorrhagic myocarditis can also occur and may cause myocardial necrosis, hemopericardium, and congestive cardiac failure. However, survivors of acute cardiac toxicity do not show any residual electrocardiographic or echocardiographic abnormalities.

Besides bone marrow suppression, reduction of fertility, and a heightened risk of infection, cyclophosphamide therapy has been associated with secondary malignancies, which may occur years after drug cessation. Malignancies of the bladder, often of a transitional cell type, tend to occur only in those with a history of treatment-related hemorrhagic cystitis. Myeloproliferative and lymphoproliferative disorders have also been associated with cyclophosphamide use.

Other Nitrogen Mustard Derivatives

Chlorambucil, or 4-[bis(2chlor-ethyl)amino]benzenebutanoic acid, has a wide distribution in tissue and 87% oral bioavailability, but unlike cyclophosphamide, it does not require metabolism by the liver to become metabolically active.[7] The only indication approved by the US Food and Drug Administration (FDA) is for the treatment of chronic lymphocytic leukemia (CLL), but like cyclophosphamide, chlorambucil has been reported to be used in treatments for the same wide range of inflammatory conditions. The mechanism of action and side effect profile is also similar to those of cyclophosphamide, but with a higher risk of permanent aplasia.[8]

Melphalan is another phenylalanine derivative of nitrogen mustard, mainly used in treating multiple myeloma. It has been less widely adopted but has been used off-label in a variety of inflammatory conditions. Adverse effects and mechanisms are the same as those of cyclophosphamide, as described above.

LEFLUNOMIDE

Leflunomide is an inhibitor of *de novo* pyrimidine synthesis. Leflunomide (Fig. 84.5) is converted into the long-acting active compound A77 1726 (2-cyano-3-hydroxy-N-[4-trifluoromethyl]-butenamide) (Fig. 84.6), a reversible inhibitor of the enzyme dihydroorotate dehydrogenase that is involved in pyrimidine synthesis. Because of this long half-life, therapy with leflunomide is usually started with a loading dose to quickly achieve therapeutic levels. A77 1726 is highly plasma-protein bound and undergoes enterohepatic recirculation.

Mechanisms of Action of Leflunomide

By inhibiting pyrimidine synthesis, pyrimidine nucleotide availability becomes insufficient for the proliferation of immune-response cells. This deficiency is inadequately replenished by the salvage pathways, rendering cell proliferation inefficient and limiting the clonal expansion of T cells. B-cell proliferation is similarly suppressed with the reduction of Cdk2, a cyclin-dependent kinase. Leflunomide also inhibits NF-κB activation. Although the effects of moderate concentrations are reversed by uridine *in vitro*, this reversal does not occur at higher concentrations, suggesting the possible involvement of other mechanisms. Leflunomide is known to inhibit tyrosine kinase activity at higher concentrations, although the relevance of this effect to therapeutic concentrations achievable *in vivo* remains questionable.

Adverse Effects

GI symptoms are the most common side effect, and hepatic damage is the most important toxicity. Although there are similarities to the toxicity profile of methotrexate, clinical trials have shown that leflunomide and methotrexate can be safely and effectively given together to patients with RA, but transaminasemia occurs more often than with methotrexate alone.[9,10] Fulminant hepatic failure is rare, but fatal cases have occurred. Skin reactions are mostly minor; however, more serious manifestations, such as toxic epidermal necrolysis, have been reported.

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil (Fig. 84.7) is widely used in solid organ transplantation and has also been increasingly employed in the treatment of autoimmune diseases. It is rapidly absorbed and hydrolyzed into the active compound, mycophenolic acid, which is a reversible inhibitor of inosine monophosphate dehydrogenase. Since inosine monophosphate dehydrogenase is a key enzyme in the *de novo* synthesis of guanine nucleotides, its inhibition is most significant in T and B lymphocytes, which are reliant on this pathway, as they lack the hypoxanthine-guanine phosphoribosyltransferase salvage pathway. The immunological effects are numerous. DNA synthesis in lymphocytes requires the incorporation of guanine nucleotides so that proliferation of lymphocytes is suppressed. Antibody production and NK-cell activity are also reduced, and *in vitro* cytokine production by activated human mononuclear cells is affected.[11] In addition, delayed-type hypersensitivity responses are suppressed. Although effective in a subset of patients with psoriasis and RA, mycophenolate mofetil has not been widely used in these conditions because other more effective medications are available. It is, however, becoming more popular in the treatment of some diseases, such as myositis, systemic contact dermatitis, severe atopic dermatitis, chronic urticaria, refractory pyoderma gangrenosum, bullous pemphigoid, pemphigus vulgaris, and pemphigus foliaceus, where it is effective with a low risk of side effects.

Adverse Effects

Absolute contraindications for mycophenolate mofetil are drug allergy and pregnancy (Category D). Relative contraindications include lactation; renal, hepatic, or cardiopulmonary disease; and peptic ulcer. It is generally well tolerated when used in autoimmune diseases, such as RA. The most common side effects are nausea, vomiting, abdominal discomfort, diarrhea, fever, headache, skin rash, back pain, and tremor, but these do not usually lead to discontinuation. Rarely reported side effects include leukopenia and other cytopenias, cutaneous and noncutaneous malignancies, and pancreatitis. Toxic doses have not been established for this medication. One patient suffered only moderate leukopenia with no significant GI side effects after ingesting 25 g of mycophenolate mofetil. Up to 4 g/day have been used in cardiac and up to 5 g/day in hepatic transplantation patients. However, increased efficacy was not observed above 2 g/day, and patients were more likely to experience GI symptoms and neutropenia at higher doses. For this reason, doses up to 2 g/day are usually employed to treat inflammatory conditions.

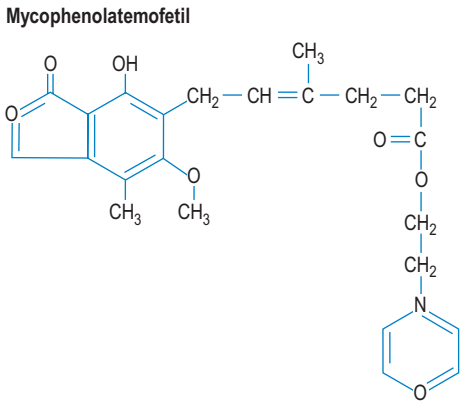

FIG. 84.7 Mycophenolate Mofetil—Chemical Structure.

HYDROXYUREA

Hydroxyurea is urea with one additional hydroxyl group. It inhibits ribonucleotide reductase, which catalyzes the reduction of ribonucleotides to deoxyribonucleotides, and is thus essential in DNA synthesis. It is effective in the treatment of psoriasis.[12] Hydroxyurea is well tolerated, with the most common side effects being hematological, usually megaloblastic anemia, but also leukopenia and thrombocytopenia. Other significant but rare adverse effects include renal and GI toxicity, a dermatomyositis-like syndrome, leg ulcers, radiation recall, and leukemias.

ORAL CYCLOSPORINE AND TACROLIMUS (FK506)

Cyclosporine (Fig. 84.8) and tacrolimus (Fig. 84.9) are structurally similar drugs that have been widely used in solid organ transplantation as well as in the treatment of immunological diseases. Cyclosporine has potent inhibitory effects in dampening the

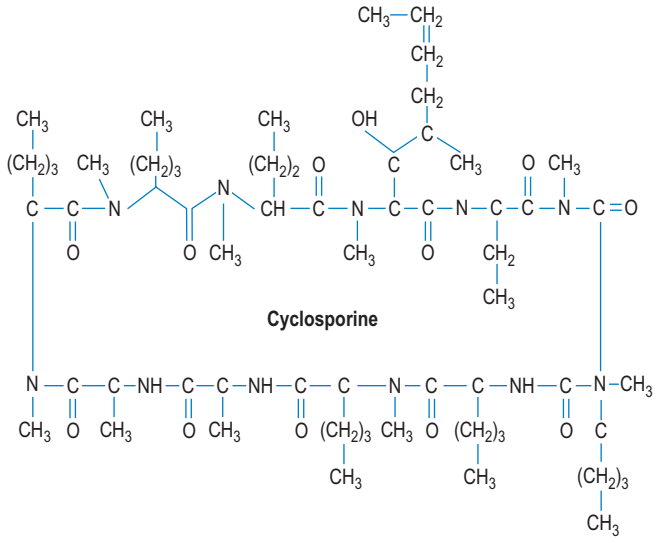

FIG. 84.8 Cyclosporine—Chemical Structure.

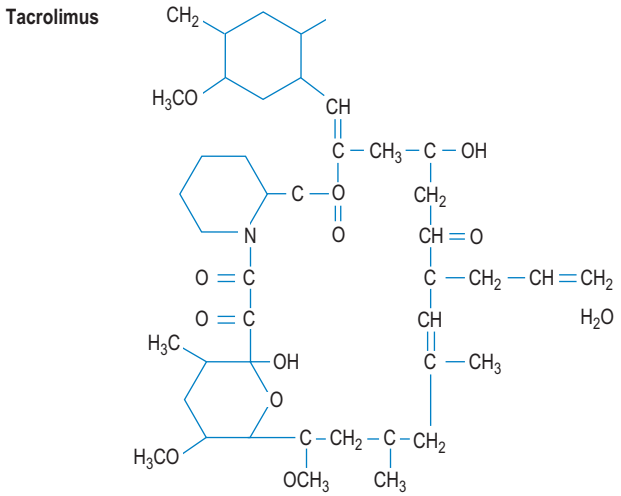

FIG. 84.9 Tacrolimus—Chemical Structure.

production of proinflammatory mediators, such as IL-2, by immunocompetent cells, most importantly T lymphocytes. It does so through binding cyclophilin, which produces a cyclosporine–cyclophilin complex. This complex binds the serine/threonine phosphatase calcineurin.[13] This disrupts the phosphorylation of regulatory proteins for which the nucleated factor of activated T cells (NF-ATs) is a critical component, preventing these proteins from translocating into the nucleus. Thus the transcription of genes, such as *IL-2*, which induces mitogenesis in activated T cells, cannot be effectively activated. Several other cytokines are affected, including IL-3, IL-6, transforming growth factor (TGF)-β, and interferon (IFN)-γ. Another T cell–specific immunophilin, FK506-binding protein (FKBP), binds tacrolimus to form a FK506-FKBP complex with similar resultant inhibitory activity on calcineurin.[14]

KEY CONCEPT

Cyclosporine: Mechanism of Action

- Association with cyclophilin
- Formation of cyclosporine–cyclophilin complex
- Binds calcineurin
- Inactivates calcineurin
- Regulatory proteins unable to translocate into nucleus
- Transcription of proinflammatory genes affected

Adverse Effects

The most common side effects of cyclosporine are hypertension, hyperkalemia, hypomagnesemia, and hyperlipidemia. More importantly, cyclosporine has well-documented short-term and long-term adverse effects on kidney function.[15] These data come from patients who had received solid organ transplants, most notably renal transplants. In such patients, initial doses of 15 to 25 mg/kg/day led to a reduction in the glomerular filtration rate (GFR) and rise in serum creatinine in a percentage of patients, as well as histologically proven nephropathy.[16] The pathogenic mechanism of kidney damage is poorly understood but is believed to consist of two phases.[17] The first phase is a period of partial ischemia secondary to vascular contraction, which is reversible with dose reduction or drug discontinuation. The later, irreversible phase results from chronic scarring of the glomeruli. Treatment recommendations for some diseases, such as psoriasis, have therefore been targeted at much lower maximum daily doses of 5 mg/kg/day, with a reduced dose if creatinine rises 30% above baseline. Otherwise healthy patients treated at these dosage levels have been successfully managed for many years on cyclosporine with no impact on the GFR.[18] Nephrotoxicity has also been a concern during tacrolimus therapy. Other adverse effects include increased rate of infections, malignancy, hepatotoxicity, GI upset, rash, tremor, headache, and insomnia.

TOPICAL PIMECROLIMUS AND TACROLIMUS (FK506)

Tacrolimus is also available in a topical formulation. Pimecrolimus is an alternative topical calcineurin inhibitor with a similar structure and identical mechanisms of action. The cyclosporine molecule is too large to penetrate the skin (1203 Da), whereas tacrolimus and pimecrolimus can, as they are much smaller molecules (804 and 80 daltons [Da], respectively). Both have been approved by the FDA for the treatment of atopic dermatitis but have found widespread use in many other conditions (psoriasis, oral and cutaneous lichen planus, vitiligo, pemphigoid, and pemphigus). They are most often used in patients or on body areas where long-term topical corticosteroids are contraindicated.

Adverse Effects

The most common side effect is local irritation at the site of application in severely inflamed skin. Therefore initial short-term treatment is often combined with topical steroids. An association with malignancy remains controversial. In 2005, 17 case reports of malignancy in patients using these topicals resulted in a black-box warning. Although further studies suggested that the rate of lymphoma from these case reports was lower than the rate observed in the general population in the United States. In 2006, the FDA revised the wording, but a black-box warning about these products remains in place.

SIROLIMUS

Sirolimus is a macrolide that binds the cytosolic protein FK-binding protein 12 (FKBP12). In contrast to the tacrolimus–FKBP12 complex, which inhibits calcineurin, the sirolimus–FKBP12 complex directly binds the mammalian target of rapamycin (mTOR) complex1 (mTORC1), thereby inhibiting the mTOR pathway. Thus it inhibits the response to IL-2, blocking the activation of T and B cells. It has shown promise in the treatment for systemic lupus erythematosus (SLE); Sjögren syndrome[19]; RA[20]; psoriasis; genetic disorders, such as tuberous sclerosis; and neoplastic disorders, such as Kaposi sarcoma.[21] The main advantage of sirolimus over tacrolimus or cyclosporine is reduced renal toxicity.

IMIQUIMOD

Imiquimod (Fig. 84.10), an imidazoquinoline drug, activates toll-like receptor (TLR)-7 and possesses both antiviral and antitumor activities.[22] As a cream preparation, it is effective in the treatment of plantar or external genital warts caused by infection with human papillomavirus (HPV). Immune amplification responses are induced through the stimulation of inflammatory cytokines.[23,24] Production of IFN-α is stimulated, and this suppresses replication of viruses in infected keratinocytes. NK-cell activity is also increased, partly through the

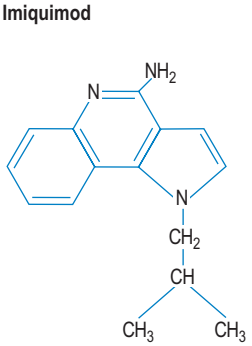

FIG. 84.10 Imiquimod—Chemical Structure.

induction of oligoadenylate synthase. The increase of dermal IFN-α transcript levels is rapid and dramatic.[25] Other cytokines modulated by imiquimod include TNF and IL-12, especially in peripheral blood monocytes.[26,27] The overall effect is a shift from a T-helper-2 (Th2)-cytokine–predominant profile toward a Th1-cytokine–predominant profile. Other conditions where imiquimod is effective include actinic keratosis, lentigo maligna, superficial basal cell carcinoma, and molluscum contagiosum.

Adverse Effects

Inflammation at the site of application represents the most common adverse reaction. However, nondermatological side effects, such as fever, fatigue, myalgia, and headache, have also been described usually when applied over large surface areas.

5-FLUOROURACIL

5-Fluorouracil is a uracil analogue that has two modes of action. First, it inhibits cell proliferation via direct incorporation into RNA causing abnormal base pairing. Second, it binds thymidylate synthetase, blocking the conversion of deoxyuridine monophosphate to deoxythymidine monophosphate, which is essential to DNA synthesis. It may also increase the expression of *p53*, a frequently mutated gene in nonmelanoma skin cancers.[28] It can be administered topically, intramuscularly, or intravenously. In topical form, its main uses are to treat actinic keratosis, superficial basal cell carcinoma, Bowen disease, keratoacanthoma, porokeratosis, and verruca vulgaris. However, intravenous treatment of recalcitrant psoriasis, mycosis fungoides, and scleroderma has also been reported.

Adverse Effects

Topical application is associated with an irritant dermatitis, but this is also seen as a marker of clinical efficacy. Parenteral administration for inflammatory conditions is not widespread; adverse effects from parenteral administration are more severe and include clinically significant bone marrow suppression, GI toxicity, and cutaneous reactions.

GLATIRAMER

Glatiramer acetate is a random polymer of glutamic acid, lysine, tyrosine, and alanine; the four amino acids found in myelin basic protein (MBP). The mechanism of action for glatiramer is unknown, but its similarity in structure to MBP may allow it to act as a decoy for immune targeting of myelin. It may also induce the expression of glatiramer acetate-specific suppressor T cells, and these are present in animal models. In contrast to imiquimod, glatiramer shifts the population of T cells from proinflammatory Th1 cells to regulatory Th2 cells that suppress the inflammatory response. It is FDA approved for the treatment of adults with relapsing-remitting multiple sclerosis (MS), even after only one event.

Adverse Effects

Absolute contraindications include allergy to glatiramer or mannitol. It is pregnancy Category B, but it is unknown if the drug is secreted in breast milk. The drug is given via subcutaneous injection, and the most common adverse effects are injection site reaction, flushing, rash, dyspnea, and transient chest pain.

FINGOLIMOD (FTY720)

Fingolimod is a relatively new immunomodulator for treating MS. It is a structural analogue of sphingosine and is phosphorylated intracellularly by sphingosine kinases.[29] Signaling via one of the sphingosine 1 phosphate receptors, S1PR1, it is believed to prevent migration of lymphocytes by halting their ability to leave lymph nodes. However, fingolimod has also been reported to act as a cPLA2 inhibitor,[30] a cannabinoid receptor antagonist,[31] and a ceramide synthase inhibitor.[32] So far, the FDA has only approved it for use in MS. However, it has also shown promise in murine models of SLE and RA, with reduced mortality from lupus nephritis[33] and improvement in arthritis, respectively.[34] It also has a potential role in the treatment of cutaneous inflammatory conditions, such as psoriasis and atopic dermatitis.[35]

Adverse Effects

The most common side effects are minor and include headache and fatigue. However, fingolimod has also been associated with serious infections, an increased rate of skin cancers, bradycardia, and one case of focal hemorrhagic encephalitis.

CONCLUSIONS

The field of small molecule immunomodulators contains both traditional and new molecules. The traditional molecules come with a long history of efficacy and side-effect data, and this allows us to safely and accurately utilize these therapies. Despite the introduction of biologics, traditional small-molecule agents, such as methotrexate and cyclosporine, are both clinically efficacious and cost-effective and thus remain the workhorses of our modern pharmaceutical armamentarium. However, as our understanding of the pathways involved in inflammation evolve, our therapeutics are also refined, allowing the production now, for example, of topically effective calcineurin inhibitors, such as tacrolimus and pimecrolimus, which avoid the adverse effects of systemic cyclosporine or topical steroids, and sirolimus, which reduces toxicity profiles of systemic FKBP2 signaling. In addition, newer agents, such as glatiramer and fingolimod, allow treatment of MS, a disease recalcitrant to more traditional therapies, and, although not currently being used in other inflammatory disorders, have shown promise in animal models. The field of small-molecule immunomodulators, therefore, remains one of both current clinical relevance and continuing, exciting new developments.

ON THE HORIZON

- Refinement of our understanding of the pathways and actions of receptors targeted by our current medications is key to producing more elegant therapies or advancing our understanding of which therapeutics are most effective to combine.
- Separating therapeutic effects from the pathways leading to side effects would enable much safer and more tolerable small-molecule medications.
- Better understanding of the dysregulation that occurs in inflammatory conditions, and the activation of the immune system, will be essential to ensuring the efficacy of such new modalities.

The challenge in the next 5 to 10 years is to continue this refinement in the targeting of small molecules. Many of the agents we currently use target early parts of pathways or indiscriminately

trigger multiple receptors. This leads to a greater range of side effects and thus limits our ability to reach adequate dosing levels. A prime example of this is methotrexate, which leads to increased adenosine levels and thus triggers all four adenosine receptors. By developing more selective molecules targeting, for instance, just the adenosine A_{2A} receptor, not only would we avoid the side effects attributable to other adenosine receptors, but we might also avoid the effects of methotrexate on bone marrow and mucous membranes via inhibition of dihydrofolate reductase. In other medications, more specific targeting of pathways may similarly reduce side effects and make for more effective therapeutics. This will require a better understanding of the immune system and its dysregulation in disease, as well as the development and application of these medications to clinically relevant models.

Protein Kinase Antagonists

Arian Laurence, Massimo Gadina, Pamela L. Schwartzberg, and John J. O'Shea

Reversible protein phosphorylation is one of the major mechanisms controlling protein activity in all eukaryotic cells. As such, it is involved in all fundamental cellular processes, including cell cycle and cell growth, cell shape and movement, metabolism, differentiation and apoptosis. This covalent modification is an important means for transmitting information from outside the cell and between sub-cellular components within the cell and is a major component of signal transduction. Phosphorylation is a key mechanism underlying signaling in healthy cells, as exemplified by insulin and other growth factors, but in addition, the importance of protein phosphorylation is supported by evidence that mutations and dysregulation of protein kinases play causal roles in human disease. This is especially true in cancer, in which mutant protein kinases or their upstream activators function as oncogenes.

From the point of view of an immunologist, protein phosphorylation is a major mechanism by which immune receptors exert their effect. A critical first step in signaling by many cytokine receptors is the activation of phosphorylation. The receptors for classical growth factor cytokines, including stem cell factor and platelet-derived growth factor (PDGF) are receptor tyrosine kinases (RTKs), whereas the receptors for transforming growth factor family cytokines are receptor serine-threonine kinases. Type I and II cytokine receptors signal via the activation of receptor-associated Janus kinases. Other cytokines such as interleukin (IL)-1 and tumor necrosis factor (TNF) initiate proximal signaling in a kinase-independent manner, but nonetheless signal through kinase cascades to exert their effects (Chapter 14).

Other key immune receptors, including the T-cell receptor (TCR), B-cell receptor (BCR), and Fc receptors, also trigger signaling via kinases. As discussed in Chapter 4, the first step in signaling by these multi-chain immune recognition receptors (MIRRs) is tyrosine phosphorylation of the receptor itself and adapter molecules mediated by the Src family protein tyrosine kinase (PTK) (Fig. 85.1). This leads to the recruitment of the PTK members Syk (spleen tyrosine kinase) and Zap70 (zeta chain associated protein kinase 70) to invariant chains of MIRRs, followed by phosphorylation of adapters like SLP-76 and the activation of Tec (tyrosine kinase expressed in hepatocellular carcinoma) family PTKs. These initial steps lead to activation of serine-threonine kinases, including the protein kinase C (PKC) family and mitogen-activated protein kinases (MAPKs); many of these downstream effectors are used by both MIRRs and cytokine receptors. We now know a great deal of how the cascade of protein phosphorylation links events at the plasma membrane to calcium modulation, cytoskeletal rearrangement, gene transcription, and other canonical features of lymphocyte activation (Chapter 10).

The non-redundant functions of various kinases in different types of immune cells are best illustrated through studies of both gene-targeted knockout mice and humans with genetic diseases, making clear that protein phosphorylation is of major importance in immune and inflammatory mechanisms. Based on these genetic findings, targeting protein kinases was proposed to be a useful strategy in the development of novel immunosuppressant drugs and is one of the most active areas of pharmaceutical drug development. The field is now so vast that it is impractical to comprehensively review all this information in one chapter; therefore, we will focus on important historical precedents and then discuss drugs and targets most relevant for immune-mediated disease (Table 85.1). We will start by briefly reviewing some of the basics of kinase biochemistry.

STRUCTURE AND FUNCTION OF PROTEIN KINASES

Protein kinases, or phosphotransferases, catalyze the transfer of the γ-phosphate from a purine nucleotide triphosphate (*i.e.*, ATP and GTP) to the hydroxyl groups of their protein substrates. They generate phosphate monoesters using protein alcohol groups (on serine and threonine residues) and/or protein phenolic groups (on tyrosine residues) as phosphate acceptors. Thus, protein kinases can be classified by the amino acid substrate preference: serine/threonine kinases, tyrosine kinases, and dual kinases (meaning that both serine/threonine and tyrosine residues can be phosphorylated). Almost all protein kinases have catalytic domains that belong to a single eukaryotic protein kinase (ePK) superfamily. The common evolutionary ancestry of the kinase domain (also known as the catalytic domain), which consists of 250 to 300 amino acid residues, gives rise to a highly conserved three-dimensional structure.

There are 518 kinases in the human genome divided into eight major groups, which in totality represent 1.7% of the

KEY CONCEPTS

Kinase Families

518 kinases in the genome
90 protein tyrosine kinases (*e.g.*, JAKs)
400 protein serine/threonine kinases:
- AGC kinase family (*e.g.*, protein kinase B/AKT)
- CAMK kinase family (*e.g.*, Calmodulin-dependent kinase)
- CMGC kinase family (*e.g.*, MAP kinases: ERK, JNK, p38)
- STE kinase family (*e.g.*, MAPK kinases, MAPKK kinases)
- TKL kinase family (*e.g.*, IRAK)
- Others: casein kinase family, GYC kinase family, IKK family

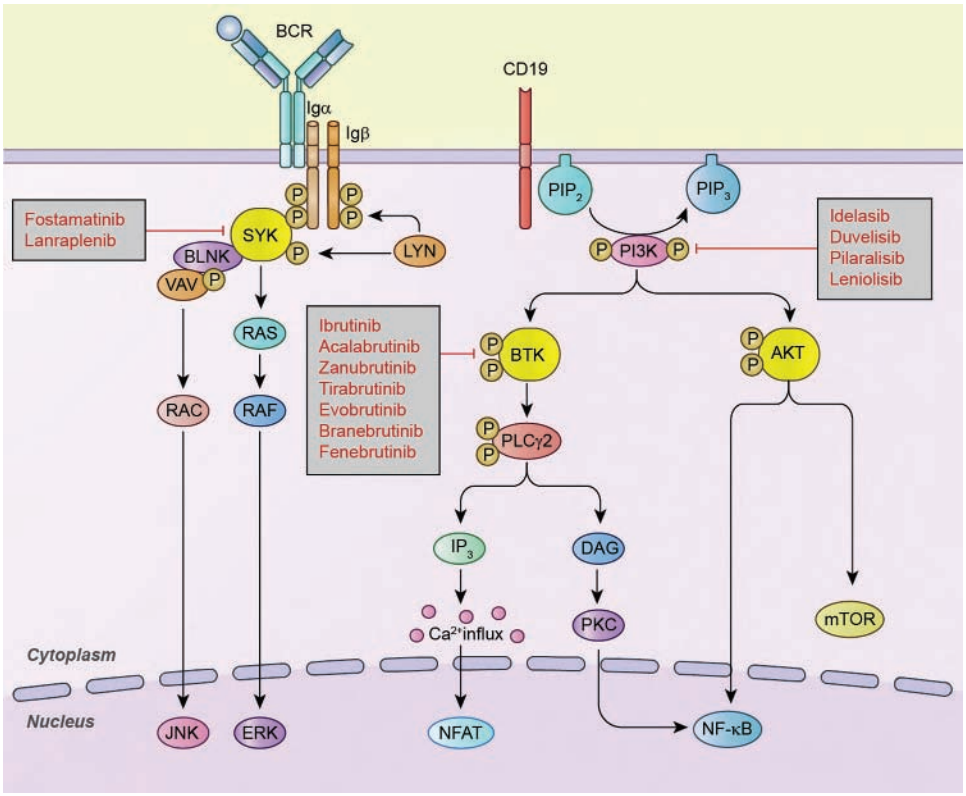

FIG. 85.1 Proximal Signaling Events in Response to B-Cell Receptor (*BCR*) Activation. Engagement of the BCR and related multichain immune recognition receptors (MIRRs) induces tyrosine phosphorylation of the receptor mediated by Src family kinases, such as Lyn. This allows recruitment of Spleen tyrosine kinase (Syk, or Zap-70 Zeta chain associated protein kinase-70) in T cells), which leads to activation of downstream serine kinases including Raf and other mitogen actived protein kinase (MAPK) family members. Signaling by MIRRs also activates the lipid kinase phosphatidylinositol 3′ kinase (PI3′K), which generates phosphatidylinositol 3,4,5, trisphosphate (PIP_3) and activates Bruton's tyrosine kinase and Akt.

Table 85.1 Kinase Inhibitors Approved for Immune-Mediated Disease

Kinase Class	Drug	Target	Indication
Abl	Imatinib	Abl	Hypereosinophilic syndrome, graft versus host disease
Janus kinase	Tofacitinib	JAK1, JAK2, JAK3	Rheumatoid Arthritis, Psoriatic Arthritis, Juvenile arthritis, Ankylosing spondyloarthritis, Ulcerative Colitis
	Ruxolitinib	JAK1, JAK2	Polycythemia vera and other Myeloproliferative neoplasms Graft versus host disease Atopic dermatitis (topical)
	Baricitinib	JAK1, JAK2	Rheumatoid Arthritis, Covid19
	Peficitinib	Pan JAK	Rheumatoid Arthritis (Japan, South Korea, Taiwan)
	Upadacitinib	JAK1 > JAK2	Rheumatoid Arthritis, Ankylosing spondyloarthritis
	Filgotinib	JAK1	Rheumatoid Arthritis (Europe, Japan)
	Abrocitinib	JAK1	Atopic Dermatitis
	Fedratinib	JAK2/FLT3	Myleloproliferative neoplasms
	Oclacitinib	Multiple JAKs	Atopic dermatitis (dogs)
	Delgocitinib	pan-JAK	Atopic dermatis - topical
Receptor Tyrosine kinase	Nintedanib	VEGFR, FGFR, PDGFR	Idiopathic pulmonary fibrosis, systemic sclerosis associated interstitial lung disease
Syk family	Fostamatinib	Syk	Idiopathic thrombocytopenic purpura
Tec family	Ibrutinib	Btk	Lymphoma
	Acalabrutinib	Btk	Lymphoma, Leukemia
	Zanubrutinib	Btk	Lymphoma, Leukemia
	Tirabrutinib	Btk	Lymphoma (Japan)

human genome. The protein tyrosine kinase (PTK) family has 90 members, one-third of which are receptor tyrosine kinases (RTK), and the remainder are cytoplasmic proteins that typically function in close proximity to, and downstream of, receptor/ligand complexes.

In terms of its catalytic role, the kinase domain has three functions: (1) the binding of the ATP (or GTP) phosphate donor as a complex with a divalent cation (usually Mg^{2+} or Mn^{2+}), (2) the binding of the protein substrate, and (3) the transfer of the γ-phosphate from ATP or GTP to the protein substrate. Despite the huge number of serine/threonine and tyrosine kinases

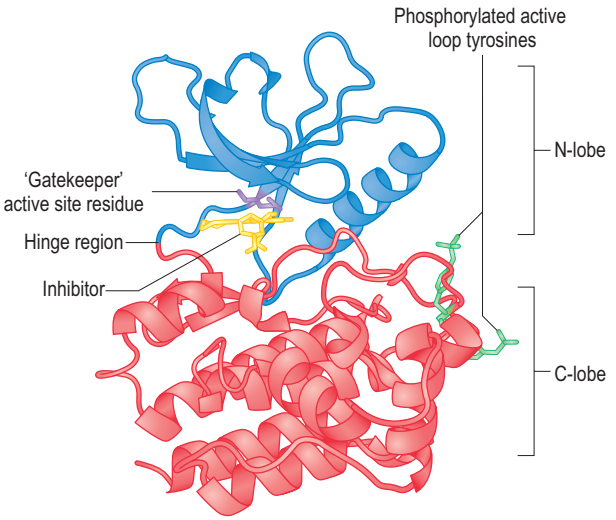

FIG. 85.2 Crystal Structure of the JAK3 Kinase Domain. This structure captures the active conformation of Janus kinase 3 (JAK3) with both active loop tyrosine residues phosphorylated *(green)*. The molecule can be described in two halves, with the N terminal lobe presented in blue and the C terminal domain in *red*. These are linked by a hinge region that forms part of the active site. Highlighted in *magenta* within the active site is the gatekeeper residue. Bound within this site is an analogue of the inhibitor staurosporine (*yellow*), and its proximity to the "gate keeper" residue highlights why this residue and this region are critical for the specificity of inhibitors for individual protein kinases.

there is evidence of a common ancestor and this is reflected in structural similarities particularly in the active (ATP bound) confirmation. The major kinase domains of all typical protein kinases consist of two lobes (N-lobe and C-lobe) that surround the nucleotide binding site (Fig. 85.2).[1] The smaller N-lobe consists of a cluster of β-pleated sheets with a single α-helix. The larger C-lobe is made up of α-helices. Within the C-lobe lies the substrate-binding site, typically a groove on the surface. A hinge region connects the two lobes. The hinge, together with two loops emerging from each lobe, form the ATP binding pocket and provide the primary target for most kinase inhibitors. In many protein kinases a loop emerging from the C-lobe, termed the activation loop, must be phosphorylated in order for the kinase to be fully active. Substrates of protein tyrosine kinases often include the activation loop of downstream kinases, creating signaling cascades of proteins that in turn phosphorylate each other; examples include the MAPKs (Fig. 85.3).

A SHORT HISTORY OF THE GENERATION OF KINASE INHIBITORS

Given that protein kinases bind ATP and that many inhibitors are competitive ATP antagonists, the notion that therapeutically useful kinase inhibitors could be generated was initially met with some skepticism. Given the hundreds of human kinases, many of which serve critical cellular functions, it was not clear *a priori* that it would be possible to attain the necessary specificity. Moreover, protein kinases are not the only kinases—there are lipid kinases and nucleotide kinases, and many other ATP-binding proteins that may share structural similarities with PTKs. For these reasons, designing a selective small molecule kinase inhibitor that sits in the ATP-binding pocket and does not target some other essential ATP-dependent process seemed daunting.[2] Fortunately, this dismal view does not reflect reality.

The first FDA-approved protein kinase inhibitor is imatinib. The mutated form of the Abelson leukemia (Abl) tyrosine kinase, BCR (breakpoint cluster region)-Abl, represents a fusion protein that is the result of a chromosomal translocation (Philadelphia chromosome) encountered in patients suffering from chronic myeloid leukemia (CML). The essential requirement for BCR-Abl kinase activity in CML made it an ideal target despite the aforementioned caveats with targeting protein kinases; in fact, imatinib has revolutionized the treatment of CML, arresting the progression of disease with minimal side effects in contrast with conventional cytotoxic chemotherapies.[3]

In addition to activity against Abl kinase, imatinib has activity against several other PTKs[3] and is effective in gastrointestinal stromal tumors and hypereosinophilic syndrome through effects on Kit and PDGFR platelet derived growth factor receptor)-FIPIL1 kinases, respectively. When considering immune-mediated disease, imatinib is used in the clinic for the treatment of fibrotic disease, including skin fibrosis associated with chronic graft *versus* host disease (GvHD) in patients with allogeneic bone marrow transplants (Chapter 92).

Receptor tyrosine kinases also emerged as targets in oncology and multiple monoclonal antibodies including bevacizumab (vascular endothelial growth factor receptor; VEGFR), ranibizumab (VEGFR), cetuximab (epidermal growth factor receptor; EGFR), pertuzumab (HER) and trastuzumab (HER2/neu) were generated, along with small molecule antagonists including erlotinib, gefitinib and others. Of note, nintedanib is a VEFGR, PDGFR, and FGFR (fibroblast growth factor receptor) signaling inhibitor approved for treatment of idiopathic pulmonary fibrosis as well as systemic sclerosis-associated interstitial lung disease.

At the time of writing, there are more than 70 FDA-approved small molecule kinase inhibitors, the majority of which are approved for oncologic indications, and more than 100 other inhibitors in clinical trial or development[4] (https://www.icoa.fr/pkidb/).

While conservation of the kinase ATP binding pocket has theoretically posed a problem for designing kinase inhibitors, in practice this has not happened for a number of reasons. While kinases may be structurally similar in an active ATP-bound confirmation, the inactive confirmation is more unique and can be used to improve selectivity.[5] In addition, the ATP binding region is made up of six polar amino acid residues that are invariant across whole families of kinases; similarly, there are a number of lipophilic residues that are highly conserved. This critical region contains an amino acid whose amide carbonyl binds to N-6 of adenine in the active confirmation. The side chain of this amino acid sticks into the reaction pocket in the inactive state and for this reason is referred to as "the gatekeeper residue." As the side chain is not involved in direct ATP binding, it varies across kinases, and variation of this gatekeeper residue is exploited by a number of inhibitors that are able to bind the inactive confirmation of specific kinases. In the case of Abl kinase, the gatekeeper residue is threonine, which binds directly to a methyl group of the phenyl ring of the Abl kinase inhibitor imatinib. Across the collective kinase superfamily, almost any amino acid can appear as the gatekeeper, although in practice it is typically a bulky nonpolar residue (methionine, tyrosine, phenylalanine, lysine). Cyclin dependent kinase 2 (CDK2) contains an additional pocket on its C-lobe next to the ATP binding pocket that can be exploited in the design of inhibitors.

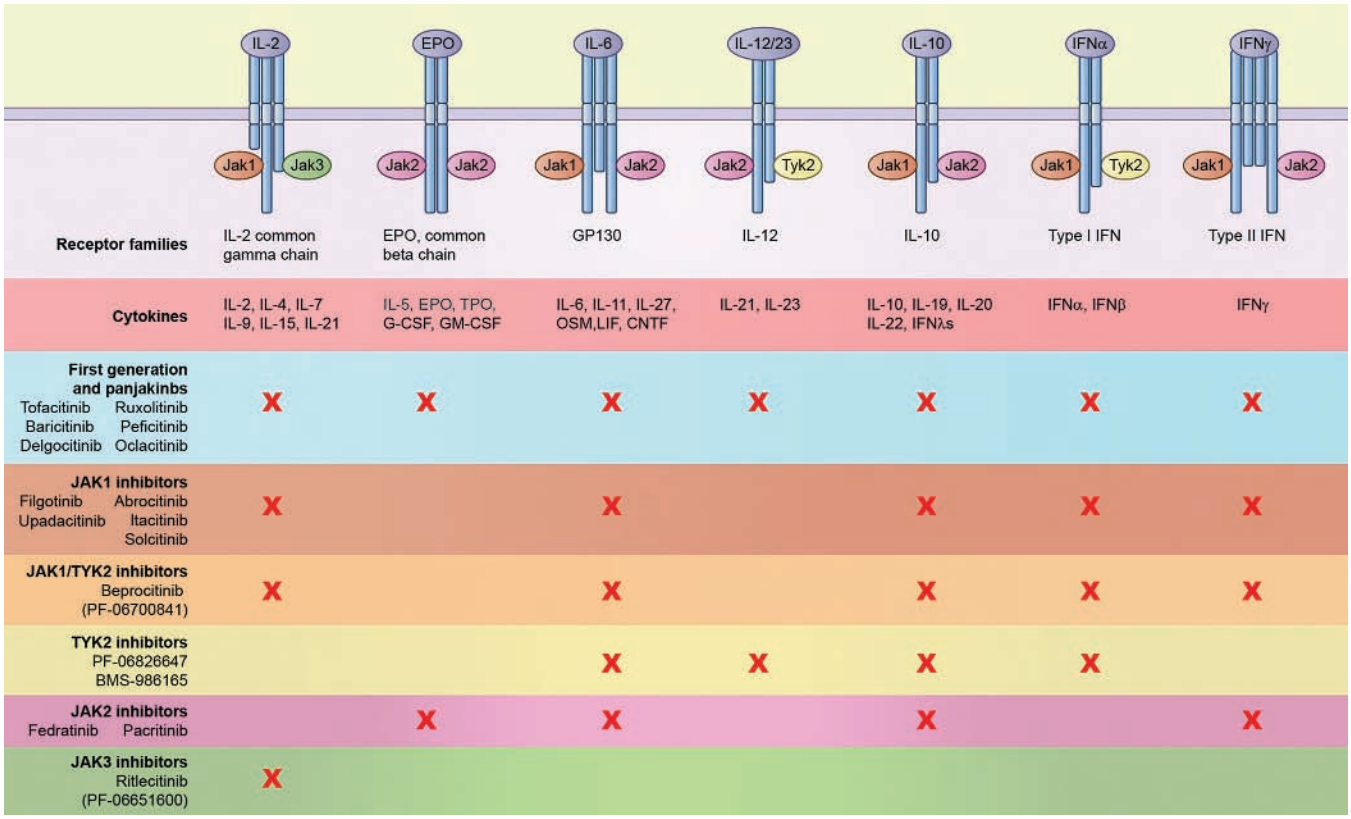

FIG. 85.3 Usage of Janus Kinases *(JAKs)* by Different Cytokine Receptors. The intracellular domains of Type I and Type II cytokine receptors are bound by JAKs, which mediate signal transduction. There are 4 JAKs that selectively bind to different receptor subunits. Some JAKs, like JAK1 and JAK2, bind to multiple classes of receptors. By contrast, JAK3 only binds to the common gamma chain. First-generation JAK inhibitors inhibit multiple JAKs, whereas newer inhibitors have greater selectivity and, therefore, inhibit a narrower range of cytokines.

Of further structural significance is the emergence of tumor drug resistance in response to the continued use of protein kinase inhibitors. Mutant forms of BCR-Abl, Kit and EGFR are associated with loss of drug activity and disease relapse, with a common site of mutation being the gatekeeper residue. This has led to a generation of "multikinase" inhibitors, including dasatinib and sunitinib, with partial inhibition of multiple kinases being less toxic than originally feared, and the lack of specificity potentially contributing to improved response rates in the treatment of CML.

TARGETING CYTOKINE SIGNALING

Cytokines regulate growth, survival, development, differentiation and activation of immune cells.

Their importance in driving inflammatory and immunological responses and their utility as targets for immune-mediated disease is clearly illustrated by the success of anti-cytokine monoclonal antibodies or "biologics." Cytokines can be divided into six large families on the basis of their receptors. We shall explore three of these families in greater detail.

JAKINIBS AND THE TYPE I/II CYTOKINE RECEPTOR FAMILY

Fifty-seven cytokines bind to receptors of the type I/II cytokine receptor family, receptors that lack intrinsic enzymatic activity and rely on recruiting intermediary Janus kinases for cell signaling (**see** Fig. 85.3). The essential in vivo function of JAKs was first established by mutations encountered in patients and shortly thereafter confirmed by knockout mice. Loss of *JAK3* results in a severe combined immunodeficiency, characterized by absence of T cells and natural killer cells and defective B cells. This phenocopies deficiency of the cognate receptor that associates with JAK3, the IL-2 receptor common γ chain, cγc (encoded by *IL2RG*), mutation. This mutation leads to X-linked severe combined immunodeficiency (X-SCID). Loss-of-function (LOF) mutations of *TYK2* (tyrosine kinase 2) are also associated with primary immunodeficiency characterized by bacterial, viral, and fungal infections.[6] *JAK1* LOF mutations cause primary immunodeficiency associated with atypical mycobacterial infection, whereas *JAK1* gain-of-function (GOF) mutations are associated with systemic immune dysregulation and hypereosinophilic syndrome. Somatic *JAK2* GOF mutations are associated with myeloproliferative neoplasms (*e.g.*, polycythemia vera). Mice lacking *Jak3* or *Tyk2* have severe but restricted immune phenotypes, whereas deficiency of *Jak2* or *Jak1* in mice is lethal, consistent with the broad range of critical cytokines that employ these respective kinases for signaling. These genetic phenotypes strongly supported the strategy for the development of a new class of immunomodulatory drugs. There are now multiple JAK inhibitors (jakinibs) approved for the treatment of immune and neoplastic disease and more in clinical trials (Tables 85.1 and 85.2).

TABLE 85.2 Selected Kinase Inhibitors in Clinical Trials

Drug	Target	Diseases
Itacitinib	JAK1	Chronic GVHD
Beprocitinib	Tyk2/JAK1	Atopic dermatitis, SLE
PF-06826647	Tyk2	Psoriasis, ulcerative colitis
Deucravacitinib	TYK2	Psoriasis, SLE
Momolotenib	JAK2	Myeloproliferative neoplasms
Gandotinib	JAK2	MPN, GvHD
Gusacitinib	JAK/Syk	Atopic dermatitis
Cerdulatinib	JAK/Syk	Vitiligo (topical)
Ritlecitinib	JAK3/Tec	Rheumatoid arthritis, alopecia areata, Crohn disease
PF-06650833	Irak4	RA, hidradenitis suppurative
GSK2982772	RIP1K	RA, Psoriasis, UC
Evobrutinib	Btk	Multiple sclerosis, rheumatoid arthritis
Branebrutinib	Btk	SLE, Rheumatoid arthritis, primary Sjogren syndrome
Fenebrutinib	Btk	Rheumatoid arthritis, urticarial
DNL747	RIPK1	Alzheimer disease, amyotrophic lateral sclerosis
Lanraplenib	Syk	SLE, lupus membranous nephropathy, Sjogren syndrome
Leniolisib	PI3K	Activated PI3Kδ syndrome
ATI-450	MK2	RA

THERAPEUTIC PRINCIPLES

- Drugs can inhibit protein kinases with a high degree of specificity
- Kinase inhibitors are useful in a wide range of immune-mediated diseases
- Multi-kinase inhibitors can be well tolerated and may be more efficacious than single kinase inhibitors (*e.g.*, second generation Abl kinase inhibitors), but high doses can be associated with more side effects.

Tofacitinib was the first jakinib to be used *in vivo* in mouse models of allogeneic organ transplantation and other models of immune-mediated disease.[7] It principally inhibits JAK1 and JAK3; to a lesser extent it inhibits JAK2 but has little effect on TYK2. Consequently, tofacitinib potently inhibits a broad range of cytokines, including those that contribute to the pathogenesis of autoimmune disorders, such as IL-6, cγc cytokines, interferons, IL-12, IL-23, and others. Functionally, tofacitinib inhibits the differentiation of T cells into cytokine-producing effector subsets but also blocks innate immune responses.[8]

Baricitinib is a JAK1/JAK2 inhibitor approved for the treatment of RA and has been successful in Phase 2 testing in systemic lupus erythematosus.[9] Of note, baricitinib also inhibits adapter associated kinase 1 (AAK1) and cyclin G-associated kinase (GAK), kinases involved in endocytosis that can impede viral entry. For this reason, baricitinib has received emergency use authorization for treatment of COVID-19 caused by the SARS-CoV2 virus, serving to inhibit both viral replication as well as the attendant cytokine storm.[10] Upadacitinib is a newer jakinib approved for treatment of rheumatoid arthritis (RA), which has a high degree of selectivity for JAK1 over JAK2. Abrocitinib has been approved for the treatment of atopic dermatitis and other jakinibs have been approved for this indication in Europe and the UK. Oclacitinib is a pan-JAK inhibitor approved for dogs with allergic dermatitis. Delgocitinib is a topically applied pan-JAK inhibitor approved in Japan for atopic dermatitis.[11,12]

The discovery that GOF mutations of *JAK2* underlie primary polycythemia and myelofibrosis provide a strong rationale for pharmacologically targeting JAK2. In fact, the JAK1/JAK2 inhibitor, ruxolitinib was the first FDA-approved JAK inhibitor for the treatment of myelofibrosis in 2011 and was subsequently approved for the treatment of primary polycythaemia in 2014. Ruxolitinib has also been approved for the treatment of acute graft-versus-host disease (GVHD)[13] and has completed Phase III trials in the treatment of chronic GVHD. Momelotinib is another JAK1/JAK2 inhibitor being evaluated for myeloproliferative neoplasms, and gandotinib is being studied for patients who have failed ruxolitinib. Fedratinib is a JAK/Flt3 (FMS-like tyrosine kinase 3) inhibitor approved for myeloproliferative neoplasms although this is principally due to its ability to inhibit the latter receptor tyrosine kinase. Jakinibs are also being tested in a variety of oncologic indications beyond myelofibrosis and related diseases.

CLINICAL PEARLS

Genetic mutations reveal key functions of kinases in patients with primary immunodeficiencies and provide clues to the impact of targeting signaling pathways

- Common-γ-chain deficiency, JAK3 deficiency: severe combined immunodeficiency
- ZAP70 deficiency: severe combined immunodeficiency
- TYK2 deficiency: rare cause of hyper IgE syndrome
- IRAK4 Autosomal recessive immunodeficiency with severe bacterial infections
- PI3KD (*PIK3CD*): autosomal dominated combined immunodeficiency with autoimmunity
- BTK: X-linked agammaglobulinemia
- ITK: autosomal recessive T cell immunodeficiency with EBV-associated lymphoproliferative disease

Among the side effects of first generation JAK inhibitors are infections, including both serious and opportunistic infection. The incidence of infection is similar to other drugs, including biologics, used to treat various autoimmune disorders, except for the increased cases of herpes zoster seen with jakinibs.[14,15] This increased risk for viral infection is likely related to the inhibition of JAK1-dependent interferon signaling. It may then come as a surprise that a number of JAK inhibitors have been used as therapies for COVID-19. A minority of patients infected with SARS-CoV2 develop an acute respiratory distress syndrome associated with the elevation of inflammatory cytokines, consistent with a virally induced macrophage activation syndrome. The IL-6 blocker tocilizumab was not effective for preventing intubation or death in patients with Covid-19.[16].

The combined use of jakinibs with other immunosuppressive drugs increases the incidence of infection. Anemia, thrombocytopenia, and leukopenia are all common complications, likely related to the fact that first generation jakinibs block JAK2 and interfere with cytokines, including erythropoietin, thrombopoietin, IL-11, oncostatin M, and colony-stimulating factors that drive bone marrow cell production. The use of tofacitinib and baricitinib in RA patients has been associated with an increased incidence of venous thromboembolism (VTE). The mechanism remains unclear as ruxoltinib is associated with a reduced rate of VTE when used in patients with primary polycythemia and myelofibrosis, diseases that are associated with an increased risk of VTE. Little reduction in $CD4^+$ T cells has been seen, but significant reductions in NK cells and $CD8^+$ T cells can occur. Despite this, patients have tolerated continued JAK inhibition for nearly a decade. Jakinibs are associated with increases in cholesterol, and compared to a tumor necrosis factor inhibitor are associated with increased cardiovascular events.[18]

In an effort to reduce some of the side effects, especially those related to JAK2 inhibition, a number of second generation jakinibs has been generated. Selective JAK1 inhibitors include filgotinib, abrocitinib and itacinib. Filgotinib has undergone multiple phase 2 and 3 studies in RA, ankylosing spondyloarthritis and ulcerative colitis and is approved in Europe. Abrocitinib has shown efficacy in clinical studies in psoriasis and is approved for atopic dermatitis.[19,20] Itacitinib failed a phase III trial when added to corticosteroid in the treatment of acute GVHD (GRAVITAS-301), although it is still being investigated in the treatment of chronic GVHD. It is possible that the ability to block JAK2 may offer some added benefit as GM-CSF, which signals through JAK2, may contribute to GVHD severity.[21,22]

Beprocitinib is a Tyk2/JAK1 inhibitor (PF-06700841) being studied in atopic dermatitis, and SLE (PF-06826647) is a TYK2 inhibitor being studied presently in Phase 2 in psoriasis and ulcerative colitis. Deucravacitinib is also a TYK2 inhibitor; however, it differs from other jakinibs in that it targets the JAK kinase-like domain rather than the ATP binding site in the catalytic domain. It has shown efficacy in psoriasis[23,24] and is being studied in SLE.

Ritlecitinib (PF-06651600) is a JAK3 inhibitor that also inhibits Tec family kinases (see below). Ritlecitinib has shown efficacy in Phase 2 trials in RA[25,26] and is also being studied in alopecia areata and Crohn disease.

IL-1 Family Receptors and Toll-Like Receptors

IL-1 is the prototypical member of an 11-member family of cytokines. The rest of the family has been renamed several times over the years and currently consists of IL-18, IL-33, four IL-36 members, IL-37, IL-38, and the IL-1 receptor antagonist (IL-1RA). The bulk of the cytokines in this family are associated with inflammation with the exception of IL-1RA, IL-36RA, and IL-37, the first two of which are natural inhibitors of IL-1 and IL-36, respectively. Deficiency of IL-1RA or IL-36RA cause the auto-inflammatory diseases DIRA and DITRA, respectively. IL-1RA is available as the biologic pharmaceutical, anakinra. It has modest benefit in RA, but has potent activity in juvenile idiopathic arthritis, Bechet disease, crystal arthopathies including gout, auto-inflammatory syndromes and, more recently, in macrophage activation syndrome.

Receptors of the IL-1 family and Toll-like family of pattern recognition receptors are found on macrophages and associate with the adapter molecule, myeloid differentiation primary response 88 (MyD88), which drives signaling that culminates in the activation of the signalosome (Fig. 85.4) A key link is the family of interleukin-1 receptor activated kinases (IRAKs), of which IRAK-1 and IRAK-4 play key roles that lead to cytokine release in activated macrophages together with the closely related TGFβ activated kinase (TAK1 a.k.a. MAP3K7). Deficiency of *IRAK4* in humans is associated with susceptibility to pyogenic infections. Selective IRAK4 inhibitors have been generated and are currently in clinical trials. A phase 2 trial using PF-06650833 in RA has shown efficacy, with infections being a common side effect (Phase 2 RA).[26] It is also being studied in hidradenitis suprativa.

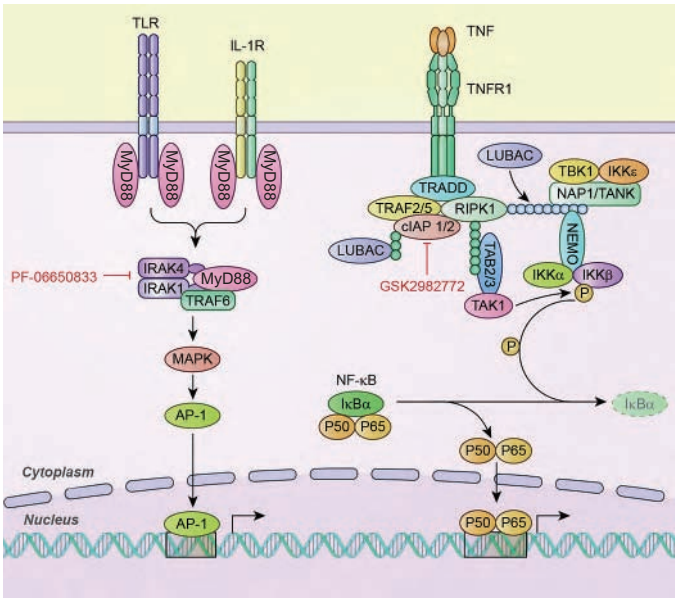

FIG. 85.4 Interleukin *(IL)*-1 and Tumor Necrosis Factor *(TNF)* Signaling. IL-1 family cytokines associate with the adapter molecule, myeloid differentiation primary response 88 (*MyD88*) that couples the receptor to activation of interleukin-1 receptor activated kinases (*IRAKs*), IRAK-1 and IRAK-4. TGFβ _activated kinase (*TAK1* a.k.a. *MAP3K7*). Receptor-interacting protein kinase 1 (*RIPK1*), a target of TAK1, that promotes proinflammatory cytokine production, apoptosis and necroptosis in response to TNF receptor engagement via the formation of a multi protein complex containing: TANK binding kinase 1 (TBK1), Tumor necrosis factor receptor type 1-associated DEATH domain protein (TRADD), cellular inhibitor of apoptosis proteins 1 and 2 (cIAP1/2), NF-kB activating kinase associated protein 1 (NAP1), TRAF family member-associated NFKB activator (TANK), linear ubiquitin chain assembly complex (LUBAC), and I kappaB kinase (IKK). Downstream of TAK1, which is also associated to TAK1)-binding protein 2/3 (TAB2/3 and RIPK1 lies the p38 mitogen activated protein kinase (MAPK) signaling pathway which leads to translocation of activator protein-1 (AP-1) in the nucleus.

TARGETING KINASES INVOLVED IN TNFR SIGNALING

TNF is an inflammatory hormone ubiquitously expressed in both lymphoid and myeloid cells. Its central role in disease pathophysiology was identified with the success of TNF antibodies in the treatment of RA and inflammatory bowel disease.[27,28] TAK1 lies downstream of both the IL-1 and TNF receptor families and thus contributes to inflammatory responses (see Fig. 85.4). A selective TAK1 inhibitor (takinib) has been generated and is efficacious in preclinical arthritis models.[29,30]

Receptor-interacting protein kinase 1 (RIPK1), a target of TAK1, is another regulator of proinflammatory cytokine production, apoptosis and necroptosis in response to TNF receptor engagement. GSK2982772 is a RIPK1 inhibitor studied in psoriasis. Subjects showed improvement with no severe drug-related AEs reported. The drug is also being studied in ulcerative colitis, which often responds to TNFα blockade. DNL747 is another RIPK1 inhibitor and is being studied in Alzheimer disease and amyotrophic lateral sclerosis. Downstream of TAK1 and RIPK1 lies the p38 MAPK signaling pathway that will be discussed later in this chapter.

TARGETING ANTIGEN- AND RELATED RECEPTOR SIGNALING

Antigen receptors play a key role in the initial activation of cells of the adaptive immune system; these include the T-cell receptor (TCR) and B-cell receptor (BCR) in lymphocytes, and the receptors for the Fc portion of immunoglobulin molecules (FcR) in macrophages and other cells. In all these cases the receptor complex lacks intrinsic receptor kinase activity and relies instead on the recruitment of members of the Src family of tyrosine kinases. The importance of Src family kinases in antigen receptor signaling (**see** Fig. 85.1) made members of this family attractive therapeutic candidates. Deficiency of Lck in mice leads to a progressive lymphopenia, and several Lck inhibitors have been developed; however, suitable agents for use as an immunosuppressive agents, remain elusive. For multichain immune recognition receptors, activation of Src kinases leads to the recruitment of a second set of tyrosine kinases that associate with receptor complexes, namely Zap70 or spleen tyrosine kinase (Syk). Deficiency of Zap70 causes severe combined immunodeficiency and preferential loss of $CD8^+$ T cells, but a successful Zap70 inhibitor has yet to be obtained. In contrast, Syk inhibitors have been generated; fostamatinib is approved for the treatment of immune thrombocytopenia purpura (ITP). Lanraspenib is in clinical trials for multiple indications including SLE, lupus membranous nephropathy, and Sjogren syndrome. As indicated above, combined JAK/Syk inhibitors have been generated, and one agent, cerdulatinib, is being tested in lymphoid malignancies. A topical formulation of cerdulatinib is being tested in vitiligo. Gusacitinib is a Syk/JAK inhibitor being studied in psoriasis and atopic dermatitis.

Downstream kinase activation of (phospholipase C) γ1 leads to production of intracellular calcium, which in turn activates the phosphatase calcineurin. Calcineurin dephosphorylates and activates nuclear factor of activated T cells (NFAT), which translocate to the nucleus, and, in cooperation with AP-1 transcription factors, activates expression of IL-2 and other key lymphocyte genes. Drugs that inhibit calcineurin, including cyclosporine and tacrolimus, have revolutionized organ transplantation, but despite their success, these drugs are associated with renal toxicity that can limit their long-term use. Voclosporin is a calcineurin inhibitor approved for lupus nephritis. In addition to the release of intracellular calcium, PLCγ1 activity leads to the generation of free diacylglycerol (DAG), which is critical for activation of members of the protein kinase C (PKC) family that in turn activate the transcription factor complex NF-κB. DAG also leads to activation of the Ras guanine nucleotide exchange factor (RasGEF). PKCs play important roles in oncology, but despite many attempts at generating useful inhibitors, no candidates have emerged to be useful agents for the treatment of immune-mediated disorders.

Lipid Kinases and Downstream Signaling

Kinases can phosphorylate lipids in addition to proteins, and these modifications are relevant in signal transduction mediated by both antigen and cytokine receptors. In addition to the production of inositol triphosphate and DAG by the action of PLCγ1, there is a second pathway of inositol lipid metabolism regulated by diverse receptors, including costimulatory molecules (*e.g.*, CD28), cytokines, and chemokines. This response is mediated by the Class I group of phosphatidylinositol 3 kinases (PI3Ks), which is composed of four isoforms (PI3Kα, β, γ, and δ), which phosphorylate the 3′-OH position of the inositol ring of phosphatidylinositol[4,5] bisphosphate ($PI(4,5)P_2$) to produce $PI(3,4,5)P_3$ (**see** Fig. 85.1). This lipid and its metabolite $PI(3,4)P_2$ bind to the pleckstrin homology (PH) domains of proteins and either induce localization of the protein to defined areas of the plasma membrane where activation can occur or induce conformational changes that allow for allosteric modifications of activity. Targets for D3 phosphoinositides in T cells include a number of downstream protein serine/thronine kinases, the Tec family of tyrosine kinases and the Rac-1 and RhoA guanine nucleotide exchange proteins.

The small molecule PI3K inhibitors, Wortmannin and LY294002, are both potent inhibitors of lymphocyte activation, although toxicity prevents either from being clinically useful. In contrast to the more widely expressed PI3Kα and β isoforms, PI3Kγ and δ are primarily expressed in hematopoietic cells. Deletion of PI3Kγ in mice results in defective migration of neutrophils and macrophages to sites of inflammation. The limited expression makes PI3Kγ a potentially useful target, and selective PI3Kγ inhibitors have shown to be effective in mouse models of collagen-induced arthritis. However, the recent description of combined immunodeficiency in patients with bi-allelic inactivating mutations affecting PI3Kγ suggests that such inhibitors may have more wide-ranging effects.

PI3Ks comprise two subunits: a catalytic subunit (p110α, β, γ, and δ) and a regulatory subunit (p85) (**see** Fig. 85.1). Both gain- and loss-of-function mutations affecting *PIK3CD* (encoding p110δ) and *PIK3R1* (encoding p85α) cause a combined immunodeficiency syndrome, referred to as activated PI3Kδ syndrome (APDS; or p110δ-activating mutation causing senescent T cells, lymphadenopathy and immunodeficiency [PASLI]).[31] Idelalisib, duvelisib, and copanlisib are PI3Kδ inhibitors approved for treatment of lymphomas and chronic lymphocytic leukemia. Leniolisib is a PI3Kδ inhibitor that is currently being tried for treatment of APDS.[32]

The Tec family kinases, which include Tec, Bmx bone marrow tyrosine kinase on chromosome X), Rlk (resting lymphocyte kinase), Itk (inducible tyrosine kinase) and Btk (Bruton's tyrosine kinase, contain PH domains (with the exception of Rlk) and are recruited to the plasma membrane by the presence of $PI(3,4,5)P_3$, where they are part of antigen receptor signaling complexes and are required for full PLCγ activity (**see** Fig. 85.1).[33] However, Btk is also involved in other signaling pathways, including those downstream from TLRs. The importance of this class of kinases is exemplified by the fact that mutations affecting *BTK* underlie Bruton agammaglobulinemia, a condition characterized by the absence of all B cells. Ibrutinib was the first FDA approved BTK inhibitor approved for the treatment of lymphoma, leukemias, and GvHD. Ibrutinib also has activity against the Tec kinase Itk, which is expressed in T cells and is important for activation of PLCγ1 and T-cell activation. Mutations affecting *ITK* also lead to a primary immunodeficiency. Zanubrutinib, tirabrutinib, and acalabrutinib (which is more specific for Btk), have also been approved. Fenebrutinib has shown efficacy in RA.[33] Other Btk inhibitors have been generated, evobrutinib and branebrutinib, and being studied for the treatment of malignancies and autoimmune diseases. Preliminary studies suggest that Btk inhibitors may be useful in the treatment of cytokine storm associated with COVID-19 due to their effects on innate cell cytokine production, and are being tested for this indication.[34]

$PI(3,4,5)P_3$-regulated kinases activated both by the TCR and IL-2 family cytokines include protein kinase B (PKB/AKT) and mechanistic target of rapamycin (mTOR). Both have been seen as targets for novel anti-cancer and anti-inflammatory agents

with mixed success. PKB regulates the activity of many proteins that are critical for cell survival and metabolism including the mTOR complex 1 (mTORC1), which regulates protein synthesis in response to cellular nutrient and energy availability. Many signaling pathways link growth factor receptors with activation of mTOR including the AMP dependent kinase (AMPK) and PI3K. mTORC1 promotes cell growth by activation of p70 S6K1 and inactivation of 4E-BP1,[35] which are critical for translation of new proteins.

As its name suggests, mTOR is inhibited by the macrolide rapamycin, now licensed for the treatment of graft rejection as the drug sirolimus. Sirolimus does not inhibit mTOR by direct binding to the ATP binding pocket but acts indirectly, associating with FK506 binding protein 12 (FKBP12). This in turn inhibits the kinase complex made up of mTOR, mLST8 and raptor (mTORC1). Sirolimus has been successfully used as an immunosuppressant, typically as part of a combination regimen for allograft rejection prophylaxis. Temsirolimus and everolimus are approved for treatment of malignancies, organ rejection, and tuberous sclerosis complex. In view of the ubiquitous expression of mTOR and its role in protein translation, it is not surprising that side effects include myelosuppression, hyperlipidemia, hypertriglyceridemia, myelosuppression, and delayed wound healing. There is some evidence of renal toxicity, but this is minor compared to the calcineurin inhibitors cyclosporine A and tacrolimus.

MAP Kinase Pathways

Another key set of kinases activated downstream of cytokine, antigen, and other adaptive and innate immune receptors is the Mitogen Activated Protein Kinase (MAPK) family. These kinases constitute a complex phospho-relay system of signal transduction, composed of sequentially activated kinases that are themselves modulated by phosphorylation. Three main MAPK cascades have been identified in mammalian cells—the ERK (Extracellular signal Regulated Kinase) cascade, the JNK (c-Jun N-terminal Kinase) cascade, and the p38 MAPK cascade. All start with a membrane-localized activator followed by three MAPKs (MAPKKK, MAPKK, and MAPK) that sequentially phosphorylate each other (see Fig. 85.3). Substrates of MAPK pathways include transcription factors, phospholipases, cytoskeletal proteins, and other protein kinases.

ERK1 and 2 were identified as kinases that were activated in response to growth factor stimulation, which are mimicked by expression of constitutively active Ras, an upstream activator of the ERK pathway that is frequently mutated in cancers. Fast-track designation was granted for the farnesyl inhibitor, tipifarnib, for *HRAS*-mutant head and neck squamous cell carcinomas. Ras is linked to ERKs by MEK1 and RAF1, a MAPK kinase (M3K). Sorafenib inhibits numerous kinases, including RAF, as well as receptor tyrosine kinases including PDGFR, VEGFR, Kit and FLT-3; however, its role as an immunosuppressant has yet to be explored. There are three RAF isoforms: A-RAF; B-RAF and C-RAF. A number of cancers are associated with B-RAF mutations resulting in a constitutively active kinase; the best known of these is the V600E mutant. These observations have led to a number of successful FDA-approved inhibitors of MAPK pathways. Binimetinib and cobmetinib are MEK1/2 inhibitor approved for treatment of melanoma.

Another limb of the MAPK pathways involves the c-Jun N-terminal kinase (JNK pathway). Many inflammatory agents including LPS, TNF and IL-1 are able to activate the JNK pathway. Many small molecule inhibitors of Jun kinases have been identified, but few have advanced to clinical trials, in part due to problems with selectivity. Brimapitide is being studied for the treatment of inflammatory eye disease and acute hearing loss.

The p38 MAPK cascade was originally identified as part of a drug screen looking for inhibitors of TNFα-mediated inflammatory responses.[36,37] TLR-dependent production of IL-1 and TNFα is p38 MAPK-dependent. The success of TNFα blocking antibodies in the treatment of RA has led to much interest in the development of p38 MAPK inhibitors. However, as with JNK, many p38 inhibitors have been generated, but their development into therapeutic drugs has been frustrated by either unacceptable toxicity or poor efficacy. A topically activating inhaled p38 MAPK inhibitor JNJ 49095397 (RV568) has had some success in phase II trials of chronic obstructive pulmonary disease. ASK1 (Apoptosis signal-regulating kinase 1) is a kinase that lies upstream of both p38 and JNK and has been investigated as an alternative target: multiple ASK1 inhibitors have been generated.[38] Selonsertib was investigated for the treatment of liver fibrosis, and while found to inhibit p38 *in vivo*, unfortunately was not efficacious.[39] MAPK-activated kinase 2 (MK2) is activated downstream by p38 MAPK. ATI-450 is a selective inhibitor of MK2 that inhibits proinflammatory cytokine production, spares other downstream kinases,[40] and is being studied in RA.

CONCLUSIONS

ON THE HORIZON

- New kinase inhibitors with improved selectivity have been approved and are in development.
- Topical and inhaled kinase inhibitors will hopefully be efficacious and safer.
- Further understanding of the pathophysiology of autoimmune disease will lead to the increased use and creation of kinase inhibitors.
- Increasing use of targeted therapy—specific kinase inhibitors—may improve our understanding of the detailed pathophysiology of autoimmune disease.

The scientific advances in the 1990s led to the elucidation of multiple intracellular signaling pathways that link membrane-bound receptor and cytokine signaling with changes in gene expression and cellular activation necessary to trigger an immune cell response. Many of these pathways are interconnected, leading to a complex array of networks made up of enzymes, adaptor proteins, and transcription factors; many of then became targets for drug discovery in the quest for therapies that effectively treat allergic and autoimmune diseases with an acceptable degree of immunosuppression. The success of the anti-cancer BCR-ABL inhibitor, imatinib and the immunosuppressive mTOR inhibitor, sirolimus placed the protein kinases center stage as targets of future drug discovery. More than two decades since the identification of many of these new targets, the numerous drugs designed to interfere with specific immune cell-signaling pathways have now been brought to the clinic. Development and testing of many new agents for an array of indications is well underway. Precisely how best to use these drugs separately and in combination, in different phases of immune pathology, and what biomarkers we need to use to optimize effectiveness remain important challenges.

Biologic Response Modifiers

John M. Bridges and Walter Winn Chatham

In recent decades, the elucidation of specific inflammatory mediators as well as lymphocyte lineages that contribute to the pathology underlying chronic inflammatory disorders has identified immunologic targets amenable to modification by use of recombinant DNA technologies. The resulting biologic modifiers of inflammatory diseases have revolutionized the treatment of inflammatory, autoimmune, and allergic disorders. These targeted therapies, while costly, offer patients affected with these disorders options for better disease control with less of the morbidity associated with exposure to broader immune suppression and/or corticosteroid use.

IMMUNOMODULATORY CYTOKINES

IL-2 (rIL-2, Aldesleukin)

First identified as a T-cell growth factor, recombinant interleukin-2 (rIL-2) has potent immunomodulatory and antitumor activity, promoting the proliferation, differentiation, and recruitment of T and B cells, and natural killer (NK) cells as well as proinflammatory T-cell cytokines, such as IL-1, tumor necrosis factor-alpha (TNF-α), and interferon-gamma (IFN-γ) (Table 86.1). These all likely play a major role in dose-related IL-2 toxicity that may include hypotension, cardiac arrhythmias, increased capillary permeability with pulmonary edema, fever, and rarely death. Therapeutic use of rIL-2 was traditionally in patients with advanced melanoma and renal cell carcinoma, but the use of aldesleukin in cancer patients has been increasingly supplanted by more targeted immune-enhancing "check-point" therapies targeting T-cell death receptors (PD-1) and cytotoxic T-lymphocyte antigen-4 (CTLA4) that have comparable antitumor effects with much less acute toxicity.

More recently, the administration of low-dose rIL-2 has been shown to promote preferential growth and proliferation of regulatory T cells (Treg) without significantly affecting release of inflammatory mediators by $CD4^+$ T cells. Such low-dose regimens of rIL-2 have been used with success in suppressing manifestations of graft-versus-host disease (GvHD) and may also favorably impact the course of type 1 diabetes. The use of rIL-2 and/or other cytokine therapies promoting enhanced Treg differentiation and proliferation may, therefore, provide novel interventions for managing a variety of inflammatory disorders associated with autoimmunity, including systemic lupus erythematosus (SLE).[1]

Interferons

Interferons (IFNs), released primarily by T lymphocytes as well as dendritic cells in the context of stimulation of Toll-like receptors (TLRs), have a wide array of immunomodulatory effects that include upregulation of genes governing angiogenesis, cell differentiation, expression of human leukocyte antigens (HLAs), and production of inflammatory cytokines. IFN-α and IFN-β bind to the same cell surface receptor (IFN-1R) and are designated type 1 IFNs, while IFN-γ binds to a different receptor (IFN-2R) and is designated as a type 2 IFN. Recombinant preparations of all three interferons have been used for management of inflammatory disorders associated with chronic viral infection, primary immunodeficiency, or select autoimmune disorders (most notably multiple sclerosis [MS]). While there are immunomodulatory attributes that render interferons useful in certain circumstances, constitutional symptoms and upregulation of a wide variety of genes that promote inflammation frequently limit the use of both type 1 and type 2 interferons.

Interferon-α

Recombinant IFN-α2b (rIFN-α2b) has most commonly been used in combination with ribavirin for treatment of hepatitis C, including hepatitis C virus (HCV)-associated cryoglobulin syndromes. Other disorders linked to viral infections, including lymphomatoid granulomatosis caused by Epstein-Barr virus (EBV), and polyarteritis nodosa caused by hepatitis B virus (HBV), have been successfully treated with regimens incorporating IFN-α2b as part of the treatment regimen.[2] Refractory retinal vasculitis in the context of Behçet disease, severe flares of familial Mediterranean fever not responding to treatment with colchicine, and eosinophilic granulomatosis with polyangiitis (EGPA) have also been reported to respond favorably to treatment with rIFN-α2b.[2] Common side effects of rIFN-α2b include flu-like syndrome, fatigue, anorexia and nausea, weight loss, hair loss, emotional lability and depression, cytopenias, and induction of autoantibodies with enhancement of autoimmune disease.

Interferon-β

Recombinant interferon-β1a (rIFN-β1a) or rIFN-β1b has been shown to decrease relapse rates, disease severity, and central nervous system magnetic resonance imaging (MRI) lesions in patients with relapsing multiple sclerosis (MS). However, there are conflicting data with regard to the efficacy of IFN-β1a or IFN-β1b preparations for patients with secondary progressive variants of MS.[3] Immunomodulatory effects attributed to the beneficial impact of IFN-β1b on MS include enhancement of suppressor T-cell activity, reduction of proinflammatory cytokines, downregulation of antigen presentation, and reduced trafficking of lymphocytes into the central nervous system.[3] Side effects observed during treatment with both rIFN-β

TABLE 86.1 Recombinant Immunomodulatory Cytokines

Molecule	Construct	Half-Life	Dosing
Aldesleukin	rIL-2	1.5 h	0.3–3×10^6 IU/m^2 sc qd
IFN-α2b	rIFN-α2b	1.7 h	3–10×10^6 IU 3×/wk
IFN-α2b pegylate	rIFN-α2b pegylate	17 h	50–150 mcg/wk
IFN-β1a	rIFN-β1a	69 h	8.8–44 mcg sc 3×/wk
IFN-β1b	rIFN-β1b	0.2–4.3 h	2–8×10^6 IU q.o.d.
IFN-γ	rIFN-γ	6 h	50 mcg (1×10^6 IU)/m^2 sc 3×/wk

preparations include injection-site reactions as well as most of the effects observed during treatment with rIFN-α2b. Reported autoimmune complications include features often associated with lupus, such as immune complex glomerulonephritis, cutaneous vasculitis, and panniculitis.[4]

Interferon-γ

Recombinant interferon-γ (rIFN-γ) is effective in decreasing the frequency and severity of infections in patients with chronic granulomatous disease (CGD), an inherited disorder associated with any number of genetic defects that impair assembly of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and production of superoxide anion metabolites in neutrophils.[5] Fever, myalgias, skin rash, fatigue, and diarrhea are the most common adverse events associated with IFN-γ treatment. During intercurrent infections, treatment with rIFN-γ often enhances infection-related constitutional symptoms, potentially obscuring responses to antimicrobial therapy. With greater adherence to antimicrobial prophylactic regimens incorporating combination therapy with itraconazole and trimethoprim-sulfa, the added benefit of treatment with rIFN-γ in CGD patients may be marginal.

KEY CONCEPTS

- Interferon-alpha (IFN-α) has been used with success to enhance resolution of chronic viruses, notably hepatitis C virus (HCV); newer antivirals are supplanting the need for IFN therapy in HCV.
- IFN-β has immunomodulatory effects that are of benefit in the treatment of certain subsets of patients with multiple sclerosis.
- Type-1 IFNs (including IFN-α and IFN-β) may unmask or trigger flares of autoimmune disease, most notably systemic lupus erythematosus (SLE).
- Interferon-gamma may be of some benefit in the management of patients with chronic granulomatous disease (CGD) not responding to anti-fungal and and-bacterial prophylactic regimens.

INHIBITORS OF INFLAMMATORY CYTOKINES

Tumor Necrosis Factor-α Inhibitors

TNF-α is a significant mediator of inflammation associated with psoriasis, rheumatoid arthritis (RA), spondyloarthopathies, and chronic inflammatory bowel diseases (IBDs: Crohn disease and ulcerative colitis [UC]). TNF-α promotes the ingress of immunocompetent cells at sites of inflammation through activation of the vascular endothelium and upregulation of adhesion molecules. TNF-α also stimulates synthesis of other proinflammatory cytokines (IL-1β, IL-6, granulocyte–macrophage colony-stimulating factor [GM-CSF]), chemokines (IL-8), and inflammatory eicosanoids (prostaglandin E_1 [PGE_1], leukotriene B_4 [LTB_4]). In RA, TNF-α stimulates macrophages and monocyte-derived osteoclasts to release mediators destructive to bone and cartilage, including matrix metalloproteinases such as collagenase and stromelysin.[6] These noted effects of TNF-α have, therefore, prompted the development of both soluble receptor and monoclonal reagent strategies to inhibit effects of TNF-α in disorders in which it appears to have a significant role in promoting inflammation and tissue injury (Table 86.2).

Etanercept is a recombinant soluble p75 TNF receptor (TNFR–CD120b)-IgG Fc fusion protein that binds soluble TNF-α as well as lymphotoxin-β. The avidity of the p75 TNFR for soluble TNF-α is comparable to that of the p55 TNFR and therefore effectively decreases net TNF signaling through either of these receptors. The clinical impact of binding lymphotoxin-β is not entirely known. Recent work highlighting the role of lymphotoxin-β in maintaining the physiologic regulatory function of macrophages around lymphoid germinal centers suggests that inhibition of this cytokine may enhance the delivery of apoptotic body-derived self-antigens to germinal centers—a consideration of potential clinical relevance in patients at risk for SLE or related autoimmune syndromes (see below).

Infliximab, adalimumab, and *golimumab* are monoclonal antibody reagents with comparable avidity for both soluble as well as cell-bound TNF-α, but differ with regard to the derivation of the antigen-binding sequence and half-life. *Certolizumab pegol* is a construct consisting of recombinant human sequence-derived F(ab)' anti-TNF-α covalently linked to 40 kDa polyethylene glycol. The pegolated construct enhances the half-life of the reagent, and the absence of Fc and complement-binding domains renders certolizumab less likely to engender local injection site reactions and also precludes placental crossing of certolizumab into the fetal circulation when administered to pregnant women.

In cytokine profile studies of joint tissues and synovial fluids derived from patients with RA, TNF-α is consistently among the highest expressed inflammatory cytokines.[6] All five TNF-α inhibitors have been shown to decrease the signs and symptoms of disease activity as well as inhibit the progression of structural damage in rheumatoid arthritis, with greatest benefits and probability of disease remission seen among patients with early RA.[7]

TNF-α levels are also notably increased in biopsy samples of skin and synovial tissues from patients with psoriasis and psoriatic arthritis, and all of the TNF-α inhibitors have been shown to be highly effective in suppressing manifestations of plaque psoriasis as well as articular disease in psoriatic arthritis.[8] Improvements in joint symptoms (axial and peripheral) and uveitis manifestations are observed in patients with other spondyloarthropathies, including ankylosing spondylitis during treatment with TNF-α inhibitors. However, use of these agents has not been shown to delay fusion of axial joints in patients with spondylitis. The known inhibitory effect of TNF-α on Smad pathway-mediated bone formation by osteoblasts suggest that TNF inhibition may potentially promote ossification at sights of inflammation and increased bone turnover.

Monoclonal antibody inhibitors of TNF-α as well as certolizumab (but not etanercept) have been shown to be beneficial in the management of intestinal inflammation in patients with Crohn disease or UC and are approved for treatment of these disorders.[9]

Although very well tolerated as a class, TNF-α inhibitors may impair innate host defenses, resulting in delay of resolution of

TABLE 86.2 Recombinant Inhibitors of Proinflammatory Cytokines

Molecule	Construct	Half-Life	Dosing (maintenance)
Etanercept	sTNFR:Fc	3–4 days	50 mg sc q wk or 25 mg sc 2×/wk
Infliximab	aTNFα (chimeric IgG1κ)	7–12 days	3–10 mg/kg iv q4–8 wk
Adalimumab	aTNFα (human IgG1κ)	10–20 days	10–40 mg sc q1–2 wk
Certolizumab	aTNFα (humanized Fab')-PEG	14 days	200–400 mg sc q2–4 wks
Golimumab	aTNFα (human IgG1κ)	14 days	50–100 mg sc q4 wk 2 mg/kg iv q8 wk
Anakinra	sIL-1ra	4–6 h	1–8 mg/kg sc daily (max 200 mg/d)
Rilonacept	IL-1R1:Fc(IgG1):IL-1RAcP	8–9 days	2.2 mg/kg (max 160 mg) sc q wk
Canakinumab	aIL-1β (human IgG1κ)	26 days	2–8 mg/kg sc (max 600 mg) sc q8 wk
Tocilizumab	aIL-6R (humanized IgG1κ)	13 days	4–12 mg/kg (max 800 mg) iv q2–4 wk 160 mg sc q1–2 wk
Satralizumab	aIL-6R (humanized IgG2)	22–37 days	120 mg sc every 4 weeks
Sarilumab	aIL-6R (human IgG1)	8–10 days	150–200 mg sc every 2 weeks
Siltuximab	aIL-6 (chimeric IgG1k)	14–30 days	11 mg/kg iv every 3 weeks
Ustekinumab	aIL-12/23 p40 (human IgG1κ)	15–32 days	0.75 mg/kg (ped) or 45–90 mg sc q12 wk
Gesulkumab	aIL-23 p19 (humanized IgG1κ)	15–18 days	100 mg sc every 8 weeks
Tildrakizumab	aIL-23 p19 (humanized IgG1κ)	20–28 days	100 mg sc every 12 weeks
Risankizumab	aIL-23 p40 (humanized IgG1κ)	28–29 days	150 mg sc every 12 weeks
Secukinumab	aIL-17A (human IgG1κ)	22–31 days	150–300 mg sc q4 wk
Ixekizumab	aIL-17A (humanized IgG4κ)	13 days	80 mg sc q2–4 wk
Brodalumab	aIL-17A (human IgG2)	11 days	210 mg sc every 2 weeks

intercurrent infections. TNF-α inhibitors are associated with reactivation of tuberculosis and fungal infections, including histoplasmosis, coccidioidomycosis, and viral infections, such as hepatitis B. In all circumstances of intercurrent infection, the standard recommendation is for treatment with TNF-α inhibitors to be withheld until the infection has resolved. No complications have been reported regarding their use in patients with intercurrent hepatitis C infection or in patients with HIV infection that is well controlled with highly active antiretroviral therapy.

In the context of its role in promoting cell apoptosis, TNF-α constitutes a component of the host defense against tumor cell survival and growth. As such, the incidence and prevalence of cancer in populations treated with TNF-α inhibitors have been emphasized in pharmacovigilance programs. Lymphoma has been reported in patients taking TNF-α inhibitors, with most reported cases occurring in the context of treatment for RA. However, the relative risk for lymphoma in patients with RA in the pre-biologic era approximates 3.0 and the prevalence of lymphoma in RA patients exposed to TNF-α inhibitors has not been shown to exceed the expected prevalence among patients with RA. Among patients with RA, spondyloarthropathies—or psoriasis—the risk of cancer has not been shown to be increased in the context of treatment with TNF-α inhibitors.[10] While it is often recommended that TNF-α inhibitor therapy be discontinued in the setting of a newly diagnosed cancer—and that initiation of such therapy be avoided in patients with known malignancy—there are no clinical data to confirm continued treatment with TNF-α inhibitors impairs the therapeutic response to cancer therapies.

The role of TNF-α inhibition in facilitating apoptosis is also of relevance with regard to the development or potentiation of autoimmunity. Although rare, the development of psoriaform skin eruptions, demyelinating syndromes, and drug-induced lupus erythematosus are well documented occurrences in patients treated with TNF-α inhibitors.[11] Infliximab, adalimumab, and golimumab may induce release of apoptotic products in the context of antibody-dependent cellular cytotoxicity (ADCC) of cells bearing surface TNF-α, potentially driving production of antibodies to nucleoproteins.[12] Binding of lymphotoxin-β by etanercept may alter the clearance of apoptotic products by germinal center adjacent follicular dendritic cells and macrophages.[13] Given these collective considerations, it is generally recommended that TNF-α inhibitors be discontinued in patients who develop autoimmune complications during treatment with this class of biologic therapy. Moreover, anti-TNF-α therapy is not recommended for patients with established SLE or related overlap syndromes associated with autoantibody production.

KEY CONCEPTS

- TNF-α inhibitor treatment significantly improves patient symptoms and function and inhibits structural damage in patients with RA.
- TNF-α inhibitors are very effective in suppressing skin lesions due to psoriasis as well as enthesal inflammation in patients with seronegative spondyloarthopathies; they do not appear to have any inhibitory effects on the development of bony ankyloses.
- Vigilance for underlying fungal disease or mycobacterial disease is prudent prior to commencing with and during treatment courses with TNF-α inhibitors.
- TNF-α inhibitors may exacerbate certain autoimmune syndromes and should be used with caution or avoided in patients with autoantibody-associated immune disorders such as systemic lupus erythematosus (SLE).

IL-1β Inhibitors

IL-1β is synthesized as an inactive precursor, with activation of IL-1β occurring following engagement of nucleotide-binding oligomerization domain (NOD)-like receptors by a variety of exogenous or endogenous danger signals, which then trigger formation of molecular platforms (NALP-inflammasomes) that facilitate cleavage of the IL-1β precursor by IL-1 converting enzyme (ICE). IL-1β stimulates proliferation of lymphocytes, upregulates the expression of adhesion molecules, and triggers the release of a variety of inflammatory mediators from leukocytes, including chemotactic factors, prostaglandins, proteases, and procoagulants. In patients with rheumatoid arthritis, IL-1β triggers the release of proteases from phagocytic cells and macrophages that are destructive to bone and cartilage. Inflammasone activation has also been shown to mediate acute flares of arthritis in patients with gout or calcium pyrophosphate

deposition. Dysregulation of NLRP3 due to gain-of-function mutations in inflammasome-related genes has been implicated in the pathogenesis of familial cryopyrin-associated periodic syndromes (CAPS; cryopyrinopathies), familial Mediterranean fever (FMF), and the pyogenic arthritis, pyoderma gangrenosum, and acne syndrome (PAPA). Increased expression and levels of IL-1β are also noted during flares of inflammation in patients with adult-onset Still disease (AoSD), systemic-onset juvenile idiopathic arthritis (soJIA), and macrophage activation syndromes (MAS) associated with these and other autoimmune or infectious disorders. The naturally occurring IL-1 receptor antagonist (IL-1ra) prevents the binding of IL-1β and IL-1α to the IL-1 receptor (IL-1R), but tissue levels of IL-1ra in the above disorders may be insufficient to counteract the effects of IL-1β.

Anakinra is a recombinant non-glycosylated IL-1 receptor antagonist (rIL-1ra) that differs from the endogenous IL-1Ra by a single amino acid addition at the amino terminus. Administered subcutaneously at daily (or for some indications more frequent) intervals due to its very short serum half-life, anakinra functions as a competitive inhibitor of IL-1α and IL-1β binding to IL-1 receptors.

Anakinra is presently approved for the treatment of rheumatoid arthritis and inhibits joint erosions. However, compared to the clinical responses observed with use of TNF inhibitors and IL-6 inhibitors with regard to tender and swollen joints, such responses with anakinra are much more modest. Given these observations with biologics that require much less frequent dosing, *anakinra* is used infrequently in the treatment of RA. With the increased understanding of the role of IL-1 inflammasome activation in crystal-induced arthropathies—such as gout and systemic inflammatory disorders such as soJIA and AoSD—there has been increased interest in anakinra and other IL-1 inhibitors as therapeutic options in these disorders. Case reports reinforce the use of *anakinra* in managing acute flares of gout or flares of calcium pyrophosphate associated pseudogout when the use of corticosteroids or nonsteroidal antiinflammatory drugs (NSAIDs) is not favored due to comorbid conditions, such as uncompensated heart failure or diabetes with significant renal impairment.[14]

Prompt resolution of inflammatory markers and clinical manifestations have been reported in patients with severe flares of AoSD and soJIA treated with *anakinra*, including those associated with MAS.[15,16] In a study re-examining outcomes from a previous sepsis trial, survival was improved in patients with clinical features of MAS who were randomized to *anakinra* treatment.[17] The relatively short half-life of *anakinra* may render its use feasible when short-term blockade of IL-1 may be of benefit in managing severe flares of IL-1–driven inflammation when there is a concern for emerging intercurrent infection.

Rilonacept (also referred to as IL-1-Trap) is a recombinant fusion protein composed of the extracellular domain of the IL-1 accessory protein and IL-1 receptor type 1 attached to the Fc portion of IgG1. *Rilonacept* binds to IL-1a and IL-1b with high affinity and is approved for the treatment of cryopyrin-associated periodic syndromes (CAPS). Recent studies have confirmed efficacy of *rilanacept* in the management of recurrent idiopathic pericarditis.[18] Similar to anakinra, *rilonacept* is generally well tolerated with injection-site reactions being the most common adverse events.

Canakinumab is a human genome sequence-derived monoclonal antibody with specificity for IL-1β. Approved for the treatment of CAPS as well as soJIA, *canakinumab* has the longest half-life of the currently approved therapies that target IL-1. In a randomized clinical trial comparing the use of *canakinumab* to parenteral *triamcinolone* administration for acute gout flares, *canakinumab* was shown to have greater reductions in joint pain/swelling, decreased needs for rescue medications, and a greater time to subsequent flare.[14] However, given observed rates of serious infections were twice as high in the *canakinumab* arm, a half-life that well exceeds the duration of typical flares, and a cost that greatly exceeds the cost of current therapies effective for managing acute gout, the use of *canakinumab* has not found favor in treatment paradigms for managing gout.

IL-6 Inhibitors

IL-6 mediates activation of macrophages and osteoclasts, terminal proliferation and differentiation of B cells, differentiation of Th17 cells, and production of liver acute phase proteins.[19] However, IL-6 also governs homeostatic processes, including granulopoiesis, enteric epithelial proliferation, and antiinflammatory responses involved in resolution of inflammation, such as production of the soluble TNF receptor p55 and the IL-1 receptor antagonist (IL-1ra).[19]

The biology of IL-6 signaling is complex in that signaling may occur directly through the cell membrane–bound IL-6 receptor (IL-6R)/gp130 protein complex (classic signaling) or through binding of IL-6 to soluble IL-6R (sIL-6R) with the resulting heterodimer then ligating a variety of other gp130-containing membrane receptors (trans-signaling) that mediate signaling from cytokines other than IL-6. Whereas IL-6R is expressed primarily on leukocytes, hepatocytes, and megakaryocytes, gp130-containing receptor complexes are expressed in almost all organs, including heart, kidney, spleen, liver, lung, placenta, and brain. In murine models of inflammation employing sgp130:Fc constructs that selectively bind and neutralize IL-6/sIL-6R, trans-signaling appears to mediate many of the observed inflammatory consequences of the upregulation of IL-6, whereas classic signaling through membrane IL-6R primarily mediates homeostatic processes such as granulopoiesis, thrombopoiesis, and epithelial cell proliferation.[19] As greater understanding of the different IL-6 signaling pathways in humans evolves, implementation of therapeutic strategies targeting IL-6 will require consideration of the impact of blocking classic membrane-bound IL-6R signaling and IL-6/sIL-6R trans-signaling.

Tocilizumab is a humanized mAb with specificity for the human IL-6 receptor that blocks the binding of IL-6 to IL-6R, inhibiting both classic signaling by IL-6 through membrane IL-6R and formation of IL-6/sIL-6R heterodimer ligands that engender trans-signaling. Treatment with tocilizumab improves tender and swollen joint counts and slows the development of joint erosions in patients with RA. It is also effective as a steroid-sparing therapy in patients with giant cell arteritis.[20] Treatment with tocilizumab is also reported to be of benefit in patients with soJIA, AoSD, multicentric Castleman disease, and cytokine release syndrome in treated cancer patients.[20,21]

Satralizumab is a humanized monoclonal antibody targeting the IL-6 receptor that has been studied primarily in patients with neuromyelitis optica spectrum disorder. When added to standard immunosuppressive regimens, *satralizumab* was shown to decrease occurrence of relapse compared to the immunosuppressive regimen alone.[22]

Sarilumab is a monoclonal antibody also with specificity for IL6R, binding both membrane-bound IL6R and soluble IL6/sIL6R heterodimers. Safety and efficacy comparable to that of

tocilizumab and superior to the anti-TNF inhibitor *adalimumab* has been shown in studies using *sarilumab* for treatment of RA.[23]

Siltuximab is a monoclonal antibody with specificity for soluble IL-6 that has demonstrated efficacy and has been approved for use in the treatment of idiopathic (non-HIV [human immunodeficiency virus] and non-HHV8 [human herpesvirus 8]-associated) multicentric Castleman disease.[24]

Presumably related to the role of IL-6 in promoting granulopoiesis, neutropenia has been observed in some patients following treatment with antibodies targeting IL-6R, but this is uncommon. Thrombocytopenia and elevated serum aminotransferase levels have also been uncommonly observed. A predictable mild increase in serum lipid levels is observed following the initiation of treatment with anti-IL-6R therapies; the clinical significance of this remains indeterminate but monitoring of lipid levels is recommended. Reactivation of tuberculosis and invasive fungal infections can occur, and rare instances of gastric and intestinal rupture have been reported in patients treated with tocilizumab.

ON THE HORIZON

Other Anti-IL-6 and sgp130:Fc Reagents

Sirukumab is a humanized anti-IL-6 monoclonal construct that has also been shown in phase II trials to have efficacy in RA. *Clazakizumab* (humanized anti-IL6) has shown promising results for the treatment of RA as well as psoriatic arthritis; by virtue of engineered aglycosylation, *clazakizumab* has a longer half-life than other monoclonal reagents targeting IL-6 or IL-6R, thereby requiring less frequent dosing.

Of potentially greater interest have been studies with the development of *olokizumab*—a humanized monoclonal reagent that targets the gp130-binding domain of IL-6—and soluble gp130 covalently linked to immunoglobulin Fc (sgp130:Fc), both of which primarily block the interaction of the IL-6/sIL-6R complex with membrane gp130, thereby selectively inhibiting IL-6/sIL-6R trans-signaling.[25] Selective inhibition of the trans-signaling pathway linked to inflammatory responses may be superior to complete IL-6 blockade, because important physiologic functions of IL-6 (hematopoiesis, maintenance of intestinal integrity) mediated through membrane-bound IL-6R are left intact.

KEY CONCEPTS

- IL-β inhibitors are very effective in the treatment of disorders associated with constitutional or secondary activation of the IL-1 inflammasome, including cryopyrin syndromes, familial Mediterranean fever flares, recurrent pericarditis, and flares of crystal-induced arthropathy (gout and CPPD/pseudogout).
- Use of IL-1β inhibitors may be of benefit in managing severe flares of inflammation associated with macrophage activation, such as soJIA, AoSD, and severe sepsis syndromes.
- IL-6 signaling is complex in the context of homeostatic signaling through the IL-6R and proinflammatory trans-signaling through many other receptors engendered by IL-6/sIL-6R complexes.
- Monoclonal antibody or soluble receptor constructs that inhibit IL-6 binding to IL-6R or IL-6/sIL-6R complexes to membrane-bound gp130 are very effective in suppressing clinical manifestations of rheumatoid arthritis.

IL-23 and IL-17 Inhibitors

IL-23 is a heterodimeric molecule composed of a p19 subunit and a common p40 subunit shared with IL-12. IL-23 is secreted by B cells as well as innate immune cells including activated dendritic cells, monocytes, macrophages, and innate lymphoid cells. A key function of IL-23 is to promote the survival and expansion of Th17-lineage T cells, primarily by stabilizing RORγt transcription factor.[26] Although sharing a common subunit, IL-12 and IL-23 have different immunologic effects on T-cell-lineage development, with IL-12 primarily promoting development and maturation of Th1 T cells. Strategies targeting the shared p40 subunit of IL-12/IL-23 in murine models of autoimmune inflammation yielded promising results and led to the development and approval of a biologic reagent targeting p40 for treatment of psoriasis, psoriatic arthritis, and inflammatory bowel disease. However, comparative IL12/23p40, IL-12p35, and IL-23p19 knock-out studies in murine models of inflammation suggested the observed ameliorative effects of anti-p40 on inflammation are likely primarily due to IL-23 inhibition, and selectively targeting IL-23 as well as IL-17 (the primary effector cytokine of Th17 cells) evolved as strategies to target autoimmune inflammation.[26]

Ustekinumab is a monoclonal antibody with specificity for the common p40 subunit of IL-12 and IL-23 and is approved for the treatment of psoriasis, psoriatic arthritis, Crohn disease and ulcerative colitis. *Ustekinumab* significantly improves psoriatic skin lesions and decreases both peripheral and axial joint/enthesis manifestations in psoriatic arthritis.[27] Significant improvements in Crohn disease were observed among patients who failed to respond adequately to anti-TNF-α therapies.[28] Higher than expected rates of infection or malignancy have not been observed in controlled studies of *ustekinumab* in psoriatic disease, spondylitis, or inflammatory bowel disease. Nonetheless, vigilance for mycobacterial, fungal, and *Salmonella* infections is recommended given the role of IL-12 and IL-23 in host defense against these pathogens.

Guselkumab is a monoclonal antibody that selectively binds the p19 subunit component of IL-23, blocking its interaction with the IL-23 receptor and thereby limiting the release of IL-23 triggered proinflammatory cytokines. It is approved for the treatment of moderate to severe plaque psoriasis and was shown to be more effective at reducing skin involvement as measured by Psoriasis Area and Severity Index (PASI) than a*dalimumab* or *secukinumab*.[29] In reported clinical trials, treatment with *gesulkumab* was not associated with a significant increase in rates of infection or other serious adverse events compared to placebo. Several phase III trials for the use of *guselkumab* in psoriatic arthritis (NCT03158285, NCT03162796) and in lupus nephritis (NTC04376827) are ongoing.

Tildrakizumab is a humanized monoclonal antibody that targets the p19 component of IL-23 approved for the treatment of moderate-to-severe plaque psoriasis in adults. In two phase III clinical trials, *tildrakizumab* had no significant increased risk of infections or serious adverse events compared to placebo, although diarrhea was more likely in those treated with tildrakizumab compared to those treated with placebo.[29] *Tildrakizumab* is currently in phase II studies for psoriatic arthritis, ankylosing spondylitis, and non-radiographic axial spondyloarthritis (NCT04314544, NCT03552276).

Risankinzumab is a humanized monoclonal antibody targeting the p19 component of IL-23 approved for the treatment of moderate-to-severe plaque psoriasis in adults. Compared to placebo, *risankizumab* increased the risk of infection (mostly upper respiratory infections and tinea infections), though there was no appreciable difference in rates of serious infections. In comparison to *adalimumab, risankizumab* showed significantly

greater efficacy in improving skin involvement in patients with moderate-to-severe plaque psoriasis.[29] Phase III trials for its use in inflammatory bowel disease (NCT03398148, NCT 03104413, NCT03105102, NCT04524611, NCT03105128), hidradenitis suppurativa (NCT03926169), and psoriatic arthritis (NCT03675308) are ongoing.

ON THE HORIZON

The anti-IL23(p19) mAb *mirikizumab* has recently been studied in a completed phase III comparative trial with the IL-17 inhibitor secukinumab for treatment of plaque psoriasis. *Brazikumab*, a mAb that also targets IL23(p19), has shown promising benefit in phase II studies for treatment of inflammatory bowel disease.

IL-17 Inhibitors

IL-17 is elaborated primarily by the Th17 lineage of effector T cells, which differentiate from $Foxp3^{-}CD4^{+}$ thymocytes under the influence of IL-6 and TGFβ and proliferate/survive under the influence of IL-23. IL-17 is also produced by other innate immune cells, including neutrophils, mast cells, keratinocytes, macrophages, NK cells, NKT cells, and innate lymphoid (LLC/LTi) cells. Th17 cells are prevalent in the inflammatory lesions of a variety of inflammatory disorders including RA, inflammatory bowel disease, psoriasis, and spondyloarthropathies. IL-17 released by Th17 cells and other innate cells triggers the induction and release of IL-6, TNF-α, CCL2, CCL3, and MMPs from macrophages, induces activation of osteoclasts at sites of bone resorption, and promotes the proliferation, maturation, and chemotaxis of neutrophils.[30] As such, IL-17 is important both in the initial innate host defense to infection and also inflammation driven by acquired immune responses. Given the multitude of effects mediated by IL-17 in perpetuating inflammation in a number of autoimmune disorders, monoclonal reagent–based strategies have been developed targeting IL-17 and its receptor.

Secukinumab is a fully human mAb that selectively binds to and neutralizes IL-17A. In clinical trials, *secukinumab* has been shown to significantly decrease the activity of skin lesions in patients with psoriasis, decrease tender and swollen joints in patients with psoriatic arthritis, and decrease axial pain and limitation in patients with ankylosing spondylitis.[31,32] Rates of infection were increased over that observed in patients randomized to placebo, but not in excess of the infection rates noted with anti-TNF therapy. Clinical responses to *secukinumab* in patients with RA have been less robust. Despite the apparent role of Th17 cells in patients with inflammatory bowel disease, no significant improvement was observed in patients with Crohn disease, with some patients developing worsening of disease during treatment with *secukinumab*.[33] Given the pivotal role of Th17 in host responses to bacteria, parasites, and fungi, it is possible that alterations in the containment of microbial pathogens in the enteric mucosa may account for the failure of targeting IL-17 in inflammatory bowel disease. *Secukinumab* is currently being studies as an adjunctive treatment for lupus nephritis (NCT04181762).

Ixekizumab is a monoclonal antibody targeting IL-17A that has been shown to be effective and is approved for the treatment of plaque psoriasis.[31] Similar to what has been observed in clinical trials with *secukinumab*, rates of infection are slightly increased in patients treated with *ixekizumab* versus placebo, but the rate of serious infections has not been observed to be increased relative to placebo or a comparative arm randomized to anti-TNF treatment with *etanercept*.

Brodalumab is a monoclonal antibody targeting the IL-17A receptor. Data from two identically designed phase III randomized trials demonstrated clearing of skin lesions to be significantly greater than that observed in a comparator group receiving *ustekinumab*, but Candida infections and neutropenia were more frequent in the *brodalumab* groups than in the *ustekinumab* and placebo groups.[29,31]

ON THE HORIZON

Recently completed phase II trials have demonstrated efficacy of the dual IL17A/IL17F inhibitor *bimikizumab* in treating manifestations of psoriatic skin and joint disease as well as ankylosing spondylitis.[34]

KEY CONCEPTS

- Selective inhibition of pathways promoting differentiation and activation products of Th17 helper T cells is of significant benefit in the treatment of psoriasis and the seronegative spondyloarthropathies.
- Selective inhibition of IL-17 appears to be of marginal benefit in the treatment of inflammatory bowel disease, whereas selective inhibition of IL-23 by targeting p19 or both IL-12 and IL-23 by targeting their shared p40 subunit appears to be of benefit in both psoriasis and inflammatory bowel disease.

Inhibitors of Interferons

Emapalumab. The observed increases in IFNγ and related gene signatures prevalent in patients with cytokine storm syndromes (CSS) associated with familial variants of hemophagocytic lymphohistiocytosis (fHLH) and severe flares of soJIA or AoSD have prompted efforts to develop biologic reagents targeting this cytokine. In studies of children and adults with fHLH, the humanized anti-IFN-gamma monoclonal antibody emapalumab was shown to be efficacious in ameliorating clinical features of CSS and is now approved for use in this setting.[35] There is evolving experience in published case reports suggesting emapalumab may also be of benefit in CSS associated with severe flares of soJIA/AoSD.[36]

ON THE HORIZON

Targeting Type 1 Interferons

With recognition of the role of type-1 interferons in the immunopathogenesis of systemic lupus erythematosus (SLE), strategies to target α-IFNs for treatment of SLE have emerged.

- Initial trials with monoclonal reagents, such as *rontalizumab* or *sifalimumab* with specificity to one or more of the known α-interferon subtypes (14 known presently), have yielded modest results, emphasizing the complexity of the interferon system in SLE as autoantibodies to α-interferon subtypes are often prevalent in SLE sera.
- The alternative approach of targeting the type-1 IFN receptor in phase II and phase III trials with the monoclonal antibody **anifrolumab** has yielded more encouraging results.[37]
- Other approaches targeting the production of type-1 interferons currently under investigation include the use of monoclonal reagents to decrease activation of or deplete plasmacytoid dendritic cells (pDC), perceived to be the major source of IFN-1 in SLE.
- In clinical trials conducted thus far with antibodies targeting α-IFNs or IFN-1R, higher than expected occurrences of herpes zoster have occurred.
- Whether targeting type-1 interferons will prove efficacious, yet not at the expense of significant susceptibility to viral diseases such as varicella zoster virus and Covid-19, remains to be determined.

Complement and Kinin Pathway Inhibitors

In addition to opsonization of microbial pathogens and products of apoptosis, products of complement activation play a significant role in recruitment and activation of phagocytic cells (C3a, C5a) and inducing cell-membrane damage (C5b-9). Since both C5a and C5b-9 have potent procoagulant activity at sites of inflammation, complement activation is also hypothesized to be critical to the generation of intravascular thrombi in thrombotic microangiopathy syndromes including atypical hemolytic-uremic syndrome (aHUS), catastrophic anti-phospholipid syndrome (CAPS), paroxysmal nocturnal hemoglobinuria (PNH), and systemic lupus erythematosus.

Eculizumab is a humanized monoclonal antibody with specificity for C5 that blocks the generation of C5a and C5b by the C5 convertase (Table 86.3). *Eculizumab* is currently approved for use in patients with aHUS, severe myasthenia gravis, aquaporin-4 antibody-positive neuromyelitis optica spectrum disorder, and paroxysmal nocturnal hemoglobinuria. It has also been reported to be of benefit in patients with catastrophic antiphospholipid syndrome and SLE associated with thrombotic microngiopathy.[38,39] Because *eculizumab* inhibits terminal complement activation and life-threatening or fatal meningococcal infections have occurred in patients who received *eculizumab*, vaccination targeting both A and B serotypes of meningococcus is therefore recommended at least two weeks prior to receiving *eculizumab*. In cases wherein the risks of delaying *eculizumab* therapy outweigh the risk of developing a meningococcal infection, meningococcal vaccines should be administered as soon as possible with at least two weeks of prophylactic penicillin or macrolide antibiotics.

Ravulizumab is a humanized monoclonal antibody with a longer therapeutic half-life than *eculizumab* that also binds to C5, blocking activation of C5. It is approved in the United States and EU for use in the management of aHUS as well as the management of hemolysis in patients with paroxysmal hemoglobinuria. Clinical trials in patients with PNH have demonstrated efficacy noninferior to eculizumab and continued efficacy in patients transitioned from every two-week dosing with *eculizumab* to every 8-week dosing with *ravulizumab*.[40] Appropriate pre-treatment meningococcal vaccination or concurrent immunization with prophylactic antibiotics should be administered.

Excess generation of bradykinin, the vasodilator responsible for symptoms in hereditary angioedema (HAE), may occur in the context of a deficiency in the quantity or functional activity of C1 inhibitor (C1-INH), a regulatory inhibitor of kallikrein. Frequency of attacks of HAE may be decreased by infusions of pooled plasma derived C1-INH, but breakthrough attacks are not uncommon.

Lanadelumab is a fully human monoclonal antibody that binds to plasma kallikrein, decreasing kallikrein-mediated generation of bradykinin from high molecular weight kininogen (Table 86.3). Treatment with *lanadelumab* significantly reduces the rate of attacks in HAE patients and is approved for use in adults and children older than the age of 12 years with HAE.[41]

TABLE 86.3 Recombinant Inhibitors of Complement and Kinin Pathway Activation and Molecules Mediating Cell Migration

Molecule	Construct	Half-Life	Dosing (maintenance)
Eculizumab	Anti-C5 (humanized IgG2/4κ)	8–15 days	300–1200 mg iv q1–2 wk
Ravulizumab	Anti-C5 (humanized IgG2/4κ)	50–52 days	2100–3600 mg iv q8 wk
Lanadelumab	Anti-kallikrein (human IgG1κ)	14 days	150–300 mg sc q2–4 wk
Natalizumab	Anti-α4β1 (humanized IgG4κ)	7–15 days	300 mg iv q4 wk
Vedolizumab	Anti-α4β7 (humanized IgG1κ)	25 days	300 mg iv q8 wk

Adhesion Molecule Inhibitors

Trafficking of phagocytic cells and lymphocytes across vascular endothelium is critical to the development of inflammatory lesions and associated tissue injury. Strategies to decrease the influx of monocytes—and/or T and B lymphocytes—using biologics that target adhesion molecules have, therefore, been deployed as treatments for several inflammatory disorders, including multiple sclerosis (MS) and inflammatory bowel disease.

Natalizumab is a humanized monoclonal antibody with specificity for the α-4 subunit of the very-late activation antigen (VLA4)-integrin molecule expressed on lymphocytes and monocytes (Table 86.3). *Natalizumab* blocks association of the VLA4 α4β1 and α4β7 integrins with their respective vascular receptors, thereby limiting cell transmigration into tissue sites of inflammation in the CNS as well as intestinal mucosa. Administration of *natalizumab* blocks the interaction of T-cell α4β1 with its addressin ligand on venules in the CNS and has been shown to be effective in decreasing the frequency of relapses of multiple sclerosis (MS).[42] *Natalizumab* also inhibits the interaction of the α4β7 integrin with mucosal addressin-cell adhesion molecule-1 (MAdCAM-1) expressed on venules in the enteric mucosa and has been shown to induce remissions and prevent flares of Crohn disease in patients who have failed to have an adequate response to anti-TNF-α therapy.[42] *Natalizumab* primarily affects transmigration of Th1 cells with much less of an inhibitory effect on the transmigration of Th17 cells; as such, there may be differential efficacy of natalizumab in the treatment of Th1 versus Th17 driven subtypes of MS and/or inflammatory bowel disease.[43]

The major concern with regard to use of *natalizumab* is reactivation of JC polyoma virus in patients who are carriers, resulting in progressive multifocal leukoencephalopathy (PML). While quite debilitating and often fatal, the occurrence of PML is uncommon and the risk can be mitigated by limiting the duration of natalizumab treatment to one year in known JC virus carriers (as defined by seroconversion) and not administering natalizumab concurrent with other immunosuppressive therapy.

Vedolizumab is a humanized monoclonal antibody that specifically binds to $\alpha_4\beta_7$ integrin, blocking its interaction with mucosal addressin-cell adhesion molecule-1 (MAdCAM-1) on intestinal endothelial cells. Since *vedolizumab* does not bind to or block the interaction of the $\alpha_4\beta_1$ integrin to its addressin ligand in the CNS, the risk of developing PML during treatment is substantially lower than that associated with the use of *natalizumab*. In clinical trials, *vedolizmab* has been shown to significantly improve disease activity and reduce flares in patients with Crohn disease or ulcerative colitis.[44] This strategy may prove to be particularly useful in subsets of patients with inflammatory bowel disease who also have clinical features of SLE, in whom use of anti-TNF-α agents may carry an increased risk of SLE exacerbation.

KEY CONCEPTS

- Inhibition of C5 cleavage to its active products and resulting assembly of the membrane attack complex with eculizumab or ravulizumab is of significant benefit to patients who have complement mediated-hemolytic or thrombotic microangiopathy syndromes associated with paroxysmal nocturnal hemoglobinuria, atypical hemolytic-uremic syndrome, catastrophic anti-phospholipid syndrome, neuromyelitis optica spectrum disorder, or severe flares of SLE (systemic lupus erythematosus).
- Immunization against *Neisseria* species is recommended for patients who require dosing with complement pathway inhibitors.
- The loss of appropriate regulatory control of kallikrein by C1-INH that occurs in patients with hereditary angioedema can be effectively treated with lanadelumab, which inhibits the generation of bradykinin by kallikrein.
- Antibodies targeting the lymphocyte integrin $\alpha_4\beta_1$ (natalizumab) have been shown to be of benefit in managing multiple sclerosis and inflammatory bowel disease, but are associated with a risk of JC virus activation as PML (progressive multifocal leukoencephalopathy).
- Antibodies to the $\alpha_4\beta_7$ integrin (vedolizumab) selectively inhibit trafficking of lymphocytes into the intestinal lamina propria and are of benefit in the management of inflammatory bowel disease.

Inhibitors of B-Cell Activation

Identified targets for regulation of B-cell activation include growth and survival factors such as BLyS(BAFF) and its respective receptors (BAFF-R, TACI, and BCMA), co-stimulatory receptors and their ligands such as CD40/CD40-ligand, and cell surface receptors such as CD22 or FcγRIIb that engender inhibitory signaling when ligated. Given the prominent role of multiple autoantibodies and generalized B-cell activation in SLE, strategies to target B-cell activation have been undertaken in patients with this disorder.

Belimumab is a recombinant human genome–derived monoclonal antibody with specificity for soluble (non-membrane bound) BLyS (B-lymphocyte stimulator, BAFF) (Table 86.4). Through ligation of the BAFF-R and TACI receptors on B lymphocytes, BLyS promotes the maturation of B cells into antibody-secreting plasmablasts. Following encouraging results in murine models validating the hypothesis that autoreactive B lymphocytes may have greater dependency upon BLyS to survive and proliferate, human studies with *belimumab* demonstrated improvement in SLE disease activity using validated disease-activity measures (SLEDAI and BILAG) as well as additional secondary endpoints related to disease flares and sparing of corticosteroid use.[45] Noted clinical improvements typically do not become manifest until after 6 months of treatment with belimumab, with the majority of clinical improvements observed in musculoskeletal, mucocutaneous, and serologic domains of disease activity.[45] Subsequent studies have shown addition of *belimumab* to standard lupus nephritis induction regimens, and subsequent maintenance therapy increases the likelihood of achieving and maintaining renal remission at 2 years.[46] The potential effects on more severe neurologic domains of disease activity have not yet been assessed in controlled trials.

Significant decreases in the measured numbers of circulating activated B cells and plasmacytoid B lymphocytes are observed following 6 months treatment with *belimumab*.[47] Although receptors for BLyS (BAFF-R) and B-cell maturation antigen (BCMA) have also been identified on murine T-follicular helper (Tfh) cells—with ligation of BAFF-R promoting activation of Tfh and ligation of BCMA appearing to play a role in downregulation of Tfh responses—the significance of these findings in human SLE and what impact treatment with *belimumab* has on Tfh responses remain to be determined. In human trials there were no observed decreases in $CD4^+$ and $CD8^+$ T lymphocytes following 1 year of treatment with *belimumab*.[47] Levels of autoantibodies, including anti-dsDNA, anti-Smith, anti-SSA, and anti-cardiolipin, are decreased 40% to 50% after the first year of treatment and continue to decrease over time with long-term treatment.[47] In contrast, total antibody levels decrease on average only 15% with no significant decreases in measured pre-existing antibody titers to influenza, tetanus toxoid, or pneumococcal serotypes. Furthermore, treatment with *belimumab* does not appear to have any significant effects on the primary immune responses to pneumococcal bacterial antigens.[45] In the two major randomized phase III trials of 52 and 76 months duration, the frequency of infections was not shown to be increased in the *belimumab* treatment arms.[45]

TABLE 86.4 Recombinant Inhibitors of Lymphocyte Proliferation, Survival, and Activation

Molecule	Construct	Half-Life	Dosing (maintenance)
Belimumab	aBLyS/BAFF (human IgG1λ)	19 days	10 mg/kg iv q4 wk
Abatacept	CTLA4:IgG1Fc	13 days	10 mg/kg; 500–1000 mg sc or iv q4 wk
Belatacept	CTLA4:IgG1Fc	10 days	10 mg/kg iv q4 wk
Basiliximab	aCD25/IL-2ra (chimeric IgG1κ)	7–9 days	20 mg iv (repeat ×1 at 4 days)
Dupilumab	aIL-4Rα (human IgG4)	Unknown[a]	300 mg sc q2 weeks

ON THE HORIZON

Other Inhibitors of B-Cell Activation

Atacicept is a recombinant human fusion protein containing the extracellular, ligand-binding portion of the receptor TACI (transmembrane activator and CAML interactor) and a modified Fc portion of human IgG. *Atacicept* binds both BLyS (BAFF) and a proliferation-inducing ligand (APRIL), thereby functioning as an antagonist to the ability of these two ligands to stimulate B lymphocytes. However, the therapeutic window with this approach may be relatively narrow as membrane-bound TACI is the major receptor mediating immunoglobulin class switch during B-cell maturation, and excess of the soluble receptor administered over time may result in significant humoral immune deficiency due to decreases in IgG-secreting B cells and plasma cells. Human SLE studies using TACI-Ig as a therapeutic intervention remain underway to determine its potential efficacy and safety in lupus and IgA nephropathy (NCT02808429).

Dapirolizumab is a pegylated anti-CD40-ligand F(ab)′ monoclonal construct that interferes with the interaction of T-cell CD40L with B-cell CD40, thereby blocking co-stimulatory signals required for cognate T-cell help that promotes antigen-specific B-cell proliferative responses. Following favorable results targeting CD40L in murine lupus models, human trials with monoclonal anti-CD40L were undertaken but halted in the context of observed thrombotic complications. Subsequent studies demonstrated upregulation of CD40L on platelets, with platelet aggregation occurring in the

context of complement fixation to platelet membrane-bound anti-CD40L. *Dapirolizumab* appears to be free of the effect on platelet activation/aggregation and is being evaluated in human SLE trials (NCT04294667).

Rozibafusp alfa is a bispecific peptide–antibody conjugate that targets BAFF and ICOSL, thereby inhibiting both BAFF-induced survival and proliferation of B cells, as well as T-cell co-stimulation mediated by T-cell surface-bound iCOS and B-cell/dendritic cell expressed ICOSL. Early-phase clinical trials are underway to determine efficacy of the construct in SLE (NCT04058028).

Inhibitors of T-Cell Activation

Given the role of T-cell lymphocytes in orchestrating adaptive immune responses, selective inhibition of T-cell activation is an attractive target for modulating inflammatory disorders associated with immune responses to autoantigens or allografts. Blocking cell receptors for T-cell growth factors such as IL-2 has been employed to prevent allograft rejection and may be potentially of use in the management of autoimmune disorders. Since productive immune responses are not generated in the absence of effective co-stimulatory signals, blocking T-cell co-stimulation has also been an attractive target for treatment of inflammatory diseases driven by autoreactive T cells.

Basiliximab is a chimeric (murine/human) monoclonal antibody that blocks the alpha-chain of the IL-2 receptor complex expressed on activated T lymphocytes, inhibiting the binding of IL-2 to IL-2R (CD25) (Table 86.4). *Basiliximab* is approved for and used primarily in induction regimens for prevention of transplanted allograft rejection. Uncontrolled small case series report manifestations of systemic sclerosis and pulmonary complications associated with amyopathic dermatomyositis responding well to (off-label) treatment with *basiliximab*.[48]

Abatacept (CTLA4-Ig) is a recombinant human protein consisting of the extracellular domain of CTLA-4 linked to the Fc portion of IgG1 (Table 86.4). Prominent among the T-cell co-stimulatory molecules is CD28, which binds CD80/CD86 on antigen-presenting cells. In the context of T-cell activation, CTLA4 expression is upregulated on the surface of T cells, and due to greater binding, avidity to CD80/86 relative to CD28 is preferentially ligated, disrupting further co-stimulation through CD28 as well as engendering inhibitory signaling in the T cell. Although abatacept does not engender inhibitory signaling, by virtue of the higher avidity of the construct for CD80/86, T-cell co-stimulation through CD28 is inhibited.

Although the time to maximum clinical response is somewhat longer than that observed with TNF-α inhibitors, *abatacept* is equally effective in reducing disease activity and inhibiting progression of structural damage in rheumatoid arthritis that is unresponsive to treatment with *methotrexate*.[49] *Abatacept* has no direct impact on phagocytic cell responses, and its use in patients with RA may be associated with fewer bacterial infection complications relative to patients on anti-TNF therapy. It is nonetheless recommended that treatment with *abatacept* be withheld in the context of serious intercurrent microbial infections and should not be used in conjunction with other biologic therapies targeting inflammation. *Abatacept* may be associated with an increased risk of lung cancer. However, the occurrence of lymphoma in patients with RA treated with *abatacept* has not been shown to exceed the expected occurrence in patients with RA. In contrast to TNF-α inhibitors, use of *abatacept* does not promote autoimmune complications and may, therefore, be a preferred option for treatment of patients with RA needing biologic therapy who have overlap features of SLE or other autoimmune disorders.

Belatacept is a second-generation CTLA4-Ig that, compared with *abatacept*, has higher binding to both CD80 and CD86 (Table 86.4). Currently used primarily in organ transplantation, *belatacept* is associated with improved patient and renal allograft survival compared to cyclosporine. Although perceived to be of potential use in autoimmune disorders, studies of *belatacept* use in disorders such as SLE or RA have not yet been reported.

Dupilumab is a monoclonal antibody with specificity for the alpha subunit of the IL-4 receptor, blocking activation of the receptor by IL-4 as well as blocking IL-13/IL-13Rα1 complex binding to IL-4Rα, thereby preventing IL-4Rα-mediated signaling induced by both IL-4 and IL-13 (Table 86.4). In so doing, activation of IL-4–driven Th2 responses in T cells is significantly impaired, with noted decreases in serum levels of Th2 biomarkers including IL-13, antigen-specific IgE, CCL17 and CCL18, as well as intra-lesional Th2-associated gene expression in patients with atopic dermatitis.[50,51] Administration of dupilumab has been shown to be effective in the management of eczema as well as steroid-dependent asthma, improving FEV_1 (forced expiratory volume in one second), reducing steroid requirement, and reducing asthma flares.[50,51] The most commonly reported adverse effects of dupilumab include injection-site reactions, conjunctivitis, and headache. Although the half-life of *dupilumab* in humans is not known, peak serum concentrations of *dupilumab* are noted 7 days following the initial subcutaneous injection with steady-state concentrations reached at 16 weeks with repeat every-other-week dosing; the antibody is undetectable an average of 10 to 13 weeks after the last steady-state dose (Food and Drug Administraon [FDA] package insert).

ON THE HORIZON

IL-13 Inhibitors

Tralokinumab is a fully human monoclonal antibody with specificity for IL-13. Although clinical trials have failed to confirm efficacy in the treatment of asthma, *tralokinumab* has demonstrated efficacy in the management of atopic dermatitis for which an FDA approval application is pending. The monoclonal antibody *lebrikizumab* also targets IL-13, but in so doing, has also been shown to inhibit formation of the IL-13Rα/IL-4Rα signaling complex. Clinical trials with *lebrikizumab* confirm efficacy in the management of atopic dermatitis, but have thus far failed to demonstrate significant clinical impact on the course of steroid-dependent asthma.

KEY CONCEPTS

- Inhibition of BAF/BLyS over a period of 6–12 months decreases the survival and maturation of autoreactive B cells, decreases autoantibody titers, and decreases disease activity in SLE, with minimal impact on pre-existing antibody titers to microbial pathogens and pneumococcal vaccine response.
- Inhibition of T-cell co-stimulation targeting CD80/86 and CD28 via exogenous CTLA4:IgFc constructs is effective in suppressing disease activity in rheumatoid arthritis and rejection of transplanted allografts.
- Antibodies targeting the IL-4α receptor or IL-13 attenuate Th2 responses and are effective in the treatment of severe atopic dermatitis and eczema.

ON THE HORIZON

Recombinant Promoters of Treg Function

In addition to attenuating activation of Th1, Th2, and Th17 responses, alternative strategies are evolving to manage autoimmune disorders by upregulating Treg function. Low doses of recombinant IL-2 (*aldesleukin*) induce proliferation and enhance the function of Treg cells, with one small randomized trial demonstrating clinical efficacy in SLE.[1] *Efavaleukin alfa* is an Fc:IL-2 fusion protein that appears to have increased Treg selectivity compared to rIL-2; early phase studies are underway to assess its potential efficacy in systemic lupus (EudraCT 2020-003509-72). *Recombinant IL-27* may also modulate autoimmune inflammation via promotion of Treg lineage and function by antagonizing IL-6–STAT-3–mediated T-cell commitment to Th17 lineage. Treg function may also be enhanced by *recombinant IL-35*.

INHIBITORS OF MAST CELL ACTIVATION

Omalizumab is a recombinant humanized monoclonal antibody that binds to the Cε3 domain of immunoglobulin E (IgE) (Table 86.5). The binding domain is the same site at which IgE normally binds to both high- and low-affinity FcεRI on mast cells and basophils. As a consequence, free IgE is prevented from binding to the mast cell FcεRI receptor. *Omalizumab* is specific to IgE and does not bind to IgG or IgA. *Omalizumab* also cannot bind to FcεRI or to IgE already attached to FcεRI and, therefore, does not interact with cell-bound IgE or activate mast cells or basophils. *Omalizumab* is most useful and presently approved for use in the treatment of poorly-controlled asthma despite inhaled corticosteroid use and in the setting of documented sensitization to a perennial allergen in the setting of serum IgE levels 30 IU/mL or greater.[51] It is also approved for use in adults and adolescents with chronic idiopathic urticaria who remain symptomatic despite H1 antihistamine treatment. Omalizumab may also decrease the severity of asthma in patients with non-atopic (intrinsic) asthma, occupational asthma, viral-induced asthma, and eosinophilic granulomatosis with polyangiitis, but its use has not been fully studied in these populations to merit approved labeling. Controlled and long-term use studies of *omalizumab* have shown the incidence of adverse events is not significantly increased.[51]

Observed clinical-pathologic responses to treatment with *omalizumab* include a marked downregulation of the surface expression of FcεRI on basophils and mast cells and reductions in FcεR1-mediated production of Th2 cytokines by basophils.

TABLE 86.5 Recombinant Inhibitors of Mast Cell and Eosinophil Activation

Molecule	Construct	Half-Life	Dosing (maintenance)
Omalizumab	aIgE (humanized IgG1κ)	24–26 days	150–300 mg sc q2–4 wk
Mepolizumab	aIL-5 (humanized IgG1κ)	16–22 days	100 mg sc q4 wk
Reslizumab	aIL-5 (humanized IgG4κ)	24 days	3 mg/kg iv q4 wk
Benralizumab	aIL-5Ra (humanized IgG1)	15–18 days	30 mg sc q4-8 wk

Markers of airway inflammation are significantly reduced, with demonstrated reductions in sputum eosinophil counts and reduced numbers of eosinophils, $CD3^+$, $CD4^+$, and $CD8^+$ T lymphocytes, B lymphocytes, interleukin-4 (IL-4)-positive cells, and IgE-positive cells in the bronchial mucosa.[51]

INHIBITORS OF EOSINOPHIL ACTIVATION

Eosinophils mediate airway inflammation in patients with asthma, contribute to vascular and organ inflammation in patients with eosinophilic granulomatosis with polyangiitis (EGPA), and may mediate organ injury in other hypereosinophilic syndromes. Interleukin (IL)-5 is a potent cytokine mediator of eosinophil hematopoiesis and has been shown to mediate eosinophilic inflammation in the airways. Although corticosteroids are potent suppressors of eosinophil survival, proliferation, and function, biologics targeting IL-5 or the IL-5 receptor may prove useful as steroid-sparing therapy in managing chronic disorders mediated predominantly by eosinophils.

Mepolizumab is a monoclonal antibody administered subcutaneously that binds to IL-5, thereby inhibiting its binding to the alpha chain of the IL-5 receptor complex expressed on the surface of eosinophils (Table 86.5). Mepolizumab has demonstrated efficacy in patients with severe asthma with blood eosinophil counts of 150/μL or greater and has been approved by the FDA for maintenance treatment of severe asthma in patients who are age 12 or older with demonstrated hypereosinophilia.[52] *Mepolizumab* is also efficacious and approved for use in the management of EGPA.[53] *Reslizumab* is a monoclonal antibody targeting the IL-5R-binding domain of IL-5 (Table 86.5). Administered intravenously, *reslizumab* has been shown effective in decreasing the frequency and severity of asthma exacerbations and is approved by the FDA for use in adult patients with demonstrated eosinophilia and otherwise treatment-resistant asthma.[52] Adverse events associated with use of *mepolizumab* and *reslizumab* include occasional episodes of severe hypersensitivity reactions during or following administration and occurrence of herpes zoster.

Benralizumab is a monoclonal antibody targeting the IL-5 receptor (Table 86.5). *Benralizumab* blocks activation of eosinophils by IL-5, but also depletes IL-5 receptor-bearing eosinophils and basophils via antibody-dependent cellular cytotoxicity.[52] The recombinant antibody is afucosylated, rendering a high affinity for FcγRIII and enhanced ADCC of IL-5R-bearing cells by NK cells. Benralizumab is approved by the FDA for managing asthma, with additional studies underway to confirm its clinical efficacy and utility in managing other disorders mediated by tissue infiltration of eosinophils.[51,52]

KEY CONCEPTS

- Antibodies targeting the Fc-binding domain of IgE (omalizumab) are effective in the treatment of severe asthma and recurrent mast-cell-mediated chronic urticaria.
- Antibodies targeting IL-5 or the IL-5R-binding domains of IL-5 are effective in the treatment of resistant asthma associated with eosinophilia as well as syndromes associated with eosinophil-mediated tissue injury.

B-CELL AND T-CELL DEPLETING AGENTS

Since B cells have a demonstrated role in the generation of autoantibodies as well as antigen presentation to and co-stimulatory support for autoreactive T cells, strategies to deplete B lymphocytes have been successfully employed in the treatment of autoimmune and inflammatory diseases. Case reports and limited case series have also documented the successful use of combined and T-cell and B-cell depleting strategies in the management of patients with severe, refractory flares of SLE, multiple sclerosis, and GvHD.

Rituximab is a human–murine chimeric monoclonal antibody with specificity for the B-lymphocyte surface antigen CD20, a cell-surface molecule expressed on the surface of pre-B cells through activated mature B cells (Table 86.6). Rituximab induces lysis of $CD20^+$ B cells by several mechanisms, including complement activation, antibody-dependent cell-mediated cytotoxicity (ADCC), and induction of apoptosis. Induction regimens using four weekly doses or using two larger doses administered 2 weeks apart appear to be equally effective in depleting circulating $CD20^+$ B cells, which can last up to 9 months or longer after a single course of therapy. Treatment with rituximab has also been shown to effect significant transient decreases in inflammatory $CD4^+$ T cells that express IL-17; the extent to which this is due to an indirect consequence of $CD20^+$ B-cell depletion or depletion of identified subsets of $CD4^+CD20^+$ T cells is uncertain.[54]

Rituximab improves the signs and symptoms of disease, functional status, quality of life, and slows radiographic progression of disease in patients with RA, with greater clinical responses observed among RA patients who are seropositive for rheumatoid factor (RF) and/or anti-citrullinated peptide (CCP) autoantibody compared to RF- or CCP-seronegative patients.[55] *Rituximab* has also been used with considerable success and is approved for use in the management of ANCA-associated vasculitis syndromes, with efficacy equivalent to or greater than *cyclophosphamide* in the treatment of granulomatosis with polyangiitis (GPA) or microscopic polyangiitis (MPA).[56] In cryoglobulin syndromes, *rituximab* has been shown to decrease cryoglobulin and constituent immunoglobulin titers as well as hasten resolution of cryoglobulin-associated vasculitic skin ulcers and neuropathy, glomerulonephritis, arthritis, and/or hyperviscosity complications.[56] *Rituximab* has been used with variable reported success in the management of other autoantibody-mediated disorders including SLE, primary Sjögren syndrome, inflammatory myopathy, chronic inflammatory demyelinating polyneuropathy (CIDP), multiple sclerosis, and pemphigus.[56]

Minimal increases in serious or opportunistic infections have been reported in patients with RA or ANCA (antineutrophil cytoplasmic autoantibodies) vasculitis treated with repeated cycles of rituximab. Use of rituximab is associated with increased risk of viral infections, including cytomegalovirus, herpes simplex virus, varicella-zoster virus, and hepatitis B virus (HBV), with assessments for latent HBV with HBsAg and IgM-HBcAb recommended prior to dosing. Mild decreases in the overall levels of serum immunoglobulins may be observed during treatment, but immunoglobulin levels are rarely depleted—likely due to the preservation of more mature B cells and plasma cells that have lost surface expression of CD20. However, when used concomitantly with other immunosuppressive agents impacting lymphocyte proliferation, significant hypogammaglobulinemia may ensue over time due to inability to replenish the plasma cell compartment. Reactivation of JC virus with development of progressive multifocal leukoencephalopathy (PML)—a debilitating and often fatal demyelinating disease of the central nervous system—has been reported among patients with hematologic malignancies, SLE, and RA treated with *rituximab*, but usually in the context of concomitant treatment with other therapies impacting lymphocyte survival and proliferation.[57]

Ofatumumab is a fully human mAb that binds to an epitope, encompassing both small and large loops of the extracellular domain of the CD20 cell surface antigen on B lymphocytes (Table 86.6). The binding epitope of *ofatumumab* is distinct from that of *rituximab*, residing more proximate to the cell membrane. In comparative studies with *rituximab* using chronic lymphocytic leukemia (CLL) cells, *ofatumumab* elicits similar ADCC but elicits greater complement-dependent cytotoxicity (CDC), presumably due to the greater proximity of the binding site to the cell membrane and/or binding affinity to CD20 epitopes.[58] *Ofatumumab* is currently approved for use in managing multiple sclerosis.

Ocrelizumab is a humanized anti-CD20 monoclonal antibody that depletes CD20-positive B cells through both complement-dependent cytotoxicity and antibody-dependent cellular cytotoxicity (Table 86.6). It is currently FDA approved for the treatment of both relapsing-remitting and primary/secondary progressive variants of multiple sclerosis.[58]

Obinutuzumab is a humanized, glycoengineered type II anti-CD20 monoclonal antibody that is approved for treatment of B-cell lineage lymphomas (Table 86.6). Glycoengineering the Fc portion of obinutuzumab results in a higher affinity of the antibody for FcγRIII receptors on immune effector cells such as natural killer (NK) cells and phagocytic cells, effecting greater induction of direct cell death and ADCC and cellular phagocytosis relative to *rituximab* and *ofatumumab*. However, complement-dependent cytotoxicity (CDC) is significantly reduced with *obinutuzumab*.[58] Following encouraging phase II trial results, a phase III trial is currently underway to determine whether *obitnutuzumab* improves remission rates when added to standard induction regimens for lupus nephritis (NCT04221477).

Inebilizumab is a humanized afucosylated IgG1 monoclonal reagent with specifity for CD19, effecting depletion of $CD19^+$ B

TABLE 86.6 Recombinant T- and B-Cell Depleting Agents

Molecule	Construct	Half-Life	Dosing (maintenance)
Rituximab	aCD20 (chimeric IgG1)	18–23 days	375 mg/m² iv q wk ×4 (q4–6 mo) 1000 mg iv q2 wk ×2 (q4–6 mo)
Ofatumumab	aCD20 (human IgG1)	17 days	1000 mg iv q4–8 wk
Ocrelizumab	aCD20 (humanized IgG1)	26–28 days	600 mg iv every 6 mo
Obinutuzumab	aCD20 (humanized IgG1)	24–36 days	1000 mg iv q2 wk×2
Inebilizumab	aCD19 (humanized IgG1)	16–18 days	300 mg iv every 6 m
Alemtuzumab	aCD52 (humanized IgG1)	1–14 days	12 mg iv daily× 5 days 10–30 mg sc 3×/wk

cells primarily via ADCC (Table 86.6). As CD19 is also found on plasmablasts and most plasma cells as well as pro-B cells, targeting CD19-positive cells could be a more potent strategy for controlling B-cell-mediated diseases than anti-CD20 therapy.[59] Currently approved for just treatment of aquaporin-4 antibody-positive neuromyelitis optica spectrum disorder, inebilizumab is being studied in other disorders mediated by known autoantibodies in which responses to antibodies specific for CD20 have been suboptimal.

Alemtuzumab is a monoclonal antibody with specificity for CD52, an antigen present on the surface of B and T lymphocytes as well as the majority of monocytes, macrophages, NK cells, and a subpopulation of neutrophils (Table 86.6). Approved for use in the treatment of B-cell CLL and relapsing-remitting multiple sclerosis, *alemtuzumab* has also been used with success for the treatment of T-cell prolymphocytic leukemia, prevention and for treatment of acute GvHD, and prevention of allograft rejection. *Alemtuzumab* has also been used off-label with reported success in the treatment of patients with severe SLE and Behçet disease refractory to other treatments. Despite the depletion of T lymphocyte, B lymphocyte, NK cell, and monocyte populations following treatment, reported rates of serious infections following treatment with *alemtuzuma*b are not significantly increased compared to other immunosuppressive regimens employed to manage the disorders for which it is used. However, there is a significant occurrence of secondary autoimmunity following use of *alemtuzumab*, possibly due to homeostatic proliferation of self-reactive memory T cells in the absence of an effective Treg response during immune reconstitution.[60]

KEY CONCEPTS

- Monoclonal antibody-mediated depletion of CD20⁺ B lymphocytes is effective in the treatment of ANCA-associated vasculitis, cryoglobulin syndromes, and rheumatoid arthritis; the best responses in RA patients are those with significant elevations in antibodies specific for rheumatoid factor and CCP.
- There are subsets of T cells that also express CD20, and part of the clinical efficacy of anti-CD20 monoclonal reagents may be due in part to depletion of these subsets of T cells.
- Monoclonal reagents with greater binding affinity and binding sites more proximate to the cell membrane appear to have greater efficacy to deplete CD20⁺ lymphocytes.
- Depletion of CD20⁺ lymphocytes has been associated with reactivation of hepatitis B virus, and vigilance for latent HBV reactivation is prudent when using anti-CD20 monoclonal reagents.
- Monoclonal reagents targeting CD52 target both T-helper as well as Treg T-cell subsets; imbalances in relative homeostatic T-cell reconstitution following treatment may result in autoimmune complications.

Vaccines

Katherine V. Houser, Myra Happe, Rachel Bean, and Emily E. Coates

INTRODUCTION

Vaccines are clinically simple but immunologically complex interventions that can dramatically reduce morbidity and mortality due to diseases across all age groups. Vaccines offer an elegant solution to infectious diseases as they provide a societal benefit that reaches beyond individual protection. Vulnerable community members whose immune systems are less able to adequately respond to vaccines (newborns, immunocompromised persons, the elderly) or who are unable to receive vaccines (due to allergy or a medical contraindication) depend on immunization of surrounding community members for protection against vaccine-preventable diseases. In pregnant women, vaccinations may offer the double benefit of protecting both mother and infant against the targeted pathogen.[1]

While older adults (>65 years old) experience high proportions of the total morbidity and mortality for several vaccine-preventable diseases (*e.g.*, seasonal influenza, pneumococcal disease, herpes zoster) due to immunosenescence, they are less able to mount their own protective immune responses after vaccination. Vaccination of children, who are the primary spreaders of many vaccine-preventable infectious diseases, and younger adults can provide dramatic reductions in disease incidence in older adults through community protection. Despite suboptimal vaccine responses with aging, several vaccines are specifically recommended for older adults. In addition, some vaccines for older adults now employ novel strategies to enhance immunogenicity, including higher antigen doses[2] and the addition of an adjuvant.[3]

Vaccines against microbes are increasingly appreciated for their potential role in the heightening battle against antimicrobial-resistant pathogens. Preventing an illness through vaccination obviates the need to treat a bacterial infection with antibiotics, thereby avoiding potential induction of antibiotic resistance in either the targeted pathogenic bacterium or the patient's healthy microbiota. The sparing of antimicrobial use to prevent the emergence of resistance can be considered another form of public health intervention provided by vaccines.

Over the last 300 years, vaccinology has made impressive advances in combating human suffering and death caused by infectious diseases. These advances have accelerated rapidly in the past century with the explosion of knowledge in microbiology, immunology, and genetics. Current scientific understanding has answered many questions about immunity and how to provide it through vaccination, yet significant challenges remain and are joined by emerging epidemic and pandemic infectious diseases with alarming regularity. The next-generation tools of rational vaccine design are anticipated to yield important and life-saving innovations.

This chapter first reviews selected events in the history of vaccination. The remarkable accomplishments that have resulted from programs of vaccination to date are then highlighted. We review important recent milestones in vaccine development strategies that have the potential to revolutionize the field and offer great hope for unmet vaccine needs. Vaccine development in response to recent epidemics and pandemics is reviewed. Current vaccination recommendations in the United States and around the world are then summarized. Finally, we discuss present and future challenges for the field of vaccinology.

CLINICAL RELEVANCE

- Vaccines are highly effective interventions for preventing infectious diseases with public health importance.
- Both individual protection and community (herd) immunity result from vaccination programs.
- The reductions in disease burden (morbidity and mortality) achieved through implementation of childhood vaccination programs are extraordinary.
- Vaccination is not just for children: in recent years, new adolescent and adult vaccines have become available and are now recommended.
- Clinicians of all specialties should take vaccine histories and provide access to vaccines relevant to their patients' ages and medical conditions. Access can be provided through referral or by stocking and administering the indicated vaccines.

HISTORY OF VACCINATION

The earliest known vaccines were against smallpox and were used in Asia in the second millennium. The practice was called variolation and involved exposing, usually through the intranasal route, a susceptible person to material from the dried scabs of a smallpox victim. If the recipient survived, she/he was protected against future smallpox disease. Since natural smallpox had a 30% mortality rate, and variolation had a lower (~1%) mortality rate, this ancient practice was an early example of weighing the risk-to-benefit ratio for a human health intervention. By the 1700s, variolation was employed in societies in Africa, India, the Ottoman Empire, England, and France (https://www.nlm.nih.gov/exhibition/smallpox/sp_variolation.html). The practice of variolation involved inherent risks, including occasional outbreaks of a mild form of the disease.

An English physician was searching for a safer alternative to variolation and would become known as the father of vaccinology. Dr. Edward Jenner performed a smallpox vaccination experiment on James Phipps on May 14, 1796, using cowpox pus from lesions on the hands of a milkmaid.[4] Dr. Jenner then collected lesion material from a smallpox patient to use as a viral challenge. Phipps survived both the vaccination and the challenge.

Dr. Jenner's work was disliked by some because of the introduction of a cow virus into humans. Other opponents of vaccination were those with financial interests in lucrative variolation practices. When vaccination in England was made compulsory by the Vaccination Act of 1853, an organized anti-vaccine movement quickly arose. Incredibly, even in the present day and despite the evidence supporting the safety and effectiveness of licensed vaccines, organized anti-vaccine movements continue to challenge contemporary clinicians and public health officials. The internet and social media have facilitated self-publication with rapid wide dissemination of misinformation, anti-vaccine propaganda, and pseudoscience that circumvent traditional scientific peer review to feed on the general public's fears and misunderstandings.

KEY CONCEPTS

Jenner's Work on Smallpox Vaccination Highlights Many Dimensions Relevant for Translational Vaccinology Today

- **Disease burden, surveillance, epidemiology** A significant and unacceptable burden of smallpox disease drove development of a safer intervention to improve public health.
- **Innovation** Jenner's innovation resulted from the need for an improved biomedical intervention to address the significant risk of harm associated with the centuries-old variolation practice.
- **Clinical insight** An observation that dairymaids who had recovered from an occupational illness (cowpox) were seldom affected by smallpox led to Jenner's promotion of smallpox vaccination. The observation of the protected state (immunity) in dairymaids led to a concept that was tested and promoted by Jenner.
- **Post-vaccination challenge** After the vaccination procedure, Jenner's subjects were subsequently intentionally exposed to (challenged with) wild-type smallpox and observed for safety and disease outcomes. Human challenge with smallpox would not be considered ethical today, although human challenge experiments are performed when developing vaccines for certain self-limited or treatable infectious diseases.
- **Presentation of experimental results** To disseminate his scientific findings and advocate for wider vaccination deployment, Jenner presented his work to the Royal Society and then self-published his manuscript after it was rejected for publication.
- **Branding** The name "vaccination" was applied to the intervention. Vacca is the Latin word for cow.
- **Anti-vaccination movement and conflicts of interest** Jenner experienced significant opposition to his vaccine from groups opposed to the new technique and from individuals with variolation practices who faced financial losses as public acceptance of vaccination grew.

While Dr. Jenner's smallpox challenge experiment presented a high risk to the participant that may be questioned by today's standards, certain human challenge studies remain safe, acceptable, and valuable today. Human challenge studies are performed for self-limited and/or treatable infections in order to study vaccine and therapeutic efficacy or to characterize the host response to the infection in detail, for example, influenza,[5] primary dengue,[6] norovirus,[7] and malaria.[8] A human challenge experiment can rapidly provide feedback to vaccine developers and public health officials to help prioritize resource-intensive field trial evaluations of promising candidate vaccines. If an encouraging preliminary efficacy signal is observed in a post-vaccination human challenge trial, it may support vaccine approval by regulatory agencies. In 2020 the US Food and Drug Administration (FDA) approved a single-dose live oral cholera vaccine, Vaxchora, targeting *Vibrio cholerae* serogroup O1, representing the first time human challenge data have supported vaccine approval by the FDA. For the pivotal efficacy trial, participants received vaccination with Vaxchora, followed by controlled human infection with *Vibrio cholerae*.[9] Vaccine efficacy was found to be 90% at 10 days and 80% at 3 months post-vaccination.

A second phase of vaccination's history ensued over the nineteenth century with the emergence of the germ theory, in which infectious diseases were caused by microorganisms too small to be seen without magnification. Robert Koch (1843–1910) and Louis Pasteur (1822–1895) contributed many key observations and experiments regarding both infectious diseases and vaccines. Koch's four postulates laid out the requirements for establishing causality of infectious diseases by microbes and proved that *Bacillus anthracis* was the cause of anthrax, providing the first proof of a microbial etiology of a specific disease. Through attenuation or inactivation of the wild-type microbes, Pasteur produced vaccines that induced protection against a number of diseases. He performed a number of classical vaccination and challenge experiments to show that vaccines would protect susceptible farm animals from devastating veterinary pathogens like chicken cholera and anthrax, or human pathogens like rabies.[10]

In the early twentieth century, passive immunization was developed as a therapy for infectious diseases. While active immunization involves administering a vaccine to trigger a protected state (immunity), passive immunization involves transferring the protective proteins (antibodies) from an immune donor to a susceptible patient without administering a vaccine. Emil von Bering administered sera from immune horses to humans to cure and prevent diphtheria and was awarded the Nobel Prize in 1901 for his work (http://www.nobelprize.org/nobel_prizes/medicine/laureates/1901/behring-facts.html).

Laboratory growth of poliovirus permitted the development of both the inactivated polio vaccine (IPV; Salk, licensed in 1955) and the live-attenuated oral polio vaccine (OPV; Sabin, monovalent licensed in 1961, trivalent in 1963). As a result of those vaccines, poliovirus type 2 was eradicated in 1999, and no wild-type poliovirus type 3 has been detected since 2012. A historic milestone occurred in August 2020, when after four years of no new reported cases, Africa was officially declared poliovirus type 1 free (https://www.cdc.gov/polio/why-it-matters/africa-kicks-out-wild-polio.htm). However, it remains endemic in other regions. According to CDC, there were 176 cases of poliovirus type 1 reported in two countries in 2019: 29 (16%) in Afghanistan and 147 (84%) in Pakistan. In February 2022, after five years of no cases reported in Africa, a case of wild-type poliovirus type I was detected in a young child in Lilongwe, Malawi. However, due to the isolate being genetically linked to a sequence in Pakistan's Sindh Province, the continent's wild poliovirus-free certification remains unaffected (https://www.who.int/emergencies/disease-outbreak-news/item/wild-poliovirus-type-1-(WPV1)-malawi). While the progress toward global polio eradication is impressive, final eradication will require internationally coordinated efforts, persistence in vaccinating endemic countries' populations, and sustained attention to surveillance.

Several other live attenuated viral vaccines developed in the late twentieth century, such as measles, mumps, and rubella, have become staples of childhood vaccination programs in the US and globally. The development of the Oka strain of the varicella zoster virus led to live attenuated vaccines for both chicken pox in children and herpes zoster in older adults. To produce these vaccines, the serial passage of wild-type viruses promotes viral adaptation for growth in cell cultures and diminishes virulence in humans. Importantly, these attenuated vaccine-strain

viruses are not only well-tolerated and safe in humans but retain the ability to provoke protective immune responses.

Recognition and subsequent exploitation of key antigenic substructures rather than whole microbes were important technical advances. The studies of the polysaccharide capsules of *Streptococcus pneumonia*[11] and M proteins of *Streptococcus* species,[12] respectively, led to characterization, isolation, and serotyping of these bacterial structures and their recognition as key antigens in immunity to Streptococcal diseases. Such observations led eventually to safer vaccination with components (subunits) of pathogens, as opposed to entire microbes. When delivered as vaccines, these isolated microbial components produce protective antibody and cellular immune responses but do not cause the disease induced by the complete wild-type organisms.

The polysaccharide vaccines developed for the prevention of bacterial diseases caused by *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae* were also welcome advances. These bacterial polysaccharides were covalently coupled, or conjugated, to a protein carrier such as tetanus or diphtheria toxoids. This maneuver converted the T-cell-independent polysaccharide vaccines into T-cell-dependent protein-polysaccharide conjugate vaccines and resulted in B cell memory, improved immunity, utility in newborns, and herd immunity.[13]

The molecular biology revolution of the Twenty-First Century, in particular recombinant DNA technology, along with fundamental dissections of the innate and adaptive immune responses, have generated novel approaches to vaccination. Some of these next-generation vaccine platforms, including nucleic acid vaccines and viral-vectored vaccines, are discussed further in the sections below.

ACCOMPLISHMENTS OF VACCINATION

It is generally believed that elimination of an infectious disease from human circulation through vaccination can be achieved only when the following conditions are met: (1) the pathogen has no animal reservoir, and (2) the vaccine induces long-lasting immunity (Table 87.1). Smallpox eradication was achieved after a worldwide vaccination campaign and is the signature accomplishment of vaccination. The fields of medicine and public health celebrate this remarkable success as it showcases the power of vaccines to improve human health. Smallpox was a scourge of humanity for millennia, disfiguring and blinding survivors and killing 30% of those infected. The world's last known naturally occurring smallpox case occurred in Somalia in 1977. After the disease was eliminated, routine vaccination against smallpox in the general public was discontinued since it was no longer necessary for prevention. In 1980, the World Health Organization (WHO) certified that smallpox had been eradicated.[14]

The US Centers for Disease Control and Prevention (CDC) designated vaccination as first on the list of the ten greatest public health achievements of the twentieth century,[15] and the WHO named "Vaccine Hesitancy" as one of the "Ten threats to global health in 2019" (https://www.who.int/news-room/spotlight/ten-threats-to-global-health-in-2019). In addition to smallpox eradication, the control of many common childhood infections and attendant reductions in morbidity and mortality are great achievements. Implementation of routine US childhood immunization programs led to major reductions from mid-twentieth century disease peaks to record low levels for several infectious diseases today (Table 87.2). For example, in the US, the incidence of polio, measles, rubella, and mumps declined by 100%, 99.9%, 99.9%, and 95.9%, respectively.[16] It is estimated that for each annual birth cohort of approximately four million US children, vaccines in the US childhood immunization schedule prevent an estimated 20 million cases of disease and 42,000 deaths.[17] Furthermore, while it is true that a considerable investment of resources is required to complete the annual programs of childhood vaccination, vaccines result in very significant cost savings, hence are highly cost-effective interventions. For each annual US birth cohort, vaccines result in nearly $14 billion in annual net direct cost savings and $69 billion in annual net societal cost savings, including reductions in parental missed work to care for an ill child.[17]

TABLE 87.1 Stages of Reduction of Infectious Disease Incidence by Vaccination and Other Prevention Interventions

- **Control**. The reduction of disease incidence and prevalence to a locally acceptable level due to vaccination and/or other interventions; continued interventions are needed to maintain the reduction. Example: diarrheal diseases.
- **Elimination of disease**. Reduction to zero of the incidence of a specified disease in a defined geographical area as a result of vaccination and/or other interventions; continued measures are required. Example: neonatal tetanus.
- **Elimination of infection**. Reduction to zero of the incidence of infection caused by a specific agent in a defined geographical area as a result of vaccination and/or other interventions; continued measures to prevent re-establishment of transmission are required. Example: poliomyelitis elimination from North America.
- **Eradication**. Permanent reduction to zero of the worldwide incidence of infection due to a specific agent as a result of vaccination and/or other prevention efforts; interventions are no longer needed. Example: smallpox.
- **Extinction**. An infectious agent no longer exists in either nature or the laboratory. Example: none.

TABLE 87.2 Historical Comparisons of Morbidity and Mortality for Vaccine-Preventable Diseases in the United States

Disease	Pre-Vaccination: Estimated Annual Average Number of Cases	Post Vaccination: Annual Cases (Reported or Estimated) in Year 2006	% Reduction
Diphtheria	21,053	0	100
Measles	530,217	55	99.9
Mumps	162,344	6,584	95.9
Pertussis	200,752	15,632	92.2
Paralytic Poliomyelitis	16,316	0	100
Rubella	47,745	11	99.9
Smallpox	29,005	0	100
Tetanus	580	41	92.9
Hepatitis A	117,333	15,296	87
Acute hepatitis B	66,232	13,169	80.1
Invasive Hib	20,000	<50	99.8
Invasive pneumococcal disease	63,067	41,550	34.1
Varicella	4,085,120	48,445	85

Adapted from Roush SW, Murphy TV, Vaccine-Preventable Disease Table Working Group. Historical comparisons of morbidity and mortality for vaccine-preventable diseases in the United States. *JAMA.* 2007;298(18):2155–2163.

Vaccines protect the recipient against disease and reduce transmission of disease-causing microbes to unvaccinated persons. The term for this protection is herd immunity or community immunity. A disease that has been studied closely with regard to community immunity is measles. Measles is highly contagious and easily recognizable in epidemic form. Clustering of poor vaccination coverage often occurs in communities, as demonstrated in recent measles outbreaks in the United States. In 2019, CDC reported 1282 individual cases reported in 31 states, the largest number of cases reported in the US since 1992. The majority of these cases (~89%) were among people who were not vaccinated or whose vaccination status was unknown.[18] Such outbreaks point out the importance of community immunity to protect vulnerable (unvaccinated) members of our communities. Given that many of the recent measles outbreaks in the United States have been linked to imported cases, another important lesson is that as long as a vaccine-preventable, highly transmissible infectious disease exists anywhere, it remains a potential threat everywhere—and global vaccination programs will continue to be important to ensure the health of all community members.

Another powerful example of vaccine-induced community immunity comes from pneumococcal vaccines. There are many unique challenges relating to pneumococcal vaccines: a large number of circulating serotypes, suboptimal immunogenicity of polysaccharide-only vaccines, and noninvasive carriage of the organism. In spite of these, introduction of the pneumococcal conjugate vaccines in infants in 2000 not only led to decreased invasive disease among vaccinated children, but also produced a significant decrease in adults, particularly among older adults in whom this bacterium frequently causes pneumonia.[19] The impact of this vaccine highlights the effectiveness of community immunity produced by vaccines.

Other recently introduced vaccines have made significant impact in relatively brief periods. Before the 2006 implementation of routine rotavirus vaccination, rotavirus infections were a significant cause of severe gastroenteritis in young children and accounted for an estimated 410,000 physician visits, 205,000 to 272,000 emergency department visits, and 55,000 to 70,000 hospitalizations annually with total costs of up to $1 billion in the US alone. The licensure and approval of a rotavirus vaccine reduced hospitalizations by 70% to 80%.[20] Another example is the human papilloma virus (HPV) vaccine, a recombinant virus-like particle (VLP) vaccine for primary prevention of cancer. The US CDC Advisory Committee on Immunization Practices (ACIP) recommended routine HPV vaccination for young females in 2006 and for young males in 2011. Since the introduction of the HPV vaccine, there has been a significant reduction in HPV infections and cervical precancers. A comprehensive meta-analysis of more than 60 million HPV vaccinated individuals in 14 countries demonstrated that the rate of HPV 16 to 18 infections decreased by 83% among females 13 to 19 years of age and by 66% among those 20 to 24 years of age, whereas the prevalence of precancerous lesions decreased by 51% and 31%, respectively.[21]

Recent Changes in Vaccine Development Strategies

Early vaccines were live attenuated or inactivated versions of whole wild-type human pathogens, for example, rabies, yellow fever virus, and influenza. In a few cases, attenuated zoonotic organisms closely related to human pathogens were employed to produce cross-reactive protective responses in humans, for example, vaccinia, an animal poxvirus utilized as a vaccine against human smallpox, and bacille Calmette-Guerin (BCG), an agent of bovine tuberculosis developed as a human tuberculosis vaccine. Later, split virus vaccines utilized partially purified protein antigens derived from whole inactivated viruses, for example, split virus influenza vaccines. The polysaccharide capsules of bacteria were purified from cultures of multiple serotypes of a single bacterial species leading to polyvalent polysaccharide vaccines; for example, the 23-valent pneumococcal polysaccharide and the quadrivalent meningococcal polysaccharide vaccines. Bacterial toxins were purified from cultures and made harmless by heat or chemical treatment to produce toxoid vaccines, for example, tetanus and diphtheria vaccines.

Recent decades have featured explosive discoveries in genetics, molecular biology, immunology, and microbiology, leading to new theory-based (so-called rational) approaches to vaccine design. These advances have led to structure-based vaccine design, generations of recombinant vaccines (based on combining two or more sources of DNA), recombinant viral-vectored vaccines, and nucleic acid-based vaccines (Table 87.3).

Advances in the development of a vaccine for respiratory syncytial virus (RSV) exemplify the impact of structural biology and molecular engineering on vaccine design. RSV is the leading cause of viral acute lower respiratory tract infections globally, with the highest burden of disease occurring in infants under six months of age.[22] Despite nearly 60 years of research and development efforts, no licensed vaccine for RSV exists. In the 1960s, one clinical trial administering a formalin-inactivated RSV vaccine candidate (FI-RSV) in infants and young children resulted in the hospitalization of 80 percent of vaccine recipients, with two fatalities due to disease enhancement following natural RSV infection.[23] Twenty years after the trial, it was determined that while FI-RSV elicited antibodies in nearly all recipients, the majority were directed against nonprotective epitopes.[24] Structural biology became a prominent tool in demonstrating why FI-RSV preferentially produced non-neutralizing antibodies. The fusion (F) glycoprotein of RSV, required for viral entry into host cells, exists in two conformational states: pre-fusion (pre-F) and post-fusion (post-F). While the pre-F conformation is used for viral entry, it is metastable and irreversibly rearranges to a nonfunctional post-F state.[25] Due to the unstable structure of F, formalin

TABLE 87.3 Vaccine Platforms: Classical and Next-Generation

Platform Type	Subtype	Examples
Whole pathogen	Live attenuated	Measles, mumps, rubella, varicella zoster, yellow fever vaccines
	Inactivated	Rabies vaccine
Subunit	Polysaccharide	23-valent *Streptococcus pneumoniae* vaccine
	Polysaccharide conjugated to protein	13-valent *Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis* vaccines
	Protein	Influenza vaccine
	Virus-like particle	Human papillomavirus vaccine
Next-Generation	Viral vectored	Dengue, Ebola vaccines
	Nucleic acid based	Zika (in development) and SARS-CoV-2 vaccines
	Nanoparticle based	Influenza (in development)

inactivation in FI-RSV resulted in an almost entirely post-F antigen. Recent advances in structural biology and molecular engineering were prominent features in the design of a productive RSV antigen through the introduction of stabilizing mutations to preserve the pre-F conformation. The resulting antigen, DS-Cav1, is a stabilized trimer of the pre-F RSV F glycoprotein. This protein subunit vaccine elicited neutralizing titers 70 to 80 times greater than post-F antigens in mice and nonhuman primates. Advancing to phase 1 trials, DS-Cav1 was safe and tolerable in healthy adults and elicited neutralizing antibody responses with and without adjuvant.[25] The identification and stabilization of the pre-F conformation have led to the development of several types of vaccine candidates designed specifically for infants, the elderly, and pregnant women in the third trimester intended to provide passive immunity to the infant through the first months of life.[26] At the time of this writing, further clinical development and vaccine efficacy trial outcomes are highly anticipated.

Concurrent with the advances in structural biology that enabled progress in RSV vaccine development, advances in genetics and molecular biology allowed for gene cloning and expression in recombinant molecular systems, revolutionizing vaccine development. Vaccines can now be designed based on the *in vitro* expression of one or a few genes. For example, the hepatitis B vaccine, originally developed by Hilleman, was purified hepatitis B surface antigen (HBsAg) from the blood of chronically infected humans. But soon thereafter, a second licensed hepatitis B vaccine was produced in yeast cells through recombinant DNA methods that inserted the HBsAg gene into yeast organisms for expression and purification. In 1986, this hepatitis B vaccine was the first approved recombinant vaccine in the US (RECOMBIVAX HB) (https://www.fda.gov/media/74274/download). Newer generation vaccines have since been developed (ENGERIX-B [https://www.fda.gov/media/119403/download] and HEPLISAV-B [https://www.fda.gov/media/108745/download]) and are widely used today. This platform offers advantages including protein purity, as the genes of interest are expressed in relative isolation, and vaccine safety, as it is no longer necessary to derive vaccines by partially purifying the HBsAg from paid-donor plasma of humans chronically infected with hepatitis B virus (and potentially other viruses).

Novel recombinant vaccines and recombinant viral-vectored vaccines have been approved or recommended for human use for a number of pathogens, including HPV, malaria, and dengue, as discussed below.

Human Papillomavirus

The HPV vaccine is a highly effective recombinant VLP vaccine; its public health impacts were highlighted earlier in this chapter. Recombinant HPV L proteins expressed in recombinant systems form VLPs that are purified and formulated with or without an adjuvant. The most recent polyvalent vaccine expresses VLPs representing nine HPV serotypes (GARDASIL 9).[27] HPV VLP vaccines are remarkable for their efficacy and safety and because they are primary prevention for several types of cancer in both boys and girls.[28]

Malaria

Malaria causes an annual global disease burden of 220 million cases and 400,000 deaths, with the vast majority of cases concentrated in Africa. Pregnant women and children under 5 are the two highest-risk populations, and the development of an effective malaria vaccine remains a global health priority (https://www.who.int/publications/i/item/world-malaria-report-2019). The most advanced malaria vaccine, RTS,S, is a recombinant protein subunit vaccine that targets the pre-erythrocytic stage of the *Plasmodium falciparum* parasite. It was evaluated in combination with the adjuvant AS01 in a Phase 3 trial in which RTS,S/AS01 (Mosquirix) demonstrated 36.3% vaccine efficacy four years after first vaccination in children aged 5 to 17 months who received the four recommended doses.[29] Following the phase 3 results, two WHO advisory groups jointly called for pilot implementation of the vaccine in 3 to 5 African nations. In April 2017, the WHO approved the joint recommendation and established the Malaria Vaccine Implementation Programme (MVIP) to further evaluate the vaccine's safety profile and assess the feasibility of a four-dose vaccine administration before broader use across sub-Saharan Africa (https://www.who.int/immunization/sage/meetings/2018/april/2_WHO_MalariaMVIP-update_SAGE_Apr2018.pdf?ua=1). Three pilot countries, Malawi, Ghana, and Kenya, were selected based on pre-specified criteria. In May 2018, the vaccine was approved by each country's national regulatory agency, and the first round of administration began in April 2019. In October 2021, after more than 2.3 million doses of the vaccine had been administered to over 800,000 children in the pilot nations, the WHO recommended RTS,S/AS01 for broad use in children in sub-Saharan Africa and other regions with moderate to high Plasmodium falciparum malaria transmission. The MVIP is anticipated to conclude in 2023 once the potential benefits of a 4th dose and longer-term effects on childhood deaths have been assessed (https://www.who.int/news/item/06-10-2021-who-recommends-groundbreaking-malaria-vaccine-for-children-at-risk).

Dengue

There are an estimated 390 million infections of the dengue virus globally each year, with 95 million of those infections resulting in clinical disease.[30] In 2019, the first dengue vaccine was approved in several countries, including by the US FDA, for use in dengue-endemic regions. This vaccine, Dengvaxia (CYD-TDV), is a recombinant live tetravalent viral vector based on the yellow fever virus vaccine strain 17D expressing the envelope and pre-membrane genes of all four dengue serotypes. Dengvaxia has been administered to more than 41,000 individuals across 26 clinical trials, with a favorable safety and immunogenicity profile.[31] Based on promising results, vaccination campaigns were launched in both Brazil and the Philippines, which included school-aged children. However, long-term observation of vaccine recipients revealed an increased risk of severe dengue disease in individuals who had no previous exposure to dengue at the time of vaccination (*i.e.*, baseline seronegative individuals) and in young children (regardless of serostatus).[31] During the vaccination campaigns in Brazil and the Philippines, 87 cases of dengue infection were reported, with 14 resulting in fatalities. Following an additional investigation by the WHO Global Advisory Committee on Vaccine Safety, no causality determination could be made for these fatalities.[32] Based on this increased risk of severe dengue infection in seronegative vaccine recipients, Dengvaxia is indicated only for seropositive individuals aged 9 to 45 years.[33] The results from the long-term follow-up of Dengvaxia had a detrimental impact on vaccine confidence, particularly in the Philippines. In that country, increased vaccine hesitancy is believed to have contributed to a widespread measles outbreak in 2019.[34]

Recombinant viral vectored vaccines, such as Dengvaxia, the Ebola vaccine Ervebo, which will be discussed later in this chapter, and

nucleic acid vaccines represent the next generation of vaccine technology. DNA vaccines utilize DNA plasmids as a vector for expressing pathogen antigens *in vivo*, while mRNA is packaged in a carrier molecule for cellular delivery, most often a lipid nanoparticle. The technology has been utilized for rapid vaccine production in response to outbreaks such as Zika and the COVID-19 global pandemic, which began in 2019.[35–37] In August 2021, COMIRNATY®, a COVID-19 mRNA vaccine developed by BioNTech and Pfizer, became the first nucleic acid-based vaccine to receive approval from the US FDA for use in humans (https://www.fda.gov/news-events/press-announcements/fda-approves-first-covid-19-vaccine). A second vaccine for COVID-19 using mRNA technology, SPIKEVAX® manufactured by Moderna, received FDA approval shortly after in January 2022 (https://www.fda.gov/emergency-preparedness-and-response/coronavirus-disease-2019-covid-19/spikevax-and-moderna-covid-19-vaccine). Fig. 87.1 portrays a schematic of both classical and next-generation platforms in the context of COVID-19 vaccine development, and additional discussion of the pandemic and the response is included later in this chapter.

Adjuvants

The magnitude of immune responses can be improved by adding compounds called *adjuvants* to vaccine formulations. Recent advances in our understanding of the innate immune system have led to an appreciation that adjuvants act primarily through their effects on innate immunity. Adjuvant-triggered innate signals enhance the quantity, quality, and specificity of the downstream adaptive immune responses to the vaccine antigen. Adjuvants are also used to promote increased rates of seroconversion and induce immunity even in populations with less responsive immune systems such as the elderly, infants, and immunocompromised. Another advantage of adjuvants relates to dose-sparing, or their ability to reduce the amount of antigen used or the number of vaccine administrations given to produce comparable immune responses.[38] Some of the most widely used, clinically approved adjuvants are aluminum-based, such as aluminum hydroxide (AH) and aluminum phosphate (AP). These adjuvants primarily function to amplify antibody production in response to vaccine antigens. Although aluminum adjuvants have been used for many decades, the exact mechanism underlying their immune enhancement properties is not fully understood. Aluminum adjuvants generally have safe profiles and are included in vaccine formulations at very low doses (0.85 to 1.25 mg).[39,40] Novel adjuvants in various stages of development include oil-in-water emulsions (*e.g.*, MF059 and AS03), saponin-based adjuvants (*e.g.*, QS-21), adjuvants targeting pattern recognition (*e.g.*, CpG-ODN), and Toll-like receptor and RIG-I-like receptor ligand-specific adjuvants (*e.g.*, TLR4).[38]

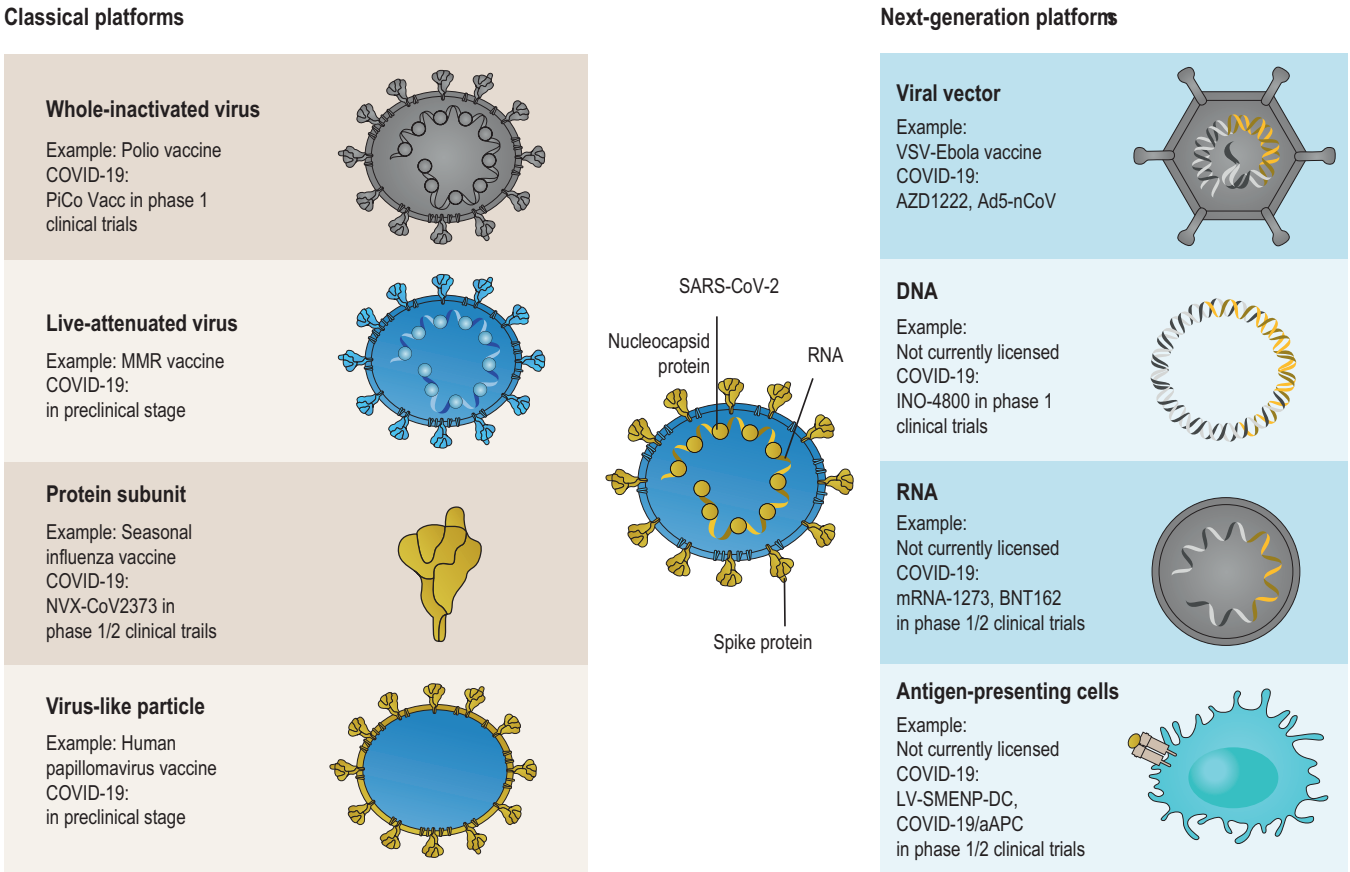

FIG. 87.1 An Overview of the Different Vaccine Platforms in Development Against COVID-19. A schematic representation is shown of the classical vaccine platforms that are commonly used for human vaccines, and next-generation platforms, where very few have been licensed for use in humans. The stage of development for each of these vaccine platforms for COVID-19 vaccine development is shown; online vaccine trackers are available to follow these vaccines through the clinical development and licensing process. (Reproduced from van Riel D, de Wit E. Next-generation vaccine platforms for COVID-19. *Nat Mater*. 2020;19[8]:810–812.) As of March 2022, two RNA vaccines are currently approved by the FDA for use in humans: COMIRNATY® (NCT04368728) and SPIKEVAX® (NCT04470427).

Systems Biology Approach to Vaccination

Over the last decade, systems biology, or systems vaccinology, approaches to vaccine development have captured considerable interest.[41] The principal objectives of a systems vaccinology approach are to elucidate complex immunological pathways that generate long-lasting immunological memory and to provide new insights into molecular and cellular signatures that can predict vaccine efficacy. In addition to the traditional cellular and humoral immunological assays (antibodies, T cells, B cells), multiple "omics" assays may be performed and used to generate computer models or algorithms describing the immune response to vaccination. Some of the applications of "omics" assays include profiling of T-cell epitopes and antibody specificity by proteomics, the discovery of predictive biomarkers by metabolomics and lipidomics, assessment of host-pathogen interactions and infection-induced immune responses by transcriptomics, and mapping of antibody glycosylation by glycomics.[42] Recent technological advances bring novel methods to systems vaccinology that include single-cell genomics and epigenomics. Single-cell technologies enable deconvolution and more in-depth resolution of immune responses by identifying cellular heterogeneity, rare cell subtypes, and unique biomarkers.[43] The use of new high-throughput assays to assess multiple dimensions of innate and adaptive immune responses generates very large data sets. Analyses and integration of these huge data sets require multidisciplinary collaboration with computational biologists and informaticians. These detailed assessments are being applied in a variety of infectious and non-infectious disease states. The impact of systems vaccinology on public health is yet to be fully realized; as the technologies supporting this approach continue to improve, new progress on vaccine development and utilization is anticipated.

Recent Responses to Epidemics and Pandemics

Despite all the advances and accomplishments of vaccine science, there remains a pressing public health concern that resonates around the globe, that is: when major epidemics of lethal and highly infectious diseases occur, can protective vaccines be developed quickly enough to respond? Advances in next-generation vaccine technology have allowed for record-speed product development over the last several years, most recently with the development of multiple COVID-19 vaccine candidates in a matter of months. Demonstrating vaccine efficacy during an ongoing epidemic or pandemic remains a challenge, and each outbreak presents unique hurdles. Below are three recent case studies of diseases that caused epidemics or pandemics and examples of vaccine development that occurred in response to these global events.

Ebola

Ebola was first discovered in 1976, and vaccine development began in the late 1990s with an initial phase 1 clinical trial of the first candidate vaccine in 2003.[44] Multiple iterations of the Ebola vaccine were developed and tested in Phase 1 clinical trials leading to refinement of the antigen design and platform approach, and testing of advanced candidates starting in 2014.[45,46] One of these candidates, rVSV-ZEBOV (Ervebo), was approved by the US FDA in 2019 for the prevention of Ebola virus disease (EVD) after demonstration of efficacy in a ring-vaccination clinical trial in 2015–16 during the West Africa Ebola outbreak (https://www.fda.gov/vaccines-blood-biologics/ervebo).[47] The VSV-EBOV vaccine is unique in that it represents the first vaccine against a filovirus to be approved in the United States and is from a novel class of vaccine based on a viral vector. VSV-EBOV is a live, attenuated recombinant vesicular stomatitis virus (VSV) in which the gene for the native envelope glycoprotein is replaced with the gene from the Ebola virus glycoprotein.[46] Additional candidate vaccines designed to prevent EVD and other filoviruses are under evaluation in clinical testing (NCT04041570, NCT03475056),[48] and a prime-boost vaccine regimen, Zabdeno® (Ad26.ZEBOV) and Mvabea® (MVA-BN-Filo), was granted Marketing Authorization from the European Medicines Agency for prophylactic use in individuals ages 1 and older in May 2020 (https://www.who.int/news-room/questions-and-answers/item/ebola-vaccines).

Zika Virus

Zika virus is a mosquito-borne flavivirus closely related to dengue that was first discovered in 1947 in Zika Forest, Uganda. This single-stranded positive sense RNA virus resulted in small human disease outbreaks over the years, but from 2015 to 2016 emerged and spread across the Americas, Africa, and other parts of the world (https://www.who.int/news-room/fact-sheets/detail/zika-virus). To date, a total of 86 countries and territories have reported evidence of mosquito-transmitted Zika infection.[49] In pregnant women, infections resulted in fetal microcephaly or other birth anomalies.[50] In general, healthy adults with symptomatic infections experience a mild to moderate self-limited viral illness which has been described as "mild dengue" and is mostly characterized by fever, rash, conjunctivitis, and arthritis. An increased association of Guillain-Barré syndrome with Zika infections has also been reported in multiple countries. Interestingly, it is believed that 80% of Zika infections are asymptomatic. In symptomatic infected adults, viremia persists for less than a week in most cases, but longer durations of viral RNA detection are reported in semen and urine.[51,52]

The development of a vaccine emerged as a top priority of the US government's response to the epidemic in 2015. Several leading candidates, including both inactivated and DNA vaccine platforms, were rapidly developed and evaluated in early phase clinical trials.[36,53] One of the candidates progressed into a multinational efficacy trial in early 2017, but the epidemic waned before an efficacy signal could be detected.[54] However, these vaccine candidates, along with others that have shown promise in preclinical studies, remain in development in preparation for another Zika epidemic.

SARS-CoV-2

In January 2020, a novel coronavirus was identified as the cause of an outbreak in China. By late September 2020, SARS-CoV-2 quickly spread worldwide with over 1 million documented deaths due to the clinical disease, COVID-19.[55] Using techniques and expertise garnered from prior pandemic responses and pre-existing coronavirus (SARS-CoV-1 and MERS) vaccine research, publicly and privately funded vaccine research teams promptly developed candidate SARS-CoV-2 vaccines for the prevention of COVID-19 disease.[56,57] The first documented COVID-19 vaccine clinical trial launched in the United States in March 2020 with multiple candidates entering clinical trials shortly after, quickly demonstrating safety and immunogenicity[37,58–60] resulting in the launch of multiple phase 3 efficacy trials by mid to late 2020 (NCT04505722, NCT04516746, NCT04470427, NCT04368728).[61] A variety of established and novel vaccine

platforms were developed predominantly expressing the SARS-CoV-2 spike protein with many specifically encoding for a stabilized version of the spike protein described in early 2020.[56] To enable rapid deployment of safe and efficacious vaccines, multiple international governments established vaccine research and production programs and the US government launched Operation Warp Speed (OWS) in May 2020, designed to utilize expertise and resources from the US government and private sectors working rapidly to develop and produce a vaccine for the US public, specifically to produce over 300 million safe and effective vaccine regimens for the US public by January of 2021. This effort funded and enabled the development of multiple candidate vaccines of various platform types (including nucleic acid, viral vector, and protein subunit).[61] At the time of this writing, two nucleic acid vaccines have received FDA approval, COMIRNATY® and SPIKEVAX®, after demonstrating 93 to 95% efficacy against symptomatic disease in final analyses of the phase 3 trials (https://www.fda.gov/emergency-preparedness-andresponse/coronavirus-disease-2019-covid-19/covid-19-vaccines).

Current Recommendations

Today in the United States, there are clear national guidelines that recommend vaccines for children, adolescents, and adults. Each February, the CDC publishes two recommended immunization schedules based on the recommendations of the CDC-appointed ACIP. One ACIP schedule of immunizations provides the adult immunization recommendations (Table 87.4). The adult schedule offers recommendations for each vaccine based on the age of the patient. For example, the ACIP recommends that all adults (persons aged 19 years and over) receive: annual influenza vaccination; tetanus-diphtheria-acellular pertussis (Tdap) vaccine once, followed by tetanus boosters every 10 years; a 2-dose recombinant zoster vaccine (RZV) administered 2 to 6 months apart for individuals aged ≥50 years; and a pneumococcal vaccination at age 65 years (https://www.cdc.gov/vaccines/schedules/hcp/index.html).

The adult schedule also provides recommendations for vaccines indicated for certain risk factors, including medical conditions (*e.g.*, immunocompromising conditions, kidney failure, diabetes), pregnancy, and certain occupations. Importantly, live

TABLE 87.4 Parts A and B: Recommended Adult Immunization Table, United States, 2020, From the Advisory Committee on Immunization Practice of the Centers for Disease Control and Prevention

A

Vaccine	19–26 years	27–49 years	50–64 years	≥65 years
Influenza inactivated (IIV4) or **Influenza recombinant** (RIV4)	1 dose annually			
or		or		
Influenza live, attenuated (LAIV4)	1 dose annually			
Tetanus, diphtheria, pertussis (Tdap or Td)	1 dose Tdap each pregnancy; 1 dose Td/Tdap for wound management (see notes)			
	1 dose Tdap, then Td or Tdap booster every 10 years			
Measles, mumps, rubella (MMR)	1 or 2 doses depending on indication (if born in 1957 or later)			
Varicella (VAR)	2 doses (if born in 1980 or later)		2 doses	
Zoster recombinant (RZV)	2 doses for immunocompromising conditions (see notes)		2 doses	
Human papillomavirus (HPV)	2 or 3 doses depending on age at initial vaccination or condition	27 through 45 years		
Pneumococcal (PCV15, PCV20, PPSV23))	1 dose PCV15 followed by PPSV23 or 1 dose PCV20 (see notes)			1 dose PCV15 followed by PPSV23 or 1 dose PCV20
Hepatitis A (HepA)	2 or 3 doses depending on vaccine			
Hepatitis B (HepB)	2, 3, or 4 doses depending on vaccine or condition			
Meningococcal A, C, W,Y (MenACWY)	1 or 2 doses depending on indication, see notes for booster recommendations			
Meningococcal B (MenB)	2 or 3 doses depending on vaccine and indication, see notes for booster recommendations			
	19 through 23 years			
***Haemophilus influenzae* type b** (Hib)	1 or 3 doses depending on indication			

Recommended vaccination for adults who meet age requirement, lack documentation of vaccination, or lack evidence of past infection

Recommended vaccination for adults with an additional risk factor or another indication

Recommended vaccination based on shared clinical decision-making

No recommendation/ Not applicable

TABLE 87.4 Parts A and B: Recommended Adult Immunization Table, United States, 2020, From the Advisory Committee on Immunization Practice of the Centers for Disease Control and Prevention—cont'd

B

Vaccine	Pregnancy	Immuno-compromised (excluding HIV infection)	HIV infection CD4 percentage and count: <15% or <200 mm³	HIV infection CD4 percentage and count: ≥15 and ≥200 mm³	Asplenia, complement deficiencies	End-stage renal disease, or on hemodialysis	Heart or lung disease; alcoholism[1]	Chronic liver disease	Diabetes	Health care personnel[2]	Men who have sex with men
IIV4 or RIV4	1 dose annually										
or										or	
LAIV4	Contraindicated					Precaution				1 dose annually	
Tdap or Td	1 dose Tdap each pregnancy	1 dose Tdap, then Td or Tdap booster every 10 years									
MMR	Contraindicated*	Contraindicated	1 or 2 doses depending on indication								
VAR	Contraindicated*	Contraindicated		2 doses							
RZV		2 doses at age ≥19 years		2 doses at age ≥50 year							
HPV	Not Recommended*	3 doses through age 26 years	2 or 3 doses through age 26 years depending on age at initial vaccination or condition								
Pneumococcal (PCV15, PCV20, PPSV23)		1 doses PCV15 followed by PPSV23 OR 1 dose PCV20(see notes)									
HepA				2 or 3 doses depending on vaccine							
HepB	3 doses (see notes)	2, 3, or 4 doses depending on vaccine or condition									
MenACWY	1 or 2 doses depending on indication, see notes for booster recommendations										
MenB	Precaution	2 or 3 doses depending on vaccine and indication, see notes for booster recommendations									
Hib		doses HSCT[3] recipients only		1 dose							

Recommended vaccination for adults who meet age requirement, lack documentation of vaccination, or lack evidence of past infection

Recommended vaccination for adults with an additional risk factor or another indication

Recommended vaccination based on shared clinical decision-makin

Precaution—vaccination might be indicated if benefit of protection outweighs risk of adverse reaction

Contraindicated or not recommended—vaccine shoulde not be administered.

*Vaccinate after pregnancy.

No recommendation/ Not applicable

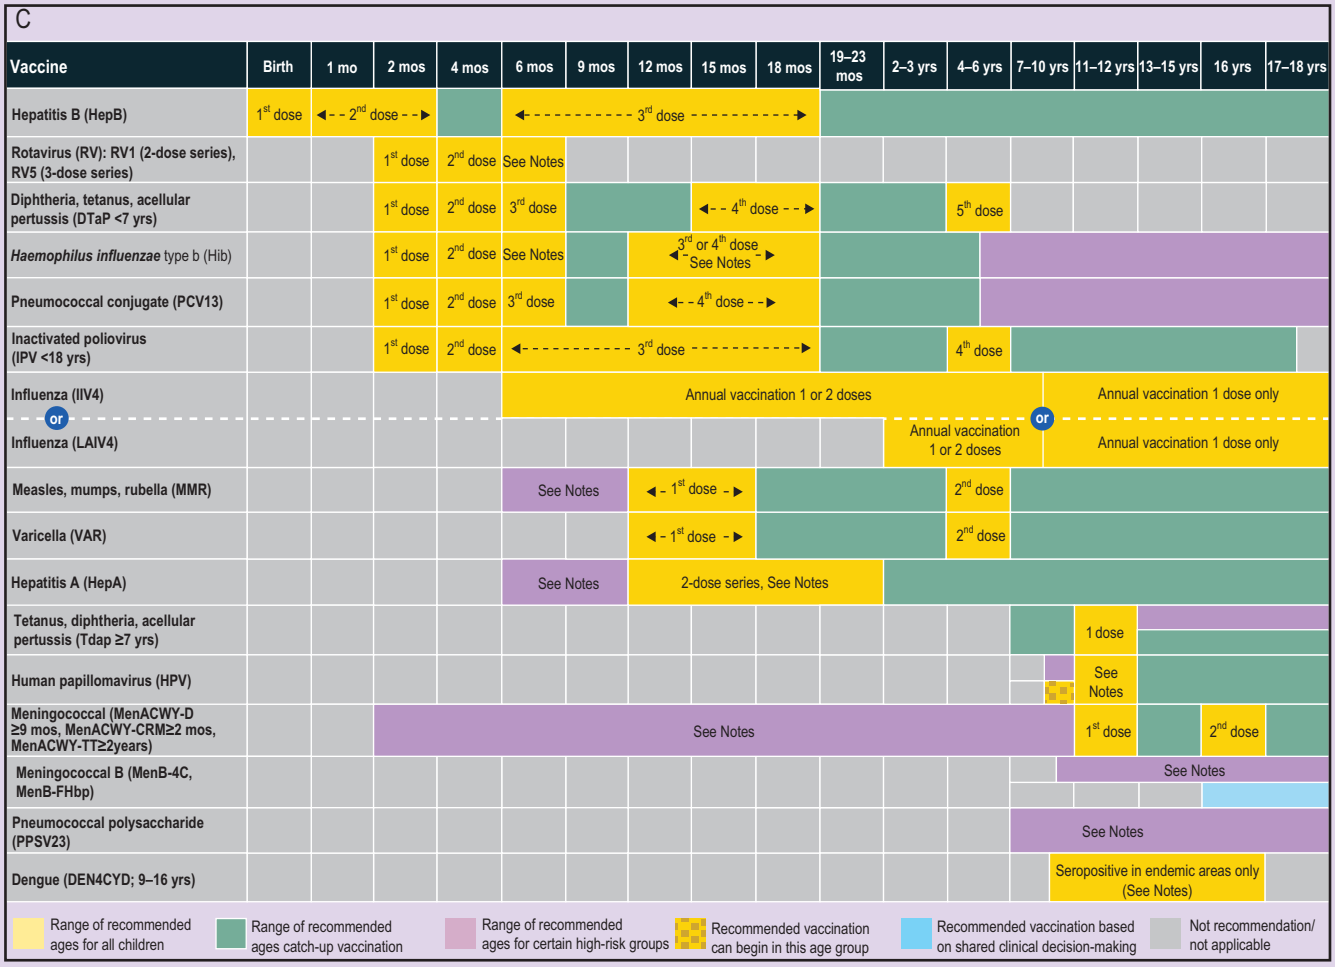
1. Precaution for LAIV does not apply to alcoholism. 2. See notes for influenza; hepatitis B; measles, mumps, and rubella; and varicella vaccinations.
3. Hematopoietic stem cell transplant.

Notes: Tetanus, diphtheria, and pertussis vaccination: Pregnancy: 1 dose Tdap during each pregnancy, preferable in early part of gestational weeks 27-36; wound management: Persons with 3 or more doses of tetanus-toxoid-containing vaccine: For clean and minor wounds, administer Tdap or Td if more than 10 years since last dose of tetanus-toxoid-containing vaccine; for all other wounds, administer Tdap or Td if more than 5 years since last dose of tetanus-toxoid-containing vaccine. Tdap is preferred for persons who have not previously received Tdap or whose Tdap history is unknown. If a tetanus-toxoid-containing vaccine is indicated for a pregnant woman, use Tdap. **Zoster vaccination:** Immunocompromising conditions (including HIV): RZV recommended for use for persons 19 years or older who are or will be immunodeficient of immunosuppressed because of disease or therapy. **Pneumococcal vaccination:** Age 19–64 years with certain underlying medical conditions or other risk factors who have not previously received a pneumococcal conjugate vaccine or whose previous vaccination history is unknown: 1 dose PCV15 or 1 dose of PCV20. If PCV15 is used, this should be followed by a dose of PPSV23 given at least 1 year after PCV15 dose. A minimum interval of 8 weeks between PCV15 and PPSV23 can be considered for adults with an immunocompromised condition, cochlear implant, or cerebrospinal fluid leak to minimize the risk of invasive pneumococcal disease caused by serotypes unique to PPSV23 in these vulnerable groups. **Hepatitis B vaccination:** Heplisay-B is not recommended in pregnancy due to lack of safety data in pregnant women. **Meningococcal vaccination:** Booster dose is recommended for those at increased risk due to an outbreak and if 5 or more years have passed since receiving MenACWY and 1 year or more since receiving MenB. Detailed information could be found at https://www.cdc.gov/vaccines/schedules/downloads/adult/adult-combined-schedule.pdf.

vaccines (varicella and MMR) are contraindicated for pregnant women, immunocompromised hosts, and HIV-infected individuals when the CD4+ T-cell absolute count is below 200 cells/mcl.

A second ACIP immunization schedule of immunizations covers birth to 18 years of age and catch-up recommendations for children or adolescents who have not received recommended vaccines (Table 87.5). The ministries of health for many European countries publish their own country-specific immunization schedules, and vaccination guidelines published by the WHO are utilized by many developing countries. The schedules are generally similar but with some region-specific differences. For example, the 2020 US ACIP immunization schedule for children recommends vaccinations against ten viral diseases: hepatitis B, rotavirus, poliovirus, influenza, measles, mumps, rubella, varicella, hepatitis A, and human papilloma virus (HPV) (https://www.cdc.gov/vaccines/schedules/hcp/index.html). Preventive viral vaccines in the WHO-recommended routine immunization schedule for children include the same 10 viral vaccines (although four—mumps, influenza, varicella, and hepatitis A vaccines—are recommended only for country immunization programs with certain characteristics). The WHO schedule also recommends additional vaccines, for example, rabies, yellow fever, Japanese encephalitis, and tick-borne encephalitis vaccines for certain high-risk populations (https://www.who.int/immunization/policy/immunization_tables/en/).

TABLE 87.5 Recommended Immunization Schedules for Persons Aged 0 Through 18 Years, United States, 2020, From the Advisory Committee on Immunization Practice of the Centers for Disease Control and Prevention



Notes: Measles, mumps, rubella (MMR): during international travel infants age 6–11 months 1 dose before departure; revaccinate with 2-dose series at age 12–15 months (12 months for children in high-risk areas) and dose 2 as early as 4 weeks later. **Hepatitis A:** during international travel infants age 6–11 months 1 dose before departure; revaccinate with 2 doses, separated by at least 6 months, between age 12–23 months. For detailed information on **Meningococcal Vaccination:** MenACWY-D, MenACWY-TT, MenB-4C, MenB-FHbp) and **Pneumococcal vaccination** see https://www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html#note-mening.

KEY CONCEPTS

Current Areas of Vaccine Need

- Human immunodeficiency virus (HIV)
- Lyme disease
- Malaria
- Powassan disease
- Rocky Mountain spotted fever
- Universal coronavirus (SARS-CoV-1, MERS, SARS-CoV-2)
- Tuberculosis (TB)
- Tularemia
- Zika

Present and Future Challenges

A few specific challenges facing those involved in vaccine research and discovery are highlighted below to illustrate the ongoing needs in the area of public health.

A Vaccine for HIV. The development of an HIV/AIDS vaccine has long been recognized as a top HIV research global priority at the US National Institutes of Health. Strong and simple treatments for those who are living with HIV infection are now available and have even been rolled out to developing countries. It has been shown that treatment-as-prevention, wherein the viral load is lowered to an undetectable level by antiretroviral treatment of infected persons, results in a benefit to the infected patient and up to 96% reduction in HIV incidence in sexual partners.[62]

More recently, antiretroviral agents have been tested globally and licensed in the United States as a once-daily pill (a combination of tenofovir and emtricitabine) for HIV/AIDS prevention in higher-risk individuals.[63] Known as pre-exposure prophylaxis (PrEP), this approach, in an idealized setting where resources and human adherence were not limiting, could have a truly dramatic impact on HIV incidence. However, to date, uptake has been low, and adherence has been a concern. A federal initiative, Ending the HIV Epidemic: A Plan for America,

which includes a plan to make PrEP medication available without cost for up to 200,000 people a year for 11 years, was announced in 2019 to help combat these issues and reduce the number of new HIV infections in the United States.[64]

While the advances in HIV treatment, treatment-as-prevention, and PrEP have been significant, the numbers of new infections globally remain unacceptably high, with 1.7 million new infections in 2019 and a total of 38 million people living with HIV infection.[65] In the United States, progress on prevention of HIV infections through condoms, education, and evidence-based interventions plateaued new infections to ~36,400 in 2018 (http://www.cdc.gov/hiv/library/reports/hiv-surveillance.html).

The global need for an HIV vaccine remains. However, the scientific challenges have proven significant, and despite more than 30 years of major effort since the identification of the viral etiologic agent of AIDS in 1984, there is no approved HIV vaccine with proven protective efficacy. The majority of efficacy trials completed to date have not achieved protection of higher-risk vaccinated subjects relative to placebo recipients.[66] Additionally, in two of the trials (which tested replication-deficient adenovirus serotype 5 recombinant vaccine vectors expressing HIV Gag, Pol, and Nef but not Env), the studies were halted early with either concern over possible enhanced HIV acquisition in a small subset of participants or lack of prevention efficacy in the vaccine groups relative to the placebo groups.[66]

Importantly, modest vaccine efficacy was observed in the RV144 efficacy trial reported in 2009.[67] Conducted by the US Army in collaboration with the government of Thailand. This 16,000-person study evaluated a prime-boost regimen of a non-replicating canarypox vector prime (expressing HIV Gag, protease, and gp120) followed by boosting with the same vector, plus a bivalent gp120 protein adjuvanted in alum. The RV144 regimen produced 61% protection in the first year post-vaccination and modest (31.2%) protection at 3.5 years post-vaccination.[67]

This first evidence of human protection by an HIV vaccine proved that the development of an HIV vaccine may be possible and has re-energized the field. The US HIV Vaccine Trials Unit Network (HVTN), National Institute of Allergy and Infectious Diseases (NIAID), National Institutes of Health (NIH), US Army, and country-level and industry collaborators have formed the Pox-Protein Public-Private partnership (also known as P5) to plan an intensive series of follow-up human studies to confirm and fully investigate the important leads provided to the field by RV144.[68] One such follow-up efficacy trial of 5407 participants in South Africa (HVTN 702) was unfortunately not as successful as RV144. This trial was investigating a poxvirus vector and a bivalent gp120 protein adjuvanted with MF59, both modified to express clade C. The HVTN 702 trial was recently halted when the data and safety monitoring board (DSMB) found that the regimen did not prevent infection compared to placebo recipients.[69] Additional analysis is ongoing to discover the reason behind these discrepant outcomes.

A holy grail for HIV vaccines remains the discovery of a vaccine immunogen that induces broadly neutralizing, protective antibodies. Such antibodies occur naturally in up to 15% of chronically infected persons, usually after years of infection. Although seen in natural infection, no vaccine has been able to readily induce these broadly neutralizing antibodies in vaccinated humans. However, several broadly neutralizing monoclonal antibodies (bnAbs) have been isolated and cloned, and several have been tested for safety and pharmacokinetics in human trials. To date, these bnAbs have proven safe and well-tolerated in both healthy and HIV-infected recipients.[70–72] In viremic recipients who do not have resistant viruses present prior to infusion, receipt of either a single or combination of bnAbs results in a temporary decrease in circulating viral load, which typically rebounds once the serum levels of the bnAb lower below a protective concentration.[73–75]

NIAID, through two of its HIV/AIDS clinical trials networks (the HVTN and the HIV Prevention Trials Network (HPTN)), is conducting two phase 2B efficacy trials of a broadly neutralizing monoclonal antibody, VRC01 (Clinical trials HVTN 703/HPTN 081 and HVTN 704/HPTN 085).[70,75] The VRC01 efficacy trials (or AMP studies for antibody-mediated protection) are randomized, double-blind, placebo-controlled clinical trials. In the AMP studies, VRC01 was infused IV every eight weeks for 18 months at doses of 0 mg/kg (placebo), 10 mg/kg, or 30 mg/kg. While VRC01 was generally well-tolerated and demonstrated a favorable safety profile, it did not prevent acquisition of resistant viral strains. It did, however, protect against sensitive isolates, providing 75% protection over the 20- month trial to at-risk populations exposed to sensative subtype B and C variants.

These results support what many experts suspected: rather than a single antibody, a combination of potent monoclonal antibodies targeting different epitopes on the gp120 envelope protein structure may be required to produce broad protection across a range of diverse subtypes. Combinations of two or three bnAbs are being evaluated in early-phase trials (NCT04173819, NCT04212091, NCT03928821).[75a]

Improved Influenza Vaccines

The disease burden due to seasonal influenza A is significant, with the highest morbidity and mortality occurring in children, older adults, pregnant women, and persons with chronic medical conditions.[76] During an average year, seasonal infections result in an estimated 3 to 5 million severe cases and 291,000 to 645,000 influenza-associated deaths worldwide.[77] In the United States, it is currently recommended that all persons 6 months or older receive an annual influenza vaccine.[76] This recommendation serves to protect the vaccinated individual as well as those in the community who cannot be vaccinated themselves.

Influenza A and influenza B viruses are responsible for the majority of human infections. Multiple subtypes of influenza A are categorized based on the amino acid (AA) sequence homology within the viral surface proteins, hemagglutinin (HA), and neuraminidase (NA). So far, 18 HA and 11 NA subtypes have been discovered. Currently, two influenza A subtypes (H1N1 and H3N2) and two antigenically distinct lineages of influenza B (Yamagata and Victoria) co-circulate in humans,[76] with one strain of each represented in the quadrivalent seasonal vaccine developed each year.

Influenza is a segmented negative-stranded RNA virus of the Orthomyxoviridae family that lacks a proof-reading function in its viral polymerase and therefore mutates rapidly. These mutations result in an antigenic drift of the surface proteins, requiring an annual vaccine reformulation. Currently, licensed vaccines are produced in either embryonated eggs or cell culture and include inactivated influenza vaccines (IIVs), recombinant influenza vaccines, and live attenuated vaccines.[76] WHO issues a new vaccine strain recommendation for the vaccine each February, and vaccine manufacturers then race to produce the year's seasonal vaccine by late summer in order to be ready for the winter influenza season. There are multiple challenges and

needs with regard to this annual process of influenza vaccine prediction, production, distribution, implementation, uptake, and protection (Fig. 87.2).

Young children (particularly those between 6 months and 5 years of age) and older adults have a higher risk of severe illness during influenza infection. Children between 6 months and eight years of age should receive two doses of vaccine administered at least four weeks apart during the first season they receive vaccination for optimal protection.[76] Quadrivalent inactivated influenza vaccines (IIVs) are approved for all ages, while live attenuated influenza vaccines (LAIVs) should only be administered to children over 2 years of age, and quadrivalent recombinant influenza vaccines (RIVs) to children over the age of 4 years. For older adults, currently licensed vaccines provide relatively weak protection overall but remain an important public health measure. Immunosenescence is a large contributor to this reduced vaccine efficacy, resulting in increased disease susceptibility and severity. One solution to this challenge has been the approval of a high-dose vaccine, containing a fourfold higher dose of antigen, for a total of 60 mcg (compared to the standard 15 mcg) of each viral HA protein. This high-dose vaccine was shown to increase efficacy and was approved for use in older adults in the United States in 2009 (trivalent) and 2019 (quadrivalent).[2,78] A vaccine formulated with the oil-in-water adjuvant, MF59, was approved for use in the United States and may increase immunogenicity in older adults (https://www.fda.gov/vaccines-blood-biologics/approved-products/fluad).[3]

An ongoing issue with seasonal influenza vaccines involves the variable vaccine effectiveness for each viral antigen within the vaccine, which is partially dependent on the degree of match between the vaccine strains and the circulating strains. In order to allow manufacturers the six months currently required for egg-based vaccine production, the vaccine strains for each subtype and lineage must be selected in February of each year for the following season's vaccine campaign. The burden of annual revaccination of the entire population against a variable viral target is high, both logistically and financially. Furthermore, uptake of the annual seasonal influenza vaccine in the general population remains suboptimal. Over the past decade, considerable effort has been put into the development of universal influenza vaccines that would produce a broad immune response capable of protecting an individual against more antigenically drifted viruses and should ideally mean protection for more than one influenza season. A common approach to the rational design of such a vaccine involves selecting antigens in the more conserved regions of the virus, including the highly conserved HA stalk rather than the hypervariable HA head and other conserved internal proteins. Some of the universal influenza vaccine candidates are moving into early phase human safety and immunogenicity clinical trials, with the ultimate goal to improve or possibly supplant the current annual vaccination

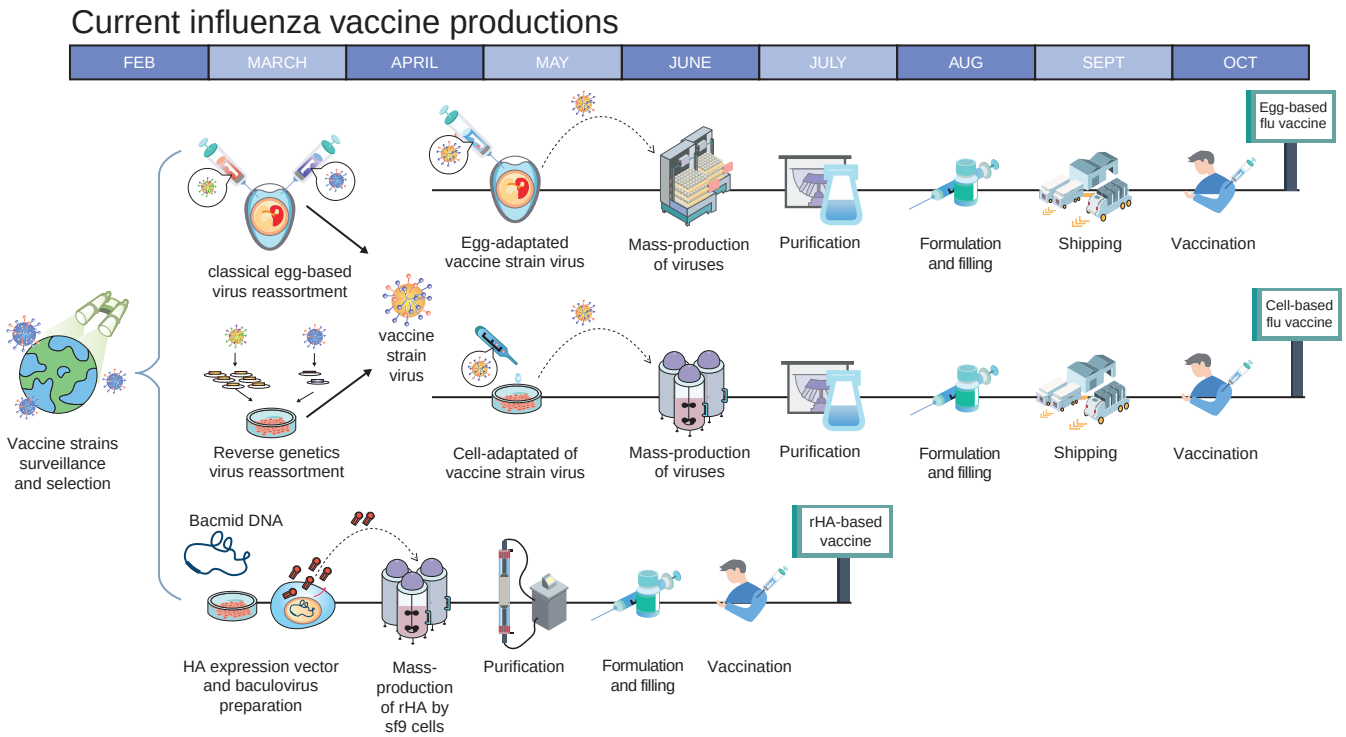


FIG. 87.2 Current Influenza Vaccine Productions. Timeline of current influenza vaccine production methods. Schematic overview of egg-based, cell-based and recombinant protein-based influenza vaccine production. Vaccine strains that match circulating influenza viruses for the upcoming flu season are selected by the World Health Organization (WHO) Global Influenza Surveillance and Response System (GISRS). High yielding vaccine strains for egg- or cell-based production are generated by either classic or reverse genetic reassortment. These adapted viruses go into mass production, either in embryonated eggs or MDCK cells with a production timeline of approximately 6 to 8 months. In recombinant hemagglutinin (HA) vaccines (rHA), the *HA* sequence is cloned into baculovirus and expressed by insect cells, significantly shortening production time. (Reproduced from Chen JR, Liu YM, Tseng YC, Ma C. Better influenza vaccines: an industry perspective. *J Biomed Sci.* 2020;27[1]:33.)

with an initial vaccination and periodic boosting. A further advantage to universal vaccines would be pandemic preparedness since the universal influenza vaccine, by targeting conserved viral domains present on all influenza viruses, may also protect against novel emerging subtypes.[79]

Selected Unmet Vaccine Needs

Along with HIV/AIDS and malaria, tuberculosis is one of the three top infectious disease killers each year, and therefore remains a major target for the development of a vaccine to reduce mortality and morbidity.[80–82] Currently, the WHO's list of diseases which "pose the greatest public health risk due to their epidemic potential and/or [the existence of] no or insufficient countermeasures" includes COVID-19, Crimean-Congo hemorrhagic fever, Ebola virus diseases, and Marburg virus disease, Lassa fever, Middle East respiratory coronavirus (MERS-CoV) and severe acute respiratory syndrome (SARS), Nipah and henipaviral diseases, Rift Valley fever, Zika, and a yet to be discovered "Disease X" (https://www.who.int/activities/prioritizing-diseases-for-research-and-development-in-emergency-contexts). There are also a number of tick-borne diseases with potential to cause significant disease burden in the United States for which there are no human vaccines including Lyme and Powassan diseases, Tularemia and Rocky Mountain spotted fever (https://www.cdc.gov/ticks/diseases/index.html).

Reflections on the Future of Vaccinology

The science of vaccinology has entered a new era with the high-throughput analytic and data approaches being applied today. Whether these advances in technology, computation, and science will result in improvements in human health remains to be seen. The potential of the big data systems biology approach has yet to be realized within vaccine science. The field must show that the massive data can be analyzed, integrated, and can produce new knowledge leading to improved vaccines that benefit human health.

In order for outstanding scientists to be retained and attracted to the field of vaccinology, it is essential that science funding agencies provide and maintain robust support for the critical discovery research projects (investigator-initiated research projects) that form the engine of innovation that drives all of science. At the same time, targeted big science vaccine program projects and networks have the potential to synergistically pool approaches in intensely focused efforts, tackling major vaccine needs and challenges, for example, HIV and TB vaccine development. In order to translate basic advances and laboratory science into improved health for patients, having well-trained translational physician-scientists leading clinical-translational human research programs is an additional component of essential infrastructure. Post-doctoral training programs that focus on vaccinology are needed, but few are in existence. The future of the field depends on attracting and training a highly qualified next generation of vaccinology research leaders.

Patients' and parents' confidence in and uptake of vaccines is derived primarily from the advice and education provided by their trusted physicians and other clinicians. But in the time-pressured office or hospital encounter, clinicians often find it challenging to prioritize discussions around vaccination. The clinician-patient interface is the most potent opportunity for education and influence, and this crucial moment must be seized in order for vaccine programs to be successful. Every clinician encounter is an opportunity to review vaccination history, recommend and discuss needed vaccines, and bring patients' vaccinations up to date. These seemingly simple, everyday actions hold incredible power to use vaccination to prevent disease and protect the health of all members of our global community.

ON THE HORIZON

- As valuable as vaccines have been in improving health in the past century, they are likely to be even more valuable in the next century.
- Emerging infections capable of severe morbidity (*e.g.*, Zika and SARS-CoV-2 viruses) or mortality (*e.g.*, Ebola virus and avian influenza A/H7N9) continue to emerge and threaten global human health with alarming regularity.
- Having vaccine platforms "on the shelf"—to enable rapid production and facilitate immediate preclinical testing for safety, immunogenicity and efficacy will be critical for timely and effective responses to global outbreaks that result from international personal contacts and air travel.
- Vaccines moving forward will depend on newer, improved methods, including cell culture-derived recombinant antigens and nucleic acid vaccines as well as automated high-throughput neutralization assays.
- There will be an increased application of new molecular adjuvants (*e.g.*, Toll-like receptor-7 [TLR-7]) that target specific biochemical pathways to direct and shape the cascade from innate immune response to desired adaptive immunity protective response.
- Nanoparticle delivery approaches will be increasingly used to prevent viral infections by targeting molecular structures of viral antigens.

Allergen Immunotherapy for Allergic Diseases

Joana Cosme and Stephen R. Durham

Allergen immunotherapy involves the administration of allergen extracts or allergen products to IgE-sensitized allergic individuals in order to induce a state of durable clinical and immunologic tolerance following allergen re-exposure.[1] This chapter gives a historical perspective and review of indications and contraindications for allergen immunotherapy. There follows a review of the evidence for subcutaneous and sublingual immunotherapy for inhalant allergies. Immunotherapy for Hymenoptera venom anaphylaxis and food allergy are briefly considered. Mechanisms of immunotherapy are reviewed along with implications for biomarker discovery and novel therapeutic approaches.

HISTORICAL PERSPECTIVE

In 1911, Leonard Noon[2] published in The Lancet that extracts of grass pollen injected into patients with seasonal pollinosis resulted in a marked reduction in conjunctival allergen sensitivity with a 10 to 30-folds increase in the concentration of grass pollen allergen necessary to provoke an immediate conjunctival response. Noon died that year, and his colleague John Freeman reported that this was accompanied by an improvement in hay fever symptoms during subsequent natural seasonal exposure. In 1921, Heintz Kustner, who was fish-allergic, demonstrated that following injection of his serum into the skin of his colleague Carl Prausnitz, a subsequent skin prick test with fish extract resulted in a weal and flare, thereby demonstrating passive transfer of allergen hypersensitivity by serum.[3] The nature of this serum factor (coined "reagin") was unknown until 45 years later when Hans Bennich and Gunnar Johansson in Sweden[4] and Kimi and Teruko Ishizaka in USA[5] officially identified immunoglobulin E as a novel class of antibody responsible for this "reaginic" activity. In 1935 Robert Cooke showed that the intradermal injection of serum obtained post-immunotherapy from a ragweed-allergic patient into the skin of a non-allergic individual conferred protection against passive transfer of immediate ragweed skin test hypersensitivity that followed intradermal injection of the same individual's pre-immunotherapy serum.[6] In 1940, Mary Loveless showed that this "blocking" serum factor resided within the immunoglobulin (presumed IgG) fraction of serum,[7] but still many years before the discovery of IgE in 1967. In 1952 William Frankland, a student of Freeman and also based at St Mary's hospital Paddington UK, published the first randomized, blinded controlled trial of grass pollen immunotherapy.[8] He showed that compared to the control diluent, a crude extract of grass pollen injected subcutaneously was effective in improving rhinitis and asthma symptoms during the pollen season. Remarkably, in the same study, he showed that it was the high-molecular-weight protein fraction rather than the non-protein-containing low-molecular-weight fraction that was responsible for the therapeutic activity of the crude grass pollen extract. In the 1960s to 1980s, there followed a series of controlled trials confirming the efficacy of subcutaneous immunotherapy (SCIT) for pollen allergy[9,10] and in mite-allergic children.[11] In 1986, a report from the Committee of Safety of Medicines questioned the safety of subcutaneous immunotherapy following a series of deaths in the UK. Fortunately, immunotherapy practice has moved on, and national and international guidelines now provide guidance for best practice. Together with the publication of large randomized controlled trials, subcutaneous immunotherapy is now recognized as safe and effective.

ALLERGEN IMMUNOTHERAPY FOR ALLERGIC RHINOCONJUNCTIVITIS AND ASTHMA: PLACE IN THERAPY

Allergen Avoidance and Pharmacotherapy

The role of allergy should be critically evaluated in all cases of rhinoconjunctivitis and in bronchial asthma, which is very commonly associated with rhinitis. An allergy history combined with either skin prick testing and/or serum IgE determinations for relevant allergens should always be part of the diagnostic work-up. It is important to identify and, where possible, avoid provoking allergens such as perennial exposure to the dander of domestic pets and house dust mites (HDM). Unfortunately, this is often very difficult in view of the psychosocial implications of owning a family pet and the relative lack of efficacy of even rigorous HDM avoidance measures.

According to ARIA (Allergic rhinitis and its impact on asthma) guidelines,[12] allergic rhinoconjunctivitis is classified according to symptom severity as mild or moderate/severe depending on whether symptoms impact quality of life and usual daily activities. Allergic rhinitis is further classified according to the duration of symptoms as intermittent (less than 4 days per week and/or for less than 4 weeks/year) and persistent (greater than 4 days per week for more than 4 weeks/year. A simplified guide of treatment according to ARIA[12] is summarized in Fig. 88.1. For mild intermittent or persistent symptoms, non/low sedating once-daily oral antihistamines, for example, loratadine or cetirizine (also intranasal antihistamines), have been shown to be effective. For moderate/severe and persistent symptoms, intranasal corticosteroids are first-line treatment and include fluticasone propionate or mometasone furoate once daily. When these treatments are not fully effective, it is

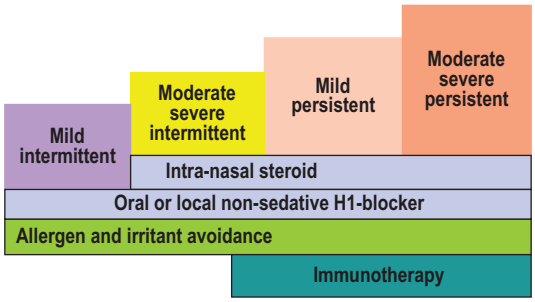

FIG. 88.1 Stepwise guide to treatment of rhinoconjunctivitis. (Simplified from ARIA guideline.[12])

essential to check compliance with therapy and intranasal spray technique. Recently a nasal spray comprising the combination of an intranasal corticosteroid (fluticasone) and antihistamine (azelastine) has been shown to be more effective than either treatment alone.[13] When patients fail to respond to these measures or develop unacceptable side effects, the diagnosis should be checked and adherence to treatment reviewed.

Allergen Immunotherapy

Allergen immunotherapy (AIT) should be considered in patients aged 5 years or older, with allergic rhinoconjunctivitis in whom a dominant allergen or limited spectrum of allergens is mainly responsible for symptoms and in whom the combination of avoidance measures and pharmacotherapy have not been adequately effective and/or resulted in unacceptable side effects.[1] General Indications and contraindications for rhinitis and asthma are summarized in Table 88.1. Immunotherapy is indicated in patients with rhinoconjunctivitis with/without mild asthma who have evidence of symptoms *on exposure* to a relevant allergen and documented *IgE sensitization* to a relevant allergen (SPT and/or Sp-IgE). Contraindications include uncontrolled asthma, malignancy, and active autoimmune disease. Immunotherapy should not be initiated during pregnancy. Recent data suggest that with extracts of proven value, polysensitized patients do as well as monosensitized patients.[14,15]

Allergen immunotherapy may be indicated for children and adults with seasonal asthma complicating rhinitis due to pollens.[14] Sublingual HDM tablet immunotherapy is indicated in adults with HDM-driven asthma as an add-on treatment to regular therapy in order to reduce exacerbations and to decrease symptoms and corticosteroid use.[15] Due to the lack of robust evidence, there are no current indications for the prescription of AIT in asthma driven by other aeroallergens.

For both rhinoconjunctivitis and asthma, a 3-year period of treatment is generally recommended in order to achieve long-term efficacy.[14] In rhinoconjunctivitis, this period can be extended up to 5 years, while for HDM-driven asthma, there does not appear to be an additional benefit of 5-year therapy compared to a 3-year period.[15]

The role of allergen immunotherapy for children and adults with atopic eczema is less clear. In patients with inhalant allergy, immunotherapy is not contraindicated in those with mild-moderate atopic eczema. In severe eczema, evidence for efficacy is weak, and the disease may be exacerbated.[16]

Allergen immunotherapy is highly effective and may be lifesaving in patients who develop anaphylaxis to insect stings of Hymenoptera species (bees, wasps, and hornets).

TABLE 88.1 Allergen Immunotherapy for Inhalant Allergens

Indications for Immunotherapy	Contraindications
• Rhinoconjunctivitis /mild asthma • Symptoms on exposure to relevant allergen • IgE sensitization to relevant allergen • Inadequate response to anti-allergic drugs • Unacceptable drug side effects • Polysensitization not a contraindication	• Severe or uncontrolled asthma • Autoimmunity • Immunodeficiency • Malignancy • Pregnancy—initiation (maintenance OK) • Lack of understanding/poor adherence

Evidence of efficacy for certain food allergies, particularly peanut, is emerging—but immunotherapy for food allergy is not yet recommended as part of routine practice.

Evidence for Efficacy of Allergen Immunotherapy

Allergic rhinoconjunctivitis. Recently the European Academy of Allergy and Clinical Immunology published a systematic review of immunotherapy for allergic rhinoconjunctivitis,[17] followed by a guideline based on this review.[14] 5932 studies were reviewed, of which 160 were suitable for systematic review. Summary data for subcutaneous and sublingual immunotherapy are presented in Fig. 88.2.[17] Efficacy measures are expressed as symptom scores, "rescue medication" scores, and combined scores—the combination of symptom and medication scores. Data are represented as standardized mean differences and 95% confidence intervals compared with placebo. The number of studies analyzed for which data were available for each category, the total number of participants receiving active or placebo treatment, the I^2 value (a measure of the heterogeneity of the data), and levels of statistical significance are shown. Overall, the level of heterogeneity was moderate to substantial for all categories. Confidence intervals were greater for the combined scores since there were fewer studies that included this recently introduced measure of efficacy. The mean differences compared to placebo varying between 0.4 and 0.6 indicate a moderate level of efficacy for both subcutaneous and sublingual immunotherapy routes.

Subgroup analyses showed that mono/polysensitization and presence/absence of asthma did not influence the level of efficacy of immunotherapy for rhinoconjunctivitis. The treatment was effective in all age groups studied, although less data were available for children and the elderly. Based on preventative studies, allergen immunotherapy initiated below the age of 5 years could be effective (or more effective). Few studies are available, and this remains an area of high priority. Immunotherapy should not be initiated in pregnancy, although effective maintenance immunotherapy may be continued during pregnancy.

Examples of individual studies include a phase III trial in the UK of 410 grass pollen allergics with moderate-severe hay fever who were randomized to receive subcutaneous alum-based grass pollen extract in two doses (containing 2 or 20 µg major allergen Phleum p 5 in maintenance injections) per week for a month, and then monthly over approximately 8 months. There was a dose- and time-dependent reduction in seasonal hay fever symptoms, with a 30% average reduction for the 20 µg group, accompanied by dose-dependent increases in specific IgG IgE-blocking antibodies.[18] In another randomized placebo-con-

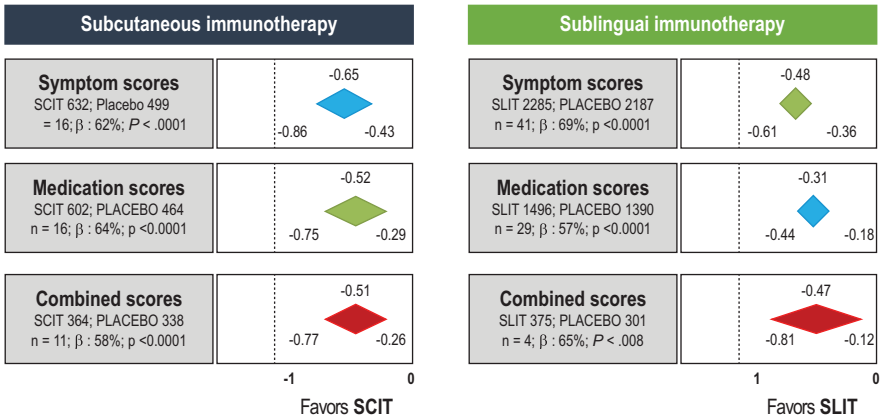

FIG. 88.2 Meta-analysis of subcutaneous immunotherapy v placebo and sublingual immunotherapy v placebo for allergic rhinoconjunctivitis. A comparison of mean differences and confidence intervals of active v placebo treatments for symptom scores, rescue medication scores, and combined scores. (Data derived from Dhami et al.[17])

trolled trial of sublingual immunotherapy in 992 HDM-allergic rhinitics, participants were randomized to receive a sublingual tablet containing approximately 15 mcg of Der p1 and Der p 2 major allergen daily (or half these doses).[19] There was a 20% reduction in total combined symptom-rescue medication scores at the end of 12 months of treatment. It is noteworthy that the World Allergy Organization criteria for a clinically meaningful reduction in the combined score is 20%. For both studies, clinical improvement was measured over and above usual treatment with anti-allergic drugs available to all participants in both active and placebo-treated arms.

Based on a systematic review of evidence using "Agree" criteria, the recent EAACI Guideline on allergen immunotherapy for allergic rhinoconjunctivitis[14] recommended that an *individual product-based* evaluation of evidence for short-term efficacy (i.e., for the duration whilst on treatment) is indicated before treatment with a specific product is initiated—with continuous subcutaneous treatment for seasonal rhinitis (Grade A evidence), pre and pre/co-seasonal SCIT, for both modified (allergoids) and non-modified allergen extracts and for SLIT aqueous solutions for grass/tree pollen. Recent evidence has also confirmed efficacy during treatment with sublingual tablets for seasonal rhinitis (grass, tree, ragweed pollens) and perennial rhinoconjunctivitis (HDM) in adults and children.

Allergic Bronchial Asthma. Allergen immunotherapy for bronchial asthma was evaluated in a recent EAACI systematic review.[20] Of 5997 records screened, 98 were suitable for qualitative review and 15 for quantitative meta-analysis with a standardized mean difference compared to placebo of −1.11 (confidence intervals −1.66, −0.56) for symptom scores and −1.21 (−1.87, −0.54) for medication scores but both with substantial evidence of publication bias. The conclusion was that immunotherapy can achieve substantial reductions in short-term symptoms and medication use for allergic asthma, although at the expense of a modest increase in the risk of systemic and local allergic reactions. From limited data on cost-effectiveness, sublingual immunotherapy was considered cost-effective for asthma, although long-term studies are required.

The EAACI guideline based on this meta-analysis included Grading of Recommendations Assessment, Development, and Evaluation approach (GRADE) criteria.[15] The expert group focused on immunotherapy for HDM allergic asthma and concluded there was insufficient evidence to make recommendations for other allergens. The committee concluded that the important prerequisites were (1) optimal selection of patients based on a history of HDM-driven asthma (with HDM provocation testing if in doubt) as confirmation of IgE-sensitization (2) use of individual allergen extracts and desensitization procedures of proven value. Only HDM tablet immunotherapy was found to have a robust effect for relevant asthma critical endpoints (exacerbations, asthma control, and safety) and was recommended for partially controlled HDM-driven asthma (conditional recommendation, moderate quality evidence).[15]

Evidence for the EAACI recommendation was from a randomized controlled trial of 12 months duration of two doses of HDM tablet immunotherapy in 834 participants with partially controlled asthma. The participants' inhaled corticosteroid treatment was withdrawn 50% after 6 months and completely at 9 months. The primary outcome was time to first moderate-severe asthma exacerbation up to 12 months. There was observed a 31% reduction for the six subcutaneous HDM tablets and a 34% reduction for the 12 subcutaneous tablets compared to placebo treatment. Side-effects were mainly local irritation and swelling in the mouth, and an overall 6% withdrawal rate due to side effects was noted.[21] HDM tablet immunotherapy now appears in the most recent GINA asthma guideline as an alternative add-on treatment at steps 3 and 4 in HDM-driven asthma. HDM SCIT was recommended in adults and children for reduction of asthma symptoms and medication needs (conditional recommendation low-quality evidence).[22]

Long-Term Benefits of Allergen Immunotherapy

Persistence of Benefit

A major advantage of allergen immunotherapy is its potential disease-modifying effects with persistence of benefit for years after its discontinuation.[23] In contrast, whereas pharmacotherapy for allergic rhinitis and asthma is effective in improving symptoms and quality of life, there are no long-term benefits. This is true not only for antihistamines and beta-sympathomimetic drugs but also for inhaled/oral corticosteroids, anti-IgE monoclonal antibodies, and modern anti-Th2 biologic therapies

In a study of 47 patients with moderate-severe grass pollen allergy, 32 had completed 3 to 4 years of high-dose alum-based subcutaneous immunotherapy and were randomized to either continue for a total of 6 to 7 years on active injections or withdrawn at 3 years of matched placebo injections of identical appearance. Fifteen matched, but non-randomized hay fever sufferers were followed during the withdrawal phase for a total of 3 years. The group that withdrew at 3 years had comparable efficacy (>30% mean difference from placebo) as those for 3 to 4 years on immunotherapy and comparable to the continued efficacy during 3 years of those that continued immunotherapy for a total of 6 to 7 years. Continued clinical improvement was accompanied by a maintained reduction in immediate cutaneous and conjunctival allergen sensitivity, marked and persistent suppression of intradermal allergen-induced late-phase skin response throughout the 7 years. There was also a reduction in allergen-stimulated CD4 T cells and IL-4 mRNA$^+$ cells as determined by immunohistochemistry and *in situ* hybridization of microscopic sections of biopsies taken from the sites of suppressed cutaneous late-phase responses at 7 years for both those maintained and withdrawn from treatment.[24]

Two independent large randomized, double-blind placebo-controlled trials of sublingual tablet immunotherapy in adults with moderate-severe grass pollen seasonal rhinitis involved either continuous treatment or a pre/co-seasonal regimen over 3 years, with blinded follow up for 2 years off treatment. Both regimens were highly effective (>30% mean difference compared to placebo) in reducing seasonal symptoms and medication scores throughout the 3 years of treatment. There was also persistence of benefit (approximately 30% reduction in symptom and medication scores) during successive pollen seasons during the 2 years' follow up off treatment.[23]

In one large randomized controlled trial of HDM sublingual tablets in adults with perennial allergic rhinoconjunctivitis, 1 year's treatment was effective in reducing symptoms and rescue medication, and the effects persisted during a second year of treatment. This raises the question of whether continuous natural exposure to a perennial allergen following a shorter course of immunotherapy may be more effective in maintaining tolerance. This requires confirmation in a prospective trial with tolerance as the primary outcome.[23]

EAACI guidelines recommend continuous grass pollen SCIT and grass pollen SLIT tablets and SLIT aqueous solution for both short-term (on treatment) and long-term (off-treatment) benefits in adults and children and for HDM tablets (but not the solution). The guidelines advise a minimum of 3 years of treatment for long-term efficacy and that the selection of individual allergen products for treatment should be evidence-based.[14,15]

Prevention of Asthma

The Prevention of Asthma Trial (PAT) was a randomized controlled trial of a subcutaneous alum-based grass pollen vaccine in children aged 5 to 12 years who had seasonal rhinitis but no asthma. The primary endpoint was time to onset of an asthma diagnosis up to 5 years, 2 years following 3 years of immunotherapy. The treatment was successful in significantly reducing asthma prevalence (odds ratio 2.68, confidence interval [1.3 to 5.7]). Limitations were that the diagnosis of asthma was based on subjective criteria, and although randomized, the trial was non-blinded for ethical reservations concerning the need for 3 years of placebo injections in children.[23]

Recent EAACI guidelines,[14,15] based on such evidence, advise the use of allergen immunotherapy for birch/grass pollen rhinoconjunctivitis in children (both sublingual and subcutaneous routes) for (1) a sustained effect on symptoms and rescue medication after cessation of treatment and for (2) prevention of the onset of asthma onset for up to 2 years post-treatment and possibly longer, but more evidence is required.

Subcutaneous versus Sublingual Immunotherapy

Indirect comparison of symptom and medication scores for subcutaneous compared with sublingual immunotherapy from the recent meta-analysis (see Fig. 88.2) might suggest a trend in favor of the subcutaneous route.[17] However, the studies for subcutaneous immunotherapy are fewer in number and include older studies that may not have been performed with the same rigor as more recent studies of sublingual immunotherapy. Furthermore, there is considerable overlap in confidence intervals.

There are few head-to-head comparisons of the two modalities.[25] In one double-blind study of birch pollen immunotherapy, reductions in seasonal symptoms and rescue medication were numerically similar, although the study was underpowered to show a significant difference if one existed. In a recent double-blind placebo-controlled comparison in patients with moderate-severe seasonal grass pollen rhinoconjunctivitis, nasal allergen provocation was used as a surrogate clinical primary endpoint.[26] Both treatments were effective compared to placebo. The onset of efficacy for subcutaneous immunotherapy (after 1 year's treatment) was earlier than for the sublingual tablet route in reducing total nasal symptom scores from 0 to 10 hours after nasal challenge. Both treatments were effective at reducing allergic rhinitis symptoms at year 2, both following nasal allergen challenge and for symptoms and quality of life during the pollen season. However, 2 years of treatment was not effective in reducing allergic rhinitis symptoms at year 3, 1 year after treatment completion. This study confirms the need for 3 years of continuous grass pollen immunotherapy treatment to achieve long-term efficacy. Phase 3 head-to-head comparisons with seasonal combined symptom-medication scores as primary endpoint would be informative.

The indications for the subcutaneous and sublingual routes are essentially the same and require a prescription by specialists familiar with the diagnosis and treatment of allergic rhinitis and asthma, knowledge of the indications for immunotherapy, and the ability to recognize and treat early signs of anaphylaxis.[25] The decision depends on the availability of local resources and patient choice (Table 88.2). Both sublingual and subcutaneous allergen immunotherapies are effective in seasonal rhinitis and, with allergen extracts of proven value, are associated with long-term remission. For perennial rhinitis, there is higher quality evidence in favor of sublingual immunotherapy. Adherence to allergen immunotherapy is crucial for efficacy and requires close monitoring. The sublingual route may be more acceptable for children, as it avoids frequent injections. In the USA, subcutaneous immunotherapy is more prevalent, whereas, in Europe, practice is more heterogeneous but swinging in favor of the sublingual route. Overall, the patient is in equipoise—any advantage of subcutaneous treatment in terms of efficacy must be weighed against the convenience and safety of the sublingual route (Fig. 88.3).[25]

Safety

Subcutaneous allergen immunotherapy is an effective and safe treatment when performed in a specialist setting, according

TABLE 88.2 Comparison of Subcutaneous and Sublingual Immunotherapy

Subcutaneous	Sublingual
• Effective in seasonal rhinitis	• Effective in seasonal rhinitis
• Induces long-term remission	• Induces long-term remission
• Effective in perennial rhinitis	• Effective in perennial rhinitis
• Evidence base less in children	• More acceptable for children
• Local side effects (pain, swelling at injection site, not troublesome)	• Local side effects (itch, swelling in mouth, may be bothersome)
• Risk of anaphylaxis	• Severe systemic reactions very rare
• Administration in a specialist clinic	• Suitable for self-administration
• Adherence easily monitored	• Adherence may be a problem
• Direct comparisons with SLIT needed	• Direct comparisons with SCIT needed

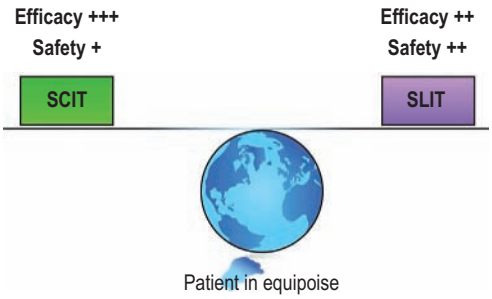

FIG. 88.3 Choice of subcutaneous v sublingual immunotherapy: a balance of efficacy, safety, and patient choice. (Reproduced with kind permission of *J Allergy Clin Immunol*.[25])

to international guidelines and with access to adrenaline and other resuscitative measures. Nonetheless, a major barrier to the wider adoption of subcutaneous immunotherapy has been the risk of systemic allergic side effects. In the UK, a Committee on Safety of medicine's report in 1986 identified 26 deaths due to "desensitization" in the preceding 30 years.

The majority of deaths occurred in a general practice setting. In the 19 deaths for whom the indication was known, 17 of these prescriptions were for bronchial asthma, the time of onset for most reactions being within 30 minutes, although for 2, it was up to 90 minutes. The committee highlighted the need for special caution in asthma that should be well-controlled and for an observation period of 2 hours following injections (subsequently reduced to 60 minutes). In a multi-center trial of alum-based grass pollen immunotherapy in the UK, 9 of 203 participants (4.3%) randomized to receive the top dose (20 µg major allergen Phleum p5) developed grade 3 systemic reactions with recovery, and none received adrenaline.[18] A 12-years survey from the USA reported fatal reactions in 1 per 2.5 million injections and an average of 3.4 deaths per year.[27] Of 17 fatal reactions, 15 occurred in patients whose asthma was not optimally controlled. Risk factors for systemic allergic reactions include dosing errors, delayed/absent use of adrenaline, a history of previous systemic reactions, use of grass pollen or cat allergen extracts, co-seasonal administration of extracts, and patient-related co-factors such as uncontrolled asthma, use of beta-blockers, upper respiratory infections, exercise, and fatigue.

Sublingual immunotherapy is safer than subcutaneous immunotherapy and suitable for home administration.[28] In a meta-analysis of 66 studies of sublingual immunotherapy that included 4000 participants and more than one million doses, one systemic reaction was observed every four treatment years and only one severe reaction for every 384 treatments.[29] There have been isolated case reports of systemic allergic reactions following sublingual immunotherapy, but no fatalities, and these tended to occur when treatment was not practiced according to published guidelines (use of unstandardized extracts, excessive allergen doses, and patients who had experienced a severe reaction during previous subcutaneous immunotherapy). Patients should be observed for at least 30 minutes after the first dose by staff able to recognize and treat anaphylaxis. Although rare, most systemic reactions to SLIT occur at home, so it is important to educate patients on how to recognize and treat reactions and when to seek medical help. Co-prescription of auto-injectable adrenaline devices is recommended in the USA, whereas this is not a routine recommendation in Europe unless there are risk factors, including a history of previous systemic reactions to immunotherapy. Local side effects such as itching and swelling in the mouth and throat irritation frequently occur in 40 to 75% of cases, although in general are mild, short-lived, last for minutes after administration, and resolve within 2 to 3 weeks. Local side effects may occasionally be more troublesome and/or persist for longer and, in clinical trials, result in discontinuation of sublingual immunotherapy in up to 4% to 8% of patients treated with sublingual tablets.

Both sublingual and subcutaneous allergen immunotherapies are effective in seasonal rhinitis and associated with long-term disease remission. For perennial rhinitis, both routes are effective with higher quality evidence in favor of sublingual immunotherapy.

Hymenoptera Venom Immunotherapy

Hymenoptera species include venomous wasps, hornets, and bees.[30] More than half the population report being stung, with adverse reactions ranging from large local reactions (>10 cms) to systemic reactions, including anaphylaxis and occasional fatalities. The rate of systemic reactions in Europe has been estimated between 0.3% and 7.5% in adults and 0.15% and 3.4% in children. Risk factors for anaphylaxis include a bee rather than a wasp sting, older age, underlying medical conditions, raised baseline serum tryptase, mastocytosis, and the history of severity and rapidity of onset of any previous systemic reaction following a sting. Diagnosis depends on the clinical history of a sting and confirmation of specific IgE sensitivity, in cases of doubt, including measurement of IgE to major allergens for bee (Api m 1) and for wasp (Vesp v 1 and 5). Large local reactions require either no treatment, the elevation of an affected limb and ice, or, if severe, oral corticosteroids for 1 to 3 days. Often, antibiotics or antihistamines are prescribed for large, local reac-

tions but are ineffective, unnecessary, and potentially harmful. Although local reactions occasionally precede subsequent systemic reactions (up to 15%), local reactions are not considered an indication for immunotherapy.[31]

Moderate-severe systemic reactors should adhere to avoidance advice and be supplied with two auto-injectable adrenaline pens and their technique of use described and rechecked at intervals, along with the expiry date of the device. Moderate-severe reactors (whose reactions exceed generalized skin reactions) should be offered subcutaneous immunotherapy, with a lowered threshold for those with a severely impaired quality of life due to fear of a subsequent sting. The threshold for immunotherapy is higher in children in view of generally milder reactions and lower risk compared with adults.

Venom immunotherapy confers complete protection from severe systemic reactions in 77 to 84% of cases for honeybee and 91% to 95% for wasp venom. Immunotherapy protocols are similar to those for inhalant allergens, with weekly updosing injections for 12 to 16 weeks followed by monthly injections for 1 year, extending to 6 to 8 weeks between maintenance injections in subsequent years—generally 3 years for wasp venom and 3 to 5 years for bee venom, depending on the risk of subsequent stings and access to medical care. Risk factors for systemic reactions (approximately 8% to 20%) during venom immunotherapy include bee venom, rapid updosing, and probably raised basal serum tryptase levels. Venom immunotherapy confers long-term tolerance although there are no long-term randomized controlled trials, so it is difficult to unravel tolerance due to long-term effects from natural tolerance due to declining IgE levels in the absence of subsequent stings.[30, 31]

Allergen Immunotherapy for Foods

Diagnosis of food allergy depends on the history combined with objective confirmation of IgE-sensitization to relevant foods by skin testing and/or serum-specific IgE. Specific IgE tests to recombinant allergens are often useful to distinguish true allergy to major protein antigens associated with severe reactions and distinguish them from cross-reacting allergens that may be either irrelevant or associated with pollen food syndromes. Oral provocation tests may be indicated when the diagnosis remains in doubt and/or to exclude food allergy to specific foods and enable their re-introduction into the diet. Standard treatment for food allergy involves accurate identification of offending foods and appropriate avoidance advice. Patients with food-induced anaphylaxis should additionally be supplied with two auto-injectable adrenaline pens with clear and repeated instructions on their use and replacement on expiry. In high-risk children with peanut allergy, anti-IgE therapy with omalizumab has been shown to be effective in raising the threshold in order to afford protection against accidental exposure, although this is expensive and would need to be continued long-term. Allergy to milk and egg in infants and children is usually self-limiting with age. Persistent allergy to egg and milk in adults is often serious and life-threatening, and attempts at oral immunotherapy are associated with a high risk of severe adverse events such that immunotherapy for egg and milk allergy is not recommended for use outside randomized controlled trials and confined to specialist centers.

A major area of research has been specific immunotherapy for peanuts. Peanut allergy is common in westernized countries where it has been estimated to affect 1.4% to 3% of the population and represents a common cause of food-induced anaphylaxis. It is a major risk factor for fatal reactions in asthmatics and is associated with expense and substantial psychosocial burden for affected individuals and their families. Most studies have focused on oral peanut immunotherapy in children, whereas sublingual and epicutaneous routes have also been tested.

PALISADE[32] was a phase 3 trial of oral peanut immunotherapy in 551 participants aged 4 to 55 years (mainly under 17) with a severe peanut allergy. Participants were selected by failing a double-blind oral food challenge at 100 mg peanut protein. They were randomized 3:1 to active or placebo treatment over a period of 24 weeks. The primary endpoint was the proportion who could ingest 600 mg peanut protein at the end of treatment. The results showed that in children and adolescents who received encapsulated peanut (AR101), approximately 2/3 achieved the primary endpoint compared with 1/25 of placebo-treated participants. Local and gastrointestinal side-effects were two-fold higher in AR1010-treated participants. Systemic allergic reactions occurred in 53/372 (14.2%), including one case of severe anaphylaxis compared to 4/124 (3.2%) in placebo-treated participants.

A recent meta-analysis (PACE) of nine randomized controlled trials of oral peanut immunotherapy[33] in over 1000 individuals showed that whereas the treatment was effective in achieving desensitization (risk ratio for passing a supervised oral peanut challenge of 12.42/1), the treatment was accompanied by a 3.12/1 risk ratio for anaphylaxis and 2.21/1 for receiving epinephrine compared to placebo. In an accompanying editorial, the question was raised whether trading treatment-related side-effects at home during treatment for allergic reactions to accidental exposures out of the house (i.e., in social situations) might be beneficial for some patients.

In contrast to inhalant allergen immunotherapy, oral immunotherapy for peanuts has not been associated with durable tolerance after discontinuation. The POISED study[34] evaluated the sustained effects of 2 years of oral peanut immunotherapy over 1 year after discontinuation. 120 participants aged 7 to 55 years with a severe peanut allergy were enrolled. A maintenance dose of 4-g peanut was achieved by 1 year in most participants. Whereas effective desensitization to 4-g peanut challenge was achieved, discontinuation, or even a reduction to 300 mg daily peanut, markedly increased the likelihood of return of clinical reactivity to peanut within months of discontinuation.

A phase 3 trial of epicutaneous immunotherapy was performed in 356 enrolled participants, median age 7 years, with peanut allergy but no history of anaphylaxis.[35] The treatment involved daily application to the skin of a peanut patch containing 250 mcg of peanut protein over 12 months. 35.3% on active treatment compared to 13.6% placebo-treated patients achieved the pre-determined peanut-eliciting dose (300 mg for most participants), although the trial did not achieve a component of the primary endpoint. Subsequent analyses and follow-up indicated persistent protection while the participants remained on treatment. In general, the treatment was well-tolerated, although local application site reactions were common for both active and placebo-treated groups (approximately 90%) and discontinuation rates were comparable (approximately 10%).

Taken together, these data suggest that oral peanut immunotherapy is effective but labor-intensive and associated with

frequent systemic allergic reactions, including increased rates of anaphylaxis and adrenaline usage during the treatment. With currently available strategies, long-term disease remission after discontinuation has not been achieved. A comparison between the oral and epicutaneous routes in terms of benefits and side-effects would be of interest. Data suggest that the earlier introduction and targeting of younger and less IgE-sensitized individuals is likely to be more effective. At present, however, immunotherapy for food allergy in general, and peanut allergy for which most data are available, should be confined to research and specialist centers and is not recommended for routine clinical use.

Mechanisms of Allergen Immunotherapy

A greater understanding of the underlying mechanisms of immunotherapy is important for developing biomarkers to assess disease severity, predict responders, and monitor response to treatment. Insights into mechanisms have provided a rationale for novel approaches to immunotherapy, including alternative routes, modified allergens, and "allergen+" strategies to improve efficacy, convenience for patients, and enable shorter, safer protocols.

Mechanisms of Allergic Rhinitis

Nasal allergen provocation has been used as a model to study mechanisms of allergic rhinitis and the influence of immunotherapy. The early nasal response at 0 to 60 minutes after challenge involves immediate sneezing followed by watery nasal discharge and eye symptoms. The early response occurs following allergen-crosslinking of IgE receptors on the surface of mast cells. A sequence of intracellular signaling events results in the immediate release of granule-associated mediators, including histamine and tryptase (the latter largely mast-cell-specific), and within minutes the release of newly formed mediators derived from membrane lipid including the sulfidopeptide leukotrienes C4 (LTC4), LTD4 and LTE4, platelet-activating factor, and, largely specific for mast cells, prostaglandin D2 (PGD2).

The late phase nasal response is associated with tissue eosinophilia and the recruitment and activation of basophils and Th2-type CD4-positive T cells. Innate lymphoid cells (ILCs) do not possess surface lineage markers and do not express T cell receptors, so they are therefore unable to recognize allergen. ILCs respond to epithelial cytokines such as thymic stromal lymphopoietin (TSLP) and IL-33. These cytokines also recruit and activate local dendritic cells ("DC2s") that promote preferential T-cell development in favor of a Th2 phenotype

An additional feature of allergic rhinitis is the activation of peripheral blood basophils and their recruitment and transepithelial migration during the pollen season. Whereas inhibition of nasal challenge is useful for proof of concept for immunotherapy and allergen dose-response studies, exposure challenges in an environmental allergen chamber are more like natural allergen exposure and have been shown to have similar underlying mechanisms.

Mechanisms of Allergen Immunotherapy

Allergen immunotherapy has been shown to inhibit the early nasal response with a corresponding inhibition of mast cell recruitment, activation, and decreases in histamine and leukotriene release as determined by measurements in collected nasal fluid. Immunotherapy inhibits the late nasal response and accompanying release of Th2 cytokines IL-4, 5, 9, and 13 and eosinophil chemotactic factors such as CCL11 (Eotaxin), CCL17, and CCL22. Local eosinophilia is reduced along with a decrease in local Th2-positive T cells. These inhibitory changes are mimicked during the pollen season. Immunotherapy additionally inhibited seasonal transepithelial migration of mast cells and basophils and CD1a-positive dendritic cells, decreased tissue eosinophilia, and inhibited local IgE-synthesis. These local reductions in Th2-dependent events are accompanied by increases in local regulatory T cells, including IL-10- and Transforming growth factor-beta (TGF-β)-producing peripheral Tregs. As well as downregulating Th2 T-cell responses, these cytokines are major switch factors in favor of IgG4 and IgA heavy chain switching, respectively, consistent with the observed local and systemic increases in allergen-specific IgG4 and IgA during immunotherapy. There are also local increases in FOXP3-expressing-CD25 high $CD3^+$ cells, presumed thymus-derived central T_{regs}. This induction of Tregs, detectable also in peripheral blood, occurs within 3 months, whereas successful immunotherapy is also accompanied by a more delayed-in-time increase in Th1 cells detectable in the skin, nose, and peripheral blood. The accompanying increase in interferon gamma$^+$ T cells suppresses IL-4 dependent IgE production and favors overall switching in favor of IgG isotypes, particularly IgG1 and IgG2, also observed during allergen immunotherapy (Fig. 88.4).[36]

Recent novel findings include inhibition of seasonal increases in peripheral blood ILC2s during the pollen season after immunotherapy and a change in ILC2 phenotype in favor of IL-10-producing ILC2s with typical regulatory properties. The induction of regulatory B cells as an alternative source of IL-10 following allergen immunotherapy is increasingly recognized.[36] Th2A cells represent a novel subset of Th2 T cells that increase during the pollen season and are characterized by low expression of the surface marker CD27. Th2A cells are inhibited following successful immunotherapy.

T follicular helper cells (Tfh) are located within the germinal centers of lymph nodes and are characterized by surface expression of CXCR5, intracellular transcription factor Bcl-6, and produce abundant IL-21. Through IL-21, Tfh cells are potent inducers, together with IL-4 of B-cell class switching to IgE. Immunotherapy has been shown to downregulate peripheral Tfh cells in favor of so-called T follicular regulatory (Tfr) cells that have a similar phenotype to Tfh cells, although additionally express FOXP3 and have inhibitory properties including inhibition of Tfh cells.[37] There is the emergence of a novel subset of IL-35-producing regulatory T cells. IL-35 has inhibitory properties like IL-10, induces regulatory B cells, and inhibits IL-4- and IL-21-stimulated human IgE synthesis *in vitro*. Peripheral IL-35 Treg numbers and IL-35 concentrations in allergen-stimulated *in vitro* T-cell culture supernatants are low in allergic rhinitis compared to normal healthy controls. Peripheral numbers of IL-35 Tregs and IL-35 production are increased during grass pollen immunotherapy and correlate with the accompanying suppression of nasal symptoms.[38]

Summary

A pattern is emerging where allergen immunotherapy for inhalant allergens is shown to potently inhibit Th2 T-cell and innate lymphoid cell activation and IgE-dependent mast cell

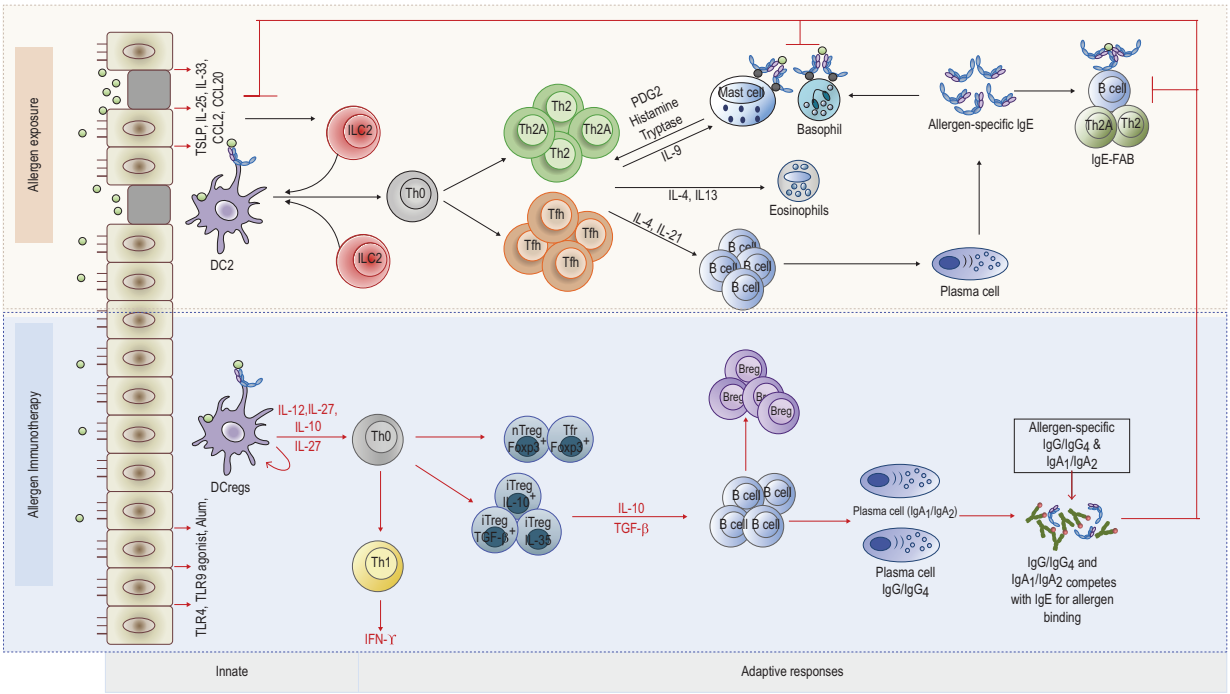

FIG. 88.4 Mechanisms of AIT. During the initial sensitization phase in patients with allergic rhinitis, low allergen exposure at the nasal mucosal surface results in activation of epithelial cells, which then activate DCs. DCs uptake and present antigens to naive T cells to induce allergic TH2 (Th2A) responses and IgE-facilitated antigen presentation. Subsequent allergen re-exposure leads to mast cell and basophil degranulation, causing classic early-phase reactions. Subsequent infiltration of other leukocytes leads to late-phase allergic inflammation. High-dose allergen exposure by immunotherapy restores DC function, which produces IL-12, IL-27, and IL-10 and promotes immune deviation from a TH2 to TH1 response and induction of Treg and Breg cells (including other B-cell subsets) that produce IgA, IgG, and IgG4 blocking antibodies. Suppressive activities of Treg cells, Breg cells, and IgG-blocking activity are indicated by red arrows. EC, Epithelial cells; TLR, Toll-like receptor. (Figure and legend reproduced with kind permission of *J Allergy Clin Immunol*.[36])

and basophil activation and tissue eosinophilia (see Fig. 88.4). This may occur because of an early induction of Treg responses, including peripheral IL-10-, TGF-beta, and IL-35-producing Tregs and a more delayed-in-time immune deviation in favor of allergen-specific Th1 responses at approximately 12 months. Different subsets of B regulatory cells are increasingly recognized as an alternative source of IL-10 following immunotherapy.[36] In addition to suppression of the Th2 response, "IgE-blocking" antibodies, particularly allergen-specific IgG4 and IgA, compete with IgE for the formation of allergen-IgE complexes. As a result, there is a decrease in both Fc€R1-dependent activation of mast cells and basophils and suppression of Fc€R2-dependent IgE-facilitated antigen-stimulated activation of Th2 T-cell development. Interestingly these "protective" IgE-inhibitory antibodies may also be detected locally in nasal fluid as well as in peripheral blood and correlate better with response to immunotherapy than simply measuring immunoreactive IgG4 and IgA levels.[39] A novel recent finding is that whereas for subcutaneous immunotherapy, the dominant blocking antibody is IgG4, for sublingual immunotherapy, the major IgE-inhibitory activity resides within IgA.[39] Thus, the two routes of immunotherapy (SCIT and SLIT) may act by distinct mechanisms, and in resistant cases, it may make sense to combine both routes—although this would first require confirmatory clinical trials.

THERAPEUTIC PRINCIPLES

- Allergen Immunotherapy is effective in seasonal and perennial allergic rhinoconjunctivitis
- Use of either SCIT or SLIT depends on the availability of resources and patient preference
- Three years of treatment with allergen extracts of proven value results in long-term efficacy
- HDM tablet immunotherapy for mite-induced asthma reduces asthma exacerbations
- Subcutaneous immunotherapy for Hymenoptera venom allergy is highly effective
- Oral peanut immunotherapy induces desensitization but not long-term tolerance
- Knowledge of mechanisms of immunotherapy should enable biomarkers to predict and/or monitor response and to develop more effective, safe, and more convenient strategies

Biomarkers of Response to Immunotherapy

At present, a history of symptoms on exposure to the relevant allergen and confirmation of IgE sensitization by skin test and/or measuring specific IgE are the two most reliable predictors of an individual's response to immunotherapy. If the history is doubtful, some centers recommend nasal or conjunctival provocation as a clinical surrogate to confirm end-organ response—although there is little information on threshold dose to confirm

clinical relevance and/or response to immunotherapy. Elevated IgG/IgG4 levels are indicative of exposure to the vaccine rather than a response to treatment, and there is evidence that functional IgE-blocking activity may more reliably predict response to treatment in clinical trials. These include inhibition by post-immunotherapy serum of allergen-IgE complex binding by CD23-expressing B cells as a surrogate of Th2 T-cell development. Second, inhibition *in vitro* of allergen-stimulated basophil histamine release. *Ex vivo* basophil activation may also be measured directly using whole blood allergen stimulation and CD63 measurement. Circulating allergen-responsive TH2A cells, ($CD27^{-}CCR4^{+}CRTH2^{+}CD45R0^{+}$ $CD4^{+}$ T cells) can be measured before/after immunotherapy. These assays require flow cytometry, which is not routinely available for clinic sampling' and real-time measurements. Recently, by use of whole blood RT-PCR, a pro-tolerogenic signature in peripheral dendritic cells that expressed high levels of C1Q and Stabilin 1 was recognized that correlated with immunotherapy response following sublingual grass pollen immunotherapy. A recent summary of potential biomarkers for immunotherapy was published by an EAACI task force report. Whether these assays may predict individual responses to immunotherapy as opposed to identifying significant associations at a group level in clinical trials remains to be determined.[40]

Novel Therapeutic Approaches

Subcutaneous allergen immunotherapy, although effective, is time-consuming and requires specialist supervision. There is a need for shorter, safer, more convenient immunotherapy products and protocols.[41] Sublingual treatment is safer and can be self-administered. Both routes require 4 to 6 months for efficacy in pre-co-seasonal regimens and a minimum of 3 years for long-term tolerance. One approach has been the chemical modification of allergens to reduce allergenicity—such allergoids may be effective but have no proven value over conventional extracts. Allergen extracts have been formulated with alum or tyrosine in order to delay absorption and have adjuvant properties. Alternative routes include epicutaneous "patch" application of allergen and intralymphatic injections directly into lymph nodes under ultrasound guidance.[41]

Peptide immunotherapy involves the use of shortened peptides derived from either crude standardized extracts or synthetic peptides. Peptide immunotherapy attempts to reduce allergenicity while preserving or increasing immunogenicity. Examples include Cat Fel d 1 peptides of 12 to 20 amino acid length that appeared effective and safe at phase 2 but have not been successful so far in phase 3 studies Similarly, medium-length peptides—either recombinant peptides or prepared by controlled hydrolysis of whole allergen extracts showed early promise but have not so far been successful at phase 3. The use of recombinant allergens, both for specific diagnosis and as products for immunotherapy, is an attractive approach as it involves a high degree of standardization and the potential to tailor products according to individual allergen sensitivities. One approach has involved a recombinant mixture of major grass allergens covalently linked to a highly immunogenic pre-S protein derived from the hepatitis C virus. The recombinant product selectively increases IgG antibody responses while reducing IgE and is currently in phase 3 trials.

In line with the experiments of Robert Cooke almost 100 years ago involving the passive transfer of immunity to ragweed by use of post-immunotherapy serum injected intradermally, an alternative approach is a passive immunotherapy by administration of recombinant antibodies of high affinity directed against major allergens. This is likely to be more effective where there is one dominant major allergen, as is the case for cat allergy (Fel d 1). In a recent study, a single injection of a combination of two high-affinity recombinant IgG4 antibodies directed against Fel d 1 (single dose 600 mg) was highly effective at suppressing the immediate response to nasal allergen challenge with whole-cat extract. In contrast to active immunization, the limitation of passive immunotherapy is that there is no possibility of durable long-term tolerance.

Another approach is the combination of allergen products with biologics that favorably modify the immune response to the allergen to enhance safety and/or favor induction of preferential tolerogenic responses. Anti-IgE (Xolair) combined with ragweed subcutaneous immunotherapy reduced systemic allergic reactions during a rush-updosing protocol by greater than 80%. Other examples include the combination of subcutaneous immunotherapy with Toll-like receptor agonists (TLR4 and TLR9 TLR2 and TLR7[42] agonists). The combination of allergen immunotherapy with monoclonal antibodies directed against Th2 cytokine pathways (for example, dupilumab targeting IL-4 receptor-alpha) or alternatively with antibodies directed against epithelial cytokines (tezepelumab, targeting TSLP). Such "allergen+" strategies may have the potential to improve efficacy and safety, and possibly enable a shorter, more efficacious course of immunotherapy and augment induction of long-term tolerance.

ON THE HORIZON

- Allergoids (chemical modified allergens)
- Allergens +Immunostimulants (TLR-4, TLR-7, TLR-9 agonists)
- Allergens +monoclonal antibodies (anti-IgE, anti-IL-4, anti-TSLP)
- Recombinant allergens (birch pollen, grass pollen, cat dander)
- Alternative routes (sublingual, intra-lymphatic, epicutaneous)
- Synthetic T-cell peptides (cat dander, house dust mites)
- Recombinant B-cell peptides (grass pollen)
- Medium-length hydrolyzed peptides (grass pollen)
- Passive immunotherapy (anti-Fel d 1 monoclonal antibodies)

Solid Organ Transplantation: Rejection, Immunosuppression, and Tolerance

Elinor C. Mannon, Kathryn J. Wood, and Roslyn B. Mannon

The clinical era of transplantation began on December 23, 1954, when Dr. Joseph Murray and colleagues performed the first successful renal transplant on the genetically identical Herrick twins. Solid organ transplantation (SOT) has since transformed the management of end-stage organ failure, as a lifesaving technique but also improving the quality of life. The development of powerful immunosuppressive regimens and cutting-edge biologic agents represents an elegant proof of concept, translating seminal work from the laboratory bench to the patient's bedside. However, there are many challenges to overcome. In addition to the major insufficiency in organ supply for the many patients waiting for transplantation, there are immunologic challenges including cellular and antibody-mediated rejection that require all recipients to be maintained on a regimen of immunosuppressive therapy for the life span of the organ. Such global immunosuppression is associated with toxicities including infection, malignancy, and cardiovascular risks that may result in fatal events. Judging the adequacy of immunosuppression is a balance, and the tools to measure sufficiency and our understanding of that process are elusive and complicated by donor–host genetics. In this chapter, we review mechanisms of host immune response to an organ transplant, discuss current and new agents for immunosuppression, insights into immunemodulation in terms of transplant tolerance, and the potential for pig organs to mitigate the demand on human donors, and emphasize the contributions of clinical trials and recent studies.

THE IMMUNE RESPONSE IN ORGAN TRANSPLANTATION

The immune system must have the ability to distinguish "self" from "non-self" or "altered-self" to avoid damaging the host. Any immune response that is generated must also be proportional to the threat; thus, antigens encountered in the context of inflammation will prime T cells and evoke a more aggressive immune response. While essential to survival, this is a major barrier to successful transplantation. Specific signals of "danger" may evoke an immune response, are nonspecific, and are managed by the innate immune response (Fig. 89.1). In contrast, allorecognition (that is, the recognition of a specific protein or antigen on a donor tissue that is different from the host or recipient) is specific and results in rejection. In animal models, transplantation between genetically identical individuals (isograft, syngeneic graft) does not result in rejection, while transplantation between disparate donors and hosts of the same species (allograft) results in an aggressive immune response. The transplantation of organs across species (xenograft) is receiving more focus, as barriers such as zoonosis and gene editing may facilitate early acceptance; this is discussed later.

Innate Immunity and Ischemia Reperfusion Injury

Deceased donor brain death leads to systemic inflammation, leading to hemodynamic responses and subsequent organ injury, whereas donation after cardiac death is associated with warm ischemic injury. At organ retrieval, organs are perfused in an attempt to mitigate the reactive oxygen species and aberrant metabolism associated with brain death.[1] Perfusion solutions have been developed to reduce biochemical injury, and coupled with cold storage, are used to reduce the injury associated with reperfusion following implantation. More recently, ex vivo approaches for organ preservation have emphasized metabolic reprogramming to improve organ function prior to implantation of multiple organs.[2] Moreover, normothermic (i.e., physiologic body temperature) oxygenated perfusion is under study to better "resuscitate" organs through a more physiologic environment. These approaches are crucial to optimizing the limited donor organ pool available.

Innate immunity plays a key role in ischemic injury, resulting in release of damage-associated molecular patterns (DAMPs) like heat shock proteins (HSPs), nucleic acids, and high-mobility group box-1 (HMGB1) protein. These molecules are recognized by invariant pattern-recognition receptors (PRRs) of the innate immune system; for example, Toll-like receptors (TLRs) (see Chapter 3). Release of inflammatory mediators, such as interleukin-1 (IL-1) and IL-6 chemokines, results in adhesion molecule upregulation that expands the immune response. This further triggers activation of macrophages and dendritic cells (DCs), resulting in greater antigen-presenting capacity and entry to a cytocidal state. Endogenous signals can also activate the complement cascade, which promotes DC maturation and subsequently their ability to activate T cells. Thus, the innate immune system, activated by local tissue injury, promotes the initiation of adaptive immune responses when there are antigenic differences between the donor and the recipient. Activation of the adaptive immune system results in a series of effector mechanisms, both cell- and antibody-mediated, which lead to further graft injury (see Fig. 89.1).

Clinical Implications

Implantation of an allograft with severe damage may result in primary non-function. In the kidney, lack of function necessitating dialysis treatments in the recipient is known as delayed allograft function (DGF),[3] occurring in about 30% of all transplanted kidneys. Such poorly functioning allografts may eventually recover

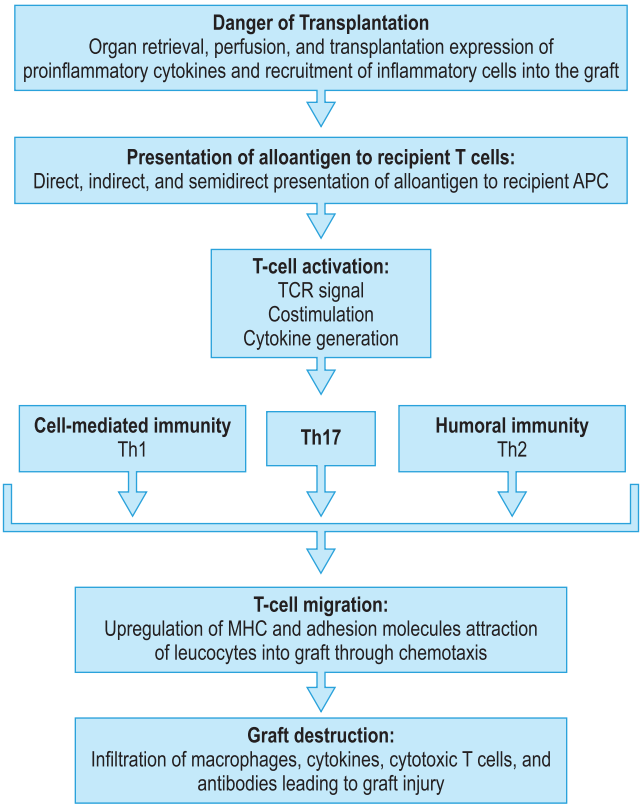

FIG. 89.1 Mechanisms Leading to Graft Injury. After the trauma of surgery ("danger of transplantation"), there is an interplay of innate and adaptive immune responses resulting in eventual graft destruction.

but are associated with inferior transplant outcomes, including more frequent rejection episodes and worse baseline function. While preclinical models of ischemia reperfusion have suggested potential clinical targets for therapy, the results of recent clinical trials with novel agents have been disappointing. The difficulty in translating therapy may relate to the complexity of organ allocation as well as clinical trial design. Understanding ischemia-related dysfunction remains an unmet need in SOT.

Activation of the Adaptive Immune Response

Recognition by T cells of differences between donor and recipient major and/or minor histocompatibility antigens is central to the adaptive immune response. The extensive polymorphism of major histocompatibility complex (MHC) genes (see Chapter 5) makes complete matching of unrelated individuals rare, and, almost inevitably, transplantation of cells or organs between genetically unrelated individuals occurs across an MHC mismatch. Knowledge of MHC structure and molecules has contributed significantly to our understanding of how rejection is triggered and facilitated the development of immunosuppressive drugs. While these differences may be overcome initially by the potency of immunosuppressive therapy, mismatch in class II DR and DQ antigens is associated with graft failure.[4]

Signal 1: Recognition of Alloantigen

Class I MHC molecules are cell surface glycoproteins expressed on most nucleated cells and are recognized by CD8 T-cell receptors (TCRs). Class II MHC molecules are not expressed by every cell in the body; rather, they are found on DCs, B lymphocytes, macrophages, and, in humans, endothelial cells. MHC class II molecules are recognized by T cells bearing the CD4 TCR. Expression of both class I and II MHC molecules can be induced during inflammation of ischemia or rejection, particularly by interferon-gamma (IFN-γ). The inflammatory response triggered in the allograft by retrieval and implantation of the organ initiates not only the migration of donor-derived passenger leukocytes but also their maturation into functional APC expressing high levels of donor MHC molecules.

Antigen processing within antigen-presenting cells (APCs) results in the production of peptides that can bind in these grooves, producing MHC–peptide complexes that are recognized by T cells (see Chapter 6). These peptides may be of self-origin or derived from foreign molecules (e.g., from an allograft after transplantation or from a virus after an infection). In general, peptides derived from molecules within the cell are processed and loaded into MHC class I molecules, whereas extracellular molecules present outside the cell are processed into peptides that load into class II molecules. However, cross-presentation can also occur.

As discussed in Chapter 4, the TCR is composed of two chains that confer MHC–peptide specificity and is associated with a complex of polypeptides referred to collectively as CD3. When the TCR of host naïve or memory T cells engages its specific antigen, CD3 delivers intracellular signals to the T cell (Chapter 10). This is the first step in T-cell activation commonly referred to as "signal 1" and is believed to take place in secondary lymphoid organs rather than in the transplanted graft itself. In clinical transplantation, treatment with calcineurin inhibitors (CNIs) to block signal 1 and/or the use of T cell–depleting agents has been highly successful in the prevention and reversal of rejection episodes.

Antigen presentation may occur in one of three pathways (Fig. 89.2). Intact allogeneic MHC molecules presented by donor-derived passenger leukocytes to host T cells is known as the *direct pathway* of allorecognition and this is the dominant pathway through which the immune response to the graft is initiated. T cells responding via direct antigen presentation constitute a vast majority of the alloreactive immune repertoire, estimated at 10% of T cells.[5] Over time, when donor APCs within the graft are depleted, the *indirect pathway* of allorecognition dominates. Here, the recipient APCs largely consisting of DCs and B cells process and present peptides derived from allogeneic MHC molecules shed from the graft (both soluble MHC molecules and apoptotic cells), as well as minor histocompatibility antigens. Experimental models suggest that indirect presentation of donor antigens may play a greater role in rejection than direct presentation overall, as it is a continuous process as long as the graft remains in situ. Finally, a third pathway referred to as the *semidirect pathway* of antigen presentation exists in which donor MHC proteins are transferred intact to recipient APCs (through membrane transfer or the exosomal route), enabling them to present allogeneic MHC–peptide complexes to host T cells. This MHC transfer is temperature and energy dependent and requires close cell-to-cell contact. Both MHC class I and class II may be transferred, although class II MHC appears to be transferred more efficiently.

Signal 2: Costimulation

T-lymphocyte activation also requires signals delivered by the interaction of several costimulatory receptors and their ligands, known collectively as "signal 2" (Fig. 89.3). During T-cell activation, the TCR–CD3 complex and costimulatory molecules are brought together in the cell membrane to form the im-

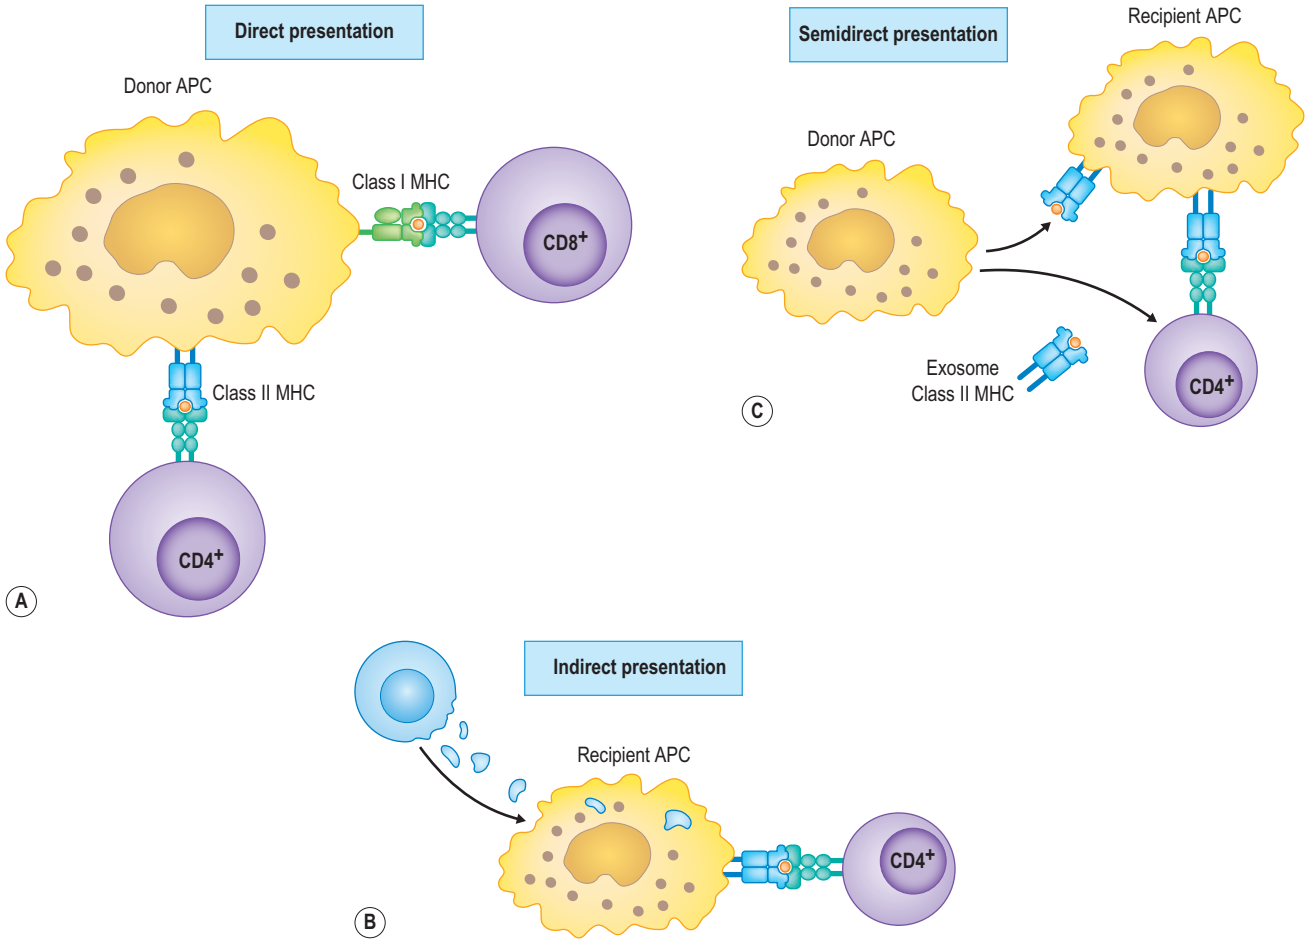

FIG. 89.2 Antigen Presentation. (A) Direct presentation: passenger donor antigen-presenting cell (*APC*) presents alloantigen to recipient T cells in lymphoid tissue. (B) Indirect presentation: alloantigen from donor cells is processed and presented by recipient APC via major histocompatibility complex (*MHC*) class II to recipient $CD4^+$ cell. (C) Semidirect presentation: donor MHC class I and class II may be transferred to the surface of recipient APCs, enabling presentation of alloantigen to recipient T cells.

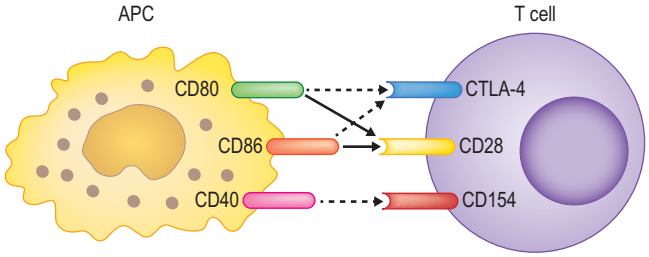

FIG. 89.3 Costimulatory Signal 2. Costimulation follows binding to major histocompatibility complex (MHC) class I and class II on antigen-presenting cells (*APCs*) and involves signal transduction via intracellular proteins and increased interaction affinity via the binding of several cell surface proteins. Several costimulatory molecule pairs have been identified, both activating and inhibitory.

munologic synapse. Signal 1 is specific for the antigen involved, whereas costimulation is not antigen-specific.

Costimulatory receptors fall into two major families; the B7 family (e.g., CD28 and CD152) and the tumor necrosis factor (TNF) family (e.g., CD154 and CD70) (see Chapter 10). Although several costimulatory molecule pairs have been identified,[6] the CD28 and CD154 pathways have been the most clearly defined in transplantation. CD80 and CD86 ligands on the surface of DCs and other cells can bind to CD28 on T cells, resulting in the activation of additional signal–transduction pathways within the T cell. This has a number of effects: lowering the threshold for T-cell activation; increasing glucose metabolism, as well as cytokine and chemokine expression, including IL-2 production; reducing T-cell death through apoptosis; and expanding the number of T cells that respond through proliferation. CD80 and CD86 are also linked to an inhibitory receptor, CD152 or cytotoxic T-lymphocyte antigen-4 (CTLA-4), which inhibits T-cell activation possibly by competing with CD28 to bind with CD80 or CD86. CTLA-4 has a 10-fold higher receptor affinity compared with CD28 and is rapidly upregulated following T-cell activation. Additionally, CTLA-4 activates tryptophan catabolism in DCs, resulting in the inhibition of proliferation and promoting apoptosis of the responding T cells. This pathway is the mechanism behind belatacept, CTLA4-Ig, a biologic used in transplantation to mitigate rejection (as discussed later in this chapter).

CD40, a member of the TNF receptor family, is expressed on all APCs and binds to CD154 (CD40L), which is present on activated CD4 cells, a subset of CD8 cells and Natural Killer (NK) cells. CD40 stimulation causes triggering signals for antibody production and induces MHC expression on APCs, thus amplifying antigen presentation. In preclinical models, treatment with

anti-CD154 promoted long-term survival of heart allografts in mice and of kidney allografts in non-human primates (NHPs).[7] The clinical efficacy of costimulatory blockade is discussed further in the Immunosuppression section.

Signal 3: T-Cell Proliferation and Differentiation

Following signals 1 and 2, a complex process known as "signal 3" begins. This signal includes the induction of three signal–transduction pathways: the calcium–calcineurin pathway, the Ras- and Rac-mitogen–activated protein kinase pathways, and the protein kinase C nuclear factor κB (NF-κB) pathway (see Chapter 10). These pathways interact with inositol triphosphate (IP3) and diacylglycerol (DAG), formed from the hydrolysis of phosphatidylinositol 4,5-bisphosphonate, to activate 3 transcription factors: nuclear factor of activated T cells (NFAT), activating protein-1 (AP-1), and NF-κB, respectively. These transcription factors cause the expression of many genes leading to upregulation of growth factors and cytokines; in particular, IL-2, a key T-cell growth factor, and CD25 (IL-2Rα). Growth signals are then delivered through the phosphoinositide-3-kinase (PI3K) and mammalian target of rapamycin (mTOR) pathways to promote cell cycle progression, and the clonal expansion and differentiation of activated T cells are initiated leading to their effector functions. These mechanisms are targeted by various immunosuppressive agents discussed in the immunosuppression section and seen in Table 89.1.

The pattern of cytokine production through the interaction of the combination of signaling processes determines the nature of the response, in which either cell-mediated or antibody-mediated immunity is seen to dominate (see Chapter 11). T-helper 1 (Th1) cells are T cells known to promote a cell-mediated response and are associated with the production of IFN-γ.

TABLE 89.1 Immunosuppressive Therapies in Transplantation: Maintenance Induction and Adjuvant Treatments

Drug	Mechanisms	Adverse Effects
Maintenance Agents		
Corticosteroids	Induces phospholipase A_2 inhibitory proteins, inhibits arachidonic acid synthesis, inhibits prostaglandins and leukotrienes	Diabetes, delayed wound healing, peptic ulcers, psychosis, osteoporosis, infection, blurred vision, fluid retention, weight gain, acne, constipation
Azathioprine	Inhibits purine and DNA synthesis, inhibits cell proliferation	Bone marrow depression, opportunistic infection, macrocytosis, liver toxicity
Mycophenolate mofetil	Inhibits inosine-monophosphate dehydrogenase, inhibits purine synthesis. and blocks cell proliferation	Gastrointestinal symptoms, bone marrow depression, opportunistic infection, in particular CMV and BK nephropathy
Cyclosporine	Binds to cyclophilin, inhibits calcineurin phosphatase, blocks NFAT dephosphorylation, blocks IL-2 transcription and T-cell activation	Hypertension, hyperlipidemia, nephrotoxicity, hepatotoxicity, pancreatitis, peptic ulcers, thrombotic microangiopathy, opportunistic infection, neurotoxicity, tremor, gingival hyperplasia, hirsutism
Tacrolimus	Binds to FKBP12, inhibits calcineurin phosphatase and blocks T-cell activation	Posttransplantation diabetes mellitus, nephrotoxicity, thrombotic microangiopathy, neurotoxicity
Rapamycin Everolimus	Binds to FKBP12, inhibits mTOR, and blocks IL-2–driven cell proliferation	Delayed graft function, delayed wound healing, mouth ulcers, pneumonitis, increased proteinuria, peripheral edema, hyperlipidemia
Belatacept	Binds CD80/86 with higher affinity than CD28 blocking signal 2 in T cells	Headache, anemia PTLD, opportunistic infection
Induction Agents		
Antithymocyte globulin	Polyclonal effects not well characterized; immunosuppressive efficacy attributed to T-cell depletion through apoptosis, antibody-dependent cytolysis, and complement-dependent lysis	Polyclonal effects: cytokine release syndrome, serum sickness, leukopenia, thrombocytopenia. De novo tumors and opportunistic infection: CMV and HSV.
Alemtuzumab	Binds to CD52 antigen, (expressed on 95% of peripheral blood lymphocytes, NK cells, macrophages, and thymocytes) Results in profound lymphopenia	Opportunistic infections: *Candida*, CMV
Basiliximab	Binds to IL-2R with similar affinity as IL-2, thereby inhibiting IL-2–driven T-cell proliferation Abrogates Signal 3	Occasional hypersensitivity reactions, inadequate immunosuppression in immunologically high-risk recipients
Adjunctive Treatments		
Intravenous Immune Globulin	Inhibition of antibody production, inhibition of B-cell differentiation, inhibition of production of interleukin-6 and tumor necrosis factor-α, induction of B-cell apoptosis, inhibits complement activation, saturates FcRn to accelerate the breakdown of endogenous alloantibody IgG, anti-idiotypic antibody blocking alloantibody function	Hemolysis, headache, acute renal failure with sucrose-containing preparations, thromboembolic events
Rituximab	Binds CD20 with cellular destruction by ADCC	Infusion side effects (headache, nausea), hypogammaglobulinemia
Eculizumab	Binds to the terminal complement component 5 limiting the production of C5b and membrane-activating complexes	Meningococcal infections, *Neisseria* infections
Proteasome inhibitors	Bind the 26 S proteasome inhibiting proper ubiquitination and protein degradation leading to cell dysfunction and apoptosis	Neuropathy, diarrhea, headache, cytopenia

ADCC, antibody-dependent cytotoxicity; *CMV,* cytomegalovirus; *DHFR,* dihydrofolate reductase; *HSV,* herpes simplex virus; *IL-2,* interleukin-2; *IL-2R,* interleukin-2 receptor; *mTOR,* mammalian target of rapamycin; *NFAT,* nuclear factor of activated T cells; *PTLD,* post-transplant lymphoproliferative disease.

T cells promoting a humoral response (i.e., Th2 cells) are associated with the generation of IL-4, −5, and −6. Additionally, a Th17 population that has been identified is characterized by the production of IL-17 and promotion of the infiltration of neutrophils. Th22 cells, which express IL-13, IL-22, and TNF-α, have also been described. A subset of CD4 cells called *regulatory T cells* (Treg) can also be induced following antigen exposure in the periphery (pTregs; see Chapter 13). These cells secrete IL-10 or transforming growth factor-beta (TGF-β) and have suppressive or regulatory functions against effector cells and APCs. Skewing the immune response in favor of Treg is being investigated as a potential strategy to improve long-term graft survival or through adoptive transfer.[8] The balance of these responses results in either graft injury or the induction of tolerance.

Following exposure to an antigen, antigen-specific memory T and B cells are generated. These memory cells are then able to produce a more rapid and intense immune reaction if the antigen is encountered on a second occasion because they have a lower activation threshold and are less dependent on costimulation. Transplant recipients, particularly older patients or those who have had previous antigen exposure through previous transplantation, blood transfusion, or pregnancy, may therefore have specific anti-donor memory cells. Memory-type responses may also occur due to antigen receptor cross-reactivity known as *heterologous immunity*. Moreover, T-effector memory cells are resistant to lymphocyte depletion therapies and $CD28^+CD8^+CD45RA^+CCR7^-$ effector memory cells are resistant to costimulatory blockade.[9]

HOW ARE GRAFTS DESTROYED: THE HOST EFFECTOR IMMUNE RESPONSE

In organ transplantation, the type of transplanted tissue, location of implanted organ, and immune status of the recipient at time of transplantation may modify the immune response. Although initiation of rejection in a naïve recipient is principally T-cell dependent, many components of the immune system contribute to the subsequent destruction of the transplanted tissue. Graft destruction may be alloantigen-specific, or may be due to bystander tissue destruction.

Acute T Cell–Mediated Rejection

As described above, following the innate response to organ acquisition, implantation, and reperfusion, the inflammatory environment within the graft promotes an adaptive cellular response to the graft itself. Naïve cytotoxic T cells, activated by CD4 cells clustering with APCs, migrate to the graft, where they recognize allogeneic class I MHC molecules. These cytotoxic cells release key molecules such as perforin and granzyme B, upregulate surface Fas ligand, and secrete soluble mediators, such as TNF-α. Perforins insert into the target cell membrane to form pores, allowing granzyme to enter the cell, causing proteolysis and activation of the apoptotic caspase cascade. Moreover, Fas ligand binds to Fas on target cells, similarly inducing apoptosis. While the clinical risk of acute T cell–mediated rejection (TCMR) occurs in the first months of transplantation, TCMR may be detected at any time following transplantation, when there is insufficient immunosuppression.

In animal models, a nonspecific delayed-type hypersensitivity response may occur, usually mediated by CD4 cells that are attracted to the graft, involving the release of multiple proinflammatory cytokines, including IL-1, IFN-γ, and TNF-α. This leads to the further recruitment and activation of leukocytes, increasing graft cell permeability and vascular smooth muscle tone, affecting graft function, and contributing to both acute and/or sustained rejection. In the latter process, CD4 alloreactive T cells responding to donor-derived peptides bound to recipient MHC class II molecules have also been correlated with chronic allograft dysfunction. In human kidney transplant recipients (KTRs), this phenomenon is called chronic active T cell–mediated rejection (CA-TCMR) and has specific histologic criteria (Table 89.2).[10] CA-TCMR is associated with prior episodes of TCMR and later development of allograft fibrosis and tubular atrophy.[11,12] This entity reflects under immunosuppression, but appropriate clinical intervention remains uncertain.

As acute allograft rejection is initiated by the recognition of polymorphic donor MHC molecules by recipient T cells, it may follow that transplantation of MHC incompatible tissues will elicit a strong T cell–dependent immune response to donor tissues, based on extent of mismatches as demonstrated in rodent models. These differences are often not apparent in clinical transplantation in the context of modern immunosuppression. Moreover, rejection may still occur between MHC-matched siblings due to T-cell recognition of minor histocompatibility antigen differences.

From work in animal models and findings in human transplant recipients, so-called "chronic rejection" was a label used to describe functionally failing organ transplants with associated inflammatory cell infiltrates coupled with alloantibody interaction of the vascular endothelium. This interaction resulted in smooth muscle cell activation and proliferation of the arterial medial wall ("vasculopathy"). This entity can be seen in heart and kidney allografts. In the latter, interstitial fibrosis and tubular atrophy are also characteristic of the failing allograft. Indirect allorecognition has been implicated in the development of "chronic rejection," though this is primarily derived from animal models (reviewed in Siu JHY, et al.[13]).

Clinical Implications

Acute graft rejection is suspected when there is a sudden deterioration in allograft function and is confirmed by allograft biopsy. As shown in Table 89.2, there are semi-quantitative measures for the intensity and location of inflammatory response, developed for all the organs.[10] An example of TCMR is shown **in** Fig. 89.4. The extent of rejection grade is associated with the number of cells within the tubular epithelial cell as well as the extent of inflammation in the graft. Vascular invasion is considered more severe and raises the grade of rejection. Typically, the severity of an episode of rejection and the level of graft dysfunction are key factors in terms of responsiveness to therapy. Finally, the frequency of rejection in the first year after transplant varies depending on the organ, ranging from 8% in the kidneys up to 39% in the small bowel,[14] reflecting the immunogenicity of the allograft and effectiveness of immunosuppressive therapy.

Detection of graft dysfunction varies based on organ, and while lab findings are used for kidney, liver, and pancreas transplants, heart transplants undergo surveillance biopsy to monitor for rejection. In kidney transplantation, the finding of rejection in a biopsy without graft dysfunction is called "subclinical" rejection. However, in a recent survey of US transplant centers, less than 25% performed surveillance biopsies even in selected patients, citing the low yield of actionable information

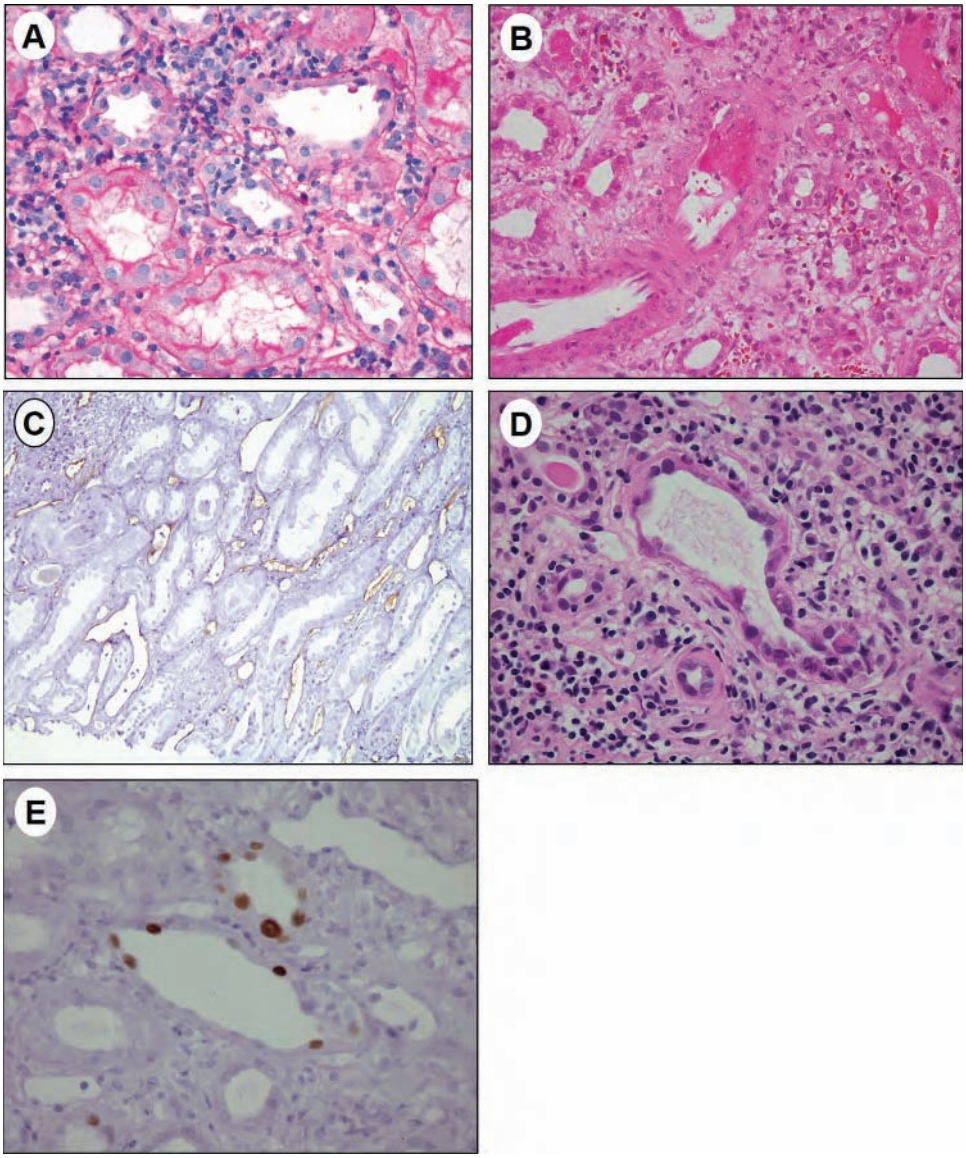

FIG. 89.4 Kidney Biopsies Demonstrating Abnormal Histology. (A) This is an example of Banff 1b T cell–mediated rejection (TCMR). Note that there is substantial interstitial inflammation (i3) but the extent of tubular infiltration by monocytes (tubulitis, t) is critical to define TCMR. (B) Antibody-mediated rejection (AbMR). The key findings are peritubular capillaritis (ptc) accompanying vasculitis (v) and thrombosis. There is also tubulitis present. (C) Immunostaining for complement component C4d, with positive staining of peritubular capillaries. (D) BK polyomavirus nephropathy. There is intense interstitial inflammation (i) and tubulitis with obliteration of the renal tubules; these findings may also be seen in TCMR. However, within the tubular epithelium are viral cytopathic changes including nuclear inclusions in tubular epithelial cells, enlarged irregular nuclei, and chromatin smudging, as well as detached tubular cells with denuded patches of basement membrane. (E) Immunostaining for SV40 T antigen demonstrating positive nuclei in the renal tubule epithelium. This finding is diagnostic for viral infection with the SV40 family of viruses that include BK.

as the primary reason for nonperformance. Moreover, the early detection of subclinical rejection identifies patients at increased risk for allograft failure who might benefit from early interventions that increase immunosuppression exposure. However, the long-term consequences of detecting and treating subclinical inflammation remain controversial, with some arguing that there are insufficient long-term benefits to justify the practice.

With the growing use of immune checkpoint inhibitors (CPIs) in advanced cancer treatment (see Chapter 80), there is increasing recognition of immune-related adverse events that occur in 70%–90% of treated patients.[15] Such events include skin disorders, acute kidney injury with acute interstitial nephritis, gastrointestinal (GI) disorders, hepatotoxicity, and endocrinopathies like thyroiditis and diabetes. The activation of T-cell antitumor activity may also adversely affect allografts in transplant recipients. Further data are needed to better assess the risks to transplanted organs and possible negative impact on patient survival beyond the impact of the tumor itself.

Antibody-Mediated Rejection

Alloantigen-specific antibodies, or alloantibodies, are produced after alloantigen-driven B-cell activation in the presence of T-cell help, which may occur during cellular rejection or following a blood transfusion. In addition to DCs, B cells themselves may

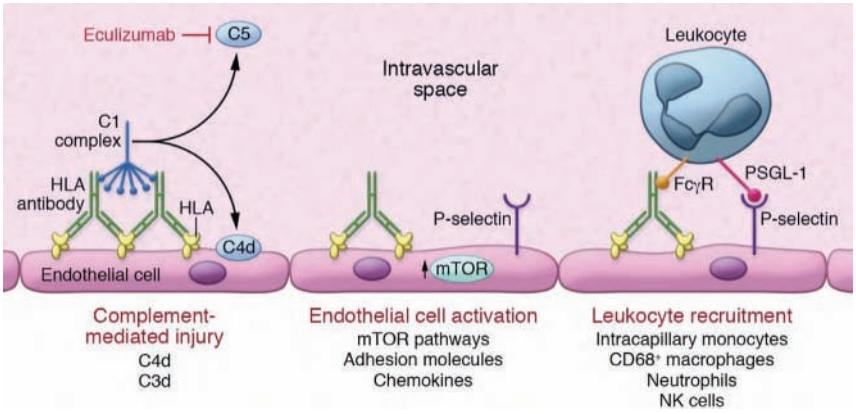

FIG. 89.5 Mechanisms of Antibody-Mediated Injury on the Vascular Endothelium. Once alloantibody is bound, activation may occur via complement–dependent pathway. Typically, non-HLA anti-donor antibodies activate through complement-independent pathways. Finally, bound antibody exposes the Fc portion of the antibody, which may bind and attract leukocytes to the endothelium, adding to the immune-mediated injury by innate immune cells. (Adapted from Valenzuela N, Reed EF. *J Clin Invest* 2017;127(7):2492. Fig. 89.2A.).

act as APCs. MHC class II molecules are presented to and bind immunoglobulins (Igs) on the surface of B cells, enabling the B cell to internalize the alloantigen and process it into peptides that are presented at the cell surface within MHC class II molecules (see Chapter 6). These activated T cells produce cytokines that activate B cells, enabling them to differentiate into alloantibody-producing plasma cells. When allospecific antibodies encounter their specific antigen, antibody-mediated rejection occurs.

There are three mechanisms by which antibody mediates tissue injury in antibody-mediated rejection (AbMR; Fig. 89.5).[16] First, bound antibody activates endothelial cells within the graft, resulting in the expression of adhesion molecules, cytokines, and chemokines, as well as the synthesis of tissue factor. This process results in increased immune cell trafficking to the site, enhancing the immune response. Second, antibody binding may trigger complement activation, which can result in cell lysis and graft damage directly or indirectly by the binding of complement components to the graft and the recruitment of macrophages and neutrophils. Finally, the exposed Fc non-antigen-specific portion of the antibody molecule may serve as a receptor for other innate immune cells, including NK cells and monocytes. This encourages NK cells and macrophages to kill any target cells with antibodies bound to their surface. This is a nonspecific process termed *antibody-dependent cellular cytotoxicity* (ADCC) and can contribute to graft rejection (see Chapter 12).

Antibodies to Human Leukocyte Antigens (HLA) antibodies may be present in all hosts. The diversity and extent of these antibodies are referred to as allosensitization. This occurs as a result of blood transfusions due to contaminating passenger leukocytes in the blood product, pregnancy, and prior organ transplant. While we typically associate alloantibodies forming after sensitizing events, their generation in the context of host infection and heterologous immunity has important clinical implications.[17]

When donor-specific anti-HLA antibodies (DSA) exist in a recipient prior to transplantation, a dramatic response known as hyperacute rejection may occur upon perfusion of the transplanted graft. Coagulation and complement cascades are activated, resulting in extensive thrombosis and graft infarction within minutes. Hyperacute rejection is rarely seen in clinical practice anymore because of the advances in screening for HLA antibodies prior to transplantation (see the following section).

Non-HLA antibodies are increasingly recognized as associated and perhaps causative of antibody-mediated injury.[18] The antigens recognized include the major histocompatibility complex class I chain-related gene A (*MICA*) or B (*MICB*), or structural proteins in the donor organ such as collagen IV in basement membranes, vimentin, or angiotensin 1 receptor. Anti-endothelial-cell antibodies to targets such as ICAM-4 and endoglin have also been identified in pre-kidney transplant sera and associated with post-transplant development of HLA DSA and AbMR, and similarly correlated to poor outcomes in heart transplantation. However, there is no consensus on the routine monitoring for detection of such antibodies, which are clinically assayed when HLA DSA are not detected in the setting of graft dysfunction and AbMR.

Clinical Implications

In the past, the assessment of HLA antibodies, and specifically those that are donor specific, utilized an in vitro ADCC cytotoxicity assay that required donor cells (lymphocytes) and the serum from the intended recipient. DSA are now measured by sensitive flow cytometry–based techniques using HLA-loaded beads and recipient serum, allowing for a more complete profile than older serologic analyses.[19] These sensitive assays are more efficient in busy laboratories but are subject to lab-to-lab differences in their performance, and hence are difficult to standardize across all transplant centers.[20] However, within a particular histocompatibility laboratory, methods and thresholds have been established to define clinically apparent antibodies. In clinical practice, laboratories perform a "virtual" cross-match in which detailed molecular typing of the donor and a detailed antibody profile of the recipient render a determination of HLA compatibility.[19] This improves the time to transplantation and also supports proper organ allocation to avoid those recipients with existing DSAs.

Diagnosis of AbMR requires an allograft biopsy. Specific criteria are shown in Table 89.2, but the recognition of injury was finally galvanized by the ability to detect complement activation within the allograft based on immunostaining of C4d in peritubular capillaries, the site of antibody–endothelial interaction (see Fig. 89.4). The dependence on this criterion has also led to debate about C4d-negative biopsies with otherwise typical findings for AbMR, and also the presence of C4d in the absence of injury findings in the context of

TABLE 89.2 Banff Diagnostic Criteria for Renal Allografts

Category 1: Normal or nonspecific changes

Category 2: Antibody-mediated changes

Active AbMR (requires all 3 criteria)

1. Histologic evidence of acute tissue injury:
   - Microvascular inflammation (g > 0 and/or ptc > 0)
   - Intimal or transmural arteritis (v > 0)[b]
   - ATM
2. Evidence of current/recent antibody interaction with vascular endothelium, including one or more of the following:
   - C4d staining in ptc
   - Moderate microvascular inflammation ([g + ptc] ≥2)
   - Gene transcripts/classifiers of ABMR
3. Serologic evidence of donor-specific antibodies (DSA).

Chronic active ABMR (requires all 3 criteria)

1. Morphologic changes of chronic tissue injury
   - Transplant glomerulopathy (cg > 0)
   - Severe peritubular capillary basement membrane multilayering
   - Arterial intimal fibrosis
2. Same as above
3. Same as above

Chronic Inactive ABMR

1. Same as above
2. Absence of criterion 2 above
3. Prior documented active or CA ABMR and/or DSA

Category 3: Borderline (suspicious for acute TCMR

Foci of tubulitis (t1, t2, or t3) with mild interstitial inflammation **(i1)**, OR mild tubulitis (t1) with moderate to severe interstitial inflammation (i2 or i3)

Category 4: T-cell–mediated rejection (TCMR)

Active TCMR

Grade IA: Interstitial inflammation (i2 or i3) with moderate tubulitis

Grade IB: Interstitial inflammation (i2 or i3) with severe tubulitis (t3)

Grade IIA: Mild to moderate intimal arteritis (v1), with/without interstitial inflammation

Grade IIB: Severe intimal arteritis (v2), with/without interstitial inflammation

Grade III: Transmural arteritis and/or arterial fibrinoid necrosis (v3), with/without interstitial inflammation

Chronic active TCMR (requires all 3 criteria)

Grade IA–Grade IB: Interstitial inflammation involving >25% of sclerotic cortex AND > 25% of total cortical parenchyma (ti2 or ti3) with moderate (t2 or **t-IFTA2**) or severe (t3 or **t-IFTA3**) tubulitis

Grade II: Chronic allograft arteriopathy

Category 5: Polyomavirus nephropathy

Class I: pvl 1 and ci 0–1

Class II: pvl 1 and ci 2–3, or pvl 2 and ci 0–3, or pvl 3 and ci 0–1

Class III: pvl 3 and ci 2–3

Histological criteria have been developed and are regularly reviewed to aid diagnosis of the cause of chronic allograft dysfunction. Determining the cause of dysfunction aids decision making with regard to pathology and management.

AbMR, Antibody-mediated rejection; *CA*, chronic active; *ptc*, peritubular capillaritis; *v*, vasculitis.

For full details, see Loupy A, Haas M, Roufosse C, et al. The Banff 2019 Kidney Meeting Report (I): Updates on and clarification of criteria for T cell- and antibody-mediated rejection. *Am J Transplant*. 2020;20(9):2318–31.

so-called accommodation.[21] This has led to revisions of standardization for AbMR biopsy diagnosis in the kidney and includes the use of gene transcripts associated with AbMR.[10]

With the increasing recognition of de novo development of DSA following transplantation contributing to late allograft failure, in part due to insufficient immunosuppressive therapy for a particular host, there is a growing consensus of the necessity for monitoring for DSA after transplantation to mitigate the contribution of antibody-mediated injury in graft failure.[22]

Late Allograft Failure

Both nonimmune and immune injury contribute to late allograft loss.[23] In the former, key contributors include advanced donor age and cell senescence, delayed graft function (as noted in the previous section), and calcineurin-mediated nephrotoxicity. These injuries involve cell signaling, promoting tissue remodeling, and interstitial fibrosis and tubular atrophy. With regard to immune-mediated injury, the notion of chronic rejection or chronic allograft nephropathy has been replaced with more refined entities, based on the analysis of large cohort studies that have pointed to the contribution of DSA anti-HLA antibodies based on data in large clinical cohorts.[24,25] Such studies and others suggest the presence of immune activation either by intentional nonadherence or immune responses that have evaded the immunosuppressive state over time. This phenomenon is seen in the lung allograft, manifested as chronic lung allograft dysfunction (CLAD),[26] and in the heart transplant, where it is known as cardiac allograft vasculopathy.[27] In both instances, there is injury and inflammation affecting the airways and vasculature, respectively.

Viral-Mediated Kidney Allograft Injury

In the last two decades, a critically important contributor to kidney transplant injury and graft failure as well as to native kidney injury in other solid organ transplants has become known as BK polyomavirus nephropathy. BK virus, a DNA virus related to JC polyomavirus and SV-40, reactivates in the host, eliciting an immune response that histologically can mimic ACR with an inflammatory, interstitial inflammatory response with tubulitis, as well as viral inclusions in tubular epithelial cells[28] associated with kidney dysfunction. This is not a systemic disease, with focal infection in the tissues of the urinary tract. The virus gains entry into urothelium via an N-linked glycoprotein containing a (2,3)-linked sialic acid receptor followed by caveolae-mediated endocytosis. Following internalization into the cell, the virus migrates through the cytoplasm and gains entry into the nucleus, where viral transcription, replication, and particle assembly take place. Innate immune responses, in part via Toll-like receptor 3 (TLR3) that senses viral double-stranded RNA as part of the viral replication, result in induction of IL-6 and IL-8. Small peptide defensins and IFN-γ inhibit viral replication. Viral-specific T-cell responses, activated following DC presentation of viral antigens, are important to control viral infection, whereas antiviral antibodies do not appear to correlate with viral clearance.

Clinical Implications

It is the extent of immunosuppression that is associated with viral reactivation and suppression of normal antiviral cellular responses. As such, clinicians use a proactive strategy to monitor for BK viral DNA in urine and/or serum by polymerase chain reaction (PCR). Once detected, reduction in immunosuppression is undertaken. With worsening kidney function, diagnosis is made by allograft biopsy, which reveals interstitial inflammation, tubulitis, and immunohistochemical staining for SV-40 T-cell antigen, so called polyomavirus replication/load level (pvl) (see Fig. 89.4). With no known effective antiviral therapy, immunosuppression may be reduced further and empiric treatments have included IVIG, conversion to cyclosporine, and corticosteroid therapy. Typically, there is progressive inflammation and fibrosis, and ultimately allograft failure.

IMMUNOSUPPRESSIVE MANAGEMENT

The potency of current immunosuppressive strategies has been associated with dramatic improvements in short-term graft outcomes due to reduced rates of TCMR. But as noted previously, long-term graft survival remains a challenge. Therapy is aimed at T cell–mediated immune responses. The treatment paradigm is induction therapy, followed by maintenance therapy. Induction may be lymphocyte-depleting or not, with the former quite popular due to the potency of this strategy of reducing the bulk of T lymphocytes (monoclonal or polyclonal antibody) at the time of implantation of the allograft. Based on the discussion of allorecognition and T-cell activation, maintenance therapy is a combination of agents to interfere with these processes (Fig. 89.6) and includes corticosteroids, anti-metabolite (typically mycophenolic acid [MPA]), and calcineurin inhibitor (typically tacrolimus). Table 89.1 lists the mechanisms of these agents and, importantly, their off-target effects, with overall concerns of opportunistic infection and malignancy. To achieve the proper level of immunosuppression, clinicians monitor 12-hour trough levels of calcineurin inhibitor (CNI) as well as MPA levels. Note that certain solid organ transplants such as the liver don't typically include induction therapy, and maintenance therapy may include two agents only. In contrast, highly immunogenic simultaneous kidney–pancreas transplants utilize "quadruple therapy" with T-cell depletion as induction. Typically over the first 3 to 6 months maintenance therapy is reduced to lower baseline levels as the risk of TCMR is reduced.

Signal 1: Blockade of Antigen Recognition

Activation of the rejection response to an allograft hinges on the recognition of antigen by the host immune system. Targeting

CLINICAL PEARLS

When graft dysfunction is detected, a biopsy is performed and therapy is based on those findings:

T cell–mediated rejection (i.e., acute cellular rejection or TCMR)
- Increase in baseline therapy doses
- High-dose steroids
- Anti-thymocyte globulin
- Alemtuzumab

Antibody-mediated rejection (AbMR)
- Plasmapheresis
- Intravenous immunoglobulin
- Rituximab

BK virus nephropathy (BKPVN)
- Immunosuppression reduction (Anti-metabolite, CNI)
- Serial monitoring of serum and/or urine viral load by PCR

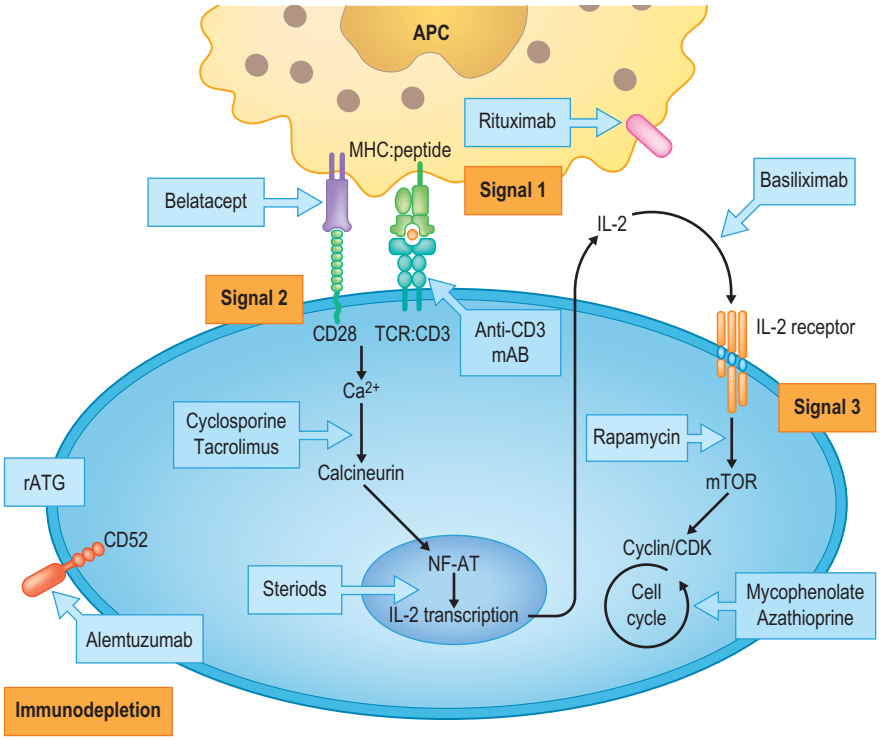

FIG. 89.6 Immunosuppressive Drugs and Their Targets. Signal 1 results from major histocompatibility complex *(MHC)*: antigen recognition through the T-cell receptor *(TCR)–CD3* complex, a process blocked by anti-CD3 mAbs and indirectly by rituximab. Signal 2 results in costimulation, a process that can be blocked by belatacept. Costimulation results in full activation of the TCR–CD3 complex, initiating signal transduction. Signal 3: downstream signaling pathways result in calcineurin activation, a stage that can be inhibited by tacrolimus and cyclosporine. Activated calcineurin dephosphorylates nuclear factor of activated T cells *(NFAT)*, allowing interleukin-2 (*IL-2*) transcription, a process that can be inhibited by steroids. IL-2 receptor stimulation, which is blocked by basiliximab, activates the mammalian target of rapamycin *(mTOR)* signaling cascade, which can be inhibited by sirolimus. This pathway induces the T cell to enter the cell cycle and proliferate, which in turn can be blocked by mycophenolate and azathioprine. Rabbit antithymocyte globulin (*rATG*) exerts polyclonal effects, and alemtuzumab binds to CD52, both resulting in immunodepletion.

THERAPEUTIC PRINCIPLES

- Patients receive induction immunosuppression

Non-lymphocyte depleting mAb or
Lymphocyte-depleting antibody or
Corticosteroids

- Maintenance therapy begins on the day of transplantation

Calcineurin inhibitor (CNI)
Anti-metabolite (mycophenolate mofetil)
Corticosteroids (or avoidance depending on induction)

- Special situations such as HLA-incompatible transplants: highly sensitized patients may also receive rituximab and/or intravenous immune globulin
- Therapeutic drug level monitoring for CNI and sometimes mycophenolic acid (MPA)

signal 1 via monoclonal antibodies has been used in both transplantation and autoimmunity and includes the already mentioned lymphocyte-depleting antibodies.

Rabbit Antithymocyte Globulin

Current therapeutic strategies are based on induction therapies that concentrate on profound immune-cell depletion at the time of transplantation, when immune activation is most intense and prior clinical uses included horse antilymphocyte globulin and anti-CD3 antibody. In current practice, the most commonly used agent is rabbit antithymocyte globulin (rATG), a lymphocyte-depleting polyclonal IgG preparation with specificity toward human thymocytes. It primarily binds to peripheral blood lymphocytes as well as to those present in the lymphoid organs, including lymph nodes, spleen, and thymus, as demonstrated by in vivo studies in NHPs. The agent's polyclonal nature enables it to display specificity toward a wide variety of molecules expressed on the surface of T cells, B cells, DCs, NK cells, and endothelial cells, including those involved in T-cell activation, proliferation, apoptosis, signal transduction, cell adhesion, and trafficking. The precise mechanism of action underlying the immunosuppressive efficacy of rATG in transplant recipients is unclear, although it has been primarily attributed to T-cell depletion. In vitro studies suggest that rATG modulates the expression of various lymphocyte surface antigens, resulting in apoptosis, antibody-dependent cytolysis, or complement-dependent lysis. Initially, this agent was primarily used for treatment of TCMR (and had approval for that purpose by the US Food and Drug Administration [FDA]), but evolving data for induction therapy have demonstrated non-inferiority with non-lymphocyte depletion induction in terms of incidence of biopsy-proven acute rejection, graft loss, or death at 6 and 12 months after transplantation, leading to FDA approval.[29] Treatment may be monitored by flow cytometry of total CD3 cells present in the recipient. Over 3 to 6 months, repopulation occurs, but with overall reduced total absolute lymphocyte count even at 1 year[30] with thymopoiesis and homeostatic proliferation contributing to immune reconstitution and expansion $CD4^+CD25^+$ Forkhead box $P3^+$ ($FOXP3^+$), CTLA-4^+, and glucocorticoid-induced TNF receptor (GITR+)$^+$ Treg from human peripheral blood lymphocytes. These Treg subsets are key to immune response modulation.

While definitive superiority compared to non-depletional induction therapy has not been demonstrated,[31] rATG has facilitated the avoidance of corticosteroids that were utilized widely in the prior decade and still utilized for immune "low-risk" patients in about 25% of KTRs. However, a systematic review has demonstrated higher rates of acute rejection but no difference in patient and graft survival at 5 years, without clear benefit or detriment beyond that.[32]

Alemtuzumab (Campath-1H)

Alemtuzumab is a humanized rat IgG2b directed against the CD52 antigen, which is expressed on 95% of peripheral blood lymphocytes, NK cells, macrophages, and thymocytes,[33] affecting nearly all mononuclear cells. The profound and long-lasting lymphopenia produced after the administration of a single dose of 30 mg of alemtuzumab is likely explained by such abundance on monocyte cell surfaces. Examination of the peripheral blood lymphocytes from recipients after alemtuzumab induction has identified a subset of T cells, predominantly CD4 central memory cells that survive despite alemtuzumab induction and appear largely resistant to depletion; these memory T cells express lower CD52 levels compared with naïve T cells. CD52 is not present on granulocytes, platelets, erythrocytes, or hematopoietic stem cells (HSCs). After binding to CD52, alemtuzumab causes cell death through several mechanisms: complement-mediated cytolysis, antibody-mediated cytotoxicity, and apoptosis. With a plasma half-life of approximately 12 days, its clinical effects are far more persistent, with greater than 99% lymphocyte depletion after a single dose, and lymph-node depletion taking up to 3 to 5 days compared with less than 1 hour seen in the peripheral lymphocytes.[34]

In this setting of severe lymphopenia, homeostatic proliferation affects the recovery of cell subpopulations, with rapid return of naïve and memory T cells that may trigger rejection.[35] CD8 cells appear to recover within 6 months, but CD4 cells may not reach pretransplant levels by 1 year, if at all. NK cells are almost unaffected and decrease only transiently (a population of $CD52^-$ NK cells has also been identified); monocyte and B-cell recovery can be seen at 3 and 12 months, respectively; T-cell levels recover to only 50% of baseline at 36 months.[34] Thus, there are lasting impacts on the recipient's peripheral blood cellular makeup, although long-term impacts have yet to show definitive damage.

While first used safely in transplantation as an induction agent in 1998 alone or with cyclosporine, other small clinical studies suggested the potency of lymphocyte depletion and ability to limit maintenance therapy with limited rejection and successful short-term graft survivals. Two randomized controlled trials in kidney transplantation have assessed the efficacy and safety of alemtuzumab compared to rATG[36,37] demonstrating alemtuzumab as an effective induction agent in both high- and low-immune-risk patients. Furthermore, it facilitates reduced exposure to CNI and mycophenolate, as well as steroid avoidance. Critically, late-term rejections have been observed with such strategies,[38] and some groups have noted AbMR as a common rejection phenotype, perhaps due to the minimization of maintenance therapy that facilitates (inadvertently) development of *de novo* DSA. Combinations of maintenance therapies including mTOR inhibitors (mTORi) and deoxyspergualin have been attempted to improve long-term engraftment. However, with the lack of pharmacokinetic data and additional trials, there is no FDA or European Medicines Agency (EMA) approval for its use in transplant and limited clinical availability unless off-label use.

Anti-CD20 Monoclonal Antibody (Rituximab)

Rituximab is an anti-CD20, chimeric mAb that eliminates most B cells from the circulation. Originally used to treat B-cell

lymphoproliferative diseases in patients other than transplant recipients as well as to treat post-transplant lymphoproliferative disease (PTLD), it is also now used in SOT as a treatment of antibody-mediated rejection and to "desensitize" patients who are receiving HLA-incompatible or ABO-incompatible transplants. However, depletion of antibody-producing cells may be incomplete because rituximab cannot target CD20-negative plasmablasts and plasma cells, which are the cells producing antibodies. The actions of rituximab in AbMR are to effectively deplete APC (e.g., B cells), limiting indirect pathway T-cell activation resulting in a sustained immune response. Recent studies of CCR5-deficient mice receiving kidney allografts demonstrated that early treatment with anti-CD20 at the time of transplantation effectively blocked the typical accelerated AbMR of control allografts, but when given at day 5, and afterwards, was unable to control the accelerated rejection.[39] While there may be a role for targeting B cells preemptively in SOT in highly sensitized individuals, additional strategies to downregulate the B-cell response are under evaluation.

Signal 2: Costimulatory Blockade: CTLA4Ig and Anti-CD40L

As already noted, a positive costimulatory signal is needed to promote T-cell activation; in its absence, partially activated T cells become hyporesponsive (anergic) or die via apoptosis.

The primary pathways of blockade for clinical implementation are CD28:CD80/86 and CD40:CD154. It has been hypothesized that the inhibition of full T-cell activation by costimulatory blockade rather than total T-cell depletion might more selectively target effector T cells and spare beneficial Treg while avoiding the many adverse effects of nonspecific immunodepletion. This has been based on preclinical studies and not been borne out in human transplantation.[7]

CTLA-4 (CD152) is an inducible T-cell surface antigen that, when bound to CD80/86 receptor ligands (B7 molecules) on APC, delivers inhibitory signals to the activated T cell. Belatacept (LEA29Y) is a fusion protein that combines a mutated version of the extracellular binding domain of CTLA-4 with the Fc portion of IgG1, with specificity for CD80/86 expressed on APC. Ligation of CD80/86 by CD28 (a surface antigen constitutively expressed on T cells) usually lowers the activation threshold of T cells (Fig. 89.6). Belatacept has a higher affinity and slower dissociation rate from human B7 molecules (i.e., CD80/86) compared with CD28, resulting in inhibition of the costimulation required for effective T-cell activation.

Belatacept has been studied in KTRs and is FDA-approved for use as prophylaxis for rejection. In the phase 2 trial KTRs,[40] belatacept treatment was associated with a low rate of rejection, similar to that in control treatment of cyclosporin A, mycophenolate, and corticosteroids. Moreover, graft function was significantly better with belatacept treatment. In two larger randomized trials,[41,42] treatment with belatacept was associated with higher rates of acute rejection in the first year of transplant compared to control treatment with cyclosporine, but with significantly better renal function and improved cardiovascular and metabolic profiles. These beneficial effects have been demonstrated out to 7 years post-transplant.[43] The higher rate of rejection with belatacept therapy has been borne out in other studies attempting to optimize its use. While these rejections are reversible and have not had demonstrable allograft loss, they make patient management impractical. Studies to understand this unexpected consequence in humans have noted the loss of CD28 on effector memory CD8 and CD4 T cells, effectively making these cells resistant to costimulatory blockade by CTLA4Ig.[44] In the latter case, they may be found in rejection biopsies and appear to acquire CD57, a marker of terminal differentiation and a ligand for P and L selectin. Their presence prior to transplant may identify patients resistant to treatment. Studies are ongoing to understand this risk and identify practical ways to implement these drugs. In clinical practice, they may also be useful in conversion when CNIs are not tolerated.[45]

Promising data in NHP models of kidney transplantation demonstrated beneficial effects of long-term allograft survival when anti-CD154 antibody was either combined with CTLA4Ig or as monotherapy.[46] However, human trials were halted due to unexpected life-threatening pulmonary emboli, with demonstration that activated platelets express and shed soluble CD154, promoting rejection, but which are also associated with the thrombosis seen in humans.[47] Removing the Fc portion of the antibody not only reduces this thrombosis but also promotes tolerance in murine models of allogeneic bone marrow and skin transplantation. For the most part, clinical attempts to use anti-CD154 antibody continue to be on hold[6] while the focus has turned to a non-activating anti-CD40 monoclonal antibody (bleselumab) to block the CD40–CD154 pathway, which showed promise in prolonging kidney and liver allograft survival in NHPs. A phase 2 trial in KTRs demonstrated three- to fourfold higher rates of biopsy-proven rejection[48] ending any potential in kidney transplants for the present. These disappointing results demonstrate the difficulty in translating immunologic findings in murine models, which are highly inbred and kept in isolation from pathogens, as compared to more complex findings in NHPs and ultimately to man.

Signal 3: Blockade of Proliferation and Differentiation

Anti-IL-2R (CD25) Monoclonal Antibody (Basiliximab)

As already discussed in Chapters 10 and 11, activated T cells produce IL-2, which binds to the IL-2 receptor high-affinity transmembrane protein subunit α (CD25), leading to signal transduction and T-cell activation. Anti-IL-2R (anti-CD25) mAb specifically target activated T cells but do not cause significant lymphocyte depletion and are not associated with major adverse effects compared with lymphocyte-depleting agents. However, other T-cell subtypes, including Treg, also express CD25, and therefore the use of these agents may impact some of the natural mechanisms of immunoregulation. Basiliximab, a chimeric mAb, binds the IL-2R with similar affinity as IL-2, thereby effectively competing with IL-2 and subsequently inhibiting IL-2–driven T-cell proliferation (Fig. 89.6).

It has been used in renal transplantation in low-immune-risk recipients and supported by consensus guidelines.[49] First transplants, well-matched organs, as well as living donors are considered "low" risk. However, in high-immune-risk situations, such as with the occurrence of detectable anti-donor HLA antibodies, re-transplantation, and the presence of high risk for acute kidney injury/DGF post-transplantation, rATG is favored.[31] With the selective and short-term immunosuppressive effect of basiliximab, confined to the highly immunogenic period immediately after transplantation, this class of drug has been under investigation to substitute for corticosteroids in early steroid withdrawal or steroid-free regimens. However, the debate

continues about the implementation of basiliximab in favor of rATG,[50] and it has also been utilized in the other solid organs.

Corticosteroids

Corticosteroids have complex immunosuppressive as well as anti-inflammatory effects (see Chapter 83). They act principally by binding to cytoplasmic glucocorticoid receptors, although at higher doses they can exhibit receptor-independent effects as well. The steroid–receptor complex translocates to the nucleus, where through DNA binding and by targeting transcription factors such as AP-1 and NF-κB affects a variety of cytokines including IL-1, IL-2, IL-3, and IL-6, TNF-α, IFN-γ; and a number of chemokines. By inhibiting cyclooxygenase, corticosteroids are also able to reduce the production of inflammatory mediators, such as leukotrienes, thromboxanes, and prostaglandins. Corticosteroids have been the mainstay of maintenance immunosuppression regimens for several decades (see Table 89.1, see Fig. 89.6). However, because of off-target effects, including its diabetogenic properties and induction of bone loss, skin changes, and other negative metabolic profiles, steroid avoidance has been utilized in many kidney transplant programs with significant success when coupled with antibody induction, at least in the short term.[37,51]

Antiproliferative Agents

With the discovery of azathioprine in 1957, anti-metabolites have been important maintenance immunosuppressive agents that interfere with DNA synthesis and prevent cell-cycle progression (see Fig. 89.6). In the context of allograft rejection, this impairs the clonal expansion of alloreactive T cells. While not used as commonly as mycophenolate, azathioprine is hepatically metabolized to the purine analogue 6-mercaptopurine and incorporated into DNA. By inhibiting purine nucleotide synthesis (and therefore DNA and RNA synthesis), it reduces gene transcription and prevents cell cycle progression. The effects of azathioprine are not lymphocyte-specific, resulting in bone marrow suppression.

In current clinical practice, mycophenolate mofetil (MMF) is the primary anti-metabolite used. MMF is metabolized in the liver to the active MPA. MPA is a noncompetitive, reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), the enzyme that catalyzes purine synthesis in the de novo pathway by conversion of inosine monophosphate to guanosine monophosphate. As the salvage pathway of purine synthesis from guanine is less active in lymphocytes, they are relatively dependent on the de novo pathway of purine synthesis compared with other cell types. As a result, the effects of MMF are more lymphocyte-specific than azathioprine, and less myelosuppressive. MMF therapy is utilized in all solid organs transplanted and is considered a standard of care following FDA approval in 1995 and EMA approval in 1996 for prophylaxis for transplant rejection.[52]

Calcineurin Inhibitors

Since their clinical introduction in the early 1980s with cyclosporin A (CsA) and tacrolimus (Tac) in early 1990s, this class of agent has had a substantial impact on transplantation, with a significant reduction in acute rejection rates and improved graft survival. About 95% of renal transplant recipients currently receive CNI.[14] Both CsA and Tac bind cytoplasmic immunophilins (cyclophilin and FK506-binding protein 12 [FKBP12], respectively) to form complexes that can inhibit the calcium-dependent phosphatase calcineurin, a rate-limiting enzyme in the TCR signal–transduction pathway (see Fig. 89.6). By preventing translocation of the transcription factor NFAT to the nucleus, calcineurin inhibition impairs upregulation of many molecules important for T-cell proliferation and the generation of an effective immune response, including the cytokines IL-2, IL-4, TNF-α, and IFN-γ, and costimulatory molecules, such as CD154. However, CNIs are associated with nephrotoxicity, both for native kidneys when used in other solid organs and in kidney allografts. Indeed, there have been many attempts to avoid and/or minimize their use, but this has been challenging with the occurrence of improved kidney function, albeit with a strong risk of rejection.[53] As already noted, the development of *de novo* DSA and late antibody-mediated rejection are consequences of patient- or physician-implemented minimization. The "Symphony" study, a large, randomized control study of ~1700 KTRs compared four maintenance regimens including reduction in tacrolimus target dosing and basiliximab induction. When compared to a CsA-based regimen or mTORi regimen, Tac treatment was associated with a significantly lower rejection rate (12% in the first year with a 95% 1-year graft survival and better renal function) than the other regimens, and this rate was maintained out to 3 years post-transplantation.[54] In the last few years, long-acting Tac preparations have been developed, allowing once-daily dosing to enhance adherence and reduce both pill burden and side effects such as tremor and nausea.[55]

Mammalian Target of Rapamycin Inhibitors

Sirolimus (rapamycin) and everolimus bind to the same immunophilin as tacrolimus (FKBP12), although the complexes formed do not interact with calcineurin but instead bind to the regulatory kinase mTOR, which has a critical role in cytokine receptor signal transduction (Fig. 89.6). mTOR activates the ribosomal enzyme p70 S6 kinase and blocks an inhibitory protein 4E-BP1, both of which are required for translation of proteins necessary for progression from the G_1 (growth) phase to the S (DNA synthesis) phase of the cell cycle. Therefore, inhibition of this pathway in T cells blocks the action of cytokines, such as IL-2, IL-4, and IL-15, preventing cell-cycle progression and clonal expansion. mTORi have also been tested in a variety of tumors with modest impact but are under investigation as a "sensitizer" for chemotherapy. In some vascularized cancers, the tumor suppressor gene *PTEN*, which is also a negative regulator of mTOR, loses function, leading to ongoing mTOR activity and tumorigenesis.

Unfortunately, this class has a substantial side-effect profile, including disabling extremity edema, pneumonitis, and dyslipidemia, as well as proteinuria. A recent study using everolimus in place of MPA with CNI demonstrated outcomes that were not inferior to standard immunosuppressive therapy.[56] While these agents are not used commonly in de novo maintenance therapy, they have been studied intently to avoid or minimize CNI. Conversion at 1 to 6 months post-transplant to sirolimus was associated with significantly improved renal function and similar rejection frequency as CsA-based therapy.[57] Another large randomized controlled trial used conversion to everolimus at 4.5 months, but with higher rejection rates, although graft function remained superior on everolimus, regardless of

rejection.[58,59] Late conversion has had mixed results. Practically speaking, for kidney transplantation, these agents are reserved as alternatives when other drugs have side effects and for use in kidney-transplant recipients who have repeated squamous cell cancers of the skin and who are at high risk for cancer recurrence post-transplantation, to mitigate the development of new tumors.[60] Finally, in heart transplantation, these agents are employed to mitigate the development of coronary vasculopathy.[61]

An interesting feature of mTORi therapy is their promotion of Treg generation and survival, as demonstrated in animal models of transplantation with prolonged graft survival.[62] In kidney and liver recipients, de novo mTORi use has also been associated with enhanced Treg development,[63,64] suggesting that mTORi are attractive agents to potentially promote tolerance, discussed subsequently in this chapter.

Desensitization and Antibody-Mediated Rejection Treatments

A major challenge, as noted above, is the development of AbMR. While we avoid preformed DSA prior to transplantation, some patients have such broad sensitization to HLA that it isn't possible to find a donor that is HLA-compatible. In order to facilitate a transplant, clinicians resort to *desensitization* therapy. While protocols vary and the approaches differ, the agents used here primarily are plasmapheresis to reduce total antibody load coupled with intravenous immune globulin (IVIG). IVIG treatment has broad effects, including anti-idiotypic antibodies to block response on endothelium, as a general anti-inflammatory binding cytokines and chemokines, and, importantly, blocking FcRn and facilitating excretion of anti-HLA antibody by the kidney (see Table 89.1). Rituximab is also used. Unfortunately, neither is FDA-approved, but they are used in humans based on substantial preclinical and mechanistic data and by consensus.[65]

Another approach to mitigate AbMR in this situation is to disrupt complement activation. Eculizumab, a humanized monoclonal antibody against complement C5 (Fig. 89.5), inhibiting the cleavage into C5a and C5b and thus MAC formation (see Chapter 3), has been utilized to mitigate the injury of AbMR. While the data for its use are limited, two studies in de novo showed that its use in HLA-incompatible transplantation were associated with low rates of AbMR, particularly in deceased-donor transplants,[66] but less significantly in living donor transplants[67] where the control treatment had very low rejection rates as well. Interestingly, eculizumab has no effect on the development of chronic AbMR in sensitized patients with high levels of DSA at the time of transplantation. Hence, eculizumab use is infrequent and typically reserved for resistant AbMR not responding to standard treatments. C1 esterase inhibitors are currently under study in AbMR treatment and mechanistically may be more effective in blocking complement injury more proximally.[68]

Plasma cells, the factories for antibody production, are an important potential target for treatment in AbMR. Several approaches are under investigation that seem promising.[69] Proteasome inhibitors bortezomib and carfilzomib, FDA-approved for treatment of multiple myeloma, function by inhibiting the 26 S proteasome, disrupting ubiquitination and protein degradation, ultimately disrupting the cell cycle and leading to cell apoptosis (see Table 89.1). Both bortezomib and carfilzomib have been successful in desensitizing KTRs but with rebound of antibody levels weeks after treatment. This allows engraftment without early rejection, but there is a return of DSA associated with later rejection. They have also been used in lung and heart allograft desensitization, in which bortezomib may be more effective. When used for late AbMR, bortezomib was not successful in reducing DSA levels or improving renal function, and was associated with significantly reduced DSA levels but could not mitigate late injury and was associated with hematologic, cardiac, and neurologic side effects, limiting its use.[70] Finally, promising preclinical work using novel combinations of proteasome inhibitor with anti-CD40 or with belatacept has been applied to patients, in sensitized heart[71] and kidney transplant candidates.[72] These studies demonstrate the ability to reduce HLA antibodies in the host, facilitate the transplant, and mitigate the development of AbMR when used in combination targeting both plasma cells and T-follicular helper cell/B-cell costimulation and activation that leads to AbMR. Other approaches that affect plasma cells include anti-CD38 antibody (daratumumab, isatuximab), which in preliminary studies decreases DSA in heart allograft rejection and targets IL-6, a proinflammatory cytokine produced by plasma cells either by neutralizing antibody or by blocking the IL-6 receptor.[69]

As another means to aggressively remove HLA antibodies in highly sensitized patients to facilitate transplantation, recent reports have utilized a novel agent IdeS (imlifidase). IdeS is an endopeptidase derived from *Streptococcus pyogenes* that has specificity for human IgG, and when infused intravenously results in the rapid cleavage of immunoglobulin. There have been several small studies in KTRs who were not transplantable due to high levels and broad specificity of HLA antibodies and were treated within 24 hours of transplantation. Treatment was associated with a dramatic drop in HLA antibody load, allowing transplantation[73,74] although AbMR occurred in 10 of 25 patients with only 1 graft loss. This approach was used for deceased donors as well as living donors because therapy can be given so proximally to the transplant and antibody loss is so comprehensive. Larger studies are underway to determine if this is a generalizable approach.

TOLERANCE

With organ grafts succumbing over time to graft loss due to immune-mediated injury, and the overall toxicity of chronic immunosuppression, numerous investigators have attempted to develop treatments that lead to donor specific hyporesponsiveness (i.e., tolerance) while maintaining an intact immune response for pathogens. In 1953, Billingham and co-workers first introduced the term *transplantation tolerance*, with the report that inoculation of fetal mice with lymphoid cells from an allogeneic adult donor mouse of a different strain led to later acceptance of skin grafts from the original skin graft donors. This work resulted in the Nobel Prize for Medicine in 1960.

The mechanisms of tolerance include deletion, anergy, immune regulation, clonal exhaustion, and ignorance and are discussed in detail in Chapter 10. The clinical approaches have leveraged our understanding of these fundamental mechanisms.[75] When an SOT recipient exhibits a well-functioning graft and lacks histologic signs of rejection after receiving no immunosuppression for at least 1 year, they have achieved *operational tolerance* (OT).[76] Importantly, these patients must also be capable of responding to other non–transplantation-related immune challenges, including infections and vaccinations. Over recent years, experimental models have shown that it is possible to exploit the processes by which immune homeostasis and tolerance

to self-antigens are maintained to induce tolerance to alloantigen. The optimal outcome for patients after transplantation would be the harnessing of these mechanisms to induce specific immunologic unresponsiveness or tolerance to the graft, thus avoiding the adverse side effects associated with current immunosuppressive regimens (see Table 89.1).

While ideal, OT in humans is extremely difficult to induce intentionally and has only been identified in a subset of transplant recipients. While rodent models have had success, translation into NHPs and humans has been more difficult. Another challenge is the lack of definitive laboratory parameters that give a clear indication of whether a particular recipient is tolerant of his or her graft. Furthermore, OT appears to be organ dependent. For example, recipients of a liver transplant have an advantage in developing OT because of the immune-privileged status of the liver. In humans, several studies demonstrate that a permanent and stable immunosuppressive-free state can be safely attempted and sometimes achieved in patients who have received a liver transplant.[77] However, OT has not been reported after intestinal, islet, or whole-organ pancreas transplantation, whereas two exceptional cases of OT have been described after lung and heart transplantations.[78] There have been more reports of late with cases in renal transplantation, based on wide nationwide surveys.[79,80] Important questions in studying these populations are the biologic signatures or biomarkers of OT.[79] The potential of these biomarkers goes beyond simply identifying potential individuals that may be "susceptible" to OT for immunosuppressive withdrawal. Some are assays assessing antigen-specific responses but are challenging, requiring abundant cellular material from both donor and recipient. A molecular approach seems to have the most interest, with a goal of a gene expression profile in peripheral blood with non–antigen-specific transcripts that correlate to outcome. Such a molecular profile or signature overcomes the complexity of a system with practically infinite individual cell combinations.

KEY CONCEPTS

Barriers to Transplantation Tolerance

- T-cell memory
  - Presensitization—direct exposure to alloantigen (e.g., pregnancy or blood transfusion).
  - Heterologous immunity—cross-reactivity in the T-cell repertoire among antiviral, antibacterial, environmental, and transplantation antigens.
  - Homeostatic proliferation—induced by lymphocyte-depleting antibodies (i.e., alemtuzumab).
  - Memory T cells generated by the above mechanisms—can result in rapidly formed effector immune responses upon rechallenge. These T cells are less sensitive to T-cell-depleting antibodies and costimulatory blockade. and thus may be more resistant to some tolerance induction strategies.
- B-cell response
  - Recipients treated with lymphocyte-depleting antibodies display a general increase in the naïve B-cell population.
  - There is a prevalent development of alloantibody in recipients treated with depleting antibody therapy.
  - Much focus of tolerogenic strategies is on the T-cell response. However, recent data suggest that the humoral immune system may play a more significant role than previously thought, possibly contributing to more long-term outcomes. Further work in this area continues.
- Lack of tolerance signature
  - An episode of acute rejection can severely affect graft survival in most transplanted organs.
  - There is absence of validated biomarkers of tolerance or predictors of rejection.
  - It is clinically difficult to often justify high-risk tolerizing strategies in patients who would otherwise do moderately well with standard immunosuppression.

Clinical Protocols in Tolerance Induction

Molecule-Based Protocols

One of the earliest attempts at OT was the administration of presumed tolerogenic induction therapy, followed by immunosuppressive withdrawal. As noted above in the immunosuppression section, the initial use of alemtuzumab in human recipients of kidney transplants with reduction in maintenance immunosuppression is defined as "prope," or near tolerance.[81,82] Complete withdrawal of immunosuppression has not been successful and even with modification of maintenance therapy to include mTORi, late AbMR has been noted. At best, reduction of baseline immunosuppression has been achieved with extremely close follow-up, making them impractical in kidney transplant programs that are high-volume and involve sensitized recipients. Moreover, it is now apparent that leukocyte depletion is not accompanied by a permanent and complete deletion of alloaggressive donor-reactive cells, and the establishment of a regulatory network is required to maintain tolerance. In contrast, numerous studies in liver transplant recipients have occurred with an overall tolerance rate of about 20% to 30% of the study population.[77] These results are dependent on the tolerogenic nature of the liver, the age of recipient, maintenance immunosuppression, and cause of liver disease, whether metabolic or immunologic/infectious.[76]

Full Chimerism

The more robust experimental strategies for the induction of tolerance to foreign antigen utilize the mechanisms of central deletion to eliminate T-cell clones with specificity for the foreign antigens in question, thereby preventing them from entering the periphery. The establishment of hematopoietic chimerism, through bone marrow transplantation, can reliably achieve this. Stable engraftment of donor HSCs results in repopulation of the recipient thymus with donor-type thymic DCs, and T cells with anti-donor specificity are deleted by negative selection.

Full chimerism requires the ablation of the recipient's immune system with high-dose radiation and/or chemotherapy. Alternatively, nonablative conditioning regimens may be used, followed by the infusion of donor's marrow to colonize the recipient completely. This phenomenon paves the way for the onset of tolerance in the case of a subsequent SOT from the same donor.[83] As proof of concept, numerous patients have undergone successful bone marrow transplant (BMT) for hematologic malignancy indications and have subsequently been successfully transplanted with a kidney from the same donor, without the requirement for increased immunosuppression.[84] It is important to highlight that in all these cases, the use of BMT was justified on the basis of the need for treatment of hematologic malignancies.

An alternative approach to achieving full chimerism in HLA-*mis*matched unrelated stem cell/renal transplant human recipients involves infusing a cell product enriched for tolerogenic graft facilitating cells (FCs) as well as HSCs and T cells ("FCRx") rather than just bone marrow graft alone.[85,86] These bone mar-

row–derived FCs, which are $CD8^+$ but do not express a TCR, potently enhance engraftment of allogeneic HSCs in conditioned recipients. FCs are composed predominantly of a plasmacytoid precursor DC subpopulation, induce the generation of antigen-specific Treg in vitro and in vivo, and have been found to effectively prevent graft-versus-host disease (GvHD) in mice. Initial studies have demonstrated macrochimerism with no incidence of GvHD or engraftment syndrome in a small number of patients, and were immunosuppression-free—that is, these patients were clinically operationally tolerant. In vitro studies indicated that chimeric donor lymphocytes were tolerized to the recipient, with a significant increase in the CD4 Treg/T-effector cell population ratio observed in these patients when compared with those who had lost chimerism. This approach to establish high levels of donor multilineage chimerism has exciting therapeutic implications for disorders for which HSC transplantation can provide a "functional cure," including inherited metabolic disorders, hemoglobinopathies, and autoimmune disease, as well as in SOT. Longer-term follow-up data on these initial patients as well as data from a phase 3 clinical trial are anticipated.

Mixed Chimerism

Another promising approach is the induction of mixed hematopoietic chimerism, which can be achieved in experimental models and clinical settings using nonmyeloablative conditioning regimens with far less toxic induction therapy.[87] Examples include either a combination of depleting anti-CD4 and anti-CD8 antibodies together with mild, nonmyeloablative total body irradiation or costimulatory blockade with anti-CD154 and/or CTLA4Ig. When these induction protocols are followed by BMT, the result is mixed chimerism, meaning the continued survival of both donor and recipient hematopoietic progenitor cells. In mouse and NHP models that have undergone these therapies, there is durable tolerance to donor-type allografts, which have a much lower incidence of GvHD compared with full chimeras; similar results have been demonstrated in early studies in human recipients as well.

Regulatory T Cells

Treg have the capability of suppressing immune responses and are thus a focus in transplantation to mitigate alloantigen responses and/or induce tolerance. As discussed in Chapter 13, Treg may exist as thymic-derived naturally occurring $CD25^+CD4^+$ cells (tTreg) or induced Treg (iTreg) that are either differentiated from $CD25^-CD4^+$ nonregulatory cells or expanded from $CD25^+CD4^+$ cells in response to antigen. Both tTreg and iTreg have been demonstrated to play important roles in transplant tolerance.[88] Expression of the transcription factor FOXP3 is essential for the development and function of Treg. However, tTreg and iTreg differ in origin, antigen experience, methylation patterns of FOXP3, and suppressive mechanisms. Unlike mice, FOXP3 in humans is also expressed transiently by activated non-regulatory T cells that also upregulate CD25 expression. Thus, not all $CD25^+FOXP3^+CD4^+$ cells will be genuine human Treg, and so isolation strategies based on $CD25^{hi}CD4^+$ are likely to be imperfect. In humans, $CD127^{lo}CD25^+CD4^+$ T cells are characterized by a higher level of FOXP3 expression and a more pronounced suppressive capacity.[88,89]

Strategies exist for both in vivo or ex vivo generation and/or expansion of Treg. The most common ex vivo approach is based on stimulation with anti-CD3 and anti-CD28 beads in the presence of high concentrations of IL-2, which stimulates proliferation sometimes with rapamycin (mTORi) present.[90,91] Importantly, ex vivo–expanded $CD25^{hi}CD4^+$ and $CD127^{lo}CD25^+CD4^+$ Treg are effective at inhibiting vasculopathy seen in late allograft rejection in a humanized mouse model, whereas $CD127^{lo}CD25^+CD4^+$ T cells are five times more efficient than those not expressing a low level of CD127.[62] In humans, infusion was well tolerated and in some cases reduced intragraft inflammation. Despite the generation of sufficient numbers of Treg for cellular therapy, this mode of expansion is *antigen nonspecific*, without any enrichment steps for the cells of interest.

Donor-antigen-specific Treg are more appealing for clinical application in transplantation, as they may be more potent on a cell-per-cell basis at controlling allograft rejection. Here, exposure to antigen may either expand tTreg or induce the generation of iTreg from cells that do not originally possess regulatory activity. Results from the ONE study consortium of six nonrandomized trials across multiple transplant centers included 104 patients receiving Treg, DCs, or macrophages with an overall rejection rate of 16%, as compared to 12% in standard therapy patients. Forty percent of treated subjects tolerated weaning to tacrolimus alone,[92] demonstrating the safety of regulatory-cell adoptive transfer. Treg therapy in liver transplant recipients resulted in reduced anti-donor T-cell responses post-transplantation.[93] However, questions remain regarding such therapy, including stability and plasticity of such cells, migration patterns, and optimal maintenance immunosuppressive therapy.

Finally, typical immunosuppressive therapy may affect Treg function in vivo. CNIs, in particular cyclosporine, are detrimental to Treg expansion and growth, whereas the mTORi rapamycin appears to be beneficial to Treg in terms of both in vivo generation and function in mouse models and in vitro cultures of human Treg.

There are other cell-based therapies being investigated for their tolerogenic potentials. It should be stressed that these studies have been conducted in limited numbers of patients and include mesenchymal stromal cells (MSCs)[94] and regulatory macrophages to facilitate immunosuppression minimization as well as regulate inflammation in other inflammatory conditions.

Biomarkers of Rejection or Tolerance

A major challenge in the field of transplantation is the ability to determine the sufficiency of immunosuppression in each transplant recipient and provide a more personalized approach to care. Current methods for care include monitoring trough drug levels and assessment for viral infections. Even so, recipients may still develop infection or rejection even when they appear to be adherent to their regimen. Moreover, there is new recognition that inflammation in the transplant may occur prior to functional changes, and this "subclinical" inflammation leads to late graft loss. As functional changes reflect clinical inflammation, surveillance biopsies may be employed, both in the kidney and heart allografts, to detect inflammation. These are costly, invasive, and have complications. Hence, the ability to noninvasively determine the immune status of the recipient, predict and/or diagnose rejection, and detect tolerance would allow for individualized immunosuppressive therapy.[95]

Technical advances in multiparameter flow cytometry, antigen-specific lymphocyte assays, and genome-wide analyses have led to the development of powerful and more standardized

techniques to characterize alloimmune responses. Gene expression profiles in peripheral blood have been a critical focus for detecting transplant tolerance[80] or detecting rejection,[96] with the latter achieving commercialization. Gene expression in allograft biopsies has made significant progress creating a "molecular microscope" as an adjunct to the histologic features that suffer from inter-observer variability and limited sample.[97] In plasma, the detection of donor-derived cell-free DNA correlates with organ rejection in heart and kidney allografts[98] and is commercialized for use in the latter.

While these are exciting developments for patient care, and some of these tools are commercialized, there is a need for validation in larger cohorts.[99] None of the referenced assays are FDA-approved for clinical use. Moreover, biomarker qualification for regulatory drug development is an entirely different process, but a recent meeting with leading experts provided some significant guidance for advancing transplant therapeutics.[100]

NEW FRONTIERS IN ORGAN SUPPLY FOR TRANSPLANTATION: XENOTRANSPLANTATION

There remains a critical shortage of solid organs for those patients who would benefit from transplant, and many individuals die waiting to be transplanted. To address this challenge, new strategies in mitigating the shortage are being investigated, including using human immunodeficiency virus (HIV)-positive donor organs into HIV-positive recipients, and using hepatitis C–infected organs that would otherwise be discarded and transplanting into hepatitis C naïve recipients followed by antiviral treatment.[101] An alternative strategy is using animal organs that are genetically manipulated to limit adaptive immune responses for human transplantation, a strategy called xenotransplantation.

Xenotransplantation began in the early 1960s, with studies of kidneys transplanted from NHP into human patients with end-stage kidney disease being met with limited success. In 1985, headlines were made when a baboon heart was transplanted into an infant with a severe congenital heart defect, with fatal rejection. With little success using NHP–human xenotransplantation and concerns of zoonosis, advancements stalled. Current research is focused on enhancing the suitability of pig-organ transplantation for human recipients, primarily through the genetic modification of pigs using NHPs as the recipients most closely matching humans.

The critical barrier for engraftment is the presence of preformed natural antibodies against donor antigens expressed on grafts from other species. For clinical purposes, the most important have been antibodies to galactose-α−1,3-galactose (α-gal). These preformed antibodies are responsible for instances of hyperacute rejection and graft failure in the early xenotransplant experiments involving pig solid organs from genetically *un*modified animals.[102] Further research in pigs, NHPs, and humans has revealed a number of additional immune proteins that play important roles in species–specific host immunologic responses. To enhance the longevity of the pig xenografts, investigators have genetically modified the donor pig in two ways: by reducing complement activation and by deleting GAL. In the former, protective constructs can be introduced into the genome, such as those of human complement regulatory proteins (e.g., hCD59), to dampen the human host complement response to the xenograft. In the latter, deletion of GAL, which is now accomplished more easily than homologous recombination using CRISPR-Cas9 technology, can prevent a destructive host response.[103] Coupled with treatment with anti-CD154 antibody and standard immunosuppressive agents, survival can be extended beyond a few days to months in heart and kidney xenotransplants. Given the progress in this area, it has been speculated that a clinical trial in xenotransplantation is anticipated within the next few years.[104] This will require optimization of immunosuppressive therapy and assessment of the presence of human recipient anti-HLA antibodies, which may cross-react with swine leukocyte antigens to design the compatible pig organ.

ON THE HORIZON

- Clinical introduction of antigen-specific regulatory T-cell therapy for tolerance induction
- Implementation of biomarker monitoring of allografts for subclinical immune-mediated injury
- Development of pig organs for the first pig-to-man kidney xenotransplant
- Identification of safe and effective treatments for antibody-mediated rejection

Allogeneic Transplantation for Immunodeficiency

Sung-Yun Pai

Following the discovery of the major human leukocyte antigens (HLA) in 1958, hematopoietic stem cell transplantation (HSCT) became a widespread treatment for a variety of congenital and acquired disorders. The cure of an infant with severe combined immunodeficiency (SCID) in 1968 was the first successful experience in HSCT, marking the beginning of a new era in medicine. Shortly thereafter, success was achieved also with HSCT in a child with Wiskott-Aldrich syndrome (WAS).

For many years, the successful use of HSCT in severe primary immune deficiency (PID) was largely restricted to transplantation from HLA-matched sibling donors (MSD), as HSCT from mismatched related family donors (MMRDs), usually haploidentical parents, was followed by severe complications, graft-versus-host disease (GvHD) in particular. In the late 1970s, it was demonstrated in animal models that removal of mature T lymphocytes from the graft obtained from mismatched marrow allowed successful reconstitution upon injection into lethally irradiated recipient animals. This important achievement opened the way to the broader use of HSCT in severe forms of PID. Transplantation of hematopoietic stem cells (HSCs) from adult volunteer matched unrelated donors (MUD), and of umbilical cord blood (UCB), has been increasingly used in individuals with PID. Overall, since 1968, over 2000 transplantations have been performed in patients with PID, most of them in children with SCID.[1,2] The increasing number of transplantations over the years reflects an increased awareness of PID, the broader availability of diagnostic tools (including newborn screening for SCID), improved outcomes as a result of advances in supportive and critical care before and after HSCT, increasingly improved strategies to prevent GvHD, and the greater availability of MUD and UCB for transplantation.

HEMATOPOIETIC STEM CELL TRANSPLANTATION: GENERAL CONSIDERATIONS

Sources of Hematopoietic Stem Cells for Transplantation

HSCs with distinct properties can be retrieved from bone marrow, peripheral blood, or UCB (Table 90.1) (Chapter 2). Bone marrow is the most traditional source and is obtained by multiple small volume (5 to 10 mL) aspirations from along the iliac crests, usually while the donor is under general anesthesia. The volume of marrow obtained is typically 1 L for adults or 10 to 20 mL/kg of the recipient weight. Blood group matching for ABO antigens is not required for HSCT, as mature red blood cells (RBCs) or anti-ABO antibodies can be removed by RBC depletion and plasma depletion, respectively. In the case of HLA-identical transplantation, marrow stem cells are then injected intravenously without further manipulation into the recipient. In the case of mismatched transplantation, bone marrow cells have historically been T-cell depleted *ex vivo*, or *in vivo* administration of cyclophosphamide has been employed to prevent GvHD.

HSCs can also be retrieved from peripheral blood following *in vivo* administration of agents that cause mobilization of stem cells into the peripheral circulation, including granulocyte-colony-stimulating factor (G-CSF) and/or plerixafor. These cytokines are given to the donor typically over 5 days before the harvest of peripheral blood HSCs.

Finally, UCB is another rich source of HSCs. At birth, cord blood is collected in a heparinized medium and stored in liquid nitrogen, with small aliquots preserved for HLA typing. Whenever sufficient compatibility is identified between a patient and stored cord blood, the latter is thawed and injected into the recipient without further manipulation. More recently, *in vitro* expansion of cord blood stem cells, and transplantations with multiple cord blood units, have been used to overcome the limitation of the small volume of cord blood available in the sample.

Donor Selection and Manipulation of the Graft

KEY CONCEPTS

Human Leukocyte Antigen Testing and Matching

- The human leukocyte antigen (HLA) genes, which encode class I and class II major histocompatibility complexes (MHCs), are located in closely linked fashion on chromosome 6. They are inherited as blocks, termed haplotypes, one from each parent.
- HLA genes are inherited in Mendelian fashion. Hence the likelihood of a sibling being fully matched is ~1 in 4. Siblings have a 50% chance of being haploidentical or sharing one haplotype, and a 25% chance of not matching at all. Crossovers within the HLA locus lead to different degrees of matching between siblings.
- HLA class I genes used commonly for typing are HLA-A, HLA-B, and HLA-C, while HLA class II genes are HLA-DRB1, HLA-DQB1, and HLA-DPB1.
- Improved HLA typing has changed the definition of a full match:
  - 6/6 match: matched at both HLA-A, HLA-B, and HLA-DRB1 genes.
  - 8/8 match: matched 6/6 plus both HLA-C genes.
  - 10/10 match: matched 8/8 plus both HLA-DQB1 genes.
  - 12/12 match: matched 10/10 plus both HLA-DPB1 genes.
- Early methods of HLA typing were serological, using antibodies from multiparous women. Current methods employ panels of sequence-specific oligonucleotides or DNA sequencing.
- The greater the degree of HLA mismatch, the higher the chance of both graft rejection and GvHD.

TABLE 90.1 Sources of Hematopoietic Stem Cells for Transplantation

	Bone Marrow	Peripheral Blood Stem Cells	Umbilical Cord Blood
General properties	Used since 1950s Obtained from a postnatal donor	Used since 1980s Obtained from a postnatal donor	Used since 1990s Obtained from newborn umbilical cord
Collection	Bone marrow harvest under general anesthesia	Collection by leukapheresis after administering subcutaneous mobilization agents for 5–6 days	Collection at the time of birth, then cryopreserved
Donor types	Matched related Matched or mismatched unrelated (8–10 of 10) Mismatched related (haploidentical)	Matched related Matched or mismatched unrelated (8–10 of 10) Mismatched related (haploidentical)	Matched related Matched or mismatched unrelated (4–6 of 6)
Infection risk	May transmit bloodborne infections	May transmit bloodborne infections	Practically no risk of transmitting bloodborne infections
Cellular properties	Will contain antigen-specific memory T cells Potent driver of GVHD	Will contain antigen-specific memory T cells Potent driver of GVHD, contains ~1 log more T cells than bone marrow Higher dose of $CD34^+$ cells compared to bone marrow	Little to no antigen-specific memory T cells Less GVHD at a comparable degree of matching ~1 log less nucleated cells and $CD34^+$ cells/kg compared to other sources
Typical minimal cell dose	2×10^8 nucleated cells/kg 2×10^6 $CD34^+$ cells/kg	2×10^8 nucleated cells/kg 2×10^6 $CD34^+$ cells/kg	2.5×10^7 nucleated cells/kg at time of cryopreservation
Median time to neutrophil engraftment	18 days	13 days	23 days
Median time to platelet engraftment	26 days	18 days	60+ days
Additional considerations	May harvest donor repeatedly if needed Volunteer unrelated donor must be willing and pass medical clearance	May harvest donor repeatedly if needed Volunteer unrelated donor must be willing and pass medical clearance	Repeat transplantation from donor is not possible Cells are available immediately frozen Cell dose is usually limiting for adults, may be overcome by using two different donor units Donor is not screened, and could have underlying hematologic or immunologic abnormalities

Hematopoietic Stem Cell Transplantation From a Related Human Leukocyte Antigen–Identical Donor

The use of unfractionated stem cells from an HLA-identical sibling offers the best chance of rapid engraftment and immune reconstitution. In such cases, the HLA-identity between recipient and donor minimizes the risk of GvHD. Furthermore, the mature T cells contained in the graft provide the first line of immune reconstitution after transplantation, as they may expand and lead to a rapid increase in the number of circulating T lymphocytes as early as 2 weeks after HSCT. Engraftment of these mature T cells transplanted with the bone marrow of a matched related donor (MRD) is particularly important in infants with SCID, as it is early evidence of immune reconstitution in a severely immunocompromised host.

Hematopoietic Stem Cell Transplantation From a Haploidentical Donor

Unfortunately, the option of related HLA-identical HSCT is limited to a minority of patients. HSCT from a haploidentical parent was historically the next considered option, particularly in infants with SCID. The rationale for haploidentical HSCT is based on the ability of donor-derived stem cells to repopulate the recipient's vestigial thymus and give rise to fully mature T lymphocytes. Indeed, this is a life-saving procedure that has been successfully applied to several hundreds of infants with SCID.[1,2] However, donor T lymphocytes that would otherwise cause severe GvHD must be eliminated. Several methods are available to attain T-cell depletion.

In the past, the most frequent method was soybean lectin agglutination and E-rosetting. With this method, soybean lectin induced agglutination of the majority of mature marrow cells, which were removed by sedimentation. Further depletion of T lymphocytes was achieved by rosetting with sheep erythrocytes (E-rosetting technique) and density gradient centrifugation. Importantly, T-cell depletion by soybean lectin agglutination and E-rosetting maintains all immature marrow cells in the final preparation. T-cell depletion can also be achieved by incubation of bone marrow with monoclonal antibodies (mAbs) to T lymphocytes plus complement. Campath-1 G, Leu 1, and other mAbs have been used for this purpose, but the degree of T-cell depletion that is achieved with these agents is less complete than with the soybean lectin and E-rosetting, and therefore a higher incidence of GvHD has been reported.

A major advance in graft processing occurred with the development of devices that used antibodies and magnetic beads to positively or negatively select cells of interest. T-cell depletion by graft manipulation is now most frequently achieved either by (1) positive selection of $CD34^+$ cells, enriching for HSC and very immature progenitors, or (2) negative selection of T cells. For $CD34^+$ selection, the CliniMACS device (Miltenyi) employs mAb against CD34 that are directly conjugated to magnetic beads; after binding the anti-CD34 magnetic bead/cell conjugate, release of the magnetic force releases the cells. The CliniMACS device, in general, leads to more efficient and consistent T-cell depletion, often to $<10^4$ $CD3^+$ T cells/kg of recipient

weight. This device is widely used beyond its labeled indication of adults with acute myelogenous leukemia (AML) undergoing MSD transplant, through a humanitarian device exemption. This extremely robust method of T-cell depletion also removes $CD34^-$ progenitors, and other cells (especially stromal marrow cells) that can facilitate stem cell engraftment.

Negative selection of T cells has also been used to preserve progenitors that support short-term engraftment, early post-transplant, and other cells, such as natural killer (NK) cells, that facilitate engraftment and/or improve control of disease in patients with hematologic malignancy. In addition to depletion of $CD3^+$ T cells, more recently, depletion of cells bearing αβ T-cell receptors (TCR) has been increasingly used with success in many PID, including SCID.[3] Agents such as the anti-B cell antibody CD19 can be added to deplete B cells, thereby reducing transmission of Epstein-Barr virus (EBV).

The T-cell depletion methods described above can be very effective at preventing GvHD but come with consequences, including increase in the risk of graft rejection, slowing immune reconstitution, and leaving patients vulnerable to severe viral infections post-transplant. Post-transplant cyclophosphamide (PTCy) has emerged recently as a technique to deplete donor T cells *in vivo* after infusion of unmanipulated haploidentical marrow or peripheral blood stem cells (PBSC). PTCy is typically given on days +3 and +4 at 50 mg/kg. In principle, mature T cells from the donor that are contained within the graft and are directed against recipient alloantigens will vigorously proliferate and be most susceptible to the action of PTCy. The increasing use of PTCy has been fueled by its low cost, particularly in resource-poor areas where the depletion technology and machinery are not available.

Hematopoietic Stem Cell Transplantation From Matched Unrelated Donors

HSCT from MUD has been increasingly used to treat severe PID since 1977. Transplantation from MUD has been facilitated by the increasing number of volunteer donors included in registries worldwide and advances in the techniques for HLA typing, which permit the identification of an optimal MUD and reduction in the risk of GvHD. As of February 2021, more than 38 million donor volunteers and UCB units were included in the World Marrow Donor Association registry. At present, it takes only a few weeks to identify a MUD. However, the probability of finding a suitable donor is lower for ethnic or racial groups that have extreme polymorphism of haplotypes, such as those of African ancestry, or are from populations poorly represented among volunteer donors.

Hematopoietic Stem Cell Transplantation Using Unmanipulated Cord Blood

As opposed to MUD HSCT, which requires identification, willingness, and medical clearance of an adult volunteer, stored cord blood is readily available as a source of stem cells for transplantation. In addition, the risk of GvHD at any given degree of HLA matching is lower when using cord blood, compared with MUD HSCT, so that greater HLA disparity with the recipient can be tolerated. However, the number of cells in a unit is still a major limitation of cord blood. Low cell dose is not usually a problem for HSCT performed in infants because of the low weight of the recipient. Indeed, unrelated UCB transplantation has been successfully used in hundreds of patients with severe PID.[4] In practice, an unrelated HSC donor should be simultaneously sought in cord blood banks and bone marrow donor registries for patients lacking an HLA-identical sibling HSC donor. The option of performing UCB transplants should be based on urgency of the transplantation, the cell dose required, and the number of HLA disparities. Outcomes of transplant for nonmalignant disease for overall survival, graft rejection, and acute GvHD are better with UCB with mismatches at two or more HLA alleles than with MUD with a full match or one allele mismatch.[4]

Principles of Conditioning and Effect on Hematopoietic and Immune Reconstitution

Before HSCT for all malignant and nonmalignant disorders other than SCID, administration of agents to prevent immune-mediated graft rejection and promote engraftment of donor HSC are required (Table 90.2). This pre-HSCT treatment, or 'conditioning,' prevents immunological rejection using agents that target T cells and/or NK cells, and provides 'space' for donor HSC to engraft using agents that damage or kill recipient HSC. Some agents achieve more than one purpose, such as high-dose total body irradiation (1200 to 1400 cGy), which in the case of acute lymphoblastic leukemia has long been favored to eliminate leukemia from sanctuary sites, such as the testes or the central nervous system.

The backbone of conditioning for PIDs other than SCID was historically high-dose busulfan as a stem-cell-directed agent and cyclophosphamide as an immune-cell-directed agent (Bu/Cy). Other alkylating agents that target HSC include melphalan, thiotepa, and treosulfan, the latter approved only in Europe as of 2021. Fludarabine, a nucleoside analog, has now largely replaced cyclophosphamide and generally leads to less organ toxicity than regimens with more than one alkylating agent. Antibodies that deplete immune cells, termed serotherapy, such as anti-thymocyte globulin or alemtuzumab, and low-dose total body irradiation (TBI) (200 to 400 cGy) are also effective for depleting T cells. The likelihood of graft rejection is increased when there is greater HLA disparity (related vs. unrelated donors, matched vs. mismatched donors), pre-sensitization of the host to donor antigens (*e.g.*, through blood transfusions), and when the graft has been depleted of donor T cells. It must be noted, however, that serotherapy agents, due to their long half-life, do not act solely on recipient T cells; if not fully consumed by the time of HSC infusion, these agents will also act on T cells contained within the donor graft. In contrast, TBI has effects only on recipient cells.

Bu/Cy is a typical myeloablative conditioning (MAC) regimen, in that hematopoiesis will not recover unless stem cells are infused. Individualized pharmacokinetic monitoring and adjustment of busulfan dose to achieve a desired area-under-the-curve (AUC) exposure is now standard clinical practice. Reduced toxicity and reduced intensity conditioning (RIC) regimens may employ a lower AUC target of busulfan or other alkylating

TABLE 90.2 Agents Used for Conditioning

Myeloablation	Lymphoablation
Busulfan (may use pharmacokinetic adjustment to achieve a given exposure)	Cyclophosphamide
Melphalan	Fludarabine
Treosulfan	Anti-thymocyte globulin
High-dose total body irradiation (1200–1400 cGy)	Alemtuzumab
Thiotepa	Pentostatin
	Low- or high-dose total body irradiation (as little as 200–400 cGy)

TABLE 90.3 Classification of Common Conditioning Regimens

Myeloablative (MAC)	Busulfan (16 mg/kg or adjust to cAUC 50–70) Cyclophosphamide (200 mg/kg) TBI 1200–1400 cGy Cyclophosphamide or fludarabine or other agents
Reduced toxicity (RTC)	Busulfan (adjust to cAUC 80–90) Fludarabine (120–180 mg/m²) Treosulfan Cyclophosphamide Treosulfan Fludarabine
Reduced intensity (RIC)	Busulfan (adjust to cAUC 45–65) Fludarabine (120–180 mg/m²) +/– anti-thymocyte globulin or alemtuzumab Fludarabine (120–180 mg/m²) Melphalan (100–140 mg/m²) Anti-thymocyte globulin or alemtuzumab
Immunosuppression alone (Minimal intensity)	Fludarabine Cyclophosphamide Anti-thymocyte globulin or alemtuzumab TBI 200 cGy Fludarabine Anti-thymocyte globulin or alemtuzumab

AUC, Area-under-the-curve; *TBI*, total body irradiation.

TABLE 90.4 Measurement of Busulfan Exposure in Different Units

Target Cumulative Exposure (cAUC)	Schedule	Target Range Per Dose: μM × min	Target Range Per Dose: Css ng × min/L
80–90 mg × h/L	Every 6 h × 4 days	~1200–1400	~850–950
	Every 12 h × 4 days	~2400–2800	~850–950
	Daily × 4 days	~4900–5500	~850–950
45–65 mg × h/L	Every 6 h × 4 days	~700–1000	~450–700
	Every 12 h × 4 days	~1400–2000	~450–700
	Daily × 4 days	~2800–4000	~450–700
20–30 mg × h/L	Daily × 2 days	~2400–3600	~400–650

AUC, Area-under-the-curve.

agents thought to be milder than busulfan. RIC regimens are expected, at least some of the time, to result in a mixture of donor and recipient cells, termed mixed chimerism, and autologous recovery after RIC is possible without stem cell infusion. Typical regimens, associated AUC targets, and range of exposure per dose in different units are given in Tables 90.3 and 90.4.

The profound absence of T-cell development and function in patients with SCID makes them unable to reject an allogeneic graft, allowing HSCT to be performed in the absence of conditioning to eliminate host T cells and NK cells. Successful reconstitution of T cells depends on the engraftment of HSC and progenitors in the thymus, leading to sustained neogenesis of T donor-derived cells. After MAC or RIC, donor-derived HSCs engraft in the bone marrow, typically replacing all hematopoietic cells with donor-derived cells; a state termed full-donor chimerism (Fig. 90.1). In contrast, HSCT without conditioning in SCID patients leads to minimal to no HSC engraftment in the bone marrow. While T cells generated in the thymus are donor-derived, all other cells arising from HSC in the bone marrow (B cells, NK cells, neutrophils, monocytes, RBCs, platelets) are recipient-derived; a state termed split chimerism (see Fig. 90.1).

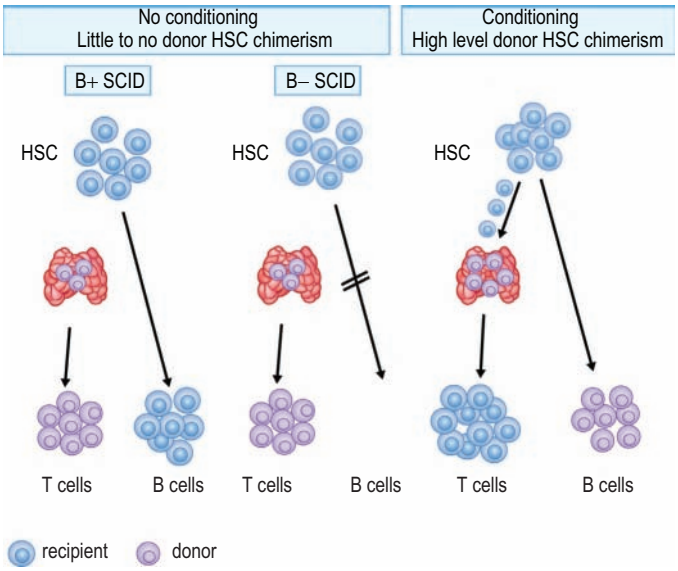

FIG. 90.1 T-cell and B-cell donor chimerism after hematopoietic stem cell *(HSC)* transplantation with or without conditioning in patients with severe combined immunodeficiency *(SCID)*. (With permission from Fig. 1 from Pai S-Y. Treatment of primary immunodeficiency with allogeneic transplant and gene therapy. *Hematology*. 2019;2019[1]:457–465.)

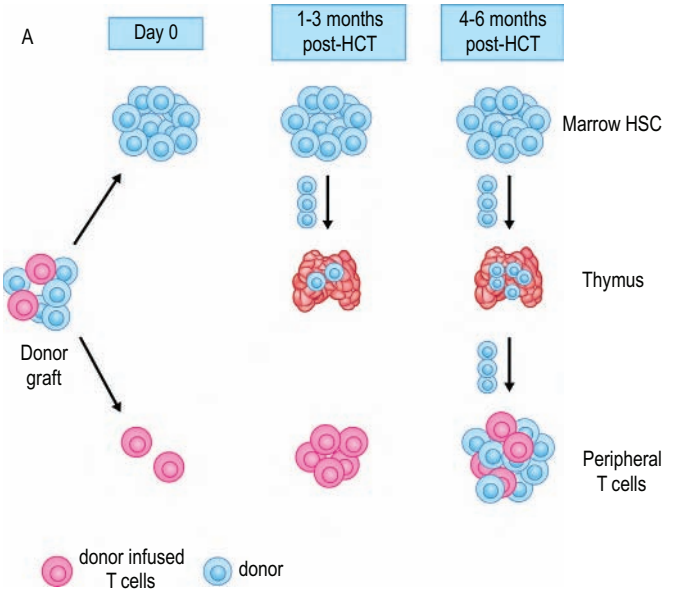

FIG. 90.2 Kinetics of extrathymic versus thymic reconstitution of donor-derived T cells post-hematopoietic cell transplantation *(HCT)*. *HSC*, Hematopoietic stem cell. (With permission from Fig. 2A from Pai S-Y. Treatment of primary immunodeficiency with allogeneic transplant and gene therapy. *Hematology*. 2019;2019[1]:457–465.)

The kinetics of T-cell reconstitution proceeds in two phases, a thymus-independent phase, followed by a thymus-dependent phase (Fig. 90.2). When the graft is first infused, mature T cells

contained in the graft expand, driven by the lymphopenia of the host and cytokines such as IL-7. This occurs over the first 1 to 3 months after HSCT, and it is these donor-derived allogeneic T cells that may spark GvHD. Donor-derived progenitors developing in the thymus meanwhile give rise to naïve T cells, which are selected to be tolerant of the host thymic epithelium. This process takes much longer, 4 to 6 months, and may be impeded due to age, or medication-related damage to thymic epithelium.

KEY CONCEPTS

Principles of Conditioning

- Currently, agents used to target recipient HSCs are either alkylating agents or irradiation (see Table 90.2). As such, these agents cause DNA damage to non-hematopoietic tissues, leading to acute toxicities such as mucositis and veno-occlusive disease of the liver.
- Potential long-term effects of alkylating agents and irradiation are also related to DNA damage and include decreased final height, hypothyroidism, delayed puberty due to hypogonadism, infertility (low sperm count in boys, premature ovarian failure in girls), learning problems, and secondary malignancies (typically myelodysplastic syndrome or soft tissue or bony tumors).
- Cyclophosphamide, an alkylating agent, was the most commonly used immunosuppressive agent for the prevention of rejection. More recently, several other agents, that are not alkylating agents, may be used, which should have fewer long-term toxicities.
- The composition of the conditioning regimen, in general, must be adjusted to the donor type because of the role of donor T cells in promoting engraftment. The immunologic activity of the donor T cells against recipient T cells and recipient marrow facilitates engraftment. If the graft is T-cell depleted, as is commonly done for MMRD haploidentical HSCT, more immunosuppression must be included to prevent recipient T cells from rejecting the graft.
- Agents such as anti-thymocyte globulin (ATG) and alemtuzumab are antibodies that target T cells and/or other lymphocytes. These agents have a half-life of weeks, with variable clearance depending on the lymphocyte content in the host. Even when given before transplant, these agents may be circulating in sufficient quantity to have effects on donor T cells infused with the graft. The dosing and timing are thus critical to control the effect of these agents as intended.

Complications of Hematopoietic Stem Cell Transplantation

A variety of complications can compromise the success of HSCT. Incompatibility between donor and recipient can lead to graft rejection by the host immune system or GvHD caused by alloreactivity of donor-derived lymphocytes to the recipient's cells. Conditioning regimens can cause the toxicity of several organs. The frequency and severity of these complications depend on the type of donor, the type and intensity of the conditioning regimen, specific considerations related to the underlying disorder, and to the clinical status of the recipient before transplantation.

Acute Graft-Versus-Host Disease

Acute GvHD (aGvHD) is the result of alloreactivity of donor-derived T lymphocytes against the recipient's antigens and is one of the most severe complications of HSCT. It may occur as early as 1 week after HSCT and is potentially fatal. Clinical manifestations of a GvHD include maculopapular skin rash (that tends to be confluent), diarrhea, and liver abnormalities (hepatomegaly, elevated liver enzymes, increased levels of conjugated bilirubin).[5] The disease may progress to severe skin manifestations with exfoliative dermatitis and significant liver and gut damage (with intractable watery or bloody diarrhea, protein-losing enteropathy, and abdominal pain). Bone marrow aplasia and high susceptibility to infections are also often observed in severe aGvHD.

TABLE 90.5 Staging and Grading of Acute Graft-Versus-Host Disease

Stage	Skin	Liver (Bilirubin)	Gastrointestinal System (Stool Output)
0	None	<2 mg/dL	Adult: <500 mL/day Child: <10 mL/kg/day
1	Rash <25% BSA	2–3 mg/dL	Adult: 500–999 mL/day Child: 10–19.9 mL/kg/day or persistent nausea, vomiting, or anorexia, with a positive upper GI biopsy
2	Rash 25%–50% BSA	3–6 mg/dL	Adult: 1000–1500 mL/day Child: 20–30 mL/kg/day
3	Rash >50% BSA (generalized erythroderma)	6.1–15 mg/dL	Adult: >1500 mL/day Child: >30 mL/kg/day
4	Generalized erythroderma with bullous formation	>15 mg/dL	Severe abdominal pain with or without ileus

Grade	
Grade 0	No stage 1–4 of any organ
Grade 1:	Stage 1 or 2 skin involvement; no liver or gut involvement
Grade 2:	Stage 1–3 skin involvement; Grade 1 liver or gut involvement
Grade 3:	Stage 2 or 3 skin involvement
Grade 4:	Stage 1–4 skin involvement; stage 2–4 liver or gut involvement

The severity of aGvHD is evaluated according to a grading scale (Table 90.5). Major risk factors for aGvHD include HLA-mismatch between donor and recipient, older age of the recipient or donor, gender mismatch, and stem cell source.[5] However, aGvHD may also be observed following related HLA-identical HSCT, particularly when a conditioning regimen is used.

Finally, transfusion-associated aGvHD is a very severe complication after HSCT, which can be effectively prevented by using irradiated (1500 to 3000 rad) and filtered blood derivatives.

Chronic Graft-Versus-Host Disease

Chronic GvHD (cGvHD) has traditionally been defined as symptoms that persist or appear 100 days after transplantation. cGvHD is better defined by its distinct clinical manifestations rather than the time of onset alone.[6] These clinical manifestations include skin changes (scleroderma-like lesions, hyperpigmentation, hyperkeratosis, skin atrophy, ulcerations), tissue fibrosis and limitation of joint mobility, fibrosis of exocrine glands ("sicca syndrome"), fibrosis of lungs and liver, increased susceptibility to infections, immune dysregulation, and autoimmunity. Consequently, cGvHD may have a major effect on quality of life and can be fatal. Although the incidence of cGvHD is lower in children than in adults treated by allogeneic HSCT, the risk factors and the spectrum of clinical manifestations are similar.

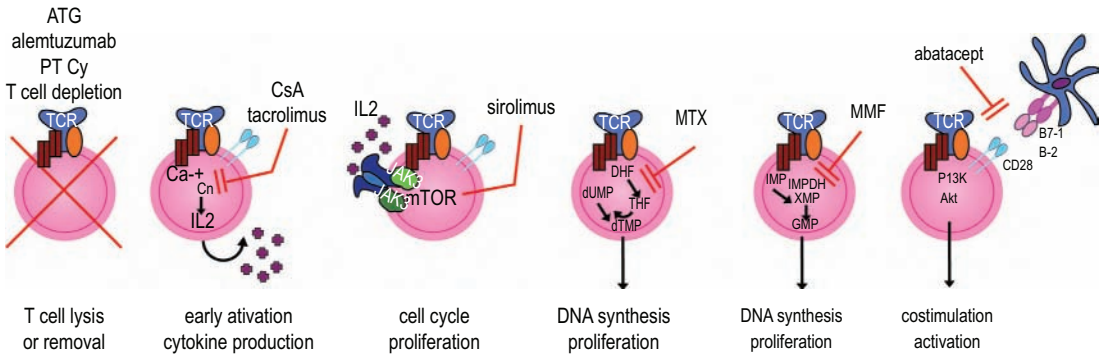

FIG. 90.3 Mechanism of action of medications or manipulations commonly used for graft-versus-host disease *(GvHD)* prophylaxis. Agents such as anti-thymocyte globulin *(ATG)*, alemtuzumab, post-transplant cyclophosphamide *(PTCy)*, or graft manipulation via T-cell depletion eliminate T cells by lysis or removal. Cyclosporine A *(CsA)* and tacrolimus inhibit calcineurin *(Cn)* a calcium (Ca^{2+})-dependent phosphatase triggered by T-cell receptor *(TCR)* stimulation by antigen, leading to elaboration of early cytokines including interleukin-2 *(IL2)*. Sirolimus inhibits mammalian target of rapamycin *(mTOR)*, a key signaling molecule downstream of cytokine receptors including the IL2 receptor which signals via Janus kinases 1 and 3 (JAK1, JAK3) to induce cell cycle entry and proliferation. Methotrexate *(MTX)* inhibits dihydrofolate reductase, which catalyzes the conversion of dihydrofolate *(DHF)* to tetrahydrofolate *(THF)*. Conversion of THF back to DHF by thymidylate synthase catalyzes the conversion of deoxyuridine monophosphate *(dUMP)* to deoxythymidine monophosphate *(dTMP)* needed for DNA synthesis and cell proliferation. Mycophenolate mofetil *(MMF)* inhibits inosine monophosphate dehydrogenase *(IMPDH)*, which catalyzes the conversion of inosine monophosphate *(IMP)* to xanthine monophosphate *(XMP)*, a key step in generating guanosine monophosphate *(GMP)* needed for DNA synthesis and cell proliferation. Abatacept is a fusion of CTLA4 with immunoglobulin that binds B7-1 and B7-2, ligands for CD28, whose engagement costimulates T cells triggered by antigen binding to the TCR and leads to T-cell activation.

Acute GvHD represents a major risk factor for cGvHD, yet cGvHD can be observed even without preceding aGvHD, and when present, it does not represent merely the continuation of aGvHD. The use of peripheral blood stem cells carries an increased risk of cGvHD compared with the use of bone marrow stem cells.

Prevention of GvHD

Prevention is the most effective approach to GvHD; the mechanism of action of agents commonly used for prevention and/or treatment of GvHD largely targets T cells (Fig. 90.3). Use of a fully matched donor remains the best, though not assured, method of prevention, but of course, it is not available to most patients. If a related HLA-mismatched donor is used for transplantation, vigorous T-cell depletion must be performed either *ex vivo* (using graft manipulation) or *in vivo* (using PTCy). Whenever a conditioning regimen is used in the transplantation protocol, pharmacological prophylaxis of GvHD must also be included, even in the case of HSCT from a related HLA-identical donor.

Long-standing approaches to prevention of GvHD include the use of a calcineurin inhibitor, either cyclosporine or tacrolimus for 6 months post-HSCT in combination with methotrexate (15 mg/m^2 on the first day after HSCT, and then 10 mg/m^2 at days +3, +6, and +11 after transplantation). Mycophenolate mofetil and sirolimus can be used instead of methotrexate. Serotherapy with ATG or alemtuzumab is often included in the preparatory regimen, to reduce the risk of GvHD. The timing of administration of alemtuzumab as part of the preparatory regimen has opposed effects on the prevention of aGvHD and the speed of T-cell reconstitution. In particular, use of alemtuzumab in the days that immediately precede transplantation has more potent effects on aGvHD prevention but is associated with delayed T-cell reconstitution, whereas the opposite is observed when the drug is administered a few weeks before HSCT. Finally, abatacept, a fusion protein of CTLA4 and Ig which disrupts engagement of CD28 by its ligands, has received breakthrough designation from the FDA for prevention of aGvHD (see Fig. 90.3). While in general, MUD grafts are infused unmanipulated with pharmacological prophylaxis, PTCy and TCRαβ/CD19 depletion have also been used with MUD grafts, particularly for mismatched grafts.

Treatment of Graft-Versus-Host Disease

Once GvHD has developed, treatment is based mainly upon the use of immunosuppressive drugs. Corticosteroids remain the first-line therapy and are usually effective, especially for mild and moderate aGvHD. A multitude of second-line agents for steroid-dependent or steroid-refractory disease include pentostatin, etanercept, sirolimus, daclizumab, and basiliximab; but few if any have shown dramatic efficacy. In 2019, ruxolitinib, an inhibitor of JAK1 and JAK2 kinases, became the first FDA-approved agent in the United States for treatment of steroid-refractory aGvHD for adults and pediatric patients ≥12 years of age; a milestone in the field.

Our understanding of the cellular mechanisms of cGvHD is growing, though therapies remain woefully limited in their efficacy.[7] Treatment of cGvHD is based on immunosuppression, either by inhibiting T cells, inhibiting B cells, or expanding regulatory T cells (Treg). Topical steroids and calcineurin inhibitors may alleviate mucosal and skin symptoms. Systemic steroids have been shown to improve survival, but at the risk of significant adverse effects. Extracorporeal photopheresis can be used to induce tolerance; typically, its benefits, if present, are delayed until 2 to 3 months after initiation of treatment. The promise of inhibiting B cells was realized in 2017 when ibrutinib was the first agent to be FDA-approved in the United States

for the treatment of refractory cGvHD. Many other agents including mycophenolate mofetil, anti-TNF-α mAb, etanercept, anti-CD20 antibodies, sirolimus, ruxolitinib, and chronic low-dose IL-2 have also been used with variable efficacy.

Infections

Infections are a major complication following HSCT. Patients with severe PID are intrinsically highly susceptible to infections. In infants with SCID and with other forms of combined immune deficiency, viral and opportunistic infections can develop before transplantation and are one of the factors that adversely affect the outcome of HSCT itself.[1,2,8] Regardless of the type of underlying PID, T-cell-depleted HSCT carries a high risk of infections because of the longer time required to achieve immune reconstitution. Furthermore, conditioning regimens with myeloablative and immunosuppressive drugs, and GvHD prophylaxis, increase susceptibility to infections after HSCT. Strict isolation of the patients during and after HSCT and prophylactic administration of antibiotics have been associated with better survival, particularly after related HLA-mismatched transplantation for SCID.[1]

Challenging viruses in infants with SCID include adenovirus, cytomegalovirus (CMV), parainfluenza type III virus, and EBV. In particular, CMV infection after HSCT can cause interstitial pneumonia, enteritis, hepatitis, and encephalitis. EBV can also cause lymphoproliferative disease. The risk of transfusion-associated infections can be reduced by the removal of leukocytes or selecting CMV-negative donors. Several antiviral drugs (acyclovir, ganciclovir, foscarnet, cidofovir, letermovir) are now available and are effective, especially against CMV[9]; and preemptive administration of anti-CD20 mAb helps to prevent EBV-driven lymphoproliferative disease. Furthermore, transfusion of virus-specific cytotoxic T lymphocytes (CTL), either donor-derived, autologous engineered, or third party, represents another important resource to fight severe viral infections.[10]

Pneumocystis jiroveci is a common cause of pneumonia in severely immunocompromised patients. The first-line treatment is intravenous sulfamethoxazole/trimethoprim.

Aspergillus infection is a severe complication in patients with chronic granulomatous disease (CGD) and patients with profound neutropenia. Voriconazole offers some advantage compared with liposomal amphotericin B for treatment of invasive aspergillosis, whereas prophylactic itraconazole reduces the incidence of fungal infections in patients with CGD before transplantation.

Bacterial infections are usually amenable to successful treatment if the pathogen is identified and aggressive use of appropriate antibiotics initiated. Prophylactic immunoglobulin (IgG) infusions following HSCT also reduce the frequency and severity of infections. Administration of Bacille Calmette-Guérin (BCG) vaccine at birth to prevent tuberculosis is still practiced in many countries worldwide. In severely immunocompromised infants who undergo HSCT, this live vaccine may cause disseminated disease, which often manifests at the time of engraftment with local and systemic immune reconstitution inflammatory syndrome (IRIS).

Toxicity Related to Conditioning Regimen

Chemotherapeutic agents in the conditioning regimen often cause significant short-term and long-term toxicity. Myeloablative regimens cause temporary anemia, thrombocytopenia, and leukopenia. Consequently, supportive treatment with RBC and platelet transfusions is necessary during the aplastic phase. Conditioning damages the lining of the intestine, leading to painful mucosal ulcers and need for nutritional support for several weeks. Finally, severe leukopenia, in conjunction with loss of intestinal barrier function, predisposes to life-threatening bacterial or fungal infections until neutrophil engraftment and healing occur. Chemotherapeutic drugs that damage the liver vascular endothelium, particularly busulfan and cyclophosphamide, can cause veno-occlusive disease (VOD), which is clinically marked by painful hepatomegaly, jaundice, ascites, fluid retention, weight gain, and can ultimately result in fatal multi-organ failure. Defibrotide is the most effective agent studied to date in the treatment of VOD. Busulfan can also cause seizures and lung damage. Cyclophosphamide can cause hemorrhagic cystitis, a syndrome of inappropriate antidiuretic hormone secretion, or more rarely, cardiac disturbances.

Long-term hormonal complications are more common when TBI is used. However, the busulfan and cyclophosphamide regimen can cause delayed puberty or sterility, and thyroid dysfunction is frequently observed, even in patients who have not received TBI. Delayed or incomplete tooth eruption is also a possible consequence of conditioning regimens given to infants or young children. Effects on final height and growth, as well as long-term neurocognitive effects, are emerging as more children surviving after treatment are followed up with. Patients with defects of DNA repair (*e.g.*, some forms of SCID) are particularly at risk for toxicities related to conditioning.

Hematopoietic Stem Cell Transplantation forv Severe Combined Immunodeficiency

General Considerations

SCID is a medical emergency and is uniformly fatal unless promptly diagnosed and successfully treated. While the alternative strategies, including gene therapy (Chapter 91), are gaining prominence, allogeneic HSCT remains the standard treatment for these disorders.

The virtual lack of T lymphocytes strongly impairs the ability of a SCID patient to reject the graft. Furthermore, donor-derived lymphoid progenitor cells have a striking advantage for *in vivo* T-cell differentiation. Use of pre-transplantation chemotherapy and immune suppression is thus not required to attain T-cell reconstitution for SCID. There is a general consensus that no conditioning is needed for HSCT from an HLA-identical related donor. In the last two decades, considerable advances have been made in the field of allogeneic transplantation, including improvements in HLA typing, in unrelated donor transplant techniques, T-cell depletion, prevention and treatment of infection, early diagnosis of SCID through universal newborn screening, and definition of the genes responsible for ~90% of cases of SCID. These advances, in combination with results published by multi-institutional consortia, the Inborn Errors Working Party of the European Blood and Marrow Transplant Society (IEWP-EBMT), and the Primary Immune Deficiency Treatment Consortium (PIDTC) in North America, have changed how HSCT is performed for SCID, leading to expanded donor options and tailoring of conditioning to genotype.

CLINICAL PEARLS

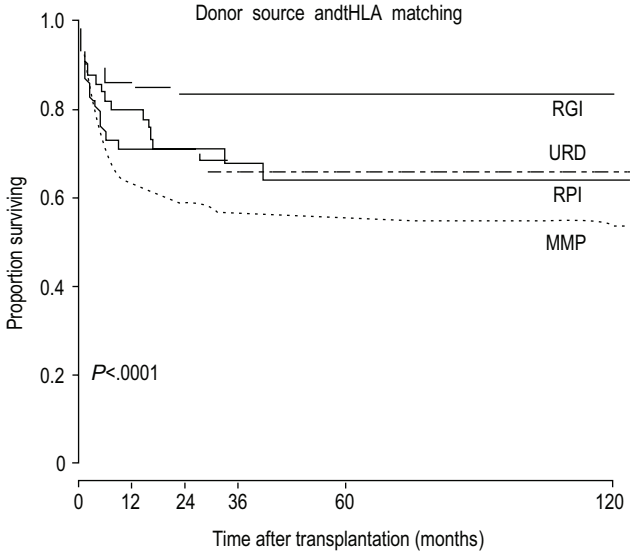
Unique Considerations of Stem Cell Transplantation for Severe Combined Immunodeficiency Versus Other Primary Immunodeficiencies

- Patients with SCID have little or no ability to reject allogeneic cells. Therefore no chemotherapy is required to achieve T-cell reconstitution following HSCT.
- All other patients must receive at least some conditioning to prevent rejection and remove enough recipient HSCs to allow donor HSC engraftment.
- After HSCT, early T-cell reconstitution in the first few months relies on the expansion of mature T cells infused with the graft. In SCID patients receiving MSD grafts without conditioning, graft-versus-host disease (GvHD) rarely occurs. In contrast, for patients undergoing HSCT with conditioning, medications to prevent GvHD or T-cell depletion must be used.
- Generation of naïve T cells that are tolerant to the recipient relies on differentiation of donor progenitors in the thymus, a process requiring 4 months or more after HSCT.
- Patients undergoing T-cell-depleted HSCT, via either graft manipulation or post-transplant cyclophosphamide, are dependent on thymus-dependent T-cell reconstitution.
- The longevity and quality of T-cell reconstitution in SCID patients after unconditioned HSCT is, in general, inferior to HSCT with conditioning. High-level engraftment of donor-derived HSC, generally achieved only after conditioning, leads to sustained T-cell generation.

Survival Following Hematopoietic Stem Cell Transplantation for Severe Combined Immunodeficiency

Two large retrospective reports of patients with SCID treated by HSCT have been published, the IEWP-EBMT cohort of 699 cases, and the PIDTC cohort of 663 cases.[1,2] The IEWP study reported on patients transplanted between 1968 and 2005, of who 203 patients received HSCT from MSD ($n=135$) or phenotypically matched other relatives ($n=68$), 415 from MMRD, and 81 from MUD. As expected, 10-year survival was best after MSD HSCT at 84% and superior to all non-MSD graft sources, which were similar in outcome, with 64%, 54%, and 66% survival, respectively (Fig. 90.4). Important factors this study defined in multivariate analysis as hurting survival included older age at transplantation (>12 months of age), poor clinical status of the patient (respiratory impairment, septicemia, viral infection), T-cell depletion of the graft, lack of supportive measures (protected environment, antimicrobial prophylaxis), and SCID phenotype (B^+ SCID being more favorable than B^- SCID). There was also a significant improvement in survival in the 2000 to 2005 era compared to the pre-1995 era (see Fig. 90.4).

The PIDTC report of Haddad *et al.*[8] spanned an overlapping timeframe from 1982 to 2012, confirming many findings in the IEWP study, while also extending and expanding on factors found to be important in a smaller report of 240 patients transplanted between 2000 and 2009. As expected, MSD recipient survival was superior at 94% compared to all other donor sources, and no single non-MSD graft type was superior to another. Analysis focused on the 571 patients receiving non-MSD grafts (phenotypically matched other related donors, MMRD, MUD) confirmed the importance of young age and freedom from infection, in that the best survival was achieved in patients <3.5 months of age at HSCT, and those of any age who had never been infected; those >3.5 months of age who had an active infection or even infection that had resolved, had poorer survival. Importantly a survival advantage was shown in this study according to the underlying genetic cause of SCID, with patients with defects in *IL2RG*, *JAK3*, *IL7R/CD3/CD45*, and *RAG1/RAG2* defects surviving better than those with ADA-deficient SCID or Artemis-deficient SCID due to defects in the *DCLRE1C* gene (Fig. 90.5). Patients with unknown genotypes also had relatively poor survival. Neither the use of conditioning nor whether the patient had typical SCID versus leaky SCID or Omenn syndrome had any effect on survival.[2]



Months	0	6	12	24	36	60	120

Survival after related genotypical identical *(RGI)*, related phenotypical identical *(RPI)*, unrelated *(URD)*, and mismatched related *(MMR)* donors is shown. (Redrawn after Fig. 1 of Gennery AR, Slatter MA, Grandin L, et al. Transplantation of hematopoietic stem cells and long-term survival for primary immunodeficiencies in Europe: entering a new century, do we do better? *J Allergy Clin Immun.* 2010;126[3]:602–610.e11.)

Quality and Kinetics of T-Cell Immune Reconstitution

The most critical goal of HSCT in SCID patients is a normalization of the number and function of T cells, which rescue the patient from death due to opportunistic infection. Factors that affect the quality and kinetics of T-cell immune reconstitution include the impact of donor type and HLA match, graft manipulation, use of conditioning, and underlying genetic cause of the SCID.

The high degree of success of MSD transplant without conditioning reflects the rapid reconstitution achieved when mature T cells are included in the graft and no immunosuppression, as part of conditioning or GvHD prophylaxis, is given. Mature HLA-matched T cells contained within the stem cell graft when infused into the lymphopenic SCID patient

Survival for patients with mutations in adenosine deaminase *(ADA)*, DNA cross-link repair protein 1C *(DCLRE1C)*, common gamma chain or interleukin-2 receptor gamma *(γC)*, Janus kinase 3 *(JAK3)*, interleukin-7 receptor *(IL7R)*, CD3 subunits, CD45, recombination-activating genes 1 and 2 *(RAG)*, other genes including purine nucleoside phosphorylase *(PNP)*, unknown genotype or not done *(ND)* are shown. (Redrawn after Fig. 2 of Haddad E, Logan BR, Griffith LM, Buckley RH, et al. SCID genotype and 6-month posttransplant CD4 count predict survival and immune recovery. *Blood*. 2018;132[17]:1737–1749.)

vigorously expand in response to high levels of cytokines such as IL-7. These donor T cells are detectable within 1 to 3 months and begin to mediate antigen-specific responses to their cognate antigens. Such T cells are primarily of a memory phenotype. In contrast, newly generated, naïve ($CD45RA^+$ $CD31^+$) T lymphocytes from donor-derived progenitors engrafting in the thymus do not appear in the peripheral circulation until 4 to 6 months after HSCT (see Fig. 90.2), irrespective of the type of transplant (HLA-identical or mismatched); their number tends to peak approximately a year after HSCT, by which time a fully polyclonal T-cell repertoire is usually observed. These naïve T lymphocytes are the product of ongoing active thymopoiesis and contain T-cell receptor excision circles (TRECs). TRECs are extrachromosomal DNA episomes generated during V(D)J recombination (Chapters 32 and 34) and are not duplicated during mitosis. TRECs are now used broadly as a method to identify babies with SCID at birth.[11] The rapid early reconstitution with mature lymphocytes followed by robust thymopoiesis and generation of T cells that are immediately functional, unhampered by GvHD prophylactic immunosuppression, underlie the success of this approach.

The speed and quality of T-cell reconstitution, after all other types of grafts, can be predicted based on the procedures used and the intrinsic properties of non-MSD grafts. MUD and UCB transplants are typically performed without T-cell depletion; however, the use of serotherapy to prevent GvHD is common, which in turn depletes mature T cells that could otherwise expand and mediate early immunity. Furthermore, T cells contained within UCB are antigen-inexperienced, which favors their safety for mediating GvHD but means that they will not provide antigen-specific immunological memory responses. MMRD grafts, the majority of which are haploidentical, require *ex vivo* or *in vivo* T-cell depletion, either by graft manipulation or post-transplant administration of PTCy. In such cases, T-cell reconstitution is almost exclusively dependent on thymopoiesis, which, as stated, occurs over many months. Indeed in the PIDTC cohort, MMRD recipients were more likely than MUD recipients to need another transplant, presumably due to poor engraftment of the initial one; whether this was primarily due to HLA mismatch or due to T-cell depletion of the graft is uncertain.[2] Finally, the health of the thymic epithelium must be considered. Transplantation performed early in life (at <3.5 months of age) leads to superior thymic output. This may reflect a lack of thymic damage (which is often observed in older infants after infections). Alternatively, it is possible that a younger thymus better supports thymopoiesis.

Conditioning using stem cell-targeted agents (RIC or MAC) was also associated with superior T-cell reconstitution. Engraftment of donor-derived long-term HSC achieved with RIC or MAC allows for continued seeding of the thymus with progenitors, which is thought to sustain thymopoiesis after the initial directly seeded short-term progenitors have died out. The study of genotype-specific outcomes lends support to the concept that T-cell reconstitution is influenced by the biology of the defect and the nature of the block in T-cell development. When compared to patients with *IL2RG/JAK3* defects, patients with RAG or Artemis SCID undergoing non-MSD transplant were less likely to have robust T-cell reconstitution 2 to 5 years post-HSCT, independent of conditioning.[2,12] One likely explanation is that arrest of thymocyte development in RAG and Artemis SCID, which both affect V-D-J recombination, interferes with the ability of donor-derived progenitors to engraft, particularly in the absence of conditioning. T-cell neogenesis is further compromised in the unconditioned setting due to a loss of the initially engrafted progenitors and lack of donor-derived HSC in the marrow to replace them. The presence of autologous NK cells in these NK^+ forms of SCID may also contribute to graft rejection. Finally, in a series of 106 patients with SCID caused by adenosine deaminase deficiency (ADA^- SCID), unconditioned transplantation from MMRDs was associated with a high risk of graft failure.[13]

CLINICAL PEARLS

Considerations related to underlying disease, donor match, and clinical condition

- Historically, only SCID and severe aplastic anemia were immediate indications for HSCT.
- Accumulated experience and improvements in tissue typing, supportive care, and GvHD prevention and management have made a cure with HSCT possible for more diseases.
- Lack of an MSD no longer precludes HSCT if a well- MUD can be found.
- Diseases for which HSCT is now indicated, include WAS, CGD, immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX), and other combined immunodeficiencies.
- Diseases that have both hematopoietic and non-hematopoietic manifestations should be approached with caution, as only the hematopoietic manifestations will be corrected by HSCT.
- The timing of HSCT depends on the natural history of the disease, the patient's age, existing morbidities, and time needed to secure a donor and optimize the patient's clinical condition.
- Organ damage already incurred is unlikely to be reversed by HSCT and increases the risks of this treatment.

Reconstitution of B- and NK-Cell Immunity

In contrast to T lymphocytes, reconstitution of B cells and B-cell function after HSCT for SCID is varied, and often incomplete. Factors now known to be associated with better B-cell reconstitution include the use of pre-transplant conditioning, donor type, and underlying genotype.

The PIDTC retrospective cohort study showed that certain genotypes are at risk of poor B-cell function post-HSCT, though not the exact same ones at risk of poor T-cell reconstitution. SCID patients with mutations in *RAG1/RAG2* and *DCLRE1C* are at higher risk of poor T-cell and B-cell function (the latter measured as freedom from immunoglobulin infusions) 2 to 5 years post-HSCT.[2] RIC or MAC are associated with improved T-cell reconstitution, as noted above, and also with a higher likelihood of B-cell function 2 to 5 years post-HSCT, particularly among recipients of non-MSD grafts.[2,8,14] These factors are independent predictors of B-cell function, but are interrelated in that only donor-derived HSC would be capable of differentiating into B cells in these two forms of B^- SCID and conditioning with RIC or MAC is required to engraft donor HSC in the bone marrow.

In contrast, patients with SCID due to defects *IL2RG* or *JAK3* have excellent T-cell reconstitution, but poor B-cell function compared to patients with defects in *IL7R/CD3/CD45* or ADA-deficient SCID. In this case, B-cell development is not the issue, but rather that IL2RG/JAK3-deficient B cells fail to respond *in vitro* to IL-21, an IL2RG-dependent cytokine, and consequently have poor class-switching and fail to secrete antibodies.[15] As a result, the rate of freedom from immunoglobulin infusions of patients with *IL2RG/JAK3* SCID, after non-MSD transplant, is much enhanced with the use of conditioning (16.7% vs. 74.2%).[2]

Finally, while all non-MSD recipients have similar T-cell reconstitution at 2 to 5 years post-HSCT, MMRD grafts have inferior B-cell function compared to those from phenotypically matched relatives and MUD, independent of genotype or conditioning. The reasons for this are not clear.

More limited data are available about the reconstitution of NK-cell function. In patients with NK^- SCID, NK cells are often the first cells to appear after haploidentical HSCT. However, lower NK-cell counts are observed at long-term follow-up after HSCT in patients with *IL2RG* or *JAK3* defects.

Complications Following Hematopoietic Stem Cell Transplantation for Severe Combined Immunodeficiency

Despite advances in prophylaxis and treatment, infections (especially those caused by viruses) remain a significant cause of death after HSCT for SCID. In a report of 166 transplantations performed at their center, Buckley *et al.*[16] indicated that viral infections, including CMV, adenovirus, EBV, enteroviruses, parainfluenza virus type 3, varicella, herpes simplex, and respiratory syncytial virus (RSV), accounted for 30 of the 40 deaths observed. In the PIDTC report, a total of 107 patients had infections associated with death, dominated by CMV, EBV, adenoviruses, parainfluenza, fungi, and bacteria.[2]

Viral and opportunistic infections are the most common early after HSCT, especially in recipients of T-cell-depleted haploidentical HSCT, because of the delay in achieving immune reconstitution. Incomplete recovery of immune function at 1 year after HSCT is associated with a higher risk of late infections. In a single-center study of 90 patients with SCID treated with HSCT, 11 (12%) developed significant infectious complications 2 to 17 years afterward.[17] Among late infections, chronic skin warts caused by papillomavirus have been observed in a significant fraction of infants with *IL2RG* or *JAK3* defects after HSCT.[17] This complication may also occur in patients who attain robust immune function and may result from signaling defects that involve extra-hematopoietic cells, such as keratinocytes.

GvHD is another major complication of HSCT for SCID. In the PIDTC series, cumulative incidence of grade 2 to 4 aGvHD and cGvHD were 23% and 16%, respectively.[2] The risk of aGvHD was related to conditioning, and possibly to maternal engraftment. While donor type and use of T-cell depletion did not impact aGvHD, in this series cGvHD was more often seen in patients who had received MMRD HSCT that was T-cell depleted by methods other than those that were standard at the time, soybean lectin agglutination and E-rosetting or $CD34^+$ selection.[2] Chronic GvHD has been reported in 10 (11%) of 90 patients who survived for at least 2 years after HSCT for SCID in Paris.[17] Six of them developed disseminated cGvHD, and 3 died of cGvHD and related infectious complications. Effective prevention of GvHD remains of paramount importance in SCID patients, who experience no benefit from it, in contrast to patients with leukemia for whom a graft-versus-leukemia (GvL) effect can be helpful.

Immune dysregulation, autoimmunity, and need for prolonged nutritional support represent additional complications of HSCT for SCID. Neven *et al.* have reported that among 90 long-term survivors after HSCT for SCID, 12 suffered from autoimmune and inflammatory complications more than 2 years after HSCT for SCID, and in 6 of them, the onset of such complications was within the first 2 years after transplantation.[17] These late manifestations of immune dysregulation are often associated with incomplete immune reconstitution and may lead to a poor outcome. The need for prolonged nutritional support was more frequent among patients treated by mismatched related or unrelated donor HSCT, especially if cGvHD, immune dysregulation, and poor immune reconstitution were also present. Infants with DCLRE1C (Artemis) deficiency (with defective DNA repair) are at a higher risk for late complications, including growth retardation, requirement for nutritional support, and dental abnormalities.[12,17]

Hematopoietic Stem Cell Transplantation for Combined Immunodeficiencies Other Than Severe Combined Immunodeficiency

Other predominant T-cell immunodeficiencies, such as purine nucleoside phosphorylase deficiency, cartilage hair hypoplasia, and other forms of T-cell activation deficiency can be treated with HSCT; overall, survival after HSCT for these disorders is worse than in typical SCID (approximately 50%).[1]

MHC class II deficiency remains a very difficult disease to treat with transplantation, although there have been substantial improvements over time. Compared to the survival of 30% to 40% in the 20th century, the survival of 19 patients in a single institution transplanted after 2008 was 94%.[1,18] Many patients with this deficiency fail to reconstitute a normal number of circulating CD4 T lymphocytes, probably because the lack of expression of HLA class II molecules on thymic epithelial cells interferes with the positive selection of CD4 lymphocytes.[18]

For patients with complete DiGeorge syndrome, HSCT or even transplantation of unmobilized peripheral blood mononuclear cells may be attempted if there is an HLA-identical donor; in such cases, immune reconstitution is provided by mature T lymphocytes contained in the graft. However, experimental implantation of allogeneic thymic tissue has become the preferred treatment, though not widely available at this time.[19,20]

Patients with CD40 ligand (*CD40L*) deficiency suffer from recurrent bacterial and opportunistic infections, particularly with *Pneumocystis jiroveci* and *Cryptosporidium parvum*, resulting in increased mortality in childhood and young adulthood. The early experience of HSCT for these patients was suboptimal, with only 26 of 38 patients transplanted in Europe surviving.[21] An updated experience of 106 patients transplanted after 2000 showed improved survival of 82.2%, attributable to patients being younger and having less organ dysfunction at the time of HSCT.[22] Successful outcome has also been reported after HSCT for CD40 deficiency.

X-linked immunodeficiency with ectodermal dystrophy, caused by mutations of the *IKBKG* (*NEMO*) gene that impair nuclear factor (NF)-κB signaling, may also present with features of combined immunodeficiency. Colitis is frequently seen and may be caused by infection and immune dysregulation as well as abnormalities of NF-κB signaling in the gut epithelial cells. Concern about the failure to correct features of the disease not intrinsic to the hematopoietic system has led clinicians to reserve HSCT for only severely affected cases. Of 29 patients in an international survey, 22 survived, with those who had pre-existing mycobacterial infection having poorer outcomes. Furthermore, colitis has been reported to persist after HSCT.[23,24] Conflicting results have also been reported after HSCT in patients with hypermorphic mutations of the *IKBA* gene, another cause of combined immune deficiency with ectodermal dystrophy.[25]

Dedicator of cytokinesis 8 (*DOCK8*) deficiency is a recently described form of combined immunodeficiency with elevated serum IgE, cutaneous viral infections, and a high risk of malignancy. HSCT is now established as an effective treatment for this disease, with a survival of 84% reported in an international retrospective study of 81 patients.[26] A trend to better survival in patients receiving RIC conditioning and suggestion of selective advantage for donor-derived T cells and switched memory B cells[27] argue in favor of RIC regimens for this disease, in which mixed chimerism may be sufficient for the amelioration of symptoms. HSCT has also been successfully used in patients with combined immune deficiency resulting from DOCK2 deficiency.[28]

Wiskott-Aldrich Syndrome

Bone marrow transplantation for correction of WAS was attempted as early as 1968, with partial success. Full correction following HSCT was first reported in 1978 when a more robust conditioning regimen was used. Since then, results of related HLA-identical HSCT in WAS have been consistently good, and excellent results have been also achieved with HSCT from MUD in children under 5 years of age. While two large multi-institutional surveys have shown survival in the 21st century of ~90% (Fig. 90.6), variability in disease correction due to mixed chimerism remains a significant challenge.[29,30] Persistent thrombocytopenia occurs when myeloid chimerism is below 50% (Fig. 90.7). Furthermore, RIC regimens for patients who cannot tolerate high-dose busulfan do not consistently achieve high-level donor chimerism.[30]

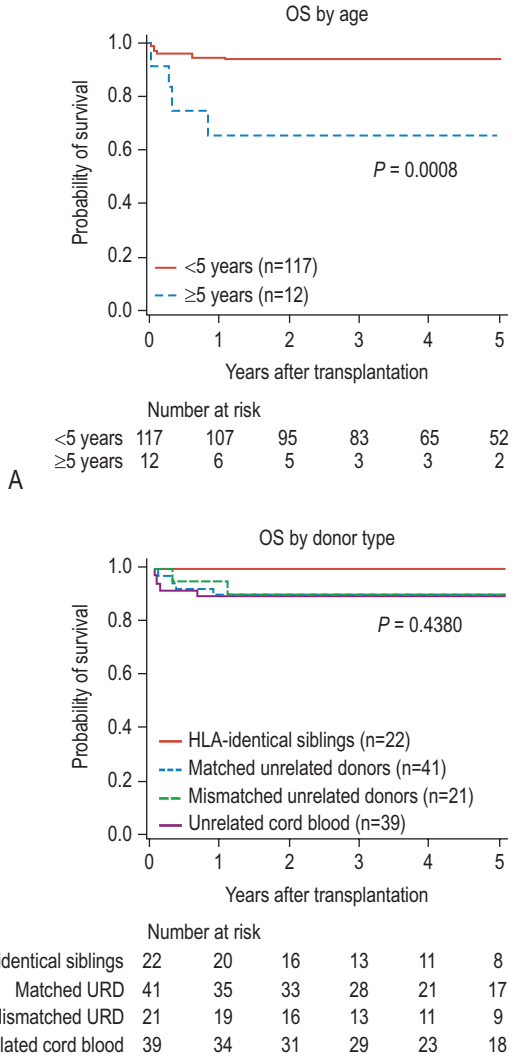

FIG. 90.6 Cumulative probability of overall survival *(OS)* of patients with Wiskott-Aldrich syndrome according to (A) age <5 years versus >5 years, and (B) donor type. *HLA*, Human leukocyte antigens; *UED*, unrelated. (Redrawn after Fig. 3 of Burroughs LM, Petrovic A, Brazauskas R, et al. Excellent outcomes following hematopoietic cell transplantation for Wiskott-Aldrich syndrome: a PIDTC report. *Blood*. 2020;135[23]:2094–2105.)

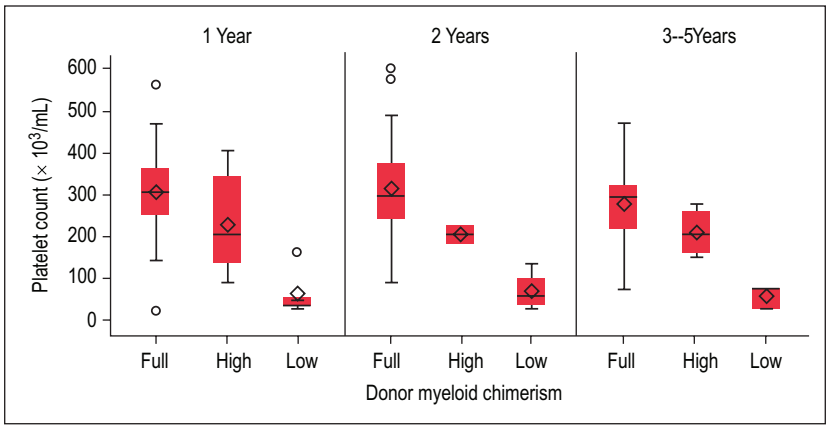

FIG. 90.7 Correlation of platelet count at the indicated times post-transplant of patients with Wiskott-Aldrich syndrome with donor myeloid chimerism. Box plots of platelet counts in patients with full donor (>95%), high donor (50% to 95%), and low donor (5% to 59%) myeloid chimerism are shown. (Redrawn after Fig. 5 of Burroughs LM, Petrovic A, Brazauskas R, et al. Excellent outcomes following hematopoietic cell transplantation for Wiskott-Aldrich syndrome: a PIDTC report. *Blood*. 2020;135[23]:2094–2105.)

Disorders Associated With Hemophagocytic Lymphohistiocytosis

Familial hemophagocytic lymphohistiocytosis (FHL) comprises a genetically heterogeneous group of disorders of T-cell and NK cell-mediated cytotoxicity. Although chemotherapy may induce remission, patients with FHL tend to relapse and ultimately die, mostly as a result of multiorgan failure that occurs in the accelerated phase of the disease. At present, HSCT is the only curative approach to FHL. However, patients with FHL often are critically ill, with extensive organ involvement and/or active infections, and may suffer from refractory disease. For these reasons, patients are unusually prone to developing transplantation-related toxicities and complications. While the use of RIC regimens has improved survival, mixed chimerism and graft failure remain significant problems.[31] Selection of optimal family donors is an important issue for HSCT in FHL. Functional and genetic studies must be used to screen potential familial donors to avoid those who may be genetically affected, but as yet asymptomatic.

Excellent results have been reported, also after HSCT for X-linked lymphoproliferative disease type 1 (XLP1). In an international series of 91 patients with XLP caused by an *SH2D1A* gene defect, survival was 81.4% in 43 patients treated with HSCT compared with 62.5% in 48 untransplanted patients.[32] Furthermore, the majority of untransplanted survivors required IgG replacement therapy, whereas good immune reconstitution was achieved in most transplanted patients. However, survival was poorer (50%) among patients with a previous history of hemophagocytic lymphohistiocytosis (HLH), suggesting that ideally the HSCT should be performed before the onset of EBV infection.[32] More recently, a single-center experience involving 16 patients with XLP1 showed that reduced-intensity conditioning with alemtuzumab, fludarabine, and melphalan is effective, even in patients with XLP1 with a history of HLH.[33] Survival was 80% at 1 year and 71% in the long term; mixed chimerism was common but, in most cases, was sufficient to control the disease. Infectious complications (especially viral infections) were recorded in the majority of the patients.[33]

XLP type 2 (XLP2), caused by mutations in the X-linked inhibitor of apoptosis (*XIAP*) gene, is associated with various phenotypes, including XLP, HLH, and severe colitis. An international survey of transplantation for this condition identified 19 patients who underwent HSCT following fully myeloablative ($n=7$), reduced-intensity ($n=11$), or intermediate-level ($n=1$) conditioning.[34] MAC was associated with poor survival (14%) and a high rate of serious, transplantation-related toxicities. Both this series and a series of 10 patients in Japan who underwent HSCT showed far better outcomes after reduced-intensity conditioning.[34,35]

The hematological and immune complications of Chediak-Higashi syndrome (CHS) can be cured with HSCT. In a series of 35 patients, 5-year survival after HSCT was 62%.[36] Mortality was higher in patients who were in the life-threatening accelerated phase of the disease at the time of transplantation and in those who received HSCT from an alternative related donor.[36] MUD HSCT represents a valid option in patients with CHS. However, the long-term outcome of patients with CHS treated with HSCT remains unclear, especially since neurological deterioration has been consistently observed several years after transplantation.

Griscelli syndrome type 2 (GS2) is a genetic disease characterized by hemophagocytic lymphohistiocytosis and a high risk of neurological complications. A recent series of 35 patients confirmed protection from HLH symptoms after HSCT, even with mixed chimerism, but the substantial risk of mortality, graft failure, and neurologic issues, particularly in those with HLH affecting the central nervous system.[37]

Phagocytic Cell Disorders

Although regular administration of prophylactic antibiotics and antifungal agents (with the possible addition of interferon [IFN]-γ) has improved survival in patients with CGD, this remains a severe disorder with a high risk of complications and death, especially in patients with oxidase-null phenotype (Chapter 39).[38] A real breakthrough in the treatment of CGD was provided by a prospective multicenter study in 56 patients with CGD, 42 of who had high-risk features, including treatment-refractory infections and severe inflammatory complications.[39] In this study, reduced-intensity conditioning (with low-dose or targeted busulfan administration, high-dose fludarabine, and serotherapy) and transplantation from matched related

($n=21$) or unrelated ($n=35$) donors resulted in a 2-year overall survival rate of 96% and an event-free survival rate of 91%. Stable (≥90%) myeloid chimerism was documented in 93% of surviving patients. A low rate of aGvHD of grade III/IV (4%) and cGvHD (7%) was observed. A retrospective review of outcomes of HSCT of 145 CGD patients performed by the PIDTC similarly showed high survival and engraftment, and importantly, showed in contrast to previous literature that patients with CGD-associated inflammatory bowel disease nonetheless had outcomes indistinguishable from those without these symptoms.[40] Studies of female carriers of X-linked CGD suggest that a threshold of 10% to 15% myeloid chimerism is likely sufficient for protection from infection, but that there is no such clear threshold for the avoidance of inflammatory symptoms.[41]

HSCT is a successful and lifesaving procedure in patients with the complete form of leukocyte adhesion defect type 1 (LAD-1). A multicenter study of 36 such patients who underwent HSCT between 1993 and 2007 reported an overall survival of 75%, with similar results in matched related and unrelated donors. Mortality was higher (four of eight cases) after haploidentical HSCT. Stable mixed multilineage chimerism is sufficient to cure the disease.[42] More recently, employing blockade of the P40 subunit of IL-23 and IL-12 with ustekinumab resolved inflammatory symptoms in a patient with LAD-1 after 1 year of therapy.[43]

Administration of recombinant G-CSF is the treatment of choice for patients with severe congenital neutropenia (SCN). However, a subgroup of these patients fail to respond to G-CSF, and some of them are at high risk for the development of myelogenous leukemia. A retrospective multicenter study of 136 patients with SCN who underwent allogeneic HSCT between 1990 and 2012 reported a 3-year overall survival rate of 82%, with 17% transplantation-related mortality. Transplantation at a younger age (<10 years) and the use of matched related or unrelated donors were associated with better outcomes.

Heterozygous mutations in the GATA2 gene result in a wide variety of clinical manifestations, including the Mono-Mac syndrome, pulmonary alveolar proteinosis (PAP), bone marrow failure, susceptibility to infection with mycobacteria and DNA viruses, myelodysplastic syndrome, and progression to acute myelogenous leukemia (AML). These hematopoietic-intrinsic defects are eminently correctable with HSCT using a variety of donors as reported in a 22 patient series.[44]

Regulatory T-Cell Defects

Immunodysregulation/polyendocrinopathy/enteropathy/X-linked (IPEX) syndrome is a severe disorder with immune dysregulation caused by mutations of the *FOXP3* gene, which plays a critical role in the development and function of regulatory T cells (Treg). Patients with IPEX syndrome often die early in infancy and manifest severe multi-system autoimmunity. HSCT is effective and is now established as a standard treatment. A report of 96 patients with IPEX, 58 of who underwent HSCT, showed 73.2% survival in contrast to 65.1% with immunomodulatory therapy alone. RIC and MAC regimens appeared to have an equal survival benefit, which may be related to the strong selective advantage for donor-derived Tregs observed in patients with mixed chimerism after HSCT.[45] Patients with more mild disease activity at the time of HSCT fared best, speaking to the importance of control of autoimmunity prior to the procedure.[46]

Small series have been published on HSCT for other disorders affecting Treg function, including activated PI3 kinase delta syndrome, STAT1 gain of function, and CTLA4 haploinsufficiency.[47–49] Outcomes in these disorders, for which donor-derived Tregs do not have a selective advantage as they do in IPEX, have been variable due to issues of poor engraftment and mixed chimerism.

Interferon-γ Pathway Disorders

IFN-γ receptor 1 deficiency leads to severe mycobacterial infections, with a high mortality rate of mortality early in life. Although HSCT should theoretically correct the disease, results have been disappointing, with few exceptions. An international survey of eight transplanted patients showed that only two were in full remission 5 years after transplantation.[50] The high level of IFN-γ in these patients inhibits engraftment of donor-derived HSCs, accounting for the high rejection rate. Correction of the disease has been reported with HSCT following control of mycobacterial infection, normalization of IFN-γ levels, and use of MAC.

ON THE HORIZON

The following strategies may improve the outcome of HSCT for primary immunodeficiency in the future:

- Antibody-based methods to increase and sustain engraftment of stem cells without systemic organ toxicity.
- Strategies to facilitate engraftment and reduce the occurrence of GvHD in patients with mismatched or matched unrelated donor transplants.
- Approaches to increase thymopoiesis to accelerate T-cell immune reconstitution.
- Improved antimicrobial protocols to reduce infectious complications of HSCT.

FUTURE DIRECTIONS FOR HEMATOPOIETIC STEM CELL TRANSPLANTATION IN THE TREATMENT OF PRIMARY IMMUNE DEFICIENCY

Although allogeneic HSCT has clear efficacy in patients with severe forms of PID, several challenges remain. The development of RIC regimens notwithstanding, efficient myeloablation without the toxicity of alkylating agents for PID patients, many of whom are young children or infants, is desperately needed. Cytolytic mAbs against CD117 (c-kit) are now being tested to remove autologous HSCs, making space for engraftment of donor-derived cells while avoiding the systemic toxicity of chemotherapy and radiotherapy.[51]

The use of cytotoxic drugs and GvHD are significant risk factors for post-transplantation T-cell deficiency as they interfere with normal thymic function.[52] Strategies aimed at improving thymic function after HSCT may include (1) protection of thymic stroma that supports thymopoiesis and (2) direct stimulation or infusion of early T-cell progenitors. It is critical that newly approved agents for the treatment and prevention of GvHD be tested in young children, so that young PID patients may benefit.

Now more than 50 years after the first successful use of HSCT, we are faced with a large cohort of adult survivors. It is important to fully capture and analyze their long-term outcomes. Natural history studies of these patients are critical to understanding the durability of HSCT, assessing the quality of

life and impact on patients' well-being, and elucidating early biomarkers that predict long-term success. By doing so, we may be able to identify patients at risk of poor long-term outcomes, deserving of further early intervention.

Gene Therapy for Primary Immune Deficiency Diseases

Caroline Y. Kuo and Donald B. Kohn

Gene therapy, as it is being applied for primary immune deficiency (PID) diseases, represents an autologous hematopoietic stem cell transplant (HSCT), in which a patient's own stem cells are genetically corrected ex vivo and then transplanted back (Fig. 91.1). Thus, gene therapy for PID builds upon decades of experience using allogeneic HSCT from a healthy donor, in which replacement of some or all of a PID patient's bone marrow hematopoietic stem cells (HSCs) with HSCs from a healthy donor can cure the disease. Although initial efforts in gene therapy did not provide clinical benefit to the patients involved, there has been steady progress with the methods to the point that there is now clear-cut therapeutic efficacy using gene therapy/autologous HSCT for the three most commonly transplanted PIDs: severe combined immune deficiency (SCID), Wiskott-Aldrich syndrome (WAS), and chronic granulomatous disease (CGD) (see Chapters 34 and 35).

Most gene therapy efforts to date have used **gene addition** methods in which a normal copy of the relevant gene is added to the patient's cells, usually using a viral vector. More recently, methods are under development to perform **gene editing**, most commonly using site-specific endonucleases (such as CRISPR/Cas9) to disrupt a target gene or modify or add new sequences by homologous recombination (HR).

The key potential advantage of autologous transplant with gene therapy, compared to allogeneic HSCT, is that it may have reduced risks and a better safety profile, because it eliminates the need for pre-transplant immune-suppressive conditioning and post-transplant immune suppression; essentially, there should be no risk of graft-versus host disease (GvHD) from the autologous graft (Table 91.1). Additionally, gene therapy could have increased efficacy compared to allogeneic HSCT in some conditions, due to the potential to overexpress the relevant gene product (e.g. adenosine deaminase [ADA] enzyme) and lead to a supraphysiological effect from the engineered graft.

However, gene therapy may have unique risks: the potential for causing malignant transformation and leukoproliferative complications from the manipulation of the genome of the stem cells, by either gene addition or gene editing. Moreover, gene therapy could have decreased efficacy if the percentage of transplanted stem cells that are successfully gene-corrected is low, if the level of expression of the inserted transgene is suboptimal, or if the process of ex vivo gene manipulation impairs the stem cells' capacity for long-term hematopoiesis. Additionally, developing gene therapies for PID requires a separate translational research process for each genetic etiology (e.g., ADA SCID, XSCID, Artemis SCID, Rag1 SCID, Rag2 SCID, etc.), whereas allogeneic HSCT is a more "one size fits all" approach, requiring less individualization for similar classes of disorders.

KEY CONCEPTS

- Some severe primary immune deficiencies (PIDs) can be treated by transplantation of hematopoietic stem cells (HSCs) from a healthy donor, but this is optimal with a well-matched immune-compatible donor and may yet entail immune complications.
- Gene therapy using autologous HSCs that have been gene-corrected (by gene addition or endogenous correction) may avoid the immune complications of allogeneic transplant and confer similar benefits.
- Stable gene addition to HSC can be done using integrating viral vectors, derived from retroviruses or lentiviruses.
- Gene therapy using γ-retroviral vectors led to immune reconstitution for several forms of severe combined immune deficiency, Wiskott-Aldrich syndrome, and chronic granulomatous disease, but some patients developed leukoproliferative complications.
- More recent trials using safer vectors are continuing to yield clinical efficacy without vector-related adverse effects and with good safety profiles.
- New techniques are being developed for precise gene editing in HSCs, which may allow application to a wider spectrum of PIDs.

GENE TRANSFER TO HEMATOPOIETIC STEM CELLS

For gene therapy to have an enduring effect in PID, the gene addition or editing must occur in the long-term pluripotent HSCs by some method that will lead to the corrective gene being passed on to the billions of progeny blood cells arising from each HSC. Gene modification of the far more numerous, but short-lived, lineage-committed progenitor cells would lead only to transient presence of gene-corrected mature blood cells. The technical challenge is for the gene delivery to HSCs to be efficient (high percentage of the cells modified), to yield persistent expression, and to have minimal immediate cytotoxicity or long-term genotoxicity.

Many of the gene transfer methods used for research purposes, such as transfection, electroporation, and nano-particle delivery, are themselves transient, and the inserted gene would be lost by dilution as the stem cells proliferate. Thus, most of the studies to date have used viral vectors derived from the Retroviridae family that integrate their genomes into the chromosomes of the target cell to achieve persistence of the normal gene (Fig. 91.2). Genes delivered by murine γ-retroviral, human lentiviral (HIV-1-based), spumaviral (foamy), or alpha-retroviral vectors remain permanently covalently linked to the cellular chromosomal DNA for stable transmission to progeny cells. The steps involved in using these types of vectors to produce a gene-modified HSC graft are described in the Therapeutic Principles box.

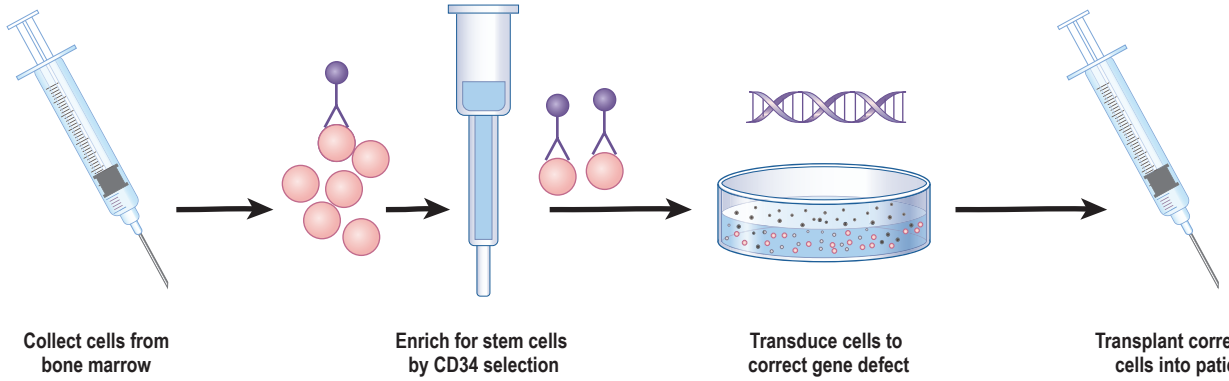

FIG. 91.1 Gene Therapy to Treat Primary Immune Deficiencies (PIDs) by Autologous Transplantation of Gene-Corrected Hematopoietic Stem Cells (HSCs). HSCs may be obtained from the bone marrow, by mobilization with granulocyte–colony-stimulating factor (G-SCF) and leukapheresis (peripheral blood stem cells [PBSCs]), or from umbilical cord blood of a patient with PID. The HSCs may be enriched by isolating the $CD34^+$ fraction of cells using immunomagnetic separation methods. The $CD34^+$ cell population is then cultured for gene manipulation (gene addition or gene editing). The gene-corrected autologous HSCs are then transplanted back to the patient.

TABLE 91.1 Advantages and Disadvantages of Allogeneic Versus Autologous (Gene Therapy) Hematopoietic Stem Cell Transplantation for Primary Immune Deficiencies

Transplant Type	Advantage	Disadvantage
Allogeneic HSCT	Normal function of relevant gene assured; benefit expected if sufficient donor chimerism	Need suitable matching donor
	Well-established and long-term experience with benefits/risks	Immune: GvHD and rejection risks
	Excellent outcomes with matched sibling donor (although most patients lack a matched sibling)	Requires immune modulation: immune ablative conditioning; graft manipulation; and GvHD prophylaxis and treatment. These may contribute to morbidity
Autologous gene therapy HSCT	Patient is donor	Potential genotoxicity from gene addition or editing causing cell loss, dysfunction, or transformation
	No risks of GvHD	Need to gene-modify high percentage of primary HSC with minimal cytotoxicity
	May not require immune suppression before (e.g., flu/ATG) and after (e.g., corticosteroids, calcineurin inhibitor) HSCT	Low fractional correction may blunt efficacy
	Risks of rejection may be less than with allogeneic cells	Prior chemotherapy or marrow dysfunction may preclude use of autologous stem cells
	Transgene overexpression may have benefits (e.g., adenosine deaminase)	Immunogenicity of transgene products is not well defined
Gene addition (e.g., lentiviral vector)	Currently showing efficacy for SCID, WAS, and CGD (and for non-PIDs; e.g., X-ALD, MLD, β-thalassemia, sickle cell disease, MPS-1)	Risks for insertional mutagenesis (gene disruption, gene activation) from semi-random insertions into target cell genomes
	Current generation of self-inactivating (SIN) lentiviral vectors has reduced genotoxicity compared to earlier-used γ-retroviral vectors	Transgene not under normal transcriptional control. Function of transgene (level, lineage, longevity) may vary and be variegated
Gene editing (e.g., nuclease/HDR)	Corrected endogenous gene should have normal function.	Risks of local or off-target gene disruption (insertion/deletion)
		Risk of translocations

ATG, Anti-thymocyte globulin; *CGD*, chronic granulomatous disease; flu, fludarabine; *GvHD*, graft-versus-host disease; *HDR*, homology directed repair; *HSC*, hematopoietic stem cells; *HSCT*, hematopoietic stem cell transplantation; *MLD*, metachromatic leukodystrophy; *MPS-1*, mucopolysaccharidosis type I {Hurler syndrome}; *PID*, primary immune deficiencies; *SCID*, severe combined immune deficiency; *WAS*, Wiskott-Aldrich syndrome; *X-ALD*, X-linked adrenoleukodystrophy.

CLINICAL TRIALS OF GENE THERAPY FOR PRIMARY IMMUNE DEFICIENCIES

To date, clinical trials of autologous transplant/gene therapy have been performed for several PID disorders, including multiple trials for ADA-deficient SCID, XSCID, CGD, and WAS, and more recent studies for Artemis-deficient SCID and leukocyte adhesion deficiency (LAD-1) (Table 91.2). These have occurred over roughly demarcated eras as the technology and clinical approaches advanced in the past three decades (Table 91.3). Because each genetic form of PID requires a separate development research path from preclinical studies to define efficacy and safety through clinical trials, gene therapy for each individual PID will be discussed separately. However, they share a common progression through the different eras.

Over these eras, the preferred vector for gene delivery to HSCs has progressed from murine γ-retroviral vectors (γ-RV) to HIV-1-based lentiviral vectors in which the enhancers in the

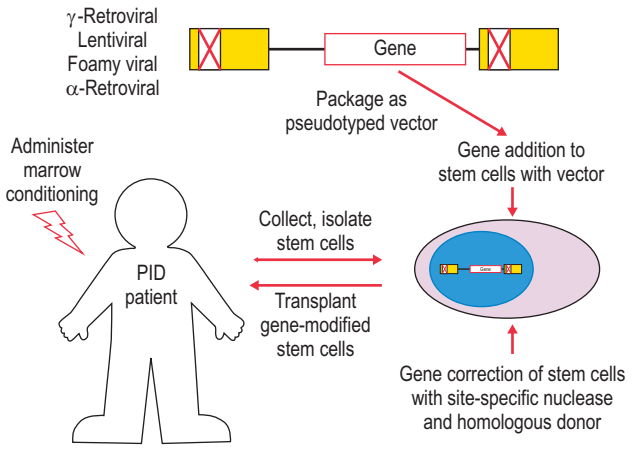

FIG. 91.2 Autologous Transplantation of Gene-Corrected Hematopoietic Stem Cells (HSCs). Gene addition may be performed using Retroviridae-derived vectors (from γ-retroviruses, lentiviruses, foamy viruses, or α-retroviruses) to transfer a normal copy of a relevant gene into HSCs collected and isolated from a patient with primary immune deficiency *(PID)*. The gene-containing vector is packaged in a suitable envelope (pseudotyped) for gene addition to human HSC. Alternatively, the HSC may be gene-edited using site-specific endonucleases to augment homologous recombination–directed gene editing. The patient may receive marrow cytoreductive conditioning prior to transplant to enhance engraftment of the gene-modified stem cells.

THERAPEUTIC PRINCIPLES

Steps for Gene Transfer to Hematopoietic Stem Cells for Clinical Transplantation

Package Retro-Lentiviral Vector

Transfect packaging cell with vector-encoding plasmid and virion protein and envelope-expressing plasmids.

Collect released vector from cell culture medium (digest residual plasmid with DNAse).

Purify and concentrate vector (e.g., ion-exchange chromatography, tangential flow filtration).

Aliquot. Certify (including absence of replication-competent virus). Release for use.

Transduce Stem Cells with Vector

Isolate $CD34^+$ stem/progenitor cells from clinical source (bone marrow, mobilized peripheral blood, cord blood).

Grow $CD34^+$ cells in serum-free medium plus recombinant cytokines (e.g., ckit ligand, flt-3 ligand, thrombopoietin) for 16–24 h.

Add vector to cells and culture for transduction for 16–24 h, during which the vector inserts gene sequences covalently into chromosomal DNA of $CD34^+$ HSC.

Formulate and characterize cell product for release.

Administer Marrow Cytoreductive Conditioning

Deliver single or combination chemotherapeutic agents or monoclonal antibodies to "make space" in HSC niches in the bone marrow.

Transplant Gene-Modified Stem Cells

Infuse gene-modified cell product intravenously, after which stem cells engraft and transmit the transgene to all progeny blood cells.

The transgene produces the necessary gene product to correct the genetic deficiency.

viral long-terminal repeats are self-inactivated during the reverse transcription steps (SIN vectors). Lentiviral vectors have several potential advantages over γ-RV, including the ability to more effectively transduce human HSCs in a shorter period of ex vivo culture; the capacity to carry longer and more complex genetic sequences (such as cellular gene enhancers and promoters); and less tendency to be inserted near the 5′ ends of genes, which may decrease risks for *trans*-activating expression of the adjacent cellular genes. The combination of recombinant cytokines used to activate the HSCs to facilitate transduction was advanced as factors were identified that acted on the earliest HSCs, including the flt-3 ligand and thrombopoietin, combined with the c-*kit* ligand.

The Role of Cytoreductive Conditioning to Facilitate Engraftment

In the initial trials of gene therapy for PID, there was no administration of pre-transplant cytoreductive conditioning, due to potential risks of chemotherapy or radiation with unknown prospects of benefit from the gene transfer procedure. It is well-known from multiple transplant studies in mice and large animal models that there is minimal, if any, engraftment of autologous HSCs when given without prior conditioning, unless extraordinarily high numbers of cells (e.g., 30 to 50× higher than standard cell dose/kg) are given; even mega-dose transplants without conditioning lead to only low levels of engraftment (e.g., 1%), although this may be persistent.[1] While there was initial reluctance to use conditioning in gene therapy trials when there had not previously been efficacy, now with the clear-cut benefits that may be obtained from gene therapy, the necessity to use conditioning for autologous gene therapy HSCT (with a dose generally lower than that needed for allogeneic HSCT) is now recognized as the standard.

The amounts and types of chemotherapy drugs used for conditioning have varied, depending on the disease setting. For SCID, where a relatively low number of gene-corrected HSCs may support immune reconstitution, reduced-intensity conditioning (RIC), such as low-dose busulfan alone (e.g., busulfan at 4 to 6 mg/kg), may be sufficient. For other disorders where less of a selective advantage may exist for the gene-corrected cells, a higher level of engraftment of modified HSC may be needed; and thus stronger conditioning regimens have been used, reaching levels for myeloablative conditioning (MAC) (e.g., busulfan, 12 to 16 mg/kg). For WAS, where it may be necessary to ablate the pre-transplant immunity to reduce risks for post-transplant autoimmunity, immune-suppressive drugs (e.g., fludarabine, rituximab) have been added to conditioning regimens. These combined iterative approaches to improving gene therapy have led to the current state, where clinical benefits are being routinely achieved, as detailed below for each disorder.

New methods are being explored to "make space" in the marrow using alternatives to chemotherapy and radiation, such as monoclonal antibodies to markers present on HSCs. Antibodies to a cytokine receptor on HSC (c-kit), a common leukocyte antigen (CD45), and a macrophage inhibitory receptor (CD47) have all been shown in animal models to improve engraftment of HSC with minimal clinical toxicity. An anti-cKit antibody is being assessed in a clinical trial to improve engraftment in patients with SCID (NCT02963064). These novel approaches to cytoreduction to facilitate engraftment with lower short-term and long-term risks may replace the current approaches using chemotherapeutic agents.

Adenosine Deaminase-Deficient Severe Combined Immune Deficiency (Chapter 34)

The first clinical trial of gene therapy for an inherited disorder (other than a premature attempt at gene therapy for beta-thalassemia in the 1970s) was directed against ADA-SCID. ADA-SCID was the first form of human SCID for which the responsible gene was identified and cloned, allowing gene therapy to be approached.[2] As a ubiquitously expressed housekeeping enzyme, the non-regulated expression of an introduced ADA gene was expected to be tolerated and potentially beneficial. Moreover, the ability to treat ADA-SCID with a bone marrow transplant from a matched sibling donor without the use of cytoreductive or immune-suppressive conditioning was taken to imply that there is a selective advantage for ADA-replete T lymphocytes over ADA-deficient cells and that only a modest number of engrafted gene-corrected HSC might provide clinical benefit.

A series of clinical trials were performed using γ-retroviral vectors targeting either peripheral blood T cells or bone marrow HSC. While initial studies in the early 1990s did not achieve clinical efficacy, subsequent trials that applied RIC prior to transplant of gene-corrected HSCs to increase engraftment have led to immune restoration in the majority of more than 80 treated patients, without vector-related complications.[3–7] The relatively low-dose chemotherapy and absence of GvHD makes these autologous transplants well-tolerated with essentially none of the clinical side effects seen in allogeneic HSCT with conditioning. One of the retroviral vectors used in studies at Telethon Gene Therapy Program for Genetic Diseases, of the Hospital San Raffaele, in Milan, Italy was licensed by GlaxoSmithKline (GSK) and has received licensure approval in the European Union, a major advance for gene therapeutics that is available for patients. Other ongoing clinical trials in the United States and the UK are using a lentiviral vector for ADA-SCID with excellent initial clinical results in terms of efficacy and safety.[8] Thus, gene therapy for ADA-SCID has become a major treatment option for patients, as the efficacy and safety profile have been favorable and may exceed those of matched unrelated or haplo-identical transplants, although there have been no randomized controlled trials.

X-linked Severe Combined Immune Deficiency (Chapter 34)

The second genetic form of human SCID for which the relevant gene was identified and cloned is the X-linked form (XSCID). The responsible gene, *IL2RG*, encodes the common cytokine receptor γ chain (or γ_c), a component of several multimeric receptors for a family of lymphopoietic cytokines: IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. Defects of γ_c severely impair the development of multiple components of the immune system, and affected patients typically have severely reduced numbers of T and natural killer (NK) cells, and may have immature but non-functional B cells. Retroviral-mediated gene transfer of a normal human *IL2RG* cDNA was shown to restore cytokine-induced signaling activity and lymphocyte function in patients' cells and in murine models.[9,10]

XSCID patients were first treated by gene therapy using γ-retroviral vectors.[11,12] No conditioning was given, relying on the potent selective advantage for survival and proliferation that gene-corrected lymphoid cells were expected to have in patients with lymphopenic SCID. Indeed, robust reconstitution of T-cell immunity was achieved, although there were variable responses of B cells. However, after 2 to 3 years from treatment, several of the patients developed a severe complication from the retroviral vector of leukemia-like clonal leukoproliferation.

New vectors (self-inactivating or "SIN" vectors) that lacked the strong enhancer elements of the retroviral vectors that caused the insertional oncogenesis were developed. One published study using a SIN γ-retroviral vector demonstrated immune restoration without any evidence of leukoproliferation. New clinical trials are in progress using lentiviral vectors.[13] The first of these studies treated a group of patients XSCID who had undergone allogeneic transplant some years earlier, but who had not achieved complete immune reconstitution and had significant morbidity from poor growth and development.[14] Following gene therapy using a lentiviral vector and non-myeloablative conditioning, all have improved general well-being, with development of sufficient antibody production to be able to stop immunoglobulin replacement therapy. Studies treating more typical newly diagnosed infants with XSCID are now underway at several centers in the United States and Europe, with results from one published showing good immune reconstitution in the treated infants.[15]

Chronic Granulomatous Disease (Chapter 39)

CGD is a rare primary immunodeficiency (1 in 200,000 live births in the United States), first termed fatal granulomatous disease of childhood in 1959 to describe individuals affected by recurrent, invasive bacterial and fungal infections complicated by granuloma formation. Its clinical presentation is explained by defects in any of the components that comprise the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex leading to phagocyte dysfunction. In its fully assembled form, the NADPH oxidase complex is composed of five proteins, two of which are membrane-bound (gp91phox and p22phox) and three of which are cytosolic (p47phox,

p67phox, and p40phox). All five components are necessary for proper NADPH oxidase function without which affected individuals are particularly predisposed to infections with *Aspergillus* spp., *Staphylococcus aureus*, *Burkholderia cepacia*, *Serratia marcescens*, *Nocardia* spp., and less commonly, *Salmonella* and BCG infections outside of North America. Defects in gp91phox encoded by the *CYBB* gene account for the most common X-linked form of CGD while the remaining four causal genetic defects are inherited in an autosomal recessive (AR) mode. Since its initial description almost six decades ago, CGD has evolved from a disease with early mortality to one with relatively good outcomes and multiple treatment options.

While prophylactic antimicrobial and immunomodulatory agents have dramatically decreased infection rates and inflammatory bowel disease in patients with CGD, curative therapy can only be achieved with HSCT. Transplant outcomes have continued to improve over the years, with good results reported even in patients with high-risk features such as intractable infections and auto-inflammation using RIC protocols.[16] Nevertheless, allogeneic HSCT can still be complicated by GvHD and pre-existing infections and is not preferred for those without an HLA-matched stem cell donor. For these patients, autologous HSCT with gene-modified cells is becoming a more viable and realistic option.

The first gene therapy trials for CGD began in the mid-1990s using γ-retroviral vectors. As with ADA-SCID, initial trials in which pre-transplant conditioning was not used did not lead to efficacy as there was minimal engraftment of gene-corrected stem cells. In subsequent studies where non-myeloablative conditioning with busulfan was used, increasingly higher levels of engraftment of corrected stem cells were achieved.[17] The best and worst of these studies was one using a γ-retroviral vector with a potent transcriptional control element to drive high-level expressions of the *CYBB* gene.[18] The three treated subjects had initial development of neutrophils with restored oxidase function and their severe resistant infections cleared. However, insertional oncogenesis occurred in this study also, and myelodysplasia or frank myeloid leukemia developed.

More recently, trials are using a lentiviral vector with a myeloid-specific transcriptional control element intended to drive *gp91phox* expression in mature myeloid cells, where it is needed, but to not have activity in HSCs that are the likely targets for transformation.[19] Initial results are showing safety and evidence of efficacy. A report of results from nine patients with XCGD treated in the United States and United Kingdom showed sustained restoration of gp91phox expression and functional oxidase activity using the dihydrorhodamine assay in six of seven patients who survived beyond the immediate post-transplant period.[20]

WISKOTT-ALDRICH SYNDROME (CHAPTER 34)

WAS, initially described as an X-linked syndrome in kindreds in Germany and the United States, presents with multiple clinical manifestations, including the classical triad of immune deficiency, eczema, and thrombocytopenia. The complex immune deficiency involves defects of T, B, NK, and antigen-presenting cells. The identified *WAS* gene encodes a 501 amino acid proline-rich protein that has multiple identified functional domains, placing it at the nexus of intracellular signaling and cytoskeleton control. Once the WAS cDNA was obtained, γ-retroviral vectors were constructed and shown to correct several manifestations of the disorder in patient-derived cells and in murine models. However, it is not fully known what levels of *WAS* transgene expression are needed to safely and effectively correct the major manifestations of lymphocyte and platelet dysfunction. A concern has been raised that suboptimal levels or low frequency of expression of WAS protein (WASP) could allow auto-immunity to develop. If correction is only partial (e.g., some proportion of B cells are not gene corrected and have defective auto-regulatory function), autoimmunity may occur.[21]

A first trial of gene therapy for WAS used a γ-retroviral vector with a very potent retroviral long terminal repeat promoter enhancer. Granulocyte colony-stimulating factor (G-CSF)-mobilized peripheral blood stem cells were used as the HSC source and conditioning with myeloablative dosages of busulfan was given prior to transplant. There were excellent initial results in terms of immune reconstitution and platelet counts, demonstrating that gene therapy can be therapeutic for this disorder. However, there was subsequently a very high incidence of acute leukemia among these patients, developing within a few years from treatment, with acute lymphocytic leukemia (ALL), acute myeloid leukemia (AML), or both occurring in a shocking seven of nine subjects.[22] The mechanism of insertional oncogenesis from the γ-retroviral vector was clearly the cause, with the leukemias showing clonal vector integrations adjacent to known proto-oncogenes, such as *LMO2* and *MDS1*.

While that trial was being initiated, work was ongoing through a multicenter collaboration in the European Union (EU) to develop a SIN lentiviral vector for WAS that uses the promoter from the *WAS* gene per se to drive expression of the WAS cDNA. Extensive preclinical studies showed the efficacy of this vector to improve immunological and hematological parameters in murine and human disease models.[23,24] Moreover, this lentiviral vector displayed significantly lower risks for genotoxicity than the type of γ-retroviral vector used in the first trial.

The lentiviral vector with the WAS promoter has now been used in parallel but independent phase I/II clinical trials performed in several countries.[25,26] Relatively high-intensity conditioning was administered in an attempt to obtain high-level engraftment of gene-corrected HSCs, with some differences among the centers in the precise conditioning regimen used. All used moderate doses of busulfan (pharmacokinetically [pK]-adjusted) and fludarabine, and variably, rituximab or other serotherapy agents. These trials have uniformly demonstrated efficacy and safety. Findings have included clinical improvement in general health, bleeding incidents, and eczema, and as expected for an autologous transplant, no problems from GvHD. Most have had good recovery of T, B, and NK cell numbers and functions. However, there have been only modest and variable improvements for platelet levels (e.g., 20 to 60,000/μL), with evidence that a higher transplanted dose of transduced cells led to higher platelet counts.[25] No new onset of autoimmunity has been reported, although in some cases, pre-existing autoimmune problems have persisted. In fact, decreases of indices of autoimmunity and improved B-cell tolerance have been documented after gene therapy for WAS.[27] Polyclonal vector integration patterns were seen, with no reported development of clonal expansions or frank leukoproliferative complications. Integration site patterns resemble those seen in other trials using lentiviral vectors into human HSCs, with highly diverse vector integration sites and no predilection for cancer-related genes, significantly different from the pattern seen in the γ-retroviral vector trials.

These results are promising and of significant clinical benefit and safety but would be better if more normal levels of platelets

could be achieved. It is possible that the level of expression of WASP from the *WAS* gene promoter in the lentiviral vector is inadequate to support normal platelet production or survival. If so, introducing more than one copy of the vector per cell could lead to higher levels of WASP and higher platelet counts. Alternatively, the absolute number of gene-corrected HSCs engrafted may mediate the platelet levels and a higher percentage of transduced cells or higher numbers of gene-corrected cells may support higher platelet levels. Relative risks of multiple integrants versus a stronger promoter are not known. As for the other disorders discussed here, direct gene correction should yield normal, physiological expression of the *WAS* gene and may lead to improvements in all relevant lineages.

Leukocyte Adhesion Defect-1 (Chapter 39)

LAD-1 is another severe PID that may be a good candidate for HSC gene therapy, as it is caused by a single gene defect (*ITGB2* encoding CD18). CD18 functions as a heterodimer with CD11a, -b or -c, which may limit activity only to the appropriate cell types where the CD11 co-chains are expressed. Bauer and Hickstein performed gene therapy for two patients with LAD-1 using a γ-retroviral vector expressing human CD18 to transduce bone marrow cells without conditioning.[28] There were no beneficial effects of gene therapy and both later succumbed to complications of their immune deficiency. More recently a clinical trial for LAD-1 using a lentiviral vector has begun enrollment (NCT03812263).

GENE THERAPY CONSIDERATIONS FOR OTHER PRIMARY IMMUNE DEFICIENCIES

Currently, a new development project is needed to bring gene therapy to clinical application for each individual PID-causing locus, such as the more than 20 human genes that may cause SCID, 5 or more CGD loci, several for hemophagocytic lymphohistiocytosis (HLP), X-linked lymphoproliferative disease (XLP), etc. Each gene and disease setting pose different challenges in terms of necessary gene transfer efficiency, level of expression, need for regulation of the transferred gene, safety considerations, and measurable endpoints.

X-linked agammaglobulinemia (XLA; Chapter 33) is another logical disease to consider treating by autologous transplant with gene therapy, since normal B-cell development from HSC with a normal Bruton tyrosine kinase *(BTK)* gene should correct the immune deficiency. Because of the good clinical effects from immunoglobulin replacement therapy for XLA and the toxicities from HSCT, especially from chemotherapy and GvHD, HSCT is rarely done for patients with XLA. A few patients with XLA have had allogeneic transplants from healthy donors and have developed B-cell reconstitution.

Gene therapy studies in *BTK* gene knock-out mice have shown that lentiviral vectors with B lymphoid-specific promoters driving BTK expression can lead to immune reconstitution.[29,30] While no adverse effects were seen from constitutive expression of the *BTK* gene in these murine studies, these do not constitute formal toxicology studies, which would be needed before clinical applications. It is likely that regulated expression of *BTK*, rather than constitutive, ubiquitous expression, is needed for highest efficacy and safety. In theory, lentiviral viral vectors using components of the *BTK* gene transcriptional regulatory sequences could yield vectors with the desired expression specificity. Alternatively, gene correction of the *BTK* gene, using the methods discussed below, could restore precise *BTK* expression regulation and may have the greatest safety profile.

Common variable immune deficiency (CVID) comprises the most common severe human PID (Chapter 33). While immunoglobulin replacement therapy can ameliorate the immune deficiency caused by hypogammaglobulinemia, the high rate of other clinical complications that CVID patients may experience necessitate new treatments. However, gene therapy requires knowing the responsible pathogenic gene, and has been limited to monogenic disorders. To date, no single gene defect has been identified in the majority of patients with CVID. There are some known CVID-causing genes, including *TNFRSF13B* (encoding TACI 8% to 10%), *TNFRSF13C* (encoding BAFF-R), NFKB1, ICOS, CD19, and MSH5, which in total may be responsible for 30% to 50% of all patients with CVID.[31] A separate gene therapy project would be needed to develop treatment for each causal gene, through the full spectrum from preclinical activities to clinical trial performance. Moreover, because most of these known CVID-causing genes are involved in cell stimulation and signaling, they may require regulated, rather than ubiquitous, constitutive expression for safety. Because of these constraints, it is not currently possible to apply gene therapy for the majority of patients with CVID.

There has been growing recognition of numerous immune dysregulation and auto-inflammatory syndromes due to deficiency of regulatory T cells (e.g., immunodeficiency, polyendocrinopathy, enteropathy, X-linked {IPEX}), cytotoxic T lymphocyte antigen 4 {CTLA4} and lipopolysaccharide-responsive beige-like anchor protein {LRBA} deficiency, and autosomal dominant gain-of-function mutations (e.g., signal transducer and activator of transcription 3 {STAT3}, MEFV, IL-1, nuclear factor kappa B {NFkB}, interferon pathways). The Primary Immune Deficiency Treatment Consortium named these disorders collectively as primary immune regulatory disorders (PIRD).[32] PIRD are characterized more by autoimmune complications than infections, in contrast to the classical PIDs. The responses of PIRD to allogeneic HSCT have been variable, and, to the extent that GvHD has been a significant component of poor outcomes, autologous gene therapy/HSCT may improve results.[33] Gene modification of a patient's HSC by addition of a shRNA cassette or gene disruption using site-specific endonucleases may suppress expression of the dominant gene. Direct correction of the pathogenic mutation could also be beneficial, as discussed below. It is likely that the gene modification would need to be highly efficient to yield a high fractional correction of the engrafting stem cells. In this setting, some pre-transplant immune suppression may be needed to ablate pre-existing autoimmunity.

Perhaps most challenging for gene therapy are the PIDs that also have major somatic or neurodevelopmental or neurodegenerative problems, such as chromosomal abnormalities, ataxia-telangiectasia, and others. Here, gene therapy with HSC may benefit the immunological components of the disorder but would not address the others; systemic delivery of genes or delivery to the CNS is under study, but it is not yet sufficiently efficient for most clinical needs.

GENE EDITING FOR GENE THERAPY OF PRIMARY IMMUNE DEFICIENCIES

A major paradigm shift in gene therapy is underway as methods of performing precise editing of the genomes of somatic cells are being developed. As an alternative to the semi-random insertion

of normal copies of the relevant gene delivered by a viral vector, as discussed for all of the studies above, techniques are being established to either correct specific bases in the DNA, or to insert (or remove) gene sequences at specific sites by harnessing cellular DNA repair pathways. These DNA repair mechanisms normally correct the many double-stranded DNA breaks that occur during DNA replication or from environmental genotoxic agents (ionizing radiation, chemicals). There are two major DNA repair pathways for rejoining the sequences that flank a double-stranded DNA break: non-homologous end joining (NHEJ) and HR. NHEJ reconnects the broken ends of the chromosomes in a way that often leads to insertion or deletion of DNA bases (indels) at the junctional site. This is, in essence, a mutagenic process and may be used to disrupt genes to knock-out their activity, examples being the HIV-1 co-receptor CCR5, dominant-active transcriptional factors such as CTLA-4, or STAT3 gain-of-function alleles, *BCL11a*, a transcriptional repressor of fetal hemoglobin, etc. There have been clinical trials for patients with HIV infection in which the gene for CCR5 HIV co-receptor was disrupted using a zinc finger nuclease (ZFN) to make a double-stranded DNA break while NHEJ was allowed to repair the break, leading to indels that inactivated the gene and co-receptor expression.[34] More recently, clinical trials have been initiated using either ZFN or clustered regularly interspaced short palindromic repeats (CRISPR)/Cas9 nucleases to disrupt the *BCL11a* gene and induce expression of fetal hemoglobin as a treatment for patients with sickle cell disease and beta-thalassemia.

HR is a more precise repair mechanism that normally uses a copied sister chromosome as a template to repair double-strand DNA breaks that may occur during DNA replication or spontaneously; sequences of the template are copied into the repair site, and, if there are differences in their sequences, the template acts as a donor for the new sequences. For gene correction, an artificial donor template is provided to the cells to instruct the introduction of the intended sequence changes (Fig. 91.3). Beyond its use for modification of single base pairs (bp), as illustrated here, HR can be used to introduce whole gene sequences into the target site by flanking a gene cassette with "homology arms" that consist of the DNA sequences homologous to the target site (Fig. 91.4).

Codon#:	1	2	3	4	5	6	7	8	9
(1) Wild-type Gene	5'-ATG	CCT	TGA	AAT	TCG	GGG	CGA	TTG	ACC-3'
	3'-TAC	GGA	ACT	TTA	AGC	CCC	GCT	AAC	TGG-5'
(2) Mutant Gene	5'-ATG	CCT	TGA	AAT	ACG	GGG	CGA	TTG	ACC-3'
	3'-TAC	GGA	ACT	TTA	TGC	CCC	GCT	AAC	TGG-5'
(3) Donor template				5'-GA	AAT	TCG	GGG	C-3'	
(4) Corrected Gene	5'-ATG	CCT	TGA	AAT	TCG	GGG	CGA	TTG	ACC-3'
	3'-TAC	GGA	ACT	TTA	AGC	CCC	GCT	AAC	TGG-5'

FIG. 91.3 Site-Specific Gene Editing by Homologous Recombination (HR). In this example, instead of the wild-type gene sequence (1), a patient's gene (2) has a mutation from a base-pair substitution of an A for a T at the start of the 5th codon *(red)*. An artificial donor template (3), here as a single-stranded deoxyoligonucleotide of 12 bases in length *(green)*, is provided with the correct base present at the site of the patient's mutation *(blue)*. If the donor template is used to repair a double-stranded DNA break induced near the mutation by a site-specific endonuclease *(red arrow)*, sequences from the donor *(green)* will be incorporated into the patient's gene (4), introducing the normal corrective base pair *(blue)*.

Although HR has been used to introduce genes into cells, such as murine embryonic stem cells to make gene knockout and knock-in mice, it is generally a low-frequency event (occurring in $1/10^6$ to $1/10^4$ cells) and requires the use of selectable markers to isolate the rare desired recombinant. Whereas cloning and expansion of murine (and human) embryonic stem cells can be done to produce populations of the rare recombinant cells, this is not currently possible with primary HSCs, which cannot be expanded to any great degree from single cells while retaining their totipotent differentiation capability. Methods achieving high efficiency of gene modification with low cytotoxicity in large numbers of primary stem cells will be needed for clinical applications to autologous HSCT. A major breakthrough in this area comes from the observation that HR is vastly more frequent when a double-stranded DNA break is introduced close to the target site; then, the repair donor molecule can be used at efficiencies in the range of approximately 1% to 50% of treated cells.[35,36]

Several classes of designer site-specific endonucleases have been derived, including ZFN, introduced above; transcription activator-like effector nucleases (TALENs); and more recently CRISPR/Cas9, all of which permit the introduction of a double-stranded DNA break at unique sites in the mammalian genome with high specificity. Current methods introduce the nuclease into HSCs by a method where it will only be present transiently, for example, electroporation of in vitro transcribed messenger RNA encoding the nuclease proteins or as recombinant protein.

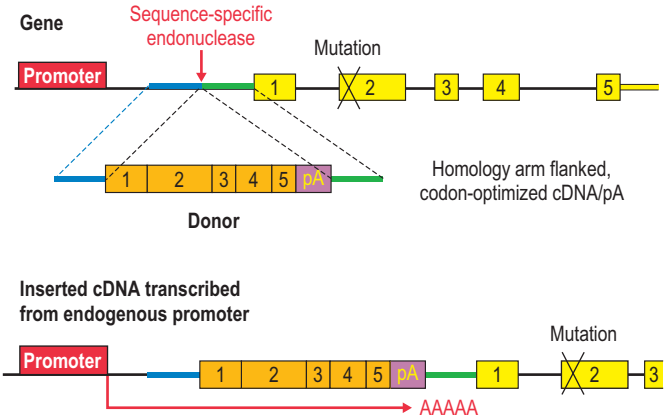

FIG. 91.4 Site-Specific Insertion of a cDNA to Override Downstream Gene Mutations. A prototypical gene is shown with 5 exons (upper diagram, *yellow boxes* 1–5) and an upstream promoter *(red box)*. An inherited mutation in exon 2 (black X) inactivates the gene. A sequence-specific endonuclease *(red arrow)* is designed to introduce a double-stranded DNA break, in this case in the 5′ untranslated region of the gene (*blue* and *green* lines). A cDNA molecule is constructed that contains the contiguous exons of the gene (*orange* 1–5), codon-optimized to increase expression and to eliminate homology with the endogenous exons to avoid illegitimate recombination events, and a polyadenylation signal (pA) to terminate transcription. The cDNA is flanked by the sequences matching the endonuclease cleavage region (*blue* and *green* lines). This donor cDNA is inserted into the nuclease target site by homologous recombination (lower diagram), positioned to be under transcriptional control of the endogenous gene promoter. The resulting cDNA transcript *(red arrow)* would override any downstream mutations in the endogenous gene to produce the correct gene product under the physiological control of the normal gene expression regulatory elements.

The homologous donor template is introduced either as a short single-stranded deoxy-oligonucleotide (e.g., 50 to 100 bases) or longer (200 to 10.000 bp) double-stranded DNA cut from plasmids or produced by polymerase chain reaction that are co-electroporated with the nuclease; or as a long sequence carried by a viral vector that does not integrate into the target cell chromosome, including adeno-associated virus (AAV) or integrase-defective lentiviral vector (IDLV), but efficiently delivers the DNA template to the cell's nucleus.

An important caveat is that potential off-target activity of the nucleases could cause genotoxicity from either disruption of unintended genes or even introduction of chromosomal translocations between two cut sites produced simultaneously (e.g., one on-target and one off-target). Current studies are assessing the consequences of this potential genotoxicity in human HSCs, while ongoing work seeks to improve the specificity of the nucleases to eliminate or greatly minimize off-target activity. An array of assays has been developed to identify off-target cleavage site by endonucleases and, in many cases, nucleases with minimal detectable off-target activity have been found.[37]

Gene editing will have several advantages over gene addition. It would avoid the potential problems from randomly inserting vectors that may disrupt or overstimulate adjacent cellular genes, as discussed above for the retroviral vectors. Crucially, correcting the endogenous gene keeps its expression under normal physiological control. This intrinsic regulation of gene expression will be essential for the gene therapy of many PIDs, where constitutive expression from a viral vector could produce malignancy or other unwanted effects. For example, retroviral vector delivery of a normal CD40 ligand gene corrected murine models of X-linked hyper-IgM syndrome (XHIM), subsequently led to the development of lymphomas in the mice from constitutive rather than regulated CD40 ligand expression.[38] BTK, defective in XLA, similarly may need to be expressed specifically at certain stages of B-lymphocyte development for safety and efficacy.

A long list of other loci involved in PIDs may similarly be best approached by gene correction that allows physiological gene expression control, including RAG1, SLAM, XIAP, JAK3, FOXP3, IL-10, IL7R, TACI, CTLA4, etc. While current gene correction techniques are below the frequency of efficiency needed to yield clinical benefits for most disorders, this field is moving at a lightning pace, with new advances in the activity and specificity of a whole host of nucleases and other genome editing tools.

Newer techniques for site-specific gene editing have been described that do not entail making double-stranded DNA breaks in the genome. Base editors use the Cas9/sgRNA system to bring to a specific genome site a catalytically inactive Cas9 protein fused to an enzyme capable of converting one nucleotide to another.[39] The first of these base editors was a fusion to cytidine deaminase that converts CG base pairs to TA base pairs. Other editors capable of making other nucleotide changes have been described; one day it may be possible to have a library of such editors that can be selected in order to make any desired specific base change.

USE OF PLURIPOTENT STEM CELLS AS A SOURCE OF HEMATOPOIETIC STEM CELLS FOR GENE THERAPY OF PRIMARY IMMUNE DEFICIENCIES

The establishment of human pluripotent stem cells (hPSCs), initially as human embryonic stem cells (hESCs) and subsequently as induced pluripotent stem cells (iPSCs), has brought the promise of novel models to study human diseases ("disease in a dish") and to provide renewable sources of patient-compatible cells for cellular therapies. The essentially unlimited ability to expand hPSCs and their capacity to produce any of the cell types in the body has led to investigations to harness them for regenerative medicines. In the treatment of PIDs, hPSCs could provide an ideal target to produce autologous HSCs with precise gene correction. While techniques have been developed to perform the gene modification strategies that may be sufficiently robust for clinical applications, the major roadblock is the current inability to produce clinically relevant numbers of transplantable HSCs from hPSCs. The HSC is a relatively evanescent state and it has not been possible to "freeze" differentiation from hPSC at that state, although it has been possible to proceed right through the HSC stage to produce relatively pure populations of mature blood lineages. As with gene correction, the pace of scientific progress with these phenomenal cells is proceeding rapidly, and it is likely that new sources of gene-corrected autologous HSCs will be available for clinical transplants in the near future.

GENE THERAPY FOR PRIMARY IMMUNE DEFICIENCIES INVOLVING SERUM PROTEIN DEFICIENCIES

Whereas many of the severe PIDs are due to blood cell defects and thus responsive to HSCT, others result from deficiencies of serum proteins, such as complement components. Here, gene therapy may be approached, as is being done for hemophilia, by direct in vivo administration of a gene-containing vector that can permanently insert the gene into target tissues—such as the liver, skeletal muscle, or endothelium—that can serve as protein factories. In vivo gene delivery is being studied using retroviral and lentiviral vectors or AAV vectors, and methods for in vivo gene correction using site-specific nucleases and homologous donor sequences are also under development. To this end, Crystal and collaborators have recently reported studies in a murine model of hereditary angioedema using an AAV vector to express the *SERPING1* gene encoding the C1 inhibitor.[40]

ADVANCING GENE THERAPY FOR PRIMARY IMMUNE DEFICIENCIES FROM EXPERIMENTAL TO STANDARD OF CARE

Initial trials of gene therapy for PIDs were all performed at tertiary-level academic medical centers, often with federal or disease-foundation research grant funding, and they tested initial hypotheses concerning safety and efficacy. These centers may continue to perform early-phase clinical trials for specific disorders, especially where there is local expertise on the disease being studied. However, there is an ongoing transition to industry-sponsored trials focused on drug product development, as the effective vectors and the gene-modified stem cell products they compose are advanced to licensure and marketing as pharmaceutical agents. A common model used by these new gene therapy companies is one of central processing, at one or a few high-grade commercial good manufacturing practice (GMP) facilities. The autologous patient cells are procured at the patient's home institution (by leukapheresis or bone marrow harvest), shipped to the central processing site for genetic manipulation and cryopreservation, and then returned to be administered locally. Currently, gene therapy transplants have been performed at a limited number of clinical trial sites due to the cell processing expertise needed; presumably under the

commercial model, such transplants may be done at any suitable HSCT center, with the company selling the processed cell product, as now occurs with medical devices or an unrelated stem cell product. Alternatively, self-contained cell processing and manipulation devices are being developed that could allow gene modification of stem cells to be done at individual institutions, without requiring highly trained staff or high-grade GMP facilities.

Major issues remain to be determined about cost and reimbursement for gene therapy. Effective gene therapy for the severe diseases being approached would be expected to lead to large lifetime savings in medical costs. The one-time price can be compared to the costs faced by the patient encumbered by the progressive nature of the underlying disease, to the costs for long-term protein-based therapies and possibly even the costs for allogeneic transplantation. However, those one-time costs are high for clinical gene therapy transplants using pharmaceutical-grade vectors and commercial-level cell processing with the attendant, essential quality control. Thus, a single large expenditure for gene therapy may eventually be cost-effective compared to ongoing medical costs; however, the method of financing the large up-front charge, at least in the United States with its multiple insurance companies, remains to be determined.

Recently approved gene therapies for an inherited retinopathy and B-lineage malignancies are being reimbursed through various models intended to distribute costs over time and in some cases to make reimbursement dependent on the measured benefits of the therapy.

CONCLUSION

In the past decades, gene therapy for PIDs has advanced from a dream for the future to a clinical reality. Gene therapy for ADA SCID, XSCID, WAS, CGD has been safe and effective in most treated patients using ex vivo gene delivery with lentiviral vectors. Approaches to direct gene editing are being developed that may broaden indications for PIDs that may be treated by gene therapy (e.g., XHIM, XLA, etc.). Thus, the continued efforts of scientists and physicians to develop gene therapy are leading to a new therapeutic modality, ideally to permanently and safely cure these diseases.

ON THE HORIZON

- Continued expansion of the genetic types of primary immune deficiencies (PIDs) being treated by gene addition using integrating vectors (e.g., other forms of severe combined immune deficiency [SCID], other forms of chronic granulomatous disease [CGD], leukocyte adhesion deficiency [LAD], hemophagocytic lymphohistiocytosis [HLH], etc.).
- Development of safe and effective marrow conditioning regimens that are not chemotherapy based (e.g., monoclonal antibodies).
- Application of gene editing to a broader spectrum of PIDs: (e.g., X-linked agammaglobulinemia, X-linked hyper-IgM syndrome [CD40 ligand deficiency], recombinase activating gene 1 (RAG1) SCID, IPEX, gain-of-function Signal Transducer and Activator of Transcription 1 [STAT1] disease).
- Understanding the molecular pathogenesis of more PIDs (e.g., CVID, auto-immune single gene disorders) and developing effective gene therapy approaches. Some may require correction of more tissue types than just HSCs (e.g., ataxia telangiectasia, in which neurodegeneration is a predominant feature).
- Production of autologous hematopoietic stem cells (HSCs) by cellular reprogramming of somatic cells to pluripotent state coupled to effective expansion of HSCs.

Hematopoietic Stem Cell Transplantation for Malignant Diseases

Pashna N. Munshi, Scott D. Rowley, and Robert Korngold

Hematopoietic stem cell transplantation (HSCT) is effective treatment for most hematological malignancies, including leukemia, lymphoma, multiple myeloma (MM), and clonal myelodysplastic and myeloproliferative diseases (MPDs), as well as a variety of nonmalignant diseases, such as autoimmune disorders and hemoglobinopathies. Autologous HSCT (auto-HSCT) is commonly used as therapy for patients with malignancies sensitive in a dose-responsive manner to chemotherapy or radiotherapy. These patients receive intensive cytoreductive regimens designed to eliminate all tumor cells; in so doing, however, they also destroy the patient's hematopoietic function needed for blood formation. Infusion of previously collected hematopoietic stem cells (HSCs) will rescue the patient from the marrow-ablative effects of this treatment. Allogeneic HSCT (allo-HSCT), in addition to reconstitution of bone marrow function, achieves an immunotherapeutic benefit from the donor natural killer (NK) and T cells within the graft attacking residual tumor cells that persist after the conditioning regimen, thereby greatly reducing the risk of later relapse of the disease. Thus allo-HSCT, in contrast to auto-HSCT, does not require administration of dose-intensive regimens to achieve complete tumor cell kill, and lower-risk nonmyeloablative regimens may be used to "condition" the host for transplantation.

Auto-HSCT (including syngeneic twins) is justified by the dose sensitivity of most hematological malignancies. Although there is some evidence that a more robust immunological recovery after auto-HSCT predicts lower risk of relapse, possibly opening an area of research in graft (or host) modification to enhance such recovery, treatment of the disease is primarily a result of the dose-intensive, myeloablative chemotherapy or radiotherapy administered. Infusion of cells is required only to recover hematopoiesis, and the stem cell infusion is, therefore, intended to treat the deleterious effect of chemotherapy on bone marrow function and not the disease itself. Marrow-toxic agents that cannot easily be incorporated into standard treatment regimens can be used in auto-HSCT. The primary complications of auto-HSCT result from the administration of a dose-intensive regimen and include a period of marrow hypoplasia, possibly requiring blood transfusions and antibiotics. Nonhematological toxicities, including mucositis resulting in inanition and diarrhea, and damage to other organs such as the lung, liver, and kidney, limit the amount of chemotherapy that can be administered. Currently, the treatment-related mortality (TRM) risk for most treatment regimens is ≤5%. Relapse of disease, particularly for patients who come to transplantation with chemotherapy-refractory disease, is the primary cause of failure of auto-HSCT. Improvements in the outcome of auto-HSCT will require innovative strategies to reduce this risk.

THERAPEUTIC PRINCIPLES

Autologous and Allogenic Transplantation

Autologous Transplantation

- Based on chemotherapy or radiotherapy dose sensitivity of disease being treated
- Requires collection and storage of adequate hematopoietic stem cells (HSCs), preferably before extensive alkylating agent or purine analogue therapy
- Lower risk of graft failure (no immunological rejection)
- No routine posttransplantation immunosuppression
- Minimal risk of graft-versus-host disease (GvHD)
- No graft-versus-tumor (GvT) effect
- More rapid posttransplantation immune reconstitution
- Risk of tumor cell contamination in HSC product
- Not useful for diseases in which normal HSCs cannot be collected (e.g., chronic myelogenous leukemia, myelodysplasia)

Allogeneic Transplantation

- Will rescue bone marrow function if dose-intensive therapy is administered
- Effective with reduced-intensity conditioning regimens
- Achieves a GvT effect in many malignancies
- Risk of GvHD distinct from the beneficial GvT effect
- Higher risk of transplantation-related complications that may offset the benefit of the GvT effect
- Risk of immunological graft rejection
- Slower posttransplantation immune reconstitution
- No risk of tumor-cell contamination with healthy donor

Allo-HSCT has a much lower relapse risk compared with auto-HSCT as a result of a beneficial immunological graft-versus-tumor (GvT) effect achieved by engraftment of the donor immune system. Allograft recipients, however, face a much higher risk of TRM from the detrimental immunological GvH response against healthy tissues of the patient. The principal nonrelapse complication of allo-HSCT is graft-versus-host disease (GvHD), which can occur early (acute GvHD, within the first several weeks) (Table 92.1) or late (chronic GvHD, months to several years) after transplantation. The rate of overall incidence of moderate to severe acute GvHD (aGvHD) is 35% to 80% for all patients receiving cells from a human leukocyte antigen (HLA)–matched related or unrelated stem cell donor, and aGvHD is a primary cause of death in 10% to 20% of these patients. Chronic GvHD (cGvHD), a clinicopathologically distinctive form of this alloreaction, occurs in up to 80% of recipients; it may involve aspects of regulatory T-cell (Treg) dysfunction and autoimmune-like responses, and may require years of therapy before tolerance is achieved, allowing withdrawal of immunosuppressant medications. Other

TABLE 92.1 Acute Graft-versus-Host Disease

Clinical Staging

Stage	Skin	Liver	Gut
1	Maculopapular rash <25% BSA	Bilirubin 2–3 mg/dL	Diarrhea 500–1000 mL/day, or persistent nausea
2	Maculo-papular rash 25%–50% BSA	Bilirubin 3–6 mg/dL	Diarrhea 1000–1500 mL/day
3	Generalized erythroderma	Bilirubin 6–15 mg/dL	Diarrhea >1500 mL/day
4	Desquamation and bullae formation	Bilirubin >15 mg/dL	Pain ± ileus

Clinical Grading

Overall Grade	Skin	Liver	Gut	Functional Impairment
0 (none)	0	0	0	0
1 (mild)	1–2	0	0	0
2 (moderate)	1–3	1	1	1
3 (severe)	2–3	2–3	2–3	2
4 (life-threatening)	1–4	1–4	1–4	3

significant complications of allo-HSCT relate to problems of inadequate reconstitution of the immune system of the patient and the concomitant risk of opportunistic infections, including viral and fungal infections that are rarely observed in healthy hosts. Despite the apparent risks associated with allo-HSCT, this treatment holds great promise as a curative therapy for several tumor types, particularly with strategies either to enhance the efficacy of the GvT effect or decrease the toxicity of the graft-versus-host (GvH) response. Efforts have been made in recent years to make HSCT less toxic by development of low-dose, nonmyeloablative conditioning regimens that allow the treatment of older patients or those with comorbid health issues that otherwise preclude treatment with high doses of chemotherapy.[1]

IMMUNE MECHANISMS RELATED TO ALLO-HEMATOPOIETIC STEM CELL TRANSPLANTATION

Histocompatibility

The HLA major histocompatibility complex (MHC; Chapter 5) is the primary consideration in the selection of a donor for allo-HSCT, since its loci contribute significantly to host-versus-graft (HvG), leading to immunological rejection of donor HSC, and to GvH (leading to GvHD and GvT) reactions. HLA antigens are classified as class I (HLA-A, -B, -C) and class II (HLA-DR, -DQ, -DP) molecules, and typing of donors and patients can be performed using low- or high-resolution techniques. The low-resolution serological techniques can determine a phenotypic mismatch (e.g., A02 vs A03), whereas high-resolution molecular techniques can identify allelic genotypic differences (*e.g.*, HLA-*A*02:01* vs. *HLA-A*02:02*). The risks of aGvHD, cGvHD, and transplantation-related mortality increase with the number of HLA mismatches, and ideally, genotypically matched unrelated donors are sought for patients lacking an HLA-identical sibling. Disparity at HLA-A, -B, -C, and DRB1 alleles are definite risk factors for survival after unrelated donor transplantation, whereas single HLA-DQ or -DP mismatches appear to be better tolerated and/or permissive, meaning they do not have a deleterious impact on clinical outcome.[2]

Not all mismatches result in a deleterious clinical outcome, and identification of permissive mismatches will increase the number of donors available to the patient. Algorithms accounting for possible permissive mismatching in the selection of unrelated donors are being developed and tested.[3]

GvHD and GvT occurring after HLA-compatible sibling transplantation demonstrate the importance of minor histocompatibility antigens (miHAs) on the outcome of allo-HSCT. miHAs are derived from polymorphic sites in normal proteins between individuals and are constantly processed by proteasome activity and presented on the cell surface by MHC molecules; they can thus be recognized by T cells from an HLA-matched donor. As a result, hundreds of miHAs may be variably expressed on host tissues and can trigger an alloresponse from donor T cells, thereby causing GvHD (and GvT). Unfortunately, only a few miHAs have been identified, such as those on the Y chromosome, leading to a higher risk of GvHD in male recipients of cells from female donors.[4] miHA matching of a male donor for a male recipient is not a component of current algorithms for donor selection.

Research in the field of additional criteria for donor selection is ongoing. Human NK cells possess clonally distributed, inhibitory receptors termed "killer cell immunoglobulin-like" (KIR) receptors that recognize epitopes shared by groups of HLA class I alleles (KIR ligands). KIR–ligand mismatching in the GvH direction appears to result in lower risk of relapse- and nonrelapse-related mortality after allo-HSCT. Activating KIRs transduce signals to activate NK cells, and the presence of these cells is associated with a lower risk of leukemia relapse after unrelated and haploidentical transplantation as well as protection against certain viral infections, such as human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) or hepatitis C virus (HCV) infection.

Graft-versus-Host Disease

GvHD is caused by mature donor T cells within the HSC inoculum, which recognize HLA or miHA differences expressed by host antigen-presenting cells (APCs) and tissues (Fig. 92.1).[5] Cytokines released from host cells after a patient has received dose-intensive tumor cytoreductive chemotherapy or radiotherapy conditioning create an inflammatory environment that enables the generation of a response of infused donor T cells against host antigens. This initiates a cascade of T-cell activation events, which results in proliferation, release of additional inflammatory cytokines, and the generation of effector T cells that can infiltrate target tissue, particularly the lymphoid system, intestinal tract, skin, and liver and mediate the destruction of host cells in those organs. Both CD4 and CD8 T cells can be involved in GvHD, depending on the specific class I or class II HLA or miHA disparities involved.

The simplest way to avoid the development of GvHD is to deplete the donor HSC graft of T cells before infusion to a cell

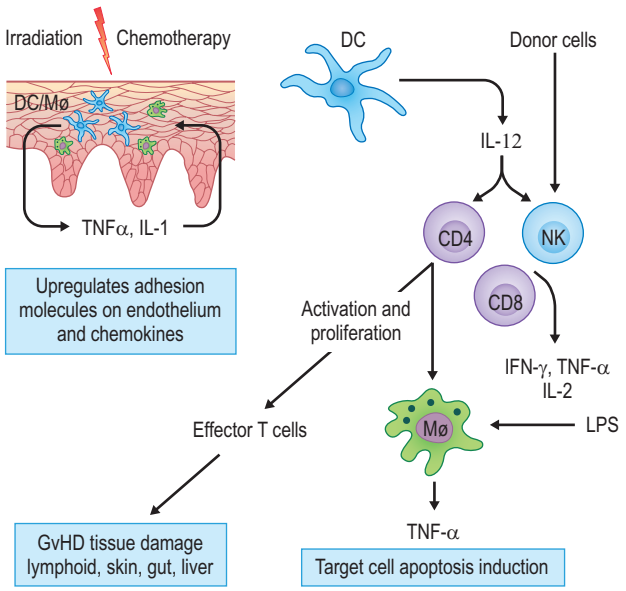

FIG. 92.1 Development of Graft-versus-Host Disease. Cytoreductive preconditioning treatment of patients with hematological malignancies with total body irradiation (TBI) or chemotherapeutic drugs causes damage to epithelium in the skin and gastrointestinal tract and activates the release of inflammatory cytokines by dendritic cells *(DCs)* and macrophages *(Mϕ)* in those tissues. These cytokines include tumor necrosis factor-*α (TNF-α)* and interleukin *(IL)*-1, which upregulate adhesion molecules and chemokine release in the vascular endothelium of the tissues. Activated DCs also migrate to the lymphoid system, where they can present recipient histocompatibility antigens to infused donor T cells that are in the hematopoietic stem cell graft. DCs release IL-12, which helps activate CD4 and CD8 T cells, as well as natural killer *(NK)* cells. These responding cells proliferate and produce additional inflammatory cytokines, including interferon-*γ (IFN-γ)*, TNF-*α*, and IL-2. M*ϕ* are activated by both IFN-*γ* and lipopolysaccharide *(LPS)* produced by bacteria found in the intestinal tract, and these cells then produce high levels of more TNF-*α*. TNF-*α* has many properties, including direct induction of apoptosis on cells in the tissues of target organs of graft-versus-host disease *(GvHD)*, but it also helps effector T cells to home to and enter tissue sites through the vascular endothelium. Effector T cells specific for host histocompatibility antigens then get reactivated and perform their effector functions, including release of inflammatory and cytolytic cytokines and direct killing of recipient-type cells in the lymphoid compartment and in the skin, gut, and liver.

KEY CONCEPTS

Graft-versus-Host Disease

- Caused by donor–recipient differences in:
  - Major histocompatibility complex (MHC) molecules
  - Minor histocompatibility antigens (miHAs)
- Mediated by mature donor CD4 and/or CD8 T cells
- Requires inflammatory cytokines
- Primary target organs include lymphoid system, skin, gastrointestinal tract, and liver
- Distinct forms of presentation and target organ involvement classified as acute or chronic

dose below 10^5 cells/kg body weight. This approach has succeeded in significantly diminishing the incidence of GvHD, but other complications related to the ensuing delay in immune reconstitution of recipients, an increased risk of relapse from loss of the GvT effect, and a higher rate of engraftment failure (also from loss of the GvH effect) have resulted in inconsistent improvement in long-term survival, compared with T cell–replete products. The conundrum is that the same alloreactive donor T cells that mediate GvHD can also cause a GvT response, although there may also be additional tumor-specific or hematopoietic tissue-specific T cells.[6] Thus the overriding goal is to be able to manipulate the donor HSC inoculum in such a way as to avoid GvHD, but to still be able to mediate a GvT effect.

Clinical Aspects of Acute Graft-versus-Host Disease

Usually developing within the first 3 months after transplantation, aGvHD is a clinical diagnosis with characteristic, but nondiagnostic, pathological findings, with the most common presenting manifestations including skin rash, nausea, anorexia, diarrhea and jaundice, depending on the target organ(s) most affected.[7] In addition to the increased risks of developing aGvHD related to the extent of HLA and miHA disparity, additional factors include the advanced age of either the donor or the recipient, gender disparity (female donor–male recipient), donor parity (female donors), and infusion of T-cell–replete HSC products. Conditioning with reduced-intensity regimens, with lower regimen-related toxicities to nonhematological tissues, also results in a lower risk of aGvHD and may delay the onset of its initial manifestation. Interactions between microbial-associated molecules and innate immune receptors (*e.g.*, Toll-like receptors [TLRs]) appear to be involved in GvHD pathogenesis, as demonstrated in both murine models and human transplantation. Research has shown an interaction between the host's gut microbiota and immune system.[8] On the basis of this knowledge, experiments to decrease transplantation-related GvHD by altering the gut microbiome are being actively pursued.

Pharmacological agents are the mainstay of aGvHD prophylaxis. Most patients receive a combination of a calcineurin inhibitor (tacrolimus or cyclosporine) along with an antimetabolite, such as methotrexate or mycophenolate mofetil (MMF). Methotrexate is associated with delayed engraftment, mucositis, idiopathic pneumonia syndrome, and other transplantation-related complications, which has prompted the development of other combination regimens, such as a calcineurin inhibitor in combination with sirolimus or MMF, or reduced doses of methotrexate. The addition of anti-thymocyte globulin (ATG) to the conditioning regimen lowers the incidence of both GvH and HvG reactions because of its persistence for several days after HSC infusion, effectively depleting T cells from the graft as well as the host. However, patients treated with ATG may face higher risks of infectious complications, including Epstein-Barr virus (EBV)–associated posttransplantation lymphoproliferative disorder as a result of the greater immunosuppression achieved.

The administration of high-dose cyclophosphamide, an alkylating agent of the nitrogen mustard family, after transplantation reduces the risks of acute and/or chronic GvHD and is a prime example of drug-induced immunological tolerance, a concept first demonstrated by Schwartz and Dameshek in their experiments using 6-mercaptopurine.[9] Subsequently, in 1963, Berenbaum and Brown demonstrated immune tolerance to skin allografts in adult mice by using cyclophosphamide.[10] Posttransplantation cyclophosphamide given on days 3 and 4 after transplantation is now

a standard regimen used in haploidentical allogeneic transplantations in combination with other immunosuppressive drugs and as a single agent in matched unrelated and related transplantations, reducing the complications of graft failure and life-threatening aGvHD associated with transplantation of HLA disparate grafts.[11] Given the successes of this approach, posttransplantation cyclophosphamide is now used for GvHD prophylaxis in unrelated donor transplants with comparable outcomes of survival, GvHD,[12] and immune reconstitution.

Glucocorticoids with a calcineurin inhibitor remain the standard approach to initial systemic management of clinically significant aGvHD. About 30% to 50% of patients will respond to initial therapy, and patients who fail to respond have a poor prognosis, as additional agents added for control greatly increase the risk of opportunistic infections and other treatment-related complications. The use of higher doses of corticosteroids, or the addition of ATG, for example, in the initial treatment of aGvHD do not improve patient outcomes and should be reserved for patients who fail initial therapy. A number of drugs, including ATG, pentostatin, switching to tacrolimus from cyclosporine, and newer monoclonal antibodies (mAbs) have shown limited activity in the salvage treatment of patients with steroid-refractory aGvHD. Extracorporeal exposure of peripheral blood mononuclear cells (PBMCs) to the photosensitizing agent 8-methoxypsoralen and ultraviolet A (UVA) radiation (photopheresis) is effective in the treatment of selected diseases mediated by T cells, including both aGvHD and cGvHD, although the mechanism of this effect remains to be elucidated. The recent approval of ruxolitinib[13] for steroid-refractory GvHD is a result of better understanding of lymphocyte activation pathways and provides encouraging treatment options for this otherwise challenging clinical condition.

Autologous Graft-versus-Host Disease

A form of aGvHD can also occur after auto-HSCT, probably as a manifestation of immune system dysregulation during reconstitution of the immune system after dose-intensive therapy. Initially studied in murine models of auto-HSCT, it was demonstrated that the abrupt withdrawal of cyclosporine could induce clinical features indistinguishable from those observed after allo-HSCT. A mechanism that involves the depletion of central memory cells has been proposed, although depletion of Treg with inhibition of peripheral tolerance may also be involved. Autologous GvHD is also reported in patients not receiving posttransplantation immunomanipulations (spontaneous GvHD). Based on the clinical benefits of GvT observed in allo-HSCT, several clinical trials with administration of cyclosporine with or without interferon (IFN) were performed in patients undergoing auto-HSCT without obvious GvT effect.[14] Both induced and spontaneous autologous aGvHD are usually self-limiting complications, and are usually easily managed with a course of corticosteroids in patients with more extensive involvement, in contrast to the more extensive and difficult-to-manage aGvHD that occurs after allo-HSCT. Furthermore, cGvHD does not occur after auto-HSCT.

A spontaneously occurring severe, and sometimes fatal, reaction, "engraftment syndrome," involves the gastrointestinal (GI) system with severe diarrhea during the periengraftment period in some patients undergoing auto-HSCT for MM and other malignancies.[15] The presentation is clearly distinct from the spontaneous or induced GvHD previously observed in patients undergoing auto-HSCT. Engraftment syndrome may be a consequence of prior treatments with immunomodulatory drugs, such as lenalidomide or thalidomide, the proteasome inhibitor bortezomib, or high doses of potent glucocorticoids before collection and storage of autologous HSCs, resulting in a period of immune dysregulation occurring early after autologous HSCT. Patients with engraftment syndrome may require intensive treatment with corticosteroids and a calcineurin inhibitor, with courses more similar to those experienced by patients undergoing allo-HSCT.

Clinical Aspects of Chronic Graft-versus-Host Disease

cGvHD is the leading cause of late TRM among those undergoing allo-HSCT and resembles autoimmune disorders, such as scleroderma, Sjögren syndrome, and primary biliary cirrhosis. Diagnosis is, as with aGvHD, based on clinical observations and secondary confirmation with laboratory or pathology tests (Table 92.2). A falling performance status, progressive weight loss, or recurrent infections are typical signs of severe cGvHD. About 50% of long-term survivors will develop cGvHD at a median of 9 months after transplantation, and patients must be monitored closely for this

TABLE 92.2 Staging of Chronic Graft-versus-Host Disease (GvHD)

Target Organ	Score 0	Score 1	Score 2	Score 3
Performance score	KPS 100%	KPS 80%–90%	KPS 60%–70%	KPS <60%
Skin	No symptoms	<18% BSA	19%–50% or sclerotic, still able to pinch	>50% or "hidebound"
Mouth	No symptoms	Mild symptoms, no limitations	Moderate symptoms, decreased oral intake	Severe symptoms with major decrease in intake
Eyes	No symptoms	Mild dry eyes	Moderate dry eyes, drops >3×/day	Severe dry eyes affecting daily activities
Gastrointestinal tract	No symptoms	Symptoms without weight loss	Symptoms with moderate weight loss (5%–15%)	Symptoms with weight loss >15%
Liver	Normal LFTs	LFTs elevated <2× upper limits of normal	LFTs elevated 2–5× upper limits of normal	LFTs elevated >5× upper limits of normal
Lungs	No symptoms	Mild symptoms FEV 60%–79%	Moderate symptoms FEV 40%–59%	Severe symptoms FEV <40%
Joints and fascia	No symptoms	Mild tightness not affecting daily activities	Tightness affecting daily activities	Contractures with significant loss of range of motion
Female genital tract	No symptoms	Symptomatic with middle signs on examination	Symptomatic with dyspareunia	Symptomatic with strictures

At least one diagnostic and one distinctive sign is necessary to make a diagnosis of cGvHD.
BSA, Body surface area; *FEV*, forced expiratory volume; *KPS*, Karnofsky performance status; *LFT*, liver function test.

complication for at least 3 years so that appropriate treatment can be initiated before extensive end-organ damage ensues. Permanent ocular or oral sicca syndrome and pulmonary dysfunction can result if cGvHD is not appropriately treated, leading to a marked deterioration in quality of life.

Factors predictive of the development of cGvHD include the degree of HLA and miHA disparity, as well as prior aGvHD, older patient age, the source of HSCs (greater risk after peripheral blood stem cell [PBSC] transplantation than after bone marrow transplantation), gender (female donor–male recipient), and donor lymphocyte infusion (DLI) after transplantation. Inflammatory events, such as sunburn or surgical procedures, can precipitate cGvHD. Patients who develop cGvHD have a higher risk of TRM but a lower risk of relapse as a result of the immunological GvT effect.[16] T-cell depletion of the graft or treatment with ATG may decrease the risk of cGvHD, although this has not been demonstrated in all studies. Most patients require at least two drugs for effective treatment of cGvHD, with the standard initial treatment being glucocorticoids and a calcineurin inhibitor. About half the patients do not achieve a complete remission (CR) with first-line therapy, although the manifold signs and symptoms of cGvHD complicate the definition of response to treatment. There are no clear recommendations regarding second-line treatments and various pharmacological and immunological techniques have been used. Photopheresis has an overall response rate of 50% to 60%, with many patients achieving CR. At least transient responses can be achieved with treatment with rituximab, an anti-CD20 chimeric antibody, which illustrates the humoral immunity contribution to cGvHD. The demonstration of activation of the Janus kinase (JAK) pathways in activated T lymphocytes has led to studies demonstrating a potential benefit of Jak2 inhibitors in the management of steroid-refractory cGvHD.

CLINICAL PEARLS

Factors Predicting Chronic Graft-versus-Host Disease

- Degree of human leukocyte antigen (HLA) incompatibility:
  - Major histocompatibility complex (MHC)
  - Minor histocompatibility antigen (miHA) disparity
- Presence of prior acute GvHD
- Source of stem cells (higher risk in peripheral blood vs. bone marrow)
- Donor gender (female donor → male recipient)
- Use of donor lymphocyte infusion (DLI) following hematopoietic stem cell transplantation (HSCT)
- Inflammatory events; surgeries, phototoxicity, alcohol consumption

Graft-versus-Tumor Responses

Although recognized in mouse models of transplantation in the 1950s, the first clinical report of a relationship between GvHD and GvT was published in 1979.[17] This relationship between the incidence (but not the severity) of aGvHD or cGvHD and the relapse rate of chronic myeloid leukemia (CML) and, to a lesser extent, acute myeloid leukemia (AML), acute lymphocytic leukemia (ALL), and MM has been observed in patients who received allo-HSCT. Relapses after HSCT occur because of survival of malignant cells after administration of the pretransplantation conditioning regimen and their outgrowth several months later. Relapse remains the major cause of treatment failure after allo-HSCT despite the intended GvT effect of this treatment modality. The ability to mediate an effective GvT response likely depends on several factors, including the presentation of appropriate antigens by MHC class I and/or class II molecules on the tumor cells that can be recognized by effector CD4 or CD8 T cells; lack of strong Treg activity that may be induced by cytokines from the tumor cells; tumor cell susceptibility to lysis by effector T cells (*e.g.*, the level of B-cell lymphoma 2 [BCL-2] expression and the ability to resist apoptosis induction); ability of T cells to home to sites of tumor growth; and the direct effect of immunosuppressive cytokines, such as transforming growth factor-β (TGF-β), produced by the tumor cells.[18] Many types of tumor cells downregulate expression of MHC on their surface, and perhaps CML and AML are most susceptible to GvT responses because the myeloid lineage is adapted for antigen presentation and high MHC expression. A number of novel immunotherapeutic approaches are being developed to overcome these obstacles and enhance GvT responses, keeping in mind that GvHD has to also be avoided or minimized to improve outcomes (Fig. 92.2). Immunotherapy remains the major strategy to combat relapse occurring after allo-HSCT. This can be achieved by reducing immunosuppression, offering a second allo-HSCT, or infusing additional lymphocytes from the HSC donor (DLI) or immune checkpoint blockade (*e.g.*, ipilimumab, nivolumab, pembrolizumab) to "boost" the donor T cells to attack the cancer.[19] As one can expect, all these modalities pose the challenge of associated morbidities, particularly GvHD.[20] More defined immunotherapeutic approaches using chimeric antigen receptors (CARs) expressed on T cells (CAR T cells; Chapter 81) also show some promise to target residual tumor cells that remain after allo-HSCT, with a possible low risk of GvHD.

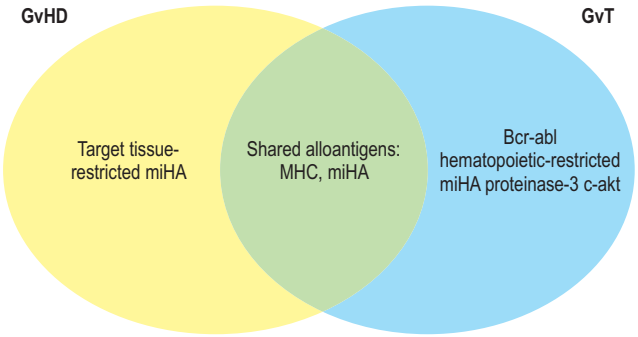

FIG. 92.2 Graft-versus-Host Disease and Graft-versus-Tumor Responses. Donor T-cell responses to recipient antigens can cause graft-versus-host disease *(GvHD)* but can also target residual leukemia cells. T cells causing GvHD may recognize ubiquitous or tissue-restricted antigens (either major histocompatibility complex *[MHC]* or minor histocompatibility antigens *[miHAs]*). Many of these recipient antigens may also be expressed by the leukemia cells and allows for a graft-versus-tumor *(GvT)* response. Additional leukemia-specific (*e.g.*, bcr-abl, proteinase 3, or c-akt) or tissue-restricted antigens (some miHAs, as those expressed only by certain lineages of hematological cells) may be dominantly expressed by the tumor cells and can be targeted by donor T cells without causing GvHD.

KEY CONCEPTS

Major Issues Related to Success of Allogeneic Hematopoietic Stem Cell Transplantation

- Graft-versus-host disease (GvHD)
- Graft-versus-tumor (GvT) responses
- Kinetics and completeness of immune reconstitution
- Opportunistic infections from delayed immune reconstitution
- Patient comorbid conditions increasing risk of toxicities
- Chemotherapy sensitivity of disease being treated

Immunomodulation is frequently the first treatment option for patients in relapse after allo-HSCT, with rapid withdrawal of immunosuppressive medications and infusion of donor T cells.[21] This treatment approach requires that donor T-cell chimerism be sustained to avoid rejection of effector cells through a HvG mechanism. Patients with low-grade lymphoid malignancies, such as CLL, indolent non-Hodgkin lymphoma (NHL), mantle cell NHL, and CML have the highest likelihood of response. However, it remains the main treatment strategy to treat relapse following allo-HSCT. DLI can be used in combination with chemotherapy to maintain disease control during the time required for the development of the GvT effect.[22]

The number of lymphocytes infused is important in achieving the DLI effect, although it may be possible to induce GvT using doses of lymphocytes that are less likely to result in GvHD. A large retrospective analysis demonstrated that using an initially lower cell dose reduced GvHD and improved survival.[23] One method to reduce GvHD risk is to genetically insert suicide genes into the T cells being given for DLI, allowing specific ablation of these cells if this complication occurs.[24] Another method to lower GvHD rates complicating DLI is to deplete the DLI product of GvHD-inducing cells. Studies in mice have shown that naïve subset of CD8 T cells lead to more GvHD, whereas the effector memory subsets (T_{EM}) of CD8 and CD4 T cells moderate the graft-versus-leukemia (GvL) effect without causing GvHD.[25,26] The delay in response between DLI and the development of a GvT effect suggests that only a minority of the cells infused recognize the tumor cell antigens and must undergo in vivo expansion before the therapeutic effect is achieved. It may be possible to develop leukemia-specific cytotoxic T cells in the laboratory, decreasing the delay in effect and possibly increasing the GvT potential. Donor immunity can be transferred, at least transiently, to the host, as demonstrated by delayed-type transfusion reactions to host red blood cells (RBCs), mediated by donor lymphocytes transfused along with the HSC product.[27] Adoptive transfer of donor immunity against specific targets can be achieved, but its persistence requires immunization of both the donor and the recipient. A clinical utility for such manipulation of the immune system has not yet been demonstrated, but it is clearly of interest as a technique to prevent posttransplantation infections and/or disease relapse.

A rapid and major leap in the field of adoptive transfer of immunity is the development of CAR T-cell therapies for patients with aggressive lymphomas, ALL, MM, and CLL, resulting in long-lasting remissions following heavy pretreatment.[28] Developed in the late 1980s and requiring decades of fine-tuning and extensive clinical trials, CAR T cells have the ability to recognize and target tumor cells via their reprogrammed T-cell receptor (TCR) toward the malignant cell and costimulatory molecules engineered into the patient's own T cells. This form of treatment, engaging a combination of gene therapy, cell therapy, and immunotherapy, has led to unprecedented results in patients without robust treatment options for their aggressive malignancies or following relapse after allo-HSCT. The primary limitation of CAR T-cell therapy is the need to identify tumor-specific antigens to avoid the serious toxicity of "on target" but "off tumor" response.

Another potential approach to augment GvT responses following HSCT to prevent or treat relapse is the use of checkpoint inhibitors, currently accomplished by mAb blockade of negative regulatory signals from either cytotoxic T-lymphocyte antigen-4 (CTLA4) or programmed death (PD)-1 proteins on the surface of activated T cells upon interaction with their respective ligands, B7-2 (CD86) and PD-L1 (B7-H1), on APCs and tumor cells (Chapter 80). Checkpoint inhibitors show strong clinical efficacy in the treatment of relapsed hematological malignancies, such as CLL and Hodgkin lymphoma.[29–31]

Adjuvant Therapy With Hematopoietic Stem Cell Transplantation

The relatively higher incidence of relapse after dose-intense therapy (compared to allo-HSCT) leads to the hypothesis that chemoablation therapy with auto-HSCT, curative for some patients, could be viewed as a platform for other approaches effective in eliminating the minimal residual disease (MRD) in patients destined to experience relapse. Additional or yet higher-dose chemotherapy or radiotherapy, unless directly targeted to the tumor, increases the risk of nonhematopoietic toxicity and TRM from causes other than relapse. The correlation of more rapid lymphocyte recovery with a decreased risk of relapse, although likely a reflection of host factors and not direct evidence of a GvT effect after auto-HSCT, supports attempts to use HSCT as a tumor-debulking platform for posttransplantation immunotherapies. Immunotherapies are of interest in this regard and include administration of posttransplantation cytokines; the addition of tumor-specific antibodies, used before and/or after HSCT as an "in vivo purge;" and the development of tumor-specific vaccines, such as with tumor antigen–pulsed dendritic cells (DCs). These therapies are under review and overall clinical benefit remains elusive.

CLINICAL HEMATOPOIETIC STEM CELL TRANSPLANTATION

Sources of Hematopoietic Stem Cells

Bone marrow, PBSCs, or umbilical cord blood (UCB) are all appropriate sources of HSCs for transplantation, with the primary differences being the quantities of HSCs in each product and the quantities and functions of other blood cells comprising most of the cellular content of the HSC product that may influence the immunological outcomes of transplantation. PBSCs have virtually replaced bone marrow as the HSC source for auto-HSCT and are widely used for allo-HSCT. Transplantation of PBSCs achieves more rapid hematological recovery in both the auto- and allo-HSCT settings, resulting in lower complication rates and lower costs of treatment. PBSCs appear to improve overall survival and disease-free survival of patients with advanced hematological malignancies who undergo allo-HSCT, although at the cost of an increased risk of extensive cGvHD.[32] Use of PBSCs results in a decreased CD4 T-helper cell-1 (Th1)/Th2 ratio, which may adversely affect the ability to counteract infections and may favor cGvHD development. It is also interesting to note that PBSC products tend to contain about 10 times more T cells than bone marrow products, yet those T cells are less functional, possibly because of inhibition by granulocytes activated by the granulocyte–colony-stimulating factor (G-CSF) used for HSC mobilization.[33]

UCB is a rich source of HSCs, with the major limitation for clinical use being the small quantity of cells collected, resulting in slower recovery of hematological function and increased risk of failure of sustained engraftment. A very significant advantage is the lower risk of GvHD because of the relative immaturity of the donor immune system, allowing for the use of

HLA-mismatched units without a prohibitory increase in the risk of GvHD. In general, as with other sources of HSCs, outcomes of UCB transplantation reflect patient characteristics, with lower survival probabilities for patients with advanced diseases or poorer performance status at time of transplantation.

KEY CONCEPTS

Selection of Hematopoietic Stem Cell Products for Transplantation

Bone Marrow
- Adequate quantities of cells can be obtained from most patients and donors
- Cytokine administration before harvesting may increase the quantities of hematopoietic stem cells (HSCs) collected and the number and function of accessory cells affecting transplant outcomes
- Lower risk of chronic graft-versus-host disease (GvHD) than peripheral blood stem cells (PBSCs)

Peripheral Blood Stem Cells
- Faster hematological recovery than with bone marrow or umbilical cord blood (UCB)
- Better survival after related-donor hematopoietic stem cell transplantation (HSCT) for patients with advanced malignancy
- Lower tumor cell contamination than with bone marrow collected from autologous patients
- Cytokine administration before harvesting may increase the quantities of HSCs collected and the number and function of accessory cells affecting transplantation outcomes

Umbilical Cord Blood
- Relative immaturity of donor immune system permits multiple antigen-mismatched transplantation
- Transplantation outcomes similar to mismatched unrelated bone marrow transplantation
- Slower hematological recovery than with either PBSC or bone marrow
- Availability of stored units facilitates transplantation for patients with immediate need of treatment

Cell dose is an important predictor of outcome for both auto-HSCT and allo-HSCT, and HSCs comprise a very small portion (generally <1%) of the marrow, PBSC, or UCB product. It is now recognized that successful establishment of donor cell chimerism after allo-HSCT is a complex interplay of pre- and posttransplantation suppression of the host immune system, dose of HSCs and accessory cells (including donor lymphocytes) contained in the graft, and donor HLA compatibility (Fig. 92.3). HLA mismatching, T-cell depletion, and less-intensive pretransplantation conditioning regimens all raise the risk of graft failure. Importantly, the duration of aplasia predicts the incidence of TRM after auto-HSCT or allo-HSCT.[34] Auto-HSCT has a negligible risk of engraftment failure if the viability of HSCs is maintained during processing and storage. The speed of hematological recovery is related to the quantity of HSCs reinfused in an exponential relationship.[35] Increasingly higher $CD34^+$ cell (a surrogate marker of immature HSCs) doses result in greater likelihood of rapid recovery of hematopoietic function. At lower doses, there is considerable heterogeneity in engraftment speed, especially for platelet recovery, with some patients experiencing quick engraftment despite low doses of PBSCs. Products containing ≥2 to 3×10^6 $CD34^+$ cells/kg recipient weight have more consistent rapid granulocyte and platelet engraftment.

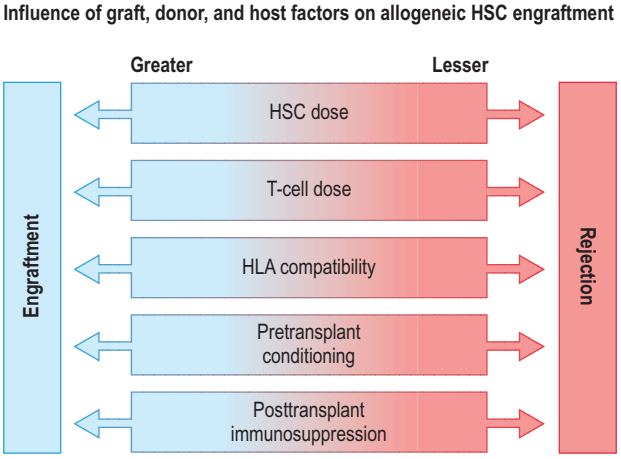

FIG. 92.3 Effect of Donor and Graft Characteristics on Allogeneic Hematopoietic Stem Cell Transplantation. Hematological engraftment requires that the host-versus-graft (HvG) reaction be overwhelmed, either by administration of a more intensive conditioning regimen before transplantation, use of more immunosuppressive medications after transplantation, closer matching of donor with host, and infusion of donor lymphocytes that can affect development of graft-versus-host disease *(GvHD)*. *HLA*, Human leukocyte antigen; *HSC*, hematopoietic stem cell.

Similarly, cell dose is a predictor of outcome for patients undergoing allo-HSCT. The actuarial 5-year TRM, overall survival, and disease-free survival significantly favored patients receiving marrow or PBSC grafts with higher cell doses,[36] but exceeding a $CD34^+$ cell dose of about 10×10^6/kg results in lower survival, likely as a result of higher risk of chronic GvHD.[37]

HSC products are not uniform in their characteristics, and the relative contributions of $CD34^+$ cell dose and the doses of accessory cells, including CD4, CD8, and NK-cell populations, on the outcome of transplantation remain unconfirmed. Whether or not this is clinically significant, the ratio and quantity of cell populations collected will be affected by changes in the cytokines and chemokines, used singly or in combination, to mobilize HSCs into peripheral blood for collection or to alter bone marrow products collected from patients and donors.

Hematological Recovery

HSC engraftment encompasses two concepts: *(i)* recovery of hematopoietic and immunological function and *(ii)* the rate at which this recovery occurs. Delay in or failure of sustained engraftment after myeloablative-conditioning regimen administration greatly increases treatment morbidity and cost. Engraftment failure can occur as a result of inadequate HSC quantity from poor collection or loss in postcollection processing, inadequate host support (stromal cell function) of the infused cells, posttransplantation events or medications, or HvG rejection (see Fig. 92.3). Engraftment failure is a very rare complication of auto-HSCT and is most likely a consequence of poor preservation of HSCs after collection. Secondary graft failure, occurring despite initial engraftment, is a delayed complication rising from infections or induced by other iatrogenic causes. In allo-HSCT, the risk of engraftment failure is proportional to the donor HLA–miHA disparity, occurring more commonly in unrelated donor transplants than in sibling donor transplants, and with HLA-mismatched transplants. Engraftment failure is also

increased by T-cell depletion of marrow inoculum because of the loss of the GvH effect against residual host immune cells.

Chimerism assessment is important in evaluating graft function after allo-HSCT. A fall in PBSC counts could indicate HvG rejection of the graft or early relapse after transplantation or could result from GvHD or viral infection. Documentation of stable persistence of donor T cells (*e.g.*, $CD3^+$ cells) in the recipient's blood will help discriminate between these possibilities. It is also important that sustained lymphoid chimerism be demonstrated if DLI is to be used in the treatment of disease relapse after transplantation. The level of donor–host chimerism after allo-HSCT is best demonstrated through evaluation of single nucleotide tandem repeats (short tandem repeats [STRs]) by using molecular analysis. Obviously, such studies are of no value in assessing engraftment after auto-(syngeneic) HSCT.

Much of the emphasis in transplantation has been on myeloid engraftment because initial patient survival depends on recovery of phagocytes and, to a lesser extent, platelets. Immune reconstitution, and in particular donor T-cell reconstitution, in patients receiving HSCT is often hampered by older recipient age, diminished functional status of the thymus, cytokine milieu at the time of transplantation, and posttransplantation immunosuppressive treatments. The thymus involutes rapidly after childhood, and in the older adult, it is only able to contribute a very small portion to the mature T-cell compartment. The thymic tissue may be damaged as a result of a myeloablative conditioning regimen, or it can also be a target of alloreactive donor T cells mediating GvHD. As a result, restoration of the T-cell compartment in patients is often slow, particularly for CD4 T cells, and may be at suboptimal levels for many months to over a year. This situation, of course, endangers the ability of the patient to stave off opportunistic infections, such as from the herpes family of viruses and fungal pathogens. If donor T cells are provided in the HSC inoculum, some reconstitution of the T-cell repertoire, mostly CD8 T cells, is provided by the mechanism of nonthymic homeostatic expansion, although the level of diversity may be limited. Experimentally, administration of cytokines, such as interleukin-7 (IL-7), after HSCT, can enhance thymic function and help donor T-cell reconstitution. B-cell reconstitution, in contrast, is not that problematic in terms of the regeneration of the immune repertoire, although the ability to actually respond effectively to an infection with antibody production may still depend on the availability of antigen-specific CD4 T cells. Administration of Ig to patients with low IgG levels can prevent some of the infectious complications. Patients receiving HSCT who are conditioned with myeloablative regimens usually attain high levels of donor chimerism in their lymphoid compartment within a few months of transplantation. This often correlates with the ability of alloreactive donor T cells, capable of mediating GvHD, to target residual recipient HSC elements so that the primary source of de novo lymphoid reconstitution will be from the donor. By the same token, high donor chimerism is also associated with a lower incidence of relapse of malignancy.

CONDITIONING REGIMENS

Dose-Intensive and Reduced-Intensity Chemotherapy

The pretransplantation regimen is intended to accomplish two goals: ablate the tumor and achieve adequate immunosuppression to allow donor engraftment. For auto-HSCT, only the dose sensitivity of the tumor being treated need be considered. Lower-dose, nonmyeloablative regimens are not used in auto-HSCT because with such regimens, infusion of HSCs to reconstitute marrow function would not be needed. Total body irradiation (TBI) was initially used for conditioning of transplant recipients. This modality achieves tumor cytotoxicity; treatment of sanctuary sites of disease such as the central nervous system (CNS) and testes; and profound immunosuppression. TBI is usually combined in sequence with chemotherapy agents, such as cyclophosphamide or etoposide. Busulfan-based regimens were developed as alternatives to TBI for patients who had received prior dose-limiting radiotherapy and to avoid the effects of TBI on growth and development in children. A review of several studies that compared the use of busulfan and TBI found no statistically significant difference in survival or disease-free survival for patients with CML or AML.[38] Specific regimens are commonly used in the treatment of certain malignancies, such as dose-intensive melphalan in the treatment of MM and carmustine (BCNU)–containing regimens used in the treatment of lymphoma.

CLINICAL PEARLS

Conditioning Regimens for Hematopoietic Stem Cell Transplantation

Autologous Hematopoietic Stem Cell Transplantation
- Allows dose-intensive therapy
- Allows use of marrow-toxic agents
- Regimens designed for optimal tumor cytotoxicity

Allogeneic Hematopoietic Stem Cell Transplantation
- Must achieve adequate patient immunosuppression (reduce host-versus-graft [HvG] reaction) to achieve engraftment
- Allows but does not require dose-intensive therapy
- Allows but does not require marrow-toxic agents
- Need not be tumor specific

The myeloablative conditioning regimens currently used have been tested in dose-escalation studies to achieve the maximal tolerated doses in otherwise healthy patients. Nonmarrow toxicities, such as pneumonitis, mucositis, and hepatic venoocclusive disease, limit further dose escalation of standard TBI- or chemotherapy-based regimens. New approaches include the addition of targeted therapies to the conditioning regimen, such as tumor-directed mAbs or radioimmunoconjugates that will not increase the toxicity to other organs. Tandem transplantation with the combination of a dose-intensive regimen with auto-HSCT followed, after recovery from the immediate regimen-related toxicities, by allo-HSCT using a reduced-intensity regimen is a novel approach to combine the benefits of each transplantation modality.

Hematological malignancies are predominantly diseases of older adults. The potent GvT effect that is observed after allo-HSCT allows allograft recipients to be treated with lower-dose nonmyeloablative regimens with the immunosuppressive properties of the regimen to reduce HvG reactions and facilitate engraftment becoming more important than direct cancer cytotoxicity. The primary requirement in developing a reduced-intensity regimen is the need to achieve adequate immunosuppression to permit the development of hematopoietic chimerism, which became feasible with the development of the purine analogue family of drugs. A variety of regimens are available, including combinations of fludarabine with melphalan and fludarabine with busulfan. Among the least toxic are regimens that involve a single fraction of TBI, based on the work by Storb and colleagues,[39] who proposed that the HvG

reaction leading to HSC rejection and the GvH reaction could both be modified by an appropriate immunosuppressive regimen administered after transplantation, allowing a reduction in the intensity of the pretransplantation conditioning regimen.[39,40]

HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR INDIVIDUAL DISEASES

The treatment of diseases by auto- or allo-HSCT continues to evolve as the understanding of the biology of these diseases becomes more clearly understood. Improvements in nontransplantation treatments available to patients, such as the development of targeted tyrosine kinase (TK) inhibitors, which are very effective in the initial treatment of CML, will reduce the numbers of patients requiring HSCT in the management of their disease. Organizations such as American Society of Blood and Marrow Transplantation have published guidelines for treatment and reviews of the efficacy of treatment, identifying areas requiring additional research.[41,42]

Acute Myelogenous Leukemia

The primary clinical questions in HSCT in the treatment of AML concern patient selection and timing of treatment. Most patients with AML will achieve remission with initial chemotherapy, but even with appropriate postremission consolidation, the majority of patients (≈65%) will relapse within 1 to 2 years. Older age, the presence of defined cytogenetic abnormalities, inability to achieve a minimal-residual disease negative CR with the initial course of therapy, and history of a preceding marrow disorder or receipt of prior chemotherapy ("secondary AML") are predictors for failure of nontransplantation therapy. Patients with these adverse risk factors may be offered HSCT in first remission in place of nontransplantation consolidation chemotherapy. Numerous studies of patients entering their first remission compared standard consolidation therapy with dose intensification with auto- or allo-HSCT. In general, auto-HSCT was not shown to be more effective than nontransplantation consolidation chemotherapy, whereas allo-HSCT had the lowest risk of relapse. Allo-HSCT in first remission is particularly beneficial for patients with adverse risk cytogenetics or leukemia that arises from prior chemotherapy or other marrow diseases, achieving a 50% to 70% disease-free survival (DFS). Features predictive of posttransplant disease relapse include adverse-risk cytogenetic mutations and presence of MRD at time of transplantation. Prophylactic use of DLIs or posttransplant maintenance with targeted agents may reduce the risk of relapse of patients with adverse-risk features or who are found to be developing disease recurrence early after transplantation.

Myelodysplastic Syndromes

Myelodysplastic syndrome (MDS) comprises a heterogeneous group of clonal hematological disorders characterized by expansion of abnormal HSCs engendering variable degrees of cytopenia and frequent evolution to AML. Currently, allo-HSCT is the only modality of treatment that can achieve long-term control of disease; auto-HSCT is not feasible because of the inability to collect normal HSCs from these patients. The best results are seen in patients with earlier-stage disease, although for patients with earlier-stage MDS, a "watchful waiting" approach, with transplantation performed at the time of disease progression, may be appropriate.

Chronic Myelogenous Leukemia

Allo-HSCT is an appropriate treatment for CML, with long-term survival rates >80% for younger patients undergoing related donor transplantation within the first year after diagnosis. However, inhibitors of the TK encoded by the Philadelphia chromosome have relegated transplantation to the treatment of patients with advanced disease or the rare patient with CML not responsive to that targeted therapy. The effect of prior therapy with a TK inhibitor on the outcome of transplantation is not known, although patients who fail multiple TKIs before coming to transplantation will experience a lower survival probability. CML is highly responsive to the immunological GvT effect, and many patients in relapse after transplantation can be salvaged by the administration of DLI. CML is a stem cell disease, and the collection of normal HSCs is unlikely for most patients, precluding auto-HSCT.

Myeloproliferative Diseases

MPDs are clonal stem cell diseases and include CML (discussed above), polycythemia vera, primary myelofibrosis, essential thrombocytosis, chronic myelomonocytic leukemia, and MPD not otherwise characterized. These disorders display overlapping clinical features and may also show features more characteristic of MDS, but they exhibit different natural histories and different therapeutic requirements. Allo-HSCT is effective in ablating the abnormal clone in these disorders. Staging systems that predict the course of the disease are used to determine the timing of transplantation. The timing of treatment is important because of the frequently long natural history of these diseases.

Acute Lymphoblastic Leukemia

In contrast to treatment of the pediatric patient with ALL (Chapter 77), only very few adults with ALL are cured with nontransplantation induction and consolidation regimens. As with AML, adverse-risk features include certain cytogenetic changes and the inability to achieve minimal residual disease–negative remission with initial induction chemotherapy. Allo-HSCT in first remission is clearly effective in the management of patients with defined adverse-risk cytogenetics, such as translocation involving chromosomes 4 and 11, or 9 and 22 (Philadelphia chromosome). Recent randomized studies also demonstrate a survival advantage for patients who have intermediate risk of disease and are undergoing allo-HSCT, especially since current salvage regimens for patients in relapse have a very low likelihood of achieving a second remission. There is little evidence to support the effectiveness of auto-HSCT despite its theoretical potential.

Chronic Lymphocytic Leukemia

Many patients and physicians are reluctant to support aggressive treatment of CLL with allo-HSCT because of the frequently indolent nature and long natural history of this disease, as well as the advanced age of most patients at time of diagnosis. Yet disease progression is inevitable, and the aggressiveness of this disease can be predicted by various features, including chromosome 17p and 11q deletions and detection of ZAP-70 mutation and CD38 expression. Therefore HSCT should be considered a treatment choice, especially for younger patients or those with adverse-risk disease features.

The exquisite sensitivity of the CLL cells to the GvT effect allows for the use of reduced-intensity regimens with lower risks of regimen-related mortality in these, generally older,

patients. Durable control of disease can be achieved for about 50% of patients. The extensive infiltration of bone marrow by malignant lymphocytes and the lack of the GvT effect preclude auto-HSCT. In the few clinical studies that have been reported, high CR responses have been obtained with auto-HSCT, but relapses were the frequent cause of treatment failure.

Multiple Myeloma

MM is a malignancy of plasma cells (Chapter 79), with a median patient age of 65 years at time of diagnosis. In MM, dose-intensive melphalan with auto-HSCT can achieve about a 40% complete response rate. Tandem auto-HSCT with two cycles of dose-intensive therapy at 2- to 6-month intervals can improve progressive free survival and overall survival, particularly for patients with adverse-risk cytogenetic features such as 17p deletion. Ultimately, most patients experience relapse. Although auto-HSCT is not considered curative for this disease, the median duration of time without treatment is 2 to 3 years, and ≈15% of patients may not need treatment for progressive disease for 5 years or longer. Allo-HSCT with use of a reduced-intensity conditioning regimen decreases the risk of TRM to less than 10%, but patients with advanced disease are unlikely to respond to this treatment. The lower risk of complications with nonmyeloablative conditioning regimens has led to studies of tandem auto-HSCT, using an intensive chemotherapy regimen to achieve tumor debulking, followed 2 to 6 months later by allo-HSCT using a reduced-intensity regimen to achieve the GvT effect. This approach to the treatment of MM was studied in large multicenter trials, with a strong GvT effect detected. However, the benefit of the GvT effect was offset by the increased regimen-related toxicity compared to tandem autologous transplantation.

Non-Hodgkin Lymphoma

The lymphomas (Chapter 78) represent a diverse group of malignant diseases of B and T lymphocytes, comprising some of the slowest- to the fastest-growing human malignancies, with a range of curability achieved by nontransplantation therapies. As a group, the lymphomas exhibit a strong dose–response relationship to chemotherapy or radiotherapy, and the benefit of dose-intensive treatment with auto-HSCT has been well established. Auto-HSCT avoids the morbidity of allo-HSCT and is the preferred approach for the majority of patients, with some prominent exceptions discussed below. Popular chemotherapy regimens include cyclophosphamide, BCNU, and etoposide (CBV) or BEAM (BCNU, etoposide, cytarabine, and melphalan). However, no single chemotherapeutic or radiation-based regimen has emerged as a superior treatment.

Low-Grade Non-Hodgkin Lymphoma

Low-grade NHL, in general, exhibits a variable and prolonged natural course, with many patients not requiring treatment until symptoms or organ toxicity appear. Therefore, most of the experience with HSCT has been in patients after relapse rather than at the time of initial diagnosis. Few randomized studies comparing auto-HSCT with nontransplantation therapies for patients have been reported. A number of phase II and registry data have been published for auto-HSCT, and although response rates are high, a continuing pattern of relapse has been observed. In contrast, patients who undergo allo-HSCT experience a higher probability of TRM but a lower risk of relapse after transplantation. Indolent B-cell NHL, similar to other low-grade diseases, such as CLL, appears to be very sensitive to the GvT effect of allo-HSCT, and using reduced-intensity regimens will result in lower transplantation-related complications. The difference in relapse rates between auto-HSCT and allo-HSCT could result from the possible reintroduction of lymphoma cells in the HSC product, but is more likely from the lack of a GvT effect of auto-HSCT.

Aggressive Non-Hodgkin Lymphoma

Auto-HSCT is the standard of care for patients with diffuse large B-cell NHL in first "chemotherapy-sensitive" relapse. The success of this therapy reflects the extent and the responsiveness of the disease to chemotherapy at the time of transplantation, with relapse the major cause of treatment failure. The Parma randomized trial for high-dose therapy followed by auto-HSCT reported a significantly higher event-free survival for patients treated with auto-HSCT than for the group receiving standard-dose treatment (46% vs. 12%). Furthermore, it is notable that no patients assigned to the conventional-dose salvage therapy could be rescued at the time of the second relapse with delayed transplantation. The efficacy of auto-HSCT is diminished for patients previously treated with rituximab, an anti–B-cell chimeric antibody, and who relapse within 12 months of initial therapy.[43] Other circumstances, in which HSCT may be indicated, include HSCT for patients who respond slowly to initial therapy, have high-risk disease, are resistant to initial therapy, or are in relapse with chemotherapy-insensitive disease.[42] Results for patients with truly chemotherapy-refractory disease are, however, poor, and such patients should be considered for allo-HSCT or treatment with autologous CAR T cells (Chapter 81).

Mantle cell lymphoma is known for its unremitting clinical course when treated conventionally and has proven relatively resistant to dose-intensive treatment, especially when used for management of relapsed disease. Mantle cell NHL appears to be very sensitive to the GvT effect of allo-HSCT, allowing treatment with reduced-intensity regimens.

Burkitt lymphoma, Burkitt-like lymphomas, and lymphoblastic lymphomas are high-grade NHLs associated with relatively poor long-term survival rates. The role of both auto-HSCT and allo-HSCT in these disorders remains unclear. There are no convincing risk models that identify clear indications for transplantation as part of the initial therapy. The lack of an obvious GvT effect in these disorders suggests that auto-HSCT can provide a reasonable treatment. Transplantation registry data suggest that disease status at the time of transplantation is the most important predictor of outcome in patients with high-grade disease.[44]

T-cell lymphomas are less common than BCLs. There is no well-defined management strategy for these disorders, and treatment is based on the disease stage and immunopathological grade. Disease control with T cell–type treatment regimens, compared with the more common B cell–type treatment regimens, is lower, although the comparison may not be appropriate, as T-cell diseases present at more advanced stages compared with B-cell diseases. The GvT effect may be more evident in T-cell NHL, particularly for virus-associated NHL, and allo-HSCT is the preferred treatment for some patients. Prospective comparative studies to guide treatment decisions have not been reported.

Hodgkin Lymphoma

Many patients with Hodgkin lymphoma will achieve durable remissions with nontransplantation chemotherapy and/or radiation therapy, and algorithms for staging and treatment of this disease are well defined. Dose-intensive therapy with auto-HSCT is available to those patients who do not achieve a remission or who relapse

after initial therapy. The outcome for patients whose remission lasted less than 1 year is dismal, with standard-dose second-line treatments, and approximately 40% to 50% of patients with Hodgkin lymphoma who suffer a relapse within 1 year will achieve durable remissions after auto-HSCT. This approach can also overcome drug resistance and lead to an overall survival rate of 34% to 50% for patients with chemotherapy-refractory disease. Outcomes are much improved for patients who achieve "positron emission tomography (PET) negativity" before undergoing auto-HSCT.

Allo-HSCT is not the first choice for the treatment of relapsed Hodgkin lymphoma because of the higher transplantation-related complications, despite the evidence of an effective GvT effect. Allo-HSCT is offered to patients who suffer relapse after auto-HSCT or who are not candidates for auto-HSCT because of aggressive, chemotherapy-refractory disease. With the front-line use of checkpoint inhibitors such as nivolumab for treatment of newly diagnosed and relapsed Hodgkin lymphoma, the risk of GvHD following allogeneic HSCT is considerable. This risk is mitigated by an appropriate "wash-out" period for the drug or potentially other strategies such as use of posttransplantation cyclophosphamide for GvHD prevention.[45]

Solid Tumors

Skin and colonic mucosa are primary targets of both acute and cGvHD, and this would suggest that allo-HSCT would be effective therapy in the treatment of cancers of these organs. Yet allo-HSCT is not effective in the control of these cancers, illustrating the discrimination between target antigens of normal tissues of GvH, such as the colonic crypt cells, compared with antigens expressed by tumors derived from these tissues targeted by GvT. With the exception of allo-HSCT in the treatment of renal cell cancer, in which a GvT effect was seen to be clinically evident in some but not all studies, transplantation in the treatment of solid tumors, such as neuroblastoma, Wilms tumor, and germ cell tumors, is limited to auto-HSCT with one or more cycles of dose-intensive chemotherapy.

FUTURE DIRECTIONS

Advances in HLA typing, chemotherapy conditioning regimens, supportive care, and our understanding of the biology of the HvG and GvH reactions have greatly reduced the toxicity of both auto-HSCT and allo-HSCT. Although the diseases treatable with HSCT are those characterized by dose sensitivity, currently available dose-intensive conditioning regimens have been pushed to maximal tolerable doses. Newer approaches to the treatment of these malignancies will likely include the addition of therapies that target the malignancy, such as radioimmunoconjugates that will add minimal toxicity to other organs. The availability of reduced-intensity regimens permits tandem transplantation, using dose-intensive therapy with auto-HSCT to achieve maximal tumor-cell debulking, followed, after recovery from transplantation-related toxicities, by allo-HSCT, using a reduced-intensity regimen to achieve an immunological GvT effect. Advancements in the field of haploidentical HSCT have facilitated immediate availability of donors for patients with high-risk malignancies when selection of unrelated donors is limited by ethnicity and time constraints. New testing techniques, such as detection of tumor-derived cell-free DNA, may be predictive of relapse, facilitating treatment of this complication of transplantation. Finally, the ability to use HSCT as a platform for protein- or cellular-based vaccination strategies is the subject of considerable interest.

ON THE HORIZON

Allogeneic Hematopoietic Stem Cell Transplantation

Continuing improvement in donor selection algorithms
Strategies to maximize graft-versus-tumor (GvT) effect
Refining haploidentical hematopoietic stem cell transplantation (HSCT) techniques for different diseases
Use of killer cell immunoglobulin-like testing for donor selection
Combination conditioning regimens
Developing regimens with lower toxicities
Developing testing predictive of early relapse
Posttransplantation maintenance/treatment to reduce risk of relapse
Immune effector cell therapies
Platform for other treatments; chimeric antigen receptor (CAR) T-cell therapy, checkpoint inhibitor blockade

Autologous Hematopoietic Stem Cell Transplantation

Tumor-specific conditioning regimens
Improve ratio of toxicity to tumor-cell cytotoxicity
Developing testing predictive of early relapse
Posttransplantation vaccination strategies
Tandem autologous transplantation with autologous CAR T-cell therapy
Checkpoint inhibitor blockade in clinical trials for high-risk malignancies

Flow Cytometry

Cristiane J. Nunes-Santos, Sergio D. Rosenzweig, and Thomas A. Fleisher

Flow cytometry has become a standard laboratory tool in evaluating hematopoietic cells, including identifying leukocyte populations and subpopulations, a method referred to as immunophenotyping. The clinical application of this technology has been facilitated by the development of instruments and data analysis systems suitable for routine use in diagnostic laboratories. In addition, the expanded range of monoclonal antibodies specific for lymphocyte (and other hematopoietic cells) surface antigens directly conjugated to a number of different fluorescent indicators (fluorochromes) provide an extensive panel of reagents that facilitate multicolor (polychromatic) studies.

The clinical needs that pushed this technology date back to the emergence of absolute CD4 T-cell counts as a critical measure for disease assessment and follow-up in managing patients infected with the human immunodeficiency virus (HIV). This was followed by the routine application of cell characterization by flow cytometry to evaluate hematologic malignancies, and more recently, in the study of immunodeficiency and immune dysregulation disorders.

Recent advances in instrumentation and fluorochrome chemistry allow for routine polychromatic flow cytometry studies, with concomitant assessment of cell surface markers and intracellular parameters (intracellular proteins, phosphorylated [phospho] proteins, and cytokines), as well as identification of changes linked to cellular activation and apoptosis. Intracellular flow cytometry also can be applied to evaluate cell cycle status (i.e., G_0-G_1, S, G_2-M) based on DNA staining, useful in evaluating tumor cells and assessing the *in vitro* lymphocyte response to various stimuli. Additionally, evaluation of lymphocyte proliferation can be performed with cell tracking dyes that allow quantitation of the rounds of cell division, and assessment of immune cell-mediated cytotoxicity can be performed. Finally, characterization of antigen-specific T cells following immunization or associated with normal and/or abnormal immune responses in association with disease states can be accomplished using multimer technology and intracellular cytokine detection following *in vitro* antigen exposure.

This chapter focuses on basic concepts of flow cytometry, including instrument characteristics, data management, lymphocyte gating, and directed use of test reagents. In addition, a brief overview of intracellular protein detection, cell activation and cell-mediated cytotoxicity studies, cell cycle analysis, apoptosis detection, and multimer technology is provided, focusing on the appropriate clinical application of these approaches and their limitations.

INSTRUMENTATION

The basic components of a flow cytometer, as shown in Fig. 93.1, include the illumination source, optical bench, fluidic system, electronics, and computer.[1] Briefly, stained cells flow into single-file due to the fluidic system and are interrogated by one or more light sources to generate light signals directed by the optical system to the photodetectors that convert light into electronic signals for storage and subsequent analysis.

The fluidic system consists of isotonic sheath fluid that moves the sample stream containing the cells for analysis. This process is accomplished by injecting the cell sample into flowing sheath fluid, resulting in a hydrodynamically focused single-file flow of cells (or other particles) that move through the analysis point while maintaining the cell stream in a constant, central location.[2] The centrally focused cell stream ensures that the illumination of all cells is virtually equivalent. Thus, the difference in magnitude of the emission signal(s) generated from each cell reflects biologic differences between the cells (rather than reflecting the variation produced by non-focused cells). Hydrodynamic focusing has the additional advantage of producing little or no change in cell shape, although it may affect cell orientation. The consistency in maintaining cell shape facilitates distinguishing "architectural" differences between specific leukocyte types (see Gating section).[3] However, this method limits flow rates to 60 to 100 µL/min, which can lead to long acquisition times for detecting very rare events. To overcome this problem, recently introduced flow cytometry instruments utilize acoustic focusing to align cells through the use of sound waves that allows sample flow rates of up to 1000 µL/min, without impacting signal quality.[4]

Illumination in standard clinical instruments is generated by two or more lasers, each of which provides a specific monochromatic light source (e.g., a sapphire laser generates a 488 nm wavelength [blue] beam). Modern lasers are small and available in multiple wavelengths, including ultraviolet (350 nm), violet (405 nm), blue (488 nm), green (532 nm), yellow (560 nm), orange (610 nm), and red (633 nm), permitting the simultaneous use of multiple fluorochromes having different excitation requirements.[5] The point where the light illuminates the cell in analytical instruments occurs within a flow cell, while in cell sorters, the beam intersects cells flowing as a stream in the air.

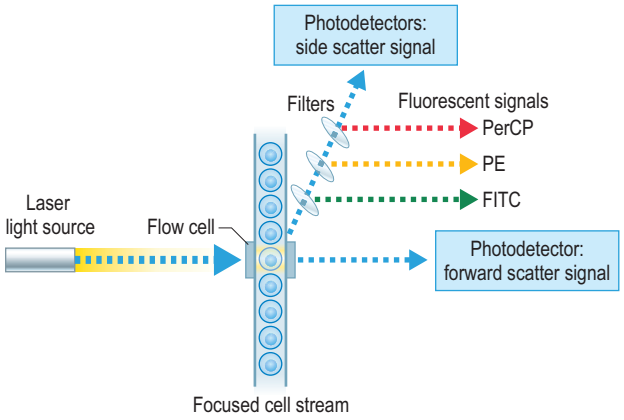

FIG. 93.1 Simplified design of a flow cytometer with one illumination source *(laser)* set up to collect five parameters. These include the two non-fluorescent parameters *(blue light)* forward, and side scatter, as well as three fluorescent parameters, green (FITC), orange (PE), and red (PerCP) light.

The optical bench contains lenses that shape and focus the illumination beam to ensure consistent excitation energy at the analysis point.

The illumination of a cell generates both non-fluorescent and fluorescent signals collected and measured by optically coupling the signal to a detection system consisting of filters linked to photodetectors. The two non-fluorescent signals, forward- and side-scatter, are measured at the same wavelength as the excitation signal (e.g., 488 nm from a blue light source; see Gating section), whereas those for the fluorescence channels utilize specific filters that allow passage of light with wavelengths specific to each fluorochrome (e.g., green, orange or red; see Fluorochrome section). Configurations with increased numbers of photodetectors allow for evaluating an expanded number of colors (parameters).[6]

The internal electronics in the flow cytometer provide the system for converting analog light signals (photoelectrons) into digital signals for acquisition and storage in a computer. The intensity of these converted signals is measured on a relative scale that is generally set in either 256 or 1024 equal increments (channels) for display and analysis. Several specialized analysis programs provide graphic displays of single-parameter histograms or two-color displays (see Data display section below). Most programs enable the operator to evaluate the number and percentage of events, mean and/or median channel fluorescence, and selected statistical measures for each identified cell, and these can be aggregated into specific populations and/or subpopulations of cells. Thus, a flow cytometer provides a platform having the capacity to assess multiple pieces of discrete information (parameters) generated from each individual cell contained within a large number of cells in the sample, and these are typically accrued at rates of 1000–2000 (or more) cells per second.

FLUORESCENCE REAGENTS

Standard monoclonal antibody reagents for clinical use are typically directly conjugated to a fluorochrome, a dye that absorbs and emits light of different wavelengths based on the energy lost during the return of excited electrons to their ground state following illumination by light of a specific wavelength. Thus, the emitted light has a longer wavelength (lower energy) than the wavelength of the excitation beam. The number of commercially available fluorochromes has increased dramatically, and dye conjugates have enhanced the capacity to perform extended polychromatic studies using instruments with three or more lasers.[5] Fluorochromes in clinical immunophenotyping include the organic dyes fluorescein isothiocyanate (FITC), phycoerythrin (PE), peridin chlorophyll protein (PerCP), and allophycocyanin (APC). Conjugations of PE and APC to cyanines (Cy5, Cy5.5, and Cy7) and Alexa Fluor dyes produce tandem dyes with additional emission spectra based on energy transfer. This allows the simultaneous evaluation of 6 to 8 or more colors in most current clinical instruments with two or three lasers.

One recent advance in the field was the development of a new class of inorganic fluorescent semiconductor nanocrystals named quantum dots (QDs).[7] These particles have broad excitation spectra (525 to 800 nm) and sharp, discrete emission spectra that varies depending on their core size. This means that QDs of different sizes (and consequently of different colors) can be excited by the same laser source, allowing simpler multiplexing. In addition, QDs have high quantum yield, high molar extinction coefficients, and extraordinary resistance to photo- and chemical degradation. These qualities make them perfectly suitable for use in biological studies, including intracellular *in vivo* imaging and fluorescence resonance energy transfer (FRET) analysis.[7]

Another advancement involves the more recently developed polymer dyes that not only provide increased sensitivity and precision but also have the potential to increase the number of colors available in polychromatic studies. Polymer dyes harvest light and can be used alone or in a tandem dye arrangement. Further advantages of these include their exceptionally bright emission as well as being photostable and resisting quenching.[8]

Additional dyes are available for functional studies and include calcium-sensitive dyes (e.g., fluo-3), glutathione-sensitive dyes (e.g., monochlorbimane), and H_2O_2-responsive dyes (e.g., dihydrorhodamine 123).[9] Assessment of DNA content can be performed with dyes that intercalate double-stranded DNA and RNA, including propidium iodide and ethidium bromide. In addition, there are ultraviolet-excited dyes that are highly specific for DNA, including Hoechst 33258 and 4,6-diamidino-2-phenylindole (DAPI); acridine orange is used for simultaneous staining of DNA/RNA.[10]

DATA ANALYSIS

Gating

KEY CONCEPTS

Gating

- Method for defining cell population of interest.
- Typically performed using forward and side scatter and lineage specific antibodies.

The proper assessment of specific cell types within a mixture requires initial identification of lineage-specific cells, an approach referred to as gating. In practical terms, immunophenotyping focused on lymphocytes requires minimizing the non-lymphocytes in the evaluation by generating a lymphocyte gate. The standard clinical sample is anticoagulated whole blood, and lymphocyte gating requires eliminating the great

majority of non-lymphocytes from the collected data such that the expression of a percentage for a specific lymphocyte subpopulation is accurate. Without gating, the data can also be negatively impacted by the co-expression of surface antigens on different cell lineages (e.g., CD4 is found on lymphocytes and monocytes at differing density). In addition, nonspecific binding of monoclonal reagents through Fcγ receptors and the level of cytophilic human immunoglobulin varies between cell types, making appropriate gating crucial to generate valid data. Gating is also used to focus the evaluation on other hematopoietic cells: monocytes, granulocytes, eosinophils, erythrocytes, and platelets.

Initial gating of whole blood typically involves using the two non-fluorescent parameters, forward scatter (FSC), and side scatter (SSC) (Fig. 93.2A).[3] FSC reflects cellular cross-sectional area (direct relationship to cell size), whereas SSC is an indication of the cellular granularity. The combination of these two non-fluorescent parameters provides a three-part differential in red blood cell lysed whole blood that distinguishes between normal lymphocytes, monocytes, and granulocytes. As shown in Fig. 93.2A, lymphocytes have the lowest FSC and SSC, monocytes have higher FSC and SSC, and granulocytes have the greatest SSC. This method is effective in distinguishing a relatively pure population of lymphocytes under most circumstances. However, the presence of nucleated red cells, large platelets, basophils, or other particulate debris can produce contaminating events (cells) within the lymphocyte gate. Furthermore, malignant or activated lymphoid cells may not fit into the previously outlined standard light scatter patterns.

A method for confirming the integrity of the light scatter-based lymphocyte gate uses the monoclonal "gating" reagents anti-CD45 and anti-CD14.[11] These two monoclonal antibodies more accurately identify the three-part differential. Lymphocytes have the highest level of CD45 binding but are CD14 negative; granulocytes have a lower level of CD45 binding and are intermediate CD14 positive; while monocytes have high levels of both CD45 and CD14 expression (see Fig. 93.2B). Importantly, non-leukocytes, including erythrocytes and platelets, are negative for these markers. However, malignant leukocytes with characteristics of early precursor cells often have altered CD45 and/or CD14 expression that must be recognized when studying hematologic malignancies. Gating reagents provide a reliable means of checking the light scatter-based lymphocyte gate for the frequency of non-lymphocytes within the gate and the extent of lymphocyte exclusion from the gate. Guidelines for an acceptable degree of contamination within the lymphocyte gate, as well as the level of lymphocyte exclusion, are contained within the US Clinical and Laboratory Standards Institute guideline for lymphocyte immunophenotyping.[12]

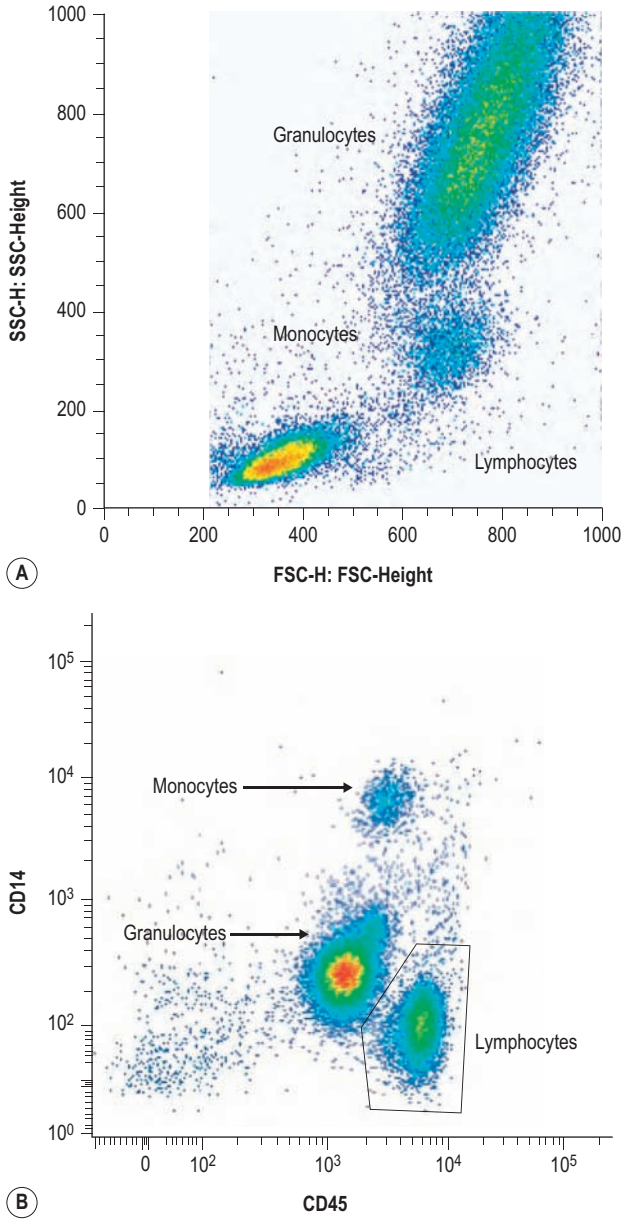

FIG. 93.2 (A) Gating based on FSC (forward scatter) and SSC (side scatter) dot plots on a lysed whole blood sample, demonstrating the basic three-part leukocyte differential with lymphocytes, monocytes, and granulocytes. (B) Dot plot with CD45/CD14 gating reagents showing the fluorescence distribution of all the three leukocyte types identified to include lymphocytes, monocytes, and granulocytes, as well as a small number of non-lysed red blood cells and/or debris.

Data Display

KEY CONCEPTS

Data Presentation

- Fluorescence intensity is plotted versus cell number.
- Can present cumulative data on more than one parameter for each cell.
- Multicolor data presentation can increase cell subpopulation resolution.

The simplest method for demonstrating flow cytometry data is the single-parameter histogram (Fig. 93.3), a graphic presentation of cell number on the *y*-axis versus fluorescence (light) intensity from a single fluorochrome on the *x*-axis. Integration of curve areas provides the number of cells, and often there are two distinct distributions; one referred to as negative identifies cells that are not bound specifically by the monoclonal reagent, and the second represents cells bound by the antibody. Negative reflects low-level fluorescence resulting from cellular autofluorescence and any nonspecific binding of the monoclonal reagent(s), the magnitude of which varies between different cell types. The interpretation of the data is simplified when there are two distinct cell populations (i.e., negative and positive), while the evaluation of two overlapping distributions is more difficult.

Multiparameter data can be evaluated using a series of single-parameter histograms that consider each fluorochrome independently. However, presenting two parameters simultaneously using a correlated display is more informative (Fig. 93.4). This approach enables the simultaneous visualization of four different populations: A^+/B^-, A^-/B^+, A^+/B^+, and A^-/B^-. More recently, these displays evolved to include a mixture of logarithmic (for higher intensity expression) and linear (for lower intensity expression) intensity for each axis to allow for better interpretation of events with very low to absent fluorescence. This combined display approach resolves events being displayed compacted against the axes even with properly compensated samples and will be used in the illustrations throughout this chapter.

The simultaneous use of *n* monoclonal reagents can identify a total of 2^n subpopulations. These different subsets can be identified sequentially by first dividing the cells into those that are positive versus negative with one reagent and then evaluating the defined subpopulations for additional reagents using a two-color approach. Alternatively, modern software can represent multiple populations as polychromatic plots, which can simplify data analysis.[13] The polychromatic approach can provide a means to further resolve subpopulations and has been particularly useful in the evaluation of cellular differentiation, activation, and functional correlates, as well as clarifying overlapping cell subpopulations.

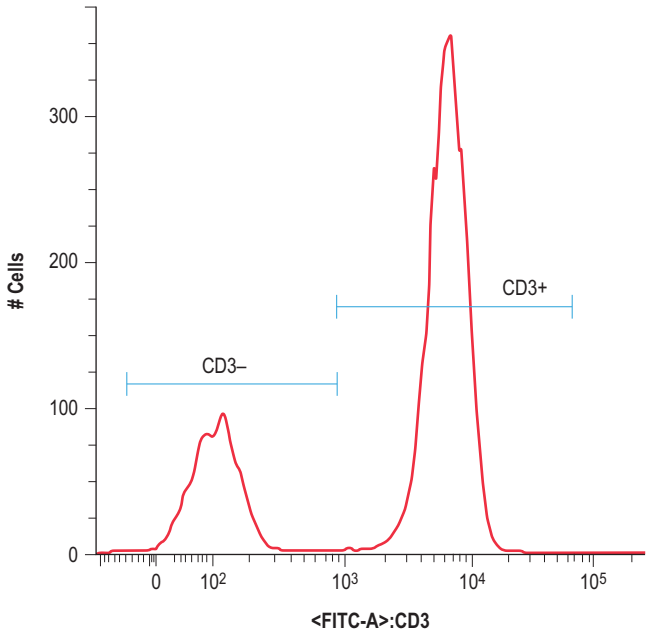

FIG. 93.3 Single-parameter histogram for CD3 expression on lymphocytes demonstrating the negative, non-T-cell population (B cells, NK cells) and a positive T-cell population. Integrating the area under each curve would provide the numbers and percentage of cells present in each of the two subpopulations.

Positive–Negative Discrimination

Evaluating clinical immunophenotyping data requires establishing criteria for the boundaries between negative or nonstained (autofluorescence plus nonspecific stained) cells and positive (specifically stained) cells. A commonly used approach involves using directly conjugated control monoclonal antibodies of the appropriate class or subclass (e.g., IgG1, IgG2a, IgG2b, or IgM) that do not specifically react with human lymphocyte surface antigens (commonly called "isotype controls"). The marker (discriminator) is set at the fluorescence histogram channel number such that it includes 98% to 99% of the negative cells (Fig. 93.5A).

The negative cell population is based on the aggregate of baseline cellular autofluorescence plus nonspecific binding that varies according to cell type. For this reason, the use of isotype controls may not correctly identify the positive-negative threshold for specific cell types, particularly when staining dimly expressed proteins. Perfectly mimicking the specific antibody used would require the isotype control to have the same antibody to fluorochrome ratio and brightness, something not easily accomplished. To overcome these difficulties, an alternative method has been described and is referred to as Fluorescence-Minus-One (FMO).[14]

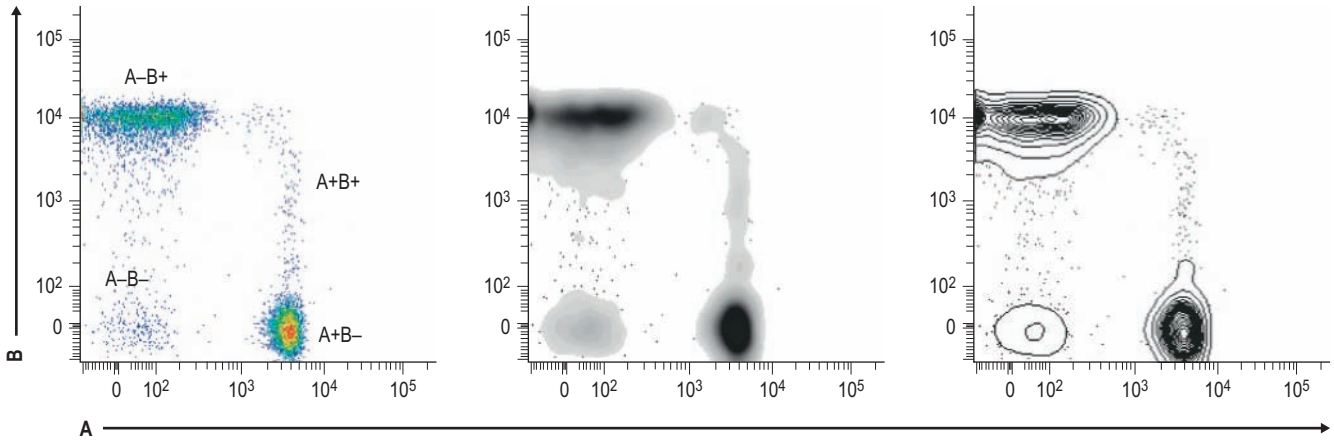

FIG. 93.4 Examples of dot pseudocolor *(left)*, density *(middle)*, and contour *(right)* displays based on the same two-color parameter data. All three techniques enable simultaneous evaluation of both parameters, in this case evaluating the expression of markers A and B. These plots identify four populations of cells, those expressing only A (A^+), only B (B^+), both A and B (A^+/B^+, very few), and expressing neither A nor B (A^-/B^-).

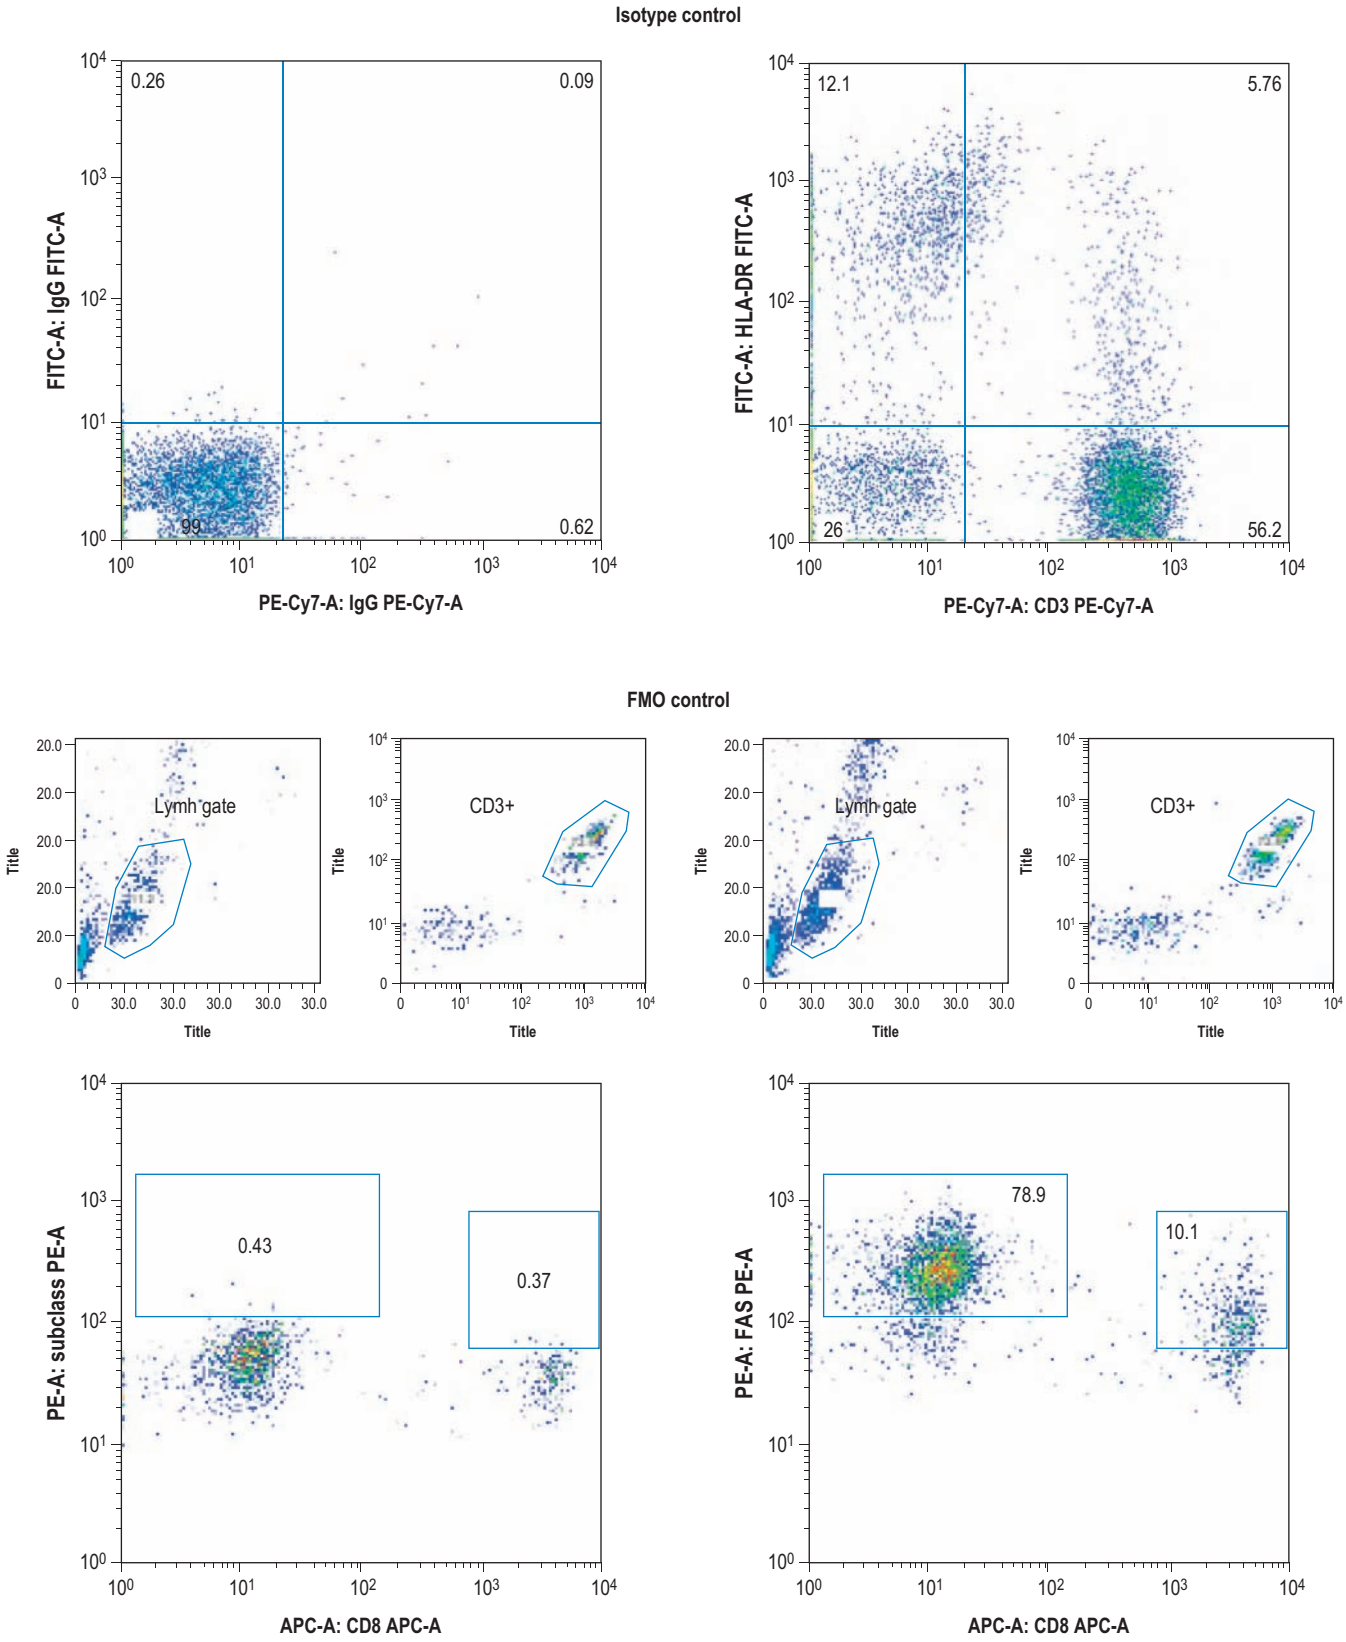

FIG. 93.5 Positive–negative discrimination strategies. (A) Nonspecific antibodies (isotypes) were used to stain the sample shown on left, and the positivity threshold determined and applied to the sample on the right. (B) FMO. The positivity threshold was determined by staining the sample on the left with the population-specific markers (CD3, TCRαβ, and CD8) and omitting antibody to CD95 (FAS). The panel on the right contains antibody to CD95. Note that the positivity threshold is slightly different for $CD8^+$ and $CD8^-$ cells.

FMO involves the staining of the sample with all the antibodies of interest, except the one targeted for positive-negative threshold. As an example, to define the negative threshold for the protein CD95 (FAS) in $CD8^+$ and $CD8^-$ T cells, the FMO control tube would include the cell subset-specific markers (CD3, TCRαβ, and CD8) and omit anti-FAS. After appropriate gating on that population, the threshold can be adequately defined, and it is different for the two exemplified populations (see Fig. 93.5B, right panel). This method is more costly due to the multiple control tubes needed for each sample.

Compensation

The fluorescence signals emitted by different fluorochromes are not completely separated by the filters. This can lead to signal overlap that is corrected by electronic subtraction of the overlapping signal, a process referred to as compensation. The overlap is particularly significant when using multiple fluorochromes, each with different spectral properties.[14] The compensation process involves subtraction of the "spillover" signal detected by the photodetector that is generated by samples stained with only one fluorochrome. Currently, most flow cytometry analysis software allows for off-line compensation, where the single reagent stained tubes are used to create a compensation matrix that is then applied to all the tubes in the experiment. This allows for much-simplified compensation procedures without the need for any hardware compensation during data collection.

Quality Control

Quality control is a critical component of clinical flow cytometry to ensure optimal results.[15] This includes monitoring instrument setup and performance, optimizing sample preparation and reagents, and standardizing controls and data interpretation. Quantitative flow cytometry based on a fluorescence standard curve provides quantitative data in units referred to as molecular equivalents of soluble fluorochrome (MESF). Finally, participation in interlaboratory proficiency testing surveys, such as the triannual samples provided by the College of American Pathologists (CAP), is an important additional measure to monitor laboratory performance, and this is mandated in US clinical laboratories by the Clinical Laboratory Improvement Amendment of 1988 (CLIA 88).

METHODS

Whole-blood lysis represents the most common technique and consists of mixing a fixed volume of anticoagulated whole blood (or bone marrow) with one or more directly conjugated monoclonal antibodies, followed by incubation at a designated temperature and time. Next, the red blood cells are lysed and the sample is washed and fixed to reduce infectious risk before being run into the flow cytometer. The non-lysed cells remaining include all peripheral blood leukocytes and any non-lysed red cells, platelets, and debris. The heterogeneity of the sample necessitates careful lymphocyte gating (see section above) to generate accurate immunophenotyping data. The advantages of the whole-blood lysis method include fewer preparation steps, less sample handling, and a lower likelihood of differential lymphocyte loss. Flow cytometry can also evaluate alternative sources of cells (e.g., bone marrow, bronchial alveolar lavage fluid, fine-needle aspirates). Patient studies must be determined with the same methods and reagents as used to determine the control ranges to ensure comparability. The number of events (cells) analyzed typically ranges from 10,000 to 20,000 in routine clinical studies but must be increased when evaluating very small subpopulations of cells to produce statistically relevant data.

TABLE 93.1 Selected Lymphocyte Surface Antigens for Immunophenotyping

T cells
Pan-T cell: CD3, CD2, CD7, CD5
Major T-cell subset: CD4, CD8
Surface antigens associated with function: CD28, CD31, CD38, CD45RA, CD45RO, CD62L, CCR7
Activation antigens: CD25, CD40L, CD69, CD71, HLA-DR

B cells
Pan-B cell: CD19, CD20, surface immunoglobulin
Major B-cell subset: CD5, CD21
Surface antigens associated with function: CD27, CD40, CD80, CD86
Activation antigens: CD23, CD25

NK cells
Pan-NK cell: CD16, CD56
NK subset: CD2, CD8, CD57

The application of control ranges must consider the fact that significant changes occur in lymphocyte distribution and development during childhood, as well as changes in lymphocytes that occur among the very elderly.[16] Other factors can also impact lymphocyte distribution, including race, gender, diurnal variation, recent or intercurrent infection.

The choice of immunophenotyping reagents depends on the cells being targeted for study and the question being asked. However, regardless of the specific set-up, the inclusion of a tube with gating reagents (anti-CD45 and anti-CD14) to confirm the integrity of the standard lymphocyte gate is recommended.[11] In addition, control reagents should be included to establish the fluorescence intensity of negative cells. Important internal controls include a pan-T-, B-, and NK-cell marker for every sample (Table 93.1), based on the principle that the whole is the sum of its parts. Thus, the total percentage of lymphocytes in the gate determined by the gating reagents should approximately equal the sum of the percentages for T, B, and NK cells. A technical or biological explanation must be identified when this relationship does not hold. These would include the presence of immature or malignant cells that were not identified by standard pan-T-, B-, and NK-cell reagents. In addition, if the gating reagents (CD45/CD14) had not been included, contaminating cells (e.g., myeloid precursors, nucleated red blood cells, large platelets) with forward- and side-scatter characteristics similar to those of lymphocytes could not be ruled out. Potential technical problems include reagent or fluorochrome degradation, failure to add a reagent, and a host of others. Evidence for any major technical error requires repeating the study.

Additional data that can be used for controls depend on the setup. For example, the availability of multiple antibodies that identify a similar cell sub-population can serve as a useful check (e.g., total T cells by comparing CD3 and CD5 or CD2; total B cells by comparing CD19 and CD20). In addition, the use of specific reagents in more than one tube enables comparison between the repeat values. The application of internal checks should be performed by the flow operator as a simple means of confirming the validity of the data. Insights regarding unusual biological findings may also be uncovered through this type of evaluation (e.g., the presence of an increased population of $CD4^-/CD8^-$ double-negative T cells).

The challenge in performing immunophenotyping is to accurately identify cells with specific surface characteristics (antigens). As previously noted, the capacity to discriminate cell subpopulations is often enhanced through the directed use of antibody combinations. The typical data generated consist of the percentage of negative versus positive cells when using one reagent and multiple subpopulations when using more than one reagent. Regardless of the experimental design, it is important to consider not only the percentage of cells within each subpopulation but also the absolute number of cells. This is most commonly obtained by multiplying the relevant percentage from the flow cytometer by the absolute lymphocyte count obtained using a white blood count and differential. For example, when assaying for CD4 T-cell counts, the percentage of $CD4^+$ cells is multiplied by the absolute lymphocyte count to yield the absolute CD4 count. However, using two separate procedures (i.e., dual platforms) to generate the final result introduces the possibility of an additive error based on the inherent errors of the two different methods. This fueled a search for approaches performing both tasks by flow cytometry (i.e., a single platform). One alternative involves the inclusion of a fixed number of fluorescent beads (in a defined volume) in each tube as a reference standard to generate absolute numbers without requiring the use of an absolute lymphocyte count. An alternative approach involves the use of impedance-based cell counting in the flow cytometer to generate an absolute lymphocyte count (dependent on a fixed volume of sample being run) to generate both percentage and absolute number for each specific population or subpopulation. Regardless of the approach, the reporting of both percentages and absolute numbers is necessary when immunophenotyping peripheral lymphocytes.

The objective of evaluating malignant cells is often to characterize the lineage and differentiation level of the abnormal cells rather than quantifying subpopulations. The pattern of reactivity combined with fluorescence intensity is often useful in identifying leukemic patterns, whereas absolute numbers are usually not required. However, flow cytometric detection and quantitation of rare abnormal cells can be useful in evaluating for minimal residual disease post therapy in lymphoproliferative disorders.

PRACTICAL APPLICATIONS OF FLOW CYTOMETRY

Immunophenotyping Studies

CLINICAL RELEVANCE

Immunophenotyping Studies

- Can be used to identify cell subsets, lineage, stage of cell differentiation, state of cell activation, and clonality.
- Lymphocyte results should be checked with T cells + B cells + NK cells = 100%.
- Immunophenotyping studies are not the equivalent of lymphocyte function studies.

The majority of immunophenotyping studies are directed to enumerate specific cell subpopulations, evaluating for the presence or absence of particular surface antigens, identifying the differentiation level of specific cells, determining cell lineage, evaluating for functional correlates based on specific antigen expression, examining for evidence of cell activation, and/or establishing evidence of monoclonality.

Quantification of a particular cell subpopulation can be readily accomplished by flow cytometry generating cell numbers based on the percentages of the respective cell types (and an absolute lymphocyte count). The evaluation of CD4 T-cell counts has formed the basis for monitoring patients infected with HIV.[17] The quantitation of $CD34^+$ hematopoietic stem cells in donor peripheral blood or bone marrow is used in many cellular reconstitution protocols.[18] Subpopulation characterization can also be useful in the evaluation of patients with clinical history and laboratory findings suggestive of immune deficiency.[19] This has taken on a higher level of significance in the setting of newborn screening for severe T-cell immune deficiency via the T-cell receptor excision circle (TREC) assay that, when abnormal, is typically followed by immunophenotyping to evaluate for naive T cells.

When evaluating for the presence or absence of surface proteins associated with specific functional attributes, it is important to realize that this approach does not assess the actual functional status of the cells. This point is clearly illustrated by the finding of normal B-cell numbers in most patients with common variable immune deficiency (CVID) despite the fact that these patients fail to produce immunoglobulins normally (see Chapter 33). However, changes in the characteristics of the B cells, particularly relative to memory B cells, provide potential insight into different phenotypes of this disorder and provide additional support for heterogeneity of patients with CVID. Due to the limitations of immunophenotyping, it is common practice when evaluating the status of the immune system to perform cell function testing in parallel.

Flow cytometry can be used to test for the presence or absence of a specific cell surface antigen. An example of this type of application is in the evaluation of a patient with a history of recurrent skin infections, delayed wound healing, and persistent granulocytosis, which suggests a diagnosis of leukocyte adhesion deficiency type 1. This disorder results from a defect in the gene encoding CD18, preventing the expression of three different heterodimeric adhesion molecules (β2 integrins), each containing CD18 (see Chapter 39). This disorder can usually be diagnosed by studying granulocytes (and lymphocytes) for the expression of CD18 (as well as the three isoforms of CD11). Patients often have decreased rather than absent CD18 expression, and further confirmation of the diagnosis can be accomplished by demonstrating a failure of CD18 upregulation following granulocyte activation.

Immunophenotyping can also help address questions regarding the level of cell differentiation. Antibodies specific to proteins expressed by early (precursor) cells represent one approach and would include evaluating for the thymocyte marker CD1 or the pre-B-cell marker CD10 (CALLA), to cite two. However, defining the developmental level of a particular cell population or subpopulation is best accomplished using a panel of reagents that span the natural history of the cell lineage. This approach represents the standard for testing leukemias and lymphomas (see Chapters 77 and 78). In addition to defining the presence or absence of specific antigens, evaluating their level of expression is also valuable, which may be altered in the abnormal cells. Malignant cells may also express antigens associated with different lineages and have altered forward- and side-scatter characteristics, as well as diminished or absent CD45 expression, requiring modified gating approaches.

Issues of monoclonality can be dealt with using flow cytometry when analyzing B cells, and in some circumstances, when studying T cells. Normally B cells are a heterogeneous mixture of mutually exclusive κ or λ light-chain-positive cells. Measuring the distribution of κ or λ light-chain expressing B-cells or plasmacytes can be informative as to the presence or absence of monoclonality (see Chapter 79). The capacity to evaluate T-cell

monoclonality by flow cytometry is less definitive and consists of using T-cell antigen receptor β-variable (Vβ) chain-specific reagents to look for evidence of significant over representation of one Vβ chain family. This approach currently consists of setting up a series of tubes, each with three different Vβ family-specific monoclonal antibodies, one conjugated with FITC, one with PE, and the third with FITC plus PE. This combination enables distinguishing the frequency of each of the three different Vβ families per tube (green$^+$, orange$^+$, green$^+$/orange$^+$) and represents a flow cytometric method to complement PCR-based spectratyping.[20]

The state of lymphocyte activation can be addressed by evaluating for the presence of surface antigens that are found only on activated cells or are upregulated following activation. These include receptors for specific growth factors (e.g., IL-2 receptor α chain, CD25), receptors for critical elements required for cell growth (e.g., transferrin receptor, CD71), ligands for cell–cell communication following activation (CD152 [CD40 ligand] on activated CD4 T cells), and surface antigens that are upregulated as a result of activation (e.g., adhesion molecules, HLA-DR, CD69). In addition, the memory status of both T cells and B cells can be assessed based on differential surface molecule expression associated with prior antigen encounter. This enables a distinction to be made between naïve T cells that express CD45RA, CD31 (recent thymic emigrants), CD62L, and CCR7 from memory T cells that express the alternative CD45 isoform, CD45RO (and varied CD62L or CCR7, depending on whether the cells are central or effector memory cells).[21] In addition, memory B cells can be detected by the expression of CD27 and be further divided into isotype-switched and non-switched memory cells based on their pattern of surface immunoglobulin expression.[22]

Defects associated with familial lymphohistiocytosis (FLH) are generally associated with abnormal NK cell function. Many of the FHL-causing defects can be determined by flow cytometry. For example, SAP and XIAP intracellular staining (see next section) can be used to evaluate for X-linked lymphoproliferative (XLP) disorders type 1 and 2, respectively. Likewise, lack of intracellular perforin expression in NK cells would be indicative of hemophagocytic lymphohistiocytosis (HLH) type 2. Additionally, the evaluation of CD107a surface expression, which is normally expressed on cytoplasmic granules and upon degranulation in response to incubation with specific target cells (e.g., K562 cells), is expressed on the surface of NK cells and is useful in determining the underlying genetic defect causing FHL.[23] Specifically, lack of surface CD107a is indicative of syntaxin-11 or MUNC-13.4 defects.

Intracellular Evaluation

Cellular Activation

CLINICAL RELEVANCE

Intracellular Flow Cytometry

- Activation-directed studies:
  - Cell (lymphocyte) proliferation
  - Calcium flux
  - Intracellular protein phosphorylation
  - Oxidative burst: neutrophils
- Intracellular cytokine studies:
  - Clarify the Th1/Th2/Th17 status of an immune response
  - Can be assessed in an *in vitro* antigen-specific response
  - Can be combined with evaluation of cell surface studies

Ligand binding and transmembrane signal transduction resulting in cellular activation can be evaluated using flow cytometry. Changes in intracellular ionic calcium concentration (Ca^{2+}) are frequently used to monitor cell activation after ligand binding. These changes are associated with the activation of phospholipase C and protein kinase C. In general, three reagents have been used to measure Ca^{2+}: quin 2, indo-1, and fluo-3. Quin 2 has a low excitation coefficient and is not useful for flow cytometry; indo-1 requires ultraviolet excitation; fluo-3 can be excited by 488 nm but does not permit ratiometric analysis. Nevertheless, because of its ease of use fluo-3 is currently the most widely used probe for intracytoplasmic Ca^{2+} evaluation by flow cytometry. Strict attention must be paid to loading conditions, the presence or absence of free Ca^{2+} in the medium, experimental temperature, baseline measurements, and calibration. This approach can be combined with cell surface marker or cell cycle evaluation.[24]

Intracellular pH changes related to cellular activation also can be evaluated. The most useful probe for pH is SNARF-1.[24] This probe can be excited at 488 nm and allows for ratiometric analysis with detection wavelengths set for 575 and 640 nm. Glutathione (glutamylcysteinylglycine [GSH]) is an important antioxidant generated during cell activation that can be measured by flow cytometry.[24] The fluorescent probe monochlorobimane is commonly used for this measurement, but it is complicated by the need to determine GSH by high-performance liquid chromatography (HPLC).

Additional approaches to evaluate cellular activation include assessment of intranuclear markers (Ki-67, PCNA) as well as surface proteins that are upregulated following cellular activation (e.g., CD69, CD25, CD71).[25] Actual cell division can be evaluated using cell tracking dyes (e.g., PKH26, CFSE, Cell Trace™ Violet) that lose 50% of their fluorescence with each round of cell division.[26] This approach has become more common in the clinical assessment of lymphocyte function due to the capacity to evaluate specific lymphocyte subpopulations responding to mitogenic and antigenic stimuli. Cell labeling dyes also can be used to label target cells in cell-based cytotoxicity assays.[27] Recently, an approach to evaluate lymphocyte proliferation following cell stimulation has been described using the thymidine analog, EdU. Detection of DNA synthesis induced by the different activating agents is measured using a copper-catalyzed click chemistry, which results in EdU being covalently bonded to a fluorescent azide.[28] This approach allows the assessment of cell proliferation at the cell population or subpopulation (e.g., CD3, CD4, CD8) level and can be used in association with mitogen and recall-antigen stimulation.

An alternative approach to the functional evaluation of cell activation is based on the detection of phosphorylated intracellular proteins associated with specific activation signals using flow cytometry. An example of this is the detection of phosphorylated signal transducer and activator of transcription 1 (STAT1) following interferon-γ (IFN-γ) stimulation of monocytes, which has been found to be equal to or more sensitive than immunoblotting.[29] Using this same principle, a more comprehensive evaluation of multiple signaling pathways using different cytokines (e.g., IL-2, IL-4, IL-6, IL-7, IL-21, and IFNα) and combinations of JAK-STAT proteins in CD4$^+$ T cells, or alternative activation pathway in macrophages (through IL-4), could also be determined (Fig. 93.6). This type of assay requires fixation and permeabilization optimized to the phosphoepitope

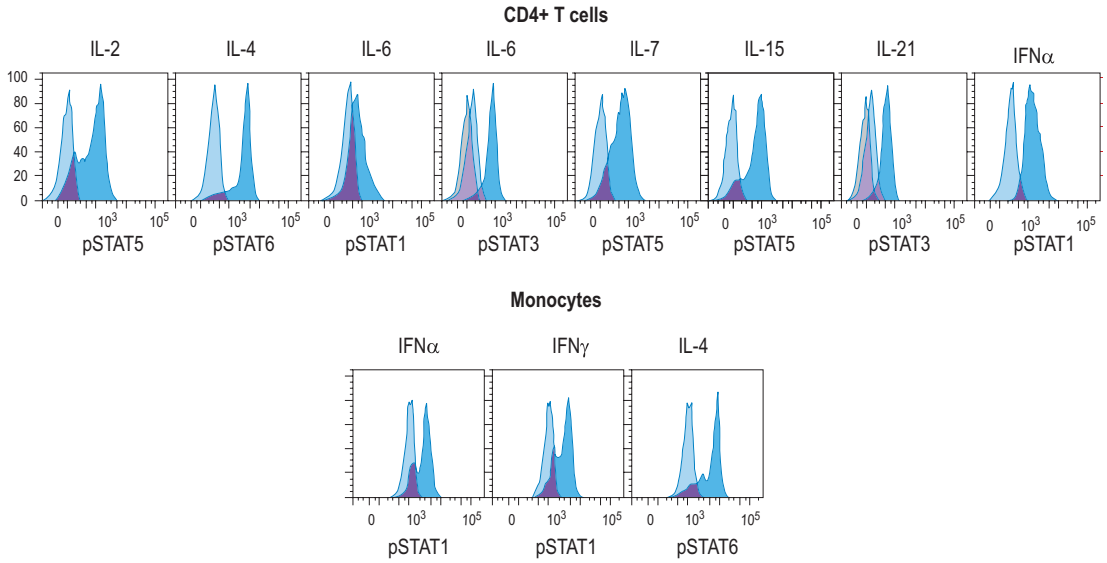

FIG. 93.6 Phosphorylation of STAT proteins in CD4⁺ T cells (upper panel) and monocytes (lower panel) upon cytokine stimulation. Isotype control is represented in gray and baseline levels in light blue.

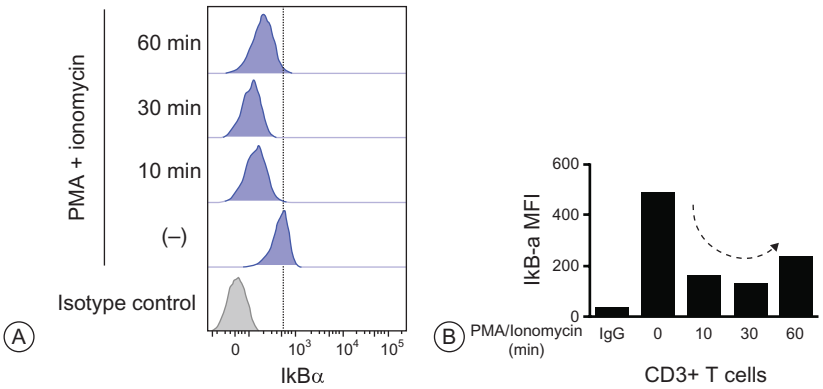

FIG. 93.7 (A) Histograms of intracellular IkBa in CD3⁺ lymphocytes at baseline (–) and upon stimulation with phorbol myristate acetate (PMA) + ionomycin. Degradation of IkBa followed by re-synthesis is seen over time. (B) Median fluorescence intensity (MFI) of IkBa at baseline (0) and three time points following stimulation.

of interest to allow the entry of the specific reagent. Similarly, the compatibility of surface epitopes and fluorochromes with certain fixation and permeabilization protocols needs to be considered. Currently, several intracellular signaling proteins that undergo phosphorylation following a specific activation signal can be assessed using commercially available reagents.

The NF-κB pathway has an important role in regulating lymphocyte development, immune responses, inflammation, cell proliferation, and cell death. Two signaling pathways have been described to be associated with NF-κB: canonical and noncanonical. Signaling through the NF-κB canonical pathway depends on IκBα phosphorylation, ubiquitination, and proteasome degradation upon cell stimulation. Once IκBα is degraded, it releases c-Rel/p65 and p50 to be translocated to the nucleus in order to initiate gene transcription. Evaluation of IκBα phosphorylation (phospho-IκBα), as well as IκBα degradation and re-synthesis kinetics using flow cytometry, and intracellular staining allows for the determination of the NF-κB canonical pathway signaling integrity (Fig. 93.7).

The assessment of oxidative burst following cell stimulation plays a central role in neutrophil function testing using the hydrogen peroxide-sensitive dye dihydrorhodamine 123 (DHR123). This procedure involves loading granulocytes with the dye, stimulating with phorbol myristate acetate (PMA), and evaluating for fluorescence by flow cytometry.[9] This test has proved to be extremely accurate in diagnosing patients with chronic granulomatous disease (CGD) and carriers of X-linked CGD.

An important advantage is its sensitivity, which allows the detection of one normal cell in a population of 1000 abnormal cells. This makes the assessment of oxidative burst a useful tool in following allogeneic granulocyte survival after transfusion into patients with CGD, as well as a means of following donor chimerism in the setting of allogeneic stem cell transplantation. It also provides a method to identify corrected cells following gene therapy in CGD and has utility in predicting disease outcome in CGD.[30]

Intracellular Cytokine Detection

Flow cytometry affords a platform to evaluate cytokine production at a single-cell level using cytokine-specific directly conjugated monoclonal antibodies following fixation and permeabilization of cells. This approach allows for the simultaneous

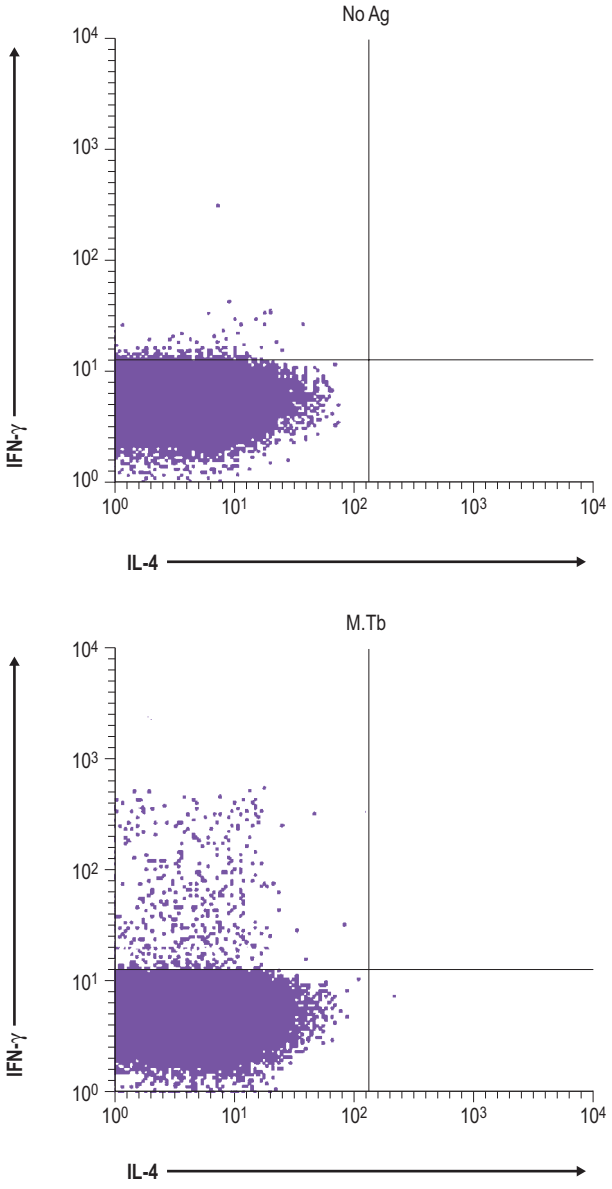

FIG. 93.8 Two-color dot plots of CD3+ T cells evaluated for intracytoplasmic interferon-γ and IL-4 expression. The donor had a positive skin test to PPD and demonstrated a Th1 pattern of cytokine expression (interferon-γ) in response to *Mycobacterium tuberculosis* antigen, with an absence of a Th2 cytokine pattern (IL-4). Courtesy of Calman Prussin, MD.

detection of two or more intracellular cytokines in combination with cell surface markers and/or other intracellular markers. Important aspects of intracellular cytokine detection include the use of a protein transport inhibitor during activation, the use of proper controls, and the choice of antibodies. As there is little or no spontaneous cytokine production in circulating human lymphocytes, intracellular cytokine detection requires *in vitro* activation. Initial experience was based on supraphysiological stimulation using PMA and ionomycin, but antigen-specific activation systems have also proven to be feasible. It should be emphasized that regardless of the activation method, the duration of activation is an important variable, as individual cells reach maximum cytokine production at different times. In addition, different cytokines have different optimal periods of activation. It is recommended that a proper kinetic profile be established for the biological system or clinical condition being studied.[31]

To increase the level of intracellular cytokines, inhibitors of intracellular protein transport and secretion (e.g., monensin or brefeldin) are commonly used, which lead to the accumulation of proteins within the cell. Nonspecific binding of the antibody reagents is an issue, as permeabilization allows access not only to the cytokine of interest but also to other proteins present in much greater quantities than on the cell surface. In addition, fixation further increases nonspecific binding and the use of both a negative-control sample, which contains an excess of unlabeled or "cold" anti-cytokine antibody, and an isotype-matched or FMO-control sample provide the optimal control. When the conjugated anti-cytokine is added to the negative-control sample, it can only bind to other proteins in a nonspecific manner, thereby providing a measure to discriminate between specific and nonspecific binding. The use of directly conjugated anti-cytokine antibodies not only simplifies the staining procedure but also provides the best distinction between specific and nonspecific binding. Because the fixation agent may change the native state of certain epitopes, it is also important to use antibodies that recognize antigens after fixation when combining cell surface characterization with intracellular cytokine evaluation.

One of the main applications of intracellular cytokine detection by flow cytometry has been the study and refinement of the Th1/Th2/Th17 paradigms. It has recently become clear that the regulated secretion of cytokines can be used to study the response of individual T cells to both polyclonal stimuli and specific antigens. Measuring antigen-specific T-cell cytokine expression in response to specific antigen offers a useful alternative to the tetramer-based approach (discussed below) to quantify the frequency of antigen-specific T cells (Fig. 93.8).[31]

Cell Cycle Analysis

CLINICAL RELEVANCE

Cell Cycle Analysis

- Useful for screening percentage of S phase and aneuploidy
- Can be combined with cell surface studies
- Can be combined with markers of apoptosis

In addition to surface immunophenotyping and cytoplasmic characterization, flow cytometry is also used in cell cycle analysis. Propidium iodide (PI) is the most used fluorochrome, owing to its optimal linear DNA-binding capacity in a variety of different cell types. Thus, a single-parameter histogram of DNA content using PI readily permits the determination of cell cycle compartments, expressed as the percentage of cells in G_0–G_1, S, and G_2-M (Fig. 93.9A). In addition to these conventional parameters, the presence or absence of aneuploidy can be determined by inspection of the G_0–G_1 peak and/or use of a DNA index (ratio of abnormal DNA content to a diploid DNA standard). Also, elevation in the S and/or G_2-M phase can be detected. The optimal display of these data uses a combination of side scatter versus DNA content. Cells observed on the histogram in the area below the level of G_0–G_1 may be undergoing apoptosis.[32] When dealing with DNA staining, a consistent cellular source of DNA (e.g., chicken erythrocytes) should be used as an internal reference for evaluating DNA content and evaluating the cell cycle distribution.

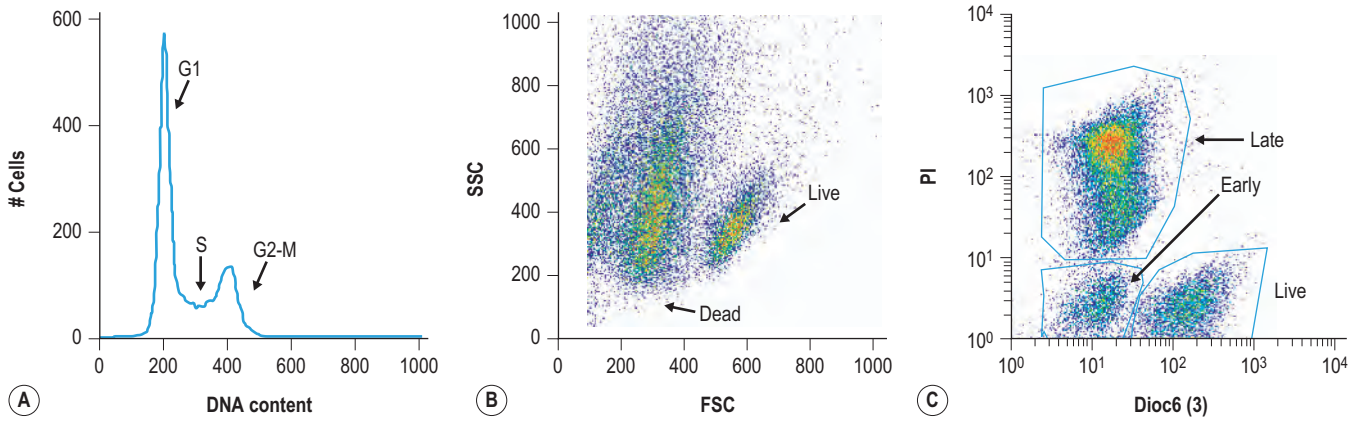

FIG. 93.9 (A) Assessment of DNA content as a reflection of cell cycle demonstrating cells in G_1, S, and G_2/M phases. (B) Assessment of live versus dead cells based on forward- and side-scatter characteristics. (C) Assessment of cell apoptosis using PI and Dioc6 (3) identifying cells that recently initiated apoptosis (early), cells that are dead (late), and cells that are alive (live).

It should be noted that several different computer algorithms have been developed to determine the relative proportion of each cell cycle compartment, and the selection of a software program is not a trivial process. The major instrument manufacturers supply cell cycle analysis programs, and there are also third-party programs available. Generally, the optimal program should be capable of modeling two or more aneuploid populations, subtracting debris (particularly if formalin-fixed paraffin-embedded archival material is used), and accurately estimating S-phase cells.[32] The combination of a surface marker and cell cycle has been very useful in differentiating normal cell populations from tumor cell populations. One example is the use of anti-κ, anti-λ, or B-cell reagents to separate the aneuploid B-cell clone from the remaining normal, reactive B cells in a lymphoid cell mixture. Another uses cytokeratin as a marker to distinguish between the tumor cells and the inflammatory cells that are present.

The other major event that has occurred in cell cycle analysis has been the development of technology using the incorporation of bromodeoxyuridine.[33] This thymidine analog is used to directly determine the percentage of S-phase cells. Also, when used in kinetic studies, it permits a determination of the individual times for the components of the cell cycle and a determination of the growth fraction.

Apoptosis Detection

Flow cytometry has become the method of choice for the detection and quantification of cellular apoptosis.[34] This is due in part to its capacity for rapid assessment of a large number of cells and samples. Many distinct features of an apoptotic cell can be evaluated by flow cytometry based on light scatter, plasma membrane changes, mitochondrial transmembrane potential, DNA content, and DNA integrity.

The light-scattering properties of a cell undergoing programmed cell death are the simplest attributes that can be assessed by flow cytometry. Dying cells typically shrink, producing a loss in FSC and, despite an initial transient SSC increase, there is ultimately a decrease in SSC (see Fig. 93.9B). The use of light scatter can be combined with cell surface staining to help characterize the dying cells. However, scatter changes alone are not specific to apoptosis and should be accompanied by an additional characteristic associated with cell death. Live cells have phospholipids asymmetrically distributed in the inner and outer plasma membrane, with phosphatidylcholine and sphingomyelin on the outer surface and phosphatidylserine (PS) on the inner side. Early during apoptosis, cells lose asymmetry, exposing PS on the outside. Annexin V is a protein that binds preferentially to negatively charged phospholipids such as PS, and directly conjugated annexin V is a useful reagent for the specific detection of apoptotic cells.[34]

Another characteristic of plasma membranes associated with live cells is that they exclude charged cationic dyes such as propidium iodide (PI) and 7-amino-actinomycin-D (7-AAD). Consequently, only cells in a late stage of apoptosis, with ruptured cell membranes, will take up these dyes. Thus, the combined use of cationic dyes (e.g., PI) with annexin V allows the discrimination between live cells (annexin V negative/PI negative), early apoptotic cells (annexin V positive/PI negative), and late apoptotic cells (annexin V positive/PI positive).

Assessment of mitochondrial transmembrane potential ($\Delta\psi m$) is yet another technique used to identify apoptotic cells. Cells decrease $\Delta\psi m$ very early in the apoptotic process before rupture of the plasma membrane, losing the ability to accumulate potential-dependent dyes such as rhodamine 123, JC-1, or 3,3″-dihexyloxacarbocyanine iodide ($Dioc6^3$). These dyes can also be used with PI to detect cells in the different stages of apoptosis (see Fig. 93.9C).

Measurement of DNA content can also be employed to distinguish live from dead cells, as described above (see Cell Cycle Analysis). This kind of analysis has to be done using a linear scale, not logarithmic, in order to discriminate dying cells from debris. DNA cleavage also exposes -OH termini associated with the DNA breaks, and these can be detected via the attachment of fluorochrome-conjugated deoxynucleotides in a reaction catalyzed by exogenous TdT, a technique called TUNEL.

Peptide–Major Histocompatibility Complex Multimers

KEY CONCEPTS

Peptide–Major Histocompatibility Complex Tetramers

- Useful for assessing the number of antigen-specific T cells
- Can be directed at both $CD4^+$ and $CD8^+$ T cells
- Requires information about the antigenic peptide and HLA (MHC) restriction

In contrast to B cells, direct visualization of antigen-specific T cells *ex vivo* has, until recently, been unsuccessful. In 1996, Altman et al. introduced a novel flow-cytometry-based methodology that enables the direct visualization and quantification of antigen-specific T cells.[35] The generation of soluble peptide-major histocompatibility complex (MHC) multimers allows for multiple TCRs being engaged at the same time, which results in markedly greater avidity of these multimeric ligands for their peptide-specific TCR. The most common multimer methodology involves engineering a biotinylation recognition sequence on the –COOH terminus of the extracellular domain of one chain of the MHC molecule that, after combining with a specific antigenic peptide, is bound by avidin or streptavidin. As both avidin and streptavidin have four biotin-binding sites, the result is a tetrameric peptide–MHC complex that serves as a ligand for T cells specific for both the peptide and MHC. Flow-cytometric detection is achieved by labeling streptavidin with a fluorochrome. The major pitfall to this approach is the need to know the antigen-derived peptide and its HLA-restrictions, as well as the HLA type of each subject studied. Since the initial report, an increasing number of tetramer-based studies have appeared. Most have focused on the MHC class I-mediated immune response in both mice and humans to a variety of infectious agents, including cytomegalovirus (CMV), HIV, Epstein–Barr virus, and others. Since the initial description with class I-restricted recognition, detection of antigen-specific CD4 T cells with tetramers of soluble MHC class II molecules and covalently linked peptide has also been reported. New methodologies now allow higher valency multimers such as pentamers, octamers, dodecamers, and dextran-based multimers.[36]

In addition to demonstrating the feasibility of this approach, the published studies have provided several new insights into the MHC class I-mediated immune response (see Chapter 5). For example, it has become clear that the extent of the MHC class I-mediated cellular response is much greater than previously estimated. Furthermore, the extensive proliferation of CD8 T cells during an acute infection is not the result of bystander activation but represents an expansion of antigen-specific CD8 T cells. Peptide–MHC -multimer assays have also shown promise in the study of the kinetics of primary and secondary immune responses, as well as in a better understanding of concepts such as immunodominance and clonal exhaustion.

An obviously attractive aspect of this technology is that tetramer staining can be combined with a variety of cell surface and intracellular phenotypic and functional markers. Already there are indications that the phenotype of antigen-specific T cells varies between individuals and between different phases of the immune response. In addition, tetramer-positive T cells can be sorted for further analysis, such as cytotoxicity assays or *in vitro* expansion. The multimer-based technology has not only proved useful for the study of the immune response to infectious agents, but it has also been applied to the study of oral tolerance, autoimmune conditions, and tumor immunology. It is likely that this highly sensitive and specific technology and other approaches that define antigen-specific response will find many more applications and will lead to new discoveries and a reassessment of certain existing concepts.[37]

CONCLUSION

ON THE HORIZON

- The combination of flow cytometry and mass spectrometry expands the number of cell markers analyzed simultaneously (>35 currently performed), including extracellular and intracellular targets to provide an extensive evaluation of functional markers. However, this technology has not yet entered the majority of clinical laboratories.
- Flow cytometry utilizing spectral rather than conventional light analysis has the potential to allow more "colors" to be accurately evaluated without the need for complex compensation schemes with conventional fluorochromes. This could facilitate more extensive polychromatic studies to be performed easily but is not currently offered by most clinical laboratories.

Flow cytometry has become readily available in clinical laboratories, and the application of this technology has moved forward in parallel to significant improvements in instrumentation and the availability of an array of monoclonal reagents. Properly performed flow cytometry can provide rapid and accurate lymphocyte subpopulation identification. The primary clinical indications of immunophenotyping remain quantifying CD4 T-cell counts in HIV infection, lineage assignment in leukemias and lymphomas, evaluation of other hematologic cell types, and assessing CD34 expression to identify stem cells for transplantation. Additional uses include characterizing immune deficiency disorders, evaluating immune-mediated inflammatory diseases, and assessing patients following organ transplantation. Generally, immunophenotyping does not represent a diagnostic procedure but rather plays a part in the evaluation and understanding of complex disorders and the longitudinal evaluation of immunomodulatory therapy.

It is critical to recognize that immunophenotyping is a means of identifying cells, but it is not directed at cell function. The expansion of flow-cytometric techniques to evaluate intracellular characteristics, assess intracellular changes associated with activation, characterize apoptosis and identify antigen-specific T cells has moved this technology into the cell function arena. These newer approaches expand the utility of flow cytometry as a valuable method for the characterization of various aspects of immune function.

Assessment of Functional Immune Responses in Lymphocytes

Roshini Sarah Abraham

The immune response is mediated by a complex network of cells, soluble and membrane-bound biological mediators, and receptors interacting within the context of specific tissues and organs to protect against pathogens. T cells recognize antigen primarily in the context of antigen-specific T-cell receptors (TCRs) and specific peptides presented by molecules of the major histocompatibility complex (MHC), either class I or class II (Chapters 5 and 6). T cells are also capable of responding nonspecifically to polyclonal stimuli, such as mitogens (in vitro) or superantigens (in vivo) that initiate a broader, non-antigen-specific proliferative response. T cells upon activation also produce cytokines that are crucial to their effector functions including activating B cells and inducing antibody production, promoting differentiation of cytotoxic T cells, activating macrophages, and promoting activation and migration of inflammatory cells. Cytokines play a role in the induction of the T-cell response when produced by antigen-presenting cells (APCs) at the time of antigen recognition. B cells recognize antigen directly via the B-cell receptor (BCR; involving surface immunoglobulin) and produce antibodies with help from T cells (T-dependent antigens) or the innate immune system (T-independent antigens). More recently, the granularity of the antibody response has been further delineated, and T-dependent antibody responses are divided into type 1, with help provided by T-follicular helper cells (Tfh), and type 2, with help provided by NKTFh cells (derived from invariant NKT cells [iNKT] expressing the Vα24 Jα18 antigen receptor). Similarly, T-independent responses are classified into three groups: type 1, induced by recognition of microbial antigens by the Toll-like receptors (TLRs) in the absence of Bruton tyrosine kinase (BTK); type 2, which requires the presence of BTK; and type 3, which has neutrophil B-helper cells.[1–3] The antibody responses to vaccination depend on a variety of factors,[4] including the mobilization of particular B-cell subsets in response to specific antigens, and subsequent antibody production. B1 B cells are considered a unique population of B cells enriched in certain secondary lymphoid tissue, which are capable of self-renewal and producing natural antibodies, specifically immunoglobulin M (IgM), and priming T cells.[5]

Regulatory (Treg) cells have been shown to play a critical role in the control of both physiological and pathological immune responses in a variety of contexts (Chapter 13). Treg cells exert a direct inhibitory effect on the development of autoimmune disease because their absence leads to the development of a severe phenotype, as manifested by the FOXP3 deficiency, IPEX (immune dysfunction/polyendocrinopathy/enteropathy/X-linked) (Chapter 34).[6] Treg cells can suppress the proliferation of antigen-stimulated naïve T cells, as demonstrated by in vitro studies, and induction of FOXP3 in conventional naïve T cells imparts suppressive function in vitro and in vivo, resulting in the generation of induced-regulatory (iTreg) T cells.[7] Besides producing antibodies to neutralize pathogens as well as presenting antigen to T cells, B cells also exert immunomodulatory control of the immune response, primarily via interleukin (IL)-10 production. IL-10-producing B cells, classified as regulatory B (Breg) cells, play an important role in immune homeostasis and protection against autoimmune responses and inflammatory damage.[8] Breg cells, in addition to producing IL-10, secrete other cytokines that act on other effector T-cell subsets, Tregs, APCs such as dendritic cells (DCs), and macrophages.

NK cells are considered to be innate immune effector cells, but they straddle the threshold of innate and adaptive immunity. NK cells are directly involved in cytotoxicity and cytokine secretion upon activation, but they also function indirectly by regulating APC and the effector T cells response. NK cell activation is controlled by synergistic signals from activating and inhibitory receptors.[9] The characteristics, responses, and assays to measure the activity and function of each of these subsets are described in detail in the sections below.

T-CELL RESPONSE

T cells form the cellular arm of the adaptive immune response, and each T cell has unique specificity derived from the presence of a functional, antigen-recognizing receptor (TCR) on the cell surface. On the surface of the T cell, the TCR associates with the CD3 complex, composed of four distinct subunits (γ, δ, ε, and ζ); the cytosolic components of the CD3 complex are involved in the intracellular propagation of signals after ligation of the TCR. Besides the CD3 complex, the TCR also clusters with a CD4 or CD8 coreceptor, depending on the type of T cell; CD4 T cells recognize antigen (Ag) in the context of MHC class II molecules, whereas CD8 T cells recognize antigen presented on MHC class I. The first signal or "cognate" signal, which is recognition of peptide–MHC complex by the TCR, results in actin-mediated reorganization of the cytoskeleton in both the T cell and APC to form the immunological synapse (Fig. 94.1). The synapse consists of the TCR along with other costimulatory molecules and adhesion receptors, which results in the formation of a large macromolecular structure called the supramolecular activation complex (SMAC). The unique organization of the SMAC results in prolonged and stronger intracellular interactions and appropriate downstream signaling activity, including phosphorylation of the CD3 receptor components. The complete culmination of the TCR-induced signals results in IL-2 production and secretion, which drives T-cell proliferation in an autocrine and paracrine manner.

It is important to recognize that various T-cell processes and stages of differentiation are specifically regulated by metabolic

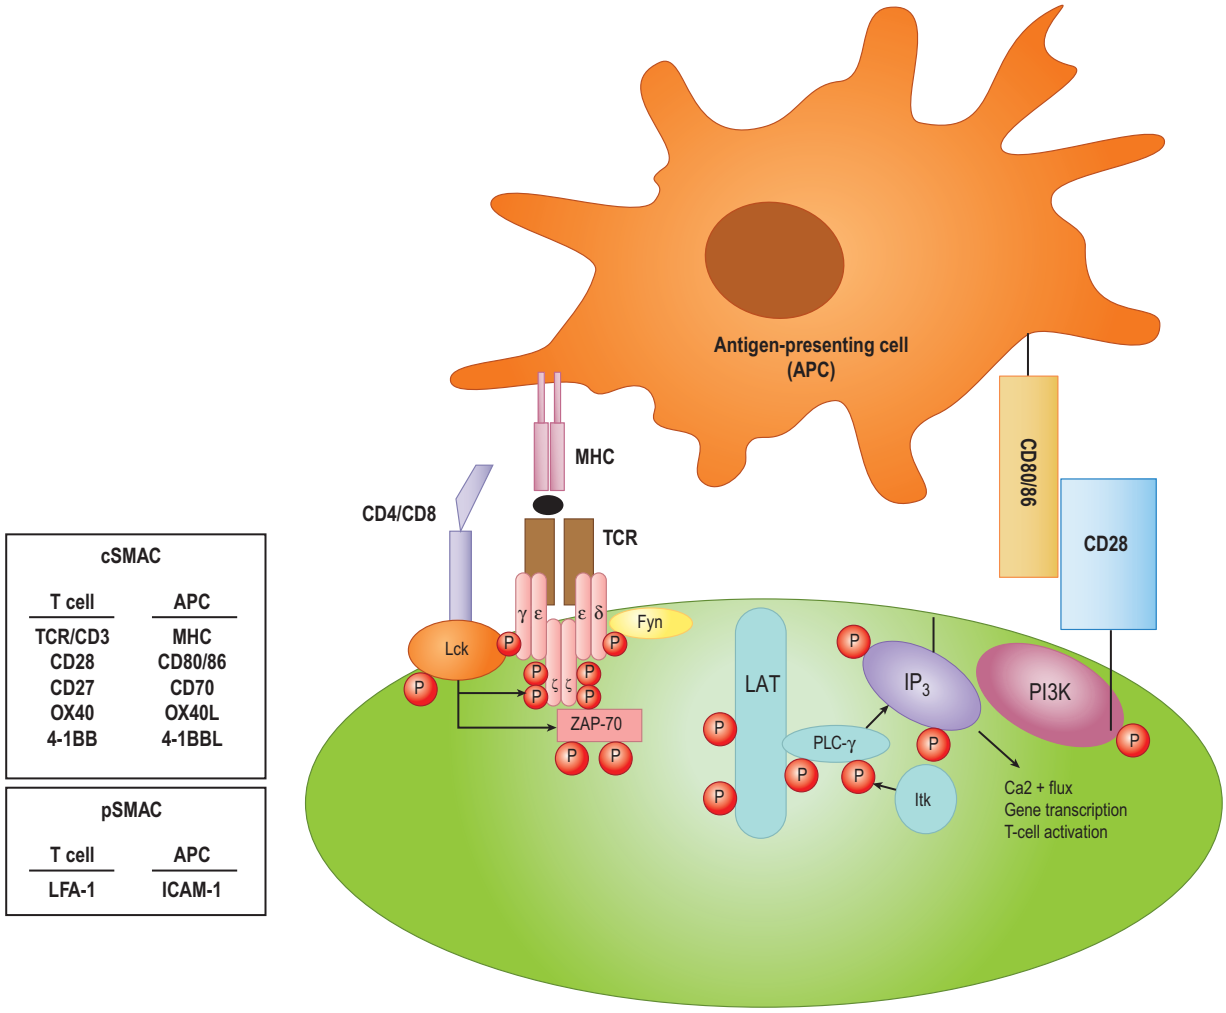

FIG. 94.1 Schematic of T-Cell Activation. T cells recognize antigen in the context of major histocompatibility complex (*MHC*) molecules on antigen-presenting cells (*APCs*). Sustained interaction between a T cell and APC results in the formation of the immunological synapse with membrane reorganization and ordering of key molecules on both cells into a supramolecular activation complex (SMAC) composed of c (central) *cSMAC* and p (peripheral) *pSMAC*. Cognate interaction with appropriate costimulatory signals results in intracellular signaling events that ultimately result in T-cell activation. *LAT*, linker for activation of T cells; *PLC-γ*, phospholipase C-gamma; *TCR*, T-cell receptor; *IP_3*, inositol 1, 4, 5 triphosphate; *P*, phosphorylation; *PI3K*, phosphatidylinositol 3′-hydroxyl kinase; *Lck* and *Fyn* are Src-family nonreceptor protein tyrosine kinases; *Itk*, IL-2–inducible T-cell kinase; *ZAP-70*, ζ-chain–associated protein kinase 70. pathways.[10,11] For example, naïve T cells rely on oxidative phosphorylation for their metabolism, with additional glycolytic metabolism during times of proliferation. On the other hand, activated effector T cells demonstrate aerobic glycolysis and increased oxidative phosphorylation. T-helper cell-1 (Th1), Th2, and Th17 CD4 effector T cells use glycolytic metabolism, whereas regulatory T-cell and memory T-cell development is enhanced by fatty acid oxidation and catabolic metabolism. In particular, memory T cells are quiescent and mainly use oxidative phosphorylation; however, on antigenic rechallenge, the use of oxidative phosphorylation and glycolysis is rapidly facilitated.[10]

CLINICAL RELEVANCE

Lymphocyte Function Evaluation

- Assessment of lymphocyte function typically refers to the measurement of T-cell function via cellular proliferation to nonspecific and specific stimuli; however, it is much broader and comprehensive, and refers to any method that assesses any of the various effector or regulatory aspects of any lymphocyte subset.
- The robustness of clinical interpretation of lymphocyte function assays is dependent on the analytical procedure, sample type, timing of collection, and clinical context, among other factors. Assays performed in clinical diagnostic immunology laboratories are standardized to minimize inconsistencies in these variables.

MEASUREMENT OF T-CELL FUNCTION VIA ACTIVATION MARKERS

Activation of T cells results in the expression of several induced markers, which can be used to ascertain the competence of T cells participating in the immune response. These include CD69, CD154 (CD40L), MHC class II, and CD25, which are expressed sequentially and can be assessed by flow cytometry.[12] In contrast to in vivo activation of T cells and subsequent expression of these

markers, in vitro assessment of T-cell function involves activation of T cells with nonspecific and polyclonal stimulants such as phorbol myristate acetate (PMA) or phytohemagglutinin (PHA), which results in expression of these markers in a kinetically regulated fashion.[12] The expression of CD40L on activated T cells, besides being useful as a global marker for T-cell activation, is used more specifically for the diagnosis of a primary immunodeficiency, X-linked hyper-IgM syndrome or CD40L deficiency (Chapter 34). CD40L on activated CD4 T cells interacts with CD40, expressed constitutively on B cells, and participates in isotype (class)-switching as well as providing costimulatory help to T cells. The expression of CD40L on activated CD4 T cells can easily be ascertained in the laboratory using an in vitro T-cell stimulation protocol. In this assay, CD69 is used as a control establishing early T-cell activation. The majority of patients (~80%) with mutations in *CD40LG* have absent protein expression on activated CD4 T cells; however, ~20% of mutations may remain permissive for protein expression, but with aberrant function. These patients can be identified by incorporating an additional component in the assay using a soluble form of the receptor CD40-muIg to assess binding of the ligand. The flow cytometric assay for CD40L expression and function offers a rapid diagnostic test for XL-hyper-IgM syndrome.[12]

ASSESSMENT OF CELLULAR VIABILITY IN LYMPHOCYTES

The flow cytometry–based assays also allow determination of viable cells in the sample, which is particularly important in the interpretation of results after peripheral blood mononuclear cell (PBMC) isolation from anticoagulated (heparinized) whole blood. The use of annexin V in a flow cytometry assay enables the visualization of apoptotic cells. In addition to visualizing apoptotic cells, dead cells can be assessed by simultaneously using 7-amino-actinomycin-D (7-AAD) (Chapter 93), which is a membrane-impermeable dye excluded from viable cells. When internalized into dying or dead cells, it binds to double-stranded DNA by intercalating between base pairs in guanine (G)-cytosine (C)-rich regions. These two dyes can be combined to provide information on the proportion of viable cells in the starting cell mixture for proliferation assays.

Measurement of T-Cell Competence Via Proliferation

Mitogens are very potent stimulators of T-cell activation and induce polyclonal T-cell proliferation. It has been suggested that mitogens can induce T-cell proliferative responses even if the lymphocytes are incapable of responding adequately to antigenic (physiological) stimuli. Therefore, abnormal T-cell responses to mitogens are considered a diagnostically less sensitive but more specific test of aberrant T-cell function. Lectin mitogens have been shown to bind to the TCR, thereby activating quiescent T cells. Mitogenic stimulation induces increased intracellular calcium (Ca^{2+}) in T cells, which is essential for T-cell proliferation. Whereas PHA is a strong T-cell mitogen (Fig. 94.2), pokeweed mitogen (PWM) is a weak T-cell mitogen that also induces B-cell activation and proliferation with a different timeline for maximal stimulation. Mitogens such as PHA activate T cells by binding to cell membrane glycoproteins, including the TCR-CD3 complex. In addition, there are many mitogenic or comitogenic antibodies, including those directed against the CD3 coreceptor that can stimulate T-cell proliferation. Typically, anti-CD3 antibodies provide an initial activation signal and provide a variable proliferative response. Addition of a costimulatory antibody (anti-CD28) to anti-CD3 results in enhanced proliferation. An exogenous T-cell growth factor, such as IL-2, can also be used as an alternate to anti-CD28 costimulation, and in patients with suspected IL-2 receptor (IL-2R)–associated signaling defects, it may be more helpful from a diagnostic perspective than the use of anti-CD28. IL-2, an autocrine cytokine, has been demonstrated to be critical in T-cell proliferation and the regulation of T-cell growth through binding to a heterotrimeric receptor complex consisting of three chains—α, β, and γ (IL-2Rα, IL-2Rβ, and IL-2Rγ)—on the surface of T cells. Triggering of the TCR leads to the synthesis of IL-2 in certain T-cell subsets with induction of high-affinity IL-2Rs on antigen- or mitogen-activated T cells, the binding of IL-2 to the IL-2R ultimately leads to T-cell proliferation. The use of exogenous IL-2 in association with anti-CD3 allows discrimination of T cells that cannot proliferate to other mitogenic signals but can respond to a potent growth factor such as IL-2.

Antigens, including *candida* antigen (CA) and tetanus toxoid (TT), have been widely used to measure antigen-specific recall (anamnestic) T-cell responses when assessing cellular immunity. This may be more revealing about cellular immune compromise than assessing the response of lymphocytes to mitogens because the latter can induce T-cell proliferative responses even if those T cells are incapable of responding adequately to antigenic (physiological) stimuli. Therefore, abnormal T-cell responses to antigens are considered a diagnostically more sensitive, but less specific, test of aberrant T-cell function. Antigens used in recall assays measure the ability of T cells bearing specific TCRs to respond to antigenic peptides presented by APCs. The antigens used for assessment of the cellular immune response are selected to represent antigens, seen by a majority of the population either through natural exposure (CA) or because of vaccination (TT) using a longer in vitro culture period (6 to 7 days) before assessing the response.

In addition to measuring cellular proliferation as a readout for T-cell function, the production of cytokines by activated T cells is another important component for evaluating T-cell functional activity. T cells typically are not monofunctional, producing a single cytokine on activation; rather, they are multi- or polyfunctional, and the range of cytokines are produced sequentially rather than simultaneously. Although a population of stimulated T cells will have individual T cells

KEY CONCEPTS

T-Cell Activation and Function

- Cognate recognition of peptide major histocompatibility complex (MHC) on the antigen-presenting cells (APCs) by the T-cell receptor results in formation of the immunological synapse.
- Activated T cells express early activation markers, such as CD69 and CD40L. Other T-cell activation markers include CD25 and MHC class II (human leukocyte antigen–D related [HLA-DR]) molecules.
- T cells can be stimulated to proliferate using nonspecific stimulants such as plant lectins (mitogens) and cross-linking of the CD3 coreceptor, along with other costimulatory molecules (e.g., anti-CD28) or in the presence of exogenous interleukin-2 (IL-2).
- The magnitude of antigen-specific T-cell proliferation is dependent on the starting frequency of antigen-specific T cells.
- Flow cytometry–based assays of T-cell proliferation offer the advantages of high resolution, accounting for cellular dilution due to T-cell lymphopenia and single-cell analysis.

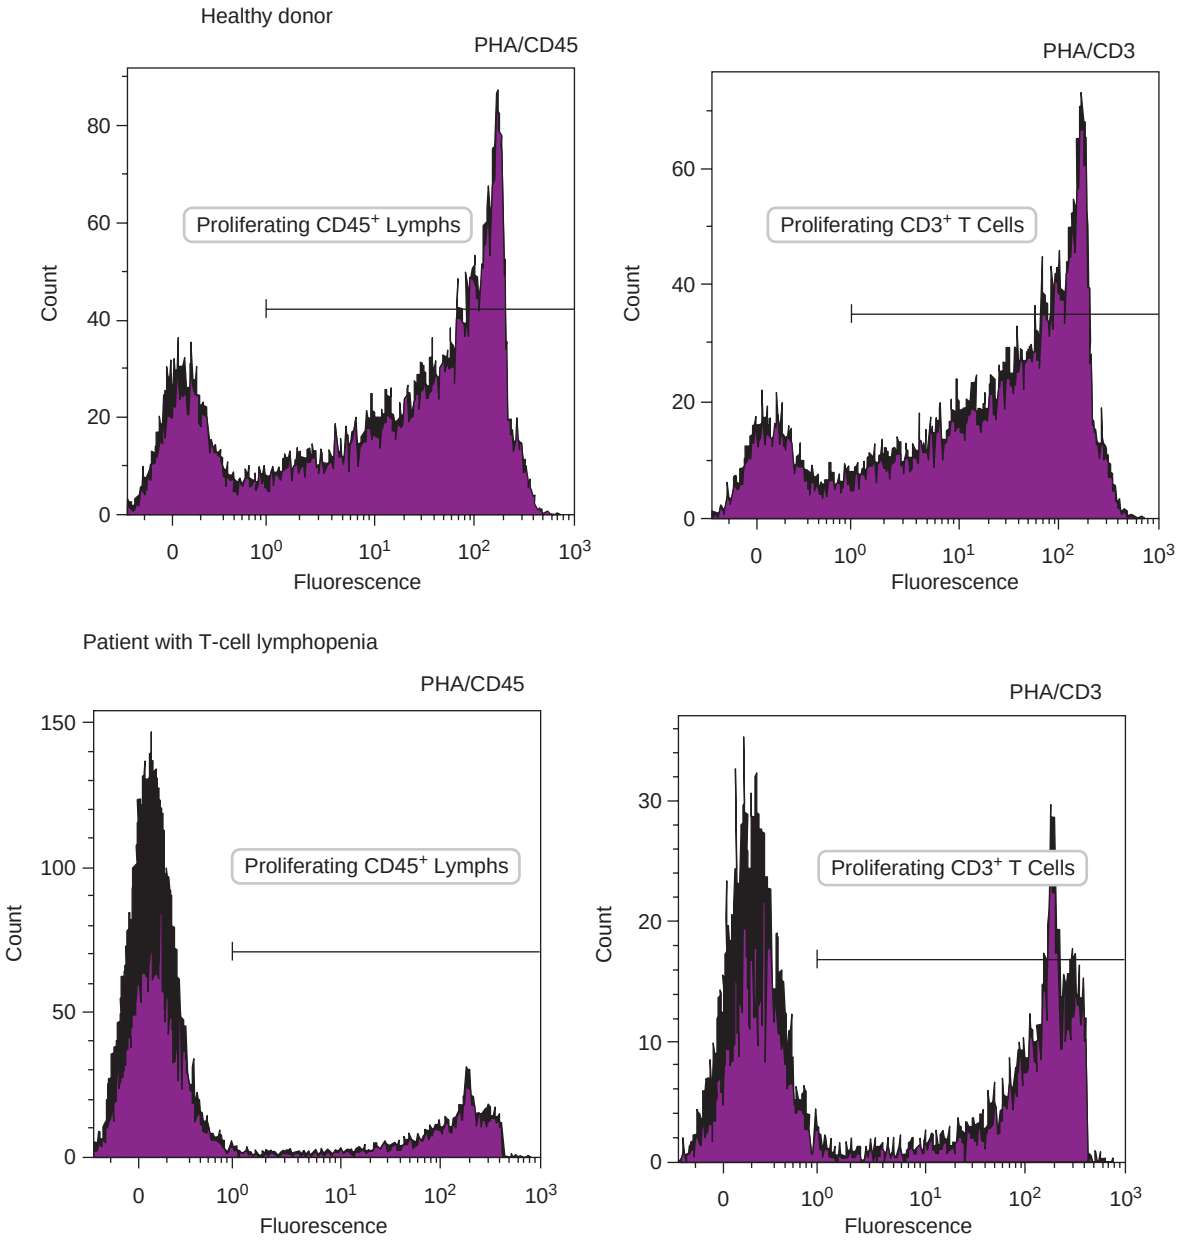

FIG. 94.2 T-Cell Proliferation to Mitogenic Stimulants. T cells can respond polyclonally to in vitro stimulation with various mitogens. T-cell proliferation assessment by flow cytometry allows analysis in total lymphocytes (*CD45*$^+$) and T cells (*CD3*$^+$). The *top panel* demonstrates T-cell proliferation to phytohemagglutinin (*PHA*) in both cell subsets. In patients with T-cell lymphopenia, where cellular dilution may be a concern, single-cell analysis by flow cytometry allows discrimination of functional versus nonfunctional T cells. In the *lower panel*, a patient with T-cell lymphopenia has abnormal proliferation when total lymphocytes are assessed; however, the response is normal when the T-cell compartment is specifically evaluated. Therefore, this patient, who would have been classified as abnormal based only on the CD45$^+$ lymphocyte response, can be reclassified as having normal T-cell proliferation based on the CD3$^+$ T-cell response, but with significant T-cell lymphopenia.

producing different cytokines in a temporally regulated manner. These cytokines can be measured by intracellular flow cytometry after T-cell activation with mitogens, in both CD4 and CD8 T-cell subsets, or in the culture supernatant of activated cells. Typically, the cytokines measured in in vitro stimulation assays include IL-2, interferon (IFN)-γ, IL-4, IL-5, IL-6, IL-17, and tumor necrosis factor (TNF)-α.

The commonly used method for assessing T-cell proliferation for decades involved the measurement of ^{3}H-thymidine (^{3}H-T) incorporated into the DNA of proliferating cells. The results are expressed as either counts per minute (cpm) or disintegrations per minute (dpm) of both activated and nonactivated cells (background) cultured for a fixed period of time, usually 72 hours for mitogens. A reference range based on proliferation results from a group of control subjects should be provided along with the patients' results (both background and post-stimulation results). Although this method remains widely employed, several disadvantages exist, including but not limited to the use of radioactive material (^{3}H-T); its inability to discriminate responder cell subsets or to account for cellular

dilution, which is particularly relevant in the context of T-cell lymphopenia; and the lack of information on the contribution of cell death after stimulation and its impact on the final result. To overcome the intrinsic shortcomings of the ^{3}H-T method, newer flow cytometry assays are currently being used in the clinical diagnostic setting and are gaining popularity because of the additional information they provide.

The flow cytometric methods for measuring cell proliferation include the use of fluorescent dyes to identify proliferating cells. One of the more commonly used dyes, carboxyfluorescein diacetate succinimidyl ester (CFSE), must be carefully used when measuring lymphocyte proliferation in vitro since it can be toxic to cells and nonoptimal labeling conditions can influence the measurement of cell proliferation and interpretation of results. CFSE is a fluorescent cell-membrane permeable dye similar in physical properties to the commonly used fluorochrome, fluorescein isothiocyanate (FITC). During cell proliferation, the intensity of staining in daughter cells is half that of parent cells, allowing visualization of the number of rounds of cell divisions associated with the successive decrease in fluorescence. The disadvantages to using CFSE in the clinical laboratory are its photo-instability, limitation in the number of cell divisions being identified (≤7 cell divisions), and interpretation that requires measuring a loss of signal rather than a gain of signal. In addition, as noted above, CFSE at concentrations of 37 nM to 10 μM can be toxic to cells, resulting in increased cell death. Furthermore, it can modulate the expression of activation markers, resulting in a decrease in CD69, human leukocyte antigen–D related (HLA-DR), and CD25 expression. Finally, it has been reported that there is an increase in the number of false-positive results with CFSE, making it suboptimal for measuring lymphocyte proliferation in patients with severe cellular immunodeficiencies. Alternatives to CFSE include related compounds, such as CellTrace Violet (CTV) and Cell Proliferation Dye eFluor 670 (CPD), which have different excitation and emission spectra compared with CFSE. These dyes also can be used for tracking lymphocyte proliferation status in vivo, in animal models, permitting measurement of up to 11 cell divisions.[1]

Another alternative to tritiated thymidine is the use of a thymidine analogue 5-ethynyl-2′-deoxyuridine (EdU), which can combine with a fluorescent azide in a copper-catalyzed cycloaddition reaction (referred to as "Click" chemistry) and permits flow cytometric evaluation of lymphocyte proliferative responses by assessing its incorporation into cellular DNA. EdU labeling is a fast and sensitive method for measuring cell proliferation and facilitates the identification of dividing cells. It is relatively more photostable than CFSE and is added to cells after completion of the stimulation period with the measurement being comparable to the thymidine method in regards to a gain of signal as the endpoint. The EdU assay has not shown the limitations of the CFSE method in the clinical laboratory and has been used to evaluate lymphocyte proliferation in a spectrum of patients, including those with severe combined immune deficiency (SCID). In fact, this assay has been particularly useful in discriminating between functional T cells and nonfunctional T cells in the context of severe T-cell lymphopenia, which cannot be achieved with the standard thymidine assay. All the proliferation data shown in this chapter utilize this EdU-based measurement of T-cell proliferation, and results are typically provided for both CD45 bright positive (total lymphocytes) and CD3 T cells, with the former being more representative of the data generated with the standard thymidine assay.* In recent years, there has been an explosion of a variety of kits meant to evaluate T-cell activation and proliferation. Each of these has pros and cons, and it is beyond the scope of this chapter to delve into the details of these kits. Very recently, an alternative flow cytometric method to assess T-cell proliferation was described, which uses STAT5A phosphorylation as the read-out for this specific cellular function.[13]

MEASUREMENT OF CELL-MEDIATED CYTOTOXICITY

CD8 T cells are considered the representative cytotoxic T-cell in the immune system, and cellular cytotoxicity is a mechanism to eliminate cells infected with intracellular pathogens, allogeneic cells, or tumor cells. CD8 T cells, like CD4 T cells, recognize antigen via the TCR and kill target cells via cytotoxic protein granule exocytosis and/or cytokine production. Over the past few decades, the cytotoxic potential of CD4 T cells has been described, particularly in viral infections. Although cytotoxic CD4 T cells are rare in the circulation of healthy individuals (<2%), they can account for substantial proportions of total CD4 T cells in certain viral infections, including but not limited to human immunodeficiency virus (HIV).

KEY CONCEPTS

Cellular Cytotoxicity

- CD8 T cells and natural killer (NK) cells are involved in the killing of cellular targets and contain intracellular granules with cytotoxic proteins, such as perforin and granzymes.
- Cytotoxic CD4 T cells are a subset of memory T cells with cytolytic potential and are usually observed in circulation in the context of chronic viral infections, e.g., cytomegalovirus (CMV), human immunodeficiency virus (HIV).
- Tetramer-based assays have been used to quantify and delineate the function of antigen-specific CD8 T cells (also CD4 T cells).
- Cellular degranulation results in the expression of CD107a on the cell surface of CD8 T cells and NK cells and is often used as a surrogate of cytotoxic activity.
- NK cells recognize target cells that lack major histocompatibility complex (MHC) class I molecules, e.g., viral cells or tumor cells that have downregulated MHC class I.
- The majority of circulating mature NK cells are cytotoxic ($CD3^{-}CD16^{++}CD56^{+/-}$), while a minority are immature cytokine-producing ($CD3^{-}CD56^{++}$).
- Interleukin (IL)-2 augments NK cell-mediated cytotoxicity (lymphokine-activated killing) and induces interferon (IFN)- γ secretion by NK cells.
- Regulatory T cells control NK cell activation and cytotoxic function by limiting the availability of IL-2.

Cellular cytotoxic activity has been conventionally measured by release of chromium (^{51}Cr) from labeled target (T) cells cultured with various ratios of effector (E) cells (varied E:T ratio). Alternative assays have been developed, including flow cytometry and ELISPOT-based methods. More recently, a method of assessing human CD8 T-cell cytotoxicity has been described

in which both the effector and target cells are primary cells (in contrast to using cell lines as target cells).[14] In this particular assay, autologous B cells isolated from PBMC are used as target cells and cocultured with antigen-specific CD8 effector cells. The killing of the fluorescently labeled target B cells (see NK cell section) is used to estimate cytotoxic activity. Antigen-specific effector cells are quantified in the total CD8 T-cell pool using MHC-peptide tetramers.[14]

A tetramer-based approach to quantifying and measuring the function of cytomegalovirus (CMV)-specific CD8 T cells has been available in the clinical diagnostic immunology laboratory for over a decade (Fig. 94.3). It has shown to be predictive in solid organ transplant patients, using an approach that includes both quantification of CMV-specific CD8 T cells along with function (CD107a expression and IFNγ production).[15] However, the limitation of the tetramer approach in the clinical diagnostic setting is that it is constrained by the number of HLA-peptide tetramer (multimer) combinations that are available for use with a particular antigen (e.g., CMV, Epstein-Barr virus [EBV]). It also requires a priori knowledge of the patient's HLA genotype, and very often it does not incorporate a comprehensive assessment of the CD8 and CD4 cytotoxic T-cell response. Although some laboratories use only a quantitative approach to determine immune competence to pathogens, such as CMV with the tetramer assay, more comprehensive assays are available that also provide a functional assessment of these antigen-specific CD8 T cells (see Fig. 94.3).

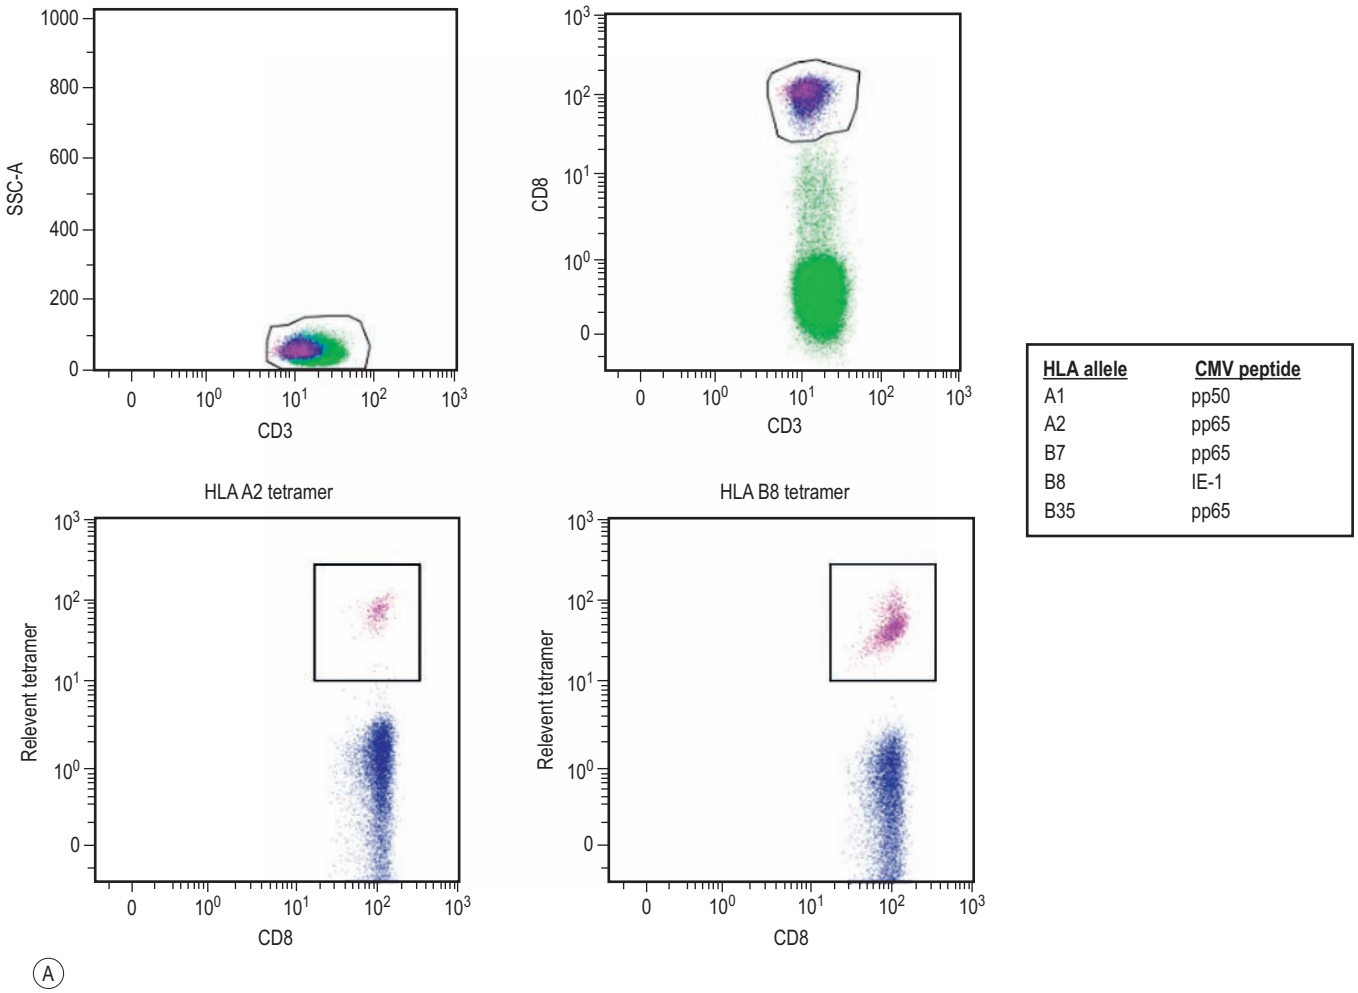

FIG. 94.3 Quantitation of Antigen-Specific CD8 T Cells and Functional Evaluation Using Major Histocompatibility Complex (MHC) Class I Tetramers. The tetramer (multimer) technology has been useful for accurate quantitation of antigen-specific CD8 (or CD4 T cells, if MHC class II tetramers are used). The *top panels* show the identification of $CD3^+$ T cells from total lymphocytes and subsequent segregation into $CD3^+CD8^+$ T cells. In this assay, cytomegalovirus (*CMV*)-specific CD8 T cells are quantitated using five MHC class I tetramers (human leukocyte antigen [*HLA*] *A1, A2, B7, B8,* and *B35*), each recognizing a unique CMV peptide from three major CMV antigenic proteins (*pp50, pp65*, and *IE-1*) as listed in the *box*. Based on the HLA class I haplotype of the individual, one or more tetramers are used for stimulation. The bottom panels show an example of a patient with HLA A2-specific CMV-CD8 T cells and another patient with HLA B8-specific CMV-CD8 T cells. These CMV-specific CD8 T cells can be assessed for functional capacity by gating on the tetramer-positive CD8 T cells and then measuring degranulation (CD107a expression) and interferon-gamma (*IFN-γ*) production after in vitro stimulation with the specific CMV peptide (*lower panel*). The data are shown for CD107a expression and IFN-γ production in unstimulated CMV-CD8 T cells and peptide-stimulated CMV-CD8 T cells.

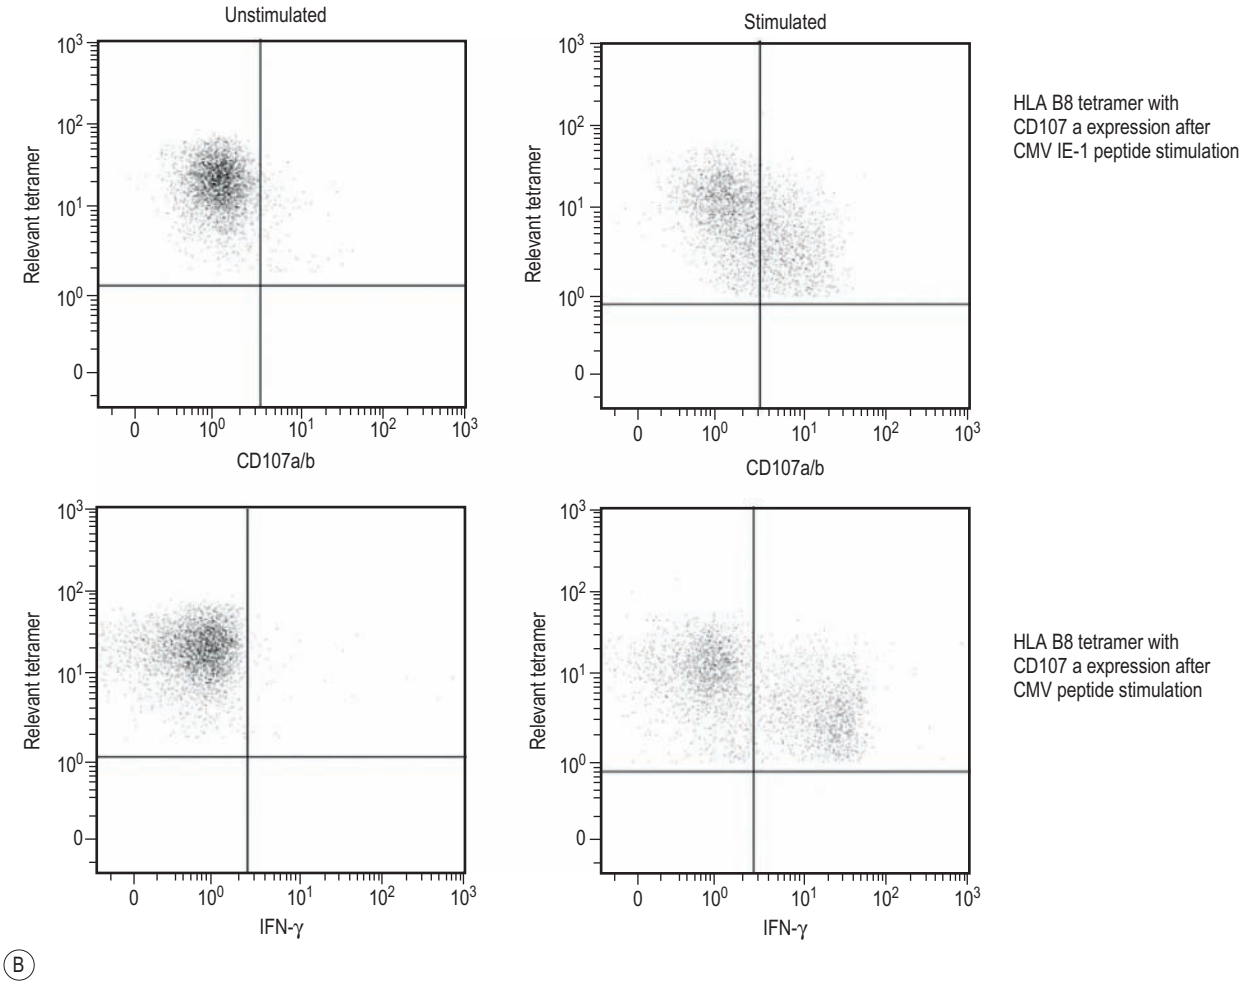

FIG. 94.3—cont'd.

An alternative approach is to evaluate for cytotoxic function, by assessing degranulation by evaluating for CD107a expression by the effector T cell (described in further detail in the NK cell function section) and/or evaluating IFN-γ production by activated cytotoxic CD8 T cells. As a positive control, CD8 T cells are polyclonally stimulated with PMA and ionomycin, and the same markers (CD107a expression and IFN-γ production) are measured. Approximately 10% to 60% of CD8 T cells in healthy adults are activated to express CD107a and to secrete IFN-γ under these conditions. An approach that avoids the use of tetramers involves the stimulation of patient-specific PBMC with overlapping peptide pools of the specific antigen and, subsequently, the evaluation of the CD8 and CD4 T cells that proliferate in response to antigenic stimulation. These T cells can also be assessed for cytotoxic potential by measuring intracellular perforin and granzyme expression as well as degranulation (CD107a expression) after stimulation.[12]

A CMV-specific assay has been developed that measures IFN-γ production in response to CD8 T-cell stimulation with a pool of MHC class I–restricted CMV peptides, the QuantiFERON-CMV (Cellestis Ltd., Melbourne, Australia).[16] This commercial assay is simpler to perform than the tetramer-based approach for quantification and functional analysis of antigen-specific CD8 T cells and does not require knowing the subjects' HLA type (Fig. 94.4). It has been applied in the context of risk prediction for CMV in organ transplant and allogeneic hematopoietic cell transplant (HCT) patients. However, this assay has theoretical limitations in that assessing the production of a single cytokine is unlikely to represent the breadth of the immune response to a complex specific antigen such as CMV.

Assessing Function of Exhausted T Cells

Previous sections have discussed the role of T-cell activation in the immune response to pathogens. An optimal immune response results in normal activation of T cells. But persistent antigenic stimulation alters the differentiation of memory T cells and can result in a state of T-cell "exhaustion" with failure of the immune response. The term "T-cell exhaustion" is broad and can have variable meanings. Nevertheless, it generally refers to effector T cells with impaired cytokine secretion and expression of molecules associated with inhibition of a response as well as expression of specific markers, such as PD-1. Exhausted T cells lose their ability to normally respond to antigenic stimulation via cytokine production and proliferation and are functionally distinct from anergic T cells. T-cell exhaustion often is represented in the context of chronic viral infection but has also been described in the setting of neoplastic disease. Exhausted T cells express a variety of cellular markers, including PD-1, CTLA4,

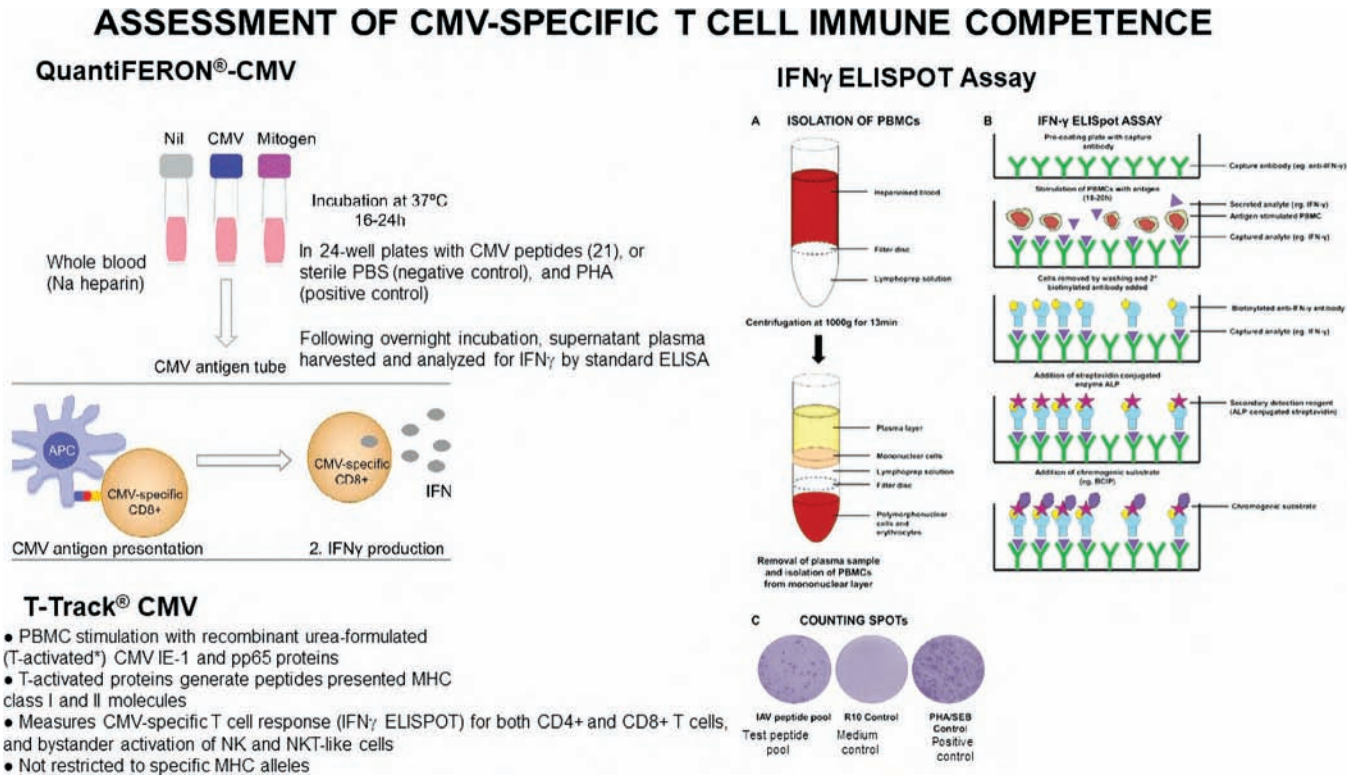

FIG. 94.4 Using Interferon-γ Secretion After Cytomegalovirus-Specific Stimulation to Measure Antigen-specific CD8 T-Cell Response. The QuantiFERON assay for assessing cytomegalovirus (*CMV*)-specific CD8 T-cell function measures interferon-γ (*IFN-γ*) produced by CD8 T cells in response to stimulation to a pool of 21 CMV peptides. The T-track assay, on the other hand, utilizes a special preparation of 2 CMV proteins (IE-1 and pp65) and measures the T (CD8, and CD4) and NK cell response using an IFN-γ ELISPOT. IFN-γ secretion assays use peripheral blood mononuclear cells (*PBMCs*), which are stimulated by CMV (or other antigen) peptide pools, with unstimulated and positive (phytohemagglutinin [*PHA*]) controls, and the secreted cytokine is detected by specific capture antibodies, and revealed by a secondary labeled antibody using either a chromogenic substrate or counting spots created on a membrane (ELISPOT).

TIM-3, and LAG-3, among others, and the pattern of expression and number of receptors can reflect the degree of T-cell impairment. Several of these markers can be assessed on T cells by flow cytometry; however, it is important to recognize that expression of these inhibitory molecules does not always imply that healthy T cells expressing these are exhausted or aberrant in function. In fact, in healthy people, the presence of circulating PD-1^{+}CD8^{+} T cells may represent effector memory T cells rather than exhausted T cells. T-cell exhaustion can be assessed in vitro using fresh human PBMCs stimulated with a superantigen, such as staphylococcal enterotoxin B (SEB) for 72 hours. The culture supernatant is harvested for cytokine analysis, specifically IL-2 and IFN-γ. Following this stimulation, the cells are washed and re-suspended into fresh medium, in the presence or absence of various therapeutic molecules, and the T-cell activation response is assessed. There is maximal production of IFN-γ and IL-2 at 72 hours post-stimulation with varying concentrations of SEB. However, the amount of cytokines produced is decreased 24 and 48 hours after withdrawal of the SEB. This assay can be used to assess the effect of therapeutic agents in vitro to reverse the state of T-cell exhaustion. This assay is not available within the clinical diagnostic laboratory for this purpose. But many laboratories have the ability to assess the expression of inhibitory receptors on T-cell subsets by flow cytometry. However, the results of these assays need to be interpreted cautiously and in context of the reasons discussed above.

T-Cell ELISPOT for Measuring T-Cell Function Through Cytokine Production

Assessing T-cell function at a single-cell level can be achieved using the ELISPOT method. The previously described CMV QuantiFERON assay (see Fig. 94.4) has been used in pediatric HCT patients and was shown to be useful for identifying patients at high risk for developing CMV viremia.[17] A different version of this ELISPOT assay, called T-Track assay[18,19] uses proprietary CMV antigens, which are urea-formulated recombinant CMV proteins, IE-1, and pp65 (called T-activated antigens), for use in an IFN-γ ELISPOT assay (see Fig. 94.4). IFN-γ ELISPOT assays have also been validated and standardized for assessing alloreactive responses in renal allograft recipients to ascertain allograft rejection.[20] While cytokine production by T cells can also be assessed by intracellular flow cytometry, the sensitivity of the ELISPOT assay, particularly at a single-cell level, appears to be higher. However, this approach requires careful standardization and validation as well as the use of appropriate tools to read and interpret the data.

NATURAL KILLER CELL ACTIVATION AND FUNCTION

Unlike T and B cells of the adaptive immune system, innate NK cells do not have antigen-specific recognition and killing

of target cells. NK cells participate directly in effector functions via cytotoxicity and production of cytokines (e.g., IFN-γ) upon activation. Proinflammatory cytokines such as IL-12, IL-15, and IL-18 trigger NK cell proliferation as well as cytotoxicity and production of IFN-γ. The negative regulation of NK cells is controlled by receptors that recognize MHC class I molecules preventing NK cell–mediated cytotoxicity. In contrast, virally infected or tumor cells typically downregulate MHC class I, making them appropriate targets of NK cell–mediated cytotoxicity in the presence of relevant ligands expressed by the target cell. NK cells, like cytotoxic T cells, contain granules with cytotoxic proteins including perforin and granzymes, which are serine proteases that recognize different substrates.

NATURAL KILLER CELL CYTOTOXICITY

The majority of NK cells can be identified by a lack of CD3 on the cell surface in conjunction with the expression of CD56 (NCAM [neural cell adhesion molecule]) and CD16 (FcγRIII). NK cells can be subdivided into two major subsets based on their relative expression of CD56 and CD16: $CD16^{+++(bright)}$ $CD56^{+/-(dim)}$ NK cells, referred to as cytotoxic (mature) NK cells, and $CD56^{+++(bright)}$ CD16 or $CD16^{+/-}$ NK cells, known as regulatory or cytokine-producing (immature) NK cells. The majority (~90%) of circulating human NK cells belong to the cytotoxic category, while a minority (10%) represent cytokine-producing NK cells. Cytotoxicity can be subdivided into natural or spontaneous cytotoxicity directed largely toward virally infected cells or tumor cells, in the absence of prior stimulation or immunization, and antibody-dependent cellular cytotoxicity (ADCC) directed against antibody-coated target cells. NK cells go through a process of education or "licensing" whereby NK cells that express inhibitory receptors to self-MHC class I molecules are called licensed, which means they are more functionally responsive to stimulation, whereas unlicensed NK cells lack receptors for self-MHC class I and are hyporesponsive (Fig. 94.5).

NK cell function is measured in the clinical laboratory by assessment of spontaneous (natural) NK cell cytotoxicity using an MHC class I–deficient myelogenous leukemia cell line, K562. Traditional methods for measuring NK cell cytotoxicity are similar to those used for assessing cytotoxic T-cell (CTL) function based on varying effector:target cell ratios in a 4- to 16-hour ^{51}Cr-release assay compared with the no-lysis and 100% lysis conditions as described for the T-cell cytotoxicity assay. However, there is interest in the use of flow cytometry to measure spontaneous or IL-2–activated (lymphokine-activated killer [LAK]) NK cell cytotoxicity in the clinical laboratory to avoid using radionuclides (Figs. 94.6A and Fig. 94.6B). One flow cytometric assay employed in the clinical laboratory involves the use of fluorescently labeled (CellTracker dyes) target cells (K562) incubated with effector cells (donor or patient PBMC) in the absence (spontaneous) or presence of IL-2 (LAK). Following co-incubation, the lysis of target cells is measured by using 7-AAD to assess for cell death (see Figs. 94.6A and Fig. 94.6B). IL-2 enhances cytotoxic function with increased lytic potential against a broad range of target cells. IL-2 has also been shown to induce IFN-γ secretion by NK cells with upregulation of activation markers, such as CD25 and CD69. Treg cells control NK cell activation and cytotoxic function by limiting access to IL-2. Other methods for measuring NK cell cytotoxic function that are primarily used in the research setting include the use of

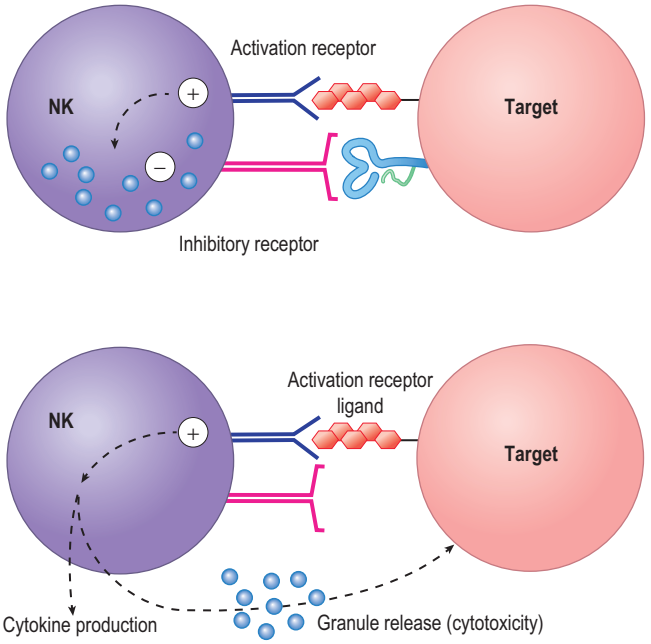

FIG. 94.5 Natural Killer Cell Recognition of Target for Cytotoxic Function. Natural killer (*NK*) cells have inhibitory receptors for self-major histocompatibility complex (MHC) class I. Therefore, NK cells do not kill target cells expressing MHC class I *(upper panel)*. However, when MHC class I expression is downregulated (viral infections, tumors), the target cell is primed for NK cell cytotoxicity, which is mediated by granule exocytosis and release of cytotoxic proteins, including perforin and granzymes *(lower panel)*. (Adapted from figure in French AR, Yokoyama WM. Natural killer cells and autoimmunity. *Arthritis Res Ther.* 2004; 6:8–14.)

image cytometry, microchip screening, and flow-based assays using other dyes, such as calcein AM.

NK cell cytotoxicity assays exhibit significant biological and analytical variability, and, therefore, are of limited utility, especially on shipped samples. Other parameters are widely used as surrogates of cytotoxicity, including flow cytometric measurement of granule exocytosis/degranulation. The membrane of cytotoxic granules in both NK cells and CD8 T cells is composed of several proteins, including CD107a (lysosomal-associated membrane protein 1 [LAMP-1]). On stimulation of NK cells and CD8 cytotoxic T cells, CD107a is upregulated and expressed on the cell surface concomitantly with cytokine secretion and target cell lysis; therefore this study has been frequently used to extrapolate the magnitude of cytotoxic activity. Degranulation (CD107a expression) assays have gained traction in the assessment of familial/primary hemophagocytic lymphohistiocytosis (FHL).[21] The exception is in patients with mutations in the gene encoding perforin (*PRF1;* FHL type 2) where degranulation (CD107a expression) of cytotoxic cells is normal while cytotoxicity is abnormal. Therefore, while degranulation assays may provide relevant information, they cannot substitute for direct measurement of cytotoxicity in all settings.

NK cells also mediate the killing of target cells, via recognition of surface-bound immunoglobulin (IgG) through the Fcγ receptors (Ig-Fc receptors, specifically CD16 or FcγRIIIa), through ADCC. ADCC assays are particularly relevant in the assessment of antitumor responses, especially of new biological

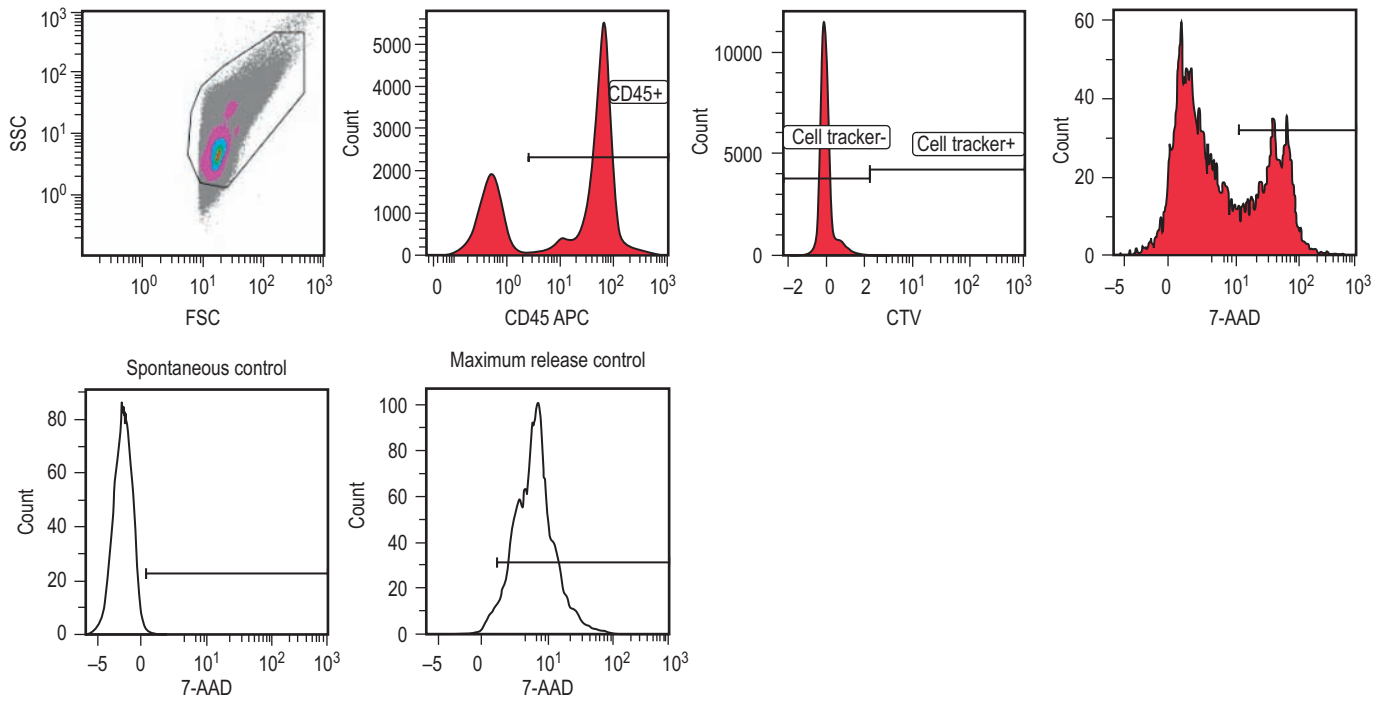

FIG. 94.6A Flow Cytometric Assessment of Natural Killer Cell Cytotoxic Function. The "gold standard" for measuring natural killer cell cytotoxicity (NKC) uses a radioactive label for target cells. In the flow-based assay, target cells (K562, a major histocompatibility complex [MHC] class I–negative erythroleukemia cell line derived from a patient with chronic myelogenous leukemia [CML] in blast crisis) are labeled with a fluorescent marker, CellTracker (*CTV*). Peripheral blood mononuclear cells (PBMC) from healthy controls or patients are cocultured with labeled target cells, and the two cell populations are identified by forward scatter (*FSC*) and side scatter (*SSC*) parameters. Afterward, $CD45^+$ lymphocytes are identified because NK cells (effector cells) are within the lymphocyte subset. CTV^+ and CTV^- cells are separated; CTV^+ cells that are also 7-amino-actinomycin D (*7-AAD*)$^+$ are identified as killed target cells, and their frequency is estimated. Negative control for spontaneous cytotoxicity is achieved by incubation of labeled target cells without effector cells added (called spontaneous control). Positive control for maximal cytotoxicity is achieved by incubating labeled target cells for the same duration but using a permeabilization/fixation method to obtain maximal cell death and fluorescent-positive cells (called maximum release control). This figure depicts spontaneous NK cell cytotoxicity with different concentrations of effector cells (PBMC; E) to a single concentration of target cells (T) starting at 30:1. The data are expressed as delta (Δ)% cytotoxicity after the spontaneous control signal is subtracted from the E:T signal for each concentration.

immunomodulatory agents, as well as of the function of alloantibodies in allograft rejection.

EVALUATION OF REGULATORY T-CELL FUNCTION

Regulatory T cells ($FOXP3^+$Treg) have been well described over the past several years as a distinct subset of T cells that are both developmentally and functionally unique as well as essential to maintaining immune homeostasis and self-tolerance. The major subpopulations of Treg cells include natural Treg (nTreg) cells that are produced in the thymus and induced Treg (iTreg) cells that are generated in the periphery from conventional $FOXP3^-CD4^+$ T cells. The dysfunction of Treg cells results in severe autoimmunity, with IPEX serving as the classic prototype (Chapter 34). Besides their role in controlling the development of autoimmunity, lack of Treg cells or abnormal Treg function has been implicated in the etiopathogenesis of graft-versus-host disease (GvHD) and allograft rejection, while its presence and normal function have been shown to promote allograft tolerance in solid-organ transplantation.

KEY CONCEPTS

Regulatory T Cells and B Cells

- Regulatory T cells (Treg) and B cells (Breg) are distinct subsets of cells with immune regulatory potential and importance in maintaining immune homeostasis and self-tolerance, preventing autoimmunity, and limiting inflammatory damage.
- FOXP3 is a transcription factor and a marker for natural regulatory T cells; while there are no specific cellular markers that define Breg, the production of interleukin (IL)-10 is considered a hallmark.
- Both Treg and Breg have been shown to play important roles in controlling autoimmunity, and graft-versus-host disease (GvHD) as well as in mediating transplant tolerance.
- Treg function is measured in vitro through different types of suppression assays, while Breg are characterized by their ability to produce IL-10 when stimulated via Toll-like receptor (TLR9)/B-cell receptor (BCR) or CD40L cross-linking.
- Natural, thymic-derived Treg are $CD4^+25^+FOXP3^+$ while Breg are $CD19^+CD24^{hi}CD38^{hi}IL\text{-}10^+$.
- Treg can also be induced in the periphery from conventional T cells through cytokine signals (iTreg).

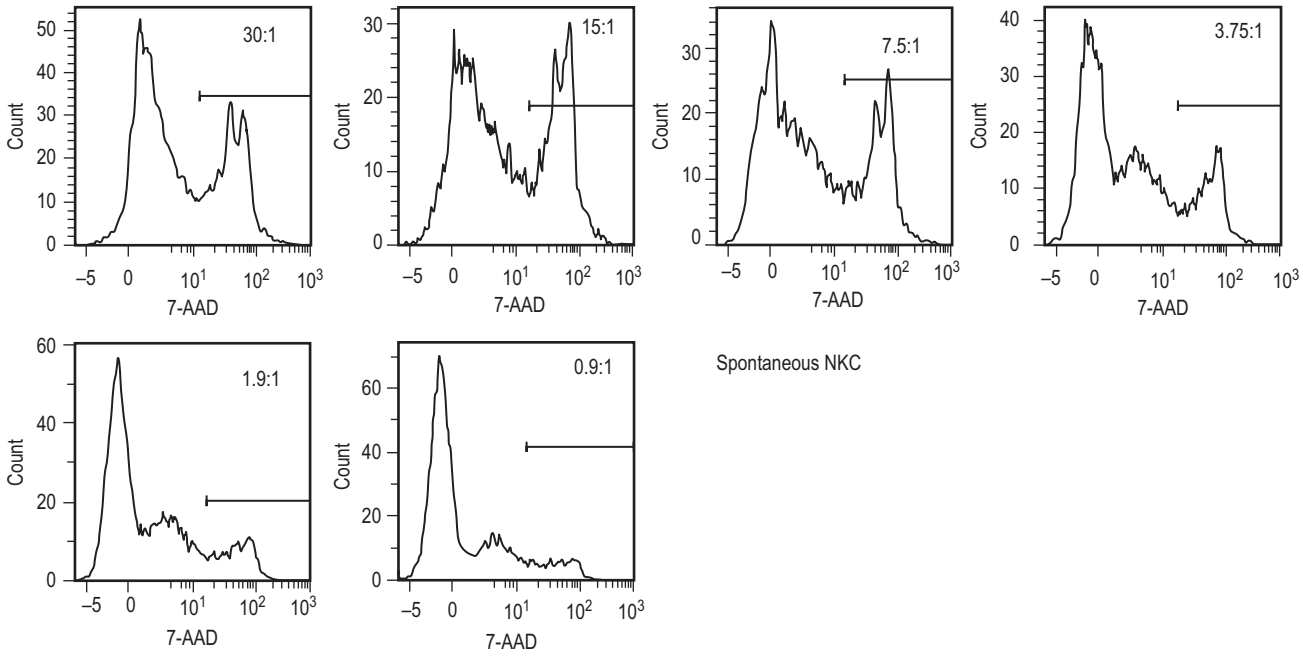

FIG. 94.6B Lymphokine-Activated Killing by Natural Killer Cells. This graph depicts IL-2-stimulated NK cell cytotoxicity (*NKC*) or lymphokine-assisted killing. The methodology is similar to what is described for Fig. 94.6A. The only difference is that a fixed concentration of IL-2 is used with each E:T ratio to activate NK cells and mediate cytotoxicity, and the mechanism of killing is different from that used in spontaneous NK cell cytotoxicity. IL-2 promotes NK cell killing to targets that are resistant to resting NK cell killing. IL-2 stimulation of NK cells results in activation of WAVE2 (WASp family verprolin-homologous 2), which allows F-actin reorganization independent of WASp (Wiskott-Aldrich syndrome protein), and associated NK cell function (Orange JS et al. IL-2 induces a WAVE2-dependent pathway for actin reorganization that enables WASp-independent human NK cell function. *J Clin Invest.* 2011;121(4):1535–1548). This is notably observed in patients with Wiskott-Aldrich syndrome (WAS) who demonstrate (IL-2-stimulated NK cell cytotoxicity but not spontaneous NK cell cytotoxicity). *7-AAD*, 7-Amino-actinomycin D.

Treg cell function is measured in vitro with Treg suppression assays, which utilize sorted $CD4^+CD25^+$ Treg cells in a coculture system with conventional effector T cells to assess suppression of proliferation. However, there are limitations to this approach, including the issue of whether the Treg suppression assays in vitro reflect the biological process in vivo. In addition, antigen-specific Treg suppression cannot be adequately assessed due to the technical difficulties in obtaining sufficient numbers of antigen-specific cells, so the use of a polyclonal activation model with bulk PBMC represents the standard to study Treg suppression. Rapid tests for Treg cell function have been described using short-term (7 to 20 hours) flow-based assays to measure suppression of T-cell activation marker expression (CD40L and CD69). These assays utilize effector T cells ($CD4^+25^-$) activated with anti-CD3/anti-CD28 beads with and without the addition of freshly isolated Treg cells or *ex vivo* expanded Treg cells. When implementing Treg suppression assays in the clinical diagnostic laboratory, a number of technical considerations can confound the interpretation of results, and these are well described by McMurchy et al.[22] In addition, it remains unclear whether standard in vitro Treg suppression assays can adequately account for the significant complexity of Treg subsets that may have different functional properties in various clinical contexts. Therefore the newer techniques of mass cytometry may be required to address the phenotypic diversity and to eventually be harnessed either to evolving applications or other technology to analyze the functional complexity of these populations.

ASSESSMENT OF SIGNALING AND DNA REPAIR PATHWAYS IN LYMPHOCYTES VIA PHOSPHOFLOW CYTOMETRY

A key aspect of studying lymphocyte responses is to assess signaling in appropriate lymphocyte subsets and its alteration in

KEY CONCEPTS

Assessment of DNA Repair Pathways by Phosphoflow

- DNA double-strand break (DSB) repair defects are relevant to VDJ recombination, isotype class switching, and lymphocyte maturation.
- Defects in this process can lead to immunodeficiency with susceptibility to infection and malignancy.
- Homologous recombination (HR), which is error-free, involves RAD50, RAD51, RAD52, and Mre11, while nonhomologous end-joining (NHEJ) is error-prone and utilizes Ku70/80, DNA-PKcs, Artemis, DNA Ligase IV, XRCC4, XLF/Cernunnos.
- ATM is a key regulator of cell-cycle checkpoints following irradiation-induced DSB and coordinates timing of phosphorylation of checkpoint proteins.
- Cell cycle analysis can help identify checkpoint defects and can be easily assessed by flow cytometry.
- Phosphorylation of H2AX (γH2AX) is a useful marker of DNA damage related to irradiation-induced DSB.
- However, several kinases phosphorylate H2AX, which can confound identification of specific defects; therefore assessing multiple proteins in the pathway allows identification of a broader group of DNA repair defects.

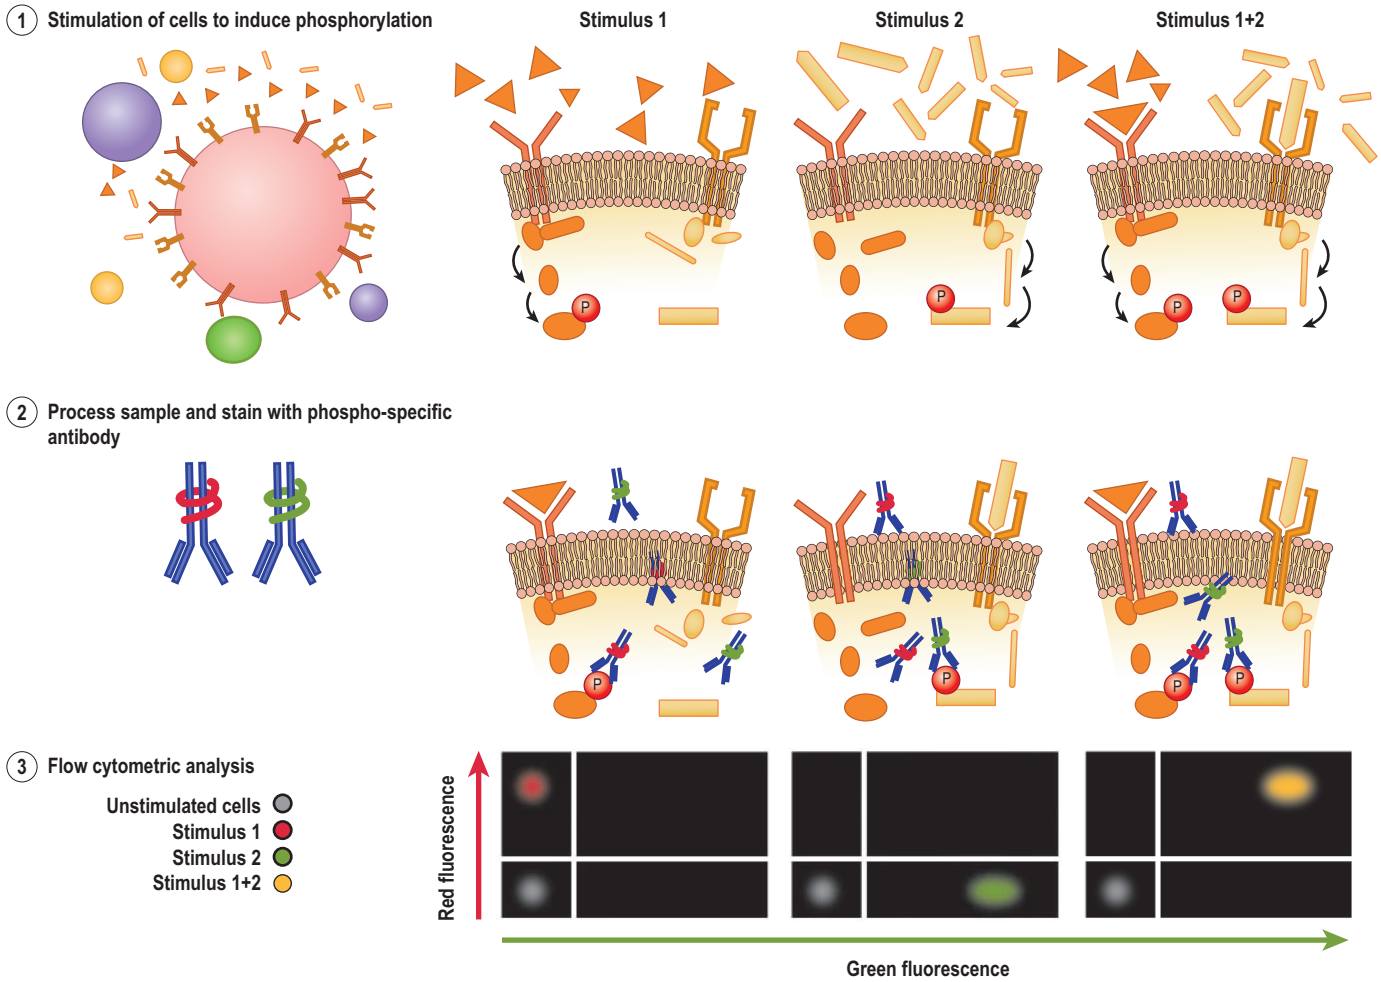

FIG. 94.7 Analysis of Phosphoproteins in Cells by Flow Cytometry. Cells activated by specific stimuli can be assessed for activation and induction of specific signaling pathways by measuring phosphoproteins. A single stimulus or multiple stimuli can be used to phosphorylate different proteins, and intracellular staining can be performed with phospho-specific antibodies, which is subsequently analyzed by multicolor flow cytometry. See text for detailed explanation. (Figure modified from Fig. 2 by Krutzik PO, et al. Analysis of protein phosphorylation and cellular signaling events by flow cytometry: techniques and clinical applications. *Clin Immunol* 2004; 110:206–2210.

pathological conditions. A versatile tool called phosphoflow is unique in its ability to allow the study of multiple intracellular signaling molecules in specific lymphocyte populations at a single-cell level. Phosphoflow assays for the signal transducer and activator of transcription (STAT) molecules (Fig. 94.7) have been well described and are discussed in Chapter 93. The use of phosphoflow assays to assess Bruton tyrosine kinase (BTK) phosphorylation in X-linked agammaglobulinemia (XLA) with leaky (hypomorphic) defects, as well as to assess radiosensitivity and the DNA repair pathway, will be covered briefly.

Mutations in *BTK* impair B-cell maturation and function, and patients with XLA can have either no peripheral B cells (null mutations) or reduced B cells (hypomorphic/leaky mutations), depending on the specific genetic defect (Chapter 33). Two regulatory tyrosine residues in BTK undergo rapid phosphorylation upon BCR cross-linking (Y551 in the SH1 domain and Y223 in the SH3 domain). In the flow assay, Y223 phosphorylation is measured after an anti-IgM antibody is used to cross-link the BCR (for 3 minutes) because Y551 phosphorylation could not be detected in the time interval the assay was performed. In addition to PBMC, Ramos cell line (a B-cell line derived from a patient with Burkitt lymphoma) is used as a control for B cells, while pervanadate (complex of vanadate with hydrogen peroxide), an irreversible protein tyrosine-phosphatase inhibitor, is used in this assay as a positive control (Fig. 94.8). In the Ramos cell line, it is possible to visualize the Y551 phosphorylation (see Fig. 94.8) with pervanadate treatment.

A number of genetic disorders, collectively classified as XCIND (x-ray [irradiation] sensitivity, cancer susceptibility, immunodeficiency, neurological involvement, and double-strand DNA breakage), cause impairment in cellular ability to repair DNA double-strand breaks (DSBs). These defects have a significant impact on the ability of cells to grow, differentiate, and function normally; they include ataxia-telangiectasia (AT) due to *ATM* gene mutations and radiosensitive severe combined immunodeficiencies (rs-SCIDs) due to mutations in the *DCLRE1C, LIG4, NHEJ1*, and *PRKDC* genes. These disorders make it very desirable to have an assay capable of rapidly assessing DNA repair in lymphocytes in response to radiation damage. A flow cytometry assay has been developed that is capable of measuring the function of several proteins in the DNA repair pathway after induction of DSBs via irradiation (Fig. 94.9A). Following

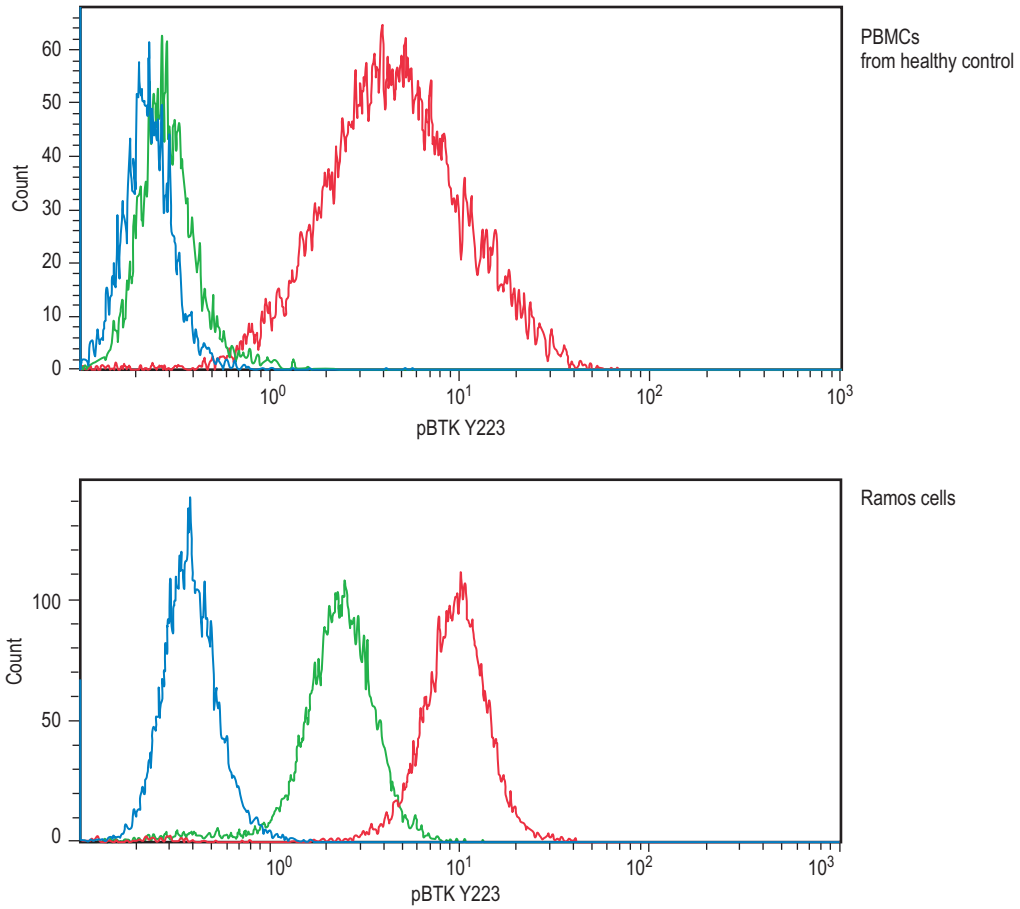

FIG. 94.8 Analysis of Bruton Tyrosine Kinase Phosphorylation in Peripheral Blood Mononuclear Cell and Ramos B-Cell Line. Bruton tyrosine kinase (*BTK*) phosphorylation can be assessed in B cells in X-linked agammaglobulinemia (XLA) patients with leaky defects who have some preserved B cells in the blood. B cells are stimulated with either anti-immunoglobulin M (IgM) (B-cell receptor [BCR] cross-linking; *green line*) or pervanadate (positive control; *red line*). The example shown here is for BTK phosphorylation at the Y223 residue in peripheral blood mononuclear cells (*PBMCs*) from a healthy donor *(top panel)* and a B-cell line, Ramos cells. The *blue line* represents the unstimulated control. In the bottom panel, BTK phosphorylation of the Y551 residue is shown for PBMCs from a healthy donor *(left)* and Ramos cells *(right)*. The phosphorylation of the Y551 residue cannot be visualized for anti-IgM stimulation, and therefore data are shown only for the positive control, pervanadate.

low-dose irradiation, the function of ATM and ATR (ATM-Rad3–related kinase) pathways are assessed by analyzing the autophosphorylation of ATM at serine 1981 (see Fig. 94.9A). This step is required for ATM activation and is followed by phosphorylation of downstream targets SMC1 and H2AX. H2AX is a histone that belongs to the H2A family and is a component of the histone octamer in nucleosomes. It is phosphorylated by both ATM and ATR and is the first step in the recruitment and localization of DNA repair proteins. In patients with AT, there is a complete absence of phosphorylation. The frequency (%) of lymphocyte subsets that phosphorylates H2AX (γH2AX) appears normal (Fig. 94.9B), as the phosphorylation by ATR and other kinases is intact; however, the magnitude of phosphorylation, as measured by the normalized median fluorescence intensity (MFI ratio), is substantially decreased (Fig. 94.9C). The kinetics of phosphorylation indicates that maximal phosphorylation occurs 1 hour after induction of DSB and that there is dephosphorylation by 24-hour post-irradiation (not shown) in healthy controls, but in AT patients, since there is a lack of ATM phosphorylation on induction of DNA DSBs, there is no kinetic regulation. This flow-based assay enables a rapid assessment of radiation sensitivity in various clinical contexts[23,24] as well as the ability to visualize the function of multiple proteins of the DNA repair pathway. It can also be used to characterize the DNA repair function of known and unknown genetic defects, and it can identify functional phenotypes in patients with atypical presentations that may be missed if only genetic information is used.

ASSESSMENT OF B-CELL FUNCTION

While T cells and NK cells form the foundation of the cellular immune response, B cells are the main driver of humoral immunity. B cells are multifaceted in their function; they produce antibodies via differentiation into plasma cells, they act as APC for T cells, and they secrete potent immunomodulatory cytokines while downregulating immune responses via IL-10 production. B cells can proliferate in response to polyclonal mitogenic stimuli such as PWM, albeit with a much weaker response than seen with T cells stimulated with PHA (see Fig. 94.2). The starting point for any evaluation of B-cell function involves measuring

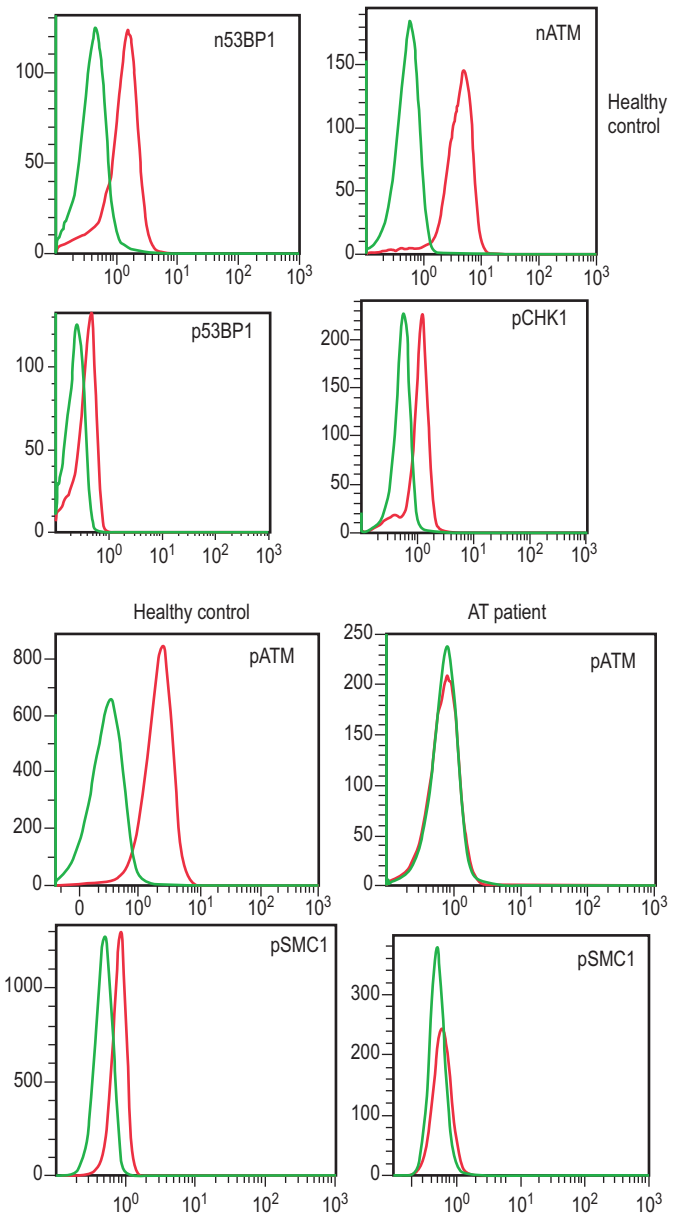

FIG. 94.9A Assessment of Radiosensitivity in Lymphocytes by Flow Cytometry. DNA repair pathway defects can be rapidly and sensitively analyzed by flow cytometry. The *left set of panels* shows ATM and SMC1 phosphorylation in T cells of a healthy control (similar data in B and natural killer (NK) cells; data not shown). The *right set of panels* shows absent phosphorylation of ATM and SMC1 in a patient with ataxia-telangiectasia (AT). The *green line* represents the unirradiated sample, and the *red line* represents the data post-irradiation with 2 Gy (low-dose) radiation. AT patients also show an inability of ATM to phosphorylate not only itself but also downstream targets, such as SMC1 in T cells. This is also true for other lymphocyte subsets (B cells and NK cells).

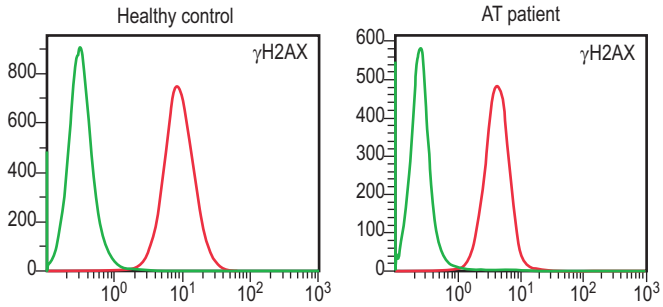

FIG. 94.9B Role of γH2AX in DNA Repair. Phosphorylated histone H2AX (*γH2AX*) is one of the earliest proteins to be mobilized in the presence of DNA double-strand breaks (DSBs), which in this case was caused by exposure to radiation. Once DNA DSBs are repaired, γH2AX is dephosphorylated and returns to baseline. In ataxia-telangiectasia (*AT*) patients, there does not appear to be any defect in phosphorylation of H2AX (γH2AX) and mobilization based on the proportion (%) of T, B, or NK cells expressing this protein.

serum immunoglobulin levels followed by in vivo antibody responses to vaccination with both protein (e.g., tetanus toxoid) and carbohydrate (e.g., Pneumovax 23) antigens.

A more recent area of focus in the laboratory evaluation of B cells has been the regulatory function of B cells, specifically concerning the subset classified as regulatory B (Breg) cells. B cells that secrete IL-10 have been described as Breg cells and are now recognized to be an important component of the host immune response that protects against autoimmunity and also limits inflammatory damage.[8] In humans, the phenotype of Breg cells has been described as $CD19^{+}CD27^{-}CD24^{hi}CD38^{hi}CD5^{+}CD1d^{hi}$. However, the ability to produce IL-10 appears to be the defining feature rather than any particular constellation of cell-surface markers. IL-10 exerts potent anti-inflammatory effects and enhances survival, proliferation, differentiation, and isotype class-switching of B cells. Both naïve and memory human B cells have the ability to produce IL-10 in response to stimulation via TLR9 and the BCR, but only ~15% of B cells can produce IL-10 in response to stimulation. In the laboratory, Breg cells can be assessed by isolating PBMC from blood and culturing with CpG-B (TLR9 stimulation) or CpG-B plus recombinant CD40L for 3 days in vitro, followed by the addition of PMA, ionomycin, and brefeldin A (BFA) for the last 5 hours of culture. Cells can then be harvested, washed, and stained with CD19 and IL-10 antibodies (the latter requires intracellular staining), and then analyzed with a flow cytometer. To assess the presence of Breg cells in blood without in vitro differentiation, blood or PBMC can be analyzed for $CD19^{+}CD24^{hi}CD38^{hi}$ B cells that are positive for intracellular IL-10 using a similar flow cytometry protocol, but the levels of these cells can be highly variable, and accuracy of detection and quantitation is likely to be dependent on the analytical method and clinical context.[2]

FIG. 94.9C Relevance of Median Fluorescence Intensity Assessment for DNA Repair Defect Measurements. Median fluorescence intensity (*MFI*) can provide additional valuable information on DNA repair defects and should be used along with frequency analysis. In ataxia-telangiectasia (AT) patients, although the proportion (%) of lymphocyte subsets expressing phosphorylated histone H2AX (*γH2AX*) appears normal, it is significantly decreased (by >50% in AT (*purple bar*) compared with healthy controls (*blue bar*). The MFI is represented as normalized to the unirradiated sample, as a ratio.

SUMMARY

In conclusion, lymphocyte responses in humans can be assessed using a variety of analytical tools as described in this chapter and applied to many clinical contexts, including but not limited to primary immune deficiencies, autoimmunity, transplantation, and immune dysregulation disorders. Most of these measurements use cells from blood and not from other lymphoid tissues, due to accessibility and ease of generating control reference ranges. This chapter is not an exhaustive treatise on all aspects of lymphocyte function and the immune response; nor does it cover all areas of normal and abnormal pathology in this context. Rather, it is meant to take the reader on a tour of the immune landscape and to provide salient highlights of the diversity and relevance of lymphocyte function.

ON THE HORIZON

- The advent of newer assays, including flow cytometry-based as described herein, have largely but not completely replaced traditional and often less sensitive radioactive or other cumbersome methods for assessing lymphocyte function.
- Standardization of flow cytometry assays can improve quality of data and reporting of results across laboratories performing similar tests (Optimized Multicolor Immunofluorescence Panels-OMIPs[25]; MiSet RFC Standards[26]; MIFlowCyt.[27]
- Microchip and advanced mass cytometry techniques, along with imaging cytometry, may offer newer, multiplex approaches to the assessment of lymphocyte subsets, individually and in cellular interactions.
- Functional and phenotypic data need to be ideally correlated with relevant genomic, transcriptomic, proteomic, metabolomic, epigenomic, and microbiome analyses for effective characterization of the complex interactions that govern the immune response in the normal and dysregulated state.
- This will necessitate further refinements of "big data" analysis, which can include but is not limited to, experimental studies in addition to computational modeling. Examples include antigen-specific characterization of specific B-cell and T-cell receptors in an individual as an extension of current "deep-sequencing" repertoire analysis or transcriptomic analysis during immune quiescence or activation on a multidimensional scale.

Assessment of Neutrophil Function

Debra Long Priel and Douglas B. Kuhns

Neutrophils, also known as polymorphonuclear neutrophils (PMNs; because of their multilobed nucleus) or granulocytes (because of the numerous granules found in the cytoplasm) are major contributors to innate host defense against invading microorganisms (particularly bacteria and fungi). Neutrophils are bone marrow–derived, terminally differentiated cells incapable of further cellular division but could be derived from progenitor populations in the spleen.[1] Early studies indicated that neutrophils have a short life span in the circulation ($t_{1/2}$ = 6–8 hours) and they survive an additional 1 to 2 days in surrounding tissue;[2] more recent findings reveal that neutrophils may survive 10 times longer in circulation, up to 5.4 days.[3]

Neutrophils, with a diameter of 10 to 15 μm and a volume of 346 μm^3, have a unique morphology. The nucleus of a mature neutrophil is segmented into 3 to 5 lobes with chromosomes randomly distributed among the lobes. Neutrophils also have an extensive array of storage granules prepackaged with specific proteins defined by the differentiation stage during maturation.[4] Granules are classified into four distinct groups: azurophilic, specific, gelatinase, and secretory granules. Azurophilic granules contain myeloperoxidase, lysozyme, antimicrobial peptides, defensins, proteases, and lysosomal acid hydrolases. The specific granules contain lactoferrin, lysozyme, and vitamin B_{12}–binding protein serving as storage pools for CD11b/CD18 and cytochrome b_{558} of the superoxide anion radical ($O_2^{\bullet}$)–generating enzyme, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, or NOX2. The gelatinase granules are a subset of the specific granules that have a high content of gelatinase. The secretory granules are highly mobilizable intracellular vesicles that contain alkaline phosphatase and other surface antigens.

The primary function of neutrophils is the ingestion (phagocytosis) and subsequent killing of microorganisms. This process requires the assembly of NOX2, the phagocyte oxidase (phox) enzyme complex consisting of at least four cytosolic components—$p47^{phox}$, $p67^{phox}$ [5], $p40^{phox}$ [6] and Rac2[7]—and two membrane components—$p22^{phox}$ and $gp91^{phox}$—that constitute cytochrome b_{558}.[8,9] This enzyme reduces molecular O_2 to $O_2^{\bullet}$ using NADPH generated by the oxidation of glucose through the pentose phosphate pathway; $O_2^{\bullet}$ either spontaneously or enzymatically converts to hydrogen peroxide (H_2O_2). In the presence of a metal, such as iron (Fe^{2+}), H_2O_2 and $O_2^{\bullet}$ can react to form the highly reactive hydroxyl radical, $OH^{\bullet}$. Alternatively, the azurophilic granule constituent (myeloperoxidase) catalyzes the formation of hypochlorous acid from H_2O_2 and chloride (Cl^-). The combined activities of these reactive O_2 species (ROS), antimicrobial peptides, and lysosomal hydrolases result in the ultimate destruction of the ingested microorganism. Excess production of ROS and release of lysosomal hydrolases into the extracellular milieu can lead to tissue damage and inflammation.

Neutrophils can also exude extracellular microbicidal activity through the formation of neutrophil extracellular traps (NETs), a matrix of DNA and granular enzymes that is purported to entrap bacteria and promote their killing.[10] During NET formation (NETosis), the nucleus loses its lobular shape, the nuclear membrane disintegrates into a chain of vesicles surrounding the DNA, and the cell loses granular integrity. The nuclear material fills most of the cell, mixing with the granular contents. The cells round up and DNA is forcibly extruded from the cell, conveying its granular enzymes trapped within the DNA matrix. Mitochondria in neutrophils (few in number with relatively little oxidative phosphorylation) play an important role in NETosis. Activation of neutrophils by immune complexes results in marked depolarization of the mitochondria, increased mitochondrial ROS production, and redistribution of the mitochondria to the periphery of the neutrophil where they contribute their mitochondrial DNA to the extruded NET.[11] A subset of neutrophils that co-sediment with mononuclear cells on a Ficoll-Paque discontinuous gradient cushion (low-density neutrophils) appears to be more prone to NET formation.[12] Many techniques measure NETosis, ranging from assays that measure extracellular elastase activity bound to DNA and releasable by DNase treatment to quantitative immunofluorescence assays that monitor the release of extracellular DNA.[13] Multicolor fluorescence-activated cell sorting assays have been described that monitor extracellular DNA, citrullinated histone h3, and myeloperoxidase (MPO) as surrogate markers for cells undergoing NETosis in vivo.[14] NETs are thought to play a role in enhancement of the inflammation seen in autoimmune diseases such as psoriasis, rheumatoid arthritis, and systemic lupus erythematosus. Recently, hypotheses reveal that unregulated NET formation contributes to the inflammatory and microvascular thrombotic complications in the lungs of patients with COVID-19.[15]

Neutrophils display a diverse array of cellular functions. Abnormalities in these functions can severely compromise host defense, leading to recurrent bacterial and fungal infections. To localize specific deficiencies of neutrophil function, assays have been developed to mimic these functions both in vivo and in vitro. Often, a preliminary screening of several neutrophil functions is performed to localize deficits and more vigorous testing of specific function is performed. Assays to assess neutrophil function should address several limitations—the number of cells required for the assay, the type of cell preparation needed (isolated neutrophils vs. whole blood), the overall incubation time for the assay, the complexity of the assay, and the rapidity of data collection. These issues become more critical if multiple functional assays are planned concurrently. Since neutrophils cannot be stored or frozen and maintain viability, neutrophils

from normal individuals are generally assayed in parallel to validate the results, doubling the number of assays to be performed. Additionally, isolation of neutrophils can take 1 to 2 hours, limiting the time available for functional assays. Fluorescent probes have increased the sensitivity of many assays and eliminated the need for radioactive probes. The use of multiwell microplates and microplate readers has reduced the number of cells required and has facilitated the collection of data. Experience in handling neutrophils and the time constraints of assays can limit the availability of this testing to laboratories that specialize in assessment of neutrophil function.

KEY CONCEPTS

Criteria to Assess Neutrophil Function

Because of (1) the time required to isolate neutrophils and (2) the shortened life span of neutrophils after isolation, assays of neutrophil function should have minimal complexity and enable rapid data collection.

ISOLATION OF NEUTROPHILS

Clinical Indications and Implications

Assays that avoid neutrophil isolation are preferred because of their artificial priming during isolation.[16] However, most assays require isolated neutrophils to eliminate any possible contributions of other leukocytes and blood components. In general, blood should be drawn using either citrate or heparin as anticoagulant and maintained at 20°C to 25°C in polypropylene containers. Most isolation protocols require 1 to 2 hours to obtain purified neutrophils.

Principles and Interpretation of Laboratory Assessment

Most neutrophil isolation protocols use differences in the cell density as the basis for the separation. The relative densities of blood cells are as follows: erythrocytes > neutrophils and eosinophils > monocytes, lymphocytes, and basophils > platelets. Ficoll-Paque is a solution of sodium diatrizoate (a dense, triiodinated compound), and Ficoll (a polysaccharide) with a density (1.077 g/cm^3) that falls between the density of neutrophils and that of the mononuclear cells. To isolate neutrophils,[17] whole blood is diluted with saline and underlaid with Ficoll-Paque solution. After centrifugation for 30 minutes at 500*g*, the less-dense monocytes, lymphocytes, basophils, and platelets remain at the upper interface of the Ficoll-Paque solution, whereas the denser erythrocytes and neutrophils pass through the solution and pellet at the bottom. The mononuclear cells are carefully harvested and the remaining Ficoll-Paque solution aspirated. The erythrocyte/neutrophil pellet is resuspended with saline and mixed with 3% dextran. Dextran promotes rouleaux formation of erythrocytes, causing them to sediment more rapidly than the neutrophils at 1*g*. The neutrophil-enriched supernatant fluid is harvested from the bulk of the (sedimented) erythrocytes. Contaminating erythrocytes are removed by a brief (30-second) hypotonic lysis with 0.2% saline. The isotonicity is quickly restored with an equal volume of 1.6% saline. A second hypotonic lysis removes many of the red blood cell (RBC) debris. In general, 1–2 × 10^6 neutrophils can be isolated per milliliter of whole blood from a normal subject with a normal white blood cell (WBC) count. All procedures are performed at room temperature, and the isolated cells are maintained in a balanced salt solution without divalent cations. The most common cell contaminants of the neutrophil preparation are eosinophils. Further purification of a standard neutrophil preparation with anti-CD16 magnetic immunobeads results in a neutrophil preparation that is generally ≥99% neutrophils. A second neutrophil isolation protocol that uses a discontinuous gradient of plasma/Percoll has often been used to minimize exposure of neutrophils to trace contamination by bacterial lipopolysaccharide (LPS) and reduce neutrophil priming.[18]

Isolated neutrophils are routinely frozen in aliquots of 5 × 10^6 cells/vial. For Western blot studies, neutrophils (1 × 10^6 cells/mL of buffer) are pretreated for 20 min with the cell permeant, irreversible serine protease inhibitor, diisopropylfluorophosphate (DFP, 1–5 mM). DFP is a volatile, potent neurotoxin that can irreversibly bind to and inactivate acetylcholinesterase and should be used with extreme caution. The cell suspension is then spun, and the supernatant fluid removed from the cell pellet before freezing. Waste solutions and disposable laboratory items should be flushed with sodium hydroxide to inactivate any residual DFP. These frozen neutrophil pellets, though not viable, can also be a source of DNA for genetic analyses.

KEY CONCEPTS

Estimated Yield From Whole Blood

In general, 1–2 × 10^6 neutrophils can be isolated per milliliter of whole blood from a normal subject with a normal white blood cell count.

HISTOCHEMICAL ANALYSIS OF NEUTROPHILS

Clinical Indications and Implications

Owing to their unique morphology, microscopic examination of neutrophil preparations with a differential stain (Wright stain) or a histochemical stain (Kaplow stain) to evaluate for myeloperoxidase, remains an essential element of neutrophil study, and can provide valuable insight into some genetic immunodeficiencies.

Principle and Interpretation of Laboratory Assessment

In Wright stain, the nucleus of a segmented neutrophil is normally multilobed (usually 3 to 5 lobes), and each lobe is connected by a narrow filament (Fig. 95.1, A). The nuclear chromatin is coarsely clumped with purple staining. Nucleoli are generally not present. In a band neutrophil, the nucleus is horseshoe shaped, with no indication of constriction into lobes. The pink-violet staining of the cytosol is associated with numerous, evenly distributed, specific granules; occasionally a dark-staining primary granule may be present. Kaplow stain[19] identifies the myeloperoxidase-containing primary granules as dark blue granules uniformly distributed throughout the cytosol (see Fig. 95.1, B). Neutrophils (and platelets) from patients with Chédiak-Higashi syndrome have giant primary granules that are pathognomonic for the disease (see Fig. 95.1, C).[20] Myeloperoxidase staining of Chédiak-Higashi neutrophils is very distinctive, with staining localized to the discrete giant primary granules (see Fig. 95.1, D). Neutrophils from a patient with specific granule deficiency exhibit primarily bilobed nuclei (pseudo–Pelger-Huët anomaly) with a paucity of specific granule staining in the cytosol (see Fig. 95.1, E).[21] Staining of the myeloperoxidase granules of neutrophils from a patient with specific granule

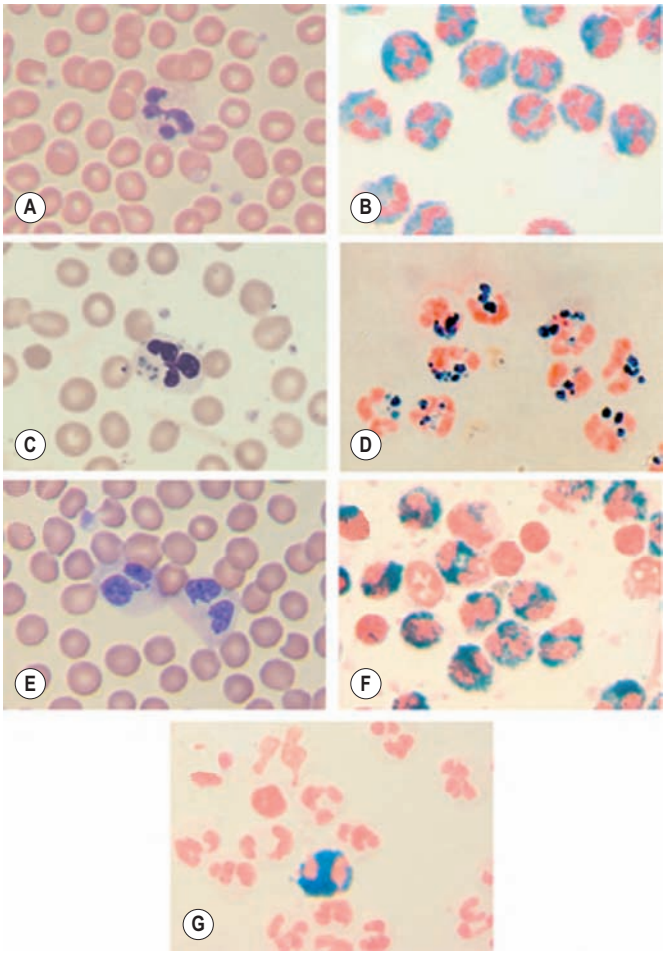

FIG. 95.1 Neutrophils stained with Wright stain and Kaplow stain. (A, C, and E) Blood smears stained with Wright stain. (B, D, F, and G) Neutrophil preparations stained with Kaplow stain. (A and B) Neutrophils from a normal individual. (C and D) Neutrophils from a patient with Chédiak-Higashi syndrome. (E and F) Neutrophils from a patient with specific granule deficiency. (G) Neutrophils from a patient with myeloperoxidase deficiency. The *blue positive-staining cell* is an eosinophil.

deficiency appears normal, since the defect is primarily associated with the granules (see Fig. 95.1, F). Neutrophils from a patient with myeloperoxidase deficiency fail to stain for myeloperoxidase.[22] However, eosinophil peroxidase stored in the eosinophilic granules continues to stain positive (see Fig. 95.1, G).

ANALYSIS OF GRANULE CONSTITUENTS

Clinical Indications and Implications

The granules of the neutrophils can be distinguished by their specific contents. Deficiency of only one granule constituent can be associated with a specific genetic defect, such as myeloperoxidase deficiency; alternatively, deficiency of multiple constituents of a certain granule can be associated with deficiency of an entire pool of granules, such as specific granule deficiency. Both enzymatic assays and immunoassays are available to determine the cellular content of many of these granule constituents.

Principles and Interpretation of Laboratory Assessment

The cellular content of neutrophils can be determined by solubilization of a neutrophil pellet with 0.2% Triton X-100, followed by sonication to disrupt the cells and generation of a homogeneous lysate. Analysis of the lysate using commercial immunoassays can identify deficiencies of certain granule contents. Diagnosis of myeloperoxidase deficiency can be confirmed by analysis of neutrophil lysates. Similarly, deficiency of both lactoferrin and neutrophil gelatinase (matrix metalloprotein-9 [MMP-9]) is indicative of specific granule deficiency,

NEUTROPHIL ADHERENCE

Clinical Indications and Implications

Adherence of neutrophils to the endothelium is a prerequisite step for migration of neutrophils into the tissues. Neutrophils isolated from patients with leukocyte adhesion defect-1 (LAD-1) who lack the common β_2-integrin subunit (CD18) exhibit abnormal adherence to the endothelium,[23] and therefore are not able to migrate efficiently into the surrounding tissues, often resulting in marked granulocytosis even in the absence of infection.[24] LAD-2 is a milder form of the disease, whereby patients exhibit a defect in fucose metabolism and glycoprotein biosynthesis.[25] Neutrophils from patients with LAD-2 exhibit abnormal expression of the glycoprotein, L-selectin, and fail to roll along the endothelium. However, they do exhibit normal β_2-integrin–mediated adherence.

Principles and Interpretation of Laboratory Assessment

Adherence of neutrophils can be assessed by measuring binding to plastic using a 96-well plate either uncoated or coated with fetal bovine serum or a specific extracellular matrix (ECM) protein (fibrinogen or fibronectin). Alternatively, endothelial cell monolayers harvested from human umbilical veins may serve as a more physiological substrate for the measurement of cell adhesion. Isolated neutrophils are preloaded with the cell permeant acetoxymethyl ester derivative of the fluorescent dye calcein (calcein-AM). Nonspecific esterases in the cytosol cleave the ester linkage, trapping the fluorescent probe in the cytosol. The labeled neutrophils are added to each well and incubated in the absence or presence of phorbol myristate acetate (PMA) to promote adherence through activation of the integrins. At the end of the incubation, the wells are washed three times to remove nonadherent cells. The fluorescence of each well is determined with a fluorescent microplate reader, and compared with the fluorescence of a control well with a fixed number of fluorescent cells. As shown in the left panel of Fig. 95.2, under controlled conditions, fewer than 10% of neutrophils adhere to plastic or to plastic coated with fetal bovine serum or fibrinogen. Treatment of normal neutrophils with PMA for 30 minutes results in the adherence of greater than 90% of the neutrophils under all conditions. This adherence assay is valuable in the diagnosis of patients with leukocyte adhesion deficiency. As shown in the right panel of Fig. 95.2, neutrophils isolated from patients with LAD-1 generally exhibit less than 5% adherence under controlled conditions and do not increase adherence after treatment with PMA.

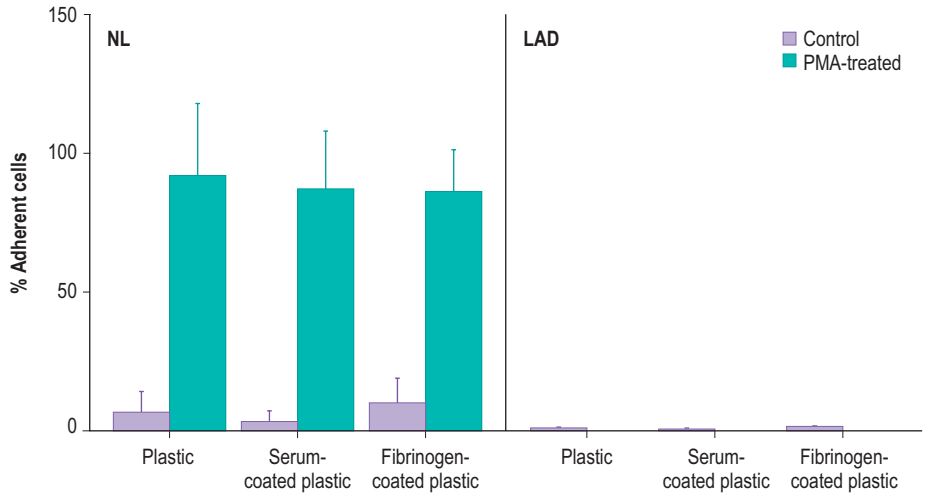

FIG. 95.2 Adherence of Neutrophils to Plastic: Normal versus Leukocyte Adhesion Deficiency. Neutrophils (1×10^7 cells/mL Hanks balanced salt solution [HBSS] without divalent cations) were preloaded with acetoxymethyl ester derivative of calcein (calcein-AM: 5 µg/mL) for 15 minutes at 37°C. The cells were washed twice and resuspended in HBSS/4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) with 2% bovine serum albumin (BSA) at a cell concentration of 2×10^6/mL. The wells of a 96-well plate were coated for 1 hour at 37°C with 32 µL of either buffer alone, fetal bovine serum, or fibrinogen (2.5 mg/mL). The wells were washed three times, and then cells were added to each well (160 µL/well, 3.2×10^5/well). After a 10-minute preincubation at 37°C, phorbol myristate acetate (*PMA*) (100 ng/mL) was added and the plate was incubated for 30 minutes at 37°C. The wells were then washed three times with HBSS/HEPES to remove nonadherent neutrophils. The percentage of adherent cells was determined by the ratio of the fluorescence of the well compared with the fluorescence of a known standard well. The panel (*NL*, normal) on the left represents the data (mean ± standard deviation [SD]) from 22 normal individuals, and the panel on the right represents the data from three patients with leukocyte adhesion deficiency (*LAD*).

NEUTROPHIL CHEMOTAXIS

Clinical Indications and Implications

Neutrophil migration is a prerequisite for neutrophil accumulation at sites of inflammation. Patients with leukocyte chemotactic defects usually show recurrent skin abscesses and occasional life-threatening invasive infections.

Principles and Interpretation of Laboratory Assessment

Chemotaxis in vitro is generally measured using a Boyden chamber. The Boyden chamber includes three components: a lower (chemoattractant) chamber, a nitrocellulose or polycarbonate filter layer, and an upper cell chamber. The lower compartment of the Boyden chamber is filled with a chemoattractant, such as formyl-methionyl-leucyl phenylalanine (fMLF; 10^{-8} M) or interleukin-8 (IL-8; 10^{-8} M). Alternatively, a rapid fluorescence-based measurement of neutrophil chemotaxis that uses a 96-well disposable chemotaxis chamber,[26] can be used and read in a fluorescence microplate reader. The lower chamber contains the chemoattractant and is separated from the cellular compartment by a filter. However, instead of a top chamber, the filter has a hydrophobic mask around each filter site that creates surface tension in the cell suspension, and aligns the suspension on the hydrophilic filter located directly above the chemoattractant chamber. Calcein-labeled neutrophils are placed on top of the filter. The chemotaxis chamber is incubated for up to 60 minutes at 37°C. Nonmigrating neutrophils atop the filter are rinsed off with buffer, and then the plate is read in a fluorescence microplate reader. The number of migrating neutrophils can be determined by comparing the calcein-based fluorescence to a standard well with a known number of fluorescent neutrophils. Less than 5×10^6 fluorescent neutrophils are needed to determine neutrophil chemotaxis using several doses of the chemoattractants (fMLF, IL-8, C5a, and leukotriene B_4). The advantages of this assay are high sensitivity, rapid acquisition and analysis of data, and reduced labor in loading the cell suspension. The 96-well format also allows for multiple comparisons to be made under identical conditions.

Imaging instrumentation is now available to monitor chemotaxis temporally. By acquiring digital images over time and analyzing those images using imaging software, the coordinates of individual cells can be determined. Changes in the distance (and velocity) directed toward the chemoattractant (directed migration) and orthogonal to the direction of the chemoattractant (random migration) can be determined. Tracks of multiple cells can be anchored at the origin and displayed graphically (see Fig. 95.3, top panels). Adding time as a dimension in the analysis of chemotaxis provides a mechanism to evaluate chemotactic and chemokinetic responses in neutrophils simultaneously, and to detect more subtle defects. Using buffer as a chemoattractant, the average cellular velocity vectors parallel and orthogonal to the direction of the chemoattractant are typically equivalent (see Fig. 95.3, bottom panel). When using a chemoattractant (e.g., fMLF, IL-8), typically there is marked increase in the average cellular velocity vector in the direction of the chemoattractant, but little change in the average cellular velocity vector orthogonal to the direction of the chemoattractant (see Fig. 95.3, bottom panel). Moreover, the ratio of the orthogonal vector to the vector in the direction of the chemoattractant equals $\tan \Theta$, where Θ equals the angle of migration, providing another useful parameter to assess the randomness of the migration.

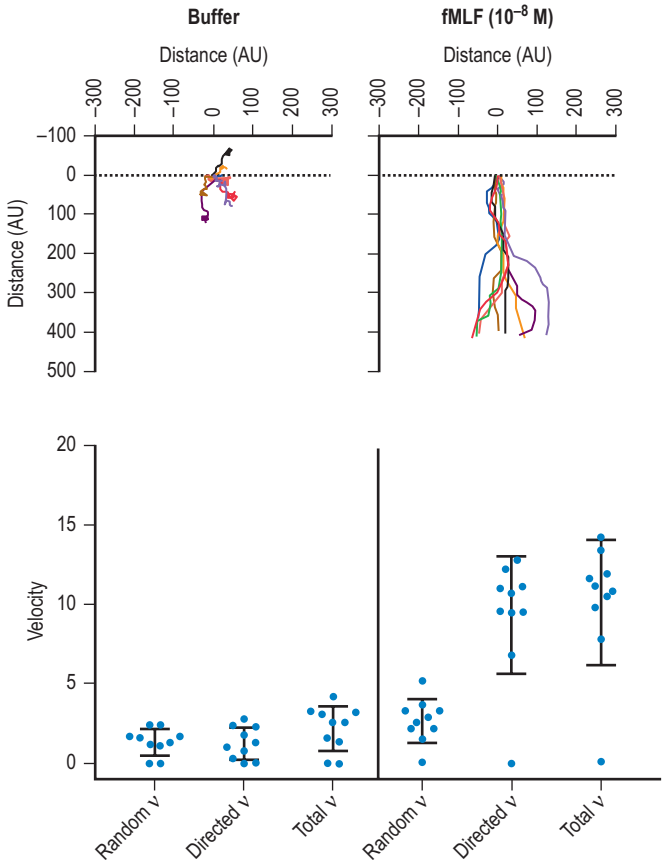

FIG. 95.3 Analysis of Chemotaxis. In the top panel, neutrophils (1 µL of 2 × 10^6 cells/mL in Hanks balanced salt solution [HBSS] with divalent cations) were added to the "Cell" well of EZ-TAXIScan and either buffer (left column) or formyl-methionyl-leucyl-phenylalanine (fMLF; 1 × 10^{-8} M, right column) was added to the "Chemoattractant" well. The cells were incubated for 60 minutes and images were collected every 2.5 minutes. Using the acquired images, 10 randomly chosen cells were electronically tracked and the paths of the cells plotted with their position at t = 0 anchored at the origin. Presented in the bottom panel are scattergrams of the average velocities of the individual cells that were tracked in the top panel.

EXPRESSION OF SURFACE ANTIGENS

Clinical Indications and Implications

The expression of neutrophil membrane antigens is altered in vivo during exudation or after challenge with intravenous endotoxin. Flow cytometric analysis of adhesion molecules on the neutrophil cell surface can indirectly reflect neutrophil adhesion function. Patients with LAD-1 exhibit a deficit in the expression of the common β_2 integrin CD18 that also results in deficiency in surface expression of CD11a, CD11b, and CD11c.[27]

Principles and Interpretation of Laboratory Assessment

The expression of cell-surface antigens is determined on neutrophils stained with specific fluorescent bound monoclonal antibodies (mAbs), and analyzed by flow cytometric analysis. Neutrophils stained with nonspecific isotype antibodies are used to determine the nonspecific background staining (Chapter 93). To determine the expression of circulating neutrophils and avoid artifacts induced by neutrophil isolation, an aliquot of whole blood can be stained with the appropriate antibody before lysis of the erythrocytes. During flow cytometric analysis, the neutrophils are easily differentiated using their forward light scatter and right angle light (side) scatter to gate on the neutrophil population. Since very little blood is needed (100 µL) to evaluate for each surface antigen, neutrophils can be stained with a panel of antibodies to many relevant surface antigens so that a more complete representation expression on neutrophils can be obtained. The panel should include the β_2 integrins (CD11a, CD11b, CD11c, and CD18); the selectin (CD62L); Fcγ receptors I, II, and III (CD64, CD32, and CD16); leukosialin (CD43); the common leukocyte antigen (CD45); and distinct surface markers for the granules—carcinoembryonic antigen-related cell adhesion molecule 8 (CEACAM8, or CD66b), a GPI-anchored glycoprotein family member stored in the specific granules, and lysosomal-associated membrane protein 3 (LAMP-3, or CD63), stored in the azurophilic granules. During exudation, the expression of CD11b and CD18 is increased over that observed in peripheral neutrophils, whereas the expression of CD43 (leukosialin) and CD62L is markedly reduced.

The antibody 7D5[28] recognizes an extracellular epitope of $gp91^{phox}$ and can be used to identify surface expression of $gp91^{phox}$ as well as monitor the mobilization of latent pools of $gp91^{phox}$ stored in the specific granules. Flow cytometric analysis of neutrophils stained with 7D5 can often be used to identify patients with X-linked chronic granulomatous disease (CGD - generally little or no 7D5 staining) and X-linked chronic carriers of CGD (mosaic pattern of staining), particularly in patients where the number of cells available for testing is limited. Flow cytometric analysis of permeabilized neutrophils stained with specific antibodies to either $p22^{phox}$, $p47^{phox}$, $p67^{phox}$, or $p40^{phox}$ has also been used to rapidly identify protein defects in patients with CGD.[29,30] These findings predict the use of permeabilized neutrophils to assess the expression of other intracellular proteins.

The expression of surface antigens can also be used to assess the responsiveness of neutrophils to ligands, such as fMLF and LPS. As shown in Fig. 95.4, neutrophils isolated from a patient who has a genetic defect in IL-1 receptor–associated kinase-4 (IRAK-4)[31] exhibit abnormal regulation of surface antigen expression to LPS but exhibit normal regulation of surface antigen expression to fMLF. Antigen expression can be upregulated because of translocation of latent antigen to the plasma membrane or downregulated due to internalization or shedding of the antigen.

NEUTROPHIL DEGRANULATION

Clinical Indications and Implications

The proteases, acid hydrolases, and inflammatory mediators released from storage granules in the neutrophils can mediate bacterial killing, tissue damage, healing, and immune regulation. Lactoferrin released from specific granules can chelate iron, resulting in a bactericidal or bacteriostatic effect. Elevation of plasma lactoferrin is an indication of intravascular activation and degranulation of neutrophils.

Principles and Interpretation of Laboratory Assessment

Stimulation of neutrophils with various secretagogues can result in the release of granular enzymes into the extracellular fluid. Treatment of the neutrophils with cytochalasin b (5 µg/mL) disrupts microfilament assembly and facilitates the release of both specific and azurophilic enzymes. Since stimulation of neutrophil degranulation is often accompanied by ROS generation

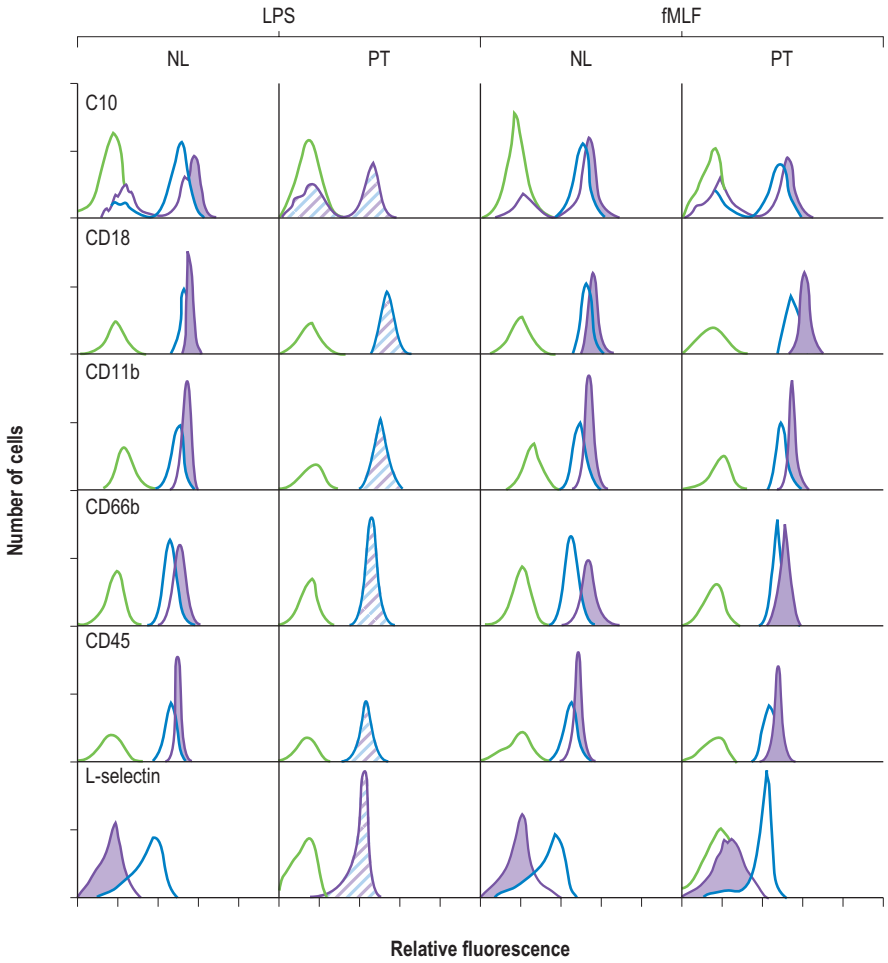

FIG. 95.4 Upregulation of Neutrophil Surface Antigen Expression. Neutrophils (2.5×10^6/mL Hanks balanced salt solution [HBSS] + 10% AB sera) isolated from a normal subject (*NL*) or from a patient with an interleukin-1 receptor–associated kinase-4 (IRAK-4) mutation (*PT*) were treated with either lipopolysaccharide (*LPS*; 100 ng/mL) or formyl-methionyl-leucyl-phenylalanine (*fMLF*; 0.1 μM) for 30 minutes at 37°C. The cells were washed and stained with C10 (an antibody that demonstrates neutrophil heterogeneity), CD18, CD11b (antibodies to β_2 integrins), CD66b (a specific granule marker), CD45 (the common leukocyte antigen), and L-selectin. The *green lines* represent the isotype control, *blue lines* represent control neutrophils, and *purple lines* represent stimulated cells. Differences between control and stimulated cells have been *shaded*. (From Kuhns DB, Long Priel DA, Gallin JI. Endotoxin and IL-1 hyporesponsiveness in a patient with recurrent bacterial infections. *J Immunol*. 1997;158:3959, with permission of the American Association of Immunologists, Inc.)

and oxidative inactivation of enzymes, both the cell supernatant fluid and the cell pellet should be analyzed to determine the percentage of enzyme released. To differentiate degranulation from cell lysis, release of the cytosolic enzyme lactate dehydrogenase should be monitored simultaneously.

The release of azurophilic granules can be assessed by determining the levels of myeloperoxidase or elastase. CD63 is also found in the membrane of azurophilic granules and migrates to the neutrophil surface after stimulation with fMLF in the presence of cytochalasin b. The release of specific granules can be assessed by determination of lactoferrin levels using an enzymatic immunoassay. The carcinoembryonic antigen CD66b is found on the neutrophil surface and the specific granules, and its expression on the surface of the neutrophils is increased after stimulation with fMLF or LPS. The secretory granules usually contain proteins that are translocated into the membrane from the cytosol during degranulation. Detection of the constituents of secretory granules can be assessed by flow cytometric analysis of the change in expression of surface proteins (adhesion molecules), and cytochrome b_{558} of the NADPH oxidase.

GENERATION OF REACTIVE OXYGEN SPECIES

Clinical Indications and Implications

The release of ROS, such as $O_2^{\bullet}$ and H_2O_2, is an important component of the bactericidal machinery of a neutrophil. Neutrophils isolated from patients with CGD have a defect in the NADPH oxidase and are unable to generate ROS, resulting in an O_2-dependent bactericidal defect. The production of ROS has become an important tool to perform risk assessment in patients with CGD. Patients with the lowest ROS generation (<1% of normal generation) have lower survival than patients with higher ROS generation (3%–10% of normal). Moreover, survival in CGD is a continuous function of ROS production, suggesting that therapeutic interventions that result in an increase in ROS generation should incur a survival benefit to patients with CGD.[32]

CLINICAL PEARLS

Reactive Oxygen Species (ROS) in Chronic Granulomatous Disease (CGD)

- Neutrophil ROS production, the primary determinant in diagnosis of patients with CGD, ranges from 0.1% to 27% of that observed in normal individuals.
- In addition, survival in CGD is strongly associated with residual ROS production as a continuous variable, independent of the specific protein defect.
- ROS production is an important and early indicator of overall risk in CGD.
- In addition, small increases (as little as 3%–5% of normal) in residual neutrophil ROS production may confer a survival benefit.
- Careful monitoring with detection of even small increases in ROS could be an important indicator of clinical efficacy during therapeutic intervention.

Principles and Interpretation of Laboratory Assessments

The nitroblue tetrazolium (NBT) test is a qualitative assay of ROS production. Either whole blood or isolated neutrophils are mixed with NBT in a chamber slide and stimulated with PMA for 15 to 30 minutes at 37°C. Once settled onto the slide, the neutrophils are air-dried, counterstained with 0.1% safranin, and examined under a microscope. The NBT test yields a visual record of the reduction of the NBT dye to the insoluble, blue-black deposits of formazan. Normal neutrophils, but not neutrophils from patients with CGD, reduce the yellow dye to black-brown-blue aggregates within cells. Owing to the random inactivation of the X-chromosome (lyonization), X-linked carriers of CGD exhibit both NBT^+ and NBT^- neutrophils. The percentage of NBT^+ neutrophils in X-linked carriers of CGD ranges from 5% to 95%. The drawback of the NBT test is the need for manual counting to obtain an accurate reflection of the percentage of positive cells. Presently the most common alternative to the NBT test is a flow cytometric assay using the dye dihydrorhodamine 123 (DHR-123).[33] Neutrophils are loaded with this non-fluorescent dye and then stimulated with PMA for 15 minutes at 37°C. The H_2O_2 produced oxidizes the dye and results in markedly increased fluorescence, which is detectable by a flow cytometer. The assay is also dependent on an endogenous MPO in the primary granules. Catalase is added to prevent cell-to-cell diffusion of H_2O_2. Since dye is localized to the cytoplasm and catalase is present in the extracellular fluid, the DHR-123 assay detects the intracellular production of ROS. As shown in Fig. 95.5, stimulation of normal neutrophils (see Fig. 95.5, A) with PMA results in a two-log shift in the fluorescence intensity. Neutrophils from an X-linked carrier of CGD (see Fig. 95.5, B) exhibit mosaicism with a negatively stained (abnormal) population and a brightly stained positive (normal) population. Neutrophils from a patient with X-linked CGD lacking $gp91^{phox}$ (see Fig. 95.5, C) express little increases in fluorescence. In addition, neutrophils from a patient with a deficiency in $p47^{phox}$ (see Fig. 95.5, D) exhibit slight increases in fluorescence. The major advantages of the DHR-123 assay are the sensitivity, the signal-to-noise ratio, and the ease of counting a larger number of cells. Moreover, it has been shown that the DHR-123 assay yields reliable results on ethylenediaminetetraacetic acid (EDTA) or heparin-treated blood samples that have been stored overnight. In general, more than 90% of the neutrophils from the control blood samples will exhibit increased DHR-123 fluorescence. For this same reason, however, overnight samples should not be used to rule out X-linked heterozygosity, since a highly lyonized CGD carrier (>90% normal vs. abnormal) could yield similar results.

The production of $O_2^{\bullet}$ can be detected using the reduction of cytochrome c. Because $O_2^{\bullet}$ causes a one-to-one stoichiometric reduction of ferricytochrome c to ferrocytochrome c, the resultant increase in the absorption spectrum at 550 nM can be used to quantify the production of $O_2^{\bullet}$. Superoxide dismutase is added to an identical tube to control for the nonspecific reduction of cytochrome c. However, since cytochrome is not permeable to the cells, the detection of $O_2^{\bullet}$ is limited to that released in the extracellular milieu. Neutrophils isolated from normal volunteers produce 0.42 ± 0.67 nmol/10^6 neutrophils/10 min under resting conditions; treatment with PMA results in production of 35.92 ± 11.92 nmol/10^6 neutrophils/10 min (Fig. 95.6). An estimate of normal $O_2^{\bullet}$ production over 60 minutes can be obtained by reducing the number of neutrophils in the assay to 2×10^5. Neutrophils isolated from patients with CGD produce little, if any, $O_2^{\bullet}$ in response to PMA treatment in 10 minutes (see Fig. 95.6). However, some patients with autosomal forms of CGD have low, but detectable $O_2^{\bullet}$ production in 60 minutes. Neutrophils isolated from X-linked heterozygous carriers of CGD can yield a full spectrum of $O_2^{\bullet}$ production, whereas neutrophils from autosomal recessive carriers of CGD generally yield a normal response (see Fig. 95.6). Although the detection of $O_2^{\bullet}$ by reduction of cytochrome c is useful in the diagnosis of patients with CGD, it cannot be used in the diagnosis of carriers because of the wide spectrum of responses that result from the degree of X-chromosome lyonization.

Studies have shown that $O_2^{\bullet}$ determinations sufficiently reliable to diagnose chronic granulomatous disease (CGD) can be obtained from neutrophils isolated from heparinized whole blood that has been stored overnight. Hence, analyses can be performed on blood samples shipped overnight. A normal control blood sample should accompany the sample to ensure adequate handling during shipment. By 48 h of storage, however, there are marked reductions in the phorbol myristate acetate (PMA) response, and the findings are no longer valid.

An alternative assay to measure reactive oxygen species (ROS) production is luminol-enhanced chemiluminescence. This versatile assay, in addition to its quick and easy setup, offers the capability to test several individuals and stimuli on the same plate using reduced number of cells while providing high sensitivity. The luminescence is read every 1–5 min for up to 2 h, and data are expressed as relative light units (RLUs). Different stimuli exhibit different kinetics (e.g., fMLF induces a rapid respiratory burst that decays quickly, whereas PMA [20–100 ng/mL] induces a peak of luminescence within 5–15 min that slowly decays by 2 h). Results from normal individuals and patients can be assessed simultaneously and monitored kinetically or using the area under the curve (AUC). Luminol-enhanced chemiluminescence is a measure of both intracellular and extracellular ROS production, although it may not detect them with equivalent efficiency. Addition of superoxide dismutase significantly reduces both peak height and AUC after stimulation with PMA, suggesting that at least a portion of the response can be attributed to $O_2^{\bullet}$. Typically, patients with CGD who are deficient in $gp91^{phox}$ have little to no detectable luminescence in this assay; however, as observed with the ferricytochrome c assay, patients with CGD with an autosomal recessive deficiency in $p47^{phox}$ have detectable luminescence that becomes most evident at later readings (40–80 min) (Fig. 95.7).

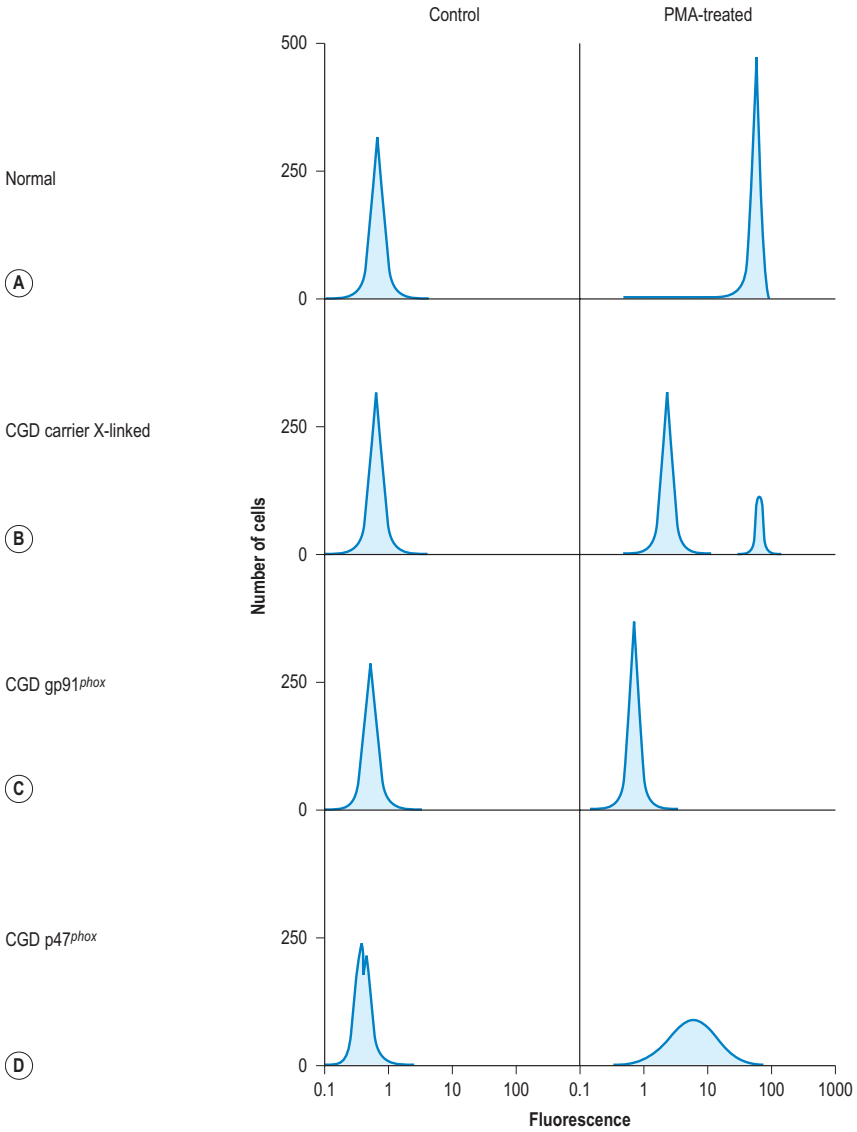

FIG. 95.5 Flow Cytometric Analysis of Dihydrorhodamine (DHR) Staining. Whole blood (1.2 mL with ethylenediaminetetraacetic acid [EDTA] as anticoagulant) collected from a normal individual (A), an X-linked chronic granulomatous disease (*CGD*) carrier (B), a gp91^{phox} CGD patient (C), and a p47^{phox} CGD patient (D) was lysed by using an ammonium chloride–potassium bicarbonate solution. The remaining leukocytes were resuspended in Hanks balanced salt solution (HBSS) and incubated with dihydrorhodamine 123 (DHR-123; 100 µM) and catalase (50 µg/mL) for 5 minutes at 37°C. The cells were then incubated an additional 15 minutes at 37°C with either buffer (control) or phorbol myristate acetate (*PMA*; 400 ng/mL). The cells were immediately analyzed by flow cytometric analysis. Neutrophils were gated using forward light scatter and right-angle light scatter. The analyses presented represent 5000 events within the gated area.

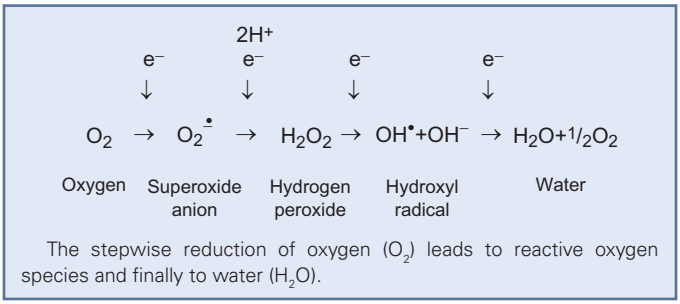
KEY CONCEPTS

Reactive Oxygen Species



The stepwise reduction of oxygen (O_2) leads to reactive oxygen species and finally to water (H_2O).

WESTERN BLOT ANALYSIS OF NADPH OXIDASE PROTEIN SUBUNITS

Clinical Indications and Implications

The NADPH oxidase consists of two membrane components (p22^{phox} and gp91^{phox}), three cytosolic components (p47^{phox}, p67^{phox}, and p40^{phox}), and several guanosine triphosphate (GTP)–binding proteins. CGD is characterized by defects in any of the following components—p22^{phox} (≈5% of patients with CGD), p47^{phox} (≈25% of patients with CGD), p67^{phox} (≈5% of patients with CGD), and gp91^{phox} (remaining 65% of patients with CGD).

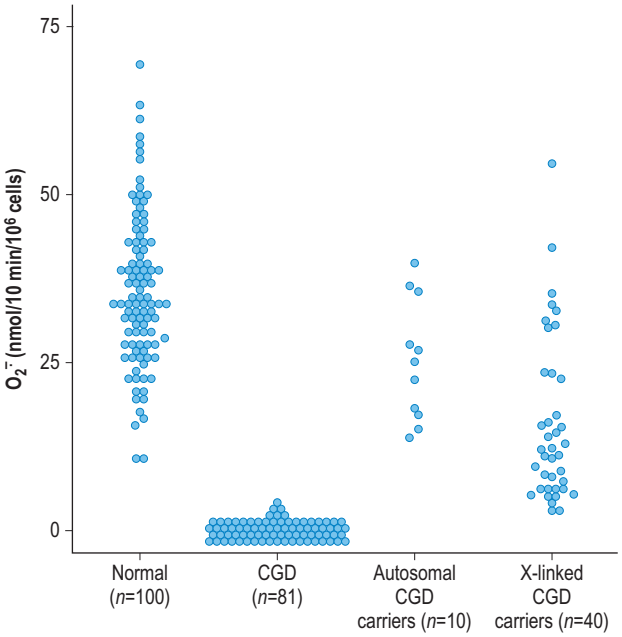


FIG. 95.6 $O_2^{\cdot-}$ Generation from Normal Subjects, Patients With Chronic Granulomatous Disease (*CGD*), and Carriers of CGD. Neutrophils (1 × 10^6/mL Hanks balanced salt solution [HBSS]) were incubated in the presence of 100 µM cytochrome c with phorbol myristate acetate (PMA; 100 ng/mL) for 10 minutes at 37°C. The reaction was terminated by centrifugation at 4°C. Reduction of cytochrome c was monitored at an analytical wavelength of 549.5 nm and a micromolar extinction coefficient of 0.0211. An identical tube containing superoxide dismutase (100 µg/mL) served as a blank.

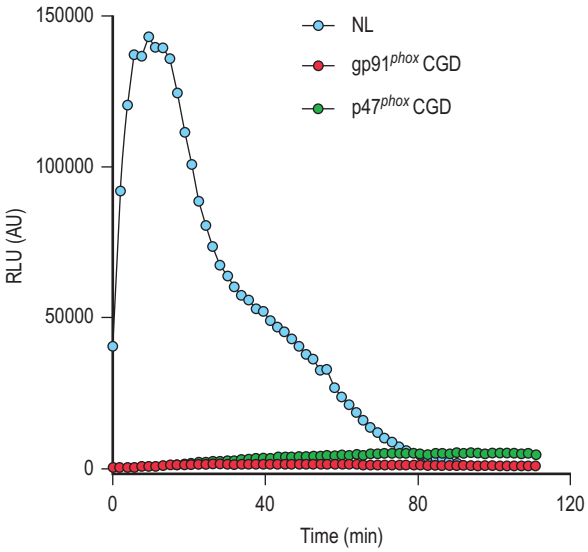

FIG. 95.7 Luminol-Enhanced Chemiluminescence. Neutrophils (1 × 10^5/200 µL) were preloaded with luminol (100 µM) for 10 min at 37°C. At t = 0, either buffer or phorbol myristate acetate (PMA; 100 ng/mL) was added and luminescence was monitored for 2 hours, with readings recorded every 2 minutes. Note that at later readings, neutrophils from a CGD patient with $p47^{phox}$ deficiency had increased luminescence compared with neutrophils from a CGD patient with $gp91^{phox}$ deficiency. *CGD*, Chronic granulomatous disease; *RLU*, relative light unit.

Principles and Interpretation of Laboratory Assessments

The severity of CGD can be related to the specific protein defect. Determination of the specific protein defect in CGD by Western blot analysis also provides direction for determination of the specific genetic defect and enables appropriate genetic counseling for the extended family. A validated normal control is included on each gel for band identification and intensity comparisons. In addition, a control sample from a patient with a known mutation in $gp91^{phox}$ CGD is included on each blot to ensure adequate development of $p22^{phox}$. Typical phox protein band patterns are presented in Fig. 95.8. Patients with CGD having mutations in $p47^{phox}$ are Western blot negative. Patients with CGD having mutations in $p67^{phox}$ are generally Western blot negative; however, we have analyzed one CGD patient with a missense mutation in $p67^{phox}$ yielding a positive Western blot. Because $p22^{phox}$ and $gp91^{phox}$ exist as a membrane complex, patients with a defect in $p22^{phox}$ are generally Western blot negative for both $p22^{phox}$ and $gp91^{phox}$. In contrast, defects in $gp91^{phox}$ yield more variable results, patients with nonsense defects in $gp91^{phox}$ generally exhibit low but detectable levels of $p22^{phox}$, while patients with missense mutations in $gp91^{phox}$ that yield detectable $gp91^{phox}$ protein exhibit proportionately higher levels of $p22^{phox}$. Neutrophils isolated from overnight samples can be used to diagnose $p47^{phox}$

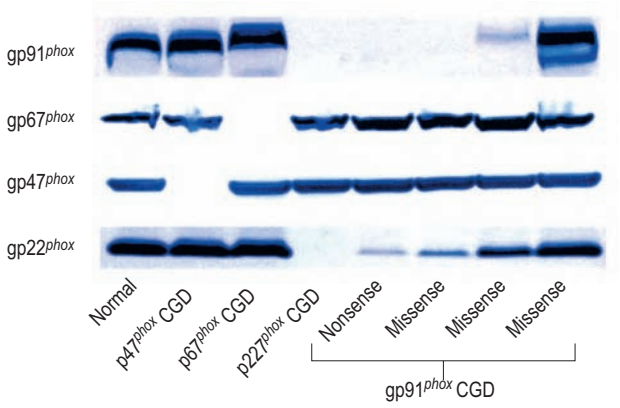

FIG. 95.8 Determination of Nicotinamide Adenine Dinucleotide Phosphate (NADPH) Oxidase Protein Defect by Western Blot Analysis. Frozen, diisopropylfluorophosphate (DFP)–treated neutrophil pellets (5 × 10^6 cells) were resuspended in polyacrylamide gel electrophoresis (PAGE) sample buffer and sonicated to break up the DNA. One million cell equivalents were loaded into each lane (10% PAGE gels for $p47^{phox}$ and $p67^{phox}$, 4% to 12% gradient PAGE gels for $gp22^{phox}$ and $gp91^{phox}$). A validated normal control was run on each gel for quality control. The gels were transferred to nitrocellulose, blocked with 5% powdered milk, and incubated overnight with specific antibodies to the phox proteins. The blots were washed, incubated with peroxidase-labeled secondary antibody, and developed with a color reagent. The blots were scanned for permanent storage, and a composite figure was created by using the relevant bands from each blot. The lanes are identified by the specific protein defect in CGD patients and, for $gp91^{phox}$, the type of mutation. *CGD*, Chronic granulomatous disease.

deficiency because of the stability of the protein. However, detection of other phox protein defects in overnight samples can be more problematic because of proteolysis of $p67^{phox}$ and the $gp91^{phox}$–$p22^{phox}$ complex.

CONCLUSIONS

Neutrophils are a critical cellular component of innate immunity in protecting the host from bacterial and fungal infections. They act as sentinels of the immune system and respond to the changing environment with their surface markers serving as a reflection of these changes. However, in other cells, the surface markers designate what function the cells have been programmed to perform (e.g., Th1 vs. Th2 lymphocytes, M1 vs. M2 monocytes) for neutrophils, surface antigen expression likely reflects their history. Neutrophils are exquisitely sensitive to perturbations, either physical trauma (e.g., shear, *g*-force, ionic stress) associated with cell isolation or physiological perturbations such as exposure to LPS or cytokines as well as transendothelial migration; such changes are reflected in their expression of surface markers, often due to mobilization of latent pools of the antigens stored in the granules (e.g., β_2 integrins), but also due to shedding of antigen by proteolysis (CD62L). These changes appear to be in preparation for the critical role that neutrophils play by internalizing and killing bacterial and fungal pathogens.

Current knowledge of neutrophil biology has developed from the study of genetic immunodeficiencies that target a specific protein and/or pathway in neutrophils. However, additional immunodeficiencies that result from defects in these recently discovered pathways are yet to be determined.

ON THE HORIZON

Developing a better understanding regarding the physiology and fate of neutrophils that survive at sites of inflammation/infection:

- Is the recycling of surface antigens permanent or can the receptors cycle back to their storage granules?
- Are antigens that have been shed replaced?

Some neutrophils appear to return to the vasculature from sites of inflammation:

- Is this reverse migration driven by chemoattraction?
- What are the surface signals that mediate their destination?
- What is the role of these altered neutrophils?
- Are these cells "fast-tracking" to their destination for destruction in the lungs, bone marrow, mucosal surfaces?
- Are the altered neutrophils so transient in circulation that they are lost within the greater population of normal circulating neutrophils?
- Does the presence of neutrophil granule proteins in plasma represent a vestige of their history, representing cells that have undergone NETosis or apoptosis?

Assessment of Human Allergic Diseases

Robert G. Hamilton

Human allergic disease comprises a spectrum of immunoglobulin E (IgE)–mediated immediate-type hypersensitivity reactions that manifest as reactions in skin (urticaria or dermatitis), the respiratory tract (asthma, rhinitis, or sinusitis), eyes (conjunctivitis), the gastrointestinal (GI) tract (abdominal pain, bloating, vomiting, or diarrhea), and, in their most extreme condition, systemic anaphylaxis. These reactions are precipitated by exposure of a genetically predisposed and sensitized (IgE antibody-positive) individual to a variety of environmental substances that are ubiquitous and usually well tolerated by most healthy individuals. This chapter reviews the principles and performance characteristics of analytical methods used in the diagnosis and management of individuals with allergic disease. It examines in vivo and in vitro methods for the quantification of total and allergen-specific IgE and mast-cell tryptase.

BIOLOGICAL PROPERTIES OF IMMUNOGLOBULIN E

In 1921, Prausnitz and Küstner (PK)[1] reported that an intradermal (ID) injection of serum from an allergic individual into the skin of an unsensitized (nonallergic) individual, followed 24 hours later by injection of specific antigen into the same skin site, induced local itching and swelling surrounded by a zone of erythema. This passively transferred allergic reaction, or *PK reaction*, reached a maximum within 10 minutes, persisted for about 20 minutes, and gradually disappeared. In 1967, this antibody was identified as a fifth human immunoglobulin isotype and designated as IgE.[2–4]

Total serum IgE concentrations are the lowest of the five human immunoglobulin isotypes (0 to 0.0001 g/L; 0.004% of the total adult serum immunoglobulin).[5] Its short biological half-life of 1 to 5 days in peripheral blood is primarily the result of a relatively high fractional catabolic rate (71% of the intravascular pool catabolized/day). IgE does not pass the placenta or activate the classical complement pathway. Its reaginic (mast-cell sensitizing) activity is dependent on its ability to bind to the α chain of the high-affinity IgE Fc-ε receptor (α-FcεRI) that resides on the membrane surface of basophils and mast cells.

CLINICAL IMPORTANCE OF TOTAL SERUM IMMUNOGLOBULIN E

The concentration of IgE in the serum is age dependent.[5] Cord serum IgE concentrations are low, usually <2 kU/L (1 kU = 2.44 μg). Serum IgE levels progressively increase in healthy children up to the age of 10 to 15 years and gradually decline from the second to the eighth decades of life. Infants with atopy have an earlier and steeper rise in serum IgE levels during their early years compared with age-matched controls without atopia.[6]

Clinically, a patient's total serum IgE level should be evaluated against reference intervals established with sera from an age-stratified, healthy skin test-negative (nonatopic) population.[6] Many clinical laboratories define a total serum IgE > 100 kU/L (240 ng/mL) as a general demarcation into the atopic region.[7]. Extreme elevations in serum IgE are common in parasitic infections (Chapter 31) and are necessary for the diagnosis of the hyper-IgE (Job) syndrome (Chapter 39). Low total serum IgE levels support the diagnosis of nonallergic (intrinsic) asthma and help exclude allergic bronchopulmonary aspergillosis. There is extensive overlap between IgE levels in atopic and nonatopic populations,[6–9] which means that an elevated serum IgE can be useful in confirming the clinical diagnosis of allergic respiratory or skin diseases; however, a low or normal value does not eliminate the possibility of an IgE-mediated mechanism. Parasitic infections, selected immunodeficiency states (e.g., DOCK-8 deficiency, Job syndrome, Omenn syndrome, and Wiskott-Aldrich syndrome), cancer (Hodgkin disease, bronchial carcinoma), rheumatoid arthritis, liver disease, and atopic dermatitis (eczema) are other disease states that have been associated with a dysregulation of total serum IgE levels. The total serum IgE must therefore be interpreted within the relevant clinical context for each patient.

Because of the overlap between individuals with atopia and those without, total serum IgE measurements have been largely replaced in the routine diagnosis of allergic disease by the quantification of allergen-specific IgE antibody. However, quantification of total serum IgE has remained important for computing the therapeutic dose of anti-IgE. Omalizumab is a recombinant, humanized IgG1-κ monoclonal antihuman IgE Fc biological that specifically binds to the region on the ε heavy chain that interacts with α-FcεR1.[10] It is used to treat moderate to severe persistent allergic asthma and chronic idiopathic urticaria by blocking IgE binding to the α-FcεR1. The binding of omalizumab to IgE in vivo reduces both the number of free IgE molecules able to interact with the α-FcεR1 and the number of α-FcεR1 receptors on the surface of effector cells. The consequence is a reduction in mediator release and allergy symptoms following allergen exposure.

CLINICAL IMPORTANCE OF ALLERGEN-SPECIFIC IMMUNOGLOBULIN E

In contrast to total serum IgE, the presence of allergen-specific IgE antibody on the surface of circulating basophils or skin mast cells or in the serum is highly predictive of an individual's

propensity to exhibit an allergic response following re-exposure to that allergen. Before its identification as a novel immunoglobulin, IgE was only detectable with in vivo bioassays (skin test, bronchial or nasal provocation tests). Purification of IgE myeloma protein and the subsequent production of antisera specific for IgE led to the development of the first in vitro assay (radioallergosorbent test [RAST]) for the detection of allergen-specific IgE antibody in serum.[4,11,12] Since then, nonisotopic autoanalyzer variants based on the original noncompetitive cellulose paper disc solid-phase RAST designs have been widely used in clinical immunology laboratories worlwide.[13]

Historical studies have compared the diagnostic performance (sensitivity and specificity) of in vivo and the in vitro assays in the diagnosis of human allergic disease. These inter-method comparisons have shown that the presence of IgE antibody, as measured by serological immunoassay methods, usually agrees well with the presence of IgE detected in leukocyte and mast-cell histamine release assays, and with provocation tests, such as the skin test, food challenge, and inhalation provocation test.[14] However, these early studies emphasize that the presence of IgE antibody as detected either in vivo or in vitro is at best a confirmatory measurement for sensitization.[15] IgE antibody is necessary, but not sufficient, to identify an individual with allergic disease. IgE antibody presence is one important risk factor in the diagnosis of allergic disease that supports a patient's medical, family, and environmental histories of a temporal association between allergic symptoms and allergen exposure. The clinical importance of differences in diagnostic sensitivity between skin test and serological detection of IgE antibody may be less important for patients with allergies to inhaled (pollen, dust mite, and epidermal) allergens than in those facing life-threatening anaphylactic reactions caused by *Hymenoptera* stings and certain drugs. In these latter cases, skin tests are preferred to serology for the detection of allergen-specific IgE antibodies.[16] Immunoassays of allergen-specific IgE antibody in serum are, however, useful in cases where antihistamines, β-receptor stimulants, or high-dose steroids reduce an in vivo provocation test's measured response as well as in children, pregnant women, and older patients, in whom skin testing may not be well tolerated and when dealing with allergens (e.g., foods, molds) where commercial extracts can be highly variable or labile.[14]

CLINICAL HISTORY

The diagnosis of human allergic disease is driven principally by the patient's clinical history in which objective evidence is collected that an allergic reaction has occurred following exposure to a known or suspected allergen source. During the history, a number of factors need to be considered.[14] These include the patient's symptom characteristics (location, reproducibility, severity, duration, and delay time from appearance following allergen exposure), atopic factors (personal and family histories, age of onset, and the presence of infantile atopic dermatitis), opportunity for sensitization (geography, seasons, duration of exposure, prior exposures, employment, and hobbies), specificity of allergen triggers, and comorbidities (e.g., nasal polyps, recurrent sinusitis, and chronic obstructive pulmonary disease [COPD]). From the history, an a priori or pretest probability or likelihood of allergic disease is derived, and this determines whether or not confirmatory IgE antibody testing for sensitization is warranted.

DIAGNOSTIC METHODS

A combination of in vivo provocation and in vitro laboratory tests may be used to confirm sensitization and provide support for the clinical diagnosis of allergic disease. The actual tests selected depend on the nature of the disease process (e.g., allergic asthma, urticaria/angioedema, rhinitis/sinusitis, or anaphylaxis) and the suspected allergen triggers (e.g., aeroallergens, venoms, drugs, foods). Not only are there a myriad of assay methods, diverse techniques, reagents (extracts and molecules) and grading, interpolation, and interpretation methods, but most importantly, there is a general absence of gold standard methods for defining the presence of allergic disease. Consequently, results of the confirmatory tests need to be viewed as additional risk factors and tests for sensitization, rather than definitive indicators of disease.[15] In the end, the choice of which confirmatory test to use is a matter of clinical judgment.

INITIAL CLINICAL LABORATORY TESTS

Following the collection of a medical history and performance of a physical examination, the patient who is suspected of having allergic disease may undergo several preliminary blood tests. A complete blood count (CBC), and/or a total blood eosinophil count, if performed, should be obtained before any systemic corticosteroids or epinephrine is administered. A normal whole blood eosinophil level ranges from 0 to 500 cells/mm^3. Children generally have higher normal levels (mean 240 cells/mm^3 95% confidence interval [CI] = 0 to 740 cells/mm^3), with peak levels occurring at 4 to 8 years of age. Most clinical laboratories consider a differential white blood cell (WBC) count with an eosinophil proportion >5% to 10% of the total WBC count to be abnormal. Blood, sputum, and nasal secretion eosinophilia is characteristic of asthma, whether or not IgE-mediated allergic processes are present. In a bronchitic sputum specimen, neutrophils predominate. A neutrophilic nasal discharge is characteristic of sinusitis. Other laboratory tests that may be ordered include pulmonary function tests and a chest X-ray or sinus computer tomography (CT) scan.

IN VIVO PROVOCATION TESTING

Both the skin test and nasal/bronchial/GI provocation tests are useful in vivo diagnostic tools for the confirmation of sensitization in the evaluation for allergic disease. They can also help identify offending allergens in an allergy patient's work-up for avoidance, or management with pharmacotherapy, immunotherapy, anti-IgE therapy, or other biological therapy.

Skin Tests

Historically, Guerin and Watson[17] described a three-phase skin response during an immediate-type skin test reaction following the administration of a stimulus (allergen or histamine-positive control). First, a bluish-white area appears that involves the constriction of capillaries that typically disappears within minutes. Second, an erythematous peripheral halo or flare appears as a result of arteriole dilatation. Finally, a circular urticarial papule or wheal is observed, as a result of extravasation of plasma into the skin. The response is generally maximal by 15 to 20 minutes. The immediate "wheal and flare" reaction can be followed by a late-phase reaction 5 to 6 hours later that appears as a poorly defined edema-like reaction that usually disappears by

24 hours. An allergen extract can be administered either by a prick or puncture or by ID injection.[18]

Puncture skin testing involves placing a drop of each test allergen extract or control solutions (histamine and saline) on the skin of the forearm or back and the introduction of allergen into the epidermis by a needle puncture. Importantly, drops are spaced at least 2 cm apart to prevent cross-over contamination that can produce false-positive reactions or difficulty reading each discrete test site because of overlapping erythema. A variety of single-point (23 to 26 gauge), multipoint, and bifurcated needles have been used.[19] An immediate reaction (wheal and erythema) is read at 15 to 20 minutes as it reaches its maximum size. Because of the direct skin irritation with some crude allergen extracts, bleeding at the site of puncture can produce false-positive results.

The ID skin test is 1000 to 30,000 times more sensitive by concentration than the puncture skin test. A 0.02- to 0.05-mL volume of diluted allergen extract or controls (histamine or saline) is injected intracutaneously through a 26- to 27-gauge needle. Importantly, the bevel of the needle needs to face up and injection should be no deeper than the superficial layers of the skin. A 0.02-mL injection will initially produce a superficial 2- to 4-mm-diameter bleb. Like the puncture test, the ID skin test is read at 15 to 20 minutes, when the reaction is maximal. Dilutions of extract >1:1000 weight/volume (w/v) are commonly used to minimize false-positive reactions due to irritation and the potential for systemic reactions, which range from 0.02% to 1.4% of patients tested.[18] Subcutaneous administration of the allergen may lead to a false-negative result. The volume of allergen extract that is injected only slightly influences the size of the wheal-and-flare reaction, whereas concentration is the most important determinant of the final ID skin test result. ID testing allows an investigator to perform a skin test titration to quantitatively determine the patient's skin sensitivity. For serial titration, the same volume (e.g., 0.02 mL) of 3- to 10-fold serial dilutions of allergen extract are injected into different skin sites and the concentration of allergen required to produce a wheal or erythema of a defined mean diameter (e.g., 8-mm wheal) is interpolated.[20] The higher the concentration of allergen required to induce the defined size of wheal or erythema, the less sensitive is the patient to that allergen preparation and/or the lower is the allergenic potency of the extract.

Variables that Influence Skin Test Responses

The quality (composition, potency, heterogeneity) of the allergen extract is the single most important variable that affects skin test performance. Most skin test extracts are non-standardized, and their potency is reported in biological or weight per volume units.[21] Many allergen extracts used in puncture skin testing contain 50% glycerin, which enhances stability. However, glycerin causes skin irritation and false-positive skin test results if used intradermally without dilution. Other factors that influence the skin test response include the area of the body that is tested (back vs. forearm), age of patient (skin wheals increase in size from infancy to adulthood), race (clarity of reading on dark vs. light skin pigmentation) and pre-administered drugs (e.g., antihistamines, tranquilizers, or corticosteroids).

The saline negative control can identify dermatographic patients and trauma-induced reactivity produced by the puncturing device. The histamine positive control (for prick or puncture at 5.43 mmol/L or 1 mg/mL of histamine base) is useful in detecting medication- or disease-induced suppression of the skin test response. It is also used as a quality control reagent to document the reproducibility of technician performance.[22]

Relationship Between Puncture and Intradermal Skin Test Responses

Fig. 96.1 shows the relationship between the ng/mL level of *Dermatophagoides pteronyssinus* (*Dpt*, dust mite) specific IgE antibody in sera from 30 subjects with dust-mite allergy, as measured in serum by an in vitro assay, as well as the ID skin test midpoint *Dpt* allergen extract titer required to produce an 8-mm wheal in the same individual. Using the same *Dpt* extract in both tests, a higher degree of skin sensitivity (i.e., lower titer of antigen required to induce an 8-mm wheal) was strongly correlated ($r^2 = 0.77$; $P < .001$) with higher serum allergen-specific IgE antibody levels in those with the higher levels of skin sensitivity (<10 ng/mL midpoint). Fig. 96.2 shows the strong correlation between the wheal size that is observed in the same patients with *Dpt* allergy receiving the same dust-mite extract by a single puncture skin test and a midpoint ID skin test titration. The maximal diameter and the midpoint perpendicular diameter are averaged to generate an index. A permanent record of the skin reaction can be made by applying adhesive cellulose tape over the wheal-and-flare skin area,

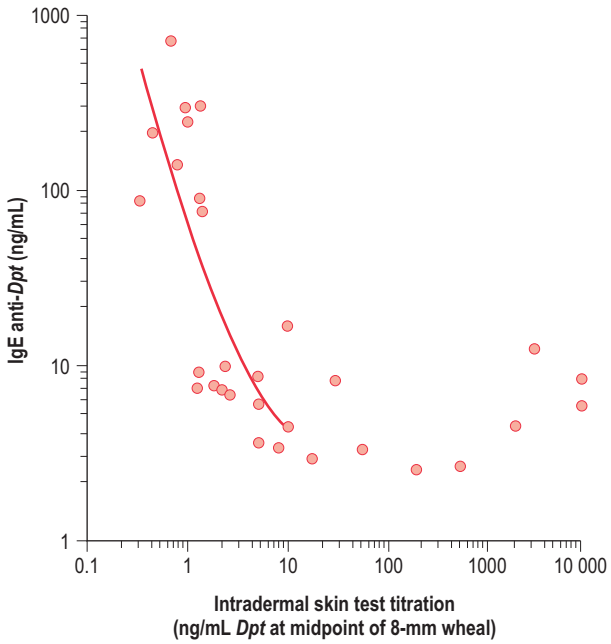

FIG. 96.1 Relationship between immunoglobulin E (*IgE*) anti–*Dermatophagoides pteronyssinus* (*Dpt*) measurements in skin (*x*-axis, intradermal [ID] skin test titration; ng/mL of *Dpt* required to produce an 8-mm wheal) and in the serum (*y*-axis, ng/mL of IgE anti-*Dpt* as measured by IgE antibody serology; sensitivity = 2 ng/mL). These results were obtained by testing the skin and serum of 30 individuals with dust-mite allergy and varying degrees of clinical sensitivity by using the same *Dpt* extract in both IgE antibody serology assay and the ID skin test titration study. A lower "titer" of antigen required to induce an 8-mm wheal (e.g., higher degree of skin sensitivity) was strongly correlated ($r = 0.77$; $P < .001$) with a higher serum IgE antibody level in individuals with the higher level of skin sensitivity (<10 ng/mL midpoint). Less sensitive patients (titers >10 ng/mL *Dpt*) had lower levels of serum antibody (2 to 15 ng/mL) that did not relate well with skin sensitivity.

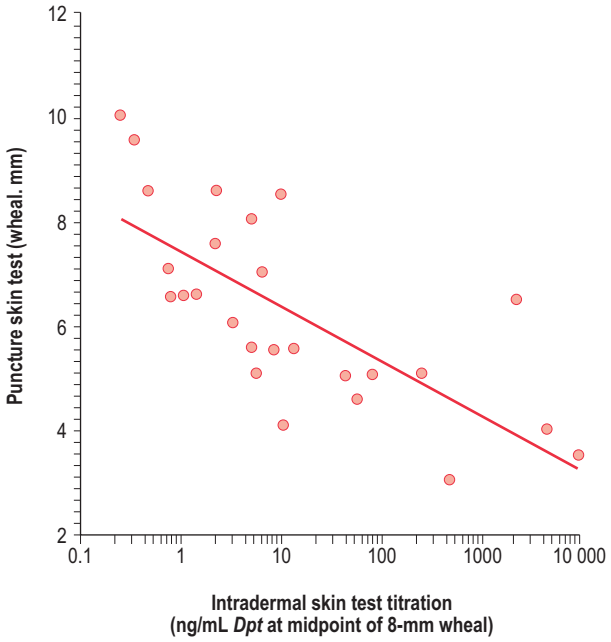

FIG. 96.2 The wheal size in millimeters at a single dose of *Dermatophagoides pteronyssinus* (*Dpt*) allergen administered in a puncture skin test compared with the titer or nanogram per milliliter (ng/mL) of the same *Dpt* allergen obtained in an intradermal (ID) skin test titration on the same 26 dust mite–allergic patients to produce an 8-mm wheal. These data indicate that the wheal size obtained with a single dose of allergen by the less labor-intensive puncture skin test is as predictive ($r^2 = 0.72$; $P < .001$) of relative patient sensitivity as the more technically complex ID skin test titration study, which involves the administration of seven increasing concentrations of the same allergen into different skin sites.

which has previously been outlined with a felt-tip or ballpoint pen. Using a single concentration of allergen, the ID skin test can be graded according to one of several reported systems (Table 96.1).[18] Alternatively, a midpoint titer can be interpolated from a skin test titration, including 3- to 10-fold serial dilutions of the allergen extract. The strong relationship between the size of the intradermal erythema and wheal observed with the mean of 304 duplicate skin tests is shown in Fig. 96.3. This relationship is useful to know because the erythema is difficult to assess in many dark-skinned subjects.

Conjunctival, Bronchial, and Nasal Provocation Tests

Conjunctival, bronchial, and nasal provocation challenges are performed primarily as research procedures to identify a relationship between allergen exposure and a change in the patient's ocular, bronchial, or nasal physiology. Along with puncture skin tests, they are more specific but less sensitive than ID skin tests.

Bronchoprovocation studies with methacholine or histamine are the most commonly performed, particularly in the diagnosis of difficult cases of asthma. The bronchoprovocation procedure involves the administration of either methacholine or histamine via a calibrated nebulizer, starting at doses of 0.03 to 0.1 mg/mL and doubling the concentration up to 10 to 25 mg/mL. Pulmonary function is monitored after each dose. A positive response is typically defined as the concentration of agonist that results in a drop in the forced expiratory volume per second (FEV_1)

TABLE 96.1 Grading System for Puncture and Intradermal Skin Testing Using Histamine as a Reference[a]

Grade or Class	Wheal Size (mm)	Erythema Size (mm)
Skin Testing Grading System[a]		
0	No discernible wheal	
1+	≤3 histamine wheal	
2+	>3 histamine and <13 histamine wheal	
3+	=size of histamine wheal ± 1 mm	
4+	>13 histamine wheal and <23 histamine wheal	
5+	>23 histamine wheal	
Alternative Skin Test Grading System for Intradermal Skin Testing Only Involving Interpretation of Wheal and Erythema Responses[a]

[a]Prick/puncture histamine (3–10 mg/mL); intradermal histamine (100 µg/mL). Modified from Norman PS. Skin testing. In: Middleton E, Ellis EF, Reed CE, eds. *Allergy: Principles and Practice*. 2nd ed. St. Louis: CV Mosby; 1982, with permission from Elsevier.

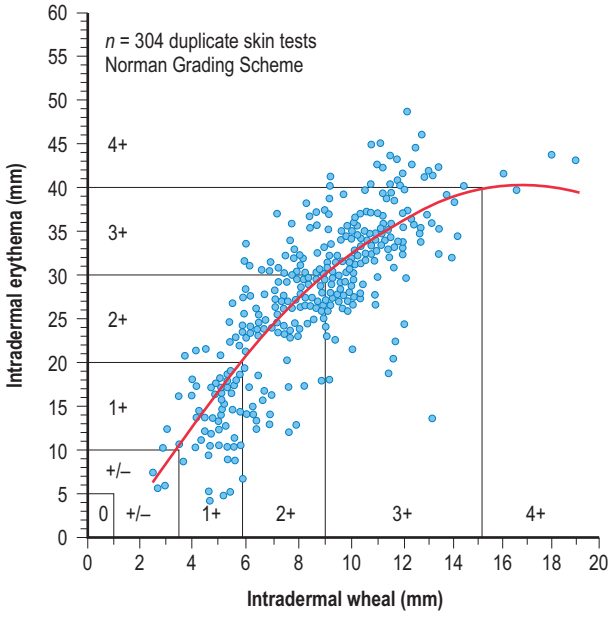

FIG. 96.3 Correlation plot of the mean wheal (*x*-axis) and erythema (*y*-axis) in millimeters for the mean of 304 duplicate intradermal (ID) skin tests to dust mite (*Dermatophagoides pteronyssinus*) obtained in a population of individuals with sensitivity to dust mites. The relationship is highly correlated ($r = 0.82$; $P < .001$) in grades 0 to 3+, indicating that either can be used to judge the degree of ID skin sensitivity. In highly allergic individuals (>35 mm erythema); however, the slope declines dramatically, indicating that wheal size may be more discriminating than erythema.

of 20% or more from the baseline. A baseline value >70% of predicted needs to occur to obtain a valid interpretation.[23]

Nasal provocation involves the controlled administration of buffer (human serum albumin–saline) or increasing concentrations of allergen into one or both sides of a washed nasal passage. The symptoms (e.g., itching, number of sneezes, rhinorrhea, and nasal conjugation) induced and/or concentration of mast-cell and basophil degranulation markers (e.g., histamine, tryptase, prostaglandin D_2, and cysteinyl leukotrienes) and cytokines (interleukin-4 [IL-4], IL-5, IL-10, and IL-13) released into nasal lavage fluids after each allergen dose indicates the relative level of sensitivity of the individual to that allergen. Nasal airway resistance is a less satisfactory endpoint because of high intrinsic variations.[24]

Oral Food Challenge Tests

Oral food challenges remain the definitive test for food hypersensitivity, since in vitro and other in vivo diagnostic methods suffer from suboptimal diagnostic specificity.[25] They are performed to establish an accurate diagnosis of food allergy or when skin tests are not possible because of atopic dermatitis or allergic GI disease or to assess the development of tolerance to a food. Passing a direct food challenge ideally permits reintroduction of the food into the patient's diet. Food-induced GI reactions (e.g., nausea, colic, vomiting, and diarrhea) can occur minutes to hours after the consumption of food allergens by a sensitized individual. Commonly eaten foods that contain potent allergens include cow milk, chicken egg white, cereal grains (wheat, rye, barley, oats), legumes (peanut, soybean, white bean), tree nuts, and fish and seafood.

Diagnosis of food allergy begins with a medical history, which includes an assessment of diet diaries and elimination diets. Skin tests and serological tests for IgE antibody to extracted food allergens and open food challenges with fresh and cooked foods are used to confirm sensitization to suspected foods. No evidence is available to indicate that food-specific IgG or IgG4 antibody levels have any diagnostic value.[26] The double-blind placebo-controlled food challenge (DBPCFC) is considered the definitive diagnostic test for food allergy.[25] The open food challenge is useful as a first-line challenge procedure because it is easier than DBPCFCs. Moreover, it is especially useful when the probability of a negative challenge is high, since a negative open challenge result can obviate the need for a DBPCFC and it reduces anxiety and the risk of bias in infants and young adults. An extensive discussion of open challenges, DBPCFCs, and variables that influence their outcome is presented elsewhere.[25]

In 2001, prospectively collected sera from 100 children and adolescents who had been previously evaluated by a skin test and DBPCFC were analyzed for food-specific IgE antibody.[27] Levels of IgE antibody specific for egg (7 kUa/L), milk (17 kUa/L), peanut (14 kUa/L), and fish (20 kUa/L) were identified, above which clinical reactivity could be predicted with more than 95% certainty. The study concluded that by measuring the concentration of food-specific IgE antibody, a subset of children who were highly likely (>95% probability) to experience a clinical reaction to egg, milk, peanut, or fish could be identified. This study and others subsequently have shown that judicious use of quantitative serological measurements for food-specific IgE antibody may be able to eliminate the need for time-consuming DBPCFCs in children who are suspected of having food allergy.

KEY CONCEPTS

Immunoglobulin E (Reaginic) Antibody Detection

- Allergen-specific immunoglobulin E (IgE) can be detected by the skin test using a puncture or intradermal (ID) administration of allergen or in the serum by laboratory-based immunoassays.
- In general, the ID skin test is more analytically sensitive than a puncture skin test, which is roughly comparable to the best in vitro methods for IgE antibody detection in serum.
- ID skin tests are the diagnostic procedure of choice in the work-up of patients with suspected *Hymenoptera* venom and drug allergy, while both in vitro an in vivo assay methods are complementary for evaluating aeroallergen-related disease.
- Serological analyses of IgE antibody specific for food allergens are often favored over extract-based skin test analyses in part because of more enhanced reagent quality control and pediatric acceptance. However, the double-blind placebo-controlled food challenge (DBPCFC) remains the gold standard for definitive diagnosis of food allergies.
- IgE antibody to allergenic molecules (components and epitopes) can in some cases (e.g., peanut and hazelnut) provide clarity in terms of the specificity of the patient's sensitization profile (genuine vs. cross-reactivity) and relative risk for mild vs. serious systemic reactions.

IN VITRO TESTING

Clinical immunology laboratories worldwide offer serological tests that are useful in the diagnosis and management of human allergic disease. Diagnostic analytes commonly measured in these laboratories include the total serum IgE, IgE antibodies to hundreds of allergen specificities, and mast-cell tryptase. IgG antibody measurements to allergens have not been shown to be predictive of protection. Basophil mediator and activation tests, although rarely offered as clinical tests because of the requirement for fresh blood, are useful investigational methods.

Total Serum Immunoglobulin E

Total serum IgE is currently the only diagnostic allergy analyte regulated under the US Clinical Laboratory Improvement Amendment of 1988 (CLIA-88). The minimum detectable concentration of commercial total serum IgE assays is 0.5 and 1 μg/L. The inter-method agreement of the different commercial IgE assays is excellent (e.g., inter-method coefficients of variation [CVs] typically <15%).[12,28] Nonatopic age-adjusted reference intervals for total serum IgE must be used for normative interpretation.[5]

Total Immunoglobulin E Measurements After Therapeutic Anti– Immunoglobulin E Administration

Omalizumab (anti-IgE) is used as a fourth therapeutic modality to supplement avoidance, pharmacotherapy, and immunotherapy in the management of persistent asthma and urticaria, and off-label for other IgE-mediated states (e.g., allergic bronchopulmonary aspergillosis, pretreatment of food allergy patients receiving immunotherapy). Since its conception, clinicians have desired to quantify total and "free" (uncomplexed) IgE levels in anti-IgE treated patients as a rationale for treatment failures or to justify modification of a patient's dosing regimen to maximize treatment success. A systematic evaluation of the impact of therapeutic anti-IgE on the performance of clinically used total IgE assays showed variable interference that resulted in a 1.9% to 51.9% reduction in accuracy, depending on the assay.[29] Accurate quantitation of the level of uncomplexed or "free" IgE in the serum of treated patients has been more technically difficult and thus is not recommended.[40]

Allergen-Specific Immunoglobulin E

Laboratories in the United States that perform clinical diagnostic allergy testing use assays that have been through rigorous validation, and have achieved unsurpassed intra-assay precision, inter-assay reproducibility, and a high degree of quantification.[12] Their basic design can be traced to the first IgE antibody assay, the RAST, reported by Wide et al. in 1967.[11]

Allergen

The most highly variable component of the IgE antibody assay is the allergen-containing reagent. Allergens are mixtures of molecules, typically proteins, glycoproteins, lipoproteins, or protein-conjugate chemicals or drugs that have been solubilized from a defined source, a portion of which can elicit an IgE antibody response in exposed and genetically predisposed individuals. They possess common properties of stability to heat and digestion because of multiple cysteine linkages. Allergens tend to be abundant in nature, form aggregates or polymers, commonly interact with lipid structures, and serve to defend their biological source. Cross-tabulation of the protein family (PFAM) database ($n = 16{,}230$ protein families) with the Structural Database of Allergenic Proteins (SDAP) identified 130 PFAMs in the Allergenic Family database of allergenic proteins. Thus, importantly, allergens comprise a small fraction of protein families with particular structures and biological functions.[30] The Clinical Laboratory Standards Institute (CLSI) has an established international guidance document that defines the expected performance characteristics of allergenic materials used in immunological assays for human IgE antibodies.[12] It provides a compendium of the genus and species of the allergen specificities of clinical interest, subdividing them into extract and component allergens. They are categorized based on their source, into weed pollen, grass pollen, tree pollen, animal dander, mold, house dust-mite fecal material, parasites, insect venoms, occupational allergens, foods, and drugs. Except for drugs, these extracts are complex heterogeneous mixtures that contain both nonallergenic and allergenic proteins. Some allergens share structural similarity or cross-reactive epitopes, and others possess unique IgE antibody-binding determinants. Extensive allergenic cross-reactivity has also been documented within pollen groups, such as the grasses (June, Brome, Timothy, Perennial Rye, Fescue, Orchard, Red Top, Salt, Sweet Vernal, Velvet). Conversely, other grass pollens, such as those produced by Bermuda Grass, Johnson Grass, and cultivated corn, oat, and wheat, are minimally cross-reactive (allergenically distinct). Variations in the allergenic content of extracted source materials, the extraction process from the raw source material, allergen-reagent manufacturing methods, differential binding to various allergosorbent supports, instability during storage, heterogeneity of internal reference allergen standards, and differences in characterization procedures (antisera, assays) make the production of reproducible allergens for in vitro use a challenge.

Cross-reactivity has also been shown at the allergen component level. There are 10 principal allergen families that show structural similarity and extensive cross-reactivity (Table 96.2).[31,32] The most prominent allergen component family is the pathogenesis-related (PR)–10 family of allergens, also known as the *Bet v 1 homologues*. These are small (17-kDa) proteins in many plant species that transport steroids and exhibit low stability at high pH and in the presence of digestive enzymes. The first allergen in this family was identified from birch pollen (Bet v 1). Others with high amino acid sequence homology include Cor a 1-hazelnut, Mal d 1-apple, Pru p 1-peach, Gly m 4-soybean, Ara h 8-peanut, Aln g 1-alder, Act d 8-kiwi, Api g 1-celery, and Dau c 1-carrot. Other component-based cross-reactivity groups include the profilins, nonspecific lipid transfer proteins, tropomyosins, serum albumins, polcalcins, lipocalins, parvalbumins, storage-binding proteins, and carbohydrate cross-reactive determinants (CCDs) (see Table 96.2). Each of these cross-reactive allergen families is extensively discussed in the *Handbook on Molecular Allergology*.[32]

Calibration

The second attribute that varies among commercially available allergen-specific IgE antibody assays is their calibration algorithm and methodology. Since no internationally recognized polyclonal human IgE antibody reference preparation exists, autoanalyzers in current commercial use employ a heterologous interpolation procedure in which allergen-specific IgE antibody response data are interpolated from a total serum IgE calibration curve. This procedure is valid as long as the total IgE calibrators and the patient's allergen-specific IgE antibody levels dilute out in parallel so that parallelism is maintained. The assays report IgE antibody levels in kUa/L units, using internal total IgE calibrators that are cross-verified and traceable to the World Health Organization (WHO) third IgE international reference preparation. This calibration system allows interpolation of IgE antibody results from a limit of quantitation of 0.1 kUa/L to 100 kUa/L levels of IgE antibody. In terms of quantitation, at least one of the IgE antibody autoanalyzers (ImmunoCAP) has demonstrated equivalence in which 1 kUa/L of chimeric allergen-specific IgE antibody was shown to be equivalent to 1 kU/L (2.4 ng/mL) of total serum IgE.[33]

Single-Plex, Multiallergen, and Multiplex Assays

The autoanalyzers in worldwide clinical use are single-plex assays in which one analyte is measured in a single analysis. In contrast, a multiplex antibody assay allows many specificities of a single antibody isotype to be individually detected and semiquantified in a single analysis. These are distinguished from a multiallergen screening assay, which is a form of single-plex analysis that involves the use of a mix of multiple allergens that is immobilized on the same allergosorbent. The purpose of the multiallergen assay is to simultaneously screen a serum for IgE antibody to a concise number (e.g., 10 to 15) allergens either of the same allergen source type (e.g., foods: chicken egg, cow's milk, peanut, soybean, cod fish) or diverse sources (e.g., respiratory allergens as an aeroallergen mix: pollen from select trees, grasses, weeds, pet epidermals, dust mites, molds).[34] A qualitative result (positive or negative) is generated, and it serves as an efficient single analysis to assess the general atopic status (IgE positivity) of an individual. Clinically, the multiaeroallergen screening assay has a high negative predictive power and thus is used to rule out IgE-mediated allergic disease where the suspicion based on the clinical history is weak.

The availability of unlimited quantities of molecular allergens has made it possible to develop multiplex chip-based microarrays for diagnostic allergy confirmatory testing. The present-day microarray for semiquantification of IgE antibody involves a preactivated glass slide (chip) on which 112 purified allergens are each immobilized in triplicate microdot arrays.[35] IgE anti–cow's milk components as measured in the multiplex immune solid phase chip or ISAC has agreed well with those obtained in a single-plex autoanalyzer using the same allergen specificities.[36]

TABLE 96.2 Principal Allergen Families and Their Associated Biological Functions

Family	Function	Diagnostic Utility and Clinical Features	Examples
Profilins	Actin-binding proteins involved in the dynamic turnover and restructuring of the actin cytoskeleton. Highly conserved, extremely cross-reactive and ubiquitous proteins in pollen and plant foods	Positive skin test and immunoglobulin E (IgE) responses to (nonrelated) pollen species (often including grasses) and plant food extracts are indicative for IgE cross-reactivity to profilins. After proof of sensitization to one profilin, pollen and plant food extracts are of no further use because of their subsequent lack of analytical specificity	Bet v 2 (birch); Phl p 12 (Timothy Grass); Hev b 8 (Natural Rubber Latex); Mal d 4 (apple)
Serum albumins	Highly cross-reactive plasma protein carriers involved in transport of hormones, enzymes, hemin, and fatty acids. Also maintains oncotic pressure	Positive skin test and IgE responses to furred animals indicate IgE cross-reactivity to mammalian serum albumins. Proof of sensitizations to one serum albumin can explain clinical symptoms to rarely or uncooked meat ("cat-pork-syndrome")	Fel d 2 (cat); Can f 3 (dog),
Pathogenesis-related proteins family 10 (PR-10), Bet v 1- homolog	Plant defense proteins; Bet v 1 is a quercetin-3-O-sophoroside-binding molecule (17 kDa); inflammation response proteins	Positive Bet v 1-specific IgE reflects sensitization to fagales tree pollen (i.e., hazel, alder, birch, beech, oak). Thermo and digestion labile Bet v 1-homologs in fruits, legumes, and vegetables. Bet v 1-sensitized individuals can cause predominantly oropharyngeal symptoms after consumption of raw food items (i.e., pip fruits, stone fruits, tree nuts, carrots, soy).	Bet v 1 (birch); Cor a 1 (hazelnut); Mal d 1 (apple); Gly m 4 (soy)
Polcalcin	Cross-reactive, ubiquitous calcium-binding proteins in pollen; involved in calcium regulation	Positive skin test and IgE responses to (nonrelated) pollen species are indicative for IgE cross-reactivity to polcalcins. After proof of sensitization to one, polcalcin pollen extracts are of no further use because of their subsequent lack of analytical specificity	Phl p 7 (Timothy Grass); Bet v 4 (birch); Amb a 10 (Short Ragweed)
Nonspecific lipid transfer proteins (nsLTP, PR-14)	Inflammation response proteins; responsible for shuttling phospholipids and other fatty acids between cell membranes	Primary food allergen after sensitization to peach lipid transfer protein (LTP) (possibly through the skin?); predominantly found in the Mediterranean subjects; variable degree of cross-reactivity between the thermally stable LTPs in fruits and vegetables frequently causing oropharyngeal and sometimes systemic symptoms (i.e., exercise-induced)	Pru p 3 (peach); Ara h 9 (peanut); Cor a 8 (hazelnut)
Lipocalins	A highly heterogeneous group of extracellular proteins within various subfamilies involved in transport of small hydrophobic molecules, such as steroids, bilins, retinoids, and lipids	Positive skin test and IgE responses to more than one or many furred animals are indicative for IgE sensitization and subsequent serological cross-reactivity to lipocalins of a certain subfamily. As a consequence, animal extracts are of no further use because of their subsequent lack of analytical specificity	Fel d 4, 7 (cat); Can f 1, 2, 4, 6 (dog)
Parvalbumins	Calcium-binding proteins; localized in fast-contracting muscles and being involved in calcium signaling	Thermostable and digestion-stable major fish allergen with fairly high, but not complete cross-reactivity and high abundance in almost all fish species. Only limited sequence homology and no cross-reactivity between fish and shellfish calcium-binding proteins	Gad c 1 (cod); Cra c 4, 6 (shrimp)
Tropomyosins	Integral components of actin filament that play a role in regulating muscle contraction. Also regulate actin filament stability in nonmuscle cells	Thermostable and digestion-stable major shellfish allergen with broad cross-reactivity and high abundance in all shellfish species. IgE sensitization is associated with allergic reactions to various panels of shellfish species	Der p 10 (dust mite); Pen m 1 (shrimp)
Seed storage proteins	Heterodimeric, stable and highly abundant proteins involved in nutrient storage: e.g., 2S albumins, 7/8S globulins (vicilins), 11S globulin (legumins)	Thermostable and digestion-stable important primary food allergens in legumes (peanut, soy), tree nuts (hazelnut), capsule fruits, and seeds with limited cross-reactivity within the subfamilies of different species; primary sensitization starts in early childhood and can persist lifelong; high allergen-specific IgE levels are associated with systemic allergic reactions	Ara h 2 and 1 and 3 (peanut); Cor a 14 and 11 and 9 (hazelnut)

Modified from the I/LA20 Guidance Document from the Clinical Laboratory Standard's Institute. Hamilton RG, Matsson PNJ, Chan S, et al. *Analytical Performance Characteristics, Quality Assurance and Clinical Utility of Immunological Assays for Human Immunoglobulin E (IgE) Antibodies of Defined Allergen Specificities*. 3rd ed. I/LA20-A3, International CLSI-Guideline. Wayne, PA: Clinical Laboratory Standards Institute; 2016.

Other groups have tried alternative multiplexing technologies to detect IgE antibodies that have included immobilizing allergen extracts on chips by using Luminex bead–based suspension arrays, employing nanotechnology biosensors, detecting surface plasmon resonance, and using plates equipped to produce electrical pulse–generated chemiluminescence. Single-plex systems have the advantage of greater analytical sensitivity or a lower limit of quantitation, greater precision and accuracy, more established internal and external quality control, and wider global availability of technology. In contrast, multiplex systems provide increased speed of analysis with reduced turnaround times, conservation of sample volume, greater simplicity, and reduced technical and reagent costs.[12]

The quality of allergen-specific IgE antibody results reported from clinical diagnostic allergy laboratories is not uniformly equivalent. In addition to the variability of results for a given serum between assays from different manufacturers as a result of allergen and calibration variance, the positive thresholds used for the same assay by different laboratories varies (e.g., 0.1, 0.35, and 0.7 kUa/L). Physicians requesting IgE antibody

testing thus bear some responsibility for determining the quality of the results they receive. In the United States, testing should be performed in a clinical laboratory that is federally licensed for highly complex immunology clinical testing under CLIA-88 (verified by requesting a copy of the federal laboratory license). The requesting physician should inquire about the assay method used, the source of its reagents, and how assays are quality controlled by the laboratory. As part of the formal record, the assay method used in patient analysis should be indicated on the final report.

Allergen-Specific Immunoglobulin G

Allergen immunotherapy is known to enhance the production of specific IgG "blocking" antibodies.[37] Quantitative measurements of allergen-specific total IgG or IgG subclass antibodies in studies of allergic rhinitis have not correlated with the control of clinical symptoms in individual patients. However, clinically successful immunotherapy is usually accompanied by high serum levels of allergen-specific IgG (typically IgG1 and IgG4) blocking antibodies. Despite a decrease to pre-immunotherapy baseline levels after 2 years of immunotherapy discontinuation, overall functional inhibitory activity, as measured by an IgE-dependent facilitated allergen binding assay, appears to be maintained.[37] For patients with *Hymenoptera* venom allergy, specific IgG antibody measurements have been used as an indicator of effective immunotherapy. Quantitative venom-specific IgG antibody levels may be useful in individualizing the dose and frequency of injections while maximizing the protective effects. However, their clinical utility may be restricted to the first 4 years of venom immunotherapy.[38] In contrast, the presence or levels of IgG antibodies specific for food antigens have shown no correlation with the results of positive DBPCFCs, and they are not indicated in the diagnostic work-up of a patient with suspected food allergy.[26]

CLINICAL PEARLS

Immunoglobulin G Antibody Measurements

- Clinically successful aeroallergen immunotherapy is almost always accompanied by high serum levels of allergen-specific immunoglobulin G (IgG; predominantly the IgG1 and IgG4 subclasses).
- Quantitative venom-specific IgG antibody levels can be of value in individualizing venom doses and frequencies for patients on venom immunotherapy for up to 4 years.
- Food-specific IgG and IgG4 assay results do not correlate with the results of double-blind placebo-controlled food challenges and are not clinically indicated.

Mast-Cell Tryptase

Mast cells have been identified in skin, respiratory, and digestive tract connective tissues and distinguished on the basis of the neutral proteases present in their secretory granules. One group of mast cells contains only tryptase, whereas the other contains both tryptase and chymase.[39] Mast-cell tryptase (MW 134 kDa) is a serine esterase with four subunits, each having an enzymatically active site. A resting mast cell contains 10 to 35 picograms (pg) of tryptase that is stored attached to heparin. When dissociated from heparin, it rapidly degrades into its monomers and loses enzymatic activity. As basophils have ~500-fold less tryptase compared with mast cells, elevated tryptase levels in serum are considered a relatively specific indicator of mast-cell involvement in a clinical reaction. Unstimulated tissue mast cells continually secrete immature protryptase into the tissue, and it diffuses into the circulation to provide a measure of total mast-cell number. α-Protryptase and β-protryptase represent the bulk of the immature tryptase in nonanaphylactic sera. α-Protryptase remains enzymatically inactive, whereas some of β-protryptase is autoprocessed from the proform within the mast cell into the mature enzyme by a dipeptidase where it is stored in granules. Only upon activation of mast cells are both the pro and mature forms of tryptase secreted in parallel with prestored histamine and newly generated vasoactive mediators. Total tryptase in serum from healthy humans ranges from 1 to 11.4 μg/L (average 3 to 5 μg/L). Mature tryptase is normally undetectable (<1 μg/L) in serum from healthy individuals who have no history of anaphylaxis during the preceding hours. Elevated levels of total tryptase (>11.4 μg/L) can be detected in serum 1 to 4 hours after the onset of systemic anaphylaxis with hypotension. Baseline levels of >20 μg/L are detected in most individuals with systemic mastocytosis. Recommended serum collection times for tryptase quantification range from 30 minutes to 4 hours after the onset of an acute event. Because serological tests for mature tryptase are not widely available, it is important to compare an acute event total tryptase level (within 4 hours) with a baseline total tryptase 24 hours after all signs and symptoms of the event have subsided. Reported mature tryptase levels in postmortem cases of fatal anaphylaxis have ranged from 12 to 150 μg/L in all nine fatalities caused by *Hymenoptera* venom and in six of eight food-induced fatalities.

ON THE HORIZON

New trends in laboratory methodology for the assessment of human allergic diseases include the following:

- Although there is a transition from the use of crude allergen extracts to allergenic components and epitopes in immunoglobulin E (IgE) antibody serological assays, extracts remain the principal allergen reagent source for the foreseeable future because of their comprehensive nature.
- Multiplexing platforms are being increasingly developed to allow rapid simultaneous detection of IgE antibodies to many allergenic components using microliter quantities of serum. However, due to their semiquantitative nature, fixed panel of specificities, and lower analytical sensitivity, single-plex assays will remain the most cost-effective and widely used assay format for the foreseeable future.
- Qualitative "point of care" IgE antibody assays to rapidly assess sensitization to aeroallergens during the patient's visit will be slow to be adopted because of their limited/fixed allergen menus, lower diagnostic sensitivity, and concern about potential patient misinterpretation of results.

The presence of IgE antibody whether detected by in vivo or in vitro assays is simply a confirmatory measurement for sensitization. Evidence of sensitization supports a patient's medical, family, and environmental histories of a temporal association between allergic symptoms and allergen exposure. For patients with allergies to inhaled allergens, both in vivo and in vitro diagnostic assays have equivalent utility in identifying sensitization. However, for those facing life-threatening anaphylactic reactions caused by venom and drug allergens, in vivo IDST and provocation methods are favored. In cases where antihistamines, β-receptor stimulants, or high-dose steroids reduce

an in vivo provocation test's measured response, as well as in children, pregnant women, and older patients, in whom skin testing may not be well tolerated and when dealing with allergens (e.g., foods, molds) where commercial extracts can be highly variable or labile, serological methods have distinct advantages. Above all, the presence of allergen-specific IgE antibody is necessary, but not sufficient, to identify an atopic state and is thus considered only one of the important risk factors that must be considered in the diagnosis of human allergic disease.

Selected CD Molecules and Their Characteristics

Thomas A. Fleisher

CD Molecule	Predominant Distribution	Identity/Function
CD1a–e	Thymocytes, subset of lymphocytes, antigen-presenting cells	MHC class I–like molecules; presentation of nonpeptide antigens to T cells; thymic T-cell development
CD2	T cells	Binds to LFA-3; receptor for CD48; T-cell activation; adhesion
CD3	T cells	T-cell signaling complex; associated with TCR
CD4	T-cell subset	TCR coreceptor; interacts with MHC class II molecules on antigen-presenting cells; identifies T cells with helper function; signal transduction
CD5	Most T cells, thymocytes, B-cell subset	Binds to CD72; regulation of cell proliferation/activation; identifies B-1 B-cell subset
CD6	Thymocytes, T cells, B-cell subset	Binds CD166 (ALCAM); adhesion; mediates binding of developing thymocytes with thymic epithelial cells; thymic development; T-cell activation
CD7	Pluripotent hematopoietic cells, thymocytes, T cells	T-cell and NK-cell development
CD8	T-cell subset	TCR coreceptor; interacts with MHC class I molecules on antigen-presenting cells; identifies T cells with cytotoxic function
CD10	B cells	Neutral endopeptidase; enkephalinase; B-cell development; common acute lymphoblastic leukemia antigen (CALLA), neutrophils
CD11a	Leukocytes	α-chain of LFA-1; pairs with CD18; interacts with ICAM; adhesion and cellular migration
CD11b	Monocytes, granulocytes, NK cells	α-chain of complement receptor type 3 (CR3); pairs with CD18; adhesion molecule
CD11c	Monocytes, granulocytes, NK cells	α-chain of complement receptor type 4 (CR4); pairs with CD18; adhesion molecule
CD13	Hematopoietic stem cells, immature and mature myeloid and monocyte elements	Appears before CD33 during myeloid differentiation
CD14	Granulocytes, monocytes/macrophages	Receptor for LPS/LPB complex; myeloid differentiation antigen; cell activation
CD15	Neutrophils, eosinophils, monocytes, basophil subset	Sialyl Lewis X antigen, plays a role in cell adhesion, defective in leukocyte adhesion deficiency type 2
CD16a,b	NK cells, monocytes/macrophages, neutrophils	FcγRIIIA and FcγRIIIB (low-affinity IgG receptors-type III); phagocytosis; ADCC
CD18	Leukocytes	β-chain of β_2-integrin molecules, including LFA-1, CR3, and CR4; pairs with CD11a, b, and c
CD19	B cells	BCR coreceptor; signal transduction; complexes with CD21, expressed pre-B cells
CD20	B cells	Role in B-cell activation/differentiation
CD21	B cells; follicular dendritic cells	Complement receptor type 2 (CR2): C3d receptor; B-cell coreceptor subunit; EBV receptor
CD22	B cells	Associates with BCR; signaling; regulation of B-cell activation; adhesion
CD23	B cells, macrophages, eosinophils, platelets, follicular dendritic cells	FcεRII; (low-affinity IgE receptor), activated B cells
CD24	Leukocytes	Heat-stable antigen; costimulation; adhesion
CD25	Activated T cells and B cells	α-chain of IL-2 receptor, low-affinity IL-2 binding; signaling for cell proliferation/differentiation
CD26	Activated T cells and B cells; macrophages	Dipeptidyl peptidase; role in extracellular adhesion; cell activation
CD27	T cells; B-cell subset	Costimulation; T-cell proliferation, memory B cells
CD28	T cells	Binds B7-1 (CD80) and B7-2 (CD86); T-cell costimulation; signal transduction
CD29	Leukocytes	Integrin β_1-chain; pairs with CD49a-CD49f to form VLA-1-VLA-6 integrins, respectively; adhesion; signal transduction; development
CD30	Activated B cells and T cells	Binds to CD153; T-cell activation/regulation/differentiation, Reed–Sternberg cells
CD31	Monocytes, granulocytes, platelets, endothelial cells, B cells Recent thymic emigrants	PECAM-1; binds to CD38; adhesion; signal transduction
CD32	B cells, monocytes/macrophages, granulocytes, eosinophils	FcgRII (low-affinity IgG receptor-type II) phagocytosis; ADCC; B-cell regulation
CD33	Myeloid progenitors, granulocytes	Binds sialic acid
CD34	Hematopoietic progenitor cells; capillary endothelium	Mucosialin; binds to CD62L; adhesion

Continued

CD Molecule	Predominant Distribution	Identity/Function
CD35	Leukocytes; erythrocytes	Complement receptor 1 (CR1); C3b and C4b receptor; phagocytosis
CD36	Monocytes/macrophages; endothelium; platelets	Binds oxidized LDL; scavenger receptor; binds apoptotic cells; adhesion and endocytic receptor; GPIIIb; platelet adhesion and aggregation
CD38	NK cells; T-cell and B-cell subsets; monocytes	Binds CD31; cyclase; hydrolase; cell activation
CD40	B cells; antigen-presenting cells	Binds CD154 (CD40 ligand); B-cell proliferation, differentiation, and survival; T-cell costimulation
CD41	Megakaryocytes/platelets	Glycoprotein IIb; a IIb integrin chain; binds fibronectin, fibrinogen, von Willebrand factor, thrombospondin; extracellular adhesion; platelet aggregation
CD43	Leukocytes (except resting B cells)	Leukocyte sialoglycoprotein; may bind CD54; signal transduction; adhesion; antiadhesion
CD44	Leukocytes; memory T cells; erythrocytes	Binds hyaluronan (H-CAM), collagen, fibronectin, laminin, osteopontin; extra- and intercellular adhesion; T-cell costimulation; leukocyte homing
CD45	Leukocytes (pan-leukocyte marker)	Protein tyrosine phosphatase; cell differentiation; lymphocyte signal transduction and activation
CD45RA	Naive T-cell marker (in conjunction with CD62L); B cells, monocytes	CD45 isoform
CD45RB	B-cell and T-cell subsets, monocytes/macrophages, granulocytes	CD45 isoform
CD45RO	Memory and activated T cells; B cells, monocytes/macrophages	CD45 isoform
CD46	Hematopoietic cells	Membrane cofactor protein (MCP); binds to C3b and C4b and regulates complement pathway
CD47R	Leukocytes; endothelium	Integrin-associated protein (IAP); leukocyte migration, extravasation, and activation
CD48	Leukocytes (not neutrophils)	Binds CD2; adhesion; costimulation
CD49a–f	Various distributions	Integrin a1-6 chain; binds to CD29 to form VLA-1 to VLA-6; binds extracellular matrix components such as fibronectin, laminin, collagen (CD49D binds VCAM-1, fibronectin, MAdCAM-1, invasin); lymphocyte homing; extracellular adhesion; embryonic development
CD50	Thymocytes, B cells, T cells, monocytes, granulocytes	ICAM-3; adhesion
CD51	Platelets/megakaryocytes, granulocytes, monocytes, T cells	Integrin α-chain; associates with CD61; binds vitronectin, fibronectin, fibrinogen; extracellular adhesion; T-cell costimulation; epithelial inflammatory response
CD52	Leukocytes	GPI linked, signaling, defined by CAMPATH-1
CD54	Broad distribution; increased on activated leukocytes	ICAM-1; binds LFA-1; adhesion; leukocyte transendothelial migration, rhinovirus receptor
CD55	Hematopoietic cells and some nonhematopoietic cells	Decay accelerating factor (DAF); binds complement fragment C3b; regulation of complement activation
CD56	NK cells, NK-T cells	NKH-1; adhesion
CD57	NK cells, T-cell subset, B cells, monocytes	Oligosaccharide expressed on cell surface glycoproteins
CD58	Hematopoietic cells and non-hematopoietic cells	LFA-3; binds CD2; adhesion; lymphocyte coactivation
CD59	Hematopoietic cells and non-hematopoietic cells	Binds complement components C8 and C9 and regulates assembly of complement membrane attack complex
CD61	Platelets/megakaryocytes, macrophages	Integrin β_3 subunit; associates with CD41 or CD51
CD62E	Endothelium	ELAM-1 or E-selection; binds sialyl-Lewis X; adhesion; mediates rolling interaction of neutrophils on endothelium and neutrophil extravasation
CD62L	B cells, T cells, monocytes, NK cells	LECAM-1, LAM-1 (or L-selectin); binds CD34 and GlyCAM; adhesion; mediates rolling interactions with endothelium and call extravasation
CD62P	Platelets/megakaryocytes, endothelium	P-selectin; binds sialyl-Lewis X; mediates interaction of platelets with neutrophils and monocytes; mediates rolling interaction of neutrophils with endothelium
CD64	Monocytes/macrophages, mature neutrophils	FcγR1 (high-affinity IgG receptor)
CD65	Neutrophils, eosinophils, basophils monocyte subset, CD56 bright NK cells	During myeloid differentiation, it appears after myeloperoxidase, appears to be the ligand for CD62L
CD66c	Differentiating myeloid cells peaks at promyelocyte stage, subpopulation of monocytes	Member of the carcinoembryonic antigen (CEA) family
CD68	Monocytes/macrophages	Macrosialin; early activation antigen; role in phagocytic activity
CD69	Activated T cells, B cells, macrophages, NK cells	Early activation antigen; costimulation
CD70	Activated B cells and T cells; macrophages	Binds to CD27; costimulation
CD71	Activated leukocytes, erythroid precursors	Transferrin receptor; cell activation
CD72	B cells	Ligand for CD5; B-cell activation and differentiation; costimulation
CD73	B-cell and T-cell subsets	Ecto-5′ nucleotidase; allows nucleoside uptake
CD74	MHC class II expressing cells	MHC class II–associated invariant chain; involved in antigen processing and peptide presentation in antigen-presenting cells
CD77	Germinal center B cells	Entering apoptosis

CD Molecule	Predominant Distribution	Identity/Function
CD79a,b	B cells	Iga, Igb; components of BCR complex that mediate signal transduction
CD80	Monocytes/macrophages, dendritic cells, activated B cells	B7-1; ligand for CD28 and CTLA-4; T-cell interaction with antigen-presenting cells; costimulation
CD81	Lymphocytes	Associates with CD19 and CD21 to form B-cell coreceptor complex; costimulation; adhesion
CD86	Monocytes, activated B cells	B7-2; ligand for CD28 and CTLA-4; T-cell interaction with antigen-presenting cells; costimulation
CD87	Granulocytes; monocytes/macrophages, activated T cells	Urokinase plasminogen activator receptor
CD88	Granulocytes, macrophages, mast cells	Complement component fragment C5a receptor
CD89	Monocytes/macrophages, granulocytes, B-cell and T-cell subsets	FcαR (IgA receptor)
CD91	Monocytes	α_2-macroglobulin receptor
CD94	NK cells, T-cell subset	Inhibits killing
CD95	Broad distribution	Fas or APO-1; induces apoptosis after being bound by Fas ligand
CD97	Activated B and T cells, monocytes, PMN	Activation antigen
CD102	Resting lymphocytes, monocytes, endothelial cells	ICAM-2; binds LFA-1 (CD11a/CD18); adhesion; T-cell costimulation
CD103	Intraepithelial lymphocytes, T-cell subset	αE integrin; T-cell development and costimulation
CD104	Epithelial cells, Schwann cells	β_4-integrin; epidermal adhesion to basement membrane
CD105	Endothelial cells, bone marrow cell subset, activated macrophages	Endoglin; adhesion
CD106	Endothelial cells	VCAM-1; ligand for VLA-4; lymphocyte adhesion; embryonic development
CD107a,b	Epithelial cells, subsets of monocytes, granulocytes, and lymphocytes	LAMP-1 and LAMP-2; adhesion
CD110	Hematopoietic stem cells, megakaryocytes, platelets	Thrombopoietin receptor; megakaryocyte proliferation and differentiation
CD114	Granulocytes	G-CSF receptor; regulates granulopoiesis
CD115	Monocytes/macrophages	M-CSF receptor; cell differentiation
CD116	Monocytes, neutrophils, eosinophils	GM-CSF a chain receptor; cell differentiation
CD117	Hematopoietic progenitors, mast cells	c-*kit*; stem cell factor (SCF) receptor; hematopoietic cell differentiation
CD118	Broad distribution	Type 1 interferon (interferon-α/β) receptor
CD119	Broad distribution	Interferon-γ receptor
CD120a	Hematopoietic cells, nonhematopoietic cells, myeloid cells	TNF receptor-type I signal transduction; apoptosis
CD120b	Hematopoietic cells, nonhematopoietic cells, myeloid cells	TNF receptor-type II; signal transduction; apoptosis
CD121a	Thymocytes, T-cell subset, fibroblasts, epithelial cells, and brain cells	IL-1 receptor-type I; signal transduction
CD121b	T-cell subset, myeloid cell subsets	IL-1 receptor-type II
CD122	NK cells, T-cell and B-cell subset	IL-2 and IL-15 receptor β chain; signal transduction; regulation of lymphocyte development, differentiation, activation, and proliferation
CD123	Bone marrow stem cells, granulocytes, monocytes, megakaryocytes	IL-3 receptor α chain; cell development and differentiation
CD124	Mature B cells and T cells, hematopoietic precursor cells	IL-4 receptor; signal transduction; lymphocyte development, activation, differentiation, and proliferation
CD125	Eosinophils, basophils, B-cell subset	IL-5 receptor; eosinophil and B-cell growth and differentiation
CD126	Activated B cells, plasma cells, T cells, granulocytes, monocytes/macrophages; also expressed on epithelial cells, fibroblasts, hepatocytes, and neural cells	IL-6 receptor α chain; regulation of B-cell and T-cell differentiation and function; hematopoiesis
CD127	Bone marrow lymphoid precursors, pro-B cells, T-cell precursors, T-cell subset, monocytes	IL-7 receptor α chain; signal transduction; B-cell and T-cell proliferation and differentiation
CD128	Neutrophils, basophils, T-cell subset	IL-8 receptor; neutrophil activation and migration
CD129	T cells	IL-9 receptor α chain; T-cell proliferation
CD130	Broad distribution	IL-6 receptor β chain (with CD126); signal transduction
CD131	Lymphocytes, granulocytes, monocytes	IL-3, IL-5, and GM-CSF receptor; common β chain; signal transduction; see CD123 and CD125
CD132	Lymphocytes	Common γ chain of high-affinity receptor for IL-2 (with CD25 and CD122), IL-4 (with CD124), IL-7 (with CD127), IL-9 (with CD129), and IL-15 (with CD122) receptors; signal transduction
CD134	Activated T cells	OX-40 antigen of TNFR superfamily (binds OX-40 ligand); T-cell–B-cell interaction and T-cell costimulation
CD135	Lymphoid and myeloid cell progenitor subsets	Flt3 ligand receptor; development of myeloid and lymphoid progenitors
CD137	Activated T cells	4-1BB; binds 4-1BB ligand and extracellular matrix components; T-cell–B-cell interaction and T-cell costimulation; extracellular adhesion; signal transduction

Continued

CD Molecule	Predominant Distribution	Identity/Function
CD138	B-cell subset, plasma cells, epithelial cells	Syndecan-1; binds interstitial matrix proteins; B cell–matrix interactions
CD140a,b	Endothelial cells	PDGF receptor α and β chain; embryonic development; signal transduction; chemotaxis
CD141	Endothelium	Thrombomodulin (binds thrombin); regulates coagulation
CD142	Endothelium	Tissue factor; binds plasma factors VII/VIIa; hemostasis, coagulation, and angiogenesis
CD143	Endothelium	Angiotensin-converting enzyme (ACE); binds angiotensin 1; regulates blood pressure
CD144	Endothelium	VE-cadherin; cell–cell adhesion; maintenance of endothelium integrity
CD146	Activated T-cell subset	Mel-CAM, adhesion molecule during development
CD150	T-cell and B-cell subsets	Surface lymphocyte activation marker (SLAM); B cell–T cell interaction; costimulation
CD151	Not defined	PETA-3; regulates platelet aggregation and mediator release
CD152	Activated T cells	CTLA-4; binds B7-1 (CD80) and B7-2 (CD86); T-cell costimulation–negative signal
CD153	T cells	CD30 ligand; T-cell activation, differentiation, and regulation
CD154	Activated T cells	CD40 ligand; T-cell costimulation
CD156a	Leukocytes, B cells	Transmembrane glycoprotein; disintegrin and metalloproteinase domain (ADAM) family member; leukocyte adhesion and protease function; infiltration of myelomonocytic cells
CD156b	Broad distribution	TNF-α-converting enzyme (TACE); disintegrin and metalloproteinase domain (ADAM) family member; cleaves TNF and transforming growth factor-α from cell surface, thereby releasing soluble form
CD158	NK cells	Killer immunoglobulin-like receptors (KIR); family of molecules that inhibit NK cytotoxic activity
CD159a	NK cells	NKG2A (killer cell lectin-like receptor)
CD161	NK cells	Natural killer cell receptor-P1; target cell recognition; NK cell activation
CD162	Granulocyte and T-cell subsets	P-selectin glycoprotein ligand-1 (PSGL-1); adhesion
CD166	Activated T cells, B cells	ALCAM; binds CD6; T-cell activation; thymocyte development
CD167a	Epithelial cells	Discoidin domain receptor 1 (DDD1); tyrosine kinase receptor; binds to collagen; cell–cell contact and adhesion
CD178	Activated T cells; various tissue cells	FAS ligand (ligand for CD95); binding to FAS triggers apoptosis
CD179a	Pro-B and pre-B cells	VpreB; forms surrogate light chain with CD179b; early B-cell differentiation
CD179b	Pro-B and pre-B cells	λ5; forms surrogate light chain with CD179a; early B-cell differentiation
CD180	B cells	RP105; toll-like receptor family; regulates B-cell recognition and signaling of LPS
CD183	Effector/memory T cells, NK cells, eosinophils	CXCR3 receptor for interferon-inducible chemokines IP10, Mig, and I-TAC; chemotactic migration of effector T cells into areas of inflammation
CD184	Leukocytes; hematopoietic progenitors	CXCR4 receptor for chemokines such as stromal cell-derived factor 1 (SDF-1) (fusin); chemotaxis; HIV-1 coreceptor
CD195	Broad distribution; myeloid cells, lymphocytes, T lymphocytes, neurons, epithelium, endothelium	CCR5 receptor for chemokines such as macrophage inflammatory proteins, MIP-1a and MIP-1b, and RANTES; chemotaxis; HIV-1 coreceptor
CDw197	Lymphoid tissues, B cells, T-cell subset	CCR7 chemokine receptor; chemotaxis; T-cell homing and migration
CD201	Endothelial cells	Protein C receptor; coagulation
CD203c	Mast cells, basophils	Member of the ectonucleotide pyrophosphatase/phosphodiesterase enzymes
CD204	Myeloid cells, monocytes/macrophages	Macrophage scavenger receptor-1 (MSR1); mediates binding, internalization, and processing of various negatively charged macromolecules
CD206	Dendritic cells, macrophages, myeloid cells, endothelial cells	Mannose receptor, C-type 1; binds microorganisms; phagocytosis
CD207	Dendritic cells, Langerhans cells	Langerin; mannose receptor; phagocytosis and internalization of antigen for processing
CD208	Dendritic cells	DC-LAMP
CD209	Dendritic cells	DC-SIGN
CDw210	Broad distribution	I1-10 receptor α and β chain
CD212	T cells, NK cells	IL-12 receptor β_1 chain
CD213a1, a2	Lymphocytes, bronchial epithelial and smooth muscle cells	IL-13 receptor α_1 and α_2 chains
CDw217	Activated T-cell subset	IL-17; cytotoxic T-lymphocyte–associated serine esterase 8; stimulates cell activation; induces osteoclast differentiation factor (ODF)
CD220	Broad distribution	Insulin receptor; stimulates glucose uptake
CD221	Broad distribution	Insulin-like growth factor 1 receptor; cell signaling; activation, and differentiation
CD222	Broad distribution	Mannose-6-phosphate receptor; insulin-like growth factor 2 receptor
CD226	NK cells, platelets, monocytes, T-cell subset	Platelet and T-cell activation antigen 1 (PTA1); adhesion
CD233–241	Erythrocytes	Various erythrocyte membrane antigens, including blood group–associated glycoproteins
CD242	Erythrocytes	ICAM-4
CD246	T cells	TCR or CD3 ζ chain; associated with TCR and CD3; couples TCR recognition with T-cell signaling
CD247	T cells	T cells ζ chain of the TcR
CD252	Activated B cells	OX40 ligand
CD253	Activated T cells	TRAIL, death receptor
CD254	Activated T cells, LN and BM stroma	RANK ligand
CD256	Monocytes, macrophages	APRIL, binds TACI and BCMA
CD257	Activated monocytes	BLyS, BAFF, binds TACI, BCMA, BAFFR, induces B-cell proliferation

CD Molecule	Predominant Distribution	Identity/Function
CD261	Activated T cells, peripheral leukocytes	TRAIL-R2, DR5, death receptor
CD262	Peripheral lymphocytes	TRAIL-R1, DR4, death receptor
CD263	Peripheral lymphocytes	TRAIL-R3, DcR1, death receptor
CD264	Peripheral lymphocytes	TRAIL-R4, DcR2, death receptor
CD265	Broad distribution	RANK
CD267	B cells, activated T cells	TACI
CD268	B cells	BAFFR, binds BLys, mature B-cell survival
CD269	Mature B cells	BCMA, binds APRIL and BAFF, B-cell survival and proliferation
CD275	B cells, dendritic cells, monocytes	ICOSL, costimulation, cytokine production
CD278	Activated T cells	ICOS, T-cell costimulation

ADCC, Antibody-dependent cellular cytotoxicity; *ALCAM*, activated leukocyte cell adhesion molecule; *APRIL*, a proliferation-inducing ligand; *BCMA*, B-cell maturation antigen; *BCR*, B-cell receptor for antigen; *DC*, dendritic cell; *CTLA*, cytotoxic T lymphocyte antigen; *EBV*, Epstein-Barr virus; *ELAM*, endothelial leukocyte adhesion molecule; *G-CSF*, granulocyte–colony-stimulating factor; *GM-CSF*, granulocyte macrophage–colony-stimulating factor; *GPI*, glycosyl-phosphatidylinositol; *HIV*, human immunodeficiency virus; *ICAM*, intercellular adhesion molecule; *ICOS*, inducible T-cell costimulator; *Ig*, immunoglobulin; IL, interleukin; *LAM*, leukocyte adhesion molecule; *LAMP*, latent membrane protein; *LDL*, low-density lipoproteins; *LECAM*, lymphocyte endothelial cell adhesion molecule; *LFA*, lymphocyte function antigen; *LPB*, lipopolysaccharide binding protein; *LPS*, lipopolysaccharide; *MAdCAM-1*, mucosal addressin cell adhesion molecule-1; *M-CSF*, macrophage colony-stimulating factor; *MHC*, major histocompatibility complex; *NK cells*, natural killer cells; *PDGF*, platelet-derived growth factor; *PECAM*, platelet endothelial cell adhesion molecule; *PETA*, platelet-endothelial cell tetraspan antigen; *PMN*, polymorphonuclear neutrophil; *SIGN*, specific intercellular adhesion molecule–grabbing nonintegrin; *TACI*, transmembrane activator and CAML interactor; *TCR*, T-cell receptor for antigen; *TNF*, tumor necrosis factor; *TNFR*, tumor necrosis factor receptor; *TRAIL*, TNF-related apoptosis inducing ligand; *VCAM*, vascular cellular adhesion molecule; *VLA*, very late antigen.

This list was adapted from the results of the Eighth International Workshop on Human Leukocyte Differentiation Antigens (HLDA8) held in Adelaide, Australia, in December 2004 (Proceedings of the 8th International Workshop on Human Leukocyte Differentiation Antigens. December 12–16, 2004. Adelaide, Australia. *Cell Immunol.* 2005;236[1–2]:1–187). Engel P, Boumsell L, Balderas R, et al. CD nomenclature 2015: human leukocyte differentiation antigen workshops as a driving force in immunology. *J Immunol.* 2015;195:4555–4563.

Immunoglobulin (Ig) levels were assessed in serum by nephelometry, and data were statistically analyzed for the mid-95% confidence interval. For total IgG and IgG subclass quantitation, data from 156 pediatric and 92 adult donors were used; for total IgA quantitation, data from 201 pediatric and 99 adult donors were used; for IgA subclasses, data from 119 pediatric and 99 adult donors were used; and for IgM quantitation, data from 212 pediatric and 401 adults were used at Mayo Medical Laboratories.

TABLE A2.2 Total Serum IgE (IU/mL)

Age	Gender	Geometric Mean	Upper 95% Confidence Limit
6–14 years	M	42.7	527
	F	43.3	344
15–24 years	M	33.6	447
	F	18.6	262
25–34 years	M	16.8	275
	F	16.6	216
35–44 years	M	21.7	242
	F	19.3	206
45–54 years	M	19.2	254
	F	13.3	177
55–64 years	M	21.3	354
	F	11.7	148
65–74 years	M	21.2	248
	F	11.5	122
>75 years	M	18.4	219
	F	9.2	124
6–75 years	all M	22.9	317
	all F	14.7	189

Data were generated using individuals with negative skin prick tests (i.e., house dust mite, Bermuda grass, tree mix, weed mix, mold mix).
From Barbee RA, Halonen M, Lebowitz M, Burrows B. Distribution of IgE in a community population sample: correlations with age, sex, and allergen skin test reactivity. *J Allergy Clin Immunol.* 1981;68(2):106–11, with permission.

TABLE A2.3 Lymphocyte Immunophenotype (see Chapter 93): Adult Reference Range Expressed as 95% Confidence Intervals

Surface Antigens	Percent Positive	Cells/MM³
T cells		
CD3	55.3–87.7	651–2804
CD3/TcR alpha/beta	53.0–83.6	585–2716
