Producing an effective adaptive immune response to *S. pyogenes* has been challenging due to the development of rheumatic heart disease, an autoimmune disorder in which cross-reactive antibodies against *S. pyogenes* bind to epitopes on heart tissue and antagonize heart valves. The mechanism by which this occurs is still unclear. Other studies have indicated that *S. pyogenes* is capable of evading B cell–mediated responses via superantigen SpeA, resulting in the production of abnormal follicular helper T cells, leading to B-cell death.[40] In contrast, B cells can produce antigen-specific IgG or IgM toward other extracellular bacterial pathogens such as *Staphylococcus aureus*. Neonates often receive IgG antibodies against *S. aureus* from their mother during pregnancy. The importance of B cells in resolving *S. aureus* infection can be seen in HIV-infected patients where the decline of CD4 T cells, responsible for assisting B-cell germinal centers, results in increased incidence of *S. aureus* infection.

Immunoglobulins

Immunoglobulins (Igs), principally secretory IgA and IgG, are present at mucosal surfaces and in mucosal secretions. Dissemination of IgA and IgG class–committed B- and T-helper (Th) cells with specificity to an antigen encountered and processed at a mucosal site to the mucosal site where the antigen was encountered and to distant mucosal sites is important in the generation of mucosal immunoglobulins. Protective mucosal antibodies against bacteria may be derived from prior colonization, vaccines, or shared cross-reactive antigens on normal flora. Mucosal immunoglobulins may neutralize bacterial toxins, facilitate phagocytosis or bactericidal activity, inhibit bacterial adherence ligands, or sterically hinder other events necessary for bacterial colonization and invasion. Many extracellular bacterial pathogens (*N. meningitidis*, *N. gonorrhoeae*, *H. influenzae*, certain streptococci) colonize and/or infect mucosal surfaces where protective IgA_1 antibodies could become available. These pathogens secrete an IgA_1 protease that cleaves IgA_1, thereby inactivating the molecule. IgA_1 protease can also recognize other substrates, notably lysosomal-associated membrane protein 1 (LAMP-1), which are important in host defense.

HOST RISK FACTORS FOR LOCAL AND SYSTEMIC INVASION BY EXTRACELLULAR PATHOGENS AND SPIROCHETES

Bacteria that breach mucosal and skin barriers and reach submucosal tissues of sites, such as pulmonary alveoli, the middle ear, and the bloodstream, induce immune responses, including cytokine release, phagocytosis, complement activation, antibody release or production, and other local or systemic induction of the inflammatory cascade (Fig. 27.5). The survival of bacteria following colonization of the epithelium and access to the bloodstream depends on the integrity of the host immune

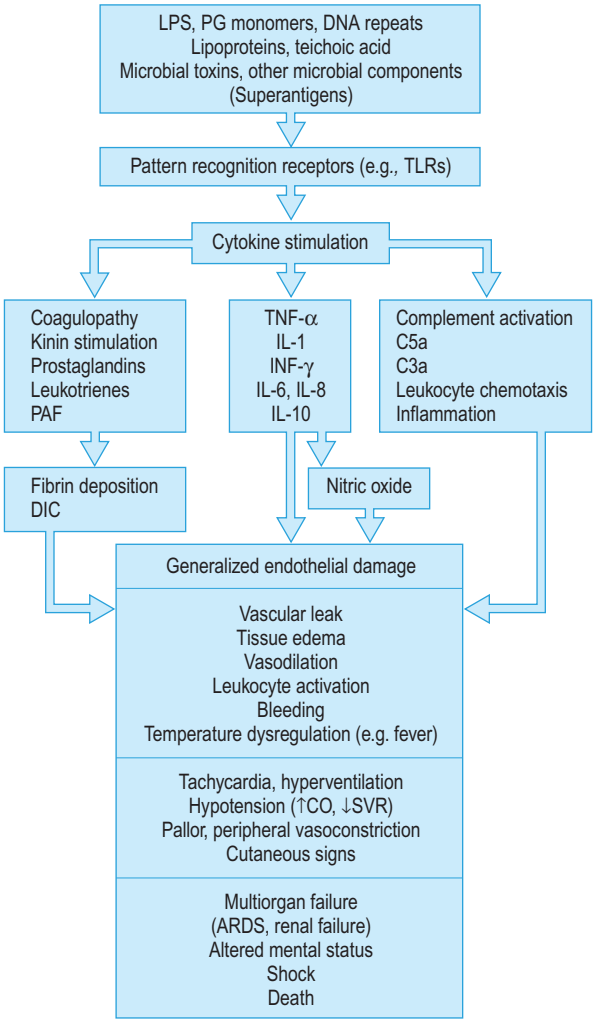

FIG. 27.5 Inflammatory Cascade Initiated During Sepsis.

response (including variability caused by genetic polymorphisms) and on the ability of the bacteria to resist this host immune response. Host factors that increase the risk for the development of systemic disease as a result of extracellular bacteria include polymorphisms in innate immune mechanisms, the absence of bactericidal or opsonizing antibodies, deficiencies in the complement pathways, and an absence of or reduction in neutrophil function or levels (see Table 27.1).

Complement deficiencies, either congenital or acquired, increase the risk for invasive bacterial diseases. Because C3 plays a critical role in the complement cascade, congenital C3 deficiency or conditions that reduce C3 (e.g., systemic lupus erythematosus, cirrhosis, nephritis, C3 nephritic factor) increase the risk for invasive disease due to pyogenic bacteria, such as *S. pneumoniae* and *N. meningitidis*. Mannose-binding lectin (MBL) is a plasma opsonin that initiates complement activation. *MBL* gene polymorphisms are associated with meningococcal and pneumococcal sepsis during childhood. Properdin deficiency, leading to defective AP killing, is also associated with severe and recurrent meningococcal infections. Terminal complement deficiencies (C5–C8) are also associated with recurrent invasive bloodstream meningococcal and gonococcal infections, indicating an important role for insertion of the complement MAC in the bactericidal activity of human serum against pathogenic *Neisseria*.

In addition to defects in innate immunity, immunoglobulins, and complement deficiencies, human genetic polymorphisms are associated with an increased risk or severity of bacterial diseases. For example, FcγIIa (CD32) receptor polymorphisms, Fcγ-receptor III (CD16), MBL, TLR4, TNF promoter region polymorphisms, plasminogen activator and inhibitor expression, and hereditary differences in cytokine induction influence susceptibility to meningococcemia. Each of these polymorphisms can influence the course of invasive bacterial infection by influencing the response of the inflammatory cascade.

DELETERIOUS HOST RESPONSES

Inflammation and Autoimmunity

The host immune response can be the leading cause of tissue injury in the acute phase of an infection. Brain edema and infarcts, which are devastating consequences of pyogenic meningitis, occur as a result of the host inflammatory response. Corticosteroids are currently recommended as an adjunctive therapy to pneumococcal meningitis, an acute pyogenic infection. The use of small molecules targeting specific immunological pathways is an area of ongoing research. As acute infections are initially characterized by an inflammatory response followed by an anti-inflammatory response, the timing of use of these compounds is of the utmost importance.[41] Molecular mimicry between a bacterial antigen and a host protein can lead to autoimmunity. Examples include rheumatic fever and glomerulonephritis after *S. pyogenes* infections, reactive arthritis following *Chlamydia trachomatis* urethritis, and the Guillain-Barré syndrome following *Campylobacter jejuni* enteritis. Molecular mimicry can also limit selection of epitopes for vaccine development.

Sepsis

Septicemia remains a leading cause of death in the United States and accounts for several billion dollars in healthcare expenditure.[41] Both gram-negative and gram-positive bacteria can rapidly multiply in the bloodstream and trigger sepsis and septic shock. Septic shock is a result of an initial and widespread systemic proinflammatory response, resulting in hypotension, organ failure, and death. The later phase of sepsis is also characterized by an antiinflammatory response. Although survival of patients with the acute phase of sepsis has improved, advances in treatment and prevention of death, which can be secondary to nosocomial infections, have been slower. These secondary infections are often caused by less virulent organisms, likely as a result of "immunoparalysis" (as a result of an exaggerated anti-inflammatory reaction) and also breaching of the physical barriers to infection as a result of invasive medical procedures (e.g., intravenous lines, intubation, and bladder catheterization). The systemic inflammatory cascade of sepsis is initiated by recognition of PAMPs by PRR, both in extracellular (e.g., LPS) and intracellular environments (e.g., DNA fragments). The severity of sepsis is also influenced by polymorphic alleles of genes involved in the inflammatory cascade.[41]

The morbidity and mortality of bacteremia and sepsis have been directly correlated with the initial levels of proinflammatory cytokines and the amount of circulating bacterial components. Indeed, the severity of gram-negative sepsis has been equated with high levels of endotoxin, increased levels of cytokines, and excessive activation of the AP. Disseminated intravascular coagulation, which often accompanies gram-negative sepsis, is

caused by excessive activation of the coagulation cascade and downregulation of the fibrinolytic system associated with high levels of LPS. Levels of natural anticoagulants in the vasculature, such as antithrombin and protein C, are often low in gram-negative sepsis. The onset and severity of disseminated intravascular coagulation may be influenced by genetic polymorphisms in plasminogen activation or inhibition. The generalized, altered vascular endothelial lining facilitates thrombosis and thrombocytosis. Although much remains to be learned about the mechanisms by which gram-negative and gram-positive bacteria and microbial products trigger sepsis, significant advances have been made recently, particularly with endotoxin-mediated sepsis. Advances during the past decade include the identification of certain LPS–host protein interactions that result in delivery of LPS to host cell receptors and gene activation events that result in elevated expression of a diverse array of proinflammatory and antiinflammatory mediators (Fig. 27.6).

For example, TLR4 signaling requires an accessory protein, myeloid differentiation protein-2 (MD-2), which binds directly to endotoxin. The key point, however, is that the LPS engagement of MD-2/TLR4 on host cells, particularly macrophages, triggers intracellular signaling events that ultimately, through nuclear factor kappa B (NF-κB) and other pathways, result in cytokine gene activation and production of cytokines (TNF, IL-1, IL-6, IL-8, IFNs). Other TLRs (e.g., TLR2) play a critical role in the recognition of lipoproteins, and the recognition of these components is a likely key determinant in the development of septic shock seen with gram-positive infections. TLR5 recognizes bacterial flagella, and such recognition is of importance in the host response to motile bacteria. Some human pathogens (e.g., *H. pylori*) produce flagellin molecules that do not engage TLR5. TLR9 has been shown to recognize bacterial DNA CpG dinucleotides. Taken together, the clinical syndrome of septic shock represents a series of interactions of bacterial products in the vascular space with pattern recognition molecules on serum proteins (lipopolysaccharide-binding protein [LBP] and soluble CD14) and with host cell receptors (MD-2/TLR4 and TLR2, other TLRs), leading to signaling events and release of transcriptional factors that modulate cytokine gene expression. These events also trigger other events in the inflammatory cascade, leading to activation of the coagulation, complement, and kinin pathways. Superantigens can activate large pools of non–antigen-specific T cells by binding to MHC class II molecules and the TCR Vβ region outside the peptide-binding domain. The result is a cytokine storm with clinical manifestations of sepsis.

Early and effective antimicrobial therapy is the primary goal in the treatment of sepsis. In contrast to the initial phase of sepsis characterized by the release of TNF, IL-1, IL-6, and IFN-γ, an antiinflammatory response may predominate during the latter phase. The clinical failures of antiinflammatory therapeutic mediators (antiendotoxin antibodies, TNF, antagonists of IL-1, or platelet-activating factor) in sepsis suggests that this hypoinflammatory state encountered in many patients at presentation could be an additional target of immune modulation.

THERAPEUTIC PRINCIPLES

Sepsis

- Early effective antibiotic therapy associated with improved outcomes
- Lack of "source control" (e.g., removal of infected lines, drainage of abscesses) linked to poor outcomes even in the presence of effective antibiotics
- Intensive and supportive care, management of fluid, electrolytes, and respiratory function
- Insulin for glucose control—unknown mechanism of protection; neutrophils have impaired function in the presence of hyperglycemia, insulin can have antiapoptotic effects

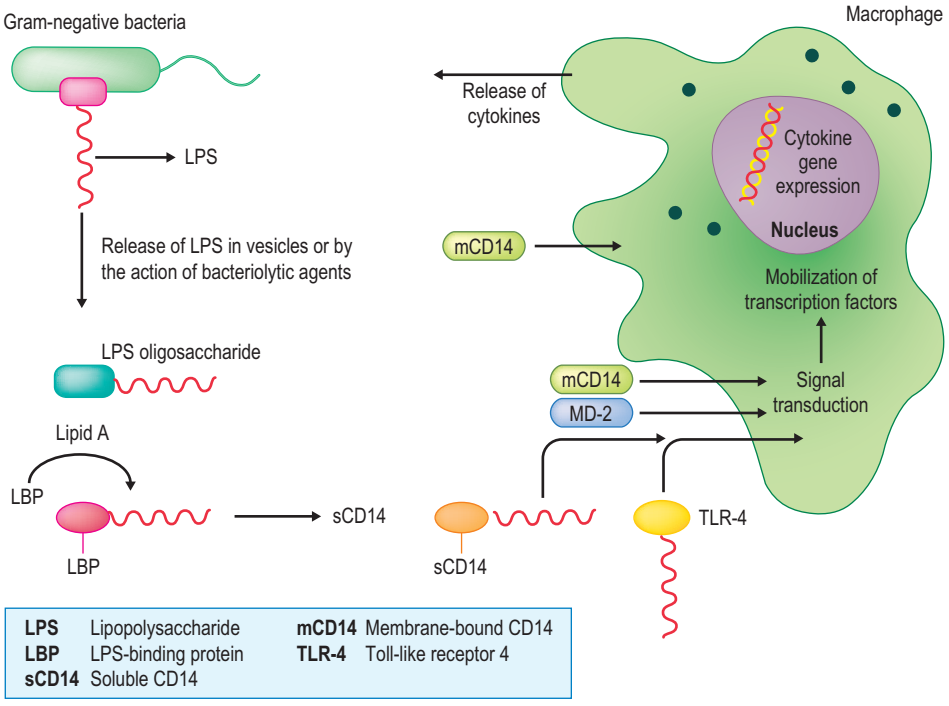

FIG. 27.6 Lipopolysaccharide *(LPS)* Triggering of Cytokine Production by Macrophages. Steps known or presumed to be necessary for LPS triggering of proinflammatory cytokines.

TRANSLATIONAL RESEARCH OPPORTUNITIES

An important challenge for the next decade will be to take the rapidly expanding basic discoveries in innate immunity, systems biology, and response to bacterial antigens into clinical applications. The design and use of bacterial vaccines through the assessment of innate immune molecular signatures after vaccination, both for general use and for subpopulations of nonresponders, is one example. A second is the continued development of small-molecule inhibitors or enhancers that target innate immune pathways to modulate bacterial immune responses. A third is the control of mucosal immune responses to prevent or eliminate colonization by bacterial pathogens. A fourth is the understanding of the role of the microbiome in shaping the immune response to pathogens and vaccines and its therapeutic potential for both infections and noninfectious diseases. Fecal microbiota transplantation for *C. difficile* colitis is an early example of therapeutic use of the microbiome. Finally, the development of new therapies for acute bacterial sepsis may be based on improved understanding and control of the immune responses in sepsis.[42]

The challenge in the next 5 to 10 years is to develop better diagnostic methods for both Lyme disease and syphilis and to devise new preventive measures. For Lyme disease, advances in genetic manipulation, as well as other means to study structure/function of key components of the spirochete, could lead to development of single or combination vaccines. Furthermore, the identification of host factors that mediate a protective response and those that contribute to inflammation may result in a better understanding of the disease. Overall, the identification of the elements that mediate specific tissue tropisms for the bacterium and their interaction with local/infiltrating cellular components can permit the design of targeted therapies in conjunction with antimicrobial treatments.

A significant effort is being made to find new antigenic determinants that can be the base for a vaccine to prevent infection with *B. burgdorferi*. While the search for spirochetal antigens continues, a new wave of research has focused on finding antigenic determinants that can prevent the efficient attachment of the tick vector to the mammalian host, which, in turn, could dampen the ability of the arthropod to transmit *B. burgdorferi* and perhaps other pathogens.

For syphilis, the study of the microorganism is hampered by the difficulties associated with its culture and manipulation. Although advances have been made in our understanding of the pathology associated with infection, a significant challenge in the near future is to fully understand this pathogen. Despite availability of a safe and effective therapy since 1943 (penicillin), syphilis control remains elusive and there has been a resurgence over the last two decades, including in high-income countries. Over the next decade, increasing uptake of existing preventive methods (e.g., male condoms), developing more effective patient-centered education methods, and new prevention methods (e.g., pre-exposure prophylaxis) could curb the current syphilis epidemic.

KEY CONCEPTS

Protective Versus Pathological Responses

Borrelia burgdorferi

- An early immune response to *B. burgdorferi* is necessary to control spirochetal burden; however, by itself, it is not sufficient to resolve infection.
- Phagocytosis is a key element of the innate immune response, which is involved in the elimination of the bacteria while also contributing to the proinflammatory output of macrophages.
- A T cell–mediated response appears to be involved in pathology arising from infection.
- A T cell–independent B-cell response is sufficient to resolve infection with *B. burgdorferi*.

Treponema pallidum

- The role of the early innate response to *T. pallidum* is poorly understood because:
- A cell-mediated immune response to *T. pallidum* is likely involved in the development of pathology following infection with the spirochete and resolution of infection.
- The humoral response is unclear; no definite antigens have been isolated due to inability to cultivate organism in vitro.

ON THE HORIZON

- Tailoring vaccine design based on assessment of innate immune molecular signatures
- New-generation vaccines for Lyme disease that target tick vectors
- Small-molecule inhibitors or enhancers specifically targeting innate immune pathways
- Identification of immune responses that prevent or eliminate mucosal bacterial pathogen colonization
- Development of new therapies modulating immune response in sepsis
- Defining microbial community and metagenome changes after antibiotic treatment
- Managing disease based on the human microbiome
- Efficient diagnostics for spirochete infection
- Investments in prophylaxis and treatments for communities at risk for syphilis

Host Defenses to Fungi

Tobias M. Hohl, Bruce S. Klein, and Michail S. Lionakis

Advances in modern medicine exemplified by immunosuppressive therapies for autoimmunity, precision, and myeloablative therapies for cancer, and hematopoietic stem cell and solid organ transplantation for hematological malignancies and end-organ failure have resulted in a significant expansion of patient populations at risk for developing life-threatening opportunistic fungal infections.[1] The acquired immunodeficiency syndrome (AIDS) pandemic continues to cause significant mortality associated with AIDS-defining mycoses, primarily cryptococcosis and *Pneumocystis* pneumonia in developing regions of the globe. Notably, although there are ~5 million different fungal species, only a few cause human disease (Table 28.1); this is explained by the inability of most fungi to grow at human body temperatures and the robust innate and adaptive antifungal immune responses in immunocompetent individuals.

In recent years, we have witnessed significant progress in understanding (1) the cellular and molecular factors that promote protective antifungal immunity in humans and (2) the genetic and pharmacological factors that heighten human susceptibility to opportunistic mycoses. This immunological knowledge is critical in informing therapeutic and vaccination strategies to combat life-threatening fungal infections in vulnerable patients. Here, we outline recent mechanistic advances on the role of fungal recognition pathways in human antifungal immunity, and we highlight the molecular and cellular basis of host defense against medically important *Candida, Cryptococcus, Aspergillus, Mucorales, Histoplasma, Coccidioides*, and *Blastomyces* with a focus on observations that have clinical and translational implications.

FUNGAL RECOGNITION PATHWAYS AND THEIR CONTRIBUTION TO HUMAN ANTIFUNGAL HOST DEFENSE

Sensing of fungal pathogen-associated molecular patterns (PAMPs) by pattern recognition receptors (PRRs) of innate immune and epithelial cells is the first step in mounting antifungal immune responses. PRR engagement induces signaling cascades that promote the orchestrated recruitment and activation of innate and adaptive immune cells in infected tissues to achieve fungal clearance.[2–5] The C-type lectin receptors (CLRs) and Toll-like receptors (TLRs) are the principal fungal-sensing PRRs, whereas retinoic acid-inducible gene I-like receptors (RLRs) and nucleotide-binding oligomerization domain-like receptors (NLRs) also recognize fungi (Table 28.2); notably, collaborative PRR engagement also occurs and can be exploited clinically as in human chromoblastomycosis.

A major recent breakthrough in the fungal immunology field has been the demonstration of the indispensable contribution of CLR-mediated fungal recognition in human antifungal immunity and the delineation of the function of several members of the CLR signaling pathway (Fig. 28.1).

In brief, binding of Dectin-1 by β-glucan and of Dectin-2, Dectin-3, or Mincle by other fungal polysaccharide PAMPs (e.g., α-mannan) sequentially activates spleen tyrosine kinase (Syk), the CARD9/MALT1/BCL10 complex, and nuclear factor kappa B (NF-κB), which results in inflammasome activation, proinflammatory cytokine and chemokine production, leukocyte recruitment and activation, and Th17 differentiation.[2–4]

CLINICAL RELEVANCE

Immunotherapy Lessons Derived From Improved Basic Understanding of Antifungal Immune Responses

- Collaboration between different fungal pattern recognition receptors may augment downstream protective responses as shown in human chromoblastomycosis where the topical application of the TLR7 agonist imiquimod on skin fungal lesions resulted in clinical remission via synergistic TLR7-Mincle–mediated immunity.
- Adult-onset invasive fungal disease caused by neutralizing autoantibodies against IFN-γ or GM-CSF may respond to B-cell– or plasma cell–depleting therapy with anti-CD20– or anti-CD38–targeted monoclonal antibodies.
- Disseminated infections by intramacrophagic fungi caused by mutations in *IL12RB1* or *STAT4* or by partial IFN-γR1 deficiency may respond to adjunct recombinant IFN-γ treatment.

KEY CONCEPTS

The C-Type Lectin Receptor Pathway

- Dectin-1 binding activates Syk via Src-dependent phosphorylation of its immunoreceptor tyrosine-based activation motif (ITAM), which involves recruitment of the tyrosine phosphatase SHP-2.
- Dectin-2, Dectin-3, and Mincle binding activates Syk via engagement of the ITAM-containing adaptor FcRγ.
- Downstream of Syk activation, the protein kinase C-δ and Vav proteins phosphorylate CARD9, which leads to the formation of the CARD9/MALT1/BCL10 complex and activation of the canonical nuclear factor kappa B (NF-κB) pathway.
- Binding of Dectin-1 can also activate the noncanonical NF-κB pathway (via RAF-1 engagement) or the ERK pathway (via H-Ras and Ras-GRF1 activation).
- CLR/Syk signaling may also negatively regulate antifungal immune responses through JNK1 signaling (via the C-type lectin receptor CD23/FCER2A) or the E3-ubiquitin ligase CBLB. Concordantly, inhibition of JNK1 or CBLB restores antifungal effector functions of phagocytes and improves survival in mouse models of invasive fungal disease.

TABLE 28.1 Common Human Fungal Diseases

Fungal Infection (Most Common Fungal Genera or Species)	Fungal Morphotype	Clinical Syndromes	Common Patient Populations With Acquired Conditions That Place Them At Risk for the Indicated Clinical Syndromes
Candidiasis (*Candida albicans, C. glabrata, C. tropicalis, C. parapsilosis, C. auris*)	Yeast (±pseudohyphae depending on the genera)	Oropharyngeal candidiasis	AIDS
		Esophageal candidiasis	AIDS
		Vulvovaginal candidiasis	Antibiotic use
		Candidemia	Critical illness (ICU)
		Disseminated infection with seeding of various deep-seated organs (kidney, liver, spleen, brain, bone)	Iatrogenic immunosuppression (neutropenia, corticosteroid use)
Cryptococcosis (*Cryptococcus neoformans, C. gattii*)	Yeast	Pneumonia	AIDS, corticosteroid use
		Meningoencephalitis	AIDS
		Disseminated infection	AIDS
Aspergillosis (*Aspergillus fumigatus, A. flavus, A. terreus, A. niger, A. ustus, A. nidulans*)	Mold	Pneumonia	Neutropenia, HSCT
		Disseminated infection	Neutropenia, HSCT
		Keratitis	Direct inoculation
		Allergic bronchopulmonary aspergillosis	Atopy
		Chronic cavitary lung disease	Structural lung disease
Mucormycosis (*Rhizopus, Mucor, Absidia, Rhizomucor, Cunninghamella, Saksenaea, Lichtheimia*)	Mold	Sinopulmonary infection	Neutropenia, HSCT
		Rhinocerebral infection	Diabetic ketoacidosis
		Necrotizing skin infection	Direct inoculation (e.g., victims of natural disasters)
Fusariosis (*Fusarium solani, F. oxysporum, F. proliferatum*)	Mold	Pneumonia	Neutropenia
		Disseminated infection	Neutropenia
		Keratitis	Direct inoculation
Scedosporiosis (*Scedosporium apiospermum, Lomentospora prolificans*)	Mold	Pneumonia	Neutropenia, HSCT
		Disseminated infection	Neutropenia, HSCT
		Skin and subcutaneous tissue infections	Direct inoculation
Histoplasmosis (*Histoplasma capsulatum*)	Dimorphic fungus	Pneumonia	Healthy individuals
		Disseminated infection	AIDS, SOT
		Fibrosing mediastinitis	
Coccidioidomycosis (*Coccidioides immitis, C. posadasii*)	Dimorphic fungus	Pneumonia	Healthy individuals
		Disseminated infection (bone, CNS)	AIDS
Paracoccidioidomycosis (*Paracoccidioides brasiliensis*)	Dimorphic fungus	Pneumonia	Healthy individuals
		Disseminated infection (skin, bone, mucosal surfaces)	AIDS
Blastomycosis (*Blastomyces dermatitidis, B. gilchristii*)	Dimorphic fungus	Pneumonia	Healthy individuals
		Disseminated infection (skin, genitourinary tract, bone, mucosal surfaces)	AIDS
Sporotrichosis (*Sporothrix schenkii*)	Dimorphic fungus	Lymphocutaneous disease (ascending lymphangitis)	Direct inoculation
		Disseminated infection	AIDS
Taralomycosis (*Talaromyces marneffei*)	Dimorphic fungus	Pneumonia	Healthy individuals
		Disseminated infection (skin, bone, mucosal surfaces)	AIDS
Pneumocystosis (*Pneumocystis jirovecii*)	Cysts and trophozoites	Pneumonia	AIDS, cancer
		Disseminated infection	AIDS
Dermatophytosis (*Epidermophyton, Trichophyton, Microsporum*)	Mold	Skin and nail infections	Healthy individuals
Chromoblastomycosis (*Fonsecaea pedrosoi, F. monophora*)	Yeast	Skin and subcutaneous tissue infections	Healthy individuals
Eumycetoma (*Maadurella* spp.)	Mold	Skin and subcutaneous tissue infections	Healthy individuals
Phaeohyphomycosis (*Exophiala* spp., *Cladophialophora* spp., *Alternaria* spp., *Phialophora* spp., *Rhinocladiella* spp.)	Yeast or mold	Pneumonia	Healthy individuals
		CNS infection	Healthy individuals, iatrogenic immunosuppression
		Skin infection	Direct inoculation
		Disseminated infection	HSCT, iatrogenic immunosuppression

AIDS, Acquired immunodeficiency syndrome; *CNS*, central nervous system; *HSCT*, hematopoietic stem cell transplantation; *ICU*, intensive care unit; *SOT*, solid organ transplantation.

TABLE 28.2 Fungal Pathogen–Associated Molecular Patterns and Their Associated Pattern Recognition Receptors

PRR (Gene)	PRR Class	Fungal PAMPs	Fungal Genera
Dectin-1 (CLEC7A)	CLR	β-Glucan	*Candida, Cryptococcus, Aspergillus, Histoplasma, Coccidioides, Paracoccidioides, Pneumocystis, Exserohilum*
Dectin-2 (CLEC6A)	CLR	α-Mannans *O*-linked mannoproteins	*Candida, Aspergillus, Coccidioides, Paracoccidioides, Blastomyces*
Dectin-3 (CLEC4D)	CLR	α-Mannans	*Candida*

CLR, C-type lectin receptor; *DC-SIGN*, dendritic cell-specific intercellular adhesion molecule-3-grabbing nonintegrin; *DHN*, 1, 8-dihydroxynaphthalene; *MDA5*, melanoma differentiation-associated protein 5; *NLR*, nucleotide-binding oligomerization domain (NOD)–like receptor; *PAMP*, pathogen-associated molecular pattern; *PRR*, pattern recognition receptor; *RLR*, retinoic acid-inducible gene I (RIG-I)–like receptor; *TLR*, Toll-like receptor.

The importance of the CLR/Syk/CARD9 pathway in human antifungal immunity is clearly demonstrated by the identification and characterization of patients with autosomal-recessive CARD9 deficiency who develop severe refractory mucocutaneous and invasive fungal diseases. Remarkably, among the ~450 known human primary immunodeficiencies (PIDs), CARD9 deficiency is the only one that manifests specifically with fungal susceptibility without accompanying bacterial, viral. or parasitic infections, or allergic, autoimmune, or neoplastic manifestations. Notably, CARD9-deficient humans develop tissue-specific infections by a select group of fungi that include *Candida* (mucosal, central nervous system [CNS], bone), molds (CNS, intraabdominal), phaeohyphomycetes (CNS, lung, skin) and dermatophytes (skin) but not *Cryptococcus*, endemic dimorphic fungi, or *Pneumocystis*.[4,6]

Instead, inherited deficiencies in TLR (i.e., MYD88, IRAK4) or other non-CLR (i.e., MDA5) PRRs predispose to bacterial and/or viral, not fungal, infections underscoring the crucial and specific role of CLR/Syk/CARD9 signaling in human antifungal immunity and its ability to compensate for other PRR deficiencies.[7] However, single nucleotide polymorphisms (SNPs) in TLR pathway constituents are linked to increased risk of invasive candidiasis and aspergillosis in patients with critical illness and/or iatrogenic immunosuppression, indicating that TLR-dependent fungal recognition contributes to optimal human antifungal immune responses in certain settings.

IMMUNE RESPONSES TO YEAST FUNGI

Two major medically important yeast fungi are *Candida* and *Cryptococcus* spp. *Candida* is commensal in the gastrointestinal and female reproductive tract of most humans. When perturbations in host immune responses or microbiota occur, *Candida* can cause opportunistic infection in the form of either mucocutaneous or deep-seated invasive disease (see Table 28.1).[8] The major etiological agents of human *Candida* infections, which form interchanging yeast and pseudohyphal structures that vary depending on the species, are *C. albicans, C. glabrata, C. parapsilosis*, *C. tropicalis*, and the emerging drug-resistant *C. auris*. Importantly, the immune requirements for protection against mucocutaneous versus invasive *Candida* infections are clearly segregated, which is reflected in the distinct patient populations who are at risk for mucocutaneous versus invasive candidiasis. Indeed, whereas lymphocytes are critical for protection against mucocutaneous candidiasis, myeloid phagocytes are indispensable for protection against invasive candidiasis, but not vice versa.[4]

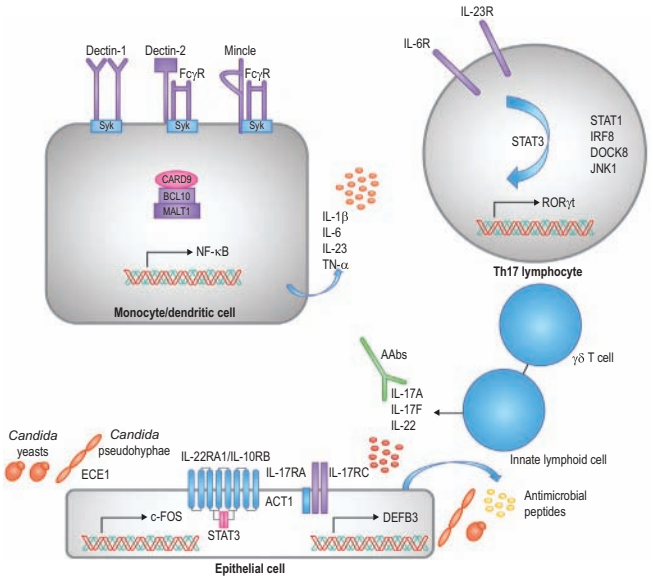

FIG. 28.1 Antifungal Immune Responses at the Mucosal Interface. *Candida albicans* sensing by C-type lectin receptors leads to sequential activation of Syk, the CARD9/MALT1/BCL10 complex and nuclear factor kappa B (*NF-κB*) signaling, which promotes the production of proinflammatory mediators that instruct Th17 differentiation. STAT3 promotes RORγt-mediated Th17 differentiation, which is defective in patients with Job's syndrome caused by dominant-negative *STAT3* mutations. CARD9, DOCK8, JNK1, and IRF8 also contribute to Th17 differentiation, and human inborn errors of immunity affecting each of these genes causes CMC. CMC also occurs in patients with *RORC* mutations who feature impaired Th17 differentiation. Heterozygous gain-of-function mutations in *STAT1* lead to a cytokine milieu that inhibits Th17 differentiation. Th17 cells produce IL-17A, IL-17F, and IL-22. IL-17A and IL-17F, via their binding to IL-17RA and IL-17RC receptors on epithelial cells of the suprabasal epithelial layer and the downstream adaptor protein ACT1, induce the epithelial cell production of antimicrobial peptides (β-defensins, S100A8/S100A9) that inhibit *Candida* growth at the mucosa. IL-17 cytokines are also produced by Tc17 cells, γδ T cells, and innate lymphoid cells, in frequencies that vary depending on the cell type and the mucosal surface. IL-22 is also produced by type-17 lymphocytes and binds to its receptor IL-22R1/IL-10RB on epithelial cells of the basal epithelial layer where it activates STAT3 to promote epithelial cell survival, proliferation, and repair. CMC develops in patients with mutations in *IL17F*, *IL17RA*, *IL17RC*, and *TRAF3IP2* (ACT1), which impair IL-17 receptor-dependent signaling, and in patients with thymoma or autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy caused by *AIRE* mutations associated with autoantibodies against Th17 cell-derived cytokines. The *Candida albicans* hyphal-associated peptide toxin candidalysin (encoded by Ece1) promotes epithelial cell c-FOS activation to produce IL-1α, IL-6, G-CSF, and GM-CSF after *Candida* infection. In humans, inherited mutations in the genes in *red font* have been described to feature CMC. Abbreviations: AAbs, autoantibodies; AIRE, autoimmune regulator; BCL10, B-cell lymphoma/leukemia 10; CARD9, caspase recruitment domain-containing protein 9; CMC, chronic mucocutaneous candidiasis; DOCK8, dedicator of cytokinesis 8; Ece1, extent of cell elongation protein 1; G-CSF; granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; IRF8, interferon regulatory factor 8; JNK1, c-Jun N-terminal kinase 1; MALT1, mucosa-associated lymphoid tissue lymphoma translocation protein 1; RORγt, RAR-related orphan receptor γ; STAT, signal transducer and activator of transcription; Syk, spleen tyrosine kinase. KEY CONCEPTS

Fungus-Specific Immune Cell Requirements for Optimal Host Defense

- Different fungal pathogens depend on different arms of the immune system for protective host defense.
- Inhaled mold fungi (*Aspergillus, Mucorales, Fusarium, Scedosporium*) depend on professional phagocytes (neutrophils, monocytes/macrophages, dendritic cells) for effective host defense.
- Commensal *Candida* depends on IL-17-producing lymphoid cells and epithelial cells for host defense at the mucosal interface.
- Instead, *Candida* depends on professional phagocytes (neutrophils, monocytes/macrophages), not lymphocytes, for host defense during deep-seated invasive infection.
- Intramacrophagic fungi (*Cryptococcus, Histoplasma, Coccidioides, Paracoccidioides, Blastomyces, Talaromyces, Sporothrix*) depend on the cross-talk between IFN-γ-producing lymphocytes and IL-12-producing macrophages for effective host defense.

As such, AIDS patients are at risk for mucosal candidiasis whereas neutropenia, receipt of cytotoxic chemotherapy, and critical illness in intensive care unit (ICU) patients represent major risk factors for invasive candidiasis. Worldwide, *Candida* causes an estimated 400,000 life-threatening invasive infections annually with mortality that exceeds 40%. Moreover, although not life-threatening, the global burden of mucosal candidiasis is substantial as ~75% of all women develop at least one episode of vulvovaginal candidiasis (VVC) during their lifetime.

The two major etiological agents of cryptococcosis are *Cryptococcus neoformans* and *C. gattii*, which are ubiquitous spherical yeasts that are inhaled into the human lung where they are efficiently contained by tissue-resident phagocytes in immunocompetent individuals. However, in patients with immune compromise, particularly those with AIDS, *Cryptococcus* escapes the lungs and causes meningoencephalitis (see Table 28.1); in fact, cryptococcosis is the most common cause

of fungal meningitis in humans. Worldwide, cryptococcosis causes ~200,000 deaths annually, most in sub-Saharan Africa where access to antiretroviral therapy is limited, and accounts for ~15% of AIDS-related deaths.

Mucosal Candidiasis

Mucosal candidiasis manifests as oropharyngeal, esophageal, or vulvovaginal infection. Over the past decade, it has become evident that effective defense against oropharyngeal candidiasis (OPC) is critically dependent on functional IL-17 receptor (IL-17R) signaling (see Fig. 28.1).[9] Mechanistically, IL-17A and IL-17F are produced by mucosal αβ T cells (primarily natural Th17 cells and less so Tc17 cells), γδ T cells, and, to a lesser extent, innate lymphoid cells during OPC. Recent work has uncovered the contribution of the *C. albicans* hyphal-associated peptide toxin candidalysin in priming natural Th17 cell responses during OPC. Engagement of IL-17RA and IL-17RC by IL-17A/IL-17F on epithelial cells of the suprabasal epithelial layer promotes the production of antimicrobial molecules (β-defensins, S100a8/S100a9) that inhibit *Candida* growth and curtail its mucosal invasion. Recent work has shed light on the mechanisms by which IL-22, another type-17 lymphocyte-derived cytokine, protects during OPC. Specifically, engagement of IL-22RA1 by IL-22 on epithelial cells of the basal epithelial layer activates STAT3, which promotes epithelial cell survival and proliferation and replenishes the IL-17RA-expressing basal epithelial layer, thereby enabling its response to IL-17A/IL-17F. Thus, IL-17 and IL-22 exert spatially distinct, yet cooperative, protective functions during OPC. Interestingly, as opposed to OPC, IL-17R signaling appears dispensable for host defense against VVC, underscoring the differential host factors that control *Candida* in various mucosal surfaces. Indeed, AIDS patients are at risk for OPC and esophageal candidiasis but not VVC. Instead, VVC is typically seen following antibiotic treatment, highlighting the role of vaginal microbiota in restricting local *Candida* growth.

Invasive Candidiasis

C. albicans causes the majority of invasive *Candida* infections, although *C. glabrata, C. tropicalis*, and *C. parapsilosis* are increasingly observed in recent years. Drug-resistant *C. auris*, which features a propensity for prolonged persistence on the human skin, is an emerging public health concern associated with large outbreaks in healthcare facilities. Herein, we focus on immunity to *C. albicans*, which has been studied in-depth relative to non-*albicans Candida*.

Three major conditions predispose humans to invasive candidiasis.[8] First, broad-spectrum antibiotics deplete certain commensal gut microbiota and the antifungal protective factors they secrete, enabling increased *Candida* gut colonization.[10] Second, breach of gastrointestinal (i.e., gastrointestinal surgery, chemotherapy-induced mucositis) and cutaneous (i.e., central venous catheters) barriers permit *Candida* translocation into the bloodstream. Third, iatrogenic immunosuppression (i.e., neutropenia, corticosteroid use) impairs innate anti-*Candida* responses and promotes *Candida* dissemination and tissue invasion.

Myeloid phagocytes, but not lymphocytes, mediate protective immunity during invasive candidiasis.[11] Prompt neutrophil recruitment and activation in *Candida*-infected tissues is critical for effective host defense, in keeping with profound susceptibility of neutropenic mice and humans to invasive candidiasis. Recent work has uncovered the fungal and host factors that promote protective neutrophil recruitment in the *Candida*-infected CNS. Specifically, CNS-resident microglia respond to Candidalysin in a p38- and c-Fos-dependent manner to produce IL-1β, which drives CXCL1 production by microglia to recruit CXCR2-expressing neutrophils in the infected CNS. This intricate network relies on functional CARD9 on microglia for generation of both IL-1β (at the levels of transcriptional pro-IL-1β induction and inflammasome-dependent IL-1β maturation) and CXCL1 and is impaired in CARD9-deficient patients who manifest CNS-specific neutropenia that underlies their CNS-targeted candidiasis phenotype.[12]

Upon recruitment into tissues, neutrophils effectively inhibit *Candida* growth via oxidative and non-oxidative mechanisms that vary depending on fungal opsonization; specifically, NADPH oxidase, Syk, FcγR, and protein kinase C operate during opsonized *Candida* killing, whereas Syk, CARD9, complement receptor 3 (CR3), and phosphoinositide 3-kinase enable unopsonized *Candida* killing. A neutrophil-natural killer (NK) cell cross-talk was recently described to drive NK cell-induced GM-CSF-dependent priming of neutrophil candidacidal activity. Inflammatory monocytes, via IL-15, and monocyte-derived dendritic cells (Mo-DCs), via IL-23, activate NK cells to produce GM-CSF.[4] In certain settings, such as upon neutrophil recovery, neutrophils may exert immunopathogenic effects causing tissue injury. Factors associated with neutrophil-driven immunopathology have recently been defined in mice and humans (i.e., CCR1, TEC, MCPIP1, IFN-γ) and may represent therapeutic targets in selected patients.[4]

Monocytes/macrophages are also critical for host defense during invasive candidiasis via fungal uptake and killing. CCR2 recruits inflammatory monocytes and promotes fungal control in the kidney and CNS, whereas tissue-resident macrophages depend upon CX3CR1 for survival and effector function in the kidney, liver, and CNS. Monocytes/macrophages also protect during *C. albicans* re-infection by exhibiting innate immunological memory, termed trained immunity. Mechanistically, β-glucan engagement of Dectin-1 on mouse and human monocytes activates a RAF-1/AKT/mTOR/HIF-1α pathway that leads to epigenetic reprogramming with histone trimethylation and acetylation and metabolic reprogramming with switching from oxidative phosphorylation to aerobic glycolysis.[4]

Cryptococcosis

An effective cross-talk between tissue-resident and recruited mononuclear phagocytes (monocytes/macrophages, microglia, DCs) and T lymphocytes is critical for *Cryptococcus* control within the lung and CNS.[13,14] In agreement, patients with defects in monocyte/macrophage function and lymphocytopenia are at risk for cryptococcosis. Instead, neutropenia is not a risk factor for human cryptococcosis and, in fact, neutrophils contribute to immunopathology in *Cryptococcus*-infected mice.

Cryptococcus PAMP recognition is redundantly mediated by several TLRs, CLRs, and NLRs and is evaded by cryptococcal virulence factors, principally the polysaccharide capsule. A protective cryptococcal response that leads to fungal eradication is associated with the induction of proinflammatory type-1 immunity with generation of an IFN-γ/IL-12/IL-18/TNF–dominant cytokine milieu, M1 (classical) macrophage activation, and Th1 differentiation.[14,15] Indeed, IFN-γ– and TNF–predominant *Cryptococcus*-specific $CD4^+$ T-cell responses and increased IFN-γ and TNF levels in the *Cryptococcus*-infected cerebrospinal fluid are associated with improved prognosis of cryptococcosis in AIDS patients. In the setting of protective type 1 immunity,

upon cryptococcal yeast internalization within the phagosome, phagosome–lysosome fusion and acidification ensue, resulting in yeast degradation that is associated with the production of reactive oxygen and nitrogen species. Phagocytes, primarily DCs, present cryptococcal antigens to T lymphocytes to initiate and direct protective adaptive immune responses. Instead, a nonprotective cryptococcal response that results in fungal persistence is associated with the induction of a type 2 immune responses, the generation of an IL-4/IL-5/IL-13–dominant cytokine milieu, M2 (alternative) macrophage activation with pathogen extracellular escape, eosinophil recruitment, and Th2 differentiation.[14,15]

Among lymphocytes, both CD4 and CD8 T cells can inhibit *Cryptococcus* growth via direct killing and via proinflammatory cytokine production that recruits and activates phagocytes for fungal killing. B lymphocytes and antibodies also contribute to protection via a variety of mechanisms that include fungal opsonization for efficient phagocyte uptake. However, T lymphocytes may also exert pathogenic effects during cryptococcosis, as exemplified by the development of immune reconstitution inflammatory syndrome in AIDS patients following initiation of antiretroviral therapy and immune restoration, during which enriched frequencies of Ki-67$^+$ PD-1$^+$ Th1- and Th17-biased CD4 T cells accumulate, associated with increased levels of proinflammatory cytokines (IL-6, IL-7, IFN-γ, TNF) and worsening clinical manifestations that require immunomodulatory treatment for amelioration.[4]

PATIENTS AT RISK FOR YEAST INFECTIONS DUE TO GENETIC OR PHARMACOLOGICAL FACTORS

Mucosal Candidiasis

Concordant with the critical contribution of IL-17R signaling to mucosal antifungal defense, patients with genetic deficiency in IL-17RA, IL-17RC, IL-17F, or the IL-17R adaptor TRAF3IP2 (ACT1) develop chronic mucocutaneous candidiasis (CMC) without invasive candidiasis (Table 28.3).[16] IL-17RA and ACT1 (but not IL-17RC or IL-17F) deficiencies also underlie skin staphylococcal and pulmonary bacterial infection susceptibility. Several other CMC-manifesting monogenic disorders are associated with direct or indirect impairment of IL-17R-dependent responses including mutations in *RORC, STAT1, STAT3, ZNF341, DOCK8, IRF8, MALT1, BCL10, IL12B, IL12RB1, CARD9*, and *JNK1* (see Table 28.3).[4,17] CMC is also seen in diseases associated with autoantibodies against Th17 cell-derived cytokines such as thymoma and autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy caused by *AIRE* mutations. Moreover, the use of biological agents targeting various constituents of IL-17R signaling (i.e., IL-12p40, IL-23p19, IL-17A, IL-17A/IL-17F, IL-17RA) for psoriasis and inflammatory bowel disease has provided another layer of evidence for the importance of IL-17 in human mucosal antifungal defense, as these patients occasionally develop refractory mucosal candidiasis (frequency, ~2% to 4%).

TABLE 28.3 Inborn Errors of Immunity That Manifest With Fungal Infection Susceptibility in Humans

Gene Name	Mode of Inheritance (Clinical Syndrome, If Applicable)	Fungal Infection Susceptibility	Nonfungal Infection Manifestations	Immunological Mechanisms Accounting for Fungal Infection Susceptibility
IL17F	AD	CMC	Atopy	Impaired IL-17R immune responses
IL17RA	AR	CMC	Skin staphylococcal infections Bacterial pneumonias Atopy	Impaired IL-17R immune responses
IL17RC	AR	CMC	None	Impaired IL-17R immune responses
TRAF3IP2	AR	CMC	Skin staphylococcal infections Bacterial pneumonias Atopy	Impaired IL-17R immune responses
RORC	AR (MSMD)	CMC	Mycobacterial infections	Impaired Th17 differentiation
DOCK8	AR (hyper-IgE syndrome)	CMC	Viral skin infections, eczema, malignancies	
STAT1	AD	CMC, aspergillosis, mucormycosis, cutaneous fusariosis, histoplasmosis, coccidioidomycosis	Bacterial and viral infections, multisystem autoimmunity, aneurysms, hypothyroidism, malignancies	Impaired Th17 differentiation
STAT3	AD (hyper-IgE syndrome; Job syndrome)	CMC, dermatophytosis, cryptococcosis, aspergillosis, scedosporiosis, histoplasmosis, coccidioidomycosis	Eczema, bacterial skin and lung infections, aneurysms, skeletal abnormalities	Impaired Th17 differentiation
ZNF341	AR	CMC	Eczema, bacterial infections, skeletal abnormalities	Impaired Th17 differentiation
MAPK8	AD	CMC	Skin staphylococcal infections, bacterial urinary tract infections, Ehlers-Danlos syndrome-like connective tissue disorder	Impaired Th17 differentiation, impaired IL-17R immune responses
AIRE	AR or AD (APECED)	CMC	Multisystem endocrine and nonendocrine autoimmunity, ectodermal dystrophy	Autoantibodies to Th17 cell-derived cytokines
MALT1	AR	CMC	Viral and bacterial infections, bronchiectasis, hypogammaglobulinemia	Impaired T-lymphocyte activation
BCL10	AR	CMC	Viral and mycobacterial infections, hypogammaglobulinemia	Lymphocytopenia

Continued

TABLE 28.3 Inborn Errors of Immunity That Manifest With Fungal Infection Susceptibility in Humans—cont'd

Gene Name	Mode of Inheritance (Clinical Syndrome, If Applicable)	Fungal Infection Susceptibility	Nonfungal Infection Manifestations	Immunological Mechanisms Accounting for Fungal Infection Susceptibility
IRF8	AR	CMC	Mycobacterial infections	Decreased number of Th17 cells
CLEC7A	AR	Vaginal candidiasis, onychomycosis	None	Decreased IL-17 production
CARD9	AR	CMC, CNS candidiasis, extrapulmonary aspergillosis, cutaneous mucormycosis, phaeohyphomycosis, deep dermatophytosis	None	Decreased number of Th17 cells (CMC), impaired microglial-neutrophil cross-talk resulting in CNS neutropenia (CNS candidiasis), impaired neutrophil *Candida* killing (invasive candidiasis)
CYBA	AR (CGD)	Invasive candidiasis (<5%), aspergillosis (~40%)	Infections by *Staphylococcus, Nocardia*, Serratia, and *Burkholderia*, colitis	Lack of superoxide generation
CYBB	X-linked (CGD)	Invasive candidiasis (<5%), aspergillosis (~40%)	Infections by *Staphylococcus, Nocardia*, Serratia, and *Burkholderia*, colitis	Lack of superoxide generation
NCF1	AR (CGD)	Invasive candidiasis (<5%), aspergillosis (~40%)	Infections by *Staphylococcus, Nocardia*, Serratia, and *Burkholderia*, colitis	Lack of superoxide generation
NCF2	AR (CGD)	Invasive candidiasis (<5%), aspergillosis (~40%)	Infections by *Staphylococcus*, *Nocardia, Serratia,* and *Burkholderia*, colitis	Lack of superoxide generation
NCF4	AR (CGD)	Histoplasmosis	Colitis	Lack of superoxide generation
MPO	AR	Invasive candidiasis (<5%)	None	Lack of hypochlorous acid generation
ELA2	AR (SCN)	Invasive candidiasis, aspergillosis	Pyogenic infections, periodontitis	Neutropenia
HAX1	AR (SCN)	Invasive candidiasis, aspergillosis	Pyogenic infections, periodontitis	Neutropenia
CD18	AR (LAD)	Invasive candidiasis, aspergillosis	Impaired wound healing, severe periodontitis, colitis	Impaired trafficking of neutrophils to infected tissues
CTSC	AR (Papillon-Lefevre syndrome)	Mucormycosis	Pyogenic infections, periodontitis, palmoplantar keratoderma	Impaired activation of granule serine proteases
GATA2	AD (MonoMAC syndrome)	Cryptococcosis, aspergillosis, histoplasmosis, blastomycosis	Viral and mycobacterial infections, leukemia, lymphedema	Monocytopenia, decreased DCs, neutrophil granule abnormalities
IFNGR1	AD (MSMD)	Histoplasmosis, coccidioidomycosis	Intramacrophagic pathogen infections	Impaired IFN-γ cellular responses
IL12B	AR (MSMD)	CMC	Mycobacterial infections	Impaired Th17 differentiation
IL12RB1	AR or AD (MSMD)	CMC, cryptococcosis, histoplasmosis, coccidioidomycosis, paracoccidioidomycosis	Intramacrophagic pathogen infections	Impaired Th17 differentiation (CMC), impaired IL-12/IL-23-dependent IFN-γ production (systemic mycoses)
STAT4	AD	Paracoccidioidomycosis	None	Impaired IFN-γ production
CD40L	X-linked	PCP	Bacterial, mycobacterial, and parasitic infections, colitis	Impaired T-lymphocyte responses
NEMO/ IKBKG	X-linked	CMC, PCP	Bacterial, mycobacterial, and viral infections, anhidrotic ectodermal dysplasia	Lymphocytopenia
IKBA	AD	CMC, PCP	Bacterial, mycobacterial, and viral infections, anhidrotic ectodermal dysplasia, colitis	Lymphocytopenia
IL21R	AR	CMC, PCP	Cryptosporidiosis with cholangitis and liver fibrosis	Impaired T-lymphocyte activation
BTK	X-linked (XLA)	PCP, cryptococcosis	Bacterial infections, hypogammaglobulinemia, colitis	Impaired B-lymphocyte signaling

AD, Autosomal dominant; *AIRE*, autoimmune regulator; *APECED*, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy; *AR*, autosomal recessive; *BCL10*, B-cell lymphoma/leukemia 10; *BTK*, Bruton tyrosine kinase; *CARD9*, caspase recruitment domain-containing protein 9; *CMC*, chronic mucocutaneous candidiasis; *CTSC*, cathepsin C; *CYB*, cytochrome B-245; *DCs*, dendritic cells; *DOCK8*, dedicator of cytokinesis 8; *ELA2*, elastase 2; *GATA2*, GATA binding protein 2; *HAX1*, HCLS1-associated protein X-1; *IKBA*, NF-κB inhibitor alpha; *IKBKG*, Inhibitor of NF-κB kinase regulatory subunit γ; *IL-17R*, interleukin receptor; *IRF8*, interferon regulatory factor 8; *JNK1*, c-Jun N-terminal kinase 1; *LAD*, leukocyte adhesion disorder; *MALT1*, mucosa-associated lymphoid tissue lymphoma translocation protein 1; *MAPK8*, mitogen-activated protein kinase 8; *MPO*, myeloperoxidase; *MSMD*, mendelian susceptibility to mycobacterial disease; *NCF*, neutrophil cytosol factor; *NEMO*, NF-κB essential modulator; *PCP*, *Pneumocystis* pneumonia; *RORC*, RAR orphan receptor C; *SCN*, severe congenital neutropenia; *STAT*, signal transducer and activator of transcription; *TRAF3IP2*, TRAF interacting protein 2; *XLA*, X-linked agammaglobulinemia; *ZNF341*, zinc finger protein 341.

Invasive Candidiasis

As mentioned above, CARD9 deficiency predisposes to mucosal candidiasis, associated with impaired Th17 differentiation, and CNS-targeted invasive candidiasis, caused by impaired microglial-neutrophil cross-talk (see Table 28.3).[6] In fact, CARD9 deficiency is the only known inherited condition that predisposes to both mucosal and invasive candidiasis, in keeping with the central positioning of CARD9 in antifungal immune responses. The advent of Syk inhibitors for the treatment of autoimmune and neoplastic conditions is likely to promote iatrogenic fungal susceptibility, as suggested by early reports of mucocutaneous fungal disease in Syk inhibitor-treated individuals.

Furthermore, a subset of patients with inherited disorders in the phagocyte oxidative burst machinery featuring complete myeloperoxidase deficiency or chronic granulomatous disease (CGD), caused by mutations in the NADPH oxidase complex, develop invasive candidiasis without associated iatrogenic risk factors (frequency, <5%) (see Table 28.3). The observation that the majority of myeloperoxidase-deficient and CGD patients do not develop invasive candidiasis indicates that intact mucocutaneous barriers and nonoxidative-dependent fungal killing mechanisms compensate for absent oxidative-dependent phagocyte functions in these patients.[7,18]

In ICU patients, SNPs in PRRs (*TLR1*), cytokines (*IL10, IL12B, TNF*), chemokines and their receptors (*CCL8, CXCR1, CX3CR1*), interferon signaling molecules (*STAT1, SP110, PSMB8*), and other immune factors (*TAGAP, CD58, LCE4A-C1orf68*) have been linked to heightened risk of invasive candidiasis and/or worse outcome following invasive candidiasis; some of them (i.e., *CXCR1-T276, CX3CR1-M280*, others) were shown to be dysfunctional as they confer phagocyte defects similar to those observed in the corresponding gene-deficient mouse phagocytes. Collectively, these SNPs show promise for the development of precision-medicine risk stratification, prophylaxis, and prognostication strategies in ICU patients.[8]

Cryptococcosis

Cryptococcosis develops in patients with mutations in the IL-12/IFN-γ signaling pathway, which underlies Mendelian susceptibility to mycobacterial disease and also predisposes to disseminated infections by other intracellular fungal (endemic dimorphic fungi, see below) and bacterial (*Salmonella*) pathogens (see Table 28.3, Fig. 28.2). These patients exhibit defective IL-12/IFN-γ-dependent lymphocyte-macrophage cross-talk that impairs intramacrophagic cryptococcal clearance. Mirroring this inherited susceptibility, cryptococcosis is also seen in adults with autoantibodies against IFN-γ. Adult-onset acquired immunodeficiency featuring cryptococcosis, primarily caused by *C. gattii*, also develops in patients with autoantibodies against GM-CSF; these autoantibody-associated conditions may respond to anti-CD20- or anti-CD38-targeted therapies. Last, cryptococcosis develops in patients with autosomal-dominant haploinsufficiency of the transcription factor GATA2, which manifests myelodysplasia, lymphedema, and broad infection susceptibility.[4]

Cryptococcosis is also observed in patients who receive biological agents that deplete T lymphocytes (i.e., alemtuzumab), inhibit Janus kinase (JAK) signaling—which abrogates intramacrophagic fungal control—or inhibit Bruton tyrosine kinase (BTK)—which impairs B-lymphocyte and macrophage responses—in agreement with reports of cryptococcosis in patients with inherited BTK deficiency (i.e., X-linked agammaglobulinemia [XLA]).

Immune Responses to Molds

Molds primarily cause invasive disease in the human respiratory tract (see Table 28.1), particularly in immunocompromised individuals. The major etiological agents of life-threatening mold pneumonia include *Aspergillus*, *Scedosporium*, *Fusarium* spp., and the *Mucorales* order, all of which form branching tubular filaments, termed hyphae. Tissue-invasive hyphae are highly destructive in human tissues and have the capacity to disseminate to extrapulmonary sites. Beyond the respiratory tree, molds are associated with severe skin and soft-tissue infections when fungal cells are introduced by traumatic inoculation (e.g. in victims of natural disasters). *Aspergillus* spp. are further linked to allergenic disease in patients with underlying atopy and asthma and to chronic cavitary disease with varying degrees of hyphal tissue invasion in patients with cystic fibrosis or structural lung disease.[19]

Molds are saprophytic organisms that thrive on decaying organic matter in the environment and form a mycelium, a collection of branching, interconnected hyphae. Coniodiophores are specialized hyphal cells that are located at the mycelial interface with air and generate conidia (i.e., vegetative spores), the infectious propagules. Humans inhale airborne mold conidia on a daily basis and exposure to these pathogens is ubiquitous. The respiratory innate immune system rapidly inactivates conidia that bypass mucociliary clearance in individuals without underlying injury to the immune system and to the lung architecture.

Worldwide, *Aspergillus* and agents of mucormycosis cause an estimated 200,000 and 10,000 life-threatening invasive infections annually, respectively. Vulnerable patient groups include individuals with disease- or therapy-related injury to the myeloid cell compartment of the immune system (e.g., patients with leukemia, lymphoma, hematopoietic stem cell, and lung transplantation), and individuals on long-term immune suppression for autoimmune diseases. More recently, critically ill patients with severe influenza or COVID-19 and patients treated with small-molecule drugs (i.e., ibrutinib) that target host signaling molecules involved in fungal immune surveillance have been identified as vulnerable to invasive mold infections, in particular invasive aspergillosis. Despite the widespread availability of two major classes of mold-active drugs, the polyenes and mold-active triazoles, fungus-attributable mortality rates for aspergillosis, fusariosis, and mucormycosis range from 25% to 90%, with the highest mortality observed in patients with extrapulmonary dissemination in the absence of myeloid cell recovery or reconstitution.[19]

Aspergillosis

There are more than 200 *Aspergillus* species, though only a handful cause human disease. *A. fumigatus* is responsible for approximately two-thirds of invasive infections, with *A. flavus*, *A. niger*, *A. terreus*, *A. ustus, and A. nidulans* observed in a minority of cases. The ensuing discussion will focus primarily on immune responses to *A. fumigatus*, since this species has been characterized and studied in-depth compared to the non-*fumigatus Aspergillus* spp.

The innate immune system plays a dominant role in defense against all filamentous molds—and against *Aspergillus* in particular. This concept arose out of clinical observations in the 1970s and 1980s in which the susceptibility of patients with acute leukemia to aspergillosis correlated with the duration of neutropenia. In addition, qualitative neutrophil defects predispose patients to aspergillosis, exemplified by a ~40% to 50% lifetime

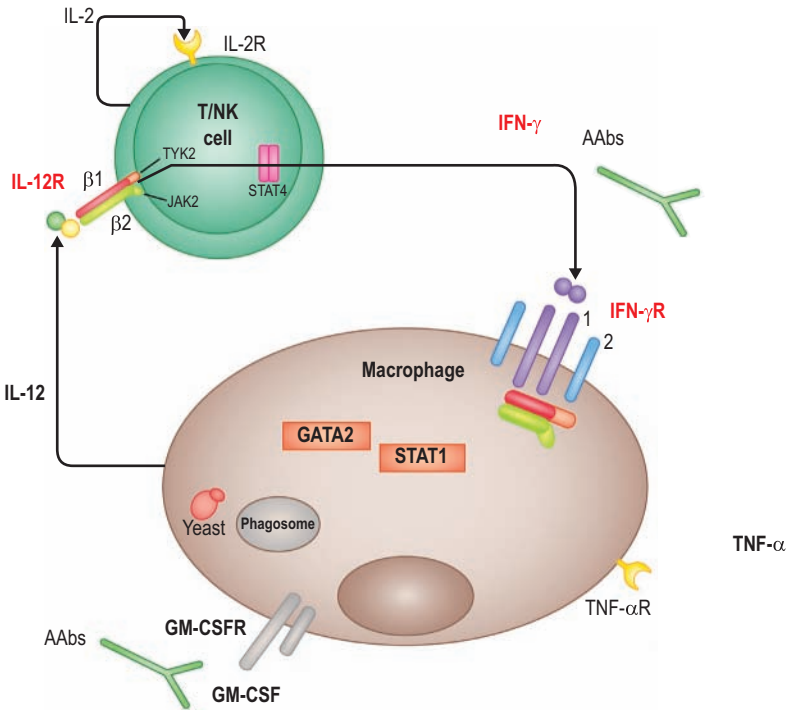

FIG. 28.2 An orchestrated lymphocyte-Macrophage Cross-Talk promotes Sterilizing Immunity Against Intramacrophagic fungi. The interplay between T lymphocytes and NK cells with monocytes/macrophages drives clearance of intramacrophagic fungi (*Cryptococcus*, endemic dimorphic fungi). IL-12 is released by monocytes/macrophages in response to fungal engulfment and binds to its receptor, which consists of IL-12Rβ1 and IL-12Rβ2 subunits on the surface of T lymphocytes and NK cells. IL-12 binding on the IL-12 receptor activates STAT4 via TYK2 and JAK2 and leads to the transcription and secretion of IFN-γ. IFN-γ then binds to its receptor, which consists of IFN-γR1 and IFN-γR2 subunits on the surface of monocytes/macrophages. IFN-γ binding on the IFN-γ receptor activates STAT1 via JAK1 and JAK2, which enables intracellular fungal killing via effector mechanisms that are not well-characterized. GATA2 is critical for monocyte, DC, and NK-cell development and effector function, and human autosomal-dominant GATA2-haploinsufficiency leads to infection susceptibility by intramacrophagic fungi. Mutations in the β1 subunit of the IL-12 receptor (*IL12RB1*), in either subunit of the IFN-γ receptor, and gain-of-function *STAT1* mutations also lead to infection susceptibility by intramacrophagic fungi (and mycobacteria). TNF and GM-CSF bind to their receptors on the surface of monocytes/macrophages, resulting in monocyte/macrophage activation. Pharmacological inhibition of TNF and autoantibodies against IFN-γ or GM-CSF are associated with infection susceptibility by intramacrophagic fungi. Inherited mutations in genes encoding the proteins in IFN-γR and IL-12R (*red font*) have been described to feature infections by intramacrophagic fungi in humans. The molecular mechanisms by which GATA2, STAT1, and TNF promote intramacrophagic fungal killing remain poorly understood. IL-2 promotes T-lymphocyte proliferation and activation by binding to its IL-2 receptor. Abbreviations: AAbs, autoantibodies; DC, dendritic cell; GATA2, GATA binding protein 2; GM-CSF, granulocyte–macrophage colony-stimulating factor; JAK, Janus kinase; NK, natural killer; STAT, signal transducer and activator of transcription; TYK2, tyrosine kinase 2. (Modified from Lionakis MS, Levitz SM. Host control of fungal infections: lessons from basic studies and human cohorts. *Annu Rev Immunol*, 2018;36:157–191.)

incidence of aspergillosis in patients with CGD, the hallmark of which is the loss of the oxidative burst, primarily in neutrophils. In contrast to the central role of myeloid cells, in particular neutrophils, in host defense against molds, humans with defects in lymphoid cell number or function, including CD4 and CD8 T, NK, and B cells, are typically not prone to these infections. These observations have been recapitulated in mouse models of mold infections, highlighting conserved principles of host defense across mammalian species.[3]

The central role of the innate immune response is to prevent the germination of inhaled mold conidia. Unchecked, inhaled mold conidia swell, form a germ tube, and extend hyphae that can pierce phagocytes and cross tissue barriers. To prevent this process, tissue-resident alveolar macrophages and DCs engulf conidia, restrict germination within the phagolysosome, and initiate the recruitment of neutrophils, circulating monocytes, and plasmacytoid DCs (pDCs) in the fungus-infected lung (Fig. 28.3). These recruited cell subsets cooperate to condition the lung inflammatory milieu to promote fungal cell killing, primarily via the action of NADPH oxidase.

Innate immune recognition of germinating conidia relies on the stage-specific exposure of fungal polysaccharides that trigger host CLR signaling pathways. In the case of molds, this process is best understood for *A. fumigatus* in which conidial swelling leads to the surface exposure of β-(1, 3) glucan polysaccharides that in turn activates the Dectin-1, Syk, and CARD9 signal transduction pathway, culminating in NF-κB nuclear translocation and in induction of proinflammatory cytokines—including IL-1β and mediators of neutrophil chemotaxis (e.g., CXCL1, CXCL2). *Aspergillus* spp. also express polysaccharide ligands that activate Dectin-2-mediated signaling via FcRγ, Syk, and CARD9. Unlike hyphae, *Aspergillus* conidia contain a pigment, termed melanin, that can activate the CLR MelLec (*clec1a*) though the downstream signaling events have not yet been elucidated. While the

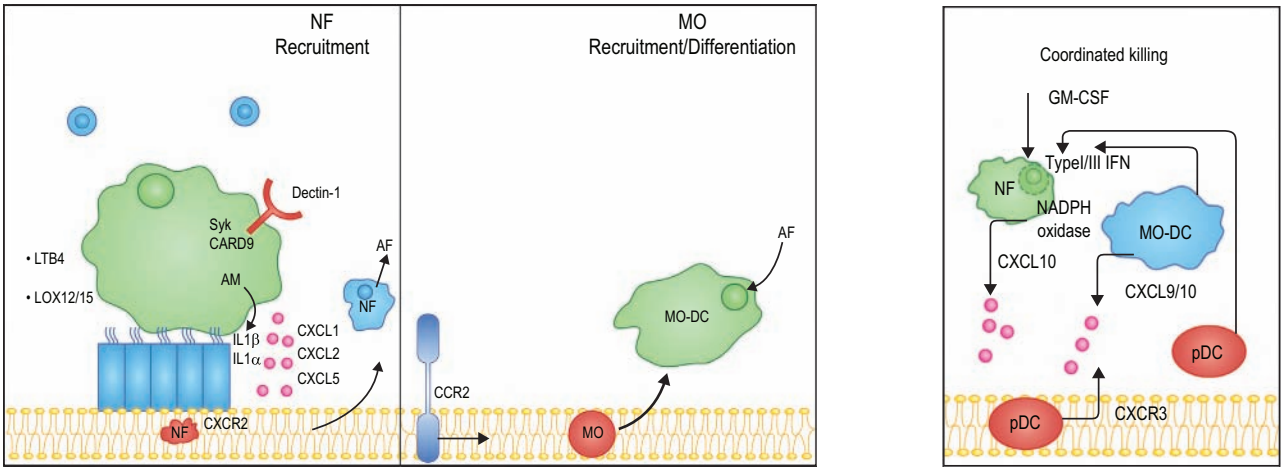

FIG. 28.3 Induction of the Innate Immune Response to Pulmonary Infection with *Aspergillus fumigatus*. *Aspergillus fumigatus* conidia are rapidly engulfed by lung-resident alveolar macrophages and trigger the induction of Dectin-1/Syk/CARD9 and eicosanoid signaling that result in the release of neutrophil- and monocyte-targeted chemoattractants (*left panel*). Neutrophils and monocytes enter the circulation and traffic into the *Aspergillus*-infected lung via CXCR2- and CCR2-mediated signals, respectively (*left and middle panels*). In the lung, fungus-engaged neutrophils and monocyte-derived dendritic cells kill conidia directly and condition the inflammatory milieu, in part through the release of type I interferons and CXCL9 and CXCL10 (*right panel*). This triggers the recruitment of $CXCR3^+$ plasmacytoid dendritic cells that further enhance the killing capacity of neutrophils by increasing the oxidative burst (right panel). These processes trigger a regulated cell death program in *Aspergillus* conidia, resulting in sterilizing immunity in the respiratory tree. *NF*, neutrophil; *MO*, monocyte; *AF*, *Aspergillus fumigatus*; *AM*, alveolar macrophages; *pDC*, plasmacytoid dendritic cells.

CLR-Syk-CARD9 signaling pathway operates in hematopoietic cells to mediate the recruitment of myeloid effector cells, *Aspergillus* infection also elicits the rapid release of IL-1α, which together with IL-1β, can activate IL-1 receptor signaling on lung stromal cells; this pathway provides an alternate source of neutrophil-targeted chemoattractants. Beyond CXCL1, CXCL2, and CXCL5, leukotriene B4 is another potent neutrophil-recruiting mediator released early in *Aspergillus* infection.[20]

As mentioned above, the primary neutrophil killing mechanism involves products of NADPH oxidase that act on conidia and on hyphae. Lung-infiltrating monocytes differentiate into Mo-DCs in the lung and contribute to direct conidial killing as well. Infected neutrophils and Mo-DCs release CXCL9 and CXCL10, both of which serve to mediate the entry of $CXCR3^+$ pDCs into the lung. Although pDCs do not appear to kill fungal cells directly, pDCs enhance the killing activity of neutrophils by boosting the oxidative burst.[21] Several additional mediators play key roles in clearing *Aspergillus* conidia and in mediating sterilizing immunity. Chief among these are type I and type III interferons, produced within hours post-infection, that, together with GM-CSF, condition the lung inflammatory environment to increase oxidative killing mechanisms.[22] Neutrophil NADPH oxidase activity kills fungal cells by inducing a regulated cell death process within conidia.

Nonoxidative killing mechanisms also contribute to sterilizing immunity. This concept has been detailed in a mouse model of *Aspergillus* keratitis, a devastating sight-threatening disease found primarily in agricultural workers in resource-limited countries. In the eye, fungal hyphae form rapidly because the resident ocular innate immune system is insufficient to control early germination, unlike the situation in the respiratory tree. When recruited neutrophils encounter *Aspergillus* hyphae, they can undergo a form of regulated cell death, termed NETosis, a process that requires NADPH oxidase activity and results in the extrusion of actin and chromatin fibers, histones, and the proteins calprotectin (S100A8/S100A9) and pentraxin-3. Calprotectin is an abundant protein in the neutrophil cytosol that acts to sequester the divalent cations Zn^{2+} and Mn^{2+}. Mice that lack calprotectin are susceptible to ocular, but not respiratory, challenge with *A. fumigatus* conidia. Host iron sequestration—for example via lactoferrin—contributes to nutritional immunity, the process by which host cells prevent *Aspergillus* nutrient acquisition. The precise role of NETosis in *Aspergillus* killing remains unclear because genetic tools that interfere with formation of NETs without affecting other antimicrobial functions are lacking. In macrophages, recent studies indicate that *Aspergillus* uptake induces LC3-associated phagocytosis (LAP), a process in which components of the autophagy machinery conjugate LC3 to fungus-containing phagosomes. The melanin pigment found in conidia can block this process. Loss of the conidial pigment during germination enhances this noncanonical form of autophagy to promote fungal killing, partly by metabolic reprogramming of macrophages.[3]

Although lymphoid cells are not essential for protection against *Aspergillus* and other filamentous molds, fungus-specific CD4 T cells, specifically Th2 and Th17 cells, contribute to *Aspergillus*-associated allergenic disease. Recent work demonstrated that CD4 T cells primed in the intestine to respond to commensal *C. albicans* can migrate to the lung and cross-react with antigens found in inhaled *Aspergillus* and other molds to exacerbate fungal asthma. These cross-reactive CD4 T cells produce IL-17, which is protective against mucosal fungal infections, but aggravates allergenic immune pathology in the lung. Moreover, *Aspergillus* encodes a number of proteases (e.g., Alp1p) that act as allergens by causing tissue damage to lung epithelial cells; this injury can activate mechanosensitive channels that promote allergen sensitization via the calcineurin signaling pathway. In another model of fungal asthma, *Aspergillus* protease antigens promote allergenic disease by cleaving the clotting protein fibrinogen; in this setting, fibrinogen cleavage products promote allergic inflammation by activating TLR4 signaling[23] (Chapter 43).

Agents of Mucormycosis

The order *Mucorales* contains the agents of mucormycosis, the most common of which are *Mucor*, *Rhizopus*, *Rhizomucor*, *Absidia*, *Cunninghamella, Saksenaea*, and *Lichtheimia* species. This class of organisms forms branching, ribbon-like aseptate hyphae in human tissues. Similar to aspergillosis, the innate immune system, and neutrophils in particular, plays a dominant role in protection against mucormycosis, with no essential requirement for adaptive immune responses in host defense, based on mouse models of disease and observations in humans with PIDs. Nutritional immunity contributes to alveolar macrophage-mediated defense against inhaled *Mucorales* conidia.

A unique characteristic of mucormycosis is the occurrence of rhinocerebral disease in patients with uncontrolled diabetic ketoacidosis. Recent laboratory studies indicate that *Rhizopus* can exploit the upregulation of glucose-regulated protein (GRP78) expressed in nasal epithelial and in endothelial cells during hyperglycemia. The *Rhizopus* spore coat protein CotH3 binds GRP78, resulting in GRP78-mediated fungal cell internalization and tissue invasion. Additional *Mucorales* CotH family members contribute to fungal pathogenesis, including CotH7 that binds to β_1 integrin. CotH family members are widely expressed among the *Mucorales* order and absent from non-*Mucorales* fungal pathogens. This finding may provide a potential explanation for the susceptibility of patients with diabetic ketoacidosis to mucormycosis. In mouse models, antibodies directed against GRP78 and CotH3 ameliorate the outcome of mucormycosis.[24]

PATIENTS AT RISK FOR INVASIVE MOLD INFECTIONS DUE TO GENETIC OR PHARMACOLOGICAL FACTORS

The link between a PID and mold infections is best established for CGD in which defects in the CYBB, CYBA, NCF1, NCF2, or NCF4 subunits of phagocyte oxidase prevent the assembly and function of the complex. Invasive aspergillosis is a hallmark infection in CGD, particularly if cultures reveal the presence of *Aspergillus nidulans* (see Table 28.3); the exception is CGD caused by NCF4 deficiency that features predominantly colitis without profound mold susceptibility. Mucormycosis is uncommon in CGD and is typically observed when patients are treated with corticosteroids or other immunosuppressants for the inflammatory sequelae of this disease. CARD9 deficiency is associated with extrapulmonary aspergillosis and cutaneous mucormycosis, likely due to the strict CARD9 dependency of neutrophil recruitment to sites of mold infections outside of the respiratory tree.[4,6]

Aspergillosis occurs in severe congenital neutropenia, caused by *ELA2* and *HAX1* mutations, and in leukocyte adhesion deficiency, caused by mutations in β_2 integrins (*CD18*, *CD11a, -b*, or *-c*) that impairs neutrophil trafficking into infected tissues. Mucormycosis has been reported in patients with Papillon-Lefèvre syndrome in which the activation of neutrophil granule serine proteases, specifically cathepsin C, is defective. Patients with GATA2 haploinsufficiency develop monocytopenia and NK-cell lymphopenia and can develop aspergillosis, among other fungal and viral infections. In Job's syndrome, termed autosomal-dominant hyper-IgE syndrome, mutations in *STAT3* lead to primary staphylococcal lung infections and ensuing secondary *Aspergillus* infections at sites of cavitary lung lesions. Autosomal-dominant mutations in *STAT1*, a transducer of interferon responses, are associated with aspergillosis, mucormycosis, and cutaneous fusariosis. A common theme to PIDs that give rise to invasive mold infections is that all result in qualitative or quantitative defects in myeloid cells.[7]

Patients treated with the BTK inhibitor ibrutinib can develop invasive aspergillosis with a predilection for CNS disease, particularly when ibrutinib was combined with other therapies that target lymphoma. However, XLA humans that carry loss-of-function *BTK* mutations were previously not observed to be susceptible to invasive mold infections. Recent laboratory studies indicate that murine BTK-deficiency enhances *A. fumigatus* susceptibility, likely due a requirement for BTK signaling in myeloid cells to achieve optimal anti-*Aspergillus* effector activity.

In allogeneic hematopoietic stem cell transplantation recipients, SNPs in membrane-bound and soluble receptors (i.e., *CLEC7A*, *CLEC1A*, *PTX3*, *TLR4, TLR6, CD209, NOD2, PLG, TNFR1*), ion chelators implicated in nutritional immunity (*S100B*), and cytokines (*IFNG, CXCL10*) have been linked to heightened risk of transplant-associated aspergillosis.[25] However, genetic defects in these molecules are not associated with mold infections in otherwise immunocompetent individuals, highlighting molecular redundancy in innate recognition of mold conidia and hyphae.

IMMUNE RESPONSES TO DIMORPHIC FUNGI

In North America, the endemic dimorphic fungi represent a significant cause of respiratory and systemic diseases (see Table 28.1). The etiological agents include *Blastomyces dermatitidis, B. gilchristii* and related species, *Histoplasma capsulatum, Coccidioides immitis*, and *C. posadasii*. These fungi are geographically distributed in the United States; *Blastomyces* and *Histoplasma* are found in the Midwestern, Southcentral, and Southeastern regions, and *Coccidioides* in the Southwest. Collectively, these pathogens produce greater than 1 million new infections annually. The fungi grow as mold in the soil and, after spores are inhaled, they convert to pathogenic yeast or spherules (*Coccidioides*). The dimorphic fungi cause infection in healthy persons, but disease may be intensified in immunocompromised hosts. Infected persons usually have no prior underlying immune impairment; those that do may manifest disease reactivation and dissemination. A variable percentage of previously healthy persons exhibit progressive pulmonary or extrapulmonary disease. In histoplasmosis, the frequency is ~10% in those with clinically apparent infection; in coccidioidomycosis, it is ~30%. In blastomycosis, the rates of progressive disease may be even higher. A hallmark of these disorders in healthy hosts is the development of lasting immunity after primary infection.

Host defense requires the development of an adaptive immune response chiefly involving antigen-specific CD4 T cells. These cells promote immunity by releasing cytokines and providing help to B cells and CD8 T cells. Loss of these functions underpins susceptibility of AIDS patients to these infections. In mice and humans, Th1- and Th17-biased responses confer protection. Th2 cells exacerbate infection by dampening Th1 responses and inducing alternatively activated macrophages. Regulatory T cells fine tune the immune response and limit collateral damage but can also promote fungal persistence.[15,26]

Histoplasmosis

There are an estimated 500,000 new *Histoplasma* infections annually in the United States. While the vast majority of infections

are asymptomatic, 10% become progressive. Infection especially poses a threat to solid organ transplant recipients, AIDS patients, and other immunocompromised hosts. Upon inhalation, *Histoplasma* spores settle into bronchioles and alveoli and convert into pathogenic yeasts within resident phagocytes and DCs. These cells transport *Histoplasma* to visceral and lymphoid organs where the infection expands. Within weeks, Th1 immunity is activated, arresting *Histoplasma* replication in monocytes and macrophages, although tissues may not be sterilized. Conversely, heightened Th2 responses exacerbate disease by producing type-2 cytokines that dampen the activity of macrophages. DCs present *Histoplasma* antigen to CD4 T cells and dictate their differentiation into Th1 cells. DCs initiate Th1 differentiation by secreting IL-12; they foster Th2 polarization by releasing soluble mediators or by contact with surface molecules such as Jagged, CD80/86, and OX40L. DCs also modulate Th1 or Th2 responses by releasing chemoattractants, including CXCL10 (Th1 cell migration), CCL17, and CCL22 (Th2 cells).[26,27]

Intracellular residence of *Histoplasma* poses a stress to the fungus as it transitions from soil, which contains more zinc than macrophages. GM-CSF, a Th1 cytokine, activates the anti-*Histoplasma* activity of macrophages, stimulates movement of zinc into the cytosol of macrophages, and triggers production of zinc-binding proteins. Metallothionein 1 and 2 sequester zinc, reduce free metal in host cells and starve the yeast. Sequestration of zinc by metallothionein also increases reactive oxygen species. Enhanced reactive oxygen species and zinc sequestration from yeast enhance fungal killing. Conversely, IL-4 production induces zinc accumulation by *H. capsulatum*, boosting its intracellular survival.[28]

Coccidioidomycosis

There are an estimated 25,000 cases of coccidioidomycosis that require medical treatment annually. Although a minority of those exposed to *Coccidioides* develop acute illness, up to 29% of community-acquired pneumonia may be due to *Coccidioides* in endemic areas. Chronic infection is common, with many lung nodules attributable to *Coccidioides* in endemic areas. Disseminated coccidioidomycosis is rare, appearing in less than 1% of infections, but is a devastating and often fatal complication.

In murine models, PRRs and signaling adaptors foster innate control of *Coccidioides* infection. MyD88 and CARD9 adaptors, Dectin-1, and IL-1R1 orchestrate the recognition of spherule wall components. CD4 T helper cells and CD8 cytotoxic cells contribute to adaptive immunity. Th1 and Th17 responses confer protection, while Th2 and IL-10-producing cells may foster pathological responses.[29]

Live attenuated vaccines confer protection in experimental animals. These include a strain with two disrupted chitinase genes (CTS2 and CTS3; *cts2*/*ard1*/*cts3*Δ mutant) and another with a *CPS1* gene deletion (Δ*CPS1* mutant). These strains are highly attenuated and well tolerated even as primary pulmonary infection, including in NSG mice that lack cellular and humoral immunity (Δ*CPS1* strain). The vaccines underscore a role for IFN-γ as a correlate of protection. The Δ*CPS1* vaccine is under study in experimental dogs. Despite the capacity of live, attenuated vaccines to elicit protective immunity in mice, they may not be safe for individuals with compromised immune systems.

A dozen *Coccidioides* antigens have been identified and characterized as vaccine candidates. Multivalent vaccines that contain two or more antigens are more potent against experimental pulmonary *Coccidioides* infection than vaccines containing a single antigen. A *Coccidioides* polypeptide vaccine consists of three antigens (cell wall antigen 2 [Ag2/Pra], *Coccidioides*-specific antigen [Cs-Ag], proximal matrix protein 1 [Pmp1]), and five pathogen-derived peptides with affinity for human major histocompatibility complex (MHC) class II molecules. When formulated in glucan particles as an adjuvant the vaccine protects both C57BL/6 and HLA-DR4 "humanized" mice. Th1 and Th17 cells participate in mediating this *Coccidioides* vaccine effect.[4]

Blastomycosis

The majority of blastomycosis cases present as fungal pneumonia. Although blastomycosis is comparatively uncommon, with perhaps ~3000 cases reported annually in highly endemic areas, the incidence may reach 40 cases per year per 100,000 population. Blastomycosis is more common in people of African American, Native American, and Asian, especially Hmong, ancestry. Some of these associations may be due to a combination of genetic and nongenetic factors.

Once in the yeast phase, *B. dermatitidis* and *B. gilchristii* upregulate *Blastomyces*-adhesin-1 (BAD1), an essential virulence factor that is specific to the yeast phase. BAD1 is an adhesin and immune evasin. BAD1 binds the yeast to host tissue and immune cells via interactions with heparin sulfate and CR3 and CD14. Surface-bound and soluble BAD1 inhibit TNF production by macrophages and neutrophils. BAD1 also inhibits CD4 T-lymphocyte activation via interaction with heparan sulfate modifications on CD47, resulting in reduced IL-17 and IFN-γ production. Other immune evasive strategies of the yeast include cleavage of chemokines that recruit $CCR2^+$ inflammatory monocytes to the lung and cleavage of type-1 cytokines such as GM-CSF by fungal dipeptidyl peptidase-4 (Dpp4).[30,31]

Although *Blastomyces* yeast subvert and evade the immune system, host macrophages and neutrophils kill a large portion of conidia inhaled into the lung. CD4 T cells coordinate adaptive immunity by activating macrophages that enhance yeast killing. This requires Th1 cytokines such as TNF and IFN-γ and production of IL-17 by Th17 cells. Cell-mediated immunity following recovery from blastomycosis can last for at least 2 years.

Deletion of BAD1 severely attenuates the fungus. *BAD1*Δ yeast can vaccinate mice against experimental infection. Upon subcutaneous injection, *BAD1*Δ yeasts are transported by inflammatory monocytes to the draining lymph nodes where resident DCs present antigen to T cells. Naïve CD4 T lymphocytes differentiate into Th1 and Th17 cells in a manner that requires Dectin-2/FcRγ/Syk/Card9, Dectin-3, and mannan receptor signaling pathways. Once differentiated, Th1 and Th17 cells migrate to the lungs in response to infection to mediate vaccine immunity by secreting IFN-γ and IL-17 to recruit and activate neutrophils and macrophages. In the absence of CD4 T cells, *BAD1*Δ vaccinated mice use IFN-γ and IL-17 CD8 T lymphocytes (Tc1 and Tc17 cells) to mediate protective immunity. Proliferation and activation of IL-17-producing CD8 T cells occurs through MyD88-Akt1-mTOR signaling. *BAD1*Δ vaccine antigens that induce protective CD4 T cells include calnexin and endoglucanase 2, which are conserved among ascomycete fungi, including *H. capsulatum, C. posadasii, A. fumigatus, Fonsecaea pedrosoi* (the agent of chromoblastomycosis), *and Pseudogymnoascus destructans* (the fungus responsible for white-nose syndrome in bats). Calnexin- and endoglucanase-based vaccines protect against pneumonia caused by the three major endemic dimorphic fungi.[30,31]

In addition, in a mouse model of blastomycosis, lung epithelial cells promote innate immunity in a manner that requires NF-κB. Signaling through IL-1R1 and MyD88 drives IL-17–producing innate lymphocytes that engage additional myeloid cells.

PATIENTS AT RISK FOR ENDEMIC MYCOSES DUE TO GENETIC OR PHARMACOLOGICAL FACTORS

Disseminated histoplasmosis is most commonly associated with the immunocompromised patient; dissemination is rare in the immunocompetent host. Common sites of dissemination include the CNS and gastrointestinal tract. Patients receiving TNF inhibitors are at risk of disseminated infection as are those receiving the anti-IFN-γ monoclonal antibody emapalumab. Progression to disseminated coccidioidomycosis is likewise rare, occurring in less than 1% of infections, but immunosuppression, including use of TNF inhibitors, increases risk of dissemination.

Many of the same genetic deficits in immunity predispose patients to disseminated histoplasmosis or coccidioidomycosis. These include loss-of-function mutations impacting IFN-γR1, IL-12Rβ1, and STAT3 and gain-of-function mutations in STAT1 (see Table 28.3). Based on a small number of reported cases of coccidioidomycosis, the fungus may disseminate preferentially to distinct sites depending on which component of immunity is impaired. For example, *STAT3* mutations are associated with dissemination to the CNS and gastrointestinal tract, while mutations that directly impact type-1 responses are associated with dissemination to bone and lymph node.[7]

Race and ethnicity influence the rates and patterns of endemic mycoses. African ancestry has been associated with increased risk of severe histoplasmosis in AIDS patients as well as increased overall risk of infection. The genetic determinants of racial disparities in *Histoplasma* pneumonia or disseminated histoplasmosis remain unknown.

The risk of disseminated coccidioidomycosis is unequal across people of different ethnicities and genetic backgrounds. Native American, African, and Pacific Islander ancestry all confer increased risk of dissemination. A few reports have addressed population-level patterns of susceptibility to disseminated coccidioidomycosis. Some of the risk may be attributable to differences in antigen presentation, as certain HLA alleles are associated with dissemination in specific populations. A preliminary genomic study of 58 patients with disseminated coccidioidomycosis identified 103 rare variants in 21 genes associated with antifungal immunity. Affected pathways included IL-17 signaling, IL-12/IFN-γ signaling, and NF-κB signaling. Two-thirds of patients had functionally relevant variants with a population frequency of less than 0.1%, including several patients with biallelic deleterious variants in key immune-related genes.

Recent work has addressed the genetic underpinning of disparate rates of blastomycosis in healthy individuals. A homozygosity mapping approach was used to study nine Hmong blastomycosis patient genomes, and candidate susceptibility variants were identified on the basis of their rarity in European populations and other features that may indicate that a given variant influences susceptibility. A block of variants near IL-6 is nearly fixed in Wisconsin Hmong but rare in European populations. Healthy Wisconsin Hmong donors had hypoactive IL-6 and antifungal Th17 responses compared to healthy European donors.[32] The latter finding is consistent with differences in IL-6 responses, which could also explain several as-yet unstudied population differences that impact T-cell development. To date, the only reported monogenic condition associated with blastomycosis is GATA2 haploinsufficiency.

SUMMARY

Fungi have emerged as significant causes of mortality in the rapidly expanding populations of immunosuppressed patients who are at risk for opportunistic fungal disease. A recent remarkable surge in immunological discoveries stemming from basic studies in animal models of fungal infections and observations in human cohorts with inherited or acquired susceptibility to mucosal and invasive mycoses has significantly advanced our understanding of the cellular and molecular factors that promote protective immune responses during fungal exposures of humans. This knowledge shows promise for devising precision-medicine strategies for risk assessment, vaccination, prophylaxis, immunotherapy, and prognostication of fungus-infected patients.

ON THE HORIZON

- The identification of CARD9 deficiency as, to date, the only known human monogenic disorder that features fungal-specific infection susceptibility underscores the critical contribution of C-type lectin receptor (CLR) signaling in human antifungal host defense and paves the way for the discovery of other novel inborn errors of immunity in CLR-related pathway genes that may underlie inherited susceptibility to tissue-specific fungal disease.
- In patients with iatrogenic immunosuppression or critical illness who develop life-threatening invasive fungal infections, the identification of dysfunctional single nucleotide polymorphisms in immune-related genes that heighten fungal infection susceptibility may lead to the development of individualized strategies for risk assessment and antifungal prophylaxis.
- A deeper understanding of the cellular and molecular immune factors that protect against fungal disease may inform immunotherapy and vaccination strategies in vulnerable patients.
- The advent of precision-medicine biological therapies that target key fungal surveillance immune pathways for the treatment of autoimmune and neoplastic disorders has resulted in new patient populations at risk for opportunistic fungal disease, and understanding the epidemiology and immunology of such infections can help devising targeted antifungal prophylaxis strategies for at-risk individuals.

Host Defenses to Protozoa

Robin Stephens, Jude E. Uzonna, and Sara M. Dann

Protozoal infections are an important cause of morbidity and mortality worldwide (Table 29.1). Protozoan pathogens exact their major toll in the tropics, but infection by these parasites remains a significant problem everywhere because of travel, military action, and immigration, the susceptibility of patients with acquired immunodeficiency syndrome (AIDS) to opportunistic protozoans, and episodic transmission within communities.

KEY CONCEPTS

Host Defense Against Protozoa

- Interaction of the parasite with host cells induces various cytokines that stimulate the innate and adaptive immune responses to eliminate the pathogen. Immunoregulatory cytokines can inhibit or downregulate both antiparasitic and host-damaging responses to enable the persistence of tissue parasitism.
- The outcome of infection is determined by the balance between the infection-promoting and the host-protective cytokines and effector cells. Often there is a mixed response, resulting in a persistent infection, but with less tissue damage than a hyper-inflammatory response would do.
- A persistently infected host may develop clinical disease if there is a waning of the immune mechanisms (e.g., in acquired immunodeficiency syndrome [AIDS]) that are critical to the control of infection, or a build-up of tissue damage over time. However, persistence can also protect from dangerous re-infection.

Protozoan pathogens make up a group of highly diverse organisms that represent a wide array of mechanisms of pathogenesis and immune evasion. There are numerous host targets for the intracellular protozoan parasites, including erythrocytes (*Plasmodium* and *Babesia*), macrophages (*Leishmania* and *Toxoplasma gondii*), or multiple cell types (*Trypanosoma cruzi, Plasmodium, Leishmania*). The luminal parasitic protozoan may be extracellular, such as amebae and the flagellates (*Giardia* and *Trichomonas*), or primarily intracellular, such as the coccidian parasite *Cryptosporidium*.

The innate and adaptive immune systems respond in diverse ways to the blood and tissue and intestinal protozoan pathogens. Neutrophils, macrophages, γδ T cells, and natural killer (NK) cells are the effector cells that mediate the innate response against the extracellular protozoan parasites. The NK cell–activated macrophage system is central to the innate response to intracellular parasites (Fig. 29.1) (Chapters 3 and 26). The innate cytokine response activates phagocytes and is critical to the induction of the adaptive immune response via antigen presentation by dendritic cells (DCs). For the intracellular pathogens (e.g., *Leishmania* spp., *T. cruzi*, *T. gondii*), the early production of interleukin-12 (IL-12) and interferon-γ (IFN-γ) drives the differentiation of T cells to a protective T-helper 1 (Th1) phenotype.[1] In most cases, CD4 T cells play a primary role in adaptive cellular immunity, but CD8 T cells can also be critically important through cytokine production (e.g., *T. cruzi*, *T. gondii*) or direct cytotoxic activity (e.g., *Cryptosporidium*). For the parasites with an extracellular stage (e.g., *Plasmodium* spp., *Trypanosoma* spp., *Giardia*, and *Trichomonas*), specific antibodies are critical to acquired immunity.

Intensive effort has been dedicated to the development of effective vaccines for protozoal diseases, but as of 2020, only one malaria vaccine (RTS,S) has reached the stage of clinical use, and efficacy and longevity are still limited. The reader is referred to the following reviews of potential vaccine candidates.[2–6] A discussion of the immune responses to some of the individual protozoal pathogens follows.

PLASMODIUM SPP.

Pathogenesis

Soon after *Plasmodium* spp. sporozoites are injected into the bloodstream by female *Anopheles* spp. mosquitos, they invade hepatocytes and undergo schizogony (asexual reproduction), multiplying asexually up to 10,000 times. Hypnozoites, a dormant form of *P. vivax* and *P. ovale*, can reside within hepatocytes for years and then undergo schizogony. *P. falciparum*, the most lethal species does not have a dormant form. Merozoites are then released from hepatocytes within a membranous structure, or merosome. Merozoites are released in the blood to invade red blood cells (RBCs). While the liver stage elicits primarily intracellular immunity, infected RBCs are the disease-causing stage. Parasite maturation within the RBC results in schizogony and release of new invasive merozoites through egress. The clinicopathological features of malaria are largely caused by the immune response to infected RBCs and egress. The cyclical release of parasites is regulated by food intake in mice and is associated with cytokine production and fever. This proinflammatory cytokine cascade plays a central role in the pathogenesis of severe malaria. Recognition of several pathogen-associated molecular patterns (PAMPs) drive this activation, including parasite proteins with glycophosphatidyl inositol (GPI) anchors, hemozoin, and uric acid in the extracellular milieu, and phagocytosed parasite nucleic acids.[7] The early production of proinflammatory cytokines (tumor necrosis factor [TNF], lymphotoxin, and IFN-γ) by NK cells and memory T cells leads to endothelial activation. This increases expression of endothelial adhesion molecules and hyper-coagulation, leading to poor perfusion due to unregulated clotting, immune cell

TABLE 29.1 Worldwide Significance of the Major Protozoal Infections

Parasite	Estimated Worldwide Cases (Annual Mortality)	Clinical Manifestations
Plasmodium spp.	200–250 million (*P. falciparum*: <1 million deaths/year, primarily children)	Fever, aches with potential complications in pregnancy and children: cerebral involvement, renal failure, pulmonary edema
Leishmania spp.	10–50 million people infected, 1.2 million new cases per year	Asymptomatic infection; skin ulcers or nodules; destructive oropharyngeal lesions; visceral disease with fever, hepatosplenomegaly, cachexia, pancytopenia
Trypanosoma cruzi	24 million (60,000 deaths)	Asymptomatic infection; dysrhythmias or chronic heart failure; hypertrophy and dilation of the esophagus, colon
Toxoplasma gondii	Several hundred million people infected worldwide. 5%–11% of healthy US adults are seropositive	Self-limited fever, hepatosplenomegaly; lymphadenopathy and encephalitis (reactivation in patients with acquired immunodeficiency syndrome [AIDS]); congenital infection, with fetal death, chorioretinitis, meningoencephalitis
Entamoeba histolytica	50 million (100,000 deaths)	Asymptomatic infection, diarrhea, dysentery, or liver abscess
Giardia lamblia	200 million (most common in young children and immunocompromised persons)	Asymptomatic infection, chronic diarrhea
Cryptosporidium parvum and *C. hominis*	Prevalence 3%–10% in patients with diarrhea in developing countries	Self-limited diarrhea in immunocompetent persons, severe intestinal and biliary disease in patients with AIDS
Trichomonas vaginalis	170 million/year	Asymptomatic infection, vaginal discharge, urethritis

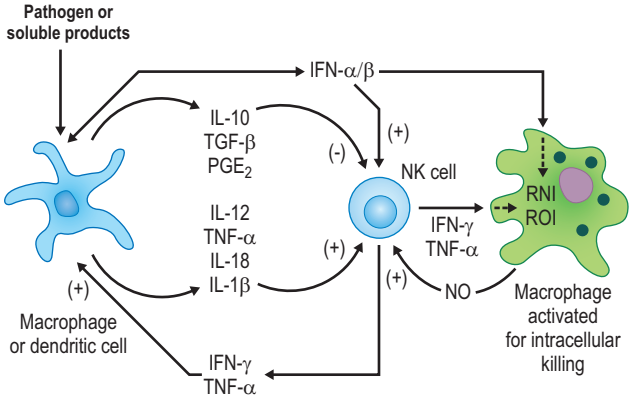

FIG. 29.1 Macrophage, Natural Killer *(NK)* Cell, and Cytokine Interactions in the Innate Immune Response to Intracellular Protozoa. Exposure of macrophages or dendritic cells to a pathogen or microbial product can result in the release of cytokines and inflammatory mediators that may stimulate (+) or suppress (–) NK cell activation. Activated NK cells produce cytokines that can then activate macrophages for intracellular killing. It must be recognized that this diagram is oversimplified and that these cytokines, most notably interferon *(IFN)*-α/β, interleukin *(IL)*-10, transforming growth factor *(TGF)*-β, and IL-12, may be produced by other types of cells, such as epithelial cells or enterocytes. *NO*, Nitric oxide; *PGE_2*, prostaglandin E_2; *RNI*, reactive nitrogen intermediates; *ROI*, reactive oxygen intermediates; *TNF-α*, tumor necrosis factor-α.

adhesion, and parasite sequestration in various organs causing symptoms of severe malaria. Early cytokine production has been linked to Toll-like receptor 2 (TLR2) on the macrophage surface, TLR7 and 9 in the endosome, and cytoplasmic STING and cGAS, leading to IFN-I production. Fever is linked to IL-1, which is NLRP3 and AIM2 inflammasome-dependent in *Plasmodium* infection. TNF family members play a strong role in severe malaria symptoms.[8]

Severe malaria includes placental malaria, severe anemia, respiratory distress, and cerebral malaria, with the latter causing up to 20% of deaths. In cerebral malaria, a combination of inflammation and vascular and multi-organ pathology leads to coma, seizures, and death. Pediatric patients may die as a result of severe edema of the brainstem leading to respiratory arrest. Severe anemia is due to the destruction of both infected and uninfected RBCs and dyserythropoiesis, which are increased by inflammatory cytokines, as is the damage in placental malaria. Immunoregulatory cytokines IL-10 and transforming growth factor-β (TGF-β) regulate the Th1 immune response, which drives parasite killing to limit pathology.[9]

KEY CONCEPTS

Immunopathogenesis of Severe Plasmodium falciparum Malaria

- Parasite components stimulate multiple innate recognition pathways to induce tumor necrosis factor (TNF) and lymphotoxin (LT), interferon type-I, and interleukin (IL)-1 production.
- TNF/LT induce vascular leakage and endothelial cell activation, with expression of adhesion molecules, platelet activation, leukocyte and parasite adhesion, and coagulation.
- Inflammatory cytokines amplify severe anemia caused by loss of infected red blood cells (RBCs) by inducing dyserythropoiesis and phagocytosis of uninfected RBCs, which can be coated with parasite antigens.
- Lethal outcomes for the fetus of infected women during pregnancy are caused by the local inflammation and vascular congestion induced by placenta-binding parasites.

Innate Immunity

While sporozoites rapidly transit from the skin to the liver, some remaining in hair follicles stimulate an immune response, including antibodies that can prevent re-infection. Complement can drive lysis of sporozoites and merozoites; however, C5 and C3 are also essential for pathogenesis of severe malaria in mice. Early production of IFN-γ by NK cells is associated with better outcomes of infection. γδ T cells are also activated

early in infection by phosphorylated lipid antigens correlating with immunity and protective vaccination. There appear to be innate specificities for both T cells and antibodies in naïve individuals that can recognize infection with *Plasmodium* spp. Macrophages stimulated by TNF and IFN-γ are important for parasite phagocytosis and killing. Animal studies have shown that phagocyte activation can limit initial growth of blood-stage parasite if strong enough, but this is regulated by the level of IFN-I triggered by each parasite strain. Antigen presentation by DCs can induce a strong adaptive immune response. These cells are replaced by inflammatory monocytes, which stimulate a less inflammatory response during prolonged infection, allowing the formation of germinal centers and parasite clearance.[7,8]

Adaptive Immunity

Immunity to *Plasmodium* spp. infection is acquired slowly. In areas of intense perennial *P. falciparum* transmission, the density of parasitemia and the incidence of severe malaria are highest in early childhood years, with severe disease declining after 1 to 2 infections. Disease immunity is likely to be due to subsequent production of a less pathogenic pattern of cytokines, though resistance to fever develops more slowly. Immunity to parasite growth is gained with exposure to multiple variants and development of strain-specific antibody. Therefore, most highly exposed adults are immune. However, in pregnant women, despite systemic immunity, the placenta can bind infected RBCs, causing mortality and morbidity in fetus and mother respectively.[8]

Adaptive immunity to the liver stage can be mediated by parasite-specific CD8 T cells via IFN-γ-induced NO-dependent killing of intra-hepatocytic parasites. While T-cell immunity to liver stage antigens is not high in exposed adults, CD8 T cells specific for pre-erythrocytic antigens can be protective. Attenuated sporozoite vaccines are in vaccine trials and are widely used in human challenge studies. One caveat is that since one escaped sporozoite can lead to malaria, anti-sporozoite vaccine induced protection would require very high antibody titers to quickly block invasion, or exceedingly high numbers of cytotoxic T cells to kill infected hepatocytes.[10]

Both humoral and cellular immunity is required against the erythrocytic stage of infection. Adoptive transfer of human immune serum is protective for naïve individuals. Antibodies directed against merozoite surface proteins can inhibit invasion by neutralization. The cytophilic isotype antibodies immunoglobulin G1 (IgG1) and IgG3 also play a significant role in naturally acquired immunity by opsonizing infected cells for phagocytosis in the spleen. However, an influx of blood-borne antigen induces a low-affinity IgM plasmablast response. Although there is an increase in atypical B cells, memory B cells and long-lived plasma cells are generated, leading to some strain-specific humoral immunity.[11] Parasite-antigen-specific B cells and CD4 T cells are required to generate germinal centers to make high-affinity antibody, to keep up with variant antigen switching, for complete clearance of parasites. CD4 T cells help B cells through a cognate interaction, and the production of IL-21 by T cells is crucial for isotype switching in *Plasmodium* infection. IFN-γ produced by CD4 and CD8 T cells, NK cells, and γδ T cells promotes phagocytosis of parasites, in synergy with TNF, IL-1, and opsonins. Although the response is characterized as Th1 due to the predominance of IFN-γ, and a little IL-4, the responding CD4 T cells express multiple cytokines. In addition to their role in helping B cells make antibody via IL-21, CD4 T cells are implicated in protection from severe pathology. CD4 T cells regulate the intense inflammatory response through production of antiinflammatory cytokines IL-10 and TGF-β, which is promoted by IL-27.[8]

Evasion of Host Immunity

Sporozoites and merozoites evade circulating antibody by rapidly entering hepatocytes or RBCs, respectively. Mature RBCs do not express MHC molecules on their surface and so avoid recognition by T cells. The few parasite proteins expressed on the erythrocyte surface either have hidden immunostimulatory epitopes or exist in multiple allelic forms that switch rapidly avoiding recognition by the adaptive immune system.[12] It is not yet clear if complement has a net protective effect, as infected RBCs express complement inhibitory receptors. Parasites also express a chemokine homologue and bind complement receptor 1, which leads to clumping of erythrocytes, a phenomenon called rosetting that probably helps parasite invasion, but also drives pathology.

TOXOPLASMA GONDII

Pathogenesis

Transmission occurs via the ingestion of oocysts, which are shed in the feces of felines or via tissue cysts present in undercooked meat. Following the oral ingestion of cysts, phagocytes recruited to the gut lumen facilitate transepithelial migration into the lamina propria. These phagocytes have been termed "Trojan horses," as they carry the parasite to new, unsuspecting host cells. Host-cell invasion starts with loose attachment facilitated by laminin. As in *Plasmodium*, intracellular tachyzoites replicate within a parasitophorous vacuole (PV) and ultimately leave the cell by using an active egress pathway. The released tachyzoites can disseminate to invade virtually any nucleated cell type, but mononuclear phagocytes are the preferred host cells. Under pressure from the host immune response, tachyzoite replication is controlled and tissue cysts, containing slowly replicating bradyzoites, are formed. The tissue cysts persist as a chronic latent infection as long as the host immune function is intact. If the latently infected person is immunosuppressed, reactivation occurs, and tachyzoites are released to infect more cells. Because tissue cysts are found in large numbers in the brain, reactivation of latent infection in the immunocompromised host most commonly manifests as encephalitis.

Innate Immunity

Similar to immunity to *Plasmodium* and *Leishmania*, type 1 immunity contributes to the control of the early stages of *T. gondii* infection.[1] Therefore, IL-12 is essential to host resistance. CD8 DCs are the primary producers of IL-12, through a MyD88-dependent mechanism. The parasite is recognized by TLR2 and TLR11 (in mice), and activation of CCR5, as well as intracellular STING.[13] IL-12-dependent activation of NK cells leads to their conversion into ILC1, which along with γδ T cells and neutrophils produce IFN-γ, which, in turn, activates macrophages to limit parasite replication.[14] In mice, the induction of immunity-related GTPases (IRG), which damage the PV membrane and kill *T. gondii* within the cytosol, is the primary macrophage effector mechanism. However, humans lack the IRG family and TLR11, and the mechanism(s) of macrophage activation in humans is unclear. Recognition by human $CD16^+$

monocytes and type 1 DCs is different from that in mice, as it comes after phagocytosis, suggesting a cytoplasmic sensor. The generation of reactive nitrogen and oxygen intermediates as well as degradation of tryptophan have all been implicated in the control of *T. gondii* in human macrophages.

Adaptive Immunity

Although serum antibodies can be used in the diagnosis of *T. gondii* infection, the systemic antibody response does not play a role in adaptive immunity. Mucosal IgA, however, does provide resistance to oral infection with *T. gondii* cysts. CD4 and CD8 T cells are highly activated during infection and are essential for adaptive immunity to prevent cyst reactivation during chronic latent infection. As such, patients with defects in T cell–mediated immune responses (e.g., patients with AIDS) are at risk for reactivation of latent infection. IL-12 also drives differentiation of Th1 cells and terminally differentiated effector CD8 T cells (Killer cell lectin-like receptor G1 positive [$KLRG1^+$]) in the response to *T. gondii* infection, and T-cell derived IFN-γ is required for protection. Parasite-specific cytolytic T cells have been demonstrated; however, CD8 T cells mediate protection primarily through the generation of IFN-γ. As in *Plasmodium* immunity, antiinflammatory molecules, particularly IL-10 and IL-27 made by Th1 cells, play an important role in modulating the adaptive immune response and restricting host tissue damage.[15]

Evasion of Host Immunity

T. gondii escapes early macrophage killing in a number of ways.[15] Virulent parasites are protected by the PV, which does not fuse with host cell lysosomes, or become acidified to kill the parasite. The infected macrophage is also a suboptimal target for T cell–induced immunity because of reduced expression of MHC class II and costimulatory molecules. Infection also induces the production of counterregulatory molecules, such as IL-10, TGF-β, IFN-I, and lipoxin A4, which both downregulate a potentially pathological host inflammatory response and inhibit macrophage antimicrobial activity. In addition, *T. gondii* interferes with normal macrophage signaling. For example, infection inhibits DNA binding of signal transducer and activator of transcription 1 (STAT1) and nuclear factor kappa B (NF-κB) activation and promotes antiinflammatory pathways downstream of the suppressor of cytokine synthesis proteins. The parasite also has several virulence proteins, including ROP5 and ROP16, which bind to the PV and reduce accumulation of the IRGs. ROP proteins also activate host STAT3 and STAT6, driving an M2 macrophage phenotype that is permissive to infection. The parasite also suppresses pDC activation through an ROP16 kinase-dependent mechanism.[15]

LEISHMANIA SPP.

Pathogenesis

The female phlebotomine sand fly becomes infected by ingesting *Leishmania* amastigotes during a blood meal. In the sand fly midgut, the amastigotes differentiate intracellularly into infectious extracellular metacyclic promastigotes that infect the vertebrate host during the next blood meal. Immunomodulatory factors present in sand fly saliva also enhance the infectivity of the parasite. Once injected into skin, promastigotes are phagocytosed by neutrophils, DCs, and macrophages (through complement–complement receptor–mediated coiling phagocytosis); they evade immunity and transform to amastigotes to replicate within the hostile acidic environment of the phagolysosome. A significant part of the pathogenesis following *T. cruzi* infection is its dissemination through the bloodstream to many tissues. The cytotoxic activity of CD8 T cells may promote cutaneous inflammation and lesion pathology.[16]

Innate Immunity

Much of what we know of immunity in leishmaniasis comes from studies of inbred mouse strains (B6 and BALB), which demonstrate genetically divergent innate and adaptive immune responses differentially shaping the outcome of infection. These studies also form the basis for much of what we know about the Th1/Th2 paradigm and cytokine-producing memory T cells in vivo. The innate immune response to *Leishmania* is mediated by complement, NK cells, cytokines, and phagocytes.[17] As in *Plasmodium* and *Toxoplasma*, IL-12 from DCs promotes crucial early IFN-γ production. Chemokines (IP-10, MCP-1, and XCL1), as well as interaction between LPG and TLR, can also promote early NK-cell activation, which can be cytolytic for *Leishmania*-infected macrophages. However, NK cell–derived IFN-γ plays a more prominent role in host defense by activating macrophages to kill the intracellular parasites through the generation of reactive oxygen intermediates (ROIs) or reactive nitrogen intermediates (RNIs). The generation of RNI by activated macrophages is the primary mechanism of parasite killing in the murine model. In human macrophages, inhibition of nitric oxide synthase 2 (NOS2) can impair killing of intracellular *Leishmania*. Parasite-induced, MyD88-dependent signaling through TLR2, TLR3, and TLR4, as well as type I IFN contribute to macrophage activation and NO production. Activated neutrophils can kill parasites through oxidative mechanisms, but their role in vivo depends on the timing of their recruitment and their interaction with other immune cells. Infiltrating neutrophils promote sand fly–transmitted infection through modulation of macrophage function following engulfment of apoptotic parasitized neutrophils.[17]

Adaptive Immunity

Within an endemic area there is acquisition of immunity in the population over time, and one infection (primary, subclinical, or healed) appears to be sufficient to induce immunity. Following primary infection, parasites persist for the life of the host and this persistence appears to be important for maintaining long-term immunity. Experimental models demonstrate that cellular immune mechanisms mediate adaptive resistance to *Leishmania* infection, and human studies have confirmed this. Because of the intracellular location of the parasite in the mammalian host, antileishmanial antibodies, which are produced at a low level in localized cutaneous leishmaniasis (LCL), and at a very high level in visceral leishmaniasis (VL), play no role in protection. The general mechanisms of cellular immunity in leishmaniasis are summarized in Fig. 29.2. Following infection in the skin, migratory dermal DCs phagocytose *Leishmania* and presumably transport the intracellular parasite to the regional lymph node, where they induce a T-cell response. Adaptive immunity is primarily mediated by parasite and IL-12-induced production of IFN-γ by CD4 T cells (Th1). CD4 T cells are absolutely required, but immunity to cutaneous disease is also mediated by CD8 T cells via production of IFN-γ.[16] Both CD4 and CD8 T cells are required for an effective defense against murine visceral *L. donovani* infection, but the precise role of CD8 T cells is unclear.

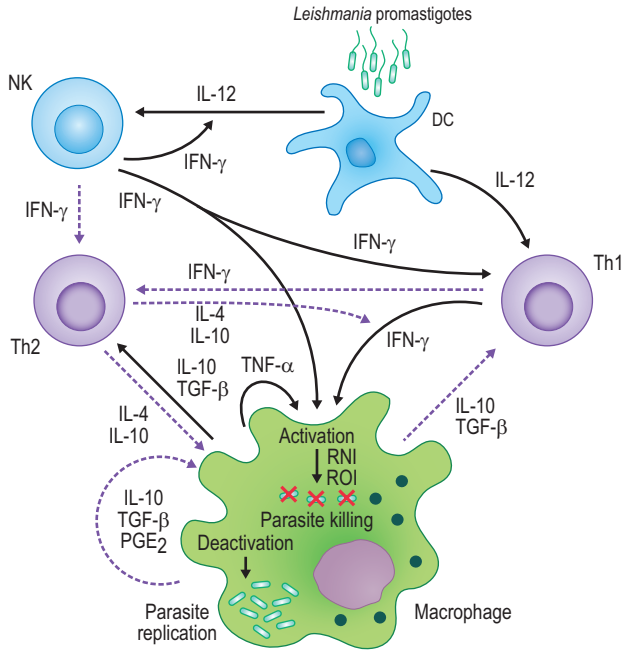

FIG. 29.2 Immunity in Leishmaniasis. Exposure of dendritic cells to parasites or parasite antigens leads to the release of interleukin *(IL)*-12, which induces natural killer *(NK)* cells to produce interferon *(IFN)*-γ and drives the adaptive immune response toward a protective T-helper 1 *(Th1)* phenotype. IL-12 production by dendritic cells and IFN-γ production by NK and Th1 cells negatively regulates the Th2 response. IFN-γ activates macrophages to kill the intracellular pathogen. In genetically susceptible individuals, a counterregulatory Th2 cytokine response can suppress the Th1 response and impair classic macrophage activation, leading to parasite replication and uncontrolled infection. Counterprotective macrophage-derived cytokines can also inhibit the Th1 response, stimulate the Th2 response, and impair classical activation through an autocrine loop. Activating stimuli are shown by *solid arrows*, and deactivating stimuli are shown by *dashed arrows*. *DCs*, Dendritic cells; *RNI*, reactive nitrogen intermediates; *PGE_2*, prostaglandin E_2; *ROI*, reactive oxygen intermediates; *TGF*, transforming growth factor.

The generation and maintenance of the protective Th1 response is critically dependent on CD40- CD40L-mediated IL-12 production by DCs. TNF also contributes to protective immunity by synergizing with IFN-γ to activate macrophages. Peripheral blood mononuclear cells (PBMCs) isolated from patients with LCL demonstrate a Th1 response to *Leishmania* antigens, and in the cutaneous lesion there is an exuberant Th1 and granulomatous response that mediates parasite killing and localized tissue damage, which usually leads to a scar. Patients with mucosal leishmaniasis (ML) exhibit vigorous cellular immune responses characterized by high levels of TNF and Th1 and Th17 cytokines contributing to the prominent tissue destruction of ML. Patients with diffuse cutaneous leishmaniasis resemble the progressive infection caused by *L. major* in BALB/c mice in that there are minimal or absent *Leishmania*-specific lymphoproliferative responses, and predominant Th2 cytokine expression. During active VL in humans, there is a marked depression of *Leishmania*-specific lymphoproliferative and IFN-γ responses, contraction of circulating memory T cells, and an absence of delayed-type hypersensitivity (DTH) response to parasite antigens.

Several subpopulations of memory CD4 T cells mediate immunity from cutaneous leishmaniasis. Effector memory cells, which are generated under conditions of antigen persistence, rapidly respond to secondary infection by migrating to the infected tissue and generating effector cytokines. Tissue resident memory cells (T_{rm}) also recruit other T cells to the site and contribute to efficient secondary anti-*Leishmania* immunity. Central memory T cells (T_{cm}) circulate throughout the lymphatic system and upon secondary challenge have a delayed response as they proliferate, and then migrate to the site of infection.[18]

Several adaptive immune mechanisms can also promote parasite replication and disease.[19] The progression of murine *L. major* infection has been correlated with the expansion of Th2 cells and the production of IL-4, IL-5, and IL-10. In susceptible mice, IL-4 production within the first day of infection was shown to downregulate IL-12 receptor β-chain expression and drive the response to a Th2 phenotype. However, other mouse strains appear to be able to overcome an early IL-4 response and develop a resistant phenotype, and susceptibility to some *L. major* strains is not strictly mediated by IL-4 (IL-13 and/or IL-10 may have a prominent role). The macrophage production of immune suppressive molecules, such as TGF-β or prostaglandin E_2 (PGE_2), may also contribute to susceptibility. The induction of T regulatory cells (Treg) in a PI3K-dependent way can also contribute to susceptibility by limiting the effectiveness of IFN-γ on infected macrophages.[2]

Evasion of Host Immunity

The *Leishmania* parasite has numerous ways in which it adapts to and survives within the vertebrate host.[20] In skin, the promastigotes may be phagocytosed by neutrophils and macrophages, which, unlike DCs, do not actively participate in T-cell priming. Furthermore, the clearance of apoptotic neutrophils is likely to make macrophages more permissive to infection. The expression of *Leishmania* surface protease GP63 and lipophosphoglycan (LPG) prevent the fusion of phagosome and lysosome, thereby enabling the parasite to replicate in phagocytes. They also confer complement resistance and facilitate the entry of complement-opsonized parasites into the macrophage without triggering a respiratory burst.

Leishmania-infected macrophages have diminished capacity to initiate and respond to a T-cell response, and the impaired antimicrobial effector activity provides a safe haven for the intracellular parasite.[20] Infected macrophages have decreased synthesis of IL-1 and IL-12, and blunted IFN-γ-mediated activation through the disruption of signal transduction pathways. Conversely, there is increased synthesis of the immunosuppressive molecules IL-10, TGF-β, and PGE_2. Parasite factors and IL-4/IL-13 enhance expression of arginase by infected macrophages. Both host and parasite arginase promote infection and pathogenesis through depletion of L-arginine, enhanced production of polyamines, and reduced NO production.[2] IL-10 produced by $CD4^+CD25^+$ Treg has an essential role in parasite persistence. Successful treatment of active disease restores an antigen-specific Th1 response.[19] Metastasizing parasites that cause mucosal disease also harbor *Leishmania* RNA virus, which subverts the host immune response and promotes parasite persistence through activation of TLR3 and the NLRP3 inflammasome.[21]

TRYPANOSOMA CRUZI

Pathogenesis

T. cruzi is transmitted to the mammalian host when the infectious metacyclic trypomastigote, which is deposited on skin in the feces of the reduviid insect vector while it takes a blood meal, is scratched into the wound or transferred to a mucous membrane (e.g., the eyes). The trypomastigotes can infect almost any cell type and replicate as amastigotes in the cytoplasm. Eventually, the amastigotes transform back into trypomastigotes and rupture the cell to enter the bloodstream, from where they invade other cells or are picked up by another insect vector. Muscle and glial cells are the most frequently infected cells, and acute myocarditis or meningoencephalitis can develop. In most cases, however, primary infection occurs without clinical symptoms (70% to 90%), and the infected individual may enter an indeterminate phase of asymptomatic seropositivity. Chronically infected individuals can develop symptomatic Chagas disease, usually involving the heart or the gastrointestinal (GI) tract. Pathologically, there are few parasites observed in cardiac tissue, but an intense chronic inflammatory infiltrate with fibrosis and loss of muscle fibers is evident. In the digestive tract, there is lymphohistiocytic infiltration of the myenteric plexuses, with reduction in the number of ganglion cells.

The tissue damage of acute *T. cruzi* infection is the result of a direct effect of the parasite and an indirect effect of the acute inflammatory and oxidative response. In chronic infection, the balance between immune-mediated parasite containment and inflammation-driven oxidative damage determines the course of disease. Whether tissue damage is caused directly by parasites or indirectly through parasite-driven inflammatory or autoimmune mechanisms, parasite persistence is a significant driver of disease (Table 29.2).[22] Autoimmunity could arise from molecular mimicry of self by parasite antigens or by the release of self molecules from damaged or dying host cells within the environment of an activated immune response.

Innate Immunity

As in the intracellular parasite immune reactions above, the early innate immune response to *T. cruzi* infection is mediated by NK cells, DCs, and macrophages.[23] Macrophages and DCs exposed to *T. cruzi* trypomastigote antigens produce IL-12 and TNF through a MyD88-dependent mechanism. A number of trypomastigote antigens, including free GPI anchors, glycoinositol phospholipids (GIPLs), GPI-linked glycoproteins, and GPI-mucins activate the innate immune response, through TLR2 and possibly TLR4. Immune activation through the Toll/IL1R domain-containing adapter protein–inducing IFN-β (TRIF), another protein involved in TLR2 signaling, promotes resistance through IFN-β and of IFN-β-inducible genes, such as the p47 guanosine triphosphatases (GTPase) *IRG47*. CpG DNA motifs in the *T. cruzi* genome also activate TLR9 and nucleotide-binding oligomerization domain (NOD)–like receptors are also activated intracellularly.[23] NK cell IFN-γ synergizes with TNF to activate macrophages to control parasite replication. The generation of NO is the primary trypanocidal mechanism in murine macrophages.

Adaptive Immunity

The innate immune response, through production of IL-12, type I IFNs, and other proinflammatory mediators, is critically linked to the generation of an effective adaptive immune response. Antibodies contribute to immunity within the bloodstream through opsonization, complement activation, and antibody-dependent cellular cytotoxicity. Several lines of evidence establish the importance of CD4 and CD8 T cells in adaptive immunity to *T. cruzi* infection. CD8 T cells specific to *T. cruzi*–infected cells confer protection when passively transferred to naïve mice. IFN-γ and TNF production by parasite-specific CD8 T cells is more important than cytolytic activity in the control of infection. CD4 T cells, followed by CD8s, are the predominant infiltrating cells in cardiac tissue.[24]

T. cruzi infection leads to a regulated Th1 cytokine response as described for *Plasmodium* and *Toxoplasma*. While IL-12/STAT4-dependent IFN-γ production is critically important to protection, the regulatory cytokines IL-10 and TGF-β can promote parasite replication by inhibiting macrophage activity, and also play a critical role in minimizing inflammation-mediated tissue pathology by regulating Th1 and TNF responses. Polymorphisms in the IL-10 gene that lead to reduced IL-10 production are associated with increased severity of cardiomyopathy in patients with Chagas disease. In addition to these regulatory

TABLE 29.2 Evidence for Autoimmune and Parasite-Induced Inflammatory Mechanisms in Chronic Chagas Disease

Evidence for Autoimmune-Mediated Disease	Evidence for Parasite-Induced Inflammatory Disease
Inflammatory disease presents in tissues with few or no parasites on routine histopathology studies	Sensitive parasite detection techniques (polymerase chain reaction [PCR], immunohistochemistry) correlate with the presence of parasites (or parasite material) and severity of inflammatory disease
Peculiar pattern of organ involvement (heart and gastrointestinal tract) in patients with chronic disease	Organs free of parasites (by sensitive parasite detection techniques) are also free of disease
Long delay in the onset of chronic disease following infection; only a minority of infected persons develops disease	Absence of effective cellular immune response (in mice or humans) almost invariably exacerbates rather than reduces the parasite burden and disease
Wide variability in the expression of disease among infected people	In chronically infected mice, the destruction of a transplanted heart is dependent on parasite infiltrating the transplanted tissue
Self-reactive antibodies and T cells demonstrable in infected people and in experimental animals. Level of antibodies to the ribosomal P protein (R13 peptide) and cardiac myosin (B13 antigen) correlate with cardiac disease	Degree of disease in hearts transplanted into chronically infected mice correlates with level of parasite burden in transplanted tissue
Transient or limited disease reported in experimental models following lymphocyte transfer	Reduction of parasite burden by chemotherapy usually leads to decreased tissue inflammation and disease

cytokines, the secretion of prostaglandins and the expansion of a myeloid suppressor cell population serve to control the intensity of the immune response.

Evasion of Host Immunity

Trypanosomal clonal variation and host genetic polymorphisms both contribute to tissue tropism, parasite persistence, and disease severity. *T. cruzi* bloodstream trypomastigotes resist complement lysis via a complement regulatory protein (GP-160). This parasite protein is functionally similar to mammalian decay-accelerating factor in that it inhibits C3 convertase formation and activation of the alternate complement pathway. *T. cruzi* invades host cells, in particular cardiomyocytes, by subverting a host plasma membrane repair pathway that promotes parasite persistence and tissue tropism. The rapid escape of the parasite from the phagosome into the cytoplasm through the action of acid-activated porins enables the organism to avoid phagolysosomal enzymatic destruction.

The establishment of chronic infection by *T. cruzi* is favored by a generalized depression of T-cell responses. A number of different mechanisms may contribute to this, including low IL-2 production or IL-2 receptor expression; downregulation of components of the T cell–receptor complex; T-cell receptor dysfunction; apoptosis of T cells; defects in the processing and presenting of antigens in the MHC class II (but not the class I) pathway; T-cell or macrophage suppressor activity; and PGE_2 production. Within the foci of myocarditis, apoptosis of both parasites and host cells occurs. The phagocytosis of these apoptotic cells by macrophages leads to their acquisition of an M2 phenotype, which enables parasite replication and persistence.

ENTAMOEBA HISTOLYTICA

Pathogenesis

E. histolytica causes asymptomatic intestinal colonization, acute diarrhea, dysentery, colitis, liver abscess, and, rarely, disseminated disease. Transmission of *E. histolytica* is through ingestion of cysts in fecal-contaminated food or water. When the cysts reach the intestine, trophozoites are released and migrate to the colon, where they adhere to the outer mucus layer covering the epithelium. In asymptomatic infections, trophozoites are confined to the outer mucus layer and survive by feeding on commensal bacteria and sugars from mucus. While mechanisms of invasive disease are unclear, *E. histolytica* is dependent on commensal bacteria for survival, but the composition of the microbiome (commensal bacteria, archaea, viruses, and eukaryotes) also contributes to driving disease pathology.[25] Risk factors for symptomatic disease, including the host's nutritional status, genetics, age, and sex, can alter the composition of the intestinal microbiome. When the microbiome is altered, trophozoites degrade the colonic mucus layers through secretion of proteases and glycosidases, allowing them to adhere directly to colonic epithelial cells by a galactose/*N*-acetylgalactosamine-inhibitable lectin (Gal/GalNAc). Exposure to the parasite induces epithelial cell lysis via contact-dependent mechanisms or through the release of lytic factors. Following epithelial damage, the parasite penetrates the mucosa and degrades connective tissue by releasing cysteine proteases, resulting in ulceration of the mucosa and submucosa (Fig. 29.3). *E. histolytica* is also capable of lysing a variety of other host cell types, including neutrophils, which release enzymes that further damage the tissue. Inflammation is a hallmark of invasive disease and characterized by the secretion of proinflammatory cytokines IL-8 and TNF and infiltration of immune cells. Amebic liver abscesses develop when trophozoites erode through the intestinal submucosa, enter the portal circulation, and disseminate to the liver.[26]

Innate Immunity

Through adherence and secretion of immunomodulatory proteins, trophozoites stimulate intestinal epithelial cells to release a variety of proinflammatory mediators, including IL-1α, IL-1β, IL 6, IL-8, and TNF that trigger the recruitment of neutrophils and macrophages to the site of invasion. Following activation by IFN-γ and TNF, neutrophils and macrophages become amebicidal through the release of reactive oxygen species and production of nitric oxide, respectively. Critical for controlling amebic liver abscesses, invariant natural killer T cells (iNKT) are specifically stimulated by amebic lipopeptidephosphoglycan (LPPG) to release IFN-γ. Production of IFN-γ reduces parasite burden and controls abscess formation.[26]

Adaptive Immunity

Secretory IgA responses against *E. histolytica* have been well characterized and shown to correlate with protection against infection and disease. For this reason, vaccines designed to generate IgA antibodies against the Gal/Gal/NAc lectin have been highly efficacious in preventing experimental *E. histolytica* infection in mice and baboons. However, the role of anti-lectin IgG is unclear, and protection may be subclass-dependent.[27] Cell-mediated immunity is also critical for host defense against *E. histolytica*. IFN-γ–producing CD4 T cells provide protection through their ability to activate macrophages and neutrophils to the parasite. CD8 T cells mediate protection through the secretion of IL-17, a key player in the secretion of mucin and antimicrobial peptides, recruitment of neutrophils, and IgA transport across the epithelial barrier. In chronic infection, *E. histolytica* promotes the development of Tregs that suppress the proliferation of responder T cells by releasing IL-10, TGF-β, and IL-35.[26] Impairment of cell-mediated immunity results in parasite dissemination. Indeed, patients with human immunodeficiency virus infection and coinfected with *E. histolytica* have high rates of invasive amebiasis, liver abscesses, and seroconversion.[27]

Evasion of Host Immunity

E. histolytica utilizes a number of strategies to circumvent the immune defenses of the host. It resists complement-mediated lysis during hematogenous spread by proteolytic degradation of C3a and C3b. In addition, the Gal/GalNAc lectin binds to C8 and C9, preventing assembly of the C5b-9 membrane attack complex. The cytolytic capability of *E. histolytica* affords protection from neutrophils, macrophages, and eosinophils, unless these cells are activated. Cytolysis by *E. histolytica* can occur via necrosis and apoptosis. Trophozoites also inhibit the macrophage respiratory burst and the production of IL-1 and TNF. A protective antibody response is subverted by the degradation of IgA and IgG by amebic cysteine proteases and by capping, ingesting, or shedding ameba-specific antibodies. Amebic proteases can also cleave the Fc region so that interaction with host cell-surface receptors is avoided. The suppression of host macrophage NO production by an array of trophozoite secretory products, including parasite-derived PGE_2, is a major factor in the persistence of amebic liver abscesses. *E. histolytica* expresses a homolog of the proinflammatory cytokine macrophage

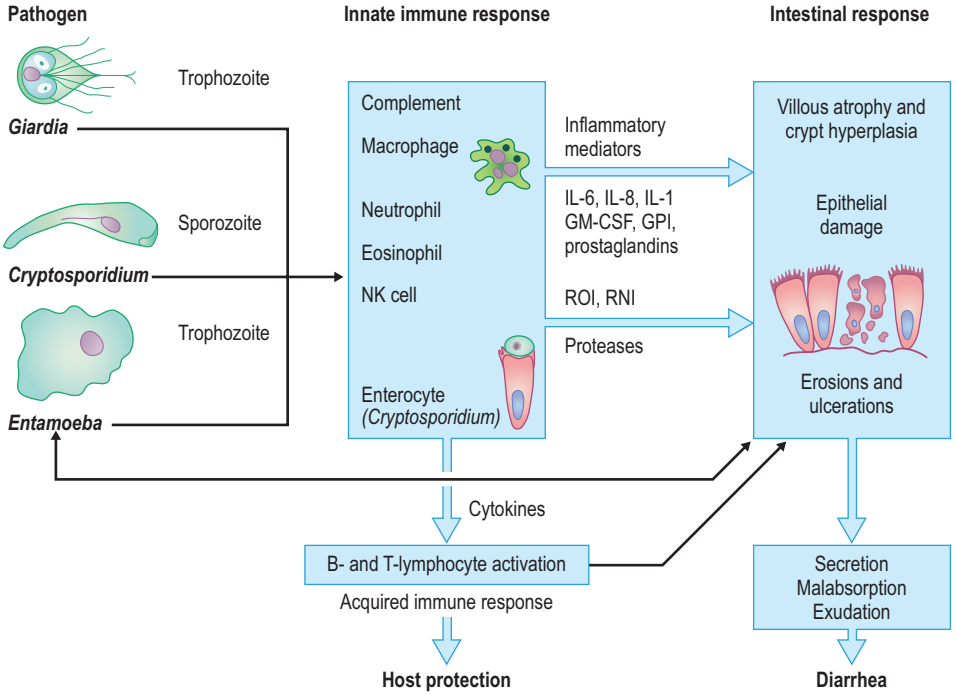

FIG. 29.3 Immunopathogenesis of Intestinal Protozoal Pathogens. After adherence (*Giardia* and *Entamoeba*) or epithelial invasion (*Entamoeba* and *Cryptosporidium*), there is release of various inflammatory mediators from macrophages and neutrophils. This causes the activation of resident phagocytes and recruitment of phagocytes into the lamina propria. Enterocyte death can be due to direct action of the parasites or to immune-mediated damage from complement, cytotoxic lymphocytes, proteases, and reactive oxygen and nitrogen intermediates (*ROI* and *RNI*, respectively). The inflammatory mediators also act on enterocytes and the enteric nervous system, inducing the secretion of water and chloride. In response to enterocyte damage, under the influence of activated T lymphocytes, the crypts undergo hyperplasia, and the villi become shorter (villous atrophy). The immature hyperplastic cells have poor absorptive ability but retain secretory ability. Damage to the epithelium can cause leakage (exudation) from lymphatics and capillaries. Similar mechanisms are probably responsible for the diarrhea that occurs in infection with *Cyclospora* and *Isospora*. *Isospora* is unique in causing an eosinophilic infiltrate. *GM-CSF*, Granulocyte macrophage–colony-stimulating factor; *GROα*, growth-related oncogene alpha; *IL*, interleukin; *NK*, natural killer.

migration inhibitory factor (MIF) and also monocyte locomotion inhibition factor (MLIF), which respectively promote gut inflammation and tissue invasion and phagocytic respiratory burst and other monocyte functions.

GIARDIA DUODENALIS

Pathogenesis

G. duodenalis (syn. *Giardia lamblia*, *Giardia intestinalis*) is a complex of eight genetic assemblages (designated A to H), two of which are infectious to humans and a variety of other mammalian hosts (assemblages A and B). The severity of giardiasis ranges from asymptomatic carriage to chronic watery diarrhea, epigastric pain, nausea, vomiting, and weight loss, depending on host factors and the virulence of the *Giardia* strain. Recent studies suggest even with treatment the parasite can elicit intestinal complications that persist for years.[28] Younger age, malnutrition, and immunodeficiency increase the risk of severe disease. Infection is initiated following the ingestion of food or water contaminated with *G. duodenalis* cysts. Exposure to stomach acids induces the excystation process that releases two trophozoites into the lumen of the proximal small intestine. Colonization occurs when the parasite attaches to the intestinal epithelium and begins to reproduce by binary fission. Trophozoites remain within the lumen and do not invade the epithelial barrier. Parasite migration into the lower intestine triggers encystation, allowing the organism to survive when excreted into the environment.

The *G. duodenalis* trophozoite initiates adherence to the intestinal epithelium via a surface mannose-binding lectin (MBL). Histopathological changes in symptomatic giardiasis range from a normal appearance to increased crypt-villous ratios, epithelial damage, and chronic inflammatory infiltrate in the lamina propria (see Fig. 29.3). The factors responsible for the structural changes in the small bowel may include injury from adherence, parasite-induced apoptosis of epithelial cells, and the release of cytotoxins, including proteases. Additional epithelial damage may be mediated by the host cellular immune response and changes in the composition of commensal microbiota. Diarrhea arises from epithelial barrier dysfunction, reduction in microvillous surface area, chloride hypersecretion, and glucose and sodium malabsorption.[29]

Innate Immunity

As *G. duodenalis* does not invade the intestinal epithelium, host defense and immune factors present within the lumen are essential for preventing and controlling tissue infection. Antimicrobial peptides made by Paneth cells, including cryptdins, neutrophil defensin, cathelicidin, and lactoferrin effectively

kill *G. duodenalis* trophozoites in vitro. NO, produced by both epithelial cells and macrophages, inhibits trophozoite division; however, the parasite can circumvent this defense by competing with host cells for arginine uptake. Mast cells have a significant role in protecting against the parasite. Mice deficient in mast cells fail to clear *G. duodenalis* infection, in part because they are unable to mount parasite-specific IgA. Mast cells also contribute to B-cell survival, activation, and differentiation into plasma cells, and together with NO induce peristalsis. Increased intestinal motility contributes to *G. duodenalis* clearance, by impairing the ability of the parasite to attach to the epithelium and resist the luminal bulk flow.[29]

Adaptive Immunity

Several lines of evidence suggest the importance of the humoral immune response in the control of giardiasis. Infection with *Giardia* results in the production of anti-*Giardia* antibodies in the serum and mucosal secretions. Patients with severe B-cell defects or selective IgA deficiency have an increased risk of developing chronic infections. Mouse studies showed key functions of secretory IgA and the polymeric immunoglobulin receptor, which transports IgA into the intestinal lumen, in controlling parasite burden.[29] A reduction or absence of CD4 T cells can also lead to chronic infection. IFN-γ- and IL-17A-producing CD4 T cells developed following infection[30] contribute to parasite clearance. IL-17A is likely involved in modulating transport of IgA into the intestinal lumen. Epidemiological studies indicate that partial immunity is acquired from *Giardia* infection, which leads to reduced risk and severity of subsequent infections.

Evasion of Host Immunity

Giardia evades the host humoral immune response with surface antigenic variation using a group of variant-specific surface proteins (VSPs). VSP switching occurs when intestinal anti-VSP IgA responses are first detected. *G. duodenalis* also produces cysteine proteases that degrade immunoglobulins, inflammatory mediators, and host defensins.[28] Although *Giardia* activates DCs for antigen presentation, it also inhibits IL-12 production, in part by enhancing IL-10 release; the net result is the dampening of a local antiparasitic inflammatory response. The trophozoite also releases arginine deiminase, which degrades arginine, making it less available for host NO production.[29]

CRYPTOSPORIDIUM SPP.

In humans, there are four intestinal coccidians that are intracellular parasites of enterocytes: *Isospora belli*, *Cyclospora cayetanensis*, and two species of *Cryptosporidium*, *C. parvum* and *C. hominis*. Of the four coccidians, *Cryptosporidium* has the greatest epidemiological significance: in 1993, an outbreak involving 403,000 persons occurred in Milwaukee, in the United States. Because of their similarity, only the immunology of cryptosporidiosis will be discussed.

Pathogenesis

Cryptosporidium typically causes self-limited (but often prolonged) diarrhea in the immunocompetent host. However, in the immunocompromised host *Cryptosporidium* can cause severe diarrhea, with malabsorption and wasting, and cholangiopathy. Infection begins with the ingestion of food or water contaminated with oocysts. The acidic environment of the stomach induces excystation and the release of four sporozoites per parasite into the small intestines. After entry into epithelial cells using its surface glycoproteins, the parasite resides within a unique intracellular but extracytoplasmic vacuole, which protects the pathogen. Here, the sporozoites grow and undergo schizogony. Individual merozoites emerge and invade neighboring epithelial cells. The merozoites may continue an asexual cycle or develop into macro- or microgametes that fuse to form oocysts. Before being excreted in feces, oocysts undergo sporulation to become infectious. Histologically, infection causes villous atrophy and blunting, and crypt hyperplasia with increased infiltration of lymphocytes, macrophages, and plasma cells.[31] Intraepithelial lymphocytes (IELs) are uncommon; neutrophils and occasional eosinophils are present between the epithelium and the lamina propria. Disorganized cells undergoing necrosis replace normal enterocyte architecture (see Fig. 29.3). There is an association between the degree of intestinal injury and malabsorption and the intensity of infection, as measured by oocyst excretion.

The neuropeptide substance P, which is produced by endothelial cells, lymphocytes, and monocytes in the lamina propria, contributes to diarrhea in patients with AIDS as well as cryptosporidiosis by increasing intestinal chloride secretion and glucose malabsorption.[32]

Innate Immunity

IFN-I and IFN-γ are critical in the innate protective response against *Cryptosporidium*. Because of the parasite's intracellular location, near the luminal surface of the enterocyte, the macrophages of the lamina propria are spatially separated from the parasite, rendering them inert and the intestinal epithelium's response critical. Endothelial cells are activated by TLR2/TLR4–dependent NF-κB activation and release of the microbicidal peptide β-defensin-2, TNF, and the chemokines IL-8, and RANTES, growth-regulated oncogene α (GROα), which act as chemoattractants and activators of neutrophils.[31]

IL-15, produced by activated monocytes, stimulates NK-cell proliferation, cytotoxicity, and cytokine production, including IFN-γ. IL-15 levels in the jejunal mucosa in immunocompetent patients inversely correlate with parasite burden. However, in patients with AIDS who have chronic uncontrolled cryptosporidiosis, IL-15 is undetectable. Infected intestinal cells also release TGF-β, which decreases necrosis and stimulates the synthesis of extracellular matrix proteins, thereby limiting epithelial damage. Prostaglandins E_2 and $F_{2\alpha}$, released by infected enterocytes, not only promote secretory diarrhea but also upregulate mucin production, which may hinder parasite attachment. They also stimulate the release of β-defensin-2, which has direct anticryptosporidial activity and is chemotactic for T cells and DCs. MBL is a serum complement protein that binds to various pathogens, including *Cryptosporidium*, and opsonizes them. Low serum levels of MBL, the result of malnutrition or genetic polymorphisms, increases susceptibility to cryptosporidiosis.[31]

Adaptive Immunity

Activated by macrophages and DCs, cell-mediated immunity plays an important role in the resolution of cryptosporidiosis and protection from re-infection.[6] In immunocompetent, adult mice CD4 IELs initiate early control of infection, whereas cytotoxic CD8 IELs appear later and function in parasite elimination. Resolution of infection depends on a balance of Th1 cytokines (IFN-γ, IL-18) needed to control the infection and

Th2 cytokines (IL-4, IL-10, and IL-13) that limit immunopathological damage. In mice, γδ T cells are rapidly recruited to control cryptosporidial infection, but their role in human infection is unknown. Severe intestinal disease or biliary involvement is usually seen in patients with AIDS whose CD4 count is less than 50/μL.[31]

The role of humoral immunity is less clear. Immunoglobulin deficiencies are often associated with persistent or recurrent infections. However, specific anti-*Cryptosporidium* IgA levels have been reported in patients with AIDS who are heavily infected with the parasite, and could play a role in neutralizing parasites, preventing attachment to the epithelium, but clearly are not sufficient.[31] In experimentally infected human volunteers, serum IgM and IgG directed toward sporozoite proteins protect against the development of symptoms, but not infection.

Evasion of Host Immunity

Cryptosporidium evades host defenses primarily by exerting control over infected enterocyte apoptosis. One of the upregulated genes is osteoprotegerin, which inhibits apoptosis by acting as a decoy receptor for TNF-related apoptosis inducing ligand (TRAIL). Control of host apoptosis is complex; early inhibition of apoptosis by NF-κB activation allows the parasite to complete its life cycle, whereas the late promotion of apoptosis facilitates merozoite release. Nevertheless, the infected cells secrete FasL, which promotes apoptosis in uninfected bystander cells. In this way, the host counters the antiapoptotic activity of the parasite by surrounding the parasitized cells with a zone of apoptotic cells. In patients with AIDS and cryptosporidiosis, the HIV Tat protein may sabotage host defense against *Cryptosporidium* by inhibiting cholangiocyte TLR4 expression.

TRICHOMONAS VAGINALIS

Pathogenesis

T. vaginalis is a flagellated protozoan parasite of the human urogenital tract that exists only as a trophozoite. It causes vaginitis, cervicitis, and urethritis. Its adherence to the vaginal squamous epithelium is facilitated by a number of adhesins. *Trichomonas* causes tissue damage by contact-dependent cytolysis caused by pore-forming proteins and proteases, and secretion of a glycoprotein cell-detaching factor that causes sloughing of the vaginal epithelium. Levels of the cell-detaching factor correlate with the severity of the disease, and vaginal antibodies directed against this factor modulate its effects. Inflammation in the genital mucosa and submucosa leads to copious secretions, and the surface epithelium may slough, causing focal erosions and hemorrhage.

The increased risk of HIV transmission in women with trichomoniasis may result from increased recruitment of inflammatory cells, mucosal erosion, or degradation of secretory leukocyte protease inhibitor (SLPI) by trichomonal proteases. Lower levels of SLPI are found in the vaginal fluid of women with trichomoniasis, which can lead to increased tissue damage and HIV transmission.[33] The LPG of *Trichomonas* induces production of the chemokines IL-8 and CCL20, which can also facilitate HIV infection by promoting DC recruitment.

Innate Immunity

Although both innate and adaptive immune responses are generated during *T. vaginalis* infection, evidence suggests that innate immunity plays a more prominent role in host protection and parasite elimination.[34] *Trichomonas* secretes a factor that promotes neutrophil chemotaxis, causing profuse leukorrhea, but the oxidative microbicidal mechanisms of the neutrophils have decreased efficacy in the anaerobic vaginal environment. Activated macrophages can destroy trichomonads in a T and B cell–independent manner and release IL-lβ and TNF. *Trichomonas* induces neutrophil apoptosis, and macrophage clearance of these apoptotic cells causes release of IL-10, which may contribute to resolution of the inflammatory response.[35]

Adaptive Immunity

Repeated infections with *T. vaginalis* do not induce immunity; however, the infection is self-limited in most cases, demonstrating that there are effective mechanisms of host defense. *T. vaginalis* induces the production of antibodies in both the serum and vaginal secretions. The serum antibody response correlates with active infection, and serum, but not vaginal, IgG from infected patients displays complement-mediated lytic activity against trichomonads in culture.[35]

Evasion of Host Immunity

Although *T. vaginalis* activates the alternative pathway of complement, the cervical mucus and menstrual blood are low in complement. Parasite virulence is enhanced, and the symptoms are exacerbated during menses. Menstrual blood supplies iron, which upregulates trichomonal adhesins and cysteine proteases, causing the degradation of complement component C3 bound to the surface of the parasite. Cysteine proteases secreted by *T. vaginalis* also degrade immunoglobulins, sabotaging the antibody response.[34] To further limit humoral immunity, the parasite secretes soluble antigens that are lytic to B and T cells or act as decoys for neutralizing antibodies. Phenotypic variation of surface antigens and ability to disguise itself by binding to host plasma proteins are additional mechanisms utilized by the parasite to escape immune detection.

ON THE HORIZON

Anticipated Approaches to Improved Control of Protozoal Diseases

- Gaining insight into the role of host genetics, gender, intestinal microbiota, and nutritional status in the outcome of protozoal infections.
- Defining host immune and inflammatory mechanisms that promote disease caused by protozoal pathogens.
- Understanding mechanisms for sustained generation of protective immunity against protozoal pathogens.
- Developing vaccines for several blood and tissue protozoa.
- Developing new host-directed treatment strategies to overcome immune evasion by protozoal pathogens.

Host Defenses to Helminth Infection

Subash Babu and Thomas B. Nutman

Parasitical helminths are complex eukaryotic organisms, characterized by their ability to maintain long-standing, chronic infections in human hosts, sometimes lasting decades. Hence, parasitical helminths are a major healthcare problem worldwide, infecting more than 1.5 billion people, mostly in resource-constrained countries (Fig. 30.1). Common helminth infections include those with intestinal helminths, and filarial and schistosome infections are a major medical, social, and economic burden to the countries in which these infections are endemic. Chemotherapy, although highly successful in some areas, still suffers from the disadvantages of the length of treatment, the logistics involved in the distribution of drugs, and, in some cases, the emergence of drug resistance. Vector control measures are at best an adjunct measure in the control of helminth infections but also suffer from the same social, logistic, and economic obstacles as those for mass chemotherapy. Therefore, the study of the immune responses to helminth infections attains great importance both in terms of understanding the parasite strategies involved in establishing chronic infection and in the delineation of a successful host immune response to develop protective vaccines against infection.

SPECTRUM OF HOST–PARASITE INTERACTIONS

Helminths have characteristically complex life cycles, with many developmental stages.[1] Transmission to humans occurs by ingestion of eggs or larvae, penetration of intact skin by larvae, or inoculation of larvae by biting insects. Thus, the host is exposed during the course of a single infection to multiple life-cycle stages of the parasites, each stage with a shared as well as a unique antigenic repertoire. For example, *Schistosoma mansoni* infection begins with penetration of the skin of humans exposed to infested waters by the free-swimming cercariae, which then develop into tissue-dwelling schistosomula. In the liver and mesenteric veins, schistosomula differentiate into sexually dimorphic adult worms, which then mate, and the resultant eggs produced migrate through tissues into the lumen of the intestine or bladder for environmental release. Similarly, in lymphatic filarial infection, the host is exposed to infective-stage larvae in skin, lymph nodes, and lymphatics; to adult worms in lymph nodes and lymphatics; and finally, to microfilariae in the peripheral circulation. Hence, the host–helminth interaction is complex not only because of the multiple life-cycle stages of the parasite but also because of the tissue tropism of the different stages.

Antigenic differences among the life-cycle stages can lead to distinct immune responses that evolve differentially over the course of a helminth infection. In addition, depending on the location of the parasite, the responses are compartmentalized (intestinal mucosa and draining lymph nodes in intestinal nematode infection, or skin/subcutaneous tissue and draining lymph nodes in onchocerciasis) or systemic (lymphatic filariasis or schistosomiasis). Moreover, the migration patterns of the parasite might elicit varied cutaneous, pulmonary, and intestinal inflammatory pathologies, as seen, for example, in *Ascaris* or *Strongyloides* infection during their migratory phase. This is further complicated by the fact that human hosts are often exposed to multiple life-cycle stages of the parasite at the same time. Thus, a patient with chronic infection with lymphatic filariasis harboring adult worms and microfilariae might be exposed to insect bites, thereby transmitting the infective-stage parasite. The immune response that ensues will not only be a reaction to the invading organism but will also bear an imprint of the previous exposures and the concurrent infection.

KEY CONCEPTS

Helminth Infection

- Divided into nematodes, trematodes, and cestodes.
- Produce chronic infections that can persist for decades.
- Characteristically cause morbidity rather than mortality.
- Multicellular parasites that do not multiply in the definitive host but can reproduce sexually to produce larval stages that ensure continued transmission.

Helminth infections can elicit a spectrum of clinical manifestations mirroring diversity in host immune responses.[2] For example, in lymphatic filariasis, most infected individuals remain clinically asymptomatic despite harboring significant worm burdens; this is thought to reflect the induction of parasite-specific tolerance in the immune system. Others exhibit acute manifestations, including fever and lymphadenopathy, and this is thought to reflect inflammatory processes induced by incoming larvae, dying worms, or superadded infections. Individuals who mount a strong but inappropriate immune response end up with lymphatic damage and subsequent immune-mediated pathology—hydrocele and elephantiasis. Finally, a group of infected individuals mount exuberant immune responses that often result in unusual pathology, such as tropical pulmonary eosinophilia. Thus, the clinical manifestations of lymphatic filariasis exemplify the spectrum of host–parasite interactions that occur during helminth infections (Fig. 30.2). Helminths also cause disease by a variety of mechanisms, including mechanical effects such as intestinal obstruction

(e.g., ascariasis), invasion of host cells or tissue with damage or loss of function (e.g., trichinellosis), or competition for nutrients (e.g., vitamin B_{12} deficiency from fish tapeworm infection).

Another hallmark of all helminth infections is their chronic nature, with many helminths surviving in the host for decades. For example, adult schistosomes and filariae may survive in host tissues for as long as 30 years, producing eggs and larval stages throughout this time. Similarly, *Strongyloides stercoralis*, with its ability to "autoinfect," can maintain its life cycle for decades. Chronic infections certainly reflect an adaptation that leads to "parasitism," as mortality induced in the host would prevent parasite transmission if the host died before larval release or egg production could occur. In addition to the long-lived nature of the infection, helminths appear to reflect a harmonious host–parasite interface such that relatively asymptomatic carriers are available as reservoirs for ongoing transmission. Of course, failure to establish this harmonious coexistence does occur, leading to pathological conditions exemplified by cirrhosis and portal hypertension in schistosomiasis and elephantiasis associated with lymphatic filariasis.

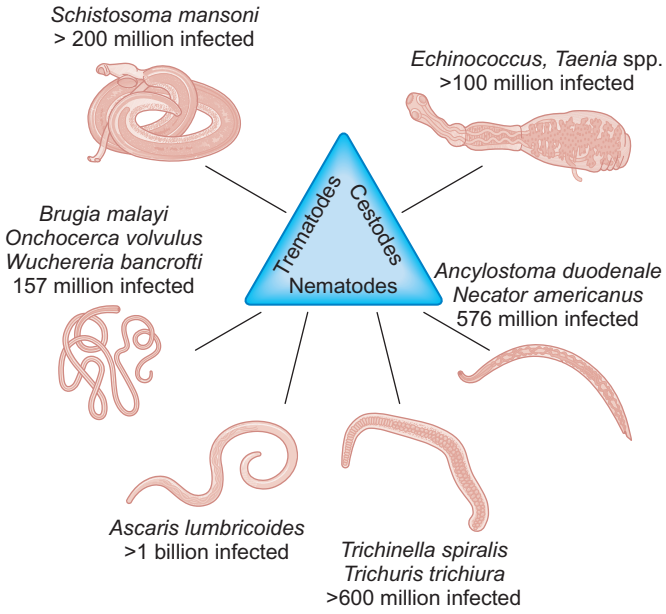

FIG. 30.1 Common and medically relevant helminth infections and their global prevalence.

PROTOTYPICAL HOST RESPONSES TO HELMINTHS

The canonical host immune response to all helminths is of the T-helper 2 (Th2) type and involves the production of cytokines, interleukin (IL)-4, IL-5, IL-9, IL-10, and IL-13; the antibody isotypes immunoglobulin G1 (IgG1), IgG4, and IgE; and expanded populations of eosinophils, basophils, mast cells, type 2 innate lymphoid cells (ILC2), and alternatively activated macrophages (AAMs).[3] However, it is also being increasingly recognized that while the predominant response is Th2 in nature, a large regulatory component involving both regulatory cytokines and cells is also part of this repertoire.[4] The Th2 response induced by helminth parasites is quite stereotypical, but its initiation, progression, and culmination requires interaction with many

different cell types, most notably *(i)* epithelial/stromal cells, *(ii)* innate lymphoid cells (ILCs), *(iii)* dendritic cells (DCs) and macrophages, *(iv)* T cells, *(v)* B cells, *(vi)* eosinophils, *(vii)* mast cells/basophils, and *(viii)* neutrophils. The Th2 response plays a role in both resistance and tolerance phenotypes in response to helminth infection.[5] Resistance mechanisms promote resistance to helminth infections, while tolerance mechanisms (such as wound healing) operate to reduce the effect of helminth infections on host immunity without causing pathology. In addition, the host–helminth interactions can lead to a variety of modulated immune responses that are mediated largely by the induction of regulatory T cells (Treg) and AAMs (Fig. 30.3).

Helminths and Epithelial Cells

Epithelial cells are the first barrier layer exposed to or breached by most helminths, and the capacity of these cells to respond by initiating an "alarm" response has recently been recognized.[6] These epithelial cells mount a prototypical response comprising of chemokines and cytokines, such as IL-25, IL-33, and thymic stromal lymphopoietin (TSLP), as well as alarmins, such as uric acid, ATB, HMGB1, and S100 proteins.[7] These signals program dendritic cells (DCs) to mount Th2 cell–mediated immunity and in doing so boost ILC2, basophil, and mast cell function. IL-25 and IL-33 are necessary for protective immunity to a variety of helminth infections by inducing the production of Th2 cytokines, while TSLP is important for promotion of Th2 cell differentiation. Epithelial cells produce chemokines, including CCL17 and CCL22 (acting on ILC2, basophils, Th2 cells, and Tregs), and eotaxins, such as CCL11, CCL24, and CCL26 (acting on eosinophils and Th2 cells). They also produce prostaglandin D_2 (PGD_2), which acts on the CRTH2 receptor to recruit ILC2, basophils, mast cells, and Th2 cells. More recently, tuft cells, a specialized secretory cell type of the intestinal epithelium, have been identified as a major player in anthelmintic immunity. Tuft cells are the sole intestinal source of IL-25, which further promotes IL-33 production.[8] Moreover, tuft cells exhibit a requirement for signaling via chemosensory receptors, raising the possibility that they use chemosensation to recognize helminths. In addition, epithelial cells in the intestine, for instance, are in constant contact with both beneficial and pathogenic bacteria and hence ideally located for immunological surveillance of the intestinal lumen. This recognition of signals by intestinal epithelial cells is essential to mucosal homeostasis, implicating these cells as central modulators of inflammatory responses. Finally, the production of mucus and mucus-associated bioactive molecules (Mucin5AC, trefoil factor-2, and resistin-like molecule-β [RELM-β]) are important in promoting protection against intestinal helminth infection.

Helminths and Innate Lymphoid Cells

The ILC family includes ILC1, which predominantly express IFN-γ; ILC2, which predominantly express IL-5 and IL-13; and ILC3, which predominantly express IL-22 and/or IL-17.[9] ILC2 are defined by their expression of the IL-33 receptor (IL-33R) and the transcriptional regulators, Id2, RORα, GATA-3, and Bcl11b. Unlike T cells, ILC2 rely on cytokines to drive activation rather than on cognate interactions mediated by antigen-specific receptors. ILC2 are a critical innate source of type 2 cytokines, including moderately large quantities of IL-5 and IL-13, but also of IL-4, IL-9, granulocyte macrophage–colony-stimulating factor (GM-CSF), and amphiregulin. These cytokines potently induce eosinophilia, mucus production from goblet

cells, activation of AAM, muscle contractility, mast cell proliferation, and tissue repair.[10] IL-25 and IL-33 play crucial roles in promoting ILC2 responses in the lung and intestine, while TSLP is necessary for ILC2 responses in the skin. In addition, the transcription factors GATA-3 and RORα, as well as Notch signaling, have been found to be essential for the development of ILC2. Also, ILC2 are regulated by the nervous system through neurotransmitters and neuropeptides (including stimulation by neuromedin U, vasoactive intestinal peptide, and calcitonin gene-related peptide, and inhibition by catecholamines and acetylcholine receptor agonists). Although the function of ILC2 and Th2 cells appear to be largely overlapping, the kinetic differences in the ability to secrete cytokines rapidly and in profuse amounts allows for a coordinated interaction between the two cell types. Moreover, ILC2 can directly regulate the activation of T cells through their expression of major histocompatibility complex (MHC) class II molecules and the accessory molecules, CD80 and CD86, albeit less efficiently compared with DCs. Finally, recent reports have linked ILC2 with metabolic homeostasis, obesity, and dietary stress, providing an indirect link by which helminths might modulate host metabolic function. Also, ILC2 can interact with neuronal cells, which produce a chemical called neuromedin U in response to helminths, and produce IL-5 and IL-13 directly.

Helminths and Dendritic Cells

DCs are professional antigen-presenting cells (APCs) that play an essential role in presenting antigen to T cells to initiate immune responses. Although the role of DCs in inducing Th1, Th17, and Treg responses is well established, their role in inducing Th2 responses has remained relatively unclear.[11] Nevertheless, a series of studies have shown that DCs are required for optimal Th2 responses in vivo. Thus in vivo depletion of DCs has been shown to inhibit the induction of Th2 responses to *S. mansoni* or *Heligmosomoides polygyrus bakeri*. Helminth products can prime DCs for the induction of Th2 responses by interaction with pattern recognition receptors (PRRs), such as Toll-like receptors (TLRs) and C-type lectin receptors (CLRs). This interaction, which depends on TLR and CLR signaling, can promote Th2 responses by suppressing antigen presentation, costimulation, and/or expression of Th1-promoting cytokines by directly interfering with these pathways. DCs that drive Th2 responses typically exhibit specialized markers, such as CD301b, PDL2, and CD11b, and several receptors for the Th2-related cytokines IL-4R, IL-13R, IL-25R, TSLP-R, and IL-33R. These DCs also express the transcription factors IRF4 and KLF4. Additionally, the extracellular signal-regulated kinase (ERK) and signal transducer and activator of transcription 4 (STAT4) pathway upregulates the costimulatory molecules CD40, OX40L, and Jagged. Activation of the major transcription factors, IRF4 and KLF4, inhibits IL-12 production and increased IL-10 secretion. In addition, DCs expressing FcεRIII can induce murine IgG1-related Th2 responses. These factors typically act individually or in concert to orchestrate Th2 responses in helminth infections. Although Th2 cell–mediated immunity requires IRF4-dependent $CD301b^{+}CD11b^{+}$ DCs in the mouse, Langerhans cells are the predominant inducers of Th2 cells ex vivo in humans. The modulation of DC function by helminth antigens appears to be generalizable and has been shown to impair their ability to respond to other infectious stimuli (e.g., *Mycobacterium tuberculosis*).

Helminths and Macrophages

Macrophages are the other important class of APCs that can serve as protective effector cells in bacterial and protozoan infections by their production of nitric oxide and other mediators. Helminth interaction with macrophages induces a population of cells preferentially expressing arginase instead of nitric oxide as a result of increased activation of *arginase-1* by IL-4 and IL-13.[12] These AAMs are characterized by their ability to upregulate arginase-1, chitinase 3-like proteins 3 and 4 (also known as Ym1 and Ym2, respectively), and RELM-α.[5] These AAMs are known to be important in wound healing and have been postulated to play a potential role in repairing wound damage that occurs during tissue migration of helminth parasites. In fact, there appear to be two distinct populations of AAMs, one derived from blood and functioning in an immune regulatory role and the other derived from tissue-resident macrophages apparently responsible for much of the fibrosis seen in chronic helminth infections. Different tissue environments have specific amplification mechanisms for AAM proliferation (e.g., surfactant protein A in the lung and complement component, C1q in the peritoneal cavity and liver). By virtue of the expression of regulatory molecules, such as IL-10, TGF-β, and PDL2, these AAMs may have a predominantly regulatory role in helminth infections. These antiinflammatory macrophages function through arginase-1, PDL2, triggering receptor expressed on myeloid cells 2 (TREM2) and RELM-α to inhibit classic macrophage inflammation and recruitment and T-cell responses. RELM-α–expressing macrophages can also reduce parasite burdens and protect lung damage during helminth infections. Similarly, macrophage-derived human resistin is induced by helminth infection and promotes inflammatory responses and increased susceptibility. AAMs are also a source of retinoic acid and can expand thymus-derived regulatory T cells or inducible regulatory T cells at the site of infection.

Helminths and T Cells

Typically, infections with helminths induce a robust Th2 response manifested by enhanced expression of IL-4, IL-5, IL-9, IL-10, and IL-13 in response to live parasites, parasite antigens, or mitogens.[7] The central player in Th2 immunity is certainly the CD4 Th2 cell.[13] It is clear that IL-4Rα, a component of both the IL-4 and IL-13 receptors, is at the epicenter of Th2 immunity, since IL-4 and IL-13, together or individually, are absolutely critical for resistance to most helminth parasites. Recent work has reported that the Th2 cell population is heterogeneous, containing both $IL\text{-}5^{+}$ and $IL\text{-}5^{-}$ Th2 cells that express IL-4 and IL-13. In addition, IL-4 and IL-13 production is spatially separated, with IL-13 expression being marked in tissues and IL-4 expression being pronounced in the lymph nodes within the Th2 cell compartment. More recently, it has been reported that this heterogeneity extends to involve the expansion of a $CD161^{+}$, $CD27^{-}$ Th2 cell compartment, which diminishes following anthelmintic treatment.[14] The major transcription and accessory factors involved in the differentiation of Th2 cells are GATA3, STAT6, STAT5, STAT3, Gfi-1, c-Maf, and IRF4. Interestingly, chronic helminth infections are associated with downmodulation of parasite antigen-specific proliferative responses as well as IFN-γ and IL-2 production, but with intact IL-4 responses to parasite antigens and global downregulation of both Th1 and Th2 responses to live parasites. Finally, the receptor NLRP3 has been shown to be a key transcription factor in Th2 differentiation.

Central memory T cells are typically associated with resistance to helminth infections and are often found at lower frequencies in helminth-infected individuals.[15] This is associated with lower systemic levels of IL-7 and IL-15. In addition, helminth infections are also associated with the expansion of a new type of memory CD8 T cells called virtual memory or bystander memory CD8 T cells, whose induction is dependent on IL-4. Although the role of tissue-resident memory T (T_{RM}) cells is well established in viral and bacterial infections, very little is known about the role of these cells in helminth infections. However, it has been shown that tissue-resident Th2 cells can exert innate (TCR-independent and IL-33–dependent) functions upon appropriate stimuli and confer protection against helminth infection. In addition, although multifunctionality (ability to produce two or more cytokines) has not been well described in the Th2 cell compartment, helminth infections are known to be associated with an antigen-dependent enhancement of mono- and dual-functional Th2 cells and its reversal after treatment. Of interest, a stable subset of parasite induced T-bet$^+$, GATA-3$^+$, Th1/Th2 hybrid T cells has been described to develop directly from naïve precursors and to play a role in limiting pathological inflammation in animal models of helminth infection.

Recently, a new subset of T cells expressing IL-9 and IL-10, but not IL-4 (and therefore different from Th2 cells), has been described in allergic inflammation and in response to intestinal parasites.[16] These cells appear to be under the control of TGF-β and IL-4 and are dependent on STAT6, GATA-3, IRF4, and PU.1. Th9 cells have been recently shown to be associated with host protection in *Nippostrongylus brasiliensis* and *Trichuris muris* infection. Finally, Th9 cells have also been shown to be predominantly associated with lymphatic pathology in filariasis. T-follicular helper (Tfh) cells are a subset of CD4 T cells that migrate to B-cell follicles after activation and promote germinal center formation and B-cell isotype switching.[17] These cells, which form an independent lineage of CD4 T cells, have been recently identified to be the predominant IL-4–producing T cells early in helminth infection. In addition, Tfh are major producers of IL-21, a cytokine that plays a crucial role in supporting polarized Th2 responses in vivo.

Th17 cells, another subset of CD4 T cells, express the prototypical cytokine—IL-17.[16] In terms of helminth infections, the role of Th17 cells has been primarily studied in animal models of *S. mansoni*, where it has been strongly associated with infection-induced, immune-mediated pathology. More recently, it has also been demonstrated in human infections, in which children with *Schistosoma haematobium*–associated pathology have higher Th17 responses compared with those who are pathology-free. Similarly, a strong association of Th17 responses with pathological responses has also been demonstrated in lymphatic filariasis. Finally, Th22 cells are yet another subset of CD4 T cells that typically secrete IL-22.[16] To date, only a few studies have examined the role of Th22 cells in helminth infections. IL-22 was shown to be induced in the intestinal mucosa after infection with *Trichuris trichiura* or *Necator americanus* in humans, whereas the frequency of Th22 cells was shown to be higher in individuals with filarial infection compared with endemic healthy controls.

Tc2 cells, which are CD8 T cells expressing IL-4 and IL-13 are also expanded in helminth infections, which in turn is regulated by the co-inhibitory molecules, CTLA-4 and PD-1. Finally, γδ T cells that express Th2 cytokines have also been described in helminth infections.

Helminths and B Cells

Helminth interactions with B cells occur both at the B-cell cytokine level and at the level of antibody production.[18] Interactions at the cellular level primarily result in B-cell activation and cytokine production, most notably by the induction of IL-10. B cells have been shown to be important for the Th2 responses to certain helminths, with IL-2–producing B cells supporting optimal development of effector and memory Th2 cells and LTα1β2-expressing B cells supporting the recruitment of Th2 promoting DCs. Immune regulation by B cells has also been recognized in schistosome infection, where B-cell deficiency leads to enhanced Th2 cell–dependent immunopathology. However, it is at the level of antibody production that B cells play a profound role in helminth infections. Susceptibility to secondary infection is increased in the absence of B cells in infection with *Litomosoides sigmodontis, S. mansoni, T. muris*, and *H. polygyrus bakeri*. IgG is reported as an antibody isotype that is important for protection against intestinal helminths, and IgM (typically produced in a T cell–independent manner) has been linked to timely elimination of filarial parasites. One of the most consistent findings in helminth infections, both in mice and humans, is the elevated level of IgE that is observed after exposure to helminths.[19] Most of the IgE produced is not antigen-specific, perhaps representing nonspecific potentiation of IgE-producing B cells or deregulation of a normally well-controlled immune response. Interestingly, these IgE antibodies persist many years after the infection has been treated, indicating the presence of long-lived memory B cells or plasma cells in helminth infections. IgE production both in mice and humans is absolutely dependent on IL-4 or IL-13. Recent findings have shown that IL-4–expressing Tfh cells induce low-affinity IgE production, while IL-13–expressing Tfh cells induce high-affinity IgE production. Other isotypes that are commonly elevated in humans with chronic helminth infection are IgG4 and IgG1, the former being most dependent on both IL-4 and IL-10.

Recent studies have highlighted the role of regulatory B cells in suppression of immune responses to helminth parasites.[20] This B-cell function involves the secretion of IL-10 and IL-35 and is similar to the regulatory activity of B cells in autoimmune diseases. These cells mostly express CD11c and T-bet. B1 cells are a subset of B cells that produce natural antibodies. B1 cells have been demonstrated to be necessary for immunity to helminth infections in animal models. Moreover, B1 cells are known to produce polyclonal IgE during helminth infections.

Helminths and Eosinophils

Blood and tissue eosinophilia is characteristic of helminth infection and is mediated by IL-5 (probably in concert with IL-3 and GM-CSF).[21] Recruitment of eosinophils to the site of infection occurs very early in experimental helminth infection—as early as 24 hours after exposure. Kinetics of blood eosinophilia in humans is harder to determine but is postulated to occur as early as 2 to 3 weeks after infection, as demonstrated in experimental infections of volunteers. Both basal eosinophil levels and tissue accumulation during helminth infection appear to be under the influence of ILC2. Apart from the rapid kinetics of recruitment, eosinophils in blood and tissue also exhibit morphological and functional changes attributable to eosinophil activation. Eosinophils possess a range of immunomodulatory factors that are released upon cell activation, including cytokines, growth factors, and chemokines. Eosinophil granular proteins, such as eosinophil cationic protein, eosinophil-derived neurotoxin,

eosinophil peroxidase (EPO), and eosinophil major basic protein (MBP), are elevated in helminth infections and diminish following anthelmintic therapy. In general, eosinophils are able to kill larval stages of several helminth species in vitro, but their role in helminth control in vivo is not clear. By using eosinophil-depleted mice, it was shown that eosinophils were not required for primary or secondary immunity to a variety of helminth infections. Unlike T and B cells, eosinophils can rapidly release cytokines within minutes in response to stimulation since most of the cytokines are stored in a preformed fashion in secretory vesicles. Moreover, eosinophils can participate in the regulation of IgE and goblet cell mucus production; they also serve as effector cells in protective immune responses and as regulatory cells influencing both innate and adaptive immunity in helminth infections. The most important chemokine for eosinophil trafficking to tissues is Eotaxin-1, and to a lesser extent Eotaxin-2, while IL-5 enhances the development and maturation of eosinophils.

Helminths and Basophils/Mast Cells

Basophils are an important component of the immune response to helminth infections.[22] Basophils are capable of secreting a variety of mediators, including histamines, cytokines, chemokines, and lipid mediators that promote Th2 responses. Basophils in humans and mice also readily generate large quantities of IL-4 in IgE-dependent and IgE-independent manners and can also secrete IL-25 and TSLP. Basophils appear to play an important role in protective immunity to secondary infection (similar to eosinophils) with *N. brasiliensis, H. polygyrus bakeri*, and *L. sigmodontis;* they also play an active role in resistance to primary infection (through secretion of IL-4 and IL-13) with *T. muris* and *Trichinella spiralis*. In addition, basophils have been shown to be critical APCs (by acquiring MHC class II molecules from DCs by a process called trogocytosis) for driving Th2 cell differentiation in different models of helminth infection and to prime ILC2 for neuropeptide-mediated inhibition.

Mast cells may contribute to inflammatory reactions directed against invasive helminth parasites.[19] These cells express high-affinity Fcε receptors that are sensitized with parasite antigen–specific IgE and can be triggered by parasite antigens. It has been postulated that cytokines and other mediators released by sensitized mast cells contribute to *(i)* the recruitment and activation of effector eosinophils; *(ii)* increased local concentrations of antibody and complement; and *(iii)* enhanced mucus hypersecretion and increased peristalsis of the gastrointestinal (GI) tract, which plays an important role in resistance to certain GI nematode infections. More recently, a role for mast cells (in an IgE-independent manner) in mediating the secretion of epithelial-derived cytokines (IL-25, IL-33, and TSLP) and optimal migration of DCs was shown in *H. polygyrus bakeri* infection. Mast cells are also crucial for induction of ILC2 by production of IL-33 and for elimination of helminth infection by promoting ILC2 expansion and goblet cell hyperplasia. Finally, mast cell granular proteins, such as mast cell tryptase and carboxypeptidase A3, are elevated in helminth infections and diminish following anthelmintic therapy.

Helminths and Neutrophils

Although neutrophils are typically considered more important in bacterial and fungal infections, a number of studies have revealed that neutrophils can act in conjunction with macrophages to contain or kill helminth parasites.[7] Thus, neutrophils are major components of the granulomas forming around filarial parasites and the cysts containing larvae of intestinal helminths. Neutrophils have been demonstrated to collaborate with macrophages in the immobilization and killing of *S. stercoralis* larvae in a process that is complement-dependent and involving neutrophil extracellular traps (NETs). Similarly, neutrophils contribute in the early antifilarial response through oxidative burst, degranulation, and NETosis and protect against infective larvae in skin. Indeed, NETs can mediate direct killing of hookworms and hookworms in turn secrete a deoxyribonuclease that degrades NETs to evade host immunity. A seminal study reported that neutrophils adopt an "N2" phenotype during experimental infection with *N. brasiliensis* in the lung and express the genes for IL-13, IL-33, RELM-α, and Ym1. These "N2" neutrophils can train macrophages to acquire a memory phenotype that protects against secondary infection. Neutrophils can rapidly upregulate the expression of Th2-related genes, including IL-13, IL-33, RELM-α, and chitinase-3-like. Finally, it was also shown that even during primary infection, the absence of neutrophils resulted in greater worm burdens because of lack of immunity in the lungs. Thus, neutrophils appear to play an unexpected role in immunity to helminths that certainly merits further investigation. Moreover, neutrophil granular proteins, such as neutrophil elastase and myeloperoxidase, are increased in helminth infections and diminish following anthelmintic treatment.

PROTECTIVE IMMUNITY AGAINST HELMINTHS

The mechanism of protective immunity to helminths is dependent on the location of the helminth infection.[7] Clearly, T cells are central to resistance against helminths.[23] For example, T cells are essential in mediating the expulsion of GI nematodes. Mice lacking T cells are defective in their ability to expel *T. muris*, but resistance can be reconstituted by transfer of T cells from normal mice. In addition, CD4 T cells from infected mice can transfer protective immunity to severe combined immunodeficiency (SCID) mice (lacking both B and T cells), indicating that CD4 T cells, not CD8 T cells, are important for protective immunity. Similarly, T cells were shown to be required for expulsion in *N. brasiliensis* infection. Both nude mice (lacking T cells alone) and SCID mice are susceptible to infection with Brugian parasites, whereas mice that lack either CD4 T cells or CD8 T cells are not. In schistosome-infected mice, T cells are essential in forming host-protective granulomas around the eggs deposited in the liver.

The role of cytokines in protective immunity has been extensively studied in murine models of both GI helminths and tissue-invasive helminths.[5] In general, type 2 (Th2) cytokines target epithelial cells, goblet cells, smooth muscle cells, and macrophages, which together coordinate parasite expulsion by increasing fluid and mucus production, encapsulation and barrier formation, epithelial cell turnover, smooth muscle cell contraction, and production of anthelmintic effector molecules, such as RELM-β. The cytokines involved in both responses are IL-4, IL-5, IL-9, and IL-13.[15] Most of the studies examining resistance to intestinal helminths involve four parasitical GI nematode infections of rodent models—*T. spiralis, H. polygyrus bakeri, N. brasiliensis*, and *T. muris*.[13] These studies show that *(i)* CD4 T cells are crucial for host protection; *(ii)* IL-4 is required for host protection and limiting host pathology; *(iii)* IL-13 can substitute for IL-4 in some but not all infections; *(iv)* IL-2 and

IFN-γ inhibit protective immunity; and *(v)* IL-4 and IL-13 have multiple effects on the immune system and gut physiology, leading generally to protection. Type 2 cytokines mobilize a broad range of downstream effector mechanisms. Epithelial cells in the gut, specifically tuft cells, promote goblet cell differentiation, enhancement of mucus secretion, and the production of RELM-β, an innate effector molecule with direct anthelmintic activity. Goblet cells can also secrete gel-forming mucins, which are major macromolecular components of the mucus barrier. Two of these mucins have been shown to be critical in resistance to intestinal nematode infection—Muc2 and Muc5AC. Another group of molecules that have been found important in immunity to helminths are the trefoil factors, especially trefoil factor 2. IL-4Rα activation also leads to increased intestinal smooth muscle hypercontractility and accelerated epithelial turnover to promote an effector response akin to an "epithelial escalator," which, together with epithelial secretions, helps expel intestinal helminths. This smooth muscle activity is now known to occur in response to neurotransmitters or nerve stimuli, with serotonin and M3 muscarinic acetylcholine receptors being involved in the process. Enteroendocrine cells are also known to contribute to increased intestinal motility for parasite expulsion. Mucosal mast cells release proteases that can degrade epithelial tight junctions, thereby increasing fluid flow as part of the "weep and sweep" response, with contribution from goblet cell production of mucus. AAMs in the gut can also entrap intestinal worms and cause death by compromising worm vitality.[23]

Although the role of Th2 cytokines in immunity to GI helminth infection is well defined, their role in protective immunity to tissue-invasive helminths is not as clear. In murine models of schistosomiasis, protective immune responses can be generated by vaccination with irradiated cercariae. This resistance is dependent on a Th1-mediated immune response consisting of macrophages and endothelial cells activated by IFN-γ and TNF-α, producing nitric oxide and Th1-associated antibodies—IgG2a and IgG2b. In contrast, studies in rats and epidemiological studies in humans suggest Th2-mediated effector mechanisms involving IgA and IgE antibodies, as well as eosinophils are thought to be central to protective immunity. Protective immunity to filarial infections in mice is dependent primarily on Th2 responses in mice. Thus, mice lacking IL-4, IL-4R, or Stat6 are all susceptible to infection with *Brugian* parasites.

In tissue-invasive helminth infections, effector mechanisms involve multiple innate immune cells, with antibodies acting as initiators of immunity by activating Fc-receptor–expressing cells. Basophils, by their ability to produce high levels of IL-4, act as effectors to promote helminth killing in secondary or challenge infections. For example, basophils are important in immunity to the skin-invasive stages of intestinal helminths and, through IL-4 release, promote the activation of macrophages that trap larvae in an arginase-dependent manner. Although eosinophils are crucial players in producing IL-4 early in infection, they are also amplifiers of immune responses, rather than being critical mediators of primary immunity, since depletion of eosinophils does not alter the course of many helminth infections in murine models. The mechanism of protection mediated by eosinophils is thought to be by antibody-dependent, cell-mediated cytotoxicity, as observed in *S. mansoni* studies in vitro or through release of eosinophil granule contents. In addition, eosinophils play an important role in the protective immunity against primary infection with *Brugia malayi* and/or secondary infection with either *T. spiralis* or *N. brasiliensis*. The two most abundant granular proteins, MBP and EPO, are required for protective immunity against *S. stercoralis* and *L. sigmodontis*. Similarly, neutrophils can attack helminth larvae in response to IL-4 and IL-5, but their importance in resistance to primary helminth infections is not known.

Antibodies play a major role in mediating protection to some, but not all, helminth infections.[24] Antibody-mediated passive immunity has been demonstrated in animal models for *Ancylostoma caninum*, *Schistosoma* spp., *Taenia* spp., *Ascaris suum, Streptococcus ratti, T. muris, N. brasiliensis*, and *H. polygyrus bakeri*. Passive immunity has also been shown by using IgG monoclonal antibodies (mAbs) specific for *Fasciola hepatica* and *S. mansoni;* IgM (mAbs) specific for *B. malayi;* and IgG or IgA mAbs specific for *T. spiralis*. Using genetically-manipulated mouse models, IgM has been shown to be crucial for host protection against *B. malayi* and to *S. stercoralis*. B1B cells, a subset of B cells that secrete IgM, appear to be an important component of this protective axis. Finally, antibodies have the capacity to trap tissue-migrating helminth larvae and prevent tissue damage by driving an IL-4Rα–independent alternative differentiation of macrophages, in a process dependent on CD11b and FcγR1.

KEY CONCEPTS

Helminth-Induced Immune Responses

- Characterized by immunoglobulin E (IgE) and IgG4 antibody production, tissue and peripheral blood eosinophilia, mast cell involvement, innate lymphoid cell type 2 and Th2 cell expansion, and production of type 2 cytokines.
- Implicated both in pathogenesis of helminth infections and in mediating immunological protection.
- In mucosal immunity to helminths, T-helper 2 (Th2) cell responses are initiated and sustained by innate populations (including tuft cells and innate lymphoid cells) through interleukin (IL)-25, IL-33, and thymic stromal lymphopoietin (TSLP).
- In tissues, helminths are acted upon by the host innate effectors, including macrophages, neutrophils, eosinophils, and basophils.
- Regulated by T cells and other cells producing IL-4, IL-5, IL-9, IL-10, and/or IL-13.
- Characterized by the induction of regulatory T cells (Tregs) that mediate downmodulation of immune responses to helminth infections and impact bystander phenomena, such as allergy and autoimmunity.

In terms of protection, a major mechanism appears to be the formation of multicellular, immune cell aggregates, called *granulomas*, around incoming infectious larvae or eggs.[25] In murine models of schistosomiasis and filariasis, granulomas are primarily composed of T cells (which help in the recruitment of other cell types and mediate alternative activation of macrophages), B cells (particularly the B1 subset), and macrophages and eosinophils. Although the exact mechanism by which granulomas mediate killing of the parasite remains unknown, it is clear that formation of these structures is an important host defense mechanism. In neurocysticercosis, the dying *Taenia solium* cysticercus is enclosed in a granuloma composed of eosinophils, multinucleated giant cells, epithelioid cells, macrophages, T cells, and collagen fibers. One cell type that can mediate effector functions within granulomas is the AAM, which is exemplified by the targeting of the glycan chitin that is frequently expressed by helminths but not by the host. The chitinase and

fizz family proteins (ChaFFs), which include chitinase and chitinase-like secreted proteins, are prime candidates for mediating host resistance. These proteins include acidic mammalian chitinase (AMCase) and the RELM family proteins and are capable of enzymatic activities that potentially damage certain helminths. AAMs isolated from granulomas express high levels of surface IgG1, IgG3, FcγRs, and CD11b. Eosinophils within granulomas have been described to function by degranulation-mediated damage of the helminths as well as by enhancing antibody-dependent cell-mediated cytotoxicity. Myelin basic protein and eosinophil-stimulator-protein-mediated lysis have also been described.

PATHOLOGY ASSOCIATED WITH IMMUNE RESPONSES IN PARASITIC HELMINTH INFECTION

Typically, pathological findings associated with each parasitic infection are different and relate to the presence of the parasites in host tissues, but there are pathological reactions that stem directly from the host response.

Immune Complexes

Immune complexes are potent mediators of localized inflammatory processes that form in many parasitic infections presumably as a result of the chronic low-dose antigen release seen in these infections. Circulating immune complexes have been identified in both experimental and human filarial and schistosomal infections. These have been shown to induce lymphatic inflammation and vasculitis in filarial infections as a result of their deposition. It has been demonstrated that FcγR-mediated cell activation is the dominant pathway of immune-complex corneal disease in animal models of onchocerciasis. In addition, a common manifestation of immune-complex–mediated pathology, immune-complex glomerulonephritis (ICGN), has been documented by renal biopsy in patients with schistosomiasis and filarial infections. Other manifestations of immune complex–mediated damage, such as reactive arthritis and dermatitis, have also been described in patients with helminth infections.

Autoantibodies and Molecular Mimicry

Autoantibodies have been implicated as causing disease in a variety of helminth infections, including filarial infections, schistosomiasis, and hookworm infection, and are thought to reflect a polyclonal B-cell expansion that often accompanies these infections.[26] Autoantibodies against nuclear material have been found in a vast majority of patients with chronic schistosomiasis, and antibodies against human calreticulin and defensin have been found in onchocerciasis. New data also suggests that Nodding syndrome (an epileptic disorder) is an autoimmune disorder based on findings of cross-reacting antibodies between neuronal structures and a protein present in *Onchocerca volvulus*, called leiomodin-1. Finally, infection with *Toxocara canis* can trigger systemic vasculitis by anti-DNA, anti-nuclear, and anti-C1q antibodies.

Granulomatous Reactions

Granuloma formation is the mainstay of the protective immune response to certain helminths, but it can also lead to deleterious effects in the form of pathology. Although granulomatous reactions occur in many helminth infections (e.g., toxocariasis, *Angiostrongylus* infections, and lymphatic filariasis), parasitical granulomata have been best studied in *S. mansoni* infections, where granulomatous and fibrosing reactions against tissue-trapped eggs is orchestrated by CD4 T cells, and the fibrosis that results from the cellular response is the principal cause of morbidity in infected individuals. The severity of the inflammatory process markedly varies both in humans and in experimental animal models, with severe pathology associated with Th1 and Th17 responses and milder pathology with Th2-dominant responses. Studies in murine models of granuloma formation have demonstrated the important roles of IL-13 and TNF.

Fibrosis

Fibrosis is commonly associated with chronic helminth infections that result in chronic inflammation and dysregulated wound healing.[27] These infections activate macrophages and fibroblasts, resulting in the production of TGF-β, platelet-derived growth factor, connective tissue growth factor, IL-1β, and other factors. Macrophages also promote inflammation by recruiting and activating monocytes and neutrophils, as well as activating CD4 T cells. Hepatic stellate cells produce copious amounts of collagen, which accumulates and leads to fibrosis. In addition, fibroblasts are stimulated to synthesize matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs), leading to extracellular matrix remodeling and fibrosis. Another consequence of chronic schistosomiasis is pulmonary arterial hypertension, which has been shown to be associated with IL-4– and IL-13–mediated type 2 inflammation resulting in TGF-β–induced pulmonary vascular disease. In the same manner, IL-10 and IL-12 are known to modulate IL-13–mediated fibrosis; in the combined absence of IL-10, IL-12, and IL-13Rα, IL-13–dependent fibrosis in chronic schistosomiasis proceeds rapidly to lethal cirrhosis. One of the primary sources of morbidity and mortality in *S. haematobium*-infected individuals is egg-induced urinary tract fibrosis. Infection with *Wuchereria bancrofti* (one of the causative agents of lymphatic filariasis) is associated with similar fibrotic reactions.

Toll-Like Receptors

Immunopathology in lymphatic filariasis is associated with the presence of an endosymbiotic, *Rickettsia*-like bacteria called *Wolbachia*. *Wolbachia* are known to stimulate immune cells through TLR2 and TLR4 and to release proinflammatory cytokines, as well as vascular endothelial growth factors (VEGFs), which might contribute to lymphatic pathology.[28] *Wolbachia*–TLR4 interaction has also been shown to be the major mechanism of corneal inflammation in onchocerciasis, and a TLR-signaling molecule, IL-1 receptor–associated kinase-2 (IRAK-2), regulates pathogenic Th17-cell development in *S. mansoni* infection. TLR upregulation might also underlie post-treatment adverse events in filarial infections.

Immediate Hypersensitivity Responses

Immediate hypersensitivity responses are associated with the early and/or acute phase of infections with invasive helminth parasites, such as *Ascaris*, hookworm, schistosomes, or filariae. Patients manifest symptoms suggestive of allergic reactivity, such as wheezing or urticaria. Furthermore, in clinical syndromes associated with *Loa loa* infection (with its angioedematous Calabar swellings), with tropical pulmonary eosinophilia, and with larva currens in strongyloidiasis, IgE-mediated reactions are thought to underlie these signs and symptoms. Anaphylaxis

is a severe, life-threatening, generalized or systemic hypersensitivity reaction, and is associated with IgE interaction with high-affinity IgE receptors on basophils and mast cells. The risk of anaphylaxis in individuals with helminth infections can vary, depending on the parasite, tending to occur more frequently with echinococcosis or after *Anisakis* infection, while being extremely rare in most other helminth infections.

Wound Healing

Recent studies have shown a close association of type 2 cytokine responses with many aspects of wound healing and repair.[27] It has been proposed that the type 2 cytokine response has evolved to not only mediate resistance to helminth infection but also to activate the wound healing apparatus to repair and reconstruct tissue, since tissue damage is intricately associated with helminth infections. Thus, AAMs are intimately involved in this process as they produce MMPs, arginase-1, insulin-like growth factor 1, VEGF, and TGF-β, which together promote myofibroblast activation, angiogenesis, epithelial cell turnover, and extracellular matrix deposition. Additional signals from neutrophils, as well as lung surfactant protein A or trefoil factor 2, can also contribute to tissue repair. In addition, an ortholog of the human protein granulin from *Opisthorchis viverrini* accelerates wound repair.

Lymphangiogenesis

The anatomical changes in the architecture of lymphatics, which range from lymphangiectasia and granulomatous responses to the development of collaterals, suggest that active lymphatic remodeling involving endothelial cell growth, migration, and proliferation is an important feature of early lymphatic filarial disease.[2] Live filarial parasites (and their excretory/secretory products) have been shown to induce activation, proliferation, and tube formation in lymphatic endothelial cells (LECs) and their differentiation into tubelike networks. This was found to be associated with significantly increased levels of MMPs and TIMPs. Recent studies have also implicated the VEGF family in lymphangiogenesis, with VEGF-C being associated with lymphedema and VEGF-A with hydrocele and single nucleotide polymorphisms in MMP-2, CEACAM-1, and VEGF-R3 with lymphedema. Finally, TLR-mediated events are considered to be the main drivers of this angiogenic/lymphangiogenic process in filarial disease.

Carcinogenesis

Infection with *O. viverrini, Clonorchis sinensis*, and *S. haematobium* are classified as group 1 biological carcinogens (i.e., definitive causes of cancer).[29] The former (liver fluke) is associated with cancer of the bile duct (cholangiocarcinoma) and cancer of the liver (hepatocarcinoma), and the latter is associated with squamous cell carcinoma, an especially aggressive type of bladder cancer, as well as urothelial carcinoma. The mechanisms of helminth-induced cancer include chronic inflammation, sustained cellular proliferation, modulation of the host immune system, reprogramming of glucose metabolism and redox signaling, induction of genomic instability and destabilization of tumor proteins, stimulation of angiogenesis, resistance to apoptosis, and activation of invasion and metastasis. Seven other helminth infections have been reported to be associated with cancer, although their role remains to be firmly established.

Epileptogenesis

Neurocysticercosis, caused by the larval form of *T. solium*, is the most common preventable risk factor for epilepsy worldwide and accounts for nearly 30% of all epilepsies in some endemic areas. The manifestations are variable, depending on the location, number, and size of the cysts in the central nervous system as well as the degree of accompanying inflammation, provoked by cyst degeneration, calcification, and/or perilesional edema. The development of epileptic symptoms results from a complex interplay between the anatomical location of the cyst, environmental factors, parasite factors, host genetics, and especially host immune responses.

Epidemiological evidence has emerged pointing to a link between epilepsy and areas hyperendemic for *O. volvulus* throughout tropical Africa.[30] A 2018 longitudinal study from Cameroon suggested that the intensity of infection with *O. volvulus* has a crucial part in inducing epilepsy. Case-control studies in onchocerciasis-endemic regions in the Democratic Republic of the Congo suggested that ivermectin intake prevents the development of epilepsy in children. Living close to a river containing breeding sites of vector flies that transmit *O. volvulus* is associated with an increased risk of developing epilepsy. Onchocerciasis has been linked to two poorly understood diseases of tropical Africa: Nakalanga syndrome and nodding syndrome. Nakalanga syndrome is a child-development disorder that causes growth failure, wasting, skeletal deformities, endocrine dysfunction, intellectual disability, and epilepsy. Nodding syndrome is characterized by epileptic seizures with repeated slow dorsoventral head movements. A recent study showed that onchocerciasis eradication could eliminate nodding and Nakalanga syndromes and reduce the burden of epilepsy. Finally, nodding syndrome has been shown to be due to an immune cross-reaction to antigens of *O. volvulus*, thus conclusively providing a link.

MECHANISMS OF EVASION AND IMMUNE REGULATION BY HELMINTH PARASITES

Helminths exert profound immunoregulatory effects on the host immune system with parasite antigen–specific immune suppression as well as more generalized levels of immune suppression. It has been shown that patients with schistosomiasis or filariasis have markedly diminished responses to parasite antigens and to some measurable attenuation in responses to bystander antigens and routine vaccinations. Thus, host immunosuppression is usually antigen-specific, whereas chronic infection can be associated with some spillover effects. Among the mechanisms utilized by parasites to avoid immune-mediated elimination are those of evasion—the use of sequestration, camouflage, and antigenic variation—and suppression, regulation, or blockade of immune effector pathways.

Parasite-Derived Factors

Parasite-derived products play a very important role in host immune evasion.[31,32] Parasite products, such as the schistosome-secreted proteins, alpha-1 and omega-1, promote Th2 differentiation. Alpha-1 (also known as IL-4–inducing principle of schistosome eggs [IPSE]), released by schistosome eggs, induces IL-4 release and degranulation by human and mouse basophils by cross-linking surface IgE. Omega-1 is a ribonuclease abundantly secreted by eggs, shown to condition DCs to drive Th2 polarization. Omega-1 binds to and is internalized by DCs in a mannose receptor–dependent process and then suppresses protein synthesis through degradation of messenger RNA (mRNA).

Phosphorylcholine (PC) is a small hapten-like moiety present in the excretory/secretory products of many helminths, and one particular PC-containing molecule, called ES-62, from filarial worms has been shown to have a wide variety of immunomodulatory properties. Thus ES-62 can inhibit the proliferation of CD4 T cells and conventional B cells, decrease IL-4 and IFN-γ production, promote proliferation and IL-10 production by B1B cells, modulate complement activation, and condition APCs to drive Th2 differentiation with concomitant inhibition of Th1 responses. ES-62 has also been shown to exhibit bystander anti-inflammatory activity in collagen-induced arthritis, rheumatoid arthritis, chemical contact sensitivity, lupus-associated atherosclerosis, ear inflammation, chronic asthma, and airway hyperreactivity. Helminths utilize glycans within glycoproteins and glycolipids, which mimic host glycans, to regulate host immune responses. In addition, these host-like helminth glycans can directly interact with host glycan–binding proteins, such as CLRs and galectins, to shape innate and adaptive immune responses. Similarly, helminth lipids have also been implicated in immune modulation; schistosome phosphatidylserine induces DCs to polarize IL-4–producing T cells, whereas schistosome lysophosphatidylserine induces DCs to induce IL-10–secreting Tregs.

Helminth parasites utilize mechanisms involving cytokine mimicry and interference to establish chronic infection. Thus, parasites produce cytokine- and chemokine-like molecules to interfere with the function of host innate immune products. The first helminth cytokines were found to be homologues of TGF-β expressed by *B. malayi*, and both schistosomes and filarial parasites express members of the TGF-β receptor family. *H. polygyrus* secretes a protein called *H. polygyrus* TGF-β mimic (Hp-TGM) that binds to the mammalian TGF-β complex and drives human and mouse Treg production. Similarly, *Echinococcus granulosus* expresses a TGF-β ligand, and thus all helminth groups might have the potential to exploit TGF-β–mediated immune suppression. Various helminths, including *B. malayi*, produce homologues of macrophage migration inhibitory factors (MIFs), which are known to activate an antiinflammatory pathway through SOCS-1, a molecule involved in cytokine signaling. *T. muris* is known to express a homologue of IFN-γ, which binds to the IFN-γ receptor in vitro and induces signaling. As *T. muris* is expelled by IL-4, secretion of an IFN-γ–like protein can prolong its survival. *H. polygyrus* also secretes a cytokine-binding protein called HpAR1, which inhibits the release of alarmins.

Similarly, helminth parasites utilize chemokine- or chemokine-receptor like proteins to evade protective immunity. *A. suum* is known to express a neutrophil chemoattractant with chemokine-binding properties. *S. mansoni* eggs secrete a protein (*S. mansoni* chemokine-binding protein [smCKBP]) that binds the chemokines CXCL8 and CCL3 and inhibits their interaction with host chemokine receptors and their biological activity, resulting in suppression of inflammation. Similarly, *B. malayi* (and all of the other filariae sequenced to date) have been shown to express galectins that can bind host immune cells in a carbohydrate-dependent manner. *O. viverrini* secretes a granulin (GRN)-like growth factor, Ov-GRN-1, which promotes wound healing and angiogenesis.

Helminths secrete two major classes of protease inhibitors called *cystatins* and *serpins*, each with proposed immunomodulatory roles. Cystatins inhibit cysteine proteases (cathepsins and aspartyl endopeptidases) required for antigen processing and presentation (through the MHC class II pathway) and therefore inhibit T-cell activation as well as secretion of inflammatory cytokines. They also elicit the regulatory cytokine IL-10, leading to direct impairment of T-cell proliferation. The serpins are serine protease inhibitors, which can cause specific inhibition of the neutrophil proteinases, cathepsin G and neutrophil elastase. Aspartic proteases from *Ascaris lumbricoides* have been shown to block efficient antigen processing that is dependent on proteolytic lysosomal enzymes.

Other parasite products mediate their effect by blocking effector functions, including recruitment and activation of inflammatory cells and limiting the destructive potential of activated granulocytes or macrophages in the local extracellular milieu. For example, the host chemoattractant platelet-activating factor (PAF) is inactivated by a complementary enzyme PAF hydrolase secreted by *N. brasiliensis*. Eotaxin-1, a potent eosinophil chemoattractant, is degraded by metalloproteases from hookworms. *A. caninum* secretes a protein called *neutrophil inhibitory factor*, which binds the integrins CD11b/CD18 and blocks adhesion of activated neutrophils to vascular endothelial cells and also the release of hydrogen peroxide (H_2O_2) from activated neutrophils. *N. americanus* ES products also bind to host NK cells and augment the secretion of IFN-γ, which might cross-regulate deleterious Th2 responses. Other modulators, such as prostaglandins, and other arachidonic acid family members, such as PGE_2 and PGD_2, are known to inhibit IL-12 production by DCs. Finally, helminths susceptible to oxidant-mediated killing express both secreted and membrane-associated enzymes, such as superoxide dismutase, glutathione-S-transferase, and glutathione peroxidase, molecules that are thought to play a significant role in assisting parasite survival in inflamed tissues. Recently, a family of helminth defense molecules secreted by parasitic helminths has been shown to exhibit biochemical and functional characteristics similar to human antimicrobial peptides. These molecules can modulate innate cell activation by classic TLR ligands, such as lipopolysaccharide.

The discovery that parasitic helminths secrete extracellular vesicles (EVs) has spurred a new paradigm in the discovery of helminth-derived therapeutics and anthelmintic vaccines.[33] EVs are a heterogeneous group of lipid-enclosed vesicles in the nano- to the micrometer size range. There is increasing evidence that helminth EVs are essential players in regulating host inflammation and immunity, and their application as anti-inflammatory therapeutics has been considered. Helminth EVs are actively internalized by host cells, providing a mechanism by which the parasites transfer genetic material to the host in a bid to actively manipulate host gene expression. Both platyhelminths and nematodes have been found to release EVs from the gastrodermis. In nematodes, EVs released in the intestines may be released into the host via the anterior or posterior openings. EVs of *B. malayi* have also been found to be secreted from the excretory/secretory pore. In the case of platyhelminths, EVs can be shed directly from the tegument itself into the surrounding environment. Recent attention has now turned to identifying and testing specific EV-associated antigens, which can be formulated into a vaccine that recapitulates the protective action of vaccination with whole EVs.

Host-Related Factors

Regulatory T and B Cells

Helminths actively induce Tregs either by directly secreting factors such as TGFβ mimic Hp-TGM or indirectly by interacting

with DCs and macrophages, which in turn induce Tregs.[34] Expansion of Tregs not only enhances parasite survival but also plays a role in preventing helminth-mediated pathology. In addition, Tregs generated during helminth infection have been associated with suppression of bystander immune responses. Helminth-induced Tregs are thought to act mostly via their expression of co-inhibitory receptors, CTLA-4 and PD-1 and to a lesser extent by their production of IL-10. Tregs play a vital role in limiting host pathology by downregulating harmful Th1/Th17 responses in filarial infection and schistosomiasis. Regulatory activity can also be demonstrated in other T-cell subsets, such as the Foxp3-IL-10^{+} Tr1 cells. Moreover, filarial infection is associated with an expansion of T cells expressing the IL-10 superfamily cytokine members (IL-19 and IL-24), and inhibition of these cytokines results in increased Th1 and Th2 responses. Both Tregs and Tr1 cells are associated with an isotype switch from IgE to IgG4 and a greater IgG4 to IgE ratio in helminth infections. IgG4 is a strongly antiinflammatory isotype that does not stimulate FcγR receptor activity.

A number of studies have recently reported that B cells might have an active regulatory role in helminth infections.[20] Helminth infections, and in particular infection with schistosomes such as *S. mansoni,* are well-known to induce regulatory B (Breg) cells. Regulatory B cells suppress proinflammatory immune responses via several mechanisms, of which the ones best described are the expression of the regulatory cytokine IL-10 and induction of regulatory T (Treg) cells. CD19^{+}CD24^{hi}CD38^{hi} regulatory B cells have been described in a variety of helminth infections.

Hyporesponsive T Cells

Effector T-cell responses can be turned off or modulated through a variety of mechanisms, including through cytotoxic T-lymphocyte antigen-4 (CTLA-4) and programmed death-1 (PD-1). Interestingly, increased expression of CTLA-4 and PD-1 has been demonstrated in filarial infections, and blocking of CTLA-4 can partially restore a degree of immunological responsiveness in cells from infected individuals. Moreover, T cells have decreased induction of *T-bet*, the Th1 master regulatory gene indicating a failure at the transcriptional level to differentiate into Th1 cells. Finally, T cells from individuals with filarial infection exhibit classic signs of anergy, including diminished T-cell proliferation to parasite antigens, lack of IL-2 production, and increased expression of E3 ubiquitin ligases. Similarly, anergic T cells are found in both humans and mice with *F. hepatica* infection and schistosomiasis; in the latter case, these T cells express high levels of the anergy molecule GRAIL (gene related to anergy in lymphocytes). Finally, helminth-induced Th2 cells can exhibit PD-1/PDL-2–dependent intrinsically hyporesponsive phenotype, which is characterized by diminished IL-4/IL-5 expression and enhanced IL-21 expression.

Modulation of Antigen-Presenting Cell Function

DCs are the first APCs usually to encounter parasites, and helminth modulation of DC function has been well characterized. Filarial parasites induce downregulation of MHC class I and class II molecules, as well as cytokines and other genes involved in antigen presentation, thereby rendering DCs suboptimal in their ability to activate CD4 T cells. Schistosomes have similar effects on DCs, with subsequent Th2 polarization and inhibited responses to Th1-inducing TLR ligands. In addition, schistosomes modulate the activation of Nlrp3 (NLR family, pyrin domain containing 3) inflammasome and thus IL-β production. Excretory/secretory antigens produced by helminths can inhibit DC synthesis of proinflammatory cytokines, chemokines, and costimulatory molecules and promote DC production of the regulatory cytokines IL-10 and TGF-β. Helminth infection has also been shown to induce in vivo differentiation of a CD103^{-}CD11c^{lo} population of regulatory DCs, which are inefficient in priming effector T cells and instead favor the generation of Tregs. AAMs are able to markedly suppress target cell proliferation, as well as mediate repair of tissue that has been damaged by parasites. In addition, human filarial infection is associated with the expansion of the nonclassical monocyte subset, as well as an immunoregulatory monocyte subset. Helminth antigens can modulate MHC class II and CD80/86 expression on "antigen-presenting" basophils to induce the development of Th2 cells. Myeloid-derived suppressor cells (MDSCs) are a heterogeneous population of immature myeloid cells that share a common property of suppressing immune responses. MDSCs have been demonstrated to be induced by several helminth infections. MDSCs are inflammatory cells that secrete many types of cytokines, including GM-CSF, IL-1α, IL-6, and IL-10, among others. However, the primary suppression function-related cytokines of MDSCs are TGF-β and IL-10.

Apoptosis

Another mechanism of immune evasion is the ability of some helminths to induce host cell apoptosis. Apoptosis has been described as a host regulatory mechanism in various helminth infections, including schistosomiasis, lymphatic filariasis, and onchocerciasis. Helminths and their products have been found to trigger apoptosis pathways and anergy in host immune cells including T cells, APCs, NK cells, and eosinophils. Besides immune cells, nonimmune cells such as intestinal epithelial cells are also targeted by helminths and their products for apoptosis. The two general pathways involved in the apoptosis process are the death receptor pathway and the mitochondrial pathway.

HELMINTHS AND THE MICROBIOTA

Recent work has highlighted the importance of the microbiota in influencing host immunological and metabolic functions. Helminths secrete a variety of products that can directly influence the composition and function of the microbiota, whereas changes in microbiota can have an impact on susceptibility to helminth infection, indicating that helminth–microbiota crosstalk can regulate a variety of host processes.[35] Direct evidence that type-2-cell-derived cytokines can alter the gut microbiota during infection with *T. muris* or *H. polygyrus* has been shown in mouse models, but similar shifts have also been observed in human populations. For *Trichuris* parasites, the microbiota are essential for their developmental process. The expansion of populations of lactobacilli upon helminth colonization is one the most frequently reported observations in helminth infections. However, there have been quite a few discrepancies in the results of human studies evaluating the helminth–microbiota interaction. Helminth modification of the microbiota is also known to directly impact host immunity to other pathogens, including impaired immunity to enteric bacterial infection and enhanced immunity to respiratory viral pathogens. This can be accomplished by helminth antimicrobial peptide production, mucin expression, goblet cell proliferation, and metabolite production. Alteration of short-chain fatty acid production and

affecting the balance of proinflammatory versus antiinflammatory bacterial species play important roles.[35]

REGULATION OF ALLERGY, AUTOIMMUNITY, AND METABOLIC DISEASES IN HELMINTH INFECTION

The hygiene hypothesis postulates that the stimulation of the immune system by microbes or microbial products protects from the development of inflammatory and atopic disorders. Human studies have demonstrated that people living in areas endemic for helminth infections have a decreased reactivity to skin tests for allergens and milder forms of asthma.[36] Experimental animal models have revealed the protective effect of helminth infections against atopy and asthma. Several mechanisms have been proposed for the helminth-induced protection, the chief of which are the induction of Treg activity, regulatory B-cell activity, immunosuppressive cytokines including IL-10 and TGF-β, and the interaction between helminth-derived products and the gut/lung microbiome (barrier regulation of allergy). Similarly, exposure to helminth parasites has been shown to prevent the onset of Th1-mediated diseases, such as multiple sclerosis (MS), diabetes mellitus, and Crohn disease in experimental animal models.[37] Finally, recent studies in mice have shown that type 2 immunity, induced by helminth infection, can maintain adipose tissue homeostasis and promote adipose tissue beiging, protecting against obesity and metabolic dysfunction, and that the immunomodulatory glycan LNFPIII, which is secreted by helminths, can alleviate hepato-steatosis and insulin resistance. Finally, multiple studies have now demonstrated that helminth infections can contribute to tissue-specific and systemic metabolic homeostasis and protection against obesity-associated meta-inflammation. Epidemiological studies conducted in endemic countries have reported an inverse association between infection with the trematode *Schistosoma japonicum* and the nematode *S. stercoralis* and the prevalence of metabolic syndrome and type 2 diabetes in lean and obese subjects, respectively.[38] Improvements of the homeostatic model assessment for insulin resistance (HOMA-IR), hyperinsulinemia, and hyperglucagonemia, hallmarks of whole-body insulin resistance and metabolic dysfunctions, were also observed in rural populations infected with various species of soil-transmitted helminths. These effects were associated with eosinophilia and increased serum levels of total IgE and prototypical type 2 cytokines, IL-4, IL-5, and IL-13, suggesting that the helminth-induced type 2 immune response might play a role. Anthelmintic treatment was shown to reduce circulating markers of type 2 immunity and to impair metabolic homeostasis, as characterized by elevated HOMA-IR and hemoglobin A_{1c} (glycated hemoglobin) (HbA_{1c}).

HELMINTH THERAPY FOR INFLAMMATORY DISEASES

This is based on the principle that helminth-derived factors promote polarized regulatory or Th2 responses, which result in antiinflammatory molecule production and promotion of barrier integrity (often compromised in inflammatory bowel disease and foodborne incompatibilities) and that helminth colonization provides a diverse bacterial environment that protects against intestinal inflammation.[37] To date, two species of helminths have been tested as clinical treatment for therapy of inflammatory diseases: *Trichuris suis* ova (TSO) and infection with *N. americanus*. TSO has been demonstrated to have a minimal or no effect on Crohn disease, ulcerative colitis, and multiple sclerosis and no significant effect on rheumatoid arthritis, allergic rhinitis, or plaque psoriasis. *N. americanus* larvae have been shown to be minimally or not effective against Crohn disease and celiac disease but have no significant effect on allergic rhinoconjunctivitis, asthma, or multiple sclerosis. Further to therapeutic trials of helminth infections in inflammatory disease settings, dose-escalation controlled helminth infections in healthy volunteers are currently ongoing.[31]

ON THE HORIZON

- Identification and synthesis of helminth products that can be useful as immune therapy in a variety of inflammatory disorders.
- Deciphering the three-way cross-talk among host immunity, helminths, and the microbiota.
- Elucidation of the detailed mechanisms by which helminths manipulate immune responses to bystander antigens.
- Development of clues to production of novel vaccine candidates to protect against not only helminth infection but also helminth-induced morbidity.
- Combined approaches involving genomics, transcriptomics, proteomics, and metabolomics for assessment of host–helminth interactions.

VACCINES AGAINST HELMINTH PARASITES

Vaccines against helminth infections are a necessary tool for their elimination and eradication for several different reasons.[31,39] Four *Schistosoma* vaccines are currently in different phases of clinical development. *S. haematobium* Sh28GST did not exhibit high efficiency in a phase III trial and is currently being modified. *S. mansoni* Sm-14 is in phase II/III trials while *S. mansoni* Sm-TSP-2 is in phase II trials. Finally, *S. mansoni* Sm-p80 is now entering phase I/II trials. Three hookworm vaccine candidates, Na-GST-1, Na-APR-1, and Na-Asp-1, are in phase I clinical trials. Moreover, human challenge infection models to study the efficiency of schistosomiasis and hookworm vaccines are now established with the first studies showing proof of concept for safety and tolerability. In addition, the two *O. volvulus* vaccine candidates—Ov-103 and Ov-RAL2—are in preclinical testing. With rapid advances in the parasite genomics and proteomics, as well as the newer, better vaccine delivery systems offering more efficient and quicker assessment, the prospects for newer anthelmintic vaccines are excellent, although the potential lack of commercial markets imposes a significant impediment to their development.

Emerging Pandemic Infectious Disease Threats

David B. Corry, Peter J. Hotez, Maria Bottazzi, Jill Weatherhead, Anthony Maresso, Emmaline Heckmann, and Lynn Bimler

INTRODUCTION

Pandemic infectious diseases are caused by pathogens (usually viruses) that have adapted well to growth and reproduction within the human host and that through unique environmental, socioeconomic, and cultural circumstances are able to rapidly spread across national boundaries and even globally. Although uncommon and caused by relatively few pathogens, the extraordinary human, economic, and societal losses caused by pandemic diseases as exemplified by coronavirus disease 2019 (COVID-19) make pandemic diseases of unique importance to clinicians, immunologists, and many other scientists and health care professionals. The pathogenesis of pandemic diseases is complex and unique to each pathogen, but common to all is widespread immunological naïveté within the host population. In this chapter, we consider the pathogens of greatest concern for their pandemic potential. Most of these organisms are viruses, including betacoronaviruses, alphainfluenzavirus, ebola, and the flaviviruses, but numerous bacteria are also emerging with pandemic disease potential. For each organism, we consider the factors, especially immunological, that lead to pandemic spread and prospects for effective therapy and prevention.

HUMAN *BETACORONAVIRUS*

The human betacoronaviruses are enveloped viruses with positive-strand RNA genomes of approximately 30 kb.[1] Bats represent important natural animal reservoirs for betacoronaviruses, causing serious human infections and disease of pandemic potential including the severe acute respiratory syndrome coronavirus (SARS-CoV), Middle East respiratory syndrome coronavirus (MERS-CoV), and the most recent coronavirus disease (COVID)-19 caused by the SARS-CoV-2 virus. In addition, at least two betacoronaviruses can cause upper respiratory infections in humans—HCoV-OC43 and HCoV-HKU1 (Fig. 31.1).[1] These typically cause common cold symptoms, although rarely they can also cause more serious respiratory infections. There are also two alphacoronaviruses that cause upper respiratory infections in humans, known as HCoV-NL63 and HCoV-229E (Table 31.1).[1]

Microbiology and Clinical Expression

Coronaviruses are spherical, enveloped viruses that contain a single-stranded, positive-sense RNA genome. Their name derives from the prominently expressed surface projections composed of the surface membrane (M), envelope (E), and spike (S) structural proteins that appear as halos (coronas) on electron micrographs. The spikes are the most distinguishing feature of coronaviruses and are typically composed of a trimer of the S protein. The receptor-binding domain (RBD) of the S protein engages a variety of host receptors including angiotensin-converting enzyme 2 (ACE2), aminopeptidase N (APN), and dipeptidyl peptidase 4 (DPP4) to trigger cellular entry and the initiation of replication. Host proteins such the proteinase transmembrane protease serine 2 (TMPRSS2) are usually required to activate the S protein and facilitate cellular entry. Genome replication and virion assembly occur within the endoplasmic reticulum and Golgi apparatus and viral shedding occurs through exocytosis.

SARS-CoV, MERS-CoV, and SARS-CoV-2 are significant causes of serious human illness. These viruses are transmitted directly from person to person via aerosol droplets and readily infect epithelial cells of the upper and lower airways after inhalation; intermediate arthropod vectors are not involved in transmission. The coronavirus genome is relatively plastic and can undergo recombination with related viruses co-infecting the same host. It is thought that combinations of mutations and recombination events involving an ancestral bat coronavirus, likely transmitted through other hosts such as the civet or pangolin, led to the emergence of SARS and MERS viruses with enhanced human transmissibility and thus pandemic potential. SARS and MERS viruses cause primarily a pneumonitis-predominant syndrome marked by fever, cough, congestion, malaise, and shortness of breath. Severe disease is marked by respiratory failure and may be complicated by dysfunction of numerous other systems, including the cardiovascular, hematologic-coagulation, urinary, neurologic, and gastrointestinal systems. SARS-CoV emerged in 2002 in South China before causing epidemics in more than 20 countries, including approximately 8000 cases and 800 deaths, mostly in China, Hong Kong, Taiwan, Canada, and Singapore. MERS-CoV emerged in Saudi Arabia in 2012 causing approximately 1000 cases and more than 400 deaths, in addition to cases and deaths in other Middle Eastern countries and in South Korea. SARS-CoV-2 emerged in Wuhan, China, and is currently causing a pandemic and public health emergency of international concern (PHEIC). SARS-CoV-2 is the cause of COVID-19, that so far has caused more than one million deaths and a global financial and security crisis.

Immunopathogenesis

Evidence for acquired immunity to betacoronaviruses with pandemic potential is primarily based on persistent host antibodies in recovered patients and experimental animals. Patients who

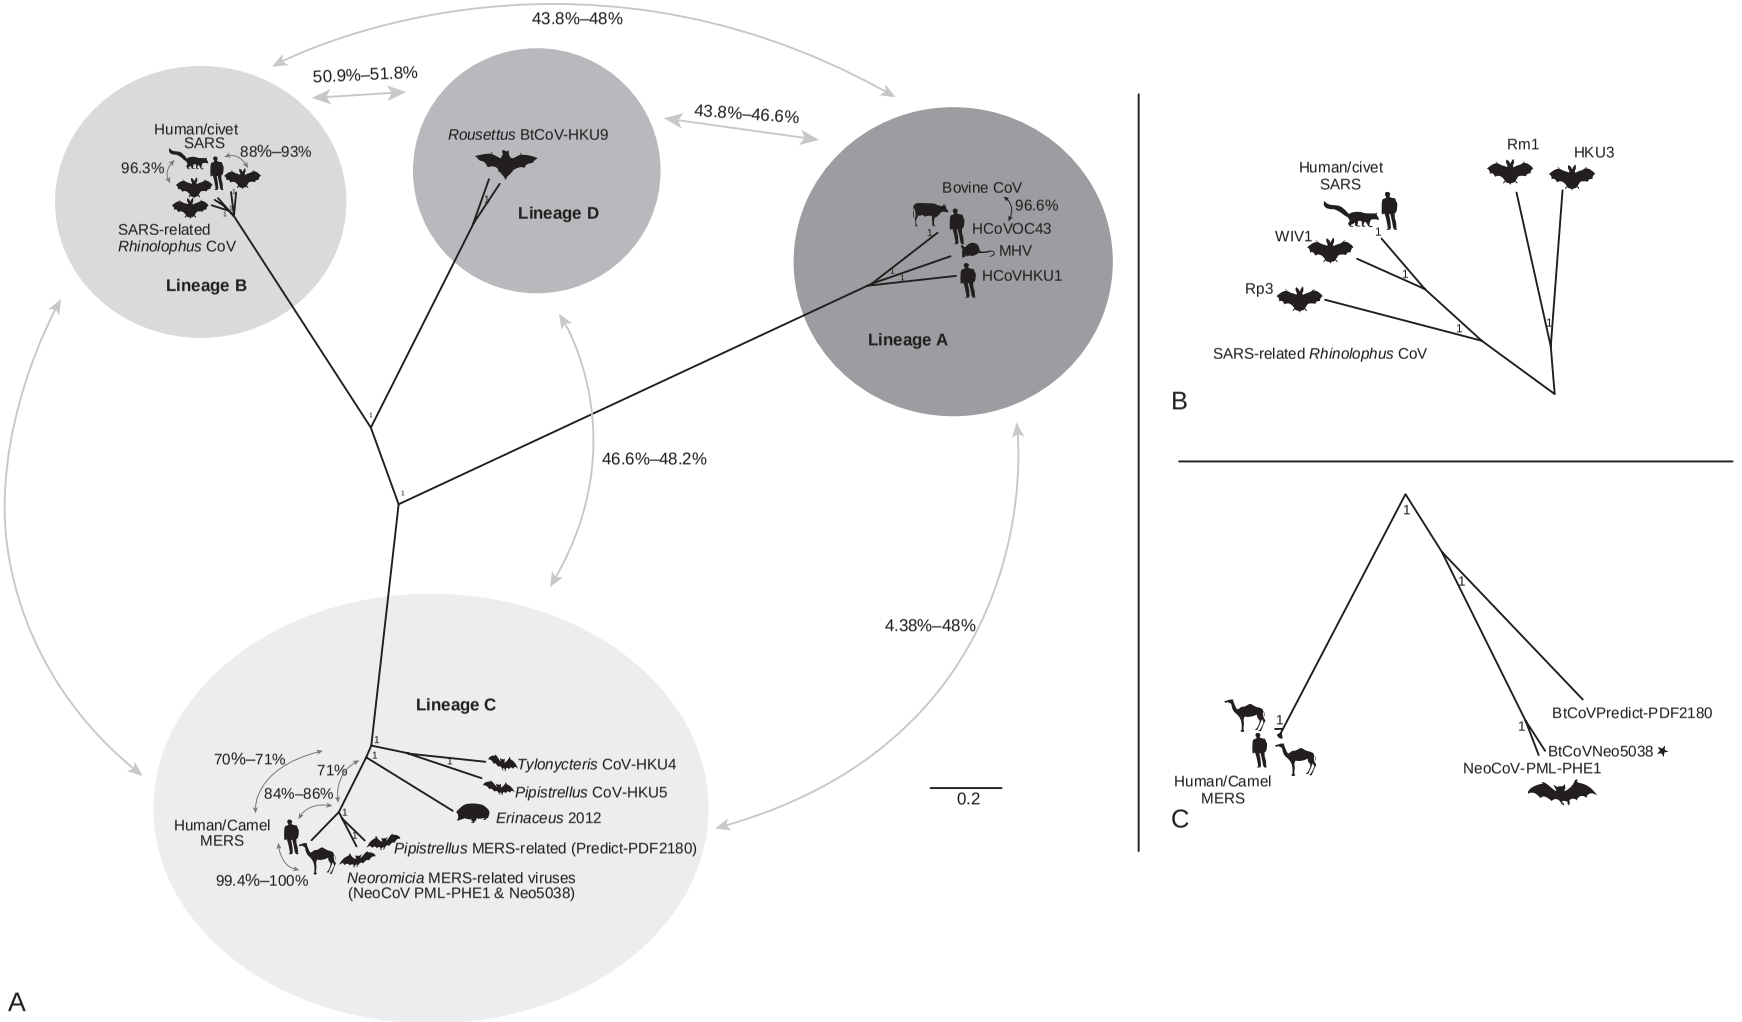

FIG. 31.1 Phylogenetic tree of the lineages of genus *Betacoronavirus* with detail for SARS-CoV and MERS-CoV. (A) The full-genome phylogeny of 4 lineages (A–D) of the genus *Betacoronavirus* constructed using BEAST software with the GTR substitution model using invariant sites and gamma distribution. The MCMC chain was set to 15,000,000 generations sampled every 1500 steps, with a 10% burn-in of the first generated trees and displayed as a radial tree in Figtree. The lineages are indicated with clipart images of host species. Also displayed are the averaged pairwise similarities between lineages as well as highlighted similarities between human coronaviruses and related viruses identified in bats (and other animals). (B) Close-up of the external nodes of the lineage B phylogeny to show relative distances of human and civet SARS-CoV strains and SARS-related *Rhinolophus* strains (WIV1, Rp3, Rm1, and HKU3). (C) Close-up of the lineage C external nodes depicting the human and camel MERS strains with the bat MERS-related viruses (BtCoVNeo5038 from this study is indicated with a star).

recover from SARS-CoV produce persistent antibodies against the coronavirus spike protein, including its RBD. The RBD is required for both SARS-CoV and SARS-CoV-2 to bind to the host ACE2 receptor, which itself is a surface-bound carboxypeptidase found in cells in the lungs, heart, vasculature, and other target organs. For many recovered SARS-CoV patients, antiviral antibody can persist for two years or more.[2] In contrast, it was reported that patients with mild or asymptomatic COVID-19 may exhibit rapidly declining levels of host antibodies,[3] whereas those with severe illness exhibit higher and durable levels of virus neutralizing antibodies, including antibodies directed against the spike protein.[4] So far, there have been a few case reports of COVID-19 patients experiencing reinfection, with at least one individual without virus neutralizing antibodies present at the second clinical presentation.[5] However, rhesus macaques were noted to be resistant to SARS-CoV-2 reinfection after homologous virus challenge, with protection correlating with virus neutralizing antibody titers.[6] In humans, even with declining virus neutralizing antibody titers, memory T and b cells may play an important role in the recall against SARS-CoV-2 antigens, and therefore host immunity.[7,8]

Treatment and Prevention

Immunity to betacoronaviruses has also been shown with passive transfer of antibodies, which confer protection in both humans and animals. In addition, and under development, is the premise that vaccines will induce protection, as seen previously in experimental animals and being evaluated in vaccine clinical trials as of 2020.

Passive Antibody Transfer

In humans, the administration of convalescent plasma was shown in a systematic review and meta-analysis to reduce both viral loads and mortality of patients with SARS-CoV.[9] However, a US National Institutes of Health panel found that for COVID-19, the current data are "insufficient" to endorse the use of convalescent plasma, and instead called for adequately powered and well-controlled randomized clinical trials, even after the US Food and Drug Administration (FDA) had released convalescent plasma under emergency use authorization.[10] Most recently in older adults, high titer convalescent plasma was shown to elicit more convincing therapeutic outcomes.[11] Recently, several monoclonal antibodies directed against the SARS-CoV-2 spike protein RBD were identified and evaluated as promising prophylactic or therapeutic reagents in experimental animal models. They include both neutralizing monoclonal antibodies that block ACE2-RBD binding, as well as those with the ability of inducing subtle or conformational alterations in the RBD protein. Some of the monoclonal antibodies are broadly neutralizing against both SARS-CoV and SARS-CoV-2, while others are virus-specific.

Experimental Vaccines

Some of the best evidence for acquired immunity to the betacoronaviruses is through experimental vaccine trials. An international effort is underway to test experimental vaccines against COVID-19, including a US-based initiative known initially as Operation Warp Speed in addition to national efforts based in Brazil, China, India, Russia, and elsewhere. Almost all of the vaccine concepts rely on inducing strong immunity to the SARS-CoV-2 spike protein, especially its RBD component, with more than 100 candidates in preclinical and clinical development.[13] Several of these vaccines have gone into preclinical testing in nonhuman primates—rhesus macaques—including vaccines using traditional technologies such as whole inactivated virus and recombinant protein vaccines, and new platform approaches such as mRNA, DNA, and adenovirus vectored vaccines. An important observation is that protection against challenge infection in nonhuman primates is associated with high levels of virus neutralizing antibodies, together with T-cell immune responses. Similar observations have been made with experimental vaccines in both rodent and nonhuman primates following SARS-CoV or MERS-CoV challenge infections. For COVID-19, several vaccines have now been released through emergency use authorization processes, based on evidence for protection in limited or expanded phase 3 randomized trials. They include whole inactivated virus, adenovirus-vectored, and nucleic acid vaccine candidates, with results indicating that at least two doses are required to reach virus neutralizing antibody levels (together with T-cell responses) equivalent or exceeding to those found in convalescent sera from recovered patients. At least one study found that protection against COVID-19 exceeds 85% when the level of virus neutralizing antibodies from the vaccine is at least 1.5 fold greater than levels found in recovered patients convalescent sera, although this finding has not yet translated fully into a true correlate of protection.

Immune Enhancement

For some human respiratory infections, it was noted how experimental vaccines for respiratory syncytial virus and measles may have actually exacerbated lung pathology following experimental challenge in preclinical models. For both of these cases, formalin-inactivated whole-virus vaccines were implicated in this phenomenon, known as immune enhancement, which resulted in host cellular infiltrates in the lungs. In some experimental animal models of coronavirus vaccines, especially for SARS-CoV and MERS-CoV, a similar phenomenon was noted, and included eosinophilic or neutrophilic infiltrates in the lungs or liver. Different immunologic mechanisms were ascribed to these observations, including Th2 or Th17 responses, as well as antibody-dependent enhancement (ADE). However, to date immune enhancement has not yet been noted either in

nonhuman primates or in humans following administration of COVID-19 experimental vaccines, as well as virus challenge in the case of the former.

KEY CONCEPTS

- The betacoronavirus SARS-CoV-2 is the causative agent of COVID-19, a worldwide pandemic disease that emerged in late 2019 that has caused devastating human morbidity and mortality in addition to widespread economic disruption.
- The emergence of betacoronaviruses with pandemic potential is related to social determinants including political destabilization, globalization and urbanization.
- Much remains to be learned about betacoronavirus immunity and vaccine development, but rapidly accumulating experience with currently available vaccines approved for emergency use indicate that they are substantially safe and effective.

FLAVIVIRUSES—DENGUE AND ZIKA VIRUS DISEASE

The flavivirus group includes many dozens of viruses, the most medically important of which are the viral causes of dengue, Japanese encephalitis, West Nile fever, yellow fever, and Zika virus disease. Of these five viruses, dengue and Zika viruses have shown the most pandemic potential given their alarming spread from their original home ranges of northern Africa and equatorial Africa and Asia, respectively, to North and South America. Although dengue virus is now endemic in North America, Zika virus is not yet endemic; the many recorded mainland US cases of Zika virus disease are believed to have been acquired abroad. Nonetheless, it is likely that dengue, Zika and other flaviviruses transmitted by Aedes mosquitoes will become endemic to the Gulf Coast of the United States due to climate change, urbanization, and human migrations, among other factors.[14] These viruses most often produce mild, inconsequential disease, but dengue virus is capable of inducing severe and lethal infections and Zika virus can induce great harm to the fetus.

Microbiology

The flaviviruses are enveloped viruses with icosahedral and spherical geometries that contain a single linear positive-sense RNA strand of approximately 11 kb in length. The RNA is transcribed into a polyprotein that is cleaved into separate polypeptides through the combinatorial use of host and viral proteinases that include three structural proteins (capsid, prM, and envelope) and seven nonstructural proteins. Positive viral RNA strands assemble at the host cell membrane where they bud through, becoming encapsulated in host lipids, leading to host cell rupture and release of new virions. Flaviviruses bind to diverse host cell proteins through the viral envelope (E) protein. Host receptors include AXL, Tyro3, DC-SIGN, and TIM-1 for Zika virus[15] and human mannose-binding receptor (MR) and DC-SIGN for dengue virus.[16] Virions enter the cell through clathrin-mediated endocytosis and then commence to replicate.

Like most other flaviviruses, transmission of dengue and Zika virus occur most often through an arthropod, usually the mosquitoes *Aedes aegypti* and *A. albopictus*, but many other arthropods are suitable vectors. These viruses are sufficiently adapted to humans, in which they replicate to a high degree, to permit re-transmission of disease through mosquitoes with no need for other intermediate hosts. However, Zika virus can also be transmitted sexually, by blood transfusion, and vertically to the fetus. It is not known whether specific strains of dengue and Zika virus or whether mutations have facilitated their rapid spread in recent years. Clearly important factors appear to be the spread of suitable mosquito vectors to urban environments where they thrive and the rapid increase in international travel that has repeatedly allowed persons acquiring infections while abroad to transmit the viruses to previously naïve vectors in their native communities, eventually establishing autochthony.[17]

Clinical Expression

Both Zika and dengue viruses typically elicit no symptoms after infection. Approximately 20% of infected subjects will after 3 to 5 days of incubation present with a similar mild syndrome that includes fever, lethargy, joint and muscle aches, joint swelling, maculopapular rash, retro-orbital headache, and conjunctivitis. A more serious form of disease, severe dengue, occurs in approximately 5% of symptomatic subjects and is marked by a systemic vasculitis that results in widespread hemorrhage and resulting organ dysfunction, most often including the liver, brain, and heart. Increasingly, severe dengue in adults has been linked to underlying co-morbid conditions including diabetes mellitus and hypertension.[18] Similar finding have been identified for COVID-19. Severe dengue, which can be fatal even with optimal supportive care, usually occurs soon after defervescence and is preceded by key warning signs. Zika virus has yet to be linked to a severe dengue-like syndrome in adults, but it can produce prostatitis-like symptoms, hematospermia, and neurologic complications including Guillain-Barré syndrome. Maternal infection with Zika virus can lead to fetal loss, intrauterine growth retardation, and CNS complications including microcephaly.[19]

CLINICAL RELEVANCE

WHO Criteria for Severe Dengue

- Severe plasma leakage leading to
  1. Shock and/or
  2. Respiratory distress
- Severe bleeding as assessed clinically
- Severe organ dysfunction
  1. Liver: alanine transaminase or aspartate aminotransferase ≥1000
  2. Central nervous system: impaired consciousness
  3. Heart and other organs

CLINICAL RELEVANCE

WHO Criteria for Dengue Warning Signs

- Abdominal pain or tenderness
- Persistent vomiting
- Fluid accumulation
- Mucosal bleeding
- Lethargy/restlessness
- Liver enlargement >2 cm
- Increase in hematocrit concurrent with thrombocytopenia

Immunopathogenesis

Both viruses are believed to initially infect dermal dendritic cells (DCs), after which they are carried to regional lymph nodes and then systemically via the lymphatic system.

Subsequent disease expression likely depends in part on host age and host and viral genetic factors, but an extremely important determinant of host outcome is immune status. Effective immunity is believed to derive from robust neutralizing antibody responses. Two antibody-related immune phenomena, ADE and original antigenic sin (Hoskins effect), critically influence the effectiveness of humoral responses to flaviviruses, but also influenza. ADE occurs when non-neutralizing antibodies bind to virions and promote their uptake through alternate receptors such as Fcγ receptors present on phagocytic and antigen-presenting cells (APCs). Viral uptake through this aberrant, antibody-dependent mechanism can lead to viral proliferation within $Fc_{\gamma\gamma}$-expressing cells, resulting in prolonged and more severe disease. The closely related Hoskins effect occurs when dengue or Zika viral infection occurs in a semi-immune host that has previously either been infected with a related, but antigenically distinct, viral strain or been vaccinated with a viral strain that is only partially related to the infecting strain. Immunity to the infecting viral strain may in these instances result only in activation of memory, not primary, responses to the previous virus or vaccine, resulting in persistent production of ineffective, non-neutralizing antibodies that may promote ADE. Only primary immunity triggers the process of affinity maturation that results in the high-affinity antibodies needed for virus neutralization.[20,21]

TREATMENT AND PREVENTION

There are currently no antiviral agents approved for use against dengue or Zika viruses, nor is a vaccine against Zika available. While candidate Zika virus vaccines are under evaluation, a major hurdle to their development is the unpredictable nature of Zika virus disease outbreaks, which have abated in recent years. A dengue virus vaccine has recently completed phase III trials and has been approved by the FDA for use in children age 9 to 16 years living in US territories with endemic dengue. While broadly effective, the vaccine can result in severe disease due to ADE in vaccinated persons who subsequently acquire new dengue virus infection.[22] Additional vaccines are under development and completing advanced clinical testing. Control of mosquito populations is an additional promising means of disease control.

KEY CONCEPTS

- Of the many known flaviviruses, dengue and Zika viruses offer the highest pandemic disease risk.
- Both dengue and Zika viruses are transmitted to humans by arthropod, usually mosquito, vectors.
- Rapid spread of vectors to new urban environments and the rise in international travel strongly contribute to the global spread of Zika virus disease and dengue.
- Infection with dengue and Zika viruses is usually inconsequential, but dengue can produce a severe, potentially fatal disease and Zika virus can be harmful or lethal to the fetus.
- Antivirals are unavailable for Zika virus disease and dengue, but a vaccine against dengue is available for children living in endemic regions, with additional vaccines pending.
- Antibody-dependent enhancement and the Hoskins effect contribute to the development of severe disease and complicate efforts to develop effective vaccines.

EBOLA

Ebola virus first emerged in 1976 independently in Zaire, present-day Democratic Republic of Congo (DRC), and Sudan.[23,24] Since 1976, Ebola virus has caused 28 outbreaks, most of which, until recently, have occurred in the Central African countries of DRC, Sudan, Gabon, and Uganda.[25] However, in 2014 to 2016, *Zaire ebolavirus* (EBOV) emerged in West Africa, beginning in Guinea and spreading to neighboring Sierra Leone and Liberia. The 2014 to 2016 EBOV outbreak is the largest Ebola virus outbreak recorded since its emergence. The extent of this outbreak, which caused 28,600 cases and 11,325 deaths, was secondary to involvement of densely populated areas with poor public health infrastructure and increased mobilization across borders leading to spread to seven additional countries including the United States.[25] The global humanitarian and economic impact of the 2014 to 2016 EBOV outbreak led to widespread initiation of public surveillance strategies and a surge in preventive and therapeutic antiviral interventions for future viral outbreaks.

Microbiology

Ebola virus is a nonsegmented, negative-sense, single-stranded RNA virus in the *Filoviridae* family with 5 species: *Zaire (EBOV), Tai Forest (TAFV), Sudan (SUDV), Bundibugyo (EDBV)*, and *Reston (RESTV)*.[23] The virus is made of seven proteins: nucleoprotein, viral protein (VP) 35, VP40, glycoprotein (GP), VP30, VP24, and polymerase L.[23] The RNA resides within the nucleoprotein nucleocapsid alongside polymerase L and transcription cofactor VP30. The viral spike is formed from the transmembrane GPs on the outer envelope and soluble GP (sGP) is a byproduct of viral GP expression.[23,24] The VPs provide structural integrity to the nucleocapsid and modulate the host immune response.[26]

Viral infection occurs as a result of Ebola virus GPs engagement with host cell membrane proteins, promoting cell entry by micropinocytosis. Once engulfed, the viral GP is processed by the host cysteine proteases cathepsin within the endosome, allowing the cleaved protein to interact with the endosomal cellular receptor cholesterol transporter Niemann Pick C1 (NPC1

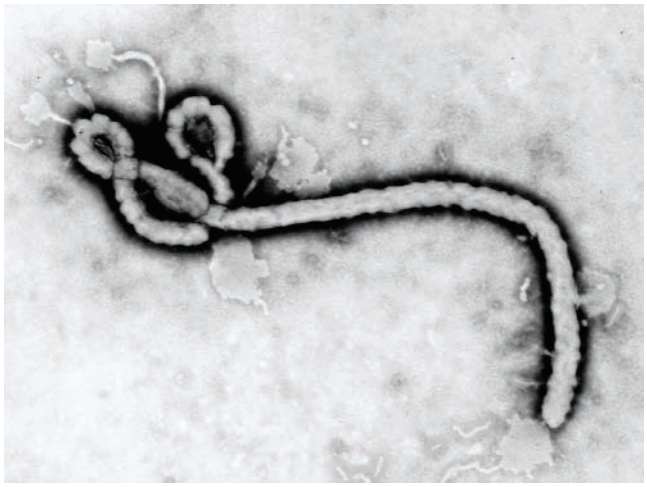

FIG. 31.2 Transmission Electron Microscopy of Ebola virus Demonstrating Filamentous Morphology. (Public Health Image Library #10815. Centers for Disease Control and Prevention and Frederick A. Murphy, 1976.)

protein). Binding of cleaved GP to NPC1 allow the virus to fuse with the endosomal membrane.[23] The viral genome is then released into the cytosol of the host cell and undergoes transcription and replication.[27] The newly replicated virus is assembled into a nucleocapsid and transported to the host cell surface for release of progeny virions.[23] Ebola viruses have the ability to attenuate or shut down host interferon alpha and beta responses leading to progressively higher viral loads. These processes occur through specific viral proteins interfering with interferon signaling cascades.[28]

All five Ebola species can infect humans. While *Zaire*, *Sudan*, and *Bundibugyo* species typically develop similar clinical syndromes, *Reston ebolovirus*, a species identified in a Filipino swine and nonhuman primates, is most commonly associated with asymptomatic infection in humans. Additionally, there is only one recorded case of *Tai Forest ebolavirus*, which occurred in 1994 in Cote d'Ivoire and was nonfatal. Ebola virus is a zoonotic pathogen that typically maintains a sylvatic cycle. It is speculated that the fruit bat, *Pteropodidae* family, is the natural reservoir of Ebola virus and may be capable of transmitting Ebola virus to other intermediate or dead-end hosts.[23]

Initial infections in humans emerge from contact with bats and their excretions or through contact with intermediate or dead hosts such as infected nonhuman primates. Human-to-human transmission can then propagate disease through direct contact with infected human blood, secretions, organs, or other bodily fluids or indirectly through contact with contaminated surfaces. People at high risk of viral transmission include family care providers, healthcare workers, and people involved in traditional burial practices. With an estimated person-to-person transmission ratio of up to 1.34, Ebola virus has the potential to rapidly spread to local and international communities.[29]

Clinical Expression

Ebola virus disease occurs 2–21 days after exposure.[2] Ebola virus disease occurs 2 to 21 days after exposure.[2] Direct viral cytopathogenic effects causing cell death and dysregulated innate and adaptive immune responses lead to a wide range of clinical presentations. Symptoms include fever, fatigue, myalgias, anorexia, nausea, and severe vomiting and diarrhea causing significant fluid losses. Systemic hypoperfusion results in multiorgan dysfunction. Bleeding in the form of microscopic hemorrhage, increased vascular permeability, and impaired coagulation occurs in less than half of cases manifesting clinically as petechiae, bleeding from gums, or bleeding in emesis or stool. Despite the general similarities between Ebola virus species, case fatality rates differ. Although the nature of these differences remain unclear, case-fatality rates range from 40% in *Bundibugyo* species to near 70% to 90% in *Zaire* species. Additionally, evidence from the 2014 to 2016 EBOV outbreak suggest a "post-Ebola syndrome" with chronic, debilitating neurologic, ocular, and musculoskeletal abnormalities in survivors.[24]

Immunopathogenesis

Ebola virus infects humans through the mucosal membranes or breaks in skin. The virus is taken up by APCs such as macrophages and DCs, which permit early intracellular replication. Migration of infected cells to lymph nodes facilitates system-wide spread. Ebola virus leads to disturbances of the innate immune response through inhibition of type I interferons (I-IFN), prolific production of cytokines (interleukin [IL]-1β, IL-1Rα, IL-6, IL-8, IL-15, IL-16, tumor necrosis factor [TNF]-α, nitric oxide [NO]) and chemokines (macrophage inflammatory protein [MIP]-1α, MIP-1β, monocyte chemotactic protein [MCP]-1, migration inhibitory protein [MIF], IP-10), impairment of DC maturation, and natural killer (NK) cell apoptosis leading to overwhelming tissue necrosis. VP35 and VP24 both suppress type-I IFN pathways, VP35 by disrupting retinoic acid-induced gene [RIG]-1 pathway and VP24 by preventing nuclear accumulation of dimerized phosphorylated signal transducer and activator of transcription 1 [STAT-1]. Furthermore, viral sGP act as an immune response accelerant, by binding and activating noninfected DC and macrophages through Toll-like receptor 4 [TLR4], enhancing proinflammatory cytokine and chemokine release. The proinflammatory milieu promotes recruitment of more inflammatory mediators to the site of infection, increasing viral targets. Inhibition of the APC–T-cell synapse due to decreased function of APCs prevents CD4 and CD8 T-cell expansion. The lack of T-cell clonal expansion blocks CD4 T-cell helper functions, including reduction in B-cell release of antigen-specific antibodies. Bystander apoptosis of lymphocytes, which are not directly infected with Ebola virus, occurs potentially due to loss of APC signaling or the overexaggerated cytokine environment. Endothelial dysfunction from proinflammatory cytokines causes increased vascular permeability, fluid extravasation, as well as consumption of coagulation factors.[24]

Treatment and Prevention

There are no approved preventive or curative interventions for Ebola virus infections. Management strategies fall largely on

TABLE 31.2 Ebola Virus Species, Geographic Locations, and Clinical Manifestations

Ebola Species	Emergence	Outbreak Locations	Clinical Manifestations	Case Fatality Rate
Zaire ebolavirus (EBOV)	DRC 1976	Central and West Africa	Fever, fatigue, myalgia, arthralgias, vomiting, diarrhea, maculopapular rash, conjunctival injection, hypovolemia, bleeding or bruising (<50%)	70%–90%
Sudan ebolavirus (SUDV)	Sudan 1976	East Africa	Fever, fatigue, myalgia, arthralgias, vomiting, diarrhea, maculopapular rash, conjunctival injection, hypovolemia, bleeding or bruising (<50%)	50%
Bundibugyo ebolavirus (BDBV)	Uganda 2007	East Africa	Fever, fatigue, myalgia, arthralgias, vomiting, diarrhea, maculopapular rash, conjunctival injection, hypovolemia, bleeding or bruising (<50%)	<40%
Tai Forest ebolavirus (TAFV)	Cote d'Ivoire 1994	Cote d'Ivoire	Unknown (only 1 case reported)	0 (to date)
Reston ebolavirus (RESTV)	Philippines 1989–1889	Philippines, potentially other Asian countries	Subclinical	0 (to date)

the availability of medical resources such as personal protective equipment and on the strength of the public health infrastructure for contact tracing. Detection of Ebola virus is critical for surveillance and initiation of public health measures to prevent outbreaks. Molecular assays including real-time polymerase chain reaction (RT-PCR) are widely used to assess acute infection but are dependent on conserved sequences and may have decreased sensitivity with the emergence of new strain variants. Additionally, RT-PCR may be negative in early disease and requires repeat testing if patient has epidemiologic risk factors and ongoing symptoms. Virus can be detected in many fluids, including blood, breast milk, and semen using RT-PCR.[2] Use of serologic assays, including immunoglobulin (Ig) M and IgG detection are critical for disease surveillance. For persons with Ebola virus disease, standard of care includes aggressive restoration of fluid status, pain control, antiemetics, treatment of co-infections, nutritional supplementation, and correction of electrolyte abnormalities.

Several experimental therapeutics have been evaluated in clinical trials. Early in the course of the 2014 to 2016 outbreak, neutralizing antibodies in the form of convalescent plasma from EBOV survivors was used with varying success. However, development of monoclonal antibodies that target virulent EBOV epitopes have become more readily available. The PREVAIL II trial demonstrated that ZMAPP, triple monoclonal antibody, led to only 22% mortality. However, in the follow-up PALM trial comparing ZMAPP, REGN-EB3 (3 human IgG1 monoclonal antibodies), Mab114 (human monoclonal antibody derived from an Ebola survivor), and remdesivir (an antiviral drug, nucleotide analogue RNA polymerase inhibitor), improved survival was documented in participants who received Mab114 (35.1% mortality) or REGN-EB3 (33.5% mortality) compared to remdesivir or ZMAPP (both with 50% mortality). Differences in effectiveness of monoclonal antibodies may reflect patient population, standard of care practice, and Ebola virus strain variant. The US FDA approved REGN-EB3 (Inmazeb) for treatment of EBOV in October 2020. Synthetic antiviral drugs such as favipiravir, galidesivir, and remdesivir may be more impactful during early viral replication. Trials to evaluate combination therapy with monoclonal antibodies and antivirals are warranted.[30]

Vaccine-driven neutralizing antibodies against Ebola virus proteins may be the key to preventing and controlling outbreaks. A live, attenuated, vectored vaccine using recombinant vesicular stomatitis virus expressing *Zaire ebolavirus* GP known as rVSV-ZEBOV-GP is now approved by the European Medicines Agency and the US FDA and has been valuable for inducing rapid community immunity. This vaccine was highly effective, achieving greater than 90% protective immunity in a devastating outbreak in the Democratic Republic of the Congo, and was instrumental in preventing the spread of Ebola virus infection across Africa. Other vaccines in clinical trial include a chimpanzee adenovirus 3 vaccine (ChAd3-EBO-Z) and the multivalent, modified vaccinia Ankara-based vaccine (MVA-BN). Used in a prime-boost model in clinical trials, MVA-BN with Ad26.EBOV, an adenovirus vector vaccine, may prove to be the most durable and provide cross-protection for several filoviruses, making it an attractive vaccine for high-risk workers and community members. Despite the advances in preventive and therapeutic options, the principles of outbreaks—diagnosis, isolation, contact tracing, quarantining to prevent transmission—remain the staples of viral containment. Building safe workspaces with appropriate biosafety protocols (Biosafety level-4) and supply of personal protective equipment in addition to education of the community on Ebola virus allow for improved outbreak control efforts.[24]

ALPHAINFLUENZAVIRUS—PANDEMIC INFLUENZA

Despite the widespread, albeit imperfect, administration of seasonal vaccines and use of effective antiviral agents, annual influenza epidemics incur high rates of hospitalization and 290,000 to 500,000 deaths worldwide.[31] Pandemic influenza, which is fortunately much less common, can cause many millions of deaths worldwide (Fig. 31.3). The unusually plastic influenza genome that underlies the remarkable tendency of this virus to change its antigenic character; the extended time required for vaccine production, itself an imperfect practice; and the development of antiviral resistance are essential factors driving the risk of pandemic disease. Here we will focus on the paradoxical virulence of influenza as seen even in populations that are widely vaccinated and otherwise immune and future prospects for medical interventions, especially novel vaccines, that may offer the potential of improved long-term protection against this ancient scourge.

Microbiology

Influenza viruses are spherical or filamentous lipid-encapsulated viruses containing 6 to 8 negative sense single RNA strands for a total genome length of 10 to 14 kb. Each RNA strand encodes a functionally distinct polypeptide, the best characterized of which include the hemagglutinin (HA) and neuraminidase (NA) subunits that dominate the viral surface and serve as key antigens recognized by the immune system.

Influenza virions are spread from human vectors by respiratory droplet and through contact with contaminated bodily fluids. Birds, swine, bats, and other mammals are also important vectors for human transmission. Viral HA engages sialic acid residues present on surface proteins of epithelial cells, triggering endocytosis and replication within nuclei. Virions assemble

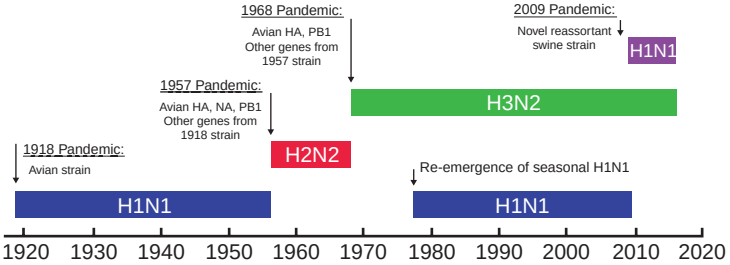

FIG. 31.3 Timeline of Pandemic Influenza Outbreaks and Etiologic Strains Since 1918.

intracellularly and bud from host cells after the RNA genome is enveloped in host phospholipids. Intact virions self-cleave from the host cell surface through the action of NA to continue the infectious cycle.

Clinical Expression

Influenza infection presents as acute respiratory illness with respiratory symptoms (coughing, congestion, etc.) accompanied by the sudden onset of severe systemic symptoms including fever, headache, fatigue, nausea and gastrointestinal symptoms, malaise, and muscle and body aches. Lower respiratory tract infections are more severe and often lead to complications including pneumonia.[32] Pandemic influenza can range in symptoms but generally is associated with more severe disease and often increased mortality in younger populations. However, during the 2009 pandemic, symptoms and mortality were mild, although there was increased mortality in young adults.[32] Avian-derived viruses often cause severe disease with high mortality rates and involve systemic dissemination that results in dysfunction of many organ systems.[32] The defining characteristic of a pandemic influenza strain is its potential to spread quickly through the human population, causing more infections, hospitalizations, and deaths than in a typical influenza season, rather than a specific or more severe clinical presentation. Symptoms, disease severity, and clinical presentation critically depend on the specific virus and immune naïveté within a given population.[32]

Immunopathogenesis

Vaccine efficacy is often measured by the level of neutralizing and HA-inhibiting antibodies produced by the vaccine and a neutralizing humoral response is the primary goal of the influenza vaccine.[31] However, while antibody neutralization of HA or NA can prevent or mitigate infection, the efficacy of these antibodies begins to decrease as the virus mutates targeted regions (i.e., HA globular head group and NA).[33] Other aspects of secondary immunity have been demonstrated to be extremely effective against influenza, including both non-neutralizing antibody responses and T-cell responses.[31,33] Nearly all non-neutralizing antibody-mediated effector functions targeting infected cells have been shown to protect against influenza, including antibody-dependent cellular phagocytosis (ADCP), antibody-dependent cell-mediated cytotoxicity (ADCC), and complement-dependent type III immunity.[33] Cellular immunity directed by T cells is often considered essential in addition to neutralizing antibody responses as it can be directed against more conserved intraviral proteins, targeting viruses that cannot be neutralized because of escape mutations and antigenic drift.[31] Both non-neutralizing antibodies and T cells are sufficient to provide protection from lethal influenza in mice, can target infected cells and highly conserved proteins, and are associated with decreased illness in patients.[31,33]

Alpha and beta influenza viruses (influenza A and B) cause annual epidemics and require annual vaccination to reduce the potential for illness. These viruses mutate rapidly in response to selective pressure from neutralizing antibodies[34] and the most immunogenic regions have a high tolerance for mutation or functional plasticity. Antigenic drift is the accumulation of mutations in viral RNA during infections, thus resulting in altered, antigenically distinct, VP. Antigenic drift is the process that is believed to be responsible for the functionally naïve responses of even heavily vaccinated populations.[34]

Influenza A viruses have high pandemic potential because they infect many species (including birds, swine, and bats) and are capable of antigenic shift, which is the rapid development of antigenically distinct influenza viruses when different influenza A viruses co-infect the same cell and exchange RNA segments (Fig. 31.4). Influenza A viruses are subdivided into serotypes based on expression of distinct HA and NA surface proteins. Each species hosts serotypes with specific HAs and mutations in HA can lead to greater infectivity of humans.[35] Genetic recombination may produce a new HA and NA combination and potentially a pandemic strain when it involves a newly human-adapted (often from birds or swine) or a highly mutated HA.[35]

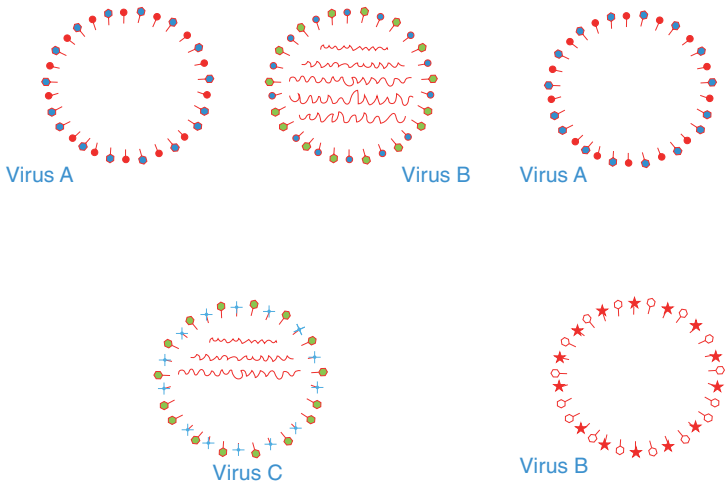

FIG. 31.4 Antigenic Shift and Drift in Influenza. Antigenic shift is the substantial genetic changes that occur during gene recombination in a host cell that is co-infected with two distinct viruses. Antigenic shift occurs rapidly and can result in new subtypes of virus with distinct surface antigens. Antigenic drift reflects the comparatively slow changes in viral surface antigenic character that occur due to naturally accumulating mutations. Antigenic drift can result in new viral strains.

Treatment and Prevention

Vaccines

The WHO leads a global effort to screen viral isolates and select three to four influenza viruses to target in the seasonal vaccine based on analysis of antigenic sites and predictions of population susceptibility.[34] There are three approved types vaccine: inactivated, recombinant, and live attenuated. Utilized in the United States since 1945, inactivated vaccines are most common. Production is relatively slow because expansion of selected viruses in chicken eggs or cell culture, the typical methods of production, are time-consuming processes. The purified and neutralized virus or VPs (HA and NA) are used to create the final vaccine. Another recombinant vaccine uses insect cells modified to express the seasonally predominant HA proteins in vitro without resorting to viral reproduction. This vaccine has the shortest production timeline.

The live attenuated vaccine is a temperature-sensitive influenza virus that expresses the selected HA and NA proteins and is expanded in chicken eggs. It produces an attenuated upper respiratory tract infection that is rarely transmitted and induces strong T cell responses.[35]

Regardless of the vaccine method used, viral strains and mutations are selected 6 months prior to the peak influenza season. Antigenic drift after selection can and does occur, limiting vaccine efficacy (between 10% and 60% since 2005). If antigenic shift occurs after selection, the vaccine will likely provide no protection against a potentially pandemic influenza strain and vaccine production is reinitiated with the novel virus strain.

Egg-based production is limited by the number of quality eggs, which could be even more limited during a pandemic of avian origin.[31] Cell culture–based methods are less limited and faster, but all methods of production are limited by resources[31] and the time required for development, manufacturing, quality control, and distribution.[34]

Developing vaccines for novel strains can have unexpected challenges. Highly virulent H5N1 avian strains initially killed eggs.[35] This and other unanticipated problems occurring during a pandemic could further hamper attempts to release a vaccine. Even optimally designed and produced influenza vaccines provide limited protection to the most at-risk population, people over age 65.[31] Experimental influenza vaccines are showing promise for eventually overcoming these limitations through the inclusion of novel vaccine formulations and adjuvants and the targeting of VPs that are less prone to developing mutations such as the M (matrix) protein.

Antiviral Therapy

There are three classes of approved influenza antivirals: adamantanes, NA inhibitors, and endonuclease inhibitors. All current treatments are approved only within 48 hours of symptom development and some can be administered prophylactically.

Amantadine and rimantadine are adamantanes and block the M2 ion channel, preventing infection. The FDA approved in 1966; adamantanes were the first treatment for influenza A and resistance remained low, with only 0.4% during the 1994 to 1995 influenza season. In 2003, resistance began to rise, reaching 12.3% in the 2003 to 2004 season and 92% in the 2005 to 2006 season. By 2009, all H3N2 and H1N1 isolates tested were resistant.[36]

The first NA inhibitor was FDA approved in 1999. Oseltamivir, zanamivir, and peramivir inhibit NA, preventing viral budding and are currently effective against > 99% of circulating influenza A and B strains. In 2009, oseltamivir-resistant H1N1 began circulating intermittently and some patients develop resistant viruses after treatment. Transmission of NA inhibitor-resistant viruses is limited, but studies report transmission in family clusters and among immunocompromised patients and mutations which may improve transmission. Zanamivir resistance is less common.[36] The Centers for Disease Control and Prevention (CDC) reports that of isolates (H1N1, H3N2, and influenza B) tested during the 2017 to 2018 season, 1% of H1N1 isolates were resistant to both oseltamivir and peramivir, and these were susceptible to zanamivir.

Approved by the FDA in 2018 to treat influenza A and B, baloxavir marboxil is a selective inhibitor that prevents the translation of viral RNA. The CDC reports the isolation of resistant strains from some patients in clinical trials.

Summary

Due to the nature of antigenic shift, pandemic influenza strains usually develop suddenly. With a minimum of six to eight months after detection to develop and mass produce a vaccine, the limited window for treatment with antivirals, the potential for resistance to or the development of resistance to one or more antiviral treatments, an influenza pandemic could cause a world health crisis. Current efforts aim to improve vaccination efficacy in high-risk groups, improve the efficiency of vaccination production, produce a universal vaccination against all serotypes of influenza A, and to improve treatments.

KEY CONCEPTS

Viral Influenza: Pathogenesis, Vaccines and Treatment

- Antigenic drift: the accumulation of mutations during normal infections.
- Antigenic shift: the exchange of RNA segments between two influenza A viruses that have infected the same cell,
- Influenza A viruses have the highest pandemic potential because they:
  - Undergo both antigenic drift and antigenic shift
  - Infect multiple species.
- Pandemic influenza strains usually develop suddenly.
- Vaccine production and limitations:
  - A minimum of 6 to 8 months after detection
  - Seasonally based on predictions
  - Limited by resources
  - Limited efficacy in high-risk groups.
- Antiviral treatments and limitations:
  - Limited window for treatment
  - Potential for resistance to or the development of resistance to one or more antiviral treatments.

EMERGING BACTERIAL THREATS

In the latter half of the 20th century, bacteria have comprised the largest fraction of new emerging infections inclusive of all infectious agents (Fig. 31.5).[37] One can classify emerging bacterial threats of the future into two broad categories, each with a unique natural history. The first are opportunistic infections that result from advances in medicine and civil engineering that otherwise

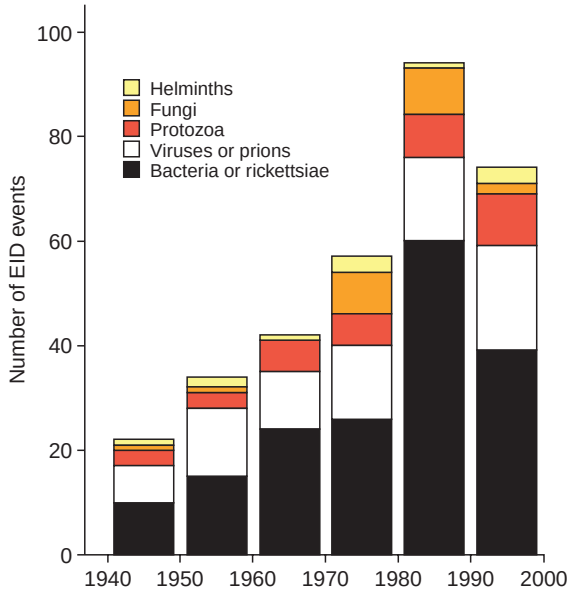

FIG. 31.5 Emerging Bacterial Infections. The number of new emerging infectious diseases *(EIDs)* per decade are indicated for bacteria and rickettsiae relative to other causative microorganisms. (Adapted from Jones KE, Patel NG, Levy MA, et al. Global trends in emerging infectious diseases. *Nature*. 2008;451:990–993.)

prolong life expectancy, temporarily suppress the immune system (such as during organ transplants or due to autoimmunity), or are associated with some type of indwelling device.[38] Such infections are termed healthcare-associated infections (HAIs) or aging-associated infections (AAIs). The human life expectancy has doubled in the last 100 years, resulting in a significantly older population than what would naturally be allowed, thus putting many individuals at a higher risk of life-threatening infections due not just to the longer exposure time to infectious organisms, but also due to senescence of the immune system and other organs. A key difference though as compared to ancient times is that whereas bacterial infections of the past were often acquired through external means (i.e., via contamination of water or food or close human-to-human contact), modern infections originate largely from bacteria that live in and on us—our microbiome. These organisms cause bacteremia and sepsis in the infirm and terminally ill, they infect and grow biofilms on devices (*e.g.*, heart-assist devices, catheters, prosthetics, etc.), and they cause chronic infections in the immunocompromised or those with other underlying illnesses.[39] They are emerging because as medical care becomes more advanced, and human life expectancy continues to push limits, the expectation is that such infections will continue to rise and cause significant morbidity and mortality.

The second classification of emerging bacterial infections are those that arise not through medical advancement, but one in which technology allows human habitation in every corner of the globe.[40] These can be termed anthropogenic-associated infections (AGAIs) because their emergence is fueled by human activity. The ease of habitation of all ecosystems, their eventual encroachment and destruction by human settlement, and the rapid transport of people or goods anywhere in the world, facilitates the emergence of unknown (or previously rare) bacterial species, and strains, into naïve or otherwise susceptible populations. Most of these types of infections can be considered as zoonotic transmissions or diseases. As much remains unknown about these infectious contexts, there is concern that one or more bacterial agents could result in pandemic disease.

Microbiology and Clinical Manifestation

Table 31.3 illustrates some important bacterial species that can be considered as emerging or concerning. The list spans those that are classified as gram-positive or gram-negative upon Gram stain as well as species of spirochetes (vector born) and mycobacteria. Most of the HAIs and AAIs comprise key hallmark species that inhabit our microbiome and include *Staphylococcus, Streptococcus, Escherichia, Pseudomonas, Enterococcus, Klebsiella, Helicobacter*, and *Enterobacter* spp. The AGAIs are more widely varied and include species of *Mycobacteria, Borrelia, Legionella, Bartonella*, and *Rickettsia* spp. The types of infections these bacteria cause and their clinical manifestations are as broad as the species themselves. Generally speaking, HAIs and AAIs are common in those undergoing treatment for cancer or are otherwise immunocompromised, have had surgery, or elderly or infirm, and have indwelling devices including catheters, left ventricular assist devices (LVADs), or implants of other prosthetics that form surfaces by which biofilms can attach. The dominant life-threatening presentation occurs when these bacteria, which are often found at mucosal surfaces, breach this barrier of defense and translocate into the blood and/or distal tissues and organs. AGAIs are often infections of lifestyle, including those that spend much time, or whose lifestyle interfaces, with the rugged outdoors (vector-borne infections from ticks), those involved in animal husbandry and farming (e.g., horses and cattle), those that live in poor sanitary conditions (especially food- or water-borne infections) or whose housing is very dense (slums and towering apartment complexes), and those with free-roaming pets (including dogs and cats).

Vaccine Development and Treatment

There are currently no vaccines for hospital- or aging-associated bacterial infections.[39] There are several reasons for this, including that many bacterial species are a normal part of the human microbiome (and therefore often adapted to pressures placed by the human immune system) and that many bacteria have malleable, pleiotropic genomes where horizontal gene transfer introduces new virulence factors that make identification of vaccine targets more challenging. *Escherichia coli*, for instance, expresses at least 10 distinct pathotypes and each pathotype not only causes a different type of infection but also displays a novel set of virulence factors that drive pathogenesis, sometimes such factors being readily exchanged between strains. In contrast, AGAIs are relatively infrequent and there is a substantial lack of knowledge as to molecular pathogenesis; both factors strongly impair vaccine development.

The most significant concern regarding emerging bacterial threats is the high level and continued rise in resistance to conventional antibiotics. This factor poses the most serious risk for pandemic disease, especially involving key species comprising the human microbiome. Some sources estimate that by 2050, the total loss of lives due to multidrug-resistant bacteria will be 10 million at a cost of $100 trillion to the world economy.[41] Because HAIs and AAIs are often exposed to antibiotics as residents of the human microflora, the very act of treatment generates selective pressures that drive the evolution of clonal groups amongst our microbiome, and these strains then

TABLE 31.3 Emerging Bacterial Pathogens of the Last 50 Years

Year	Bacterial species	Clinical Manifestations	Transmission	Treatment	Comments
N/A	ESKAPE drug-resistant bacteria				
	E*nterococcus* spp.	Endocarditis, UTI, sepsis/blood infection	Microbiome (intestine)	Multidrug due to resistance	---
	S*taphylococcus* spp.	Endocarditis, abscess, sepsis/blood, device and/or skin infection	Microbiome (skin and nares)	Multidrug due to resistance	---
	K*lebsiella* spp.	Device, lung and/or peritoneum infection, UTI	Microbiome (intestine and lung)	Multidrug due to resistance	---
	A*cinetobacter* spp.	Abscess, sepsis/blood infection, lung, and/or wound infection	Microbiome (lungs), environment	Multidrug due to resistance	---
	P*seudomonas* spp.	Lung, wound, eye and/or ear infection, UTI/catheter infection	Microbiome (intestine and lungs)	Multidrug due to resistance	---
	E*nterobacter* spp.	Prosthetics infection, abscess	Microbiome (intestine)	Multidrug due to resistance	---
	E*scherichia* spp.	UTI/catheter, intestine, sepsis/blood, meningitis, and/or peritoneum infection	Microbiome (intestine)	Multidrug due to resistance	---
1973	*Campylobacter* spp.	Diarrhea	Zoonosis	Unnecessary in most cases (macrolides, quinolones)	---
1974	*Clostridium difficile*	Pseudo-membrane colitis; toxic megacolon	Human to human	Vancomycin	Commonly associated with antibiotic use
1974	*Streptococcus bovis* group	Endocarditis	Human to human and/or zoonosis	β-Lactam	Commonly associated with adenocarcinoma of colon and chronic liver diseases
1976	*Legionella pneumophila*	Lung infection	Amoebae in water	Azithromycin, respiratory quinolones	---
1976	*Capnocytophaga canimorsus*	Sepsis	Zoonosis	β-Lactam–β-lactamase combinations	In asplenic patients, hepatic diseases, alcohol abuse
1982	*Escherichia coli* O157:H7	Hemorrhagic colitis, hemolytic uremic syndrome	Zoonosis	Not required	Known as 'hamburger disease'
1982	*Borrelia burgdorferi*	Lyme disease	Zoonosis	Doxycycline, amoxicillin	---
1983	*Chlamydia pneumoniae*	Lung infection	Human to human	Macrolides, doxycycline	First isolated in 1965 in context of trachoma vaccine trial in eye
1983	*Helicobacter pylori*	Gastric ulcers	Human to human	PPI + clarithromycin + amoxicillin/metronidazole	Associated with higher risk of gastric adenocarcinoma and lymphoma
1986	*Rhodococcus equi*	Pneumonia in immunosuppressed	Zoonosis	Multidrug therapy due to resistance	---
1987	*Ehrlichia chaffeensis*	Human ehrlichiosis	Zoonosis	Doxycycline	---
1990s	Non-diphtheria *Corynebacterium* spp.	Endocarditis in immunosuppressed, patients with underlying valve disease or prosthetic valve; other invasive infections	Human to human	β-Lactam + glycopeptides; if resistant, vancomycin	Most important: *C. amycolatum*, initially confounded as *C. xerosis, C. striatum*
1990s	Spotted fever group *Rickettsia* spp.	Spotted fever rickettsiosis	Zoonosis	Doxycycline	Notably *R. africae, R. helveticae, R. slovaca, R. mongolotimonae*
1990	*Anaplasma phagocytophilum*	Human granulocytic anaplasmosis	Zoonosis	Doxycycline	Previously thought to be *Ehrlichia* spp.
1991	*Tropheryma whipplei*	Whipple disease	?	Ceftriaxone followed by trimethoprim–sulfamethoxazole	---
1992	*Vibrio cholerae* O139	Diarrhea	Contaminated water	Not required	---
1992	*Bartonella henselae*	Cat-scratch disease, bacillary angiomatosis	Zoonosis	Generally not required in immunocompetent patients	Initially named *Rochalimaea*
1992	*Aerococcus* spp.	UTI, endocarditis	Human to human	β-Lactam, glycopeptides,	Mainly *A. urinae* and *A. sanguinicola*; especially in elderly or patients predisposing factors such as diabetes, urinary catheters

(Continued)

TABLE 31.3 Emerging Bacterial Pathogens of the Last 50 Years—Cont'd

Year	Bacterial species	Clinical Manifestations	Transmission	Treatment	Comments
1995	*Wolbachia* spp.	Associated with onchocerciasis and lymphatic filariasis	Zoonosis	Doxycycline with or without antifilarial treatment	Indirectly acts as endosymbionts of filarial
1997	*Simkania negevensis*	Lung infection	?	Macrolides, doxycycline	---
1997	*Actinobaculum schaalii*	UTI	?	β-Lactam, glycopeptides,	First considered as a contaminant; especially in elderly or patients with predisposing factors such as diabetes, urinary catheters
1997	*Parachlamydia acanthamoebae*	Lung infection	Amebae in water (?)	Macrolides, doxycycline	Isolated from water of humidifier involved in epidemic of fever in Vermont
2007	*Waddlia chondrophila*	Miscarriages	?	Macrolides, doxycycline	---
2007	*Alloscardovia omnicolens*	UTI	?	β-Lactam, cotrimoxazole, glycopeptides, fluoroquinolones	Especially in elderly or patients with predisposing factors such as diabetes, urinary catheters
2010	*Neoehrlichia mikurensis*	Neoehrlichiosis: systemic inflammatory response; vascular and thromboembolic events	Zoonosis	Doxycycline	More frequent among immunocompromised patients

PPI, proton pump inhibitor; *UTI*, urinary tract infection.
Adapted from Vouga M, Greub G. Emerging bacterial pathogens: the past and beyond. *Clin Microbiol Infect*. 2016;22:12–21.

become endemic to the population. Unlike hospital-associated infections, fortunately, infections emerging due to anthropogenic means are more often treatable with antibiotics unless the infecting species results from strains that circulate in farm animals where high doses of antibiotics (chicken, pork, and cattle) are often used.

ON THE HORIZON

- Many emerging bacterial threats have true pandemic potential, including ESKAPE bacteria.
- There are no current vaccines available against HAIs and AAI-associated organisms.
- Vaccine and new drug development efforts should begin with these species using paradigm-changing approaches that adapt to the evolution of these pathogens in real time.
- As human expansion and travel continue to increase through globalization, so will the emergence of zoonotic bacterial species capable of causing serious infections in humans.
- Future research efforts should focus on surveillance combined with rigorous basic science research programs aimed at understanding the molecular mechanism of disease causation and virulence.

Approach to the Evaluation of the Patient With Suspected Immunodeficiency

Jennifer M. Puck and Thomas A. Fleisher

The number of characterized primary immune deficiency (PID) disorders has expanded exponentially over the past three decades, with the underlying genetic basis for the majority of previously known PIDs being identified as well as many new disorders reported in the past decade.[1] PIDs are individually rare, but accurate and prompt specific diagnosis is critical for the early initiation of appropriate therapy in an attempt to prevent or diminish irreversible disease–associated complications and mortality. Hallmark features in most patients suspected of having a PID include a history of increased susceptibility to infection, often together with manifestations of immune dysregulation and/or malignancy. The types of infections experienced by a patient are often clues pointing to which immune functions may be compromised (Table 32.1). The combination of accurate clinical and laboratory characterization of patients with PID combined with mutation analysis (Chapter 18) has also revealed that many PID genotypes can manifest a wider range of clinical phenotypes than previously appreciated.

EVALUATING SUSPECTED DEFECTS IN ANTIBODY RESPONSE

The clinical circumstances that would typically lead to an evaluation for a defect involving antibody production include a history of recurrent sinopulmonary infections with encapsulated bacteria (e.g., *Streptococcus pneumoniae, Haemophilus influenzae*). This group of disorders involves both primary B-cell defects and some complement defects as well as combined defects affecting both humoral and cellular immunity.[2,3] The medical history is essential before proceeding with any directed diagnostic testing and should at a minimum include recurrent infections of the upper and/or lower respiratory tract. Additional infectious sites may involve recurrent/chronic conjunctivitis and gastrointestinal infections. Depending on the underlying defect, these patients may also develop infections with intracellular pathogens as well as evidence of immune dysregulation (e.g., arthritis, gastrointestinal disease). In many cases there will be a family history of recurrent infections such that carefully ascertaining the family pedigree is important, focusing on any relatives' history of recurrent infections, immune dysregulation, and/or malignant disease. The physical examination can also provide important information; in addition to noting evidence of cutaneous infections, easy bruising/bleeding, etc., one of the most telling findings can be whether tonsils are visible. Although a healthy child with recurrent sinusitis or otitis would be expected to have large tonsils, the absence of tonsils, a tissue containing primarily B cells, in this clinical setting strongly suggests a humoral immune defect involving an abnormality in B-cell development. The specific laboratory approach used to further evaluate the patient will depend on what is learned up to this point.

Initial screening for humoral immunity is typically accomplished by measuring serum levels of the major circulating immunoglobulin classes (isotypes), IgG, IgA, IgM, and IgE (see Table 32.1).[4] Antibody levels must be compared with age-matched reference intervals (normal ranges) typically provided as 95% confidence intervals (CIs). The need to compare results to age-specific data relates to the fact that the immune system is undergoing important maturation during infancy and childhood; immunoglobulin reference intervals change substantially until mid to late adolescence. There are no rigid standards regarding the diagnosis of immunoglobulin deficiency, although an IgG value less than 3 g/L (300 mg/dL) in an adolescent or adult or values clearly less than the age-appropriate reference interval (95% CI) in infancy or childhood should trigger further evaluation.[4] When immunoglobulin levels are decreased, it is important to rule out protein loss as the underlying cause by evaluating the serum albumin level. An additional and readily available test is to measure levels of IgG subclasses, most useful in diagnosing selective IgA deficiency with IgG subclass deficiency that is often associated with recurrent sinopulmonary infections.

Measurement of specific antibody responses is necessary to confirm defective antibody production in vivo and is now a criterion for making the diagnosis of many PIDs. In the setting of a medical history that includes recurrent bacterial infections with normal or modestly decreased immunoglobulin levels, confirming a defect in specific antibody production establishes a diagnosis of a rare condition, specific antibody deficiency.[5] One method to evaluate specific antibody responses is testing for spontaneous specific antibodies (e.g., anti-blood group antibodies [isohemagglutinins]) as well as for antibodies to documented previous immunizations or infections (Table 32.2). However, this fails to provide definitive proof of the capacity to respond to a specific antigen at the time of evaluation, which requires evaluation of in vivo antibody production following immunization using one or more protein antigens (e.g., tetanus toxoid, diphtheria toxoid) as well as polysaccharide antigens (e.g., antigens present in the 23-valent polysaccharide vaccine, Pneumovax) (see Table 32.2). Guidelines for normal responses are usually provided by the testing laboratory and typically consist of finding at least a fourfold increase in antibody titer and/or antibody levels considered to be protective in a sample obtained 3 to 4 weeks post immunization (Chapter 94).

TABLE 32.1 Screening Tests According to Immune Deficit

Affected Immunity Arm	Typical Site of Infection	Common Pathogens	Screening Tests
B cells/antibody	Sinopulmonary tract, GI tract, joints, CNS	Pyogenic bacteria: *Streptococcus, Streptococcus, Haemophilus influenzae* Enteroviruses: ECHO, polio *Mycoplasma, Ureaplasma*	IgG IgA IgM IgE Vaccine responses (titers)
T cells	Sepsis, lung, GI tract, skin	Viruses: CMV, adenovirus, measles, *Molluscum contagiosum*, Fungi: *Candida, Aspergillus Pneumocystis jirovecii* Pyogenic bacteria Protozoa: *Cryptosporidium*	CBC with differential Flow cytometry for T cells and T-cell subsets T-cell proliferation to mitogens and antigens (typically *Candida*, tetanus)
NK cells	Skin, lung, GI tract, disseminated infections	Viruses: EBV, CMV, VZV, HSV, HPV	Flow cytometry for NK cells CD107a surface expression NK cytotoxicity assays
Phagocytes	Skin infections, lymphadenitis, liver, lung, bone, GI tract, gingivitis/periodontitis	Bacteria: *Staphylococcus, Serratia marcescens, Burkholderia cepacia, Klebsiella, Escherichia coli, Salmonella, Proteus* Fungi: *Candida, Aspergillus, Nocardia*	Absolute neutrophil count Flow cytometry for expression of CD11/CD18 Dihydrorodamine 123 flow cytometry (DHR) test
Complement	Systemic infections, meningitis	Pyogenic bacteria: *Streptococcus, Haemophilus influenzae, Neisseria*	CH50 AP50

ECHO, enteric cytopathic human orphan virus

An additional approach for assessing the humoral immune response in patients receiving immunoglobulin replacement therapy involves vaccination with a neoantigen (an antigen to which the patient has not previously been exposed) such as the bacteriophage Phi X 174 (not readily available), rabies vaccine, or *Salmonella typhi* capsular polysaccharide vaccine (see Table 32.2). *Salmonella* capsular polysaccharide vaccine, generally given only for foreign travel, has been validated as a tool to assess defective antibody production in individuals receiving IgG products, which generally lack anti-*Salmonella* antibodies.[6]

Additional testing of humoral immunity focuses on characterizing B cells by flow cytometry (Chapter 93). This is useful in the evaluation of congenital forms of agammaglobulinemia that are characterized by absent or extremely low numbers of circulating $CD19^+/CD20^+$ B cells associated with genetic defects that block B-cell development (see Table 32.2).[3] More recently, characterization of B-cell subsets has focused on memory ($CD27^+$) and immature B cells ($CD27^-$) as well as non–class-switched (IgM^+) or class-switched (IgM^-) memory B cells to stratify patients with common variable immune deficiency (CVID).[7] Advanced studies testing in vitro B-cell signaling, apoptosis, and immunoglobulin biosynthesis/secretion are performed only in research centers.

EVALUATING SUSPECTED T-CELL DEFECTS

The typical clinical scenario that suggests a possible T-cell defect is a history of recurrent or prolonged viral or other opportunistic infections. Defects presenting in infancy and early childhood are often associated with a history of failure to thrive, and the clinical phenotype of these disorders may also include autoimmunity. In addition, early onset of a T-cell defect generally heralds progressively severe symptoms that can be fatal. As noted earlier, a family history is important as part of these evaluations because most primary T-cell defects are single gene disorders, and a family member may have suffered from similar events, including in the most serious T-cell disorders resulting in early childhood death. During any evaluation for an underlying T-cell defect, it is important to ensure that the patient is not exposed to harm, either by being administered blood products that have not been filtered and irradiated to eliminate leukocytes responsible for transfusion-related graft-versus-host disease (GvHD) or through infection. In T-cell deficient children, avoiding all live vaccines is necessary to prevent severe infections caused by vaccine strain organisms. The physical examination is another critical part of the evaluation in this group of patients and may reveal cutaneous or oral findings (e.g., petechiae, telangiectasias, thrush) as well as changes in the lymphoreticular system (e.g., absent or enlarged lymph nodes).

KEY CONCEPTS

Medical/Family History in Primary Immune Deficiency Diseases

- Infections
  - Frequent and/or recurrent
  - Severe
  - Persistent, despite standard therapy
  - Caused by opportunistic pathogens
- Failure to thrive in infants and children, weight loss in adults
- Dysregulated immune reactions
  - Autoimmunity
- Family history
  - Similarly affected family member(s)
  - Family member(s) with any recognized immune disorder, recurrent infections, or undiagnosed infant death
  - Parents with common ancestry, consanguinity (for autosomal recessive primary immune deficiency diseases)
  - Membership in a group carrying recognized founder mutations (Amish/Mennonite; Navajo or Apache Native American, etc.)
- Primary Versus Secondary Immune Deficiency

TABLE 32.2 Overview of Laboratory Testing to Evaluate Primary Immunodeficiencies

	Initial Tests	Secondary Tests	Advanced Tests
Suspected B-cell defects	– Quantitative immunoglobulins (IgG, IgA, IgM, IgE) – Specific antibody titers – Natural antibodies (e.g., isohemagglitinins anti-A and anti-B against blood group antigens) – Random, pre/post immunization titers to protein (e.g., tetanus toxoid, diphtheria toxoid) and polysaccharide antigens (pneumococcal vaccine)	– IgG subclasses (restricted utility) – B-cell immunophenotyping (CD19, CD20, CD10, CD21, CD23, CD27, CD38, CD40, CD81, CD138, surface Igs, κ chain, λ chain) – Antibody response to vaccination with a neoantigen (Phi X 174, rabies, *Salmonella typhi*)	– Class switching – In vitro immunoglobulin production (antibody secreting cell generation, ELISPOT for specific Ig production) – Mutation analysis (e.g., *BTK, AID, IGHM*)
Suspected T-cell defects	– CBC and differential – T-cell immunophenotyping (CD3, CD4, CD8, CD45RA/RO, TCRαβ/γδ) – TRECs (population-based newborn screening)	– Extended T-cell immunophenotyping (CD3 chains, CD62L, CD31, CCR7, CXCR5, CD40L, CD127, CD132; MHC-I, MHC-II) – Lymphoproliferation in response to mitogens (PHA, ConA, PWM, PMA+I), CD3/CD28, and antigens (including alloantigens and recall antigens) – Assessment for interstitial chromosome deletion, most commonly ch22q11.2 deletion DiGeorge syndrome	– Vβ TCR repertoire (by immunophenotyped, spectratyping or deep sequencing) – In vitro cytokine production – ADA/PNP enzyme activity and accumulation of toxic purine nucleotides – Radiosensitivity testing – Mutation analysis (e.g., *IL2RG, IL7R, JAK3, RAG1/2, DCLRE1C*)
Suspected NK and NKT cell defects	– CBC and differential – NK/NKT cell immunophenotyping (CD3, CD16, CD56)	– Expanded NK/NKT cell immunophenotyping (KIRs, CDG2/CD94, NKp46, CD117, Vα24, Vβ11) – NK cytotoxic activity on K562 cells	– NK cytotoxic activity on other cells (Raji, 721.221, SKBR3) – NK ADCC – NK cytokine production (ELISPOT) – NK redirected lysis assays
Suspected phagocyte cell defects	– CBC and differential – Morphology: smear evaluation – DHR flow cytometry assay (alternative NBT test)	– Adhesion molecule evaluation: β_2 integrins (CD18, CD11a, b, c), CD15 – Phagocyte cell evaluation, *i.e.*, APC, monocytes – Immunophenotyping (CD14, CD68, CD86, HLA-DR, IFNGR1, IL12Rβ1)	– Chemotaxis – Bactericidal activity – STAT1/STAT4 phosphorylation in response to IFN-γ/IL-12 – IL-12 production in response to IFNγ; – Mutation analysis (e.g., *CYBB, CYBA, NCF1, NCF2, NCF4, IFNGR1, IL-12RB1*)
Suspected complement defects	– CH50 – AP50	– C3, C4 – MBL	– Immunoassay for individual complement components – Functional component testing
Suspected TLR signaling defects	– CD62L shedding	– Specific TLR ligand stimulation assessed by measuring cytokine secretion	– Mutation analysis (e.g., *IRAK4, MYD88, NEMO, TLR3*)

ADA, Adenosine deaminase; *ADCC*, antibody-dependent cellular cytotoxicity; *CBC*, complete blood count; *DHR*, dihydrorhodamine 123; *Ig*, immunoglobulin; *IL*, interleukin; *IFN*, interferon; *MHC*, major histocompatibility complex; *NBT*, nitroblue tetrazolium; *NK*, natural killer; *NKT*, natural killer T; *TCR*, T-cell receptor; *TLR*, Toll-like receptor; *TREC*, T-cell receptor excision circles.

Adapted from Rosenzweig SD, Kobrynski K, Fleisher TA. Laboratory evaluation of primary immunodeficiency disorders. In Sullivan KE, Stiehm ER editors, Stiehm's Immune Deficiencies: Inborn Errors of Immunity 2nd ed. Academic Press. Cambridge, MA, 2020. page 117.

Finally, there may also be syndromic findings consistent with specific diagnoses (e.g., congenital anomalies, microcephaly, unusual facies, short limbed dwarfism).

Initial laboratory evaluation of individuals suspected to have a T-cell disorder should include a white blood cell count and differential focusing on the absolute lymphocyte count compared with age-matched control ranges for proper interpretation (see Table 32.1). Because 50% to 75% of circulating lymphocytes are $CD3^+$ T cells, any process that interferes with T-cell development or increases T-cell loss will result in absolute lymphopenia. It is important to recognize that the total lymphocyte count associated with lymphopenia differs between an infant (<2500/mm^3) and an adult (<1000/mm^3). Profound lymphopenia, particularly in an infant, should prompt immediate immunologic evaluation because it suggests severe combined immunodeficiency (SCID) or complete DiGeorge syndrome, both life-threatening conditions. However, a low number of T cells during infancy is not always found in SCID, because infants with spontaneous engraftment of maternal cells or with "leaky SCID" (including Omenn syndrome) may have normal or elevated total lymphocytes due to oligoclonal expansion.[8,9] In either of these circumstances, the T cells will consist primarily of memory ($CD45RO^+$ T cells) as compared with the T cells found normally in infants, which are primarily naïve ($CD45RA^+$ T cells) (see Table 32.2).[10]

Because of the importance of identifying lymphopenia associated with PID, it is also critical to consider alternative explanations. Lymphopenia associated with human immunodeficiency virus (HIV) infection should be ruled out, and this typically requires testing for the presence of virus nucleic acid or protein (*i.e.*, HIV viral load assay) rather than serologic testing for anti-HIV antibody, which is not reliably produced by immunodeficient individuals. In addition, mechanical loss of lymphocytes, as seen in cases of intestinal lymphangiectasis, should also be considered, especially in patients with chronic diarrhea in whom T-cell proliferation testing is normal. Chylous loss and circulatory alterations can also lead to T-cell lymphopenia.

Direct assessment of the T-cell compartment using flow cytometry provides critical information (Chapter 93).[4,11]

A standard initial clinical flow cytometry approach involves immunophenotyping of T cells with particular focus on enumerating the $CD3^+/CD4^+$ helper and $CD3^+/CD8^+$ cytotoxic T-cell subsets and determining the contribution of naïve, newly produced versus expanded memory T cells. Naïve versus memory T cells can be assessed using a combination of antibodies directed at the CD45 isoforms, CD45RA and CD45RO, respectively. This often is accompanied by in vitro functional testing (e.g., cell proliferation in response to mitogen or antigen, cytokine production, intracellular signaling) (Chapter 94; see Table 32.2).

Other useful tests in selected circumstances include consideration of syndromes due to heterozygous interstitial chromosome deletions, the most common of which is ch22q11.2 deletion associated with DiGeorge syndrome.[11] Although formerly assessed with karyotype analysis or fluorescent in situ hybridization (FISH), current methods including chromosomal microarrays or other tests of copy number, including copy number of the *TBX1* gene in the DiGeorge syndrome critical region, are preferred. Finally, T-cell defects due to adenosine deaminase (ADA) or purine nucleoside phosphorylase (PNP) deficiency require enzyme assays and measurement of the accumulation of toxic purine byproducts in erythrocytes.

NEWBORN SCREENING FOR SEVERE COMBINED IMMUNE DEFICIENCY

Screening an entire population of largely healthy individuals to flag a rare group for follow-up is radically different from the established paradigms described elsewhere in this chapter for diagnosis of immune system disorders. This approach using universal newborn screening for SCID has been adopted throughout the United States and in many other countries as a method to identify infants affected with SCID before they develop life-threatening infections. The great majority of infants with SCID have no family history or outward signs of immune system impairment at birth. However, the heel-stick blood spotted onto filters to screen infants for rare metabolic disorders can be used to isolate DNA for detection of T-cell receptor excision circles (TRECs), formed as byproducts of normal T-cell receptor (TCR) gene rearrangement as T cells mature in the thymus (Chapter 9).[12,13] This assay takes advantage of the fact that the T cell receptor delta (TCRD) locus (located in an intron of the T cell receptor alpha [TCRA] locus) is excised *en bloc*, forming a circle called the δREC-ψJα TREC in all thymocytes destined to express αβTCR antigen receptors. The number of copies of this TREC in a standard punch from a dried blood sample is detected by a quantitative polymerase chain reaction (PCR) amplifying its joined ends. Insufficient or undetectable TRECs constitute a positive SCID newborn screen result, leading to further investigation by flow cytometry as described earlier.

In addition to detecting infants with typical and leaky SCID, regardless of genotype, an abnormal TREC result also flags for further evaluation infants with insufficient T cells due to other causes.[14,15] Non-SCID syndromes, including DiGeorge syndrome, trisomy 21, ataxia telangiectasia, and others, may have neonatal T-cell lymphopenia profound enough to demonstrate an abnormal TREC screen. Secondary non-SCID T-cell lymphopenia also may be caused by T-cell loss or destruction as mentioned earlier, by extreme preterm birth, or by in utero exposure to maternal immunosuppressive medications prescribed for autoimmune disease. A particularly interesting and unanticipated category of infants with abnormal newborn screens for SCID have previously undescribed single-gene disorders, some of which, including *BCL11B* and *EXTL3* deficiencies, have been identified through deep sequencing and molecular studies.[15]

EVALUATING SUSPECTED NATURAL KILLER DEFECTS

Testing of natural killer (NK) cell function is indicated in patients experiencing recurrent viral infections, particularly infections involving the herpes virus family and papilloma virus, as well as patients with hemophagocytic syndromes known as hemophagocytic lymphohistiocytosis (HLH).[16,17] Evaluation includes enumerating NK cells by flow cytometry ($CD3^-CD16^+/CD56^+$ cells) and assaying cytotoxicity using specific in vitro assays (see Table 32.2). Human NK cells can be divided into different subpopulations with the two most characterized defined by the levels of CD56 expression. Among these two NK cell subpopulations are those with high levels of perforin and granzymes in their cytolytic granules with low CD56 expression ($CD56^{dim}$); these cells mediate cytotoxicity. In contrast, NK cells with high levels of CD56 ($CD56^{bright}$) are the most efficient cytokine producers, releasing large amounts of interferon gamma (IFN-γ), enabling this NK cell subpopulation to serve as an immune enhancer.[16]

NK cell function is tested using cytotoxicity assays that measure target cell lysis using either K562 erythroleukemia cells (NK cell cytotoxicity) or B-cell lines (e.g., Raji 721.221) coated with antibody (usually humanized anti-CD20) to assess antibody-dependent cellular cytotoxicity (ADCC). An additional approach as a surrogate in evaluating cytotoxicity depends on the generation of the immunologic synapse associated with binding of the cytotoxic effector (NK) cell to the target cell. This process results in the surface mobilization of CD107a (lysosomal-associated membrane protein [LAMP]-1) that can be evaluated using flow cytometry.[18] Perforin deficiency is unique in that the two different approaches demonstrate contrasting results with abnormal cytotoxicity but normal CD107a expression.[19] This disparity reflects normal cytolytic degranulation, but defective cytotoxicity due to the absence of the critical protein perforin.[19]

Another subset of lymphocytes that is useful to evaluate in certain PIDs (e.g., X-linked lymphoproliferative syndromes [XLP], ITK deficiency) is the natural killer T (NKT) cell. These cells constitute a distinctive subpopulation of mature lymphocytes (Chapter 3) that express the pan–T-cell marker CD3 as well as the NK cell marker CD56 and function as part of the innate immune system. NKT cells can be further subdivided into invariant NKT (iNKT) cells as well as NKT cells with more variable antigen receptors.

EVALUATING IMMUNE DEFECTS INVOLVING MACROPHAGE ACTIVATION

An emerging concept in the field of primary immunodeficiencies is that monogenic disorders can cause recurrent severe infections involving one or a very restricted range of pathogens. Patients with severe, invasive infections involving low virulence or environmental *Mycobacteria* and *Salmonella* species (and other intracellular pathogens) have been found to harbor defects in genes encoding different components of the

interleukin (IL)-12/23-IFN-γ pathway—*IFNGR1, IFNGR2, IL12RB1, IL12RB2, IL23R, IL12B*, *STAT1, TYK2, JAK1, NEMO, IRF8, RORC, ISG15*—and mutations in *SPPL2A, GATA2*, and *CYBB* have also been associated with Mendelian susceptibility to mycobacterial disease (MSMD) (see Table 32.2).[20,21] The family history is a very important part of evaluating these patients because in the majority of cases there will be a similar history of other affected family members.

The two most prevalent genetic defects among this group of patients involve *IL12RB1* and *IFNGR1*, typically resulting in either absent or diminished cell surface protein expression. These surface proteins can be readily assessed using flow cytometry with specific monoclonal reagents. In addition, there is an autosomal dominant defect affecting the *IFNGR1* gene that results in increased surface expression of this protein chain (the receptor is composed of two different proteins) that is most commonly associated with osteomyelitis, which can be detected with flow cytometry (Chapter 35).

Functional response to cytokine stimulation represents a definitive screening test for possible defects in the IL-12/23-IFN-γ axis that generally would be followed by genetic testing to identify the specific defect. For some of the defects associated with MSMD, including defects in *SPPL2a*, *RORC*, *IL23R*, and *IL12RB2*, more specialized or research laboratories are likely to be needed to confirm both protein and functional defects (Chapter 35).

EVALUATING SUSPECTED TOLL-LIKE RECEPTOR DEFECTS

Recurrent infections involving *S. pneumoniae* and *Staphylococcus* species have been associated with defects involving molecules of the Toll-like receptor (TLR) pathway, including IRAK4, MYD88, and NEMO.[22,23] One of the distinctive features of patients with autosomal recessive *IRAK4* and *MYD88* mutations is the diminished inflammatory response to systemic infection, including little or no fever as well as minimal increase in acute phase reactants.[22] NEMO deficiency is a more complex X-linked disorder with a wide range in clinical phenotypes together with varied degrees of immunologic abnormalities.[23] Finally, susceptibility to herpes simplex encephalitis has been linked to mutations in the genes encoding TLR3, the accessory protein of the TLR pathway, UNC93B, and more recently identified intracellular proteins including TBK1 and IRF3 among others.[24] The family history is a very important part of evaluating these patients as in many of the cases there may be a similar history of other affected family members. Additional defects in TLR function associated with specific clinical phenotypes are likely to be identified and represent an evolving field in clinical immunology.

Currently, the evaluation of TLR function is confined to a limited number of centers that usually screen for response using peripheral blood mononuclear cells stimulated with the various TLR-specific ligands (see earlier) followed by measuring cytokine production (intracellular expression or secretion into the culture supernatant) (see Table 32.2). This may then be followed by direct sequencing for the suspected mutant gene(s) involved in the specific TLR signaling process. It is important to recognize that screening TLR function focused on UNC93B and TLR3 defects requires evaluating the response of fibroblasts after exposure to a TLR3 ligand because testing peripheral blood mononuclear cells is ineffective in detecting the functional abnormality. Von Bernuth and colleagues described a simplified assay for screening TLR function that is reported to detect functional defects in the signaling process using whole blood samples (see Table 32.2).[25]

EVALUATING SUSPECTED PHAGOCYTE DYSFUNCTION SYNDROMES

The neutrophil is capable of phagocytosis, bactericidal and fungicidal activity, as well as removal of damaged tissue. A clinical history suggestive of either a numerical or functional abnormality involving neutrophils includes recurrent bacterial and/or fungal infections typically involving the skin and deep organs. As is the case with most PID evaluations, a careful family history should be part of the initial approach to establish if any other members of the extended family have a history of recurrent bacterial and/or fungal infections and/or early death. The physical exam is also an important part of the initial evaluation, looking for evidence of past cutaneous infections that required incision and drainage, wound healing abnormalities, periodontal disease, and other physical findings. The laboratory evaluation should start with a leukocyte count, differential, and morphologic review (see Table 32.1) as neutropenia is the most common category of neutrophil defect (Chapter 39).[26]

Once neutropenia and morphologic abnormalities have been ruled out, the evaluation should be directed at assays that provide functional information about neutrophils, and these primarily focus on two different disorders, one that affects neutrophil migration to sites of infection and the other that impacts neutrophil killing of certain bacteria and fungi (see Table 32.2). The former condition is seen in leukocyte adhesion deficiency (LAD), with the most common type being LAD-1 associated with bacterial infections involving the skin, periodontal tissue, and lungs.[27] The latter defect of neutrophil function is associated with chronic granulomatous disease (CGD), a condition that has a predisposition to bacterial and fungal infections involving the skin and deep organs as well as manifestations of hyperinflammation.[28]

Patients with a functional neutrophil defect involving adhesion abnormalities typically present with increased bacterial infections, leukocytosis (even at times of no infection), and absence of pus at sites of infection. In addition, there is often the finding of severe periodontitis and there may be short stature, distinctive facies and the Bombay (hh) blood type. Laboratory evaluation involves flow cytometric assessment of neutrophils for a defect in β_2 integrin (CD11a/CD18 [LFA1], CD11b/CD18 [Mac-1 or CR3], CD11c/CD18 [p150/95 or CR4]) characteristic of LAD-1 due to mutations in the gene encoding CD18 (see Table 32.2). The actual level of β_2 integrin expression correlates with disease severity in that patients with less than 1% expression have very severe disease, whereas those with 1% to 30% of normal expression have a milder course correlating with the actual expression level.[11] LAD-2, a very rare condition, is associated with a defect in glycosylation type IIc (defect in the GDP fucose transporter). The evaluation of LAD-2 focuses on CD15 (sialyl-Lewis-X) expression, which is absent on neutrophils from LAD-2 patients.

The functional neutrophil defect found in CGD results in recurrent and chronic infections with bacteria and fungi that typically involve the skin, lung, liver, and bone. The five most

prominent microorganisms seen in CGD patients are *Staphylococcus aureus*, *Serratia marcescens, Burkholderia* species, *Nocardia* species, and *Aspergillus* species. The metabolic abnormality associated with serious infectious risk in these patients affects the neutrophil oxidative burst pathway due to defects in the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase multiprotein enzymatic pathway. In addition, these patients typically have hyperinflammation involving the genitourinary (GU) tract and inflammatory bowel disease that is similar to Crohn disease. The most common form of CGD is X-linked recessive, but there are also four autosomal recessive forms. Screening for CGD can be accomplished using the dihydrorhodamine 123 (DHR) flow cytometry assay or the nitroblue tetrazolium (NBT) test, both of which are abnormal in patients with CGD (see Table 32.2).[29] The DHR test is a quantitative assay, meaning that the level of fluorescence is a measure of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity. Accordingly, the level of response in the DHR assay has been linked to prognosis and survival in CGD patients.[30] Furthermore, the DHR assay can usually distinguish X-linked CGD female carriers by demonstrating the presence of two distinct populations of neutrophils, normal and abnormal. A recent report established that the proportion of mutant neutrophils in female carriers can be linked to infectious risk with carriers demonstrating less than 20% normal neutrophils; this demonstrates an increased risk of infections involving microorganisms similar to those affecting CGD patients.[31]

Finally, evaluation of neutrophil-directed movement (chemotaxis) can be performed in vivo using the Rebuck skin window technique as well as in vitro with a Boyden chamber or a soft agar system. Abnormalities of chemotaxis have been observed secondary to certain pharmacologic agents as well as in LAD, Chédiak-Higashi syndrome, Pelger-Huet anomaly, juvenile periodontitis, and more recently described diseases such as DOCK2 deficiency. However, chemotaxis tests are difficult to perform and standardize with availability limited to very few laboratories.

EVALUATING SUSPECTED COMPLEMENT DISORDERS

Common phenotypes in complement deficiency are susceptibility to encapsulated bacteria (C1, C4, C2, C3 deficiencies) and neisserial susceptibility (C5, C6, C7, C8, C9 [membrane attack complex] deficiencies) (see Table 32.1).

The complement system involves three activation pathways: the classical pathway (CP), the alternative pathway (AP), and the lectin pathway (LP), all of which converge at C3 and activate a common final pathway (Chapter 40). The three complement activation pathways (the CP, AP, and LP) can be individually evaluated by CH50, AP50 (also known as AH50 or APH50), and the MBL test, respectively (see Table 32.2).[32] The CH50 test assays total complement activity via the CP and is the best single screen for complement abnormalities in that absence or decreased activity in the CH50 implies that at least one of the necessary components is missing or low. The analogous assay for AP activity, the AP50, is not as widely available as the CH50, but it is useful as a screen for complement deficiency, especially when used in conjunction with the CH50. If both CH50 and AP50 are used to screen for complement deficiency, the number of additional tests required to pinpoint the defect can be minimized. Because both assays include the same 6 terminal components (C3, C5, C6, C7, C8, and C9), results will be low or absent for both tests if one or more of these common components is missing. If a unique CP component (C1q, r, s; C4; C2) is missing, the CH50 will be low or absent, but the AP50 will be normal, whereas if a unique AP component is low or missing, the reverse will be true. Functional tests of individual components of the CP and AP are available only from a very limited number of laboratories.

CONCLUSIONS

The expanding identification of PIDs with specific clinical features makes familiarity with the clinical presentation of these disorders of increasing importance. The starting point for an evaluation of a patient for a potential PID is a detailed/directed medical and family history followed by a careful physical examination. These steps, when performed appropriately, should provide sufficient information to proceed with a focused immunologic laboratory evaluation. The appropriate and directed use of immune function testing provides not only critical diagnostic information but also directs decisions regarding the most appropriate therapy with the objective of limiting disease-associated morbidity and mortality. Genetic testing has assumed a greater role in the complete evaluation of individual patients that may also contribute to the decision regarding therapeutic options.

KEY CONCEPTS

Secondary Immunodeficiencies

Immunodeficiency is often secondary or transient, caused by nonimmune factors, including:

- Previous use of high-dose steroids, or other immunosuppressive medications
- Previous use of monoclonal antibodies (mAbs), such as rituximab (anti-CD20)
- Immunoglobulin losses via the gastrointestinal or urinary tract
- Severe illness requiring critical care
- Malnutrition
- Human immunodeficiency virus infection

Primary Antibody Deficiencies

Tracy Hwangpo and Harry W. Schroeder Jr.

Primary antibody deficiency diseases are characterized by an inability to produce sufficient quantities of protective antibodies to protect the host from hazardous antigens.[1] This may be evident from birth or manifest at a later age. In some cases, the deficiency may either resolve or worsen with time.[2] Many of these diseases are caused by mutations that alter the function of genes that regulate B-cell development or homeostasis. Others reflect mutations in immunoglobulin genes themselves. A genetic predisposition marks some of the most common conditions, although the underlying defect may remain unclear. The typical patient is referred for evaluation due to recurrent upper or lower respiratory infections and reduced serum concentrations of one or more classes of immunoglobulin (IgM, IgG, or IgA). Patients with recurrent infections may also present with normal serum immunoglobulin levels but demonstrate an inability to mount a protective response against one or more specific pathogens. Conversely, some virtually agammaglobulinemic patients can be remarkably asymptomatic. Table 33.1 provides a classification of primary antibody deficiency diseases.

Primary immune deficiency disorders are the consequence of specific defects in B-cell development (Fig. 33.1). B-cell production begins in fetal liver and shifts to bone marrow later in fetal life (Chapter 7). As B cells mature, they leave the liver and the bone marrow and migrate via the blood into secondary lymphoid organs (e.g., spleen, lymph nodes, and other peripheral and mucosal tissues). Contact with a polymeric cognate antigen (Chapter 6), such as a polysaccharide, can promote B-cell activation and differentiation into an antibody-producing plasma cell. Responses to protein antigens (e.g., toxins and viral proteins) require T-cell help. In the germinal centers, B cells can replace an upstream heavy (H) chain constant domain with a downstream one, for example, μ to γ1, altering effector function (Chapter 8). They can also introduce a large number of somatic mutations into the variable (V) domains, generating populations of B cells with increased diversity from which those with optimal tailoring of antibody to the antigen are expanded, a process termed *affinity maturation*.

CLINICAL MANIFESTATIONS

Antibody-deficient patients commonly present with recurrent sinusitis, bronchitis, and pneumonia. Patients may also manifest cellulitis, boils, gastrointestinal discomfort, myalgias, arthralgias, fatigue, and depression. Infections typically involve encapsulated bacteria (e.g., *Streptococcus pneumoniae* and *Haemophilus influenzae*). Protection against these bacteria requires production of anti-polysaccharide antibodies, a process that does not require T-cell help. Because similar bacterial infections occur among patients deficient in neutrophil function or in complement, all three of these host defense mechanisms should be evaluated in patients who present with repeated bacterial infections.

CLINICAL PEARLS

Clinical Manifestations of Antibody Deficiency

- Recurrent bacterial infections
  - Early in untreated disease, infections are primarily due to encapsulated pyogenic bacteria (e.g., *Streptococcus pneumoniae* and *Haemophilus influenzae* type b).
  - Later in untreated disease, damage to mucosal surfaces engenders susceptibility to a wider array of pathogens (e.g., staphylococci, nontypeable *H. influenzae*, and gram-negative rods).
- Recurrent viral infections
  - Typically, viral infections clear normally, but protective immunity against re-infection fails (e.g., recurrent shingles).
  - Occasionally, patients may continue to excrete virus for prolonged periods after resolution of clinical symptoms.
- Increased prevalence of other immunologic disorders
  - Paradoxical increased risk of antibody-mediated autoimmune disorders (e.g., idiopathic thrombocytopenia, autoimmune thyroiditis, systemic lupus erythematosus, pernicious anemia, and celiac disease).
  - Lymphoid hypertrophy.
  - Increased risk of allergic disorders (especially in selective IgA deficiency).

The clinical course of uncomplicated primary infections with viruses such as Varicella zoster or mumps does not differ significantly from that of the normal host. However, antibody deficient patients have difficulty generating long-lasting immunity; thus, chickenpox may repeatedly recur as shingles. The general rule is that T cells typically control established viral infections, whereas antibodies limit initial viral dissemination and cell entry, thereby preventing re-infection. As with all rules, there are exceptions. Hypogammaglobulinemic patients can have difficulty clearing hepatitis B virus from the circulation, poliovirus from the gut, and enterovirus from the brain, leading to progressive and sometimes fatal outcomes.

Because sinopulmonary infections are also common in normal infants and children, in allergic individuals, in smokers, and in patients with other pulmonary diseases (e.g., cystic fibrosis), the threshold for an extensive evaluation for immunodeficiency can be a matter of clinical judgment. However, two or more episodes of bacterial pneumonia within a 5-year period, unexplained bronchiectasis, *H. influenzae* meningitis in an older child or adult, chronic otitis media in an adult, recurrent intestinal infections and diarrhea due to *Giardia lamblia*, or a family history of immunodeficiency all warrant evaluation by an immunologist.

TABLE 33.1 Primary Antibody Deficiencies

Disorder	Gene or Locus	Chromosome
IgAD1: IgA deficiency/common variable immunodeficiency	MHC, KIR	6p21.3, 19p13.3
CVID1: ICOS deficiency (AR)	ICOS	2q33.2
CVID2/IgAD2: TACI deficiency (AD/AR)	TNFRSF13B	17p11.2
CVID3: CD19 deficiency (AR)	CD19	16p11.2
CVID4: BAFF-R (AR)	TNFRSF13C	22q13.2
CVID5: CD20 deficiency (AR)	CD20	11q12.2
CVID6: CD81 deficiency (AR)	CD81	11p15.5
CVID7: CD21 (AR)	CD21	1q32.2

AGM6: Ig-associated beta (Igβ) deficiency (AR)	CD79B	17q23.2
AGM7: PI3K regulatory subunit (AR)	PIK3R1	5q13.1
AGM8: E47 transcription factor deficiency (AD)	TCF3	19p13.3
Myelodysplasia with hypogammaglobulinemia		Monosomy 7
Thymoma with immunodeficiency (Good syndrome)		
Selective κ light chain deficiency (AR)	IGKC	2p11.12
Selective IgG subclass deficiencies		
Specific antibody deficiency with normal serum immunoglobulin levels		

AD, Autosomal dominant; *AR*, autosomal recessive; *XR*, X-linked recessive.

KEY CONCEPTS

Hypogammaglobulinemia and Antibody Deficiency

- The genetic mutations that underlie most primary antibody deficiencies tend to affect molecular pathways involved in the regulation of lymphocyte development and homeostasis.
- Clinically significant antibody deficiency is not synonymous with hypogammaglobulinemia.
  - Serum immunoglobulin concentrations vary widely with age.
  - Serum immunoglobulin levels vary with exposure to drugs (e.g., steroids and biologics), infectious agents, and other environmental stressors.
- A complete absence of IgG subclasses resulting from homozygous deletions of heavy chain genes has been observed in healthy individuals.
- Absence of a specific Vκ gene segment has been associated with an increased risk of *Haemophilus influenzae* infection in spite of normal serum Ig levels.

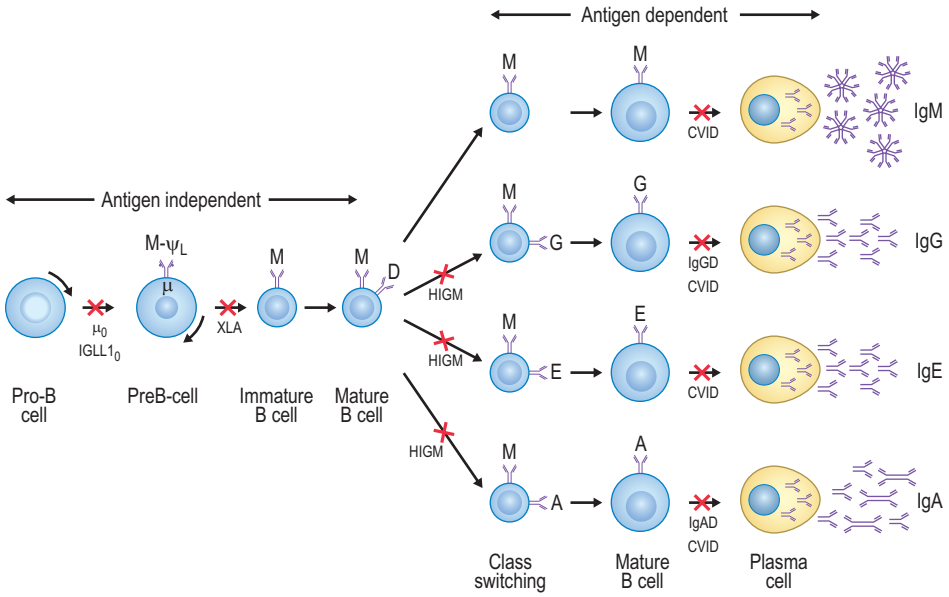

FIG. 33.1 Defects in B-Cell Development Can Lead to Humoral Immune Deficiency. Examples of autosomal agammaglobulinemias (AGM) include the homozygous absence of an immunoglobulin μ H chain (μ_0) or of the λ5 component ($IGLL1_0$) of the surrogate light chain (ψ_L). In the case of μ_0 mutations, a preB-cell receptor ($M\text{-}\psi_L$) cannot be generated, resulting in a block at the proB- to preB-cell stage (illustrated by a *red X*). Signaling through the preB-cell receptor is needed to advance the development process. Patients with X-linked agammaglobulinemia *(XLA)* have loss of function mutations in the kinase Bruton tyrosine kinase (BTK), which impairs signaling through the preB-cell receptor and the B-cell receptor (BCR), resulting in a block in B-cell development between the preB- and immature B-cell stages. Hyper-IgM syndromes (HIGM) result from either a failure to engage in proper cognate interactions with T cells or disruptions in the genes that permit class switch recombination. These failures inhibit class switching to immunoglobulins *IgA, IgG,* and *IgE*. Selective IgG deficiency (*IgGD* or hypogammaglobulinemia), selective IgA deficiency (*IgAD*), and common variable immune deficiency *(CVID)* reflect a selective or generalized impairment in the ability to progress from the mature B-cell stage to the plasma-cell stage.

The purest forms of antibody deficiency result from mutations that prevent the expression or function of the preB-cell receptor for antigen (Chapter 4). Only the B-cell lineage is affected with a loss-of-function mutation of μ heavy chain or components of the surrogate light chain [VpreB, γ14.1 (γ5)]. However, most of the diseases associated with primary antibody deficiency involve more than one cell lineage. For example, X-linked agammaglobulinemia (XLA) is the product of loss-of-function mutations in Bruton tyrosine kinase (*BTK*). Patients with X-linked hyper-IgM syndrome (HIGM1) may exhibit T-cell as well as B-cell dysfunction, placing them at risk for infection with *Pneumocystis jiroveci*. Immune deficiency also appears to place patients at risk for autoimmunity, which is increased among patients with IgA deficiency (IgAD), common variable immunodeficiency (CVID), and hyper-IgM syndrome.

Clinical manifestations of the primary immunodeficiency may also be heavily influenced by the patient's past medical history. A delayed diagnosis and failure to aggressively treat infections can lead to permanent damage to the respiratory or gastrointestinal mucosa, creating susceptibility to nontypeable *H. influenzae*, staphylococci, *Pseudomonas*, and enteric bacteria.

PRINCIPLES OF DIAGNOSIS AND TREATMENT

Diagnostic Tests and Their Interpretation

Testing for immune deficiency should be done for patients (i) with a history of repeated infections that exceeds expectations for normal individuals, (ii) who experience an infection with an opportunistic or low-virulence pathogen, (iii) who are affected with a disorder frequently associated with immunodeficiency, or (iv) who have a family history of primary immunodeficiency. Table 33.2 illustrates four levels of testing complexity.

Level I testing is both revealing and cost-effective. It includes measuring serum immunoglobulins (IgM, IgG, and IgA), complement (50% hemolytic power of serum [CH_{50}] and complement components C3, C4, and mannose-binding lectin protein [MBL]), a complete blood count with differential (CBC/diff), and an erythrocyte sedimentation rate (ESR). Lymphopenia is seen most often in disorders that affect the production or function of T cells (Chapter 34) but can also occur in patients with CVID. Congenital absence of an individual complement component will result in total absence of measurable complement-mediated hemolysis (Chapter 40). MBL deficiency increases susceptibility to respiratory infections.[3] The ESR is elevated in many, although not all, individuals with inflammatory disorders and thus useful in patients with a questionable or unclear history of recurrent or chronic infection.

KEY CONCEPTS

Tests for Immune Function Should Be Performed

- When the patient's history suggests a frequency or severity of infection that exceeds expectations for normal individuals.
- When the organism responsible for infection is of low virulence or is considered to be an opportunistic pathogen (e.g., *Pneumocystis jiroveci*, BCG).
- When there is a diagnosis of a genetic immune deficiency in the patient's family or a multisystem syndrome that can include immune deficiency (e.g., DiGeorge syndrome).

TABLE 33.2 Laboratory Diagnosis of Primary Antibody Deficiency

Level	Test	Application (s)
I	CBC with differential Complement (CH_{50}, C3, C4, mannose-binding lectin protein) ESR Quantitative serum IgM, IgG, and IgA levels	Primary screening tests
Ia	Urinalysis, 24-h urine for protein Stool for alpha-1-antitrypsin Serum albumin	Symptoms suggest protein loss through kidneys or GI tract
II	B-cell functional evaluation Quantitative IgG subclasses, IgE Natural or commonly acquired antibodies (isohemagglutinins, rubella, rubeola, tetanus) Response to immunization T-cell dependent antigens (tetanus) T-cell independent antigens (unconjugated pneumococcal vaccine, unconjugated *Haemophilus influenzae* B vaccine)	Level I normal but history suggests antibody deficiency Better definition of a Level I defect
III	Quantification of blood T- and B-cell subpopulations by immunofluorescence assays using monoclonal antibody markers T cells: CD3, CD4, CD8 B cells: CD19, CD20, CD21, Ig (μ, δ, κ, λ),	Panhypogammaglobulinemia or severely low IgM and IgA
IV	Disease-specific analysis Gene expression Gene sequencing	Gene-specific diagnosis Genetic counseling

CBC, Complete blood count; *ESR*, erythrocyte sedimentation rate; *GI*, gastrointestinal; *Ig*, immunoglobulin.

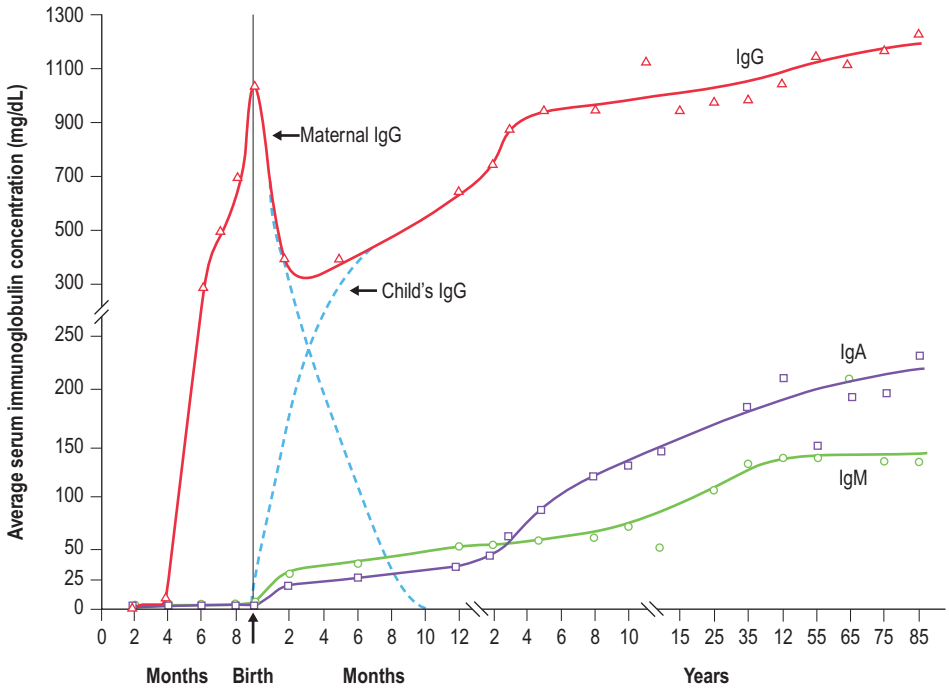

FIG. 33.2 Age-Related Changes in the Serum Concentration of Immunoglobulins. Shown are average serum immunoglobulin (*IgG, IgA*, and *IgM*) concentrations of the major isotypes as a function of age. (From De Greef GE, van Tol MJ, Van Den Berg JW, et al. Serum immunoglobulin class and IgG subclass levels and the occurrence of homogeneous immunoglobulins during the course of ageing in humans. *Mech Ageing Dev*. 1992;66[1]:29–44. Stiehm ER, Fudenberg HH. Serum levels of immune globulins in health and disease: a survey. *Pediatrics*. 1966;37:715–727.)

Interpretation of the significance of the quantitative immunoglobulin determinations requires appreciation of age-related changes in immunoglobulin concentrations (Fig. 33.2).[4,5] At the end of the second trimester of pregnancy, active transport of IgG across the placental barrier begins. By the time of birth at term, the infant's serum IgG concentration is typically 20% to 25% higher than that of the mother. Catabolism of maternal IgG coupled with the slow development of endogenous antibody production leads to a physiologic nadir of serum IgG at 4 to 6 months of age. This loss of maternally derived protection is often associated with the first appearance of otitis media or bronchitis. Thus, the onset of sinopulmonary infections within

the first 3 months of age should also raise the index of suspicion for immunodeficiency in the mother. After age 6 months, maternally derived IgG has largely been lost and IgG antibodies specific for diphtheria or tetanus become useful measures of B-cell function.

CLINICAL PEARLS

Interpreting Quantitative Immunoglobulins

- Normal ranges of serum immunoglobulin levels vary with age; hence evaluation should take the age of the patient into account.
  - As the mother's transplacental contribution of IgG is catabolized, total serum IgG concentrations reach a nadir at 4 to 6 months of age.
  - IgG2 and IgG4 subclass levels rise more slowly than IgG1 and IgG3; hence reference to adult controls can lead to the false diagnosis of IgG subclass deficiency in young children.
  - Serum IgA concentrations typically do not achieve adult values until puberty. They are often the first to decline in many primary immunodeficiencies.

KEY CONCEPTS

Functional Tests of Specific Antibody Production

- IgM T-independent responses may be assessed by measurement of serum isohemagglutinins (anti-A and anti-B titers) in patients who are not blood type AB.
- IgG T-independent responses may be assessed by measurement of antibodies produced in response to immunization with unconjugated purified pneumococcal polysaccharide vaccine.
- IgG T-dependent recall responses may be assessed by measurement of a fourfold or greater rise in titer of antibodies to diphtheria or tetanus toxoid alter booster immunization.

The common laboratory practice of defining the lower range of normal for serum immunoglobulin levels as two standard deviations below the age-adjusted mean carries with it the risk of falsely labeling otherwise normal individuals as immunodeficient. Immunoglobulin levels vary widely with environmental exposure, and normal biologic variation is much broader than that defined by the mean of the population. Patients with a combined deficiency of IgA and an IgG subclass may benefit from the aggressive use of antibiotics and/or immunoglobulin replacement therapy (IGRT); thus, quantitative measurements of all four IgG subclasses (IgG1, IgG2, IgG3, and IgG4) can be useful in fully defining the extent of humoral immune deficiency.

Among patients with borderline serum IgG levels, tests to evaluate the host's ability to produce functional specific antibody should be performed prior to making a decision to institute a more aggressive therapy, especially among patients receiving medications such as corticosteroids, which can lower total serum IgG while preserving function. The most commonly employed tests include measurement of isohemagglutinins (naturally occurring IgM antibodies to the polysaccharide antigens that define the ABO blood type system on red blood cells) and post-immunization responses to polysaccharide antigens (e.g., Pneumovax 23 or unconjugated *H. influenzae* B vaccine) and protein antigens (e.g., tetanus or diphtheria toxoids). IgM is made by the newborn, and most infants can generate isohemagglutinins, making determination of anti-A and anti-B titers a useful measurement of B-cell function even in infants. In older children and adults, isohemagglutinin titers of less than 1:8 are considered significant.[6]

Serum for specific antibody titers should be obtained before and 4 to 6 weeks after immunization. Optimally, the paired sera should be assayed simultaneously to avoid confusion that may result from single-tube dilution differences at the time the assay is performed. As a general rule, a high baseline titer or a fourfold or greater rise in a specific titer in individuals with a low baseline titer confirms that a specific humoral response is intact. The development of conjugated polysaccharide vaccines (e.g., Prevnar 13) complicates analysis for those who have received such a vaccine, although information can still be gleaned from study of responses to polysaccharide antigens present only in multivalent unconjugated vaccines (e.g., Pneumovax 23).

Protein loss through the kidneys or gastrointestinal tract can result in the selective loss of IgG because of its relatively low molecular weight and slow turnover; with severe protein loss, serum albumin levels may also be low. Should symptoms warrant, 24-hour urine for protein or a stool sample for alpha-1-antitrypsin level can document protein loss.

An elevated Inge level may support a suspicion of allergy as an underlying explanation of sinopulmonary symptoms but can also reflect parasite infestation. Serum IgE concentrations are often elevated in patients with IgAD. Extreme elevations of IgE suggest the *hyper-IgE syndrome*.

Enumeration of B cells and of T cells should be performed for any individual who has severe panhypogammaglobulinemia. The most widely used method of demonstrating B cells relies on immunofluorescent labeling of surface CD19, which is restricted in expression to mature B cells (Chapter 7). Because an infant may have serum IgG of maternal origin for the first several months of life, the determination of the number of circulating B cells is the single most useful test in making the presumptive diagnosis of XLA, a disorder in which preB-cells in the bone marrow fail to develop to cells of mature phenotype. Absence of circulating B cells also characterizes the *immunodeficiency associated with thymoma* in adults, whereas adults with *chronic lymphocytic leukemia* (Chapter 77) may have hypogammaglobulinemia with an overabundance of circulating $CD5^+$ B cells.

HIGM1 represents the product of a loss-of-function mutation of the *CD154* (*CD40L*) gene. CD154, a surface antigen found on activated T cells, binds CD40 on B cells to facilitate class switching, survival, and proliferation (Chapter 7). A fluorescent-labeled CD40 fusion protein can be used to evaluate the expression of functional CD154 on T cells by flow cytometry. Confirmation of the diagnosis, carrier detection, and prenatal diagnosis often depend on molecular or sequence analysis of the gene.

Replacement Therapy With Human Immunoglobulin

A number of commercial preparations of human immunoglobulin are US Food and Drug Administration (FDA) approved and available in the United States (Chapter 82). No commercial preparations in this country are available to supplement IgM or IgA exclusively, but some of the preparations contain minute amounts of these isotypes. Since the IgG given in IGRT comes from donors who have produced immunoglobulin in response to the antigens to which they have been exposed, the distribution of antigen specificities can vary between lots, and thus there is no generic form of commercial IgG. Clinically relevant differences between the preparations relate to the route

of administration, which can be by intravenous or subcutaneous infusion; to the method of stabilization and storage; to the donor pool; and to quantities of contaminating IgA. All commercial human immunoglobulin preparations are effective in treating patients with immunodeficiency disorders, although some are better tolerated than others. Depending on the country of origin, some preparations may provide better protection against local endemic organisms. Low IgA content is a concern for those rare individuals with immunodeficiency and absent IgA who manufacture IgG or IgE antibodies directed against IgA and have a history of anaphylactic reactions upon infusion of IgA-containing blood products.[7]

IGRT is not indicated for patients whose immune deficiency is limited to the selective absence of IgA, in part because of the risk of anaphylaxis upon receipt of IgA-containing products, even though such reactions are rare.[7] However, IGRT has been found to be beneficial in patients with a combined deficit of both IgA and an IgG subclass and who exhibit impaired antibody responses to carbohydrate antigens.[8,9]

The goal of immunoglobulin replacement is not to achieve a target IgG level in the serum, but to provide sufficient concentrations of functional antibodies to prevent disease. Specific approaches to and protocols for IGRT are described in detail in Chapter 82. **The only indication for immunoglobulin replacement in a patient with immunodeficiency is severe impairment of the ability to produce functional antibody**. Such impairment exists in primary immunodeficiency diseases associated with low levels of all five isotypes of immunoglobulin, such as XLA, CVID, HIGM, and *severe combined immunodeficiency* (SCID) (Chapter 34). Patients with a documented inability to produce specific antibodies after immunization with a history of significant morbidity from infections are also candidates for intravenous immunoglobulin (IVIG) therapy even though they may present with normal or near-normal levels of IgG.[10] This includes certain cases of IgG subclass deficiency such as those associated with compound IgA, IgG2, and IgG4 deficiency; boys with Wiskott-Aldrich syndrome; and patients with ataxia-telangiectasia. Since most patients with transient hypogammaglobulinemia of infancy (THI) can produce normal amounts of specific antibodies after immunization despite having a low total serum IgG, they usually are not candidates for immunoglobulin replacement. However, patients with a history of significant infections may benefit.

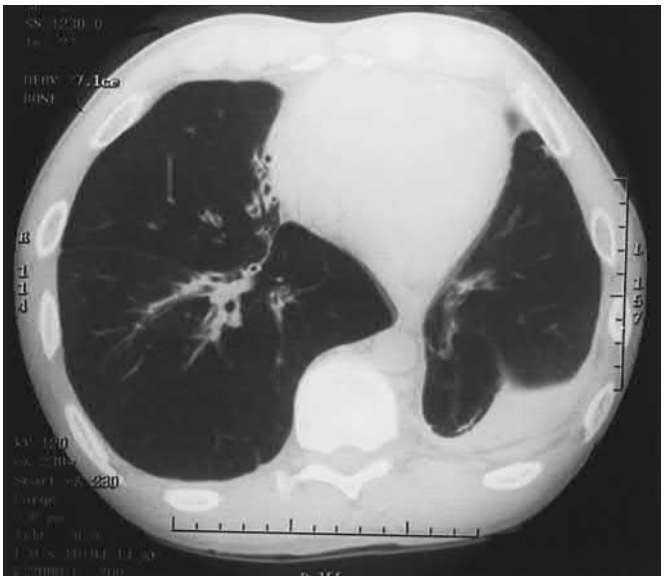

FIG. 33.3 A CT Scan, With Contrast, Demonstrates Bronchiectasis, Bronchitis, and Emphysema in the Lungs of a 36-Year-Old Man With X-linked Agammaglobulinemia. He was referred to immunology and started on immunoglobulin replacement therapy at age 16. Due to a left lower lobe lobectomy, the mediastinum has shifted to the left. As a result of bronchiectatic scarring, the diameter of the bronchi in the right lung are greater than the diameter of the corresponding blood vessels, and the bronchi remain dilated in the periphery. Bronchial plugs can be seen filling some of the bronchi on the right. Finally, due to emphysema, the right upper lobe demonstrates greater radiolucency. In addition to suffering from XLA, this patient has a 30 pack-year history of smoking, which has exacerbated his clinical condition.

X-LINKED AGAMMAGLOBULINEMIA

Diagnosis

XLA (Bruton agammaglobulinemia) is the prototypic humoral immunodeficiency.[11] Due to the transplacental transfer of maternal immunoglobulin, onset of recurrent pyogenic infections generally begins after age 5 to 6 months. Loss-of-function mutations in the *BTK* gene lead to a block in B-cell maturation, near total absence of B cells in the periphery, and panhypogammaglobulinemia (see Fig. 33.1). Testing of infants known or suspected to have XLA should begin with examination of the number of B cells in the blood. Deficient expression of BTK protein in monocytes can be detected by flow cytometry. Analysis of the *BTK* gene at the nucleotide level remains the definitive diagnostic procedure. As with most X-linked lethal diseases, approximately one-third of sporadic cases are due to de novo mutations, so diagnosis may require individual mutation analysis. There can be significant variation in the manifestations of the disease in any given family member; thus a paucity of symptoms should not prevent diagnostic evaluation even in adults.[12] Some patients with "mild" mutations of *BTK* may present with infections late in life.

Clinical Manifestations

Easy access to antibiotics and good hygiene may delay suspicion of the diagnosis well into mid-childhood or beyond.[12] Recurrent upper and lower respiratory tract infections are common. Untreated, these infections may lead to bronchiectasis (Fig. 33.3), pulmonary failure, and death at an early age. The infections are typically due to pyogenic encapsulated bacteria. Diarrhea due to *G. lamblia* is also common, although less so than in CVID. Systemic infections include bacterial sepsis, meningitis, osteomyelitis, and septic arthritis. Mycoplasma and chlamydia infections of the urogenital tract may lead to epididymitis, prostatitis, and urethral strictures. Skin infections include cellulitis, boils, and impetigo.[13]

Although patients with XLA can resolve most viral infections, they are unusually sensitive to infections with enteroviruses. Patients with XLA can develop paralytic poliomyelitis after vaccination with live virus. Echovirus and Coxsackie virus infections may involve multiple organs with the patients going on to develop chronic meningoencephalitis, dermatomyositis, and/or hepatitis.[13] Untreated patients often complain of arthritis affecting the large joints. Enterovirus and mycoplasma have been identified in affected joints. The arthritis typically resolves with IGRT.

Infections with opportunistic organisms (e.g., tuberculosis, histoplasmosis, and *P. jiroveci*) and malignancies are rare, likely reflecting intact cell-mediated immunity.

Origin and Pathogenesis

BTK belongs to a subfamily of the Src cytoplasmic protein-tyrosine kinases. BTK is phosphorylated following activation of the B-cell receptor (BCR). It plays a critical role in the proliferation, development, differentiation, survival, and apoptosis of B-lineage cells. Individuals with XLA begin with normal numbers of early B-lineage progenitors in their bone marrow. In the bone marrow, B-cell progenitors express the expected markers of B-cell differentiation (e.g., terminal deoxynucleotidyl transferase [TdT], CD19, and CD10), but there is a relative deficiency of cytoplasmic μ^+ preB-cells and development beyond the preB stage is severely impaired. Those cells that make it through the gauntlet can produce antigen-specific antibodies. Although in low numbers, these surviving B cells can produce endogenous antigen-specific immunoglobulin, class switch, and even mediate allergic or autoantibody-mediated reactions.

An X-linked recessive form of agammaglobulinemia associated with growth hormone deficiency has been reported. Genetic analysis in one such patient identified a frameshift mutation creating a premature stop codon with the loss of carboxy terminal amino acids in BTK.[14]

Treatment and Prognosis

The primary goal of therapy for B-cell deficiency is to prevent damage to the lungs. Human IGRT should be started as soon as the diagnosis is made. Patients treated with sufficient quantities (0.4 to 0.6 g/kg every 3 to 4 weeks for IVIG or 100 to 150 mg/kg every week for subcutaneous gammaglobulin [SQIG]) suffer few lower respiratory tract infections. However, these patients remain at risk for viral infections, including enteroviral meningoencephalitis. Since mucosal immunoglobulin cannot be replaced, the patients also remain at risk for recurrent upper respiratory infections, which may require prophylactic antibiotic therapy. Immunoglobulin-treated patients may lead normal lives without concern about exposure to infectious agents in childcare settings or classrooms.[15] Immunizations designed to elicit protective antibodies are unnecessary because the monthly replacement therapy will provide passive protection. Since patients are unable to mount antibody responses and vaccines, especially live vaccines, carry some risk of untoward side effects, they are relatively contraindicated.

An XLA patient who develops symptoms of enteroviral central nervous system or neuromuscular infection should have appropriate cultures of the involved organ system. For agammaglobulinemic patients with chronic enteroviral infections, immunoglobulin therapy should be given at higher doses and maintained until symptoms cease and the virus can no longer be detected. Intrathecal immunoglobulin as well as compassionate use of new antienteroviral drugs have also been used.[16]

AUTOSOMAL AGAMMAGLOBULINEMIA

Origin and Pathogenesis

The PreB-Cell Receptor and Signal Transduction Axis

Loss-of-function mutations in any one of the genes that code for components of the pre-BCR and its associated signaling complex can inhibit preB-cell development, leading to an absence of mature B cells.[17] This phenotype is seen in patients with biallelic loss-of-function mutations of mu heavy chain region (μ_0, AGM1), λ-like surrogate light chain (IGLL1, AGM2), immunoglobulin-associated alpha (Igα, CD79A, AGM3) and beta (Igβ, CD79B, AGM6) chains, and the adaptor B-cell linker protein (BLNK, AGM4), a key component of the pre-BCR signaling pathway.

E47

The *TCF3* gene, also called *E2A*, encodes two basic helix-loop-helix (bHLH) transcription factors, E12 and E47, through alternative splicing. E12 and E47 are involved in regulation of immunoglobulin gene expression. A dominant negative mutation in the E47 DNA-binding region resulted an early block in B-cell development and agammaglobulinemia.

LRRC8

Truncation of leucine-rich repeat containing 8 (*LRRC8, AGM5*), a gene of unknown function expressed in progenitor B cells, led to an absence of B cells.

PIK3R1

A homozygous nonsense mutation in *P1K3R1*, which encodes the p85a subunit of phosphoinositide 3-kinase (PI3K), resulted in decreased pro-B cell numbers. One 19-year-old female presented with agammaglobulinemia, absent B cells, and inflammatory bowel disease.

Other Agammaglobulinemia Conditions

Two pediatric patients with monosomy 7 presented with myelodysplastic syndrome of refractory anemia, hypogammaglobinemia, and low B cells. They were treated with bone marrow transplant.

Older adult patients with thymoma may present with low B-cell numbers and hypogammaglobinemia (*i.e.*, Good syndrome). They often suffer invasive bacterial infections and require immunoglobulin replacement even after thymectomy.[18]

Diagnosis and Treatment

Diagnosis requires gene mutation analysis. Treatment follows the guidelines given for XLA.

HYPER-IMMUNOGLOBULIN SYNDROME

Diagnosis

Patients with the hyper-IgM syndrome exhibit markedly reduced serum concentrations of IgG, IgA, and IgE with normal to elevated levels of IgM and normal numbers of circulating B cells.[19] This phenotype reflects polyclonal expansion of IgM synthesis in response to infection as a result of a block in the ability of B lymphocytes to switch from IgM to other isotypes. HIGM patients suffer the same infections with encapsulated bacteria common to all patients with antibody deficiency. HIGM can present as an X-linked recessive, autosomal recessive, or autosomal dominant trait. The phenotype can also result from congenital rubella, medications (e.g., calcineurin inhibitors and phenytoin), and neoplasia.[20]

Hyper-Immunoglobulin Syndrome Type 1: CD40L (CD154) Deficiency

Class switch recombination (CSR) is a multistep process that requires exquisite coordination between the B cell and its cognate helper T cell (Chapter 7). The binding of constitutively expressed CD40 on the B cell to CD40L (CD154) expressed on activated T cells helps initiate CSR. HIGM1 reflects loss-of-function mutations in *CD154* (Xq26).

Hyper-Immunoglobulin Syndrome Type 2: Activation-Induced Cytidine Deaminase dysfunction

Activation-induced cytidine deaminase (AID, 12p13), a member of the cytidine deaminase family, is required for CSR and for somatic hypermutation of immunoglobulin V domains (Chapters 4 and 7). The hyper-IgM phenotype can reflect either biallelic *AID* loss-of-function mutations or a dominant negative mutation on only one *AID* allele.

Hyper-Immunoglobulin Syndrome Type 3: CD40 Deficiency

CD40 is the cognate receptor for CD40L and is located on chromosome 20q12-q13.2. HIGM3 patients with biallelic loss-of-function mutations of *CD40* present with a phenotype indistinguishable from HIGM1.

Hyper-Immunoglobulin Syndrome Type 4: As Yet Unknown Causes

Patients presenting with a HIGM-like phenotype but lacking demonstrable mutations in genes previously associated with HIGM have been grouped into a category termed HIGM4. CSR is defective in HIGM4 patients, but somatic hypermutation appears to occur without hindrance. A genetic cause has yet to be identified and spontaneous recovery has been reported.

Hyper-Immunoglobulin Syndrome Type 5: Uracil-DNA Glycosylase Deficiency

Activation-induced deaminase (AID) acts by deaminating cytidine in DNA, leaving uracil in its place. Uracil-DNA glycosylase (UNG, 12q23–24.1) can remove the uracil, permitting normal or error-prone repair. Patients with biallelic loss-of-function mutations of *UNG* can present with recurrent bacterial infections, hyperplasia, increased serum IgM levels, and low IgG and IgA.

NEMO and IKBA Mutations

The nuclear factor kappaB (NF-κB) essential modulator (NEMO) plays a key role in the NF-kB pathway and consequently in the CD40 signal transduction pathway. NEMO acts as a scaffold for two kinases important for NF-κB activation. *IKBKG* encodes NEMO and is located on the X-chromosome (Xq28). Hypomorphic mutations in *IKBKG* lead to an ectodermal dysplasia syndrome manifesting with conical teeth, absent eccrine sweat glands, and a paucity of hair follicles. NEMO patients demonstrate defective innate and cell-mediated immunity due to defective NF-kB activation, which is important in Toll-like receptor (TLR) signaling. Laboratory abnormalities include impaired NK cell function, impaired pneumococcal responses, hypogammaglobulinemia, antigen-specific T-cell proliferative abnormalities, and increased serum IgA levels. Although fewer than 20% of NEMO patients have a hyper-IgM phenotype, they are typically grouped with the hyper-IgM phenotype.

Autosomal dominant mutations of *IKBA/IκBα* have been reported in some patients with a HIGM phenotype. Mutations in these genes block NF-κB release and thus downstream CD40 signaling.[21]

INO80 and MHSH6

INO80 and MSH6 are components of the mismatch repair machinery involved in CSR-induced generation of double-strand DNA breaks. INO80 deficiency has been described in patients with elevated IgM and low IgG and IgA who suffer with severe bacterial infections. Mutator S homolog 6 (MSH6) deficiency has been associated with elevated IgM, impaired class switching, and reduced numbers of class-switched memory B cells. Patents with MSH6 deficiency have described a personal or family history of cancer.[20]

Clinical Manifestations

CD40-CD154 Axis (HIGM1, HIGM3, NEMO)

Patients with inherited disruptions in the CD40-CD154 axis have difficulty generating germinal centers in their lymph nodes and spleen. Recurrent upper and lower respiratory tract infections are common. Patients may also exhibit recurrent neutropenia with oral ulcers, perirectal abscesses, and opportunistic infections (e.g., *P. jiroveci, Toxoplasma gondii*, or *Cryptosporidium* cholangitis). One in five patients demonstrate autoimmunity.

Without prophylaxis, one third of patients develop *P. jiroveci* pneumonia, which can be the presenting problem in affected infants. Patients are also at risk for cytomegalovirus (CMV), adenovirus, *Cryptococcus neoformans*, or mycobacterial infections. This indicates both cell-mediated and humoral immune deficiency, placing these patients within the spectrum of a combined immunodeficiency.

Chronic diarrhea occurs in more than half of the patients. Organisms include *Cryptosporidium, G. lamblia, Salmonella*, and *Entamoeba histolytica*. One quarter may require total parenteral nutrition due to diarrhea or to perirectal abscesses. Oral ulcers, gingivitis, and perirectal ulcers are associated with neutropenia, which may occur chronically or intermittently in up to two-thirds of the patients. One-fifth of patients develop sclerosing cholangitis that can lead to hepatic failure. Cryptosporidiosis is present in half of these patients.

Approximately one quarter of NEMO patients have autoimmunity or autoinflammation. An intestinal inflammatory disorder may be the presenting problem with chronic diarrhea and abdominal pain, with a few having steroid dependence.

Although originally distinguished by the high level of serum IgM, IgM levels are often normal in affected individuals. IgG is low. IgA and IgE are usually low, but they can be normal or even elevated. B- and T-cell counts are within the normal range in more than 90% of the patients and depressed in the rest.

Lymphoid hyperplasia is a common finding in patients with active infections. Individual nodes may become extremely large, and splenomegaly can develop. Hilar adenopathy causes a diagnostic dilemma, as the risk of lymphoma is increased. Although the lymphoid tissue is usually histologically abnormal, reactive processes are far more common than malignancy. Plasma cells may be abundant or sparse. Primary follicles are poorly developed. The most characteristic abnormality is the absence of germinal centers.

AID-UNG Axis (HIGM2 and HIGM5)

Infected AID-UNG deficient patients may present with giant germinal centers filled with highly proliferating B cells, presumably due to intense antigen stimulation. Approximately one-fourth of HIGM2 patients, but not HIGM5, present with evidence of autoimmunity (e.g., hemolytic anemia, thrombocytopenia, and autoimmune hepatitis). Autoantibodies are IgM.

Origin and Pathogenesis

CD40-CD154 Axis (HIGM1, HIGM3, and NEMO)

CD154, a member of the tumor necrosis factor (TNF) family, is a type II transmembrane protein. It is predominantly expressed on mature, activated CD4 T cells. Expression peaks at 6 to 8 hours post-activation and falls to resting levels by 24 to 48 hours. CD154 is also expressed on CD4 thymocytes, activated

CD8 T cells, NK cells, monocytes, basophils, mast cells, activated eosinophils, and activated platelets. Strongly stimulated neonatal T cells can also express CD154. CD40, a member of the TNF receptor superfamily, is constitutively expressed by pro-B, pre-B, and mature B cells, as well as on interdigitating cells, follicular dendritic cells, thymic epithelial cells, monocytes, platelets, and some carcinomas.

Engagement of B-cell CD40 with CD154 on an activated T cell that also expresses Fas ligand (FasL or CD95L) leads to the upregulation of Fas (CD95) on the B cell. NEMO is a part of the signaling pathway. If the B cell has concomitantly bound its cognate antigen and engaged the BCR-signaling pathway, it becomes resistant to Fas-mediated apoptosis and expresses CD80/CD86 on the cell surface. The activated B cell can then engage CD28 on the T-cell surface and trigger the T cell to secrete its cytokines. If the B cell fails to engage its BCR, the Fas pathway predominates and the B cell is eliminated. With proper activation of the CD40-CD154 pathway, exposure to interleukin-2 (IL-2) and IL-10 induces production of IgM, IgG1, and IgA, and exposure to IL-4 induces production of IgG4 and IgE. This change in immunoglobulin isotype reflects both induction of switching and the enhanced survival and proliferation of the B cell. Absent CD154, B cells can express IgM, but have difficulty switching and are likely to undergo apoptosis rather than proliferation in response to antigen.

Interactions between $CD154^+$ T cells and $CD40^+$ macrophages lead to enhanced production of IL-12, which then stimulates T cells to release interferon-γ. Activation of this pathway appears necessary for the defense against *P. jiroveci* and other opportunistic organisms.

Treatment and Prognosis

IGRT has improved the quality of life in HIGM. Adequate immunoglobulin replacement promotes reduction of serum IgM levels, prevention of infections with encapsulated bacteria, resumption of growth, and the gradual resolution of splenomegaly and lymphoid hyperplasia. Autoimmune and lymphoproliferative complications may respond to anti-CD20 therapy (e.g., rituximab).

Unfortunately, despite the improvement granted by IGRT, prognosis in patients with CD40-CD154 axis defects remains guarded. Deaths at a young age remain common, primarily the result of opportunistic infections, including pneumocystis pneumonia, cholangitis, CMV, mycobacterial infections, and cirrhosis secondary to hepatitis. Prophylaxis with trimethoprim-sulfamethoxazole can significantly reduce the risk of pneumocystis pneumonia and are indicated in those with CD40L and CD40 deficiency. Regular monitoring of gastrointestinal manifestations and management of neutropenia is mandatory. Neutropenia should be treated with a trial of GM-CSF since some have responded to this therapy. Bone marrow transplantation is a viable option for patients who fail to respond to supportive therapy.

SELECTIVE IMMUNOGLOBULIN A DEFICIENCY

Selective IgAD, selective IgG subclass deficiencies, CVID, and a syndrome of recurrent sinopulmonary infections (RESPIs) with normal serum immunoglobulin levels appear to share an overlapping set of gene defects.[22] Clinically, these disorders are marked by an increased susceptibility to upper and lower respiratory infections with encapsulated bacteria. IgAD and CVID feature similar B-cell differentiation arrests but differ in the extent of immunoglobulin deficits. The correlation between serum immunoglobulin levels and severity of infection is not absolute.[23]

Diagnosis

Approximately 1 in 600 individuals of European ancestry are unable to produce detectable quantities of IgA1 and IgA2, making selective IgAD the most frequently recognized primary immunodeficiency in the Americas, Australia, and Europe. The diagnosis is dependent on the sensitivity of the laboratory measurement. Nephelometry, for example, becomes unreliable for serum IgA levels of less than 7 mg/dL.

Uncomplicated patients with IgAD have normal serum levels of IgM, normal or elevated levels of IgG, and demonstrate normal cell-mediated immunity. A minority of patients may demonstrate additional evidence of immune dysfunction, with inability to generate appropriate IgG2 anti-carbohydrate antibodies, frank IgG subclass deficiencies, or evidence of impairment of T-cell function. Individuals with IgA serum levels that fall more than two standard deviations below the mean serum level for their age are considered to have partial IgAD. These individuals are usually healthy but can suffer from recurrent infections.

Clinical Manifestations

The likelihood that an IgA-deficient individual who was identified serendipitously will require medical attention is difficult to assess because most studies in the literature reflect patients who were ascertained due to clinical symptoms. Among IgAD patients referred to immunology clinics, more than 85% present with recurrent infections, typically with encapsulated bacteria. Among affected children, symptoms may begin in the first year of life, although the physiologic lag in serum IgA may delay the diagnosis until after the age of 2. In some patients, respiratory infections disappear with maturity. In others, infections may persist throughout adult life. Rarely, IgAD patients may experience recurrent bronchitis, pneumonia, and even bronchiectasis. These more severely afflicted patients often exhibit concurrent IgG2 and IgG4 subclass deficiencies. Some symptomatic patients have elevated IgE levels and manifest allergic or asthmatic components to respiratory dysfunction. The rise in IgE has been explained as compensatory to the absence of IgA. This appears to be a double-edged sword, because up to 20% of patients complain of allergic rhinitis, conjunctivitis, urticaria, and atopic eczema. Allergic reactions may be enhanced due to the lack of IgA-blocking antibodies in the serum, and unusually severe asthma has also been reported.

Among those less common IgA-deficient patients that are truly devoid of IgA, as many as three-fifths produce IgG or IgE anti-IgA antibodies.[24] These uncommon patients are at an uncertain risk for adverse reactions following transfusion with blood products, plasma from normal donors, or from some preparations of human immunoglobulin, which, of course, contain IgA. Patients with high anti-IgA levels (greater than 1:1000) typically have potent antibodies directed against all IgA. These patients are at risk for severe anaphylaxis. Patients with low anti-IgA antibody titers (less than 1:256) are often multiparous or multi-transfused patients. These patients rarely demonstrate severe anaphylaxis after infusion with plasma or blood products, but do present with hives and rashes.

IgAD patients often develop autoimmune diseases. Gastrointestinal disorders include pernicious anemia, inflammatory bowel disease, intestinal disaccharidase deficiency, lactase

deficiency, pancreatic insufficiency, and celiac disease. The latter in particular can be difficult to diagnose without biopsy since serologic diagnosis often relies on detection of anti-tissue transglutaminase, anti-endomysial or anti-gliadin IgA antibodies.[25] Hepatobiliary disorders include chronic active hepatitis, cholelithiasis, lupoid hepatitis, and primary biliary cirrhosis. Skin disorders include pyoderma gangrenosum, paronychia, and vitiligo. It is unclear whether this autoimmune diathesis is the end result of recurrent infections, the product of recurrent insult by antigens that would otherwise be cleared by IgA, or whether the underlying deficit that leads to IgAD also increases the risk of developing an autoimmune disorder. For example, autoimmune disorders such as insulin-dependent diabetes mellitus and celiac disease are associated with the same major histocompatibility complex (MHC) haplotypes (Chapter 5) as IgAD and CVID.

IgAD is associated with an increased risk for the development of malignancies, including epithelial tumors (e.g., gastric and colonic adenocarcinoma) and lymphoproliferative disorders (e.g., Hodgkin disease and acute lymphoblastic leukemia). Patients with chronic gastrointestinal infections may demonstrate a nodular, small intestine lymphoid hyperplasia that can lead to intestinal obstruction. Active B lymphocyte proliferation in the germinal centers of the Peyer patches is seen. These "constipated" lymph nodes have been mistaken for lymphoma. In others, the simultaneous presence of IgAD and malignancy may simply reflect the high prevalence of IgAD in the Caucasian population.

Origin and Pathogenesis

IgAD, selective IgG subclass deficiencies, and CVID are diseases that are defined by a quantitative phenotype, a paucity of serum immunoglobulins of a given isotype in spite of the presence in the blood of B lymphocytes bearing the missing isotypes. By definition, the fundamental defect involves the failure of B lymphocytes bearing a given isotype to differentiate into plasma cells. These diseases appear to represent a common endpoint for multiple pathogenic processes. All three phenotypes may be acquired and many of the recognized precipitating causes, such as phenytoin, are the same (Table 33.3).

IgAD is associated with MHC haplotypes (6p21.3) that are more common in European populations than in the peoples of sub-Saharan Africa and East Asia. In the United States, the prevalence of IgAD among African Americans is one-twentieth of that observed among Americans of European descent and in Japan the incidence is approximately 1 in 18,500. IgAD has also been observed in family members of CVID patients with altered function of the transmembrane activator and CAML interactor (TACI, 17p11.2), which is a receptor for B-cell activating factor (BAFF).

Treatment and Prognosis

Most individuals with IgAD suffer respiratory infections no more frequently than the average individual, and thus require no special treatment. All individuals with IgAD should be warned of the risk of serious transfusion reactions caused by antibodies to IgA. Wearing a medical alert bracelet is recommended. Should transfusion be necessary, the ideal donors are other individuals with IgAD. Washed erythrocytes are safer than whole blood.

Patients with selective IgAD who suffer from clinically significant, recurrent upper respiratory infections often respond to prophylactic antibiotics with potency against encapsulated bacteria. Treatment of allergy in those patients with a compensatory increase in IgE is helpful. Patients who present with combined IgA and IgG subclass deficiencies and have a poor pneumococcal antibody response may require IGRT.

TABLE 33.3 Other Conditions Associated With Humoral Immunodeficiency

Genetic disorders	
Monogenic diseases	Ataxia-telangiectasia
	Autosomal forms of SCID
	Transcobalamin II deficiency and hypogammaglobulinemia
	Wiskott-Aldrich syndrome
	X-linked lymphoproliferative disorder (EBV associated)
	X-linked SCID
Chromosomal anomalies	Chromosome 18q- syndrome
	Monosomy 22
	Monosomy 7
	Trisomy 8
	Trisomy 21
Systemic disorders	
Malignancy	Chronic lymphocytic leukemia
	Immunodeficiency with thymoma
	T-cell lymphoma
Metabolic or physical loss	Immunodeficiency caused by hypercatabolism of immunoglobulin
	Immunodeficiency caused by excessive loss of immunoglobulins and lymphocytes
Environmental exposures	
Drug-induced	Antimalarial agents
	Captopril
	Carbamazepine
	Glucocorticoids
	Fenclofenac
	Gold salts
	Imatinib
	Levetiracetam
	Penicillamine
	Phenytoin
	Sulfasalazine
	Zonisamide
Infectious diseases	Congenital rubella

COMMON VARIABLE IMMUNODEFICIENCY AND COMMON VARIABLE IMMUNODEFICIENCY-LIKE DISORDERS

Diagnosis

The diagnostic category of CVID includes a heterogeneous group of patients older than age 4 who exhibit deficient production of more than one major antibody class and whose antibody response to vaccination is significantly depressed or absent. Patients tend to have normal numbers of clonally diverse B lymphocytes in their blood. These B cells can recognize antigens and respond with proliferation, but their ability to develop into memory B cells or mature plasma cells appears quantitatively impaired. In the presence of infection, abortive differentiation can lead to massive B-lymphocyte hyperplasia, splenomegaly, and intestinal lymphoid hyperplasia.

With an estimated prevalence of 1 in 25,000, CVID is the most prevalent human primary immunodeficiency requiring medical attention.[26] Men and women are equally affected. As with IgAD, the prevalence among African Americans is one-twentieth that of Americans of European descent. Some patients present during childhood, but most are diagnosed after the third decade of life. The typical patient reports a normal pattern of recurrent otitis media as an infant and toddler that resolved in childhood. During adolescence, respiratory infections appear and steadily increase in frequency and duration. Recurrent pneumonia as a young or middle-aged adult is often the precipitating complaint that brings the patient to the attention of the clinical immunologist. Although CVID appears to be an acquired disorder, family studies have clearly documented that susceptibility for the disease can be inherited and the manifestations of the disorder may change with time. Transitions within the spectrum of normal serum immunoglobulin concentrations to IgAD to IgAD with IgG subclass deficits to frank CVID have been documented in both sporadic and familial cases.[2]

CVID is a diagnostic category of primary immunodeficiencies that includes a number of immune disorders. Most CVID patients of Northern European descent exhibit a distinctive phenotype characterized by a broad deficiency of immunoglobulin isotypes in spite of the presence of normal numbers of surface immunoglobulin bearing B-cell precursors in the peripheral blood. Almost all of these patients are IgA deficient and, by definition, demonstrate total serum IgG levels of less than 500 mg/dL. Some IgG subclasses are more affected than others, with the sequential order of involvement being IgG4 > IgG2 > IgG1 > IgG3. Most patients are also deficient in IgM and IgE.

Uncomplicated patients demonstrate normal cell-mediated immunity, although a minority of patients may have evidence of T-cell dysfunction as well as other hematopoietic cell types. In some cases, B-cell numbers are reduced, although not to the extent exhibited by disorders of pre-BCR formation or BTK signaling.

IgAD and CVID have been associated with congenital infection with rubella virus, CMV, and *T. gondii*. The administration of certain drugs has also been linked to a depression in serum immunoglobulin levels (see Table 33.3). Several medications used to treat epilepsy have been associated with the development of antibody deficiencies. For example, up to 20% of patients treated with phenytoin suffer a mild decrease in serum IgA levels, and a minority may progress to a CVID-like phenotype. Medications used for the treatment of rheumatoid arthritis, inflammatory bowel disease, and chronic myelogenous leukemia can also decrease production of antibody. Persistence of antibody deficiency usually requires continued administration of the drug or continued infection with the virus or parasite. However, recovery of immunoglobulin production may take months to years.

Clinical Manifestations

Although some CVID patients have reduced numbers of circulating B cells, the majority have normal quantities of IgA, IgG, and IgM-bearing B-cell precursors in the blood. Defects in B-cell survival, number of circulating $CD27^+$ memory B cells (including IgM^+CD27^+ B cells), B-cell activation after antigen receptor cross-linking, T-cell signaling, and cytokine expression have been observed. Both increases and decreases in the relative numbers of CD4 to CD8 T cells are common, and cutaneous anergy is a frequent finding.

The clinical manifestations of CVID are similar but more severe than the ones seen in IgAD. Respiratory symptoms often begin with recurrent sinusitis, otitis media, and mild bronchitis. The frequency and severity of the upper respiratory infections worsen in the young adult and lower respiratory infections such as pneumonia become common. Apparently asymptomatic, untreated patients may suffer recurrent subclinical pulmonary infections that can lead to irreversible chronic lung damage with bronchiectasis, unilateral hyperlucent lung, emphysema, and cor pulmonale. Recurrent cellulitis, boils, folliculitis, impetigo, or erythroderma can be presenting complaints.[27]

Intermittent or chronic diarrhea due to *G. lamblia* is a common complaint. Patients can develop a malabsorption syndrome that resembles celiac sprue but is unresponsive to gluten avoidance (Fig. 33.4). Untreated patients often complain of an asymmetrical, oligoarticular arthralgia or frank arthritis, which in some cases reflect infections with encapsulated organisms or with *Mycoplasma* species and thus require antibiotic therapy. Paradoxically, antigen-specific IgE can be produced in sufficient quantities to enable anaphylactic reactions.

CVID patients are often anergic, but only a minority suffer infections characteristic of cell-mediated immune dysfunction (e.g., mycobacteria, *P. jiroveci*, or fungi). CD8 T-cell numbers may be depressed in such patients. Most viral infections are cleared normally. Exceptions include enteroviral infections, including meningoencephalitis, as well as hepatitis B and C, which can progress to chronic active hepatitis. Lack of humoral immunity enhances susceptibility to viral reactivation. Untreated patients often complain of recurrent herpes zoster (shingles).

Autoimmune diseases are common in CVID. Coombs-positive hemolytic anemia with idiopathic thrombocytopenic purpura, a combination known as Evans syndrome, may predate diagnosis.

Non-caseating granulomas in the lung, lymph nodes, skin, bone marrow, and liver reminiscent or indistinguishable from sarcoid-like syndrome are seen in up to one-fifth of all patients and are more common in African Americans. While the granulomas can result from mycobacterial or fungal infections, in most cases the cause remains unclear and the granulomas resolve spontaneously.

There is an increased risk for the development of gastrointestinal (1.5%) and lymphoid malignancies (4.1%), especially non-Hodgkin lymphomas.[28] A confounding factor is a propensity to develop benign lymphoproliferative disorders. Lymphadenopathy, splenomegaly, or both are common in untreated patients.

Origin and Pathogenesis

The typical presenting manifestation of CVID is hypogammaglobulinemia, not agammaglobulinemia, suggesting a partial or varying block in B-cell maturation. Careful analysis of B cells in patients has also revealed a spectrum of immune deficiency ranging from the nearly complete absence of memory B cells to a less severe disorder. All of these findings serve to underline the complex etiology for the disorder, and many details remain to be elucidated. The MHC represents the most common genetic susceptibility locus for CVID.[22] Due to linkage disequilibrium, the gene, or genes, within this locus that create susceptibility have yet to be identified with certainty. However, a co-association between MHC class I and KIR alleles has been reported.[29]

Although they represent only a minority of patients, non-MHC associated single-gene defects have been identified.

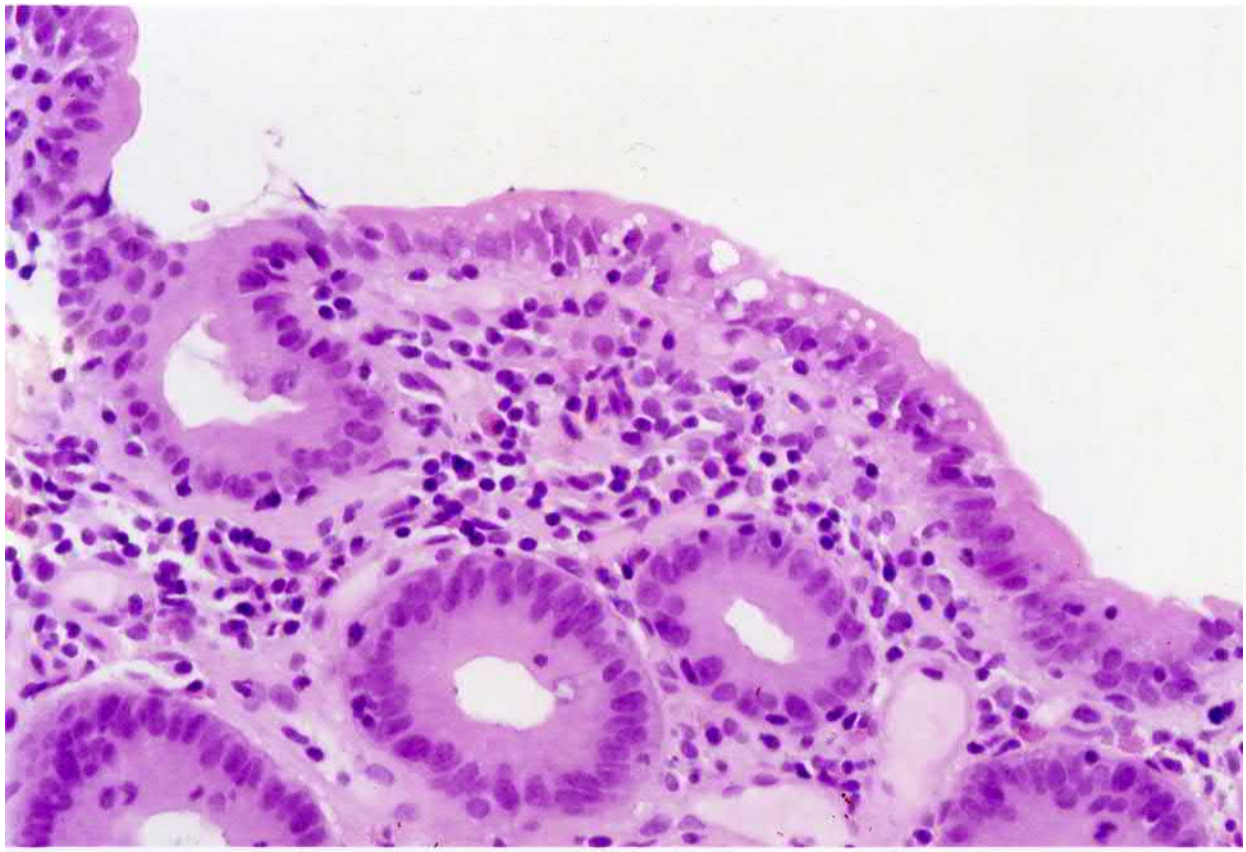

FIG. 33.4 Hypogammaglobulinemic Sprue in a 41-Year-Old White Male With Common Variable Immunodeficiency and Insulin-Dependent Diabetes Mellitus. The patient suffered from intractable diarrhea. Shown is a hematoxylin and eosin stain of a duodenal biopsy obtained by endoscopy. The villi are blunted and there is a marked increase in intraepithelial lymphocytes. However, unlike typical celiac disease, the villi are not completely blunted and few plasma cells are seen. The patient is homozygous for the HLA-DQ2, -DR17 (3), -B8 haplotype. Although the patient failed to respond to a gluten-free diet, the diarrhea resolved with corticosteroid therapy.

Included are loss-of-function mutations of genes involved in late-stage B-cell:T-cell communication, late-stage B-cell growth factors, and B-cell and T-cell signaling and activation pathways (see Table 33.1). Among these are genes for ICOS (CVID1), an immune costimulatory molecule used by T cells to activate B cells in germinal centers; BAFFR (CVID4) and TACI (CVID2), the receptors for B-cell activating factor (BAFF-R also known as CVID4), CD19 (CVID3), CD21 (CVID7) and CD81 (CVID6), components of the B-cell costimulatory receptor; CD20 (CVID5), an important marker of B-cell differentiation; and LRBA(CVID8), CTLA-4, PKCδ (CVID9), TWEAK, PIK3CD, PIK3R1, NF-κB2 (CVID10), IL-21 (CVID11), NF-κB1 (CVID12), IKAROS (CVID11), IRF2BP2 (CVID14), BLK, PTEN, TRNT1, ATP6AP1, ARHGEF1, SH3KBP1, SEC61A1, RAC2, MOGS (mannosyl-oligosaccharide glucosidase), and KMT2D which are involved in B-cell and T-cell signaling pathways.[30] TLR7 and TLR9 activation can be deficient in these patients, although the genes are intact.[31]

The Major Histocompatibility Complex

A large array of genes that play important roles in the control of the immune response are located in the MHC on chromosome 6 (Chapter 5). Many IgAD and CVID patients share parts or all of one of two extended MHC haplotypes marked by either HLA-DQ2, -DR17(3), -B8 and HLA-DQ2, -DR7,-B44. One in seven individuals homozygous for HLA-DQ2, -DR17 (3), -B8 demonstrate IgAD. These MHC alleles are also observed in patients with diabetes mellitus, pernicious anemia, celiac disease, autoimmune thyroid disease, and myasthenia gravis. Some individuals with TACI mutations inherited MHC haplotypes associated with the disease, and the combination of specific MHC and KIR alleles further increases susceptibility.[29] This suggests that epistatic interactions between different susceptibility alleles may influence development of the disorder.

The CD19 (CVID3), CD81 (CVID6), CD21 (CVID7) B-Cell Co-Receptor Complex

CD21 (complement component C3d/Epstein Barr virus receptor 2) binds to membrane IgM-bound antigen when complement C3d is also attached to that antigen (Chapter 40). In association with CD81 and CD19, this co-receptor complex enhances the antigen-binding signal, promoting B-cell activation. Patients with mutations in CD19, CD21, and CD81 have been reported.[32]

The BAFF, BAFFR (CVID4), and TACI (CVID2) axis

The TNF family members B-cell activating factor of the TNF family (BAFF) and a proliferation-inducing ligand (APRIL) bind to two receptors, B-cell maturation antigen (BCMA) and transmembrane activator and calcium-modulator and cyclophilin

ligand interactor (TACI). BCMA is expressed exclusively on B cells, whereas TACI is expressed on activated T cells as well. A third receptor unique for BAFF, BAFF-R, is expressed on B cells and on resting T cells. The BAFF/APRIL system plays a key role in mature B-cell homeostasis and development. BAFF and APRIL can also induce class switching in naive human B cells. Loss-of-function (autosomal recessive) or altered-function (autosomal dominant) TACI alleles have been reported in up to 10% of CVID patients.[33] However, two polymorphic TACI alleles in CVID, A181E, and C104R, are also present in approximately 2% of the normal population. Family members may have IgAD or may have no evidence of immune dysfunction, suggesting reduced penetrance. CVID patients with these altered alleles have a higher prevalence of complications from CVID, including lymphoproliferation, splenomegaly, and autoimmune phenomena.[34] BAFF-R deficiency has also been detected in CVID.[32]

CD20 (CVID5)

CD20 encodes a B-cell membrane-spanning molecule important in B-cell proliferation and differentiation. One female consanguineous patient with CD20 deficiency has been reported with a low IgG and normal IgA and IgM levels, and with impaired antibody responses to pneumococcal polysaccharides.[32]

ICOS (CVID1)

ICOS is a T-cell surface receptor that is important for germinal center formation, terminal B-cell differentiation, effector T-cell responses, and immune tolerance. ICOS-deficient patients have low to absent B cells and some have varying degree of defective T-cell signaling. They present with recurrent respiratory tract infections and autoimmune complications.[32,35]

LRBA (CVID8) and CTLA-4 axis

Lipopolysaccharide-responsive beige-like anchor protein (LRBA) is a cytosolic protein that functions in vesicle trafficking, autophagy, and cell survival. CTLA-4 is an inhibitory T-cell receptor that competes with the costimulatory protein CD28 for binding CD80/86, thereby preventing excessive T-cell activation and maintaining immune tolerance. LRBA plays a role in CTLA-4 surface expression.

LRBA-deficient patients display early-onset hypogammaglobulinemia with autoimmunity and inflammatory bowel disease. They show reduced levels of at least two immunoglobulin isotypes (IgM, IgG, or IgA) and suffer from recurrent infections, autoimmunity, and chronic pulmonary and gastrointestinal disorders.

Patients with haploinsufficiency of CTLA-4 demonstrate autoimmunity, recurrent infections, benign lymphoproliferation, and varying levels of immunoglobulins, B-cell, and T-cell defects.[32]

Interleukin-21

Interleukin-21 (IL-21) deficiency was found in a consanguineous family where three of eight children had inflammatory bowel disease. Hypogammaglobinemia, poor specific antibody responses to polysaccharide antigens, increased IgE, and decreased memory and switched B-cell numbers were observed.[36]

PKCδ Deficiency

PKCδ plays a key role in BCR-mediated signaling downstream of BTK and is important in B-cell proliferation, apoptosis, and tolerance. PKCδ deficiency presents with a variable phenotype with one affected patient having CVID-like characteristics (hypogammaglobulinemia and severe infections) whereas the others had lupus or ALPS-like disease.[32]

TWEAK Deficiency

A patient with an autosomal dominant mutation in TNF superfamily member 12 (TNFSF12), which encodes TNF-like weak inducer of apoptosis (TWEAK), displayed low to normal IgG, low IgM, and low IgA. There was a history of pneumococcal meningitis, osteomyelitis, thrombocytopenia, and neutropenia.[32]

NF-κB1 (CVID12) and NF-κB2 (CVID10) Deficiency

The NF-κB1 and NF-κB2 (non-canonical) pathways are important in B-cell signaling, with NF-κB2 having a more limited set of involved receptors (e.g., ICOS, TACI, BAFR-R, and BCMA), whereas NF-κB1 affects T-cell and TLR signaling as well.

Heterozygous mutations in NFK-B2 have been identified in patients who presented with early-onset panhypogammaglobulinemia, autoimmunity, and RESPI. These patients display aberrant B-cell subsets, some degree of T-cell and NK-cell dysfunction, and pituitary hormone deficiencies.

Patients with NK-κB1 autosomal dominant mutations that create unstable protein have recurrent infections, autoimmunity, benign lymphoproliferative disease, and lymphoma.[32]

PI3K Mutations

Heterozygous mutations in *PIK3CD*, which encodes the PI3K catalytic subunit p110δ, have been reported in patients with respiratory tract infections, skin infections, autoimmunity, and lymphoma. The mutation leads to overactive PI3K signaling. The phenotype associated with dominant gain-of function *PIK3CD* mutations is known as activated phosphatidylinositol 3-kinase δ syndrome (APDS).

PIK3R1 encodes the P13K regulatory subunit p85α. A dominant gain-of-function mutation of p85a also results in autosomal dominant overactive PI3K signaling. A patient with a complete loss of p85a expression has presented absence of B cells and agammaglobulinemia.

BLK, IRF2BP2 (CVID13), and IKAROS (CVID14)

A heterozygous loss-of function mutation in BLK has been noted in related patients with CVID. These patients have respiratory tract infections and bacterial skin infection with pan hypogammaglobulinemia. A gain of function mutation in IRF2BP2 has been found in members of a family with CVID. These patients have autoimmune disease and respiratory tract infections. Heterozygous mutations in *IKZF1*, which encodes the transcription factor IKAROS, has been observed in patients with a progressive loss of B cells and serum immunoglobulins.[32]

Other Genes

Among autosomal dominant conditions, PTEN deficiency has been reported in one young boy with hypogammaglobulinemia and defective specific antibody responses. Mutations in *SEC61A1* have been reported in hypogammaglobinemia with RESPI. Defects in Ras-related C3 botulinum toxin substrate 2 (RAC2) genes are associated with reduced antibody levels and decreased antibody responses and recurrent respiratory infections with normal or low B-cell numbers. PLCγ2-associated antibody deficiency and immune dysregulation (PLAID) results from gain-of-function mutations and presents with cold urticaria, hypogammaglobulinemia, impaired humoral immunity, and autoinflammation.

Among autosomal recessive conditions, TRNT1 deficiency has been reported as the cause of B-cell deficiency with hypogammaglobinemia, as well as deafness and developmental delay. *ARHGEF1* mutations have been associated with hypogammaglobinemia, recurrent infections, and bronchiectasis. Mutations in *MOGS* lead to mannosyl-oligosaccharide glucosidase deficiency, also known as congenital disorder of glycosylation type IIb (CDG-IIb), with panhypogammaglobulinemia, subpar specific antibody responses, and increased susceptibility to bacterial and viral infections.

Among X-linked conditions, mutations in *ATP6AP1* and *SH3KBP1* have been associated with immunoglobulin deficiency.

Kabuki syndrome

Patients with Kabuki syndrome (KS) present with a characteristic face, short stature, cardiac anomalies, a variable degree of intellectual disability, recurrent infections, reduced immunoglobulin levels, and autoimmunity. Mutations in *KMT2D* and *KDM6A* have been identified as the main cause.

Treatment and Prognosis

Therapy in CVID begins with the aggressive treatment of ongoing infections and the institution of prophylactic measures to prevent or ameliorate future infections. Patients suffering from moderate upper respiratory tract infections and bronchitis typically benefit from empiric therapy with agents effective against encapsulated organisms. The concomitant inheritance of mannose-binding lectin protein deficiency further predisposes to the development of bronchopulmonary complications such as bronchiectasis, lung fibrosis, and respiratory insufficiency,[3] as well as urinary tract infections. Prolonged and intravenous administration of antibiotics may be required.

The most effective therapy for hypogammaglobulinemic patients is immunoglobulin replacement. A number of studies have demonstrated a steadily decreasing incidence of infection and improvement in lung function with increasing doses of immunoglobulin administration.[37] Each patient may demonstrate his or her own individual response to therapy, exhibiting dramatic differences in the frequency and severity of infections with moderate changes in the replacement dose. Ultimately, replacement dosage must be individualized based upon the response of the patient. Patients suffering from a serious acute infection often benefit from one-time booster doses of immunoglobulin. Adverse reactions occur most frequently at the time of the first administration of immunoglobulin, likely because of concurrent infection increasing the potential for generation of immune complexes.

Some patients with CVID can sustain severe anaphylaxis when given IVIG or other blood products that contain serum or plasma. These patients may possess anti-IgA antibodies, including IgE anti-IgA antibodies.[7] For patients with a history of severe adverse reactions, it is advisable to try lots of IVIG with the lowest IgA possible and to test the patient with the different lots in an intensive care unit. Once having identified a lot that can be tolerated, the patient may receive therapy under more relaxed conditions.

Serum immunoglobulin concentrations in patients with CVID may change over time,[2] with rare patients regaining normal serum IgG levels and no longer requiring immunoglobulin therapy. Careful review of the clinical history of these patients may reveal evidence of exposure to pharmacologic agents associated with the development of hypogammaglobulinemia (e.g., phenytoin). However, the overwhelming majority of patients require replacement therapy for life.

Although IgG may be replaced, at present IgM and IgA cannot be provided to the patient. The absence of these multimeric proteins may help explain why even patients on high-dose replacement therapy may continue to suffer from recurrent sinusitis or gastrointestinal discomfort.[38] Recurrent sinusitis can be ameliorated with continued prophylactic therapy with antibiotics. Patients with CVID also are at risk from *G. lamblia*, as well as other enteric pathogens. Some patients develop lactose intolerance or gluten-sensitive enteropathy. Gluten avoidance ameliorates symptoms in only a minority of cases. A majority responds to corticosteroids or anti-TNF agents. The use of these agents can be a double-edged sword, since resistance to infection will decrease in a patient who is already immune deficient. Other patients develop a malabsorption syndrome that can lead to hypoalbuminemia and hypocalcemia (due to malabsorption of vitamin D), and decreased levels of vitamin A and carotene.[39] The cause of diarrhea and malabsorption in this latter patient subset remains unclear, and treatment is limited to supportive measures, with vitamin and mineral replacement as indicated.

Patients with bronchiectasis should be treated aggressively with replacement therapy. In severe cases, aggressive pulmonary toilet will benefit the patient, including bronchodilator therapy, position and postural drainage, or other physical therapies.

IgA-deficient mothers may fail to secrete IgA in their colostrum. Although colostral IgM levels may be elevated in an attempt to compensate for the lack of maternal IgA, the newborn remains relatively unprotected against intestinal pathogens. Of greater concern are the children of mothers with untreated CVID who are born in a state of humoral immunodeficiency and thus are at risk for life-threatening sinopulmonary infection. In order to compensate for the loss of IgG across the placenta and to provide the infant with the passive immunity it will require, the dose of replacement gammaglobulin therapy should be increased by 50% by the third trimester of pregnancy.

Splenomegaly is common in untreated patients. Hypersplenism in most patients responds to aggressive therapy with antibiotics and intravenous immunoglobulin. The presumption is that the hypersplenism is secondary to reactive hyperplasia of lymphoid follicles within the spleen attempting to respond to infection. Development of esophageal varices or other hematologic manifestations of hypersplenism (refractory thrombocytopenia, anemia, neutropenia, and lymphopenia) may require splenectomy as the therapy of last resort. The outcome for most such patients has been good, with resolution of symptoms, although patients with altered TACI alleles tend to do less well.

The development of constellation of pulmonary abnormalities that include granulomatous and lymphoproliferative (lymphocytic interstitial pneumonia [LIP], follicular bronchiolitis, and lymphoid hyperplasia) histopathologic patterns, termed granulomatous-lymphocytic interstitial lung disease (GLILD), can be an ominous sign. These patients appear more likely to develop granulomatous liver disease, autoimmune hemolytic anemia, lymphoproliferative disease, and progressive pulmonary disease.[40]

THERAPEUTIC PRINCIPLES

- The primary goal of treatment is to keep the patient infection free and maintain lung function.
- In patients whose respiratory mucosa is intact, intravenous or subcutaneous replacement IgG therapy is generally effective in protecting them from pulmonary infections.
- For those patients who have developed bronchiectasis or who continue to subject themselves to environmental toxins (e.g., smoking), replacement IgG will ameliorate but may not prevent all such infections.
- Because mucosal immunoglobulin cannot be replaced, even patients on adequate IgG replacement therapy remain at risk for sinus or gastrointestinal infections.
- Prophylactic antibiotics that are effective against encapsulated organisms can significantly reduce the frequency of upper respiratory tract infections in patients who continue to suffer despite replacement therapy with intravenous gammaglobulin.
- Prolonged diarrhea in hypogammaglobulinemic patients may be caused by *Giardia lamblia* and responds well to metronidazole therapy.
- Patients with primary antibody deficiencies should not receive live vaccines.

SELECTIVE IMMUNOGLOBULIN G SUBCLASS DEFICIENCIES

Diagnosis

Most individuals with modest reductions in serum IgG subclass levels are functionally normal. Indeed, individuals with deletions of the heavy chain immunoglobulin gene locus, some of whom completely lack IgG1, IgG2, IgG4, and IgA,[41] have been reported to be asymptomatic. The diagnosis of a functional IgG subclass deficiency can only be made with confidence when there is both a significant decrease in the serum concentration of a specific isotype and clear evidence of reduced specific antibody production (e.g., failure to respond to Pneumovax [R] 23).

Up to 10% of normal males and 1% of normal females are IgG4 deficient, which makes a diagnosis of isolated IgG4 subclass deficiency problematic. Among patients with IgG1 or IgG3 deficiency, documentation of the ability to produce protective titers of anti-tetanus toxin and anti-diphtheria toxin antibodies following standard tetanus toxoid and diphtheria immunizations is a strong indication that replacement gammaglobulin therapy is likely unwarranted, especially if pulmonary function is normal and there is no history of recurrent infection. Documentation of a strong anti-pneumococcal polysaccharide response in patients with an apparent IgG2 deficiency would suggest gammaglobulin replacement is likely not required. Conversely, the lack of a response to vaccination calls for appropriate prophylactic antibiotic therapy before a trial of IVIG is attempted.

Clinical Manifestations

The clinical spectrum of isolated IgG subclass deficiency is quite variable and deficiencies of each of the four IgG subclasses have been described.[42] Some individuals present with only a mild reduction of total IgG, but most symptomatic patients have marked deficiencies of one or more IgG subclasses despite normal total IgG concentrations. Since IgG1 makes up the majority of serum IgG in most patients, a deficiency of IgG tends to correlate with depressed serum levels of total IgG.

IgG subclass levels are rarely measured in asymptomatic individuals. Most patients with isolated IgG2 deficiency present with recurrent upper or lower respiratory infections. Individuals may have few residual symptoms between infections, but some have severe chronic inflammation with refractory sinusitis, pulmonary fibrosis, or bronchiectasis. Because protective antibodies directed against carbohydrate antigens are usually of the IgG2 subclass, many affected patients exhibit an impairment of their ability to mount specific protective responses to encapsulated pathogens. However, normal responses have also been described.[43] There is general agreement that recurrent sinopulmonary infections (RESPI), IgG2 deficiency, and a response to less than half of the polysaccharide antigens in an unconjugated vaccine meets the standard for functional immune deficiency and thus warrants aggressive prophylactic therapy up to and including immunoglobulin replacement.

IgG3 deficiency may occur alone or in association with IgG1 deficiency. Recurrent infection of the respiratory tract with chronic lung disease has been reported. With a serum half-life of only 2 weeks, IgG3 levels may be consumed rapidly during the course of an active infection in an otherwise normal individual.[44] Before making the diagnosis of IgG3 deficiency, serum levels of IgG3 should be re-checked when the individual is asymptomatic.

When compared with the serum, IgG4 is over-represented in secretions, and IgG4-committed B cells are present at mucosal sites, suggesting a role in mucosal immunity. Since IgG4 is normally present in the serum in very low concentrations, the significance of a low serum level in a patient with recurrent infection remains unclear.

Origin and Pathogenesis

The origin of IgG subclass deficiency is unknown. Homozygous deletions of portions of the immunoglobulin heavy chain constant locus associated with total absence of IgG2, IgG3, and IgG4 or combinations of these isotypes have been described in healthy individuals. IgG2 deficiency is often found in association with selective IgAD with or without IgG4 deficiency. Patients with selective IgG subclass deficiencies often inherit the same MHC haplotypes seen in IgAD and CVID. Thus, IgG-subclass–deficient patients with recurrent infections likely have a more complex defect than just the absence one or more IgG isotype. In some instances, subclass deficiency is associated with a T-cell defect, as in chronic mucocutaneous candidiasis and ataxia-telangiectasia. IgG subclass deficiency may also be acquired. Acute infections, medications, chemotherapy, irradiation, surgery, and HIV infection have all been temporally linked to the development of a deficiency in one or more IgG subclass.[45]

Treatment and Prognosis

The natural history of IgG subclass deficiency (±IgAD), especially in children, varies.[46] Associated allergic rhinosinusitis and asthma must be aggressively treated with conventional therapy, as these conditions increase the risk of purulent sinusitis and pneumonia. Evaluation of possible anatomic obstruction should be performed when persistent infection of a sinus or pulmonary segment is the presenting complaint; the role of surgical therapy should not be overlooked.

Many patients with IgG subclass deficiency do well on prophylactic antibiotics and will never need immunoglobulin supplementation. However, in patients with severe, recurrent infections, IGRT can be beneficial. Patients who begin therapy should improve within the first 2 months, but to avoid the placebo effect, a full 6-month trial is recommended.

ANTIBODY DEFICIENCY WITH NORMAL SERUM IMMUNOGLOBULIN LEVELS

Occasional patients may present with normal serum immunoglobulin concentrations and a selective inability to respond to infections with pyogenic organisms. Diagnosis requires documentation of an inability to respond to antigenic challenge. These patients may respond to replacement immunoglobulin therapy if prophylactic antibiotics fail and aggressive management of other conditions such as asthma fail.[47,48] The antibody response to specific polysaccharide antigens can be very selective. In humans, most protective anti-*Haemophilus influenzae* type b (anti-Hib) antibodies utilize the rare Vκ A2 gene. The Navajo population in the Southwestern United States suffers a 5- to 10-fold increased incidence of Hib disease. This population also exhibits a high prevalence of an A2 allele with a defective recombination signal sequence, preventing use of germline-encoded antibodies that can generate protective antigen-binding sites.

Analysis of a group of well-characterized patients, mostly female, with a history of RESPI and normal serum immunoglobulin levels revealed a high prevalence of the same MHC haplotypes observed in IgAD, selective IgG subclass deficits, and CVID.[23] These patients tend to respond to aggressive antibiotic therapy, including prophylaxis.

SELECTIVE LIGHT CHAIN DEFICIENCY

Selective κ or λ light chain deficiencies have been reported.[49–51] In one such case, the patient was the offspring of a consanguineous (uncle-niece) union, and in the second, a molecular analysis demonstrated different loss-of-function mutations in the patient's Cκ alleles. The parents of these children had no health difficulties, but each of the patients required medical attention for RESPI and diarrhea. Two of the κ deficient patients exhibited IgAD and the remaining κ deficient and the λ deficient patients were panhypogammaglobulinemic.

TRANSIENT HYPOGAMMAGLOBULINEMIA OF INFANCY

Diagnosis

As infants make the transition from dependence on maternal immunoglobulin to reliance on endogenously produced antibodies, they suffer a physiologic nadir of serum immunoglobulin at 4 to 6 months of age, a period associated with susceptibility to mild upper respiratory infections and otitis media (see Fig. 33.2). Children who (a) exhibit serum concentrations of one or more of the three major immunoglobulin classes that fall below the 95% confidence interval for age on two or more occasions during infancy, (b) demonstrate a rise in these values to or toward normal over time, and (c) lack features consistent with other forms of primary immunodeficiency fall within the catch-all diagnosis of THI.[52,53] By definition, the diagnosis of THI can be made with certainty only in retrospect.

Clinical Manifestations

Immunoglobulin concentrations are rarely measured in infants unless there is some reason to suspect an immunodeficiency. Most patients with this diagnosis come to medical attention due either to recurrent infections or to routine screening studies of family members of immunodeficient patients. Bearing in mind that 2.5% of normal infants will fall below the 95% confidence range at any one time, the diagnosis of THI is remarkably rare. Among two major centers, one in the United States and one in Germany, the diagnosis was given to only 16 of 18,000 children in whom the index of suspicion warranted immunoglobulin determinations.[54,55]

Patients with THI are typically able to synthesize specific antibodies in response to immunization with T-dependent antigens (e.g., tetanus and diphtheria toxoids).[56] They may have difficulty responding to polysaccharide antigens (e.g., isohemagglutinins and vaccination with Pneumovax 23). Some will fail to sustain protective antibody responses to antigens. Most THI patients, especially those with mild upper respiratory infections alone or positive family histories, exhibit fewer infections over time. By 2 years of age, serum immunoglobulin levels frequently normalize in the great majority of THI infants. However, a minority fails to normalize IgG, continues to suffer with recurrent infections, and may develop evidence of autoimmune disease. These patients often become part of the hypogammaglobulinemia syndrome complex that includes CVID. They may end up requiring long-term IGRT, prophylactic antibiotics, or both.

Treatment and Prognosis

Children with suspected THI should be monitored with serial determination of serum immunoglobulins and isohemagglutinin titers in order to confirm acquisition of normal immune function. Development of normal IgG levels may be delayed for several years, and some children will remain IgG subclass or IgA deficient. Treatment of THI with IGRT is warranted should the child persistently suffer with recurrent, invasive infections, including pneumonia.

ON THE HORIZON

- Elucidation of the molecular basis of selective defects in humoral responses to pathogens, in part through the use of high-throughput sequencing to characterize the precise molecular composition of antibody responses in immune deficiencies.
- Further elucidation of the molecular basis of common variable immune deficiency, hypogammaglobulinemia, and IgA deficiency.
- New approaches to treatment such as hematopoietic stem cell transplantation and gene therapy.

FRONTIERS IN RESEARCH

Bruton reported the first case of agammaglobulinemia in 1952, as well as the first successful therapy for this classic primary antibody deficiency. Since that time, there has been remarkable progress in the identification of single-gene disorders. However, for the majority of patients the underlying pathogenesis of the most common manifestation of primary antibody deficiency, hypogammaglobulinemia in the adult, still remains unclear. It seems increasingly likely that this disorder is multifactorial in nature, dependent on the inheritance of one or more susceptibility loci in association with either environmental influences or random chance. In rare cases, patients with hypogammaglobulinemia have shown resolution of their symptoms, suggesting that a better understanding of pathogenesis might yield therapies of remission. The molecular basis of selective deficiencies

in the response to pathogens in the presence of normal serum immunoglobulin levels also remains unclear. The availability of whole exome and whole genome sequencing has helped identify the genetic cause of an increasing number of presumed CVID patients. More gene regulatory and signal transduction pathways will likely be defined in the next decade.

Primary T-Cell Immunodeficiencies

Luigi D. Notarangelo

Adaptive immune responses consist of specific recognition of antigens, effector mechanisms if immunity, and development of immunological memory. T lymphocytes play an essential role in this process. By expressing either β or γ heterodimeric T-cell receptors (TCRs) on the cell surface, they are able to recognize antigenic epitopes. Moreover, while CD8 T cells are endowed with cytotoxic effector mechanisms that may contribute to killing of virus-infected cells, CD4 T lymphocytes participate in immune-mediated responses by providing soluble and membrane-bound signals that permit activation and differentiation of B lymphocytes, dendritic cells, and macrophages. CD4− CD8− T cells expressing TCR β or γ on their cell surface contribute to immune responses against mycobacteria and other pathogens. Finally, in the course of an immune response, a subset of antigen-specific T cells differentiates into memory cells that patrol the body, thereby triggering prompt and robust responses during subsequent encounters with the same antigen.

In this chapter, we review primary T-cell immunodeficiencies, a large group of genetically determined disorders characterized by abnormalities of T-cell development and/or function.

KEY CONCEPTS

T-Cell Immunodeficiencies

- A large group of disorders caused by genetic defects that affect development, maturation, and/or function of T lymphocytes
- Depending on the severity of the numerical and functional defect, T-cell immunodeficiencies can be distinguished in two categories: severe combined immune deficiency (SCID) and combined immune deficiency (CID)
- In most cases, the defect is intrinsic to the hematopoietic lineage; however, some forms of T-cell immunodeficiency may be due to abnormalities of thymus development and function
- The age of clinical onset may vary from infancy to adulthood, depending on the severity of the defect

SEVERE COMBINED IMMUNE DEFICIENCY—GENERAL CONSIDERATIONS

Severe combined immune deficiency (SCID) comprises a heterogeneous group of genetic disorders characterized by profound impairment of T-cell development and/or function (Fig. 34.1).[1,2] In some forms of SCID, the number and/or function of B and/or natural killer (NK) cells are also affected by the underlying gene defect, so that SCID may manifest with four distinct immunological phenotypes: (1) $T^-B^+NK^-$ SCID (the most common phenotype); (2) $T^-B^+NK^+$ SCID; (3) $T^-B^-NK^+$ SCID; or (4) $T^-B^-NK^-$ SCID (Table 34.1). However, because antibody responses to protein antigens require T/B-cell interaction, infants with SCID have impaired humoral immunity even if the gene defect does not directly affect the B-cell compartment.

The natural history of SCID is characterized by early-onset, life-threatening infections that may be sustained by a variety of pathogens (bacterial, viral, fungal), and even by opportunistic microorganisms. Interstitial pneumonia due to *Pneumocystis jiroveci*, cytomegalovirus (CMV), or other viruses (adenovirus, parainfluenzae virus, respiratory syncytial virus) in the first months of life, chronic diarrhea, and failure to thrive are common clinical features of infants with SCID. Because of the inability to control replication of live microorganisms, administration of live-attenuated vaccines often leads to severe, life-threatening complications in infants with SCID. Breastfeeding from a CMV positive mother may cause transmission of the virus and severe disease; therefore, screening of the mother's CMV seropositivity status is important, and if positive should prompt avoiding breastfeeding if possible. Transfusion of SCID babies with unirradiated blood products often leads to fatal graft-versus-host disease.

Engraftment of maternal T cells that cross the placenta occurs in more than 50% of infants with SCID.[2,3] Most often asymptomatic, it may cause skin rash or, less frequently, typical graft-versus-host disease with generalized rash, liver disease, profuse diarrhea, jaundice, and severe hematological abnormalities (thrombocytopenia, anemia, leukopenia) that are indicative of marrow damage.

SCID is inevitably fatal unless treated by allogeneic hematopoietic stem cell transplantation (HSCT) or, in selected cases, by gene therapy or enzyme replacement therapy (ERT).[2]

From a laboratory standpoint, severe lymphopenia and, in particular profound T-cell lymphopenia, are typical findings. Furthermore, in vitro proliferative responses to mitogens and antigens are severely reduced or absent. Immunoglobulin serum levels are often low, but serum IgG may be normal early in life, reflecting transplacental passage of maternal IgG. However, antibody response to vaccine antigens is severely impaired. Flow-cytometric analysis of the expression of surface markers specific for T, B, and NK cells permits one to define the immunological phenotype of SCID and may provide information regarding the underlying gene defect. Although most patients with SCID manifest profound T-cell lymphopenia, the number of circulating T cells may be less affected and may even be normal in patients with atypical forms of SCID (associated with residual capacity to produce T lymphocytes) or with maternal T-cell engraftment. In both cases, however, the proportion of circulating naïve ($CD45RA^+$ $CCR7^+$ or $CD45RA^+$ $CD62L^+$) T cells is severely reduced.

A major advance in the diagnostic approach to SCID has been the introduction of newborn screening, based on the quantification of T-cell receptor excision circles (TRECs) in dried blood spots collected at birth. DNA rearrangements that occur at the TCR loci during T-cell development result in the generation of

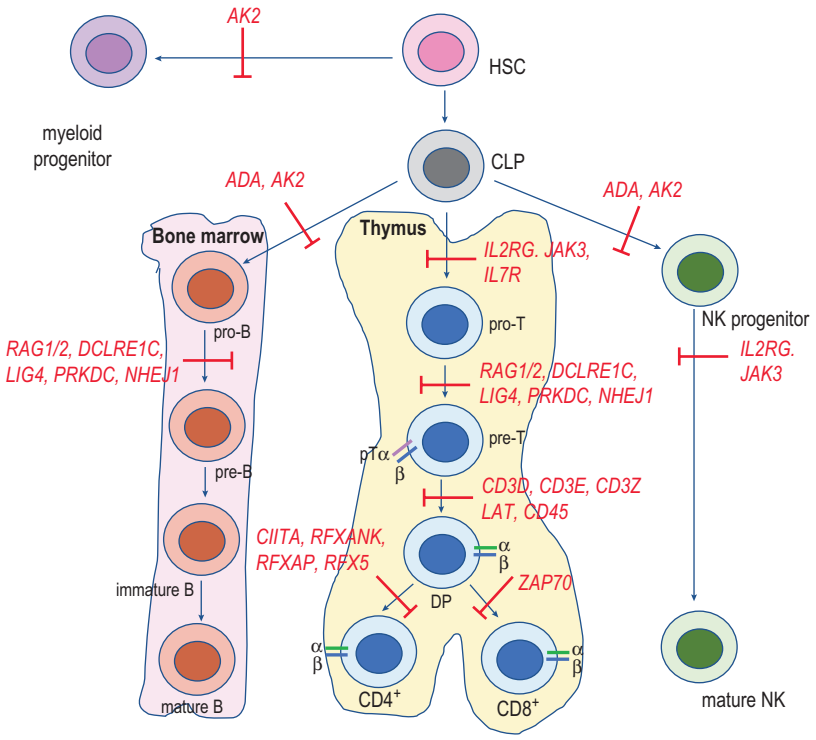

FIG. 34.1 Schematic Representation of Developmental Blocks That Characterize Various Forms of Severe T-Cell Deficiency. Common lymphoid progenitor *(CLP)* cells originate from hematopoietic stem cells *(HSCs)* and give rise to cells of T, B, and natural killer *(NK)* lineages. Differentiation of T cells in the thymus proceeds through discrete stages. Signaling through the interleukin-7 receptor *(IL-7R)* mediates expansion and survival of early T-cell progenitors. V(D)J recombination, initiated by the recombinase activating genes (*RAG1*, *RAG2*) and involving components of the nonhomologous end-joining pathway, allows DNA rearrangement at T-cell receptor (TCR) loci. Pre-T cells express on the surface a complex composed of TCRβ and pre-Tα (pTα) molecules along with CD3 subunits. Signaling through this complex promotes further rearrangements at the TCR α/δ locus, allowing generation of $CD4^+$ $CD8^+$ double-positive (DP) cells expressing the TCRαβ heterodimer. After positive and negative selection, $CD4^+$ and $CD8^+$ single-positive mature thymocytes are generated, that are exported to the periphery. Various defects along this differentiation pathway may cause severe T-cell deficiency. *Blocked red lines* identify specific stages at which known gene defects affect development of T, B, and NK cells. *ADA*, Adenosine deaminase; *AK2*, adenylate kinase 2; *IL2RG*, interleukin-2 receptor gamma chain; *JAK3*, Janus-associated kinase 3; *LAT*, linker of activated T cells; *LIG4*, DNA ligase 4; *ZAP-70*, Zeta-associated protein of 70 kDa.

excised DNA fragments that are ligated into circles (TRECs). In particular, DNA rearrangements at the TCRTCRα/δocus occur in approximately 70% of thymocytes, and generate a δrec-ψJα TREC.[4,5] Because TRECs are diluted with T-cell divisions, enumeration of TREC levels by quantitative polymerase chain reaction (qPCR) provides valid information on the capacity of the thymus to generate T cells.[6] Moreover, implementation of newborn screening for SCID has also permitted more precise definition of its incidence, now estimated to be 1:50,000 to 1:75,000 live births in the United States.[7] However, this figure is significantly higher in countries with a high rate of consanguinity and among certain genetically restricted ethnic groups due to a higher rate of autosomal recessive forms of SCID in these populations.

Ultimately, molecular analysis permits identification of the genetic basis of SCID. Appropriate gene panels or whole exome/whole genome sequencing (WES/WGS) can be used to correctly identify the gene defect. Defining the cellular and molecular bases of SCID is also important from a therapeutic standpoint. In particular, some forms of SCID are associated with defective DNA repair. These patients are at high risk of severe, potentially fatal complications if chemotherapy is used as part of the conditioning regimen during HSCT. Moreover, while the vast majority of SCID disorders are due to hematopoietic cell autonomous defects, severe T-cell lymphopenia may also reflect thymus-intrinsic defects. For the latter category of patients, thymus transplantation may be needed. Finally, the nature of the pathogenic variant often determines the severity of the immunological phenotype. Complete loss-of-expression and loss-of-function (null) mutations are associated with a more severe (typical) SCID phenotype. In contrast, hypomorphic mutations allowing residual development (and/or function) of T cells are often responsible for atypical ("leaky") forms of the disease. Diagnostic criteria distinguishing typical and atypical forms of SCID have been developed by the Primary Immune Deficiency Treatment Consortium (PIDTC) and are reported in Table 34.2. SCID genotypes have a different distribution among typical and atypical forms of SCID (Fig. 34.2).[8] Atypical forms of SCID are often associated with manifestations of immune dysregulation, with oligoclonal expansion of T cells that may infiltrate and damage peripheral organs. Infants with these features plus erythroderma, adenopathy, eosinophilia, and elevated immunoglobulin E (IgE)

KEY CONCEPTS

Severe Combined Immune Deficiency

- Severe combined immune deficiency (SCID) comprises a heterogeneous group of genetic disorders characterized by profound numerical and functional defects of T lymphocytes. The severity of T-cell lymphopenia is the main element that distinguishes typical and atypical forms of SCID. The latter is often due to hypomorphic variants in SCID-associated genes
- In some forms of SCID, also the number of B and/or NK lymphocytes is reduced. However, antibody responses are uniformly compromised, because of the lack of T-helper function
- Maternal T-cell engraftment is common in babies with SCID and may variably affect the clinical phenotype (from being clinically silent to causing severe graft-versus-host disease). In SCID infants with maternal T-cell engraftment, the T-cell count may vary, but the proportion of naïve T cells is very low
- The natural history of SCID is characterized by early-onset, life-threatening infections sustained by virus, bacteria, and fungi. Interstitial pneumonia, chronic diarrhea, and failure to thrive are common clinical features
- Omenn syndrome, characterized by generalized erythroderma, lymphadenopathy, and eosinophilia, is a peculiar phenotype associated with oligoclonal expansion of autologous T cells infiltrating the skin and other organs
- Newborn screening, with enumeration of T-cell receptor excision circles (TRECs), allows identification of babies with profound naïve T-cell lymphopenia. Additional phenotypic, functional, and genetic studies permit definitive diagnosis of SCID

TABLE 34.2 Definition of Typical and Atypical SCID According to Criteria of the Primary Immune Deficiency Treatment Consortium (PIDTC)

Typical SCID

- Absence of very low number of T cells (CD3 T cells <300/μL), **AND**
- No or very low T-cell function (<10% of lower limit of normal) as measured by response to phytohemagglutinin (PHA)
- **OR**
- T cells of maternal origin present

Atypical (Leaky) SCID

- Presence of maternal lymphocytes tested and not detected
- AND either one or both of the following:
  a. <50% of lower limit of normal T-cell function as measured by response to PHA or to anti-CD3/CD28 antibody
  b. Absent or less than 30% of lower limit of normal proliferative response to Candida and tetanus toxoid antigens
- **AND** at least two of the following:
  a. Reduced number of CD3 T cells [age ≤ 2 years: <1500 cells/μL; age >2 years ≤ 4 years: 800 cells/μL; age >4 years: <600 cells/μL]
  b. 80% of CD3 or CD4 T cells are $CD45R0^+$
  AND/OR >80% of CD3 or CD4 T cells are CD62L-negative
  AND/OR >50% of CD3 or CD4 T cells express Human Leukocyte Antigen DR (HLA-DR)
  (at <4 years of age)
  AND/OR are oligoclonal T cells
  c. Hypomorphic mutation in *IL2RG* in a male or homozygous hypomorphic mutation or compound heterozygosity with at least one hypomorphic mutation in an autosomal SCID-causing gene
  d. Low TRECs and/or the percentage of $CD4^+$ $CD45RA^+$ $CD31^+$ or $CD4^+$ $CD45RA^+$ $CD62L^+$ cells is below the lower limit of normal [for reference: see Schatorje et al.[89]]
  e. Functional testing in vitro that supports impaired, but not absent, activity of the mutant protein
- **AND** does not meet criteria for Omenn syndrome, which include infantile erythroderma rash, adenopathy, hepatomegaly, eosinophilia, elevated serum IgE, and oligoclonal T-cell expansion

SCID, Severe combined immune deficiency.

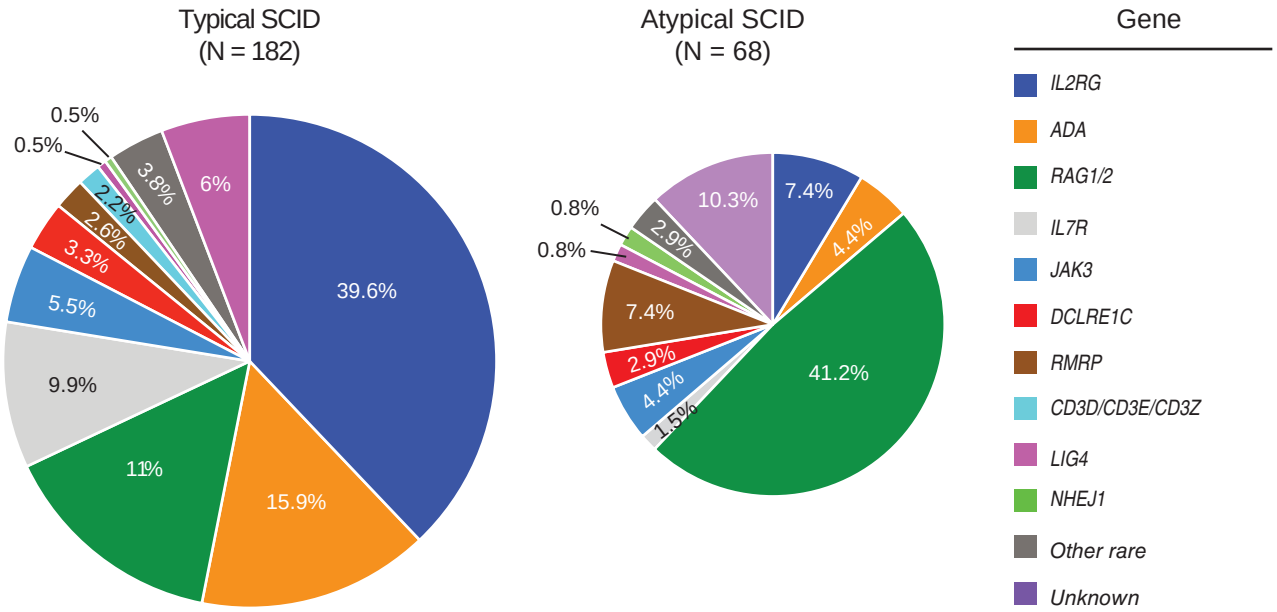

FIG. 34.2 Distribution of Scid Genotypes Among Patients with Typical and Atypical forms of SCID. Data are from reference 8 and pertain to patients with SCID identified in the period 2000–2008 and enrolled in protocols of the Primary Immune Deficiency Treatment Consortium. *SCID*, Severe combined immune deficiency.

are designated as Omenn syndrome. In patients with atypical SCID, conditioning regimes with chemotherapy and/or serotherapy may be necessary to eliminate the dysreactive T cells and permit robust and durable donor stem cell engraftment and immune reconstitution.

Finally, SCID can be divided into different groups based on the mechanisms underlying the T-cell lymphopenia:

SCID due to hematopoietic defects

- Metabolic defects affecting survival of T-cell progenitors
- Defects of cytokine-mediated signaling
- Defects of V(D)J recombination
- Defects of the CD3/TCR complex
- Other mechanisms

SCID due to non-hematopoietic defects

SCID DUE TO METABOLIC DEFECTS AFFECTING SURVIVAL OF T-CELL PROGENITORS

Adenosine Deaminase Deficiency

Adenosine deaminase (ADA), an enzyme of the purine salvage pathway, converts adenosine (Ado) and deoxyadenosine (dAdo) to inosine and deoxyinosine, respectively.[9] In the absence of ADA, intracellular concentrations of Ado, dAdo, and their phosphorylated derivatives (AXP, dAXP) increase. Although ADA is ubiquitously expressed, high levels of dAdo and dAXP are particularly toxic to developing lymphocytes; moreover, dATP inhibits ribonucleotide reductase, an enzyme required for DNA synthesis. Consequently, complete ADA deficiency (OMIM *102700) is characterized by a profound reduction of circulating T, B, and NK cells, and therefore is a cause of T^- B^- NK^- SCID.[9] Furthermore, ADA deficiency also interferes with the proliferative capacity of circulating T lymphocytes and with the function of regulatory T (Treg) cells and B-cell tolerance. ADA deficiency is inherited as an autosomal recessive trait and accounts for approximately 5% to 10% of all cases of SCID. Affected patients have typical manifestations of SCID, with early-onset, life-threatening infections. Besides lymphoid cells, ADA deficiency also affects other organs.[10] Cognitive and behavioral abnormalities and sensorineural deafness are common. Liver and renal dysfunction, costochondral abnormalities (scapular squaring, anterior rib cupping, flared costochondral junctions), and pulmonary alveolar proteinosis (due to dysfunction of alveolar macrophages) have also been frequently reported. Patients with ADA deficiency are at increased risk of Epstein-Barr Virus (EBV)-associated lymphoma and of multicentric dermatofibrosarcoma protuberans.[9]

Hypomorphic *ADA* mutations are often associated with a delayed and less severe clinical, immunological, and metabolic phenotype.[9] Somatic mosaicism with gene reversion or second-site mutations that restore (fully or in part) ADA activity and lymphocyte survival have been identified as another reason for milder clinical presentations. Immune dysregulation, with eczema, type 1 diabetes, other autoimmune manifestations, and hepatosplenomegaly, may occur in patients with residual ADA function.

Null *ADA* gene mutations are associated with low to undetectable levels of TRECs upon newborn screening. Hypomorphic variants allowing residual development of T cells may escape identification by newborn screening with TREC quantification but can potentially be correctly identified by tandem mass spectrometry, although this is not widely performed at present.[11] Measurement of ADA enzymatic activity and of dAdo and dAXP levels in erythrocytes represents the gold standard for diagnosis. However, if the patient has received red cell transfusions, measurement of ADA activity and of levels of toxic metabolites should be performed on other cell types, such as peripheral blood mononuclear cells. Mutation analysis provides definitive confirmation.

HSCT and gene therapy represent efficacious definitive therapies for ADA deficiency[12] and are discussed in Chapters 90 and 91. ERT with intramuscular injections of bovine recombinant

ADA conjugated with polyethylene glycol (PEG-ADA) allows rapid detoxification and is often used as a bridge therapy between diagnosis and definitive therapy. Improvement of T- and B-cell count and function has been observed in approximately 80% of the patients treated with ERT, although persistent lymphopenia and progressive decline of immune function over time have been reported in most of them.

Reticular Dysgenesis

Reticular dysgenesis (OMIM *267500) is an autosomal recessive form of SCID, characterized by extreme lymphopenia, absence of neutrophils, and sensorineural deafness.[13] The disease is caused by mutations of the adenylate kinase 2 (*AK2*) gene that result in apoptosis of myeloid precursors of neutrophils and of lymphoid progenitor cells. Hypomorphic mutations that allow residual lymphopoiesis and granulopoiesis are associated with atypical presentations, including generalized erythroderma suggestive of Omenn syndrome, autoimmunity, or isolated hypogammaglobulinemia. HSCT represents the only available treatment.[13,14]

SCID DUE TO DEFECTS OF CYTOKINE-MEDIATED SIGNALING

X-Linked Severe Combined Immune Deficiency

X-linked SCID (OMIM *300400) is the most common form of typical SCID. It affects only males as it is caused by hemizygous mutations of the X-linked *IL2RG* gene, encoding the membrane-spanning common gamma chain (γ_c), shared by the cytokine receptors for interleukin (IL)-2, IL-4, IL-7, IL-9, IL-15, and IL-21 (Fig. 34.3).[15] Proliferation of thymic T-cell progenitors depends on IL-7, and NK-cell development requires IL-15.[16] Consequently, patients with X-linked SCID manifest a T^- B^+ NK^- phenotype. Moreover, while human B-cell development is spared in patients with X-linked SCID, B-cell function is defective because IL-21 is required for plasmablast differentiation.[17] Surface γ_c expression is abolished in patients with null *IL2RG* mutations but may be preserved in those with missense variants or truncations of the terminal exons encoding the intracellular domains of the molecule.

Most patients with X-linked SCID present with typical manifestations of SCID starting in the first months of life.[2] Their thymi are severely atrophic and not visible by imaging studies. However, milder clinical features and delayed clinical onset, associated with preserved presence of T and/or NK cells (consistent with atypical SCID) and partially preserved thymic architecture, have been reported in unusual patients with hypomorphic mutations or with somatic gene revertants. In the latter, revertant T cells may persist for up to several years.[2] Carrier females are asymptomatic and display nonrandom X-chromosome inactivation in T and NK cells.

Treatment of X-linked SCID requires allogeneic HSCT (see Chapter 90) or transplantation of autologous gene-corrected cells (see Chapter 91). Very promising results have been recorded also after gene therapy in both infants and older patients who had failed previous attempts with HSCT for X-linked SCID.[18]

Interleukin-7 Receptor Deficiency

Autosomal recessive interleukin-7 receptor (IL-7R) deficiency[2] (OMIM *146661) is characterized by a T^- B^+ NK^+ phenotype, reflecting the critical role played by IL-7 in thymocyte survival and proliferation. Clinical manifestations are typical of SCID. Treatment is allogeneic HSCT.

JAK3 Deficiency

All of the γ_c-containing cytokine receptors depend on Janus-associated kinases (JAKs) for signaling (see Fig. 34.3). In particular, the γ_c is constitutively associated with JAK3. Accordingly, autosomal recessive JAK3 deficiency (OMIM *600802) shares similar clinical and laboratory features with X-linked SCID, but due to the gene location on chromosome 19 instead of the X chromosome, homozygous or compound heterozygous mutations affect females as well as males. Patients present early in life with typical features of SCID and manifest a T^- B^+ NK^- phenotype.[19] Atypical forms, including delayed-onset disease and presentation with severe warts and increased risk of lymphoma, have been reported in patients with hypomorphic mutations.[2]

SCID DUE TO DEFECTS OF V(D)J RECOMBINATION

Expression of antigen-specific receptors on the surface of T and B lymphocytes depends on rearrangement and ligation of the variable (V), diversity (D), and joining (J) gene segments of the TCR and immunoglobulin loci by V(D)J recombination (Chapters 4, 7 and 9). Any of several gene defects may impair this process, causing T^- B^- SCID.

Defects of Recombination Activating Genes (RAG) 1 and RAG2

RAG1 and RAG2 are lymphoid-specific proteins that form a heterotetramer (with two subunits of each protein). They recognize recombination signal sequences that flank the *V*, *D*, and *J* gene elements and introduce DNA breaks at the TCR and immunoglobulin loci, thereby initiating V(D)J recombination.[20] RAG1 and RAG2 deficiencies are inherited as autosomal recessive traits and account for approximately 20% of all cases of SCID.[8] Patients with null mutations in these genes manifest T^- B^- NK^+ SCID and suffer from typical early-onset clinical features. However, hypomorphic mutations allowing residual generation of T (and in some cases, B) cells are associated with a spectrum of clinical phenotypes that includes Omenn syndrome, atypical SCID, and combined immunodeficiency with granulomas and/or autoimmunity (CID-G/AI).[21] In particular, Omenn syndrome is characterized by generalized erythroderma, hepatosplenomegaly, and lymphadenopathy. Immunological features of the disease include a variable number of autologous, oligoclonal T cells with an activated phenotype that infiltrate the skin and other target organs. Eosinophilia, hypogammaglobulinemia, and elevated serum IgE (despite profound hypogammaglobulinemia) are prominent features of immune dysregulation. While hypomorphic *RAG* mutations are the most common cause of Omenn syndrome, genetic defects in other SCID-associated genes that drastically reduce (but do not completely abrogate) the capacity to generate T cells may also cause the syndrome. When Omenn syndrome is caused by *RAG* defects, circulating B cells are absent or markedly reduced in number. Autoimmune manifestations (in particular, autoimmune hemolytic anemia) may occur in patients with RAG deficiency manifesting as atypical SCID. A subset of these patients develops an expansion of $TCR\gamma\delta^+$ T cells after CMV infection, and increased risk of EBV-induced lymphoproliferation has been reported. In contrast to patients

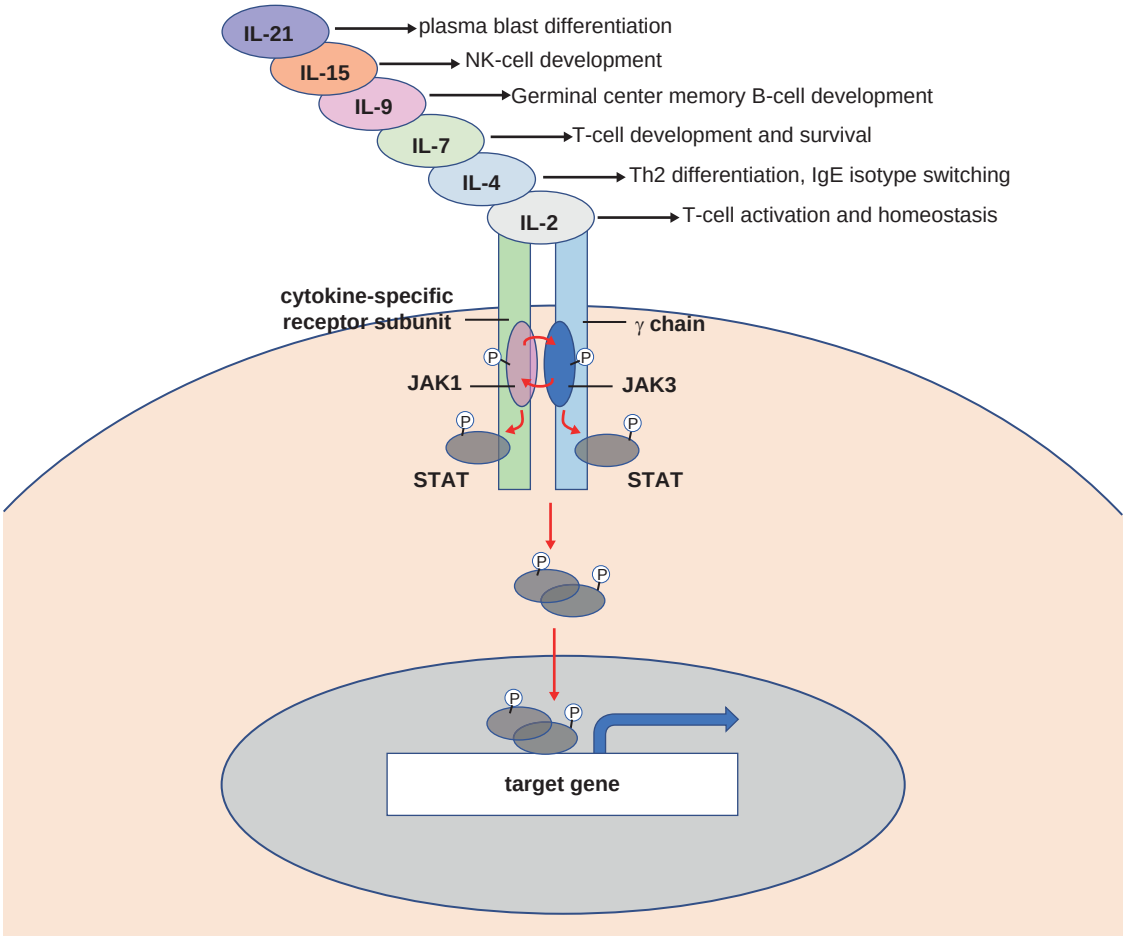

FIG. 34.3 Functional Role of Cytokines Signaling Through the γc//JAK/STAT Pathway. Cytokine receptor engagement triggers cross-phosphorylation and activation of the JAK proteins, allowing phosphorylation of the cytokine receptor chain and docking of the STAT proteins. The JAK proteins also mediate phosphorylation of the STAT proteins, which dimerize and translocate to the nucleus, inducing transcription of cytokine-responsive genes. *JAK*, Janus-associated kinase; *STAT*, signal transducer and activator of transcription.

with T^- B^- NK^+ SCID, Omenn syndrome, or atypical SCID, those with CID-G/AI may present later in life (even in adulthood). Autoimmune cytopenias, organ-specific autoimmunity, and granulomas involving the skin or other organs are typical manifestations.[22] The autoimmunity is secondary to defects of negative selection of self-reactive T cells and impaired Treg generation in the thymus, as well as to defective receptor editing, a process mediated by RAG gene re-expression in the bone marrow and that allows to purge the developing B-cell repertoire from self-reactive specificities. Presence of the rubella virus vaccine strain has been documented in the granulomas of several patients with CID-G/AI; this phenomenon is not unique to patients with hypomorphic RAG defects, but can also be observed in patients with various forms of combined immune deficiency.[23] Because patients with CID-G/AI have a variable number of T and B cells and variable hypogammaglobulinemia, the diagnosis is often delayed. Furthermore, while the TREC assay at birth identifies patients with RAG mutations manifesting as SCID or Omenn syndrome, it is unclear to what extent it also detects patients with CID-G/AI, whose RAG mutations often support levels of recombination activity that allows generation of a relatively diversified repertoire of T cells. Treatment of RAG deficiency is based on HSCT, but chemotherapy and serotherapy may be needed to attain durable stem cell engraftment and immune reconstitution.[24] The autoimmune and inflammatory manifestations of CID-G/AI are often refractory to medical management but tend to resolve after HSCT.

ARTEMIS Deficiency

ARTEMIS, encoded by the *DCLRE1C* gene, is required to open the hairpins that seal the DNA broken ends generated by RAG proteins during V(D)J recombination. This triggers the interventions of several other proteins involved in DNA repair. ARTEMIS deficiency (OMIM *605988) is an autosomal recessive form of T^- B^- NK^+ SCID.[2,25] Besides typical manifestations of SCID, oral and genital ulcers are common. In addition, patients with ARTEMIS deficiency manifest a generalized cellular radiosensitivity, and when exposed to ionizing radiation or alkylating agents they are at high risk of serious complications, including growth failure, malabsorption requiring parenteral nutrition, endocrine abnormalities, renal disease, and dental problems. Patients with hypomorphic *DCLRE1C* are at increased risk of EBV-driven lymphoma and may develop granulomas. HSCT represents the mainstay of treatment, but caution must be used in the choice and tissue exposure of agents for conditioning. A clinical trial of gene therapy is currently under way.

CLINICAL RELEVANCE

T-cell Immunodeficiencies With Radiation Sensitivity

Clinical features and management strategies:

- Gene defects that affect DNA repair are responsible for severe combined immune deficiency (SCID) and other combined immunodeficiencies associated with increased cellular radiosensitivity
- Besides an increased risk of infections, these disorders are often characterized by other clinical features, including microcephaly, growth retardation, neurodevelopmental delay and other neurological signs, accelerated aging, bone marrow failure, and increased rate of malignancies
- Genetic tests and in vitro radiosensitivity assays are the mainstays of diagnosis
- Exposure to ionizing radiation and to alkylating agents carries serious risks in patients with radiosensitive T-cell disorders and should be avoided unless strictly necessary
- Radiosensitive SCID can be cured with hematopoietic stem cell transplantation. However, patients remain at risk of some complications (short stature, tooth problems, malabsorption) as the result of cell damage in non-hematopoietic tissues and of the use of chemotherapeutic agents

DNA-PKcs Deficiency

The DNA-dependent protein kinase catalytic subunit (DNA-PKcs), encoded by the *PRKDC* gene, is involved in the non-homologous end-joining (NHEJ) pathway of DNA repair. Deficiency of DNA-PKcs (OMIM #615966) is inherited as an autosomal recessive trait and is characterized by T^- B^- NK^+ SCID associated with cellular radiosensitivity.[25] Neurodevelopmental delay has been reported in some patients. Hypomorphic mutations may cause atypical SCID and autoimmunity. HSCT can cure the immunodeficiency, but use of alkylating agents should be avoided.

DNA Ligase IV Deficiency

DNA ligase IV is another component of the NHEJ DNA repair pathway. Deficiency of this enzyme (OMIM #606593) causes autosomal recessive T^- B^- NK^+ SCID, associated with microcephaly, developmental delay, and an increased risk of bone marrow failure and hematological malignancies.[25] Hypomorphic variants are associated with milder cellular defects, contributing to significant variability of the clinical and immunological phenotype.

Cernunnos/XLF Deficiency

Cernunnos deficiency (OMIM #611291), caused by mutations of the *NHEJ1* gene, is another form of autosomal recessive radiosensitive SCID and is characterized by progressive T- and B-cell lymphopenia, microcephaly, and growth retardation.[25]

SCID DUE TO DEFECTS OF THE CD3/TCR COMPLEX

The T-cell receptor heterodimeric (TCRαβ or TCRγδ) molecules are expressed on the surface of T cells in association with CD3γ, CD3δ, CD3ε, and CD3ζ invariant chains. Antigen recognition by the TCR induces activation of the p56Lck kinase, which phosphorylates the CD3 molecules, allowing recruitment and activation of the zeta-associated protein of 70 kDa (ZAP-70). This in turn triggers activation of downstream molecules (LAT, RHOH, STK4, ITK) and initiation of Ca^{2+} flux (Fig. 34.4).

CD3 deficiency includes various genetic defects affecting CD3δ (OMIM *186790), CD3ε (OMIM *186830), and CD3ζ (OMIM *186780), causing a block in thymocyte development leading to T^- B^+ NK^+ SCID.[26] Hypomorphic defects of these genes may cause atypical presentations. In contrast, CD3γ deficiency (OMIM *186740) results in milder T-cell deficiency and variability of the clinical phenotype that often includes autoimmunity.[26]

Deficiency of the linker of activated T cells (LAT) (OMIM *602354) causes T^- B^+ NK^+ SCID;[27] atypical variants with splenomegaly, lymphadenopathy, and autoimmunity have also been reported.

CD45 deficiency (OMIM *151460) is an autosomal recessive form of SCID due to mutations of the CD45 phosphatase involved in signaling. Patients manifest T^- B^+ NK^+ SCID and profound hypogammaglobulinemia.

SCID DUE TO OTHER HEMATOPOIETIC DEFECTS

Coronin-1A Deficiency

Coronin-1A is involved in intracellular signaling, actin cytoskeleton regulation, and cell motility. Deficiency of this protein (OMIM *615401) causes autosomal recessive T^- B^+ NK^+ SCID; hypomorphic mutations have been associated with CD4 T-cell lymphopenia, warts, granulomatous lesions, and an increased risk of EBV-induced lymphoproliferative disease and severe varicella.[28]

RAC2 Gain-of-Function Mutations

Gain-of-function (GOF) mutations of the small GTPase RAC2 cause an autosomal dominant form of SCID (OMIM *602049) with low numbers of T and B cells, as well as neutropenia associated with increased content of F-actin in leukocytes and defective cell migration.[29]

SCID With Multiple Intestinal Atresia

This autosomal recessive condition (OMIM *609332) is due to mutations of the tetratricopeptide repeat domain 7 A (*TTC7A*) gene.[30] The degree of T-cell lymphopenia is variable but is often very severe. The number of circulating B cells may be normal or low, but immunoglobulin serum levels are markedly reduced. Patients are at increased risk of life-threatening bacterial, viral, and fungal infections. Intestinal atresias may affect multiple areas of the gastrointestinal tract. There is a high mortality rate early in life. HSCT may correct the immune defect but not the gastrointestinal manifestations.

Veno-Occlusive Disease With Immunodeficiency

Veno-occlusive disease with immunodeficiency (VODI) (OMIM #235550) is an autosomal recessive disease characterized by liver abnormalities (veno-occlusive disease, fibrosis, often progressing to liver failure) and immunodeficiency, with onset in the first months of life.[31] Patients are prone to recurrent infections with viruses, bacteria, and opportunistic pathogens (*P. jirovecii, Candida*, CMV). Thrombocytopenia is frequent. Immunological defects include low number of memory T and B lymphocytes, defective B-cell differentiation in vitro into antibody-secreting cells, and hypogammaglobulinemia.[31] The disease is caused by mutations of the *SP110* gene, which encodes a nuclear body protein that acts as a transcription factor. The prognosis is dismal. HSCT is the only curative approach, but there is a high risk of severe liver toxicity due to conditioning.[32]

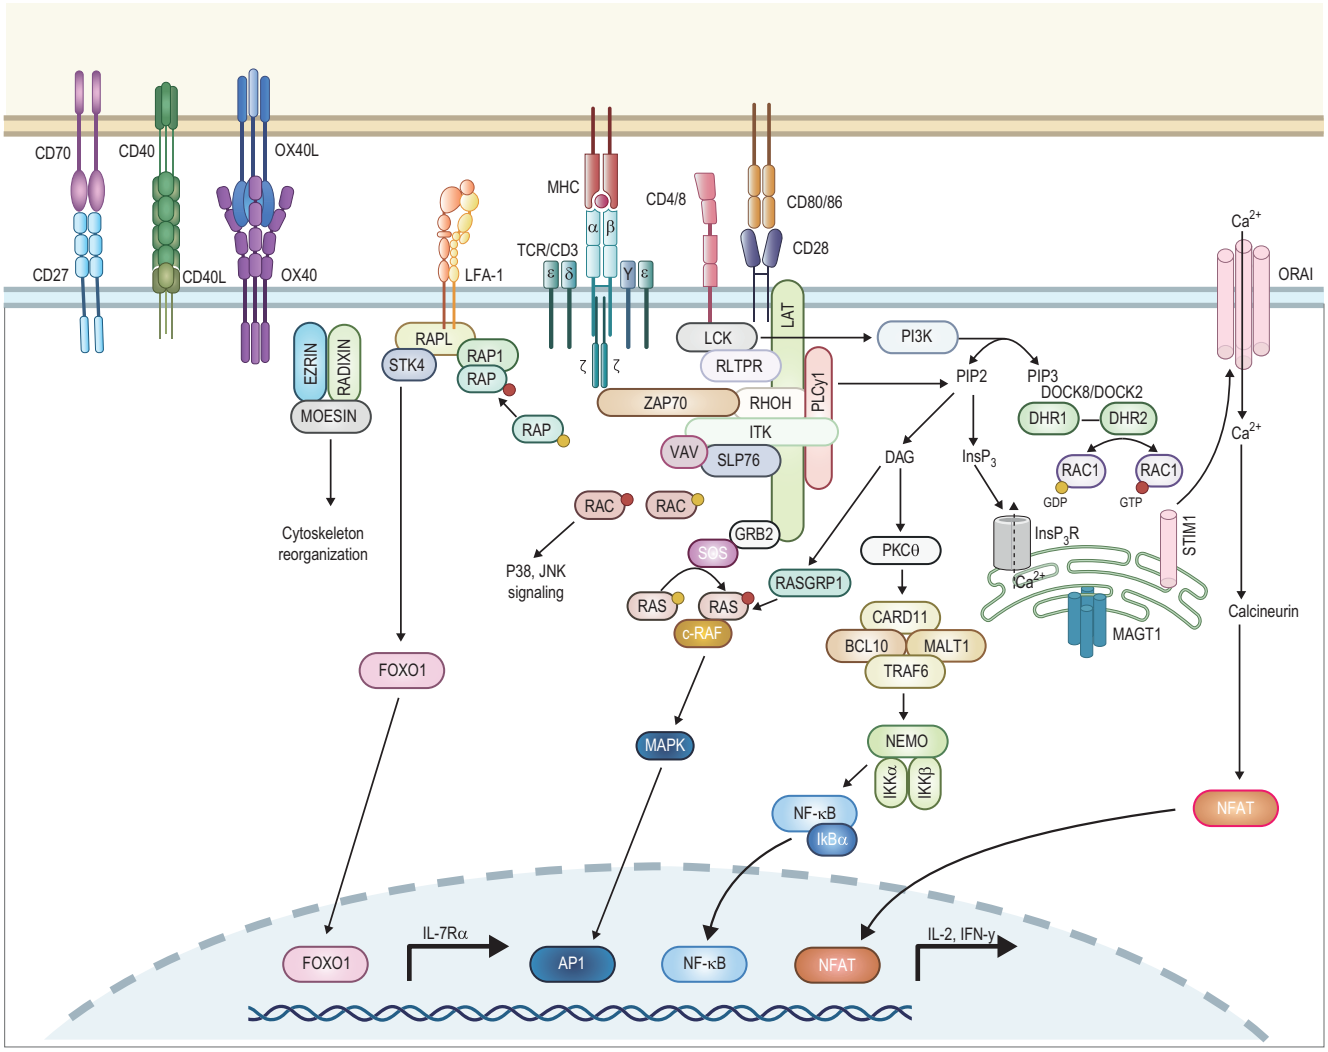

FIG. 34.4 Schematic Representation of Tcr-Mediated Intracellular Signaling and of Receptor/Ligand Pairs That Participate at T-Cell Activation. Activation of T cells through the T-cell receptor *(TCR)* induces a signaling cascade that ultimately results in cytoskeleton reorganization, calcium flux, and activation of transcription factors that drive expression of target genes. CD27, CD40LG, and OX40 are T-cell surface molecules that interact with counter-receptors expressed by other cell types (B cells, dendritic cells, monocyte/macrophages) and contribute to T-cell activation. Several forms of T-cell immunodeficiency are due to mutations of the genes encoding molecules involved in T-cell activation. *AP-1*, Activator protein 1; *BCL10*, B-cell lymphoma/leukemia 10; *CARD11*, caspase recruitment domain family member 11; *DAG*, diacylglycerol; *DHR1/2*, Dock homology region 1/2; *DOCK2*, dedicator of cytokinesis 2; *DOCK8*, dedicator of cytokinesis 8; *GRB2*, growth factor receptor bound protein 2; *IKBα*, inhibitory subunit of NF-κB α; *IKKα*, IκB kinase α; *IKKβ*, IκB kinase β; *$InsP_3$*, inositol 1,4,5-trisphosphate; *$InsP_3R$*, $InsP_3$ receptor; *ITK*, interleukin-2 induced tyrosine kinase; *LAT*, linker of activated T cells; *LCK*, lymphocyte-specific protein tyrosine kinase; *LFA-1* lymphocyte function-associated antigen 1; *MAGT1*, magnesium transporter 1; *MALT1*, mucosa-associated lymphoid tissue lymphoma translocation protein 1; *MAPK*, mitogen-activated protein kinase; *MHC*, major histocompatibility complex; *NEMO*, NF-κB essential modulator; *NFAT*, nuclear factor of activated T cells; *NF-κB*, nuclear factor-κB; *PI3K*, phosphoinositide 3-kinase; *PIP2*, phosphatidylinositol 4,5-bisphosphate; *PIP3*, phosphatidylinositol (3,4,5)-trisphosphate; *PLCγ1*, phospholipase C-γ1; *RAP*, ras-related protein; *RAPL*, regulator of adhesion and polarization enriched in lymphocytes; *RASGRP1*, Ras guanyl releasing protein 1; *RHOH*, Ras homolog family member H; *RLTPR*, RGD-leucin-rich repeat, tropomodulin domain, and proline-rich domain-containing protein; *SLP76*, SH2 domain-containing leukocyte protein of 76 kDa; *SOS*, son of sevenless; *STIM1*, stromal interaction molecule 1; *STK4*, serine/threonine kinase 4; *TCR*, T-cell receptor; *TRAF6*, tumor necrosis factor receptor-associated protein 6; *ZAP-70*, zeta-associated protein of 70 kDa.

SCID DUE NON-HEMATOPOIETIC DEFECTS

Although the vast majority of patients with SCID harbor gene defects that affect hematopoietic and lymphoid development, extra-hematopoietic defects, and in particular defects of thymus development, may also cause severe T-cell lymphopenia at birth. Establishing a correct diagnosis is important because the latter group of patients do not benefit from HSCT but may respond to implantation of thymus tissue from a suitable donor source. In vitro assays analyzing the T-cell differentiation potential of hematopoietic stem cells help to distinguish between hematopoietic cell-autonomous and extra-hematopoietic causes of SCID.[33]

Complete DiGeorge Syndrome

DiGeorge syndrome (DGS) (OMIM #188400) is a multisystem developmental disorder characterized by the triad of congenital heart disease, immunodeficiency and hypoparathyroidism, stemming from defects in tissues derived from the fetal branchial arch and pouch structures. Congenital defects of the cardiac outflow tract include interrupted aortic arch type B and truncus arteriosus; hypocalcemia is due to parathyroid insufficiency, and immunodeficiency is secondary to thymus aplasia or hypoplasia.[34] Other features include developmental disabilities and renal and craniofacial anomalies, including micrognathia, hypertelorism, downward slanting eyes, and ear malformations. However, there is significant phenotypic variability. A third of DGS patients have velopharyngeal incompetence, leading to feeding difficulties and speech delay; 10% have a cleft palate. As young adults, many DGS patients develop social, behavioral, and psychiatric problems. In most cases, DGS is due to a heterozygous interstitial deletion of chromosome 22q11.2. However, approximately 2% of the patients have small deletions in chromosome 10p, and others have intragenic mutations resulting in haploinsufficiency of the *TBX1* gene, located in the DiGeorge minimal deletion region of 22q11.2.

There is a high incidence of autoimmune diseases, such as cytopenia and thyroiditis in DGS, reflecting perturbed thymic architecture and a reduced number of regulatory T cells. Around 20% of DGS patients have naïve T-cell lymphopenia in infancy, with those at the lowest end of the lymphopenic spectrum detected with low TREC levels upon newborn screening. According to the severity of the immunodeficiency, "partial" and "complete" forms of the disease are recognized. Patients with "partial DGS" have a low T-cell count but with residual (>50 cells/μL) naïve T cells. In contrast, approximately 1% of all cases have "complete DGS" with virtual absence of naïve T cells, thereby mirroring what is observed in SCID. The term "complete atypical DGS" refers to oligoclonal expansion of activated T cells in patients with DGS infiltrating various tissues, often associated with clinical manifestations of Omenn syndrome. Cardiovascular anomalies require prompt attention and appropriate medical treatment of hypocalcemia. Experimental thymus implants have become the treatment of choice for patients with complete typical or complete atypical DGS.[35]

CHARGE Syndrome

Coloboma, Heart defects, Atresia of the choanae, Retarded growth, Genital hypoplasia, and Ear anomalies (CHARGE) syndrome is caused by heterozygous mutations of the *CHD7* or the *SEMA3E* genes (OMIM *608892, 608166) that may also affect thymus development. The number and function of T cells may be reduced, such that some patients meet criteria for SCID.[36]

FOXN1 Deficiency

The FOXN1 transcription factor plays a critical role in development of thymic epithelial cells and hair follicles and in regulation of keratin expression. Biallelic *FOXN1* mutations cause thymic aplasia, alopecia totalis, and nail dystrophy (OMIM *601705). The T-cell count at birth is often very low, consistent with a SCID phenotype. In rare cases, the disease may manifest with only immunodeficiency. Heterozygous loss-of-function *FOXN1* mutations may also cause T-cell lymphopenia which, however, is less severe and tends to improve with time.[37]

PAX1 Deficiency

PAX1 is a transcription factor involved in differentiation of the third and fourth pharyngeal pouches. PAX1 deficiency causes a syndromic form of SCID with impaired thymus development associated with ear, facial, and vertebral defects (OMIM *615560). Some patients manifest an Omenn syndrome phenotype.[38]

COMBINED IMMUNE DEFICIENCY—DEFINITION

According to criteria defined by the European Society for Immune Deficiencies, genetically determined combined immune deficiency (CID) comprises a heterogeneous group of conditions characterized by reduced (but not absent) number and/or function of T and B lymphocytes, associated with infections and/or clinical features of immune dysregulation, such as autoimmunity, lymphoproliferation and granuloma formation and/or occurrence of malignancies (Table 34.3).[39] However, it should be noted that these criteria also require exclusion of syndromic disorders associated with impaired T-cell function, such as ataxia telangiectasia (A-T) and cartilage hair hypoplasia (CHH), and yet these conditions are often associated with laboratory and clinical features of CID. Therefore, they are also discussed in this chapter. As compared to infants with SCID, patients with CID often present with later onset (beyond 1-year of age). Poor control of viral infections is a common feature. Along with hypomorphic defects in SCID-associated genes allowing

KEY CONCEPTS

Combined Immunodeficiencies

- Combined immunodeficiencies include a heterogeneous group of conditions with numerical and/or functional defects of T cells. The T-cell lymphopenia (>300 cells/μL) is less severe than in patients with SCID
- Chronic viral infections (EBV, CMV, HPV, molluscum) are particularly common and may be a cause of lymphoproliferative disease and malignancies (lymphoma, squamous cell carcinoma)
- Autoimmune manifestations (cytopenias in particular) and other manifestations of immune dysregulation (granulomas, elevated serum IgE) are also frequent and indicate abnormalities of T-cell homeostasis
- Flow-cytometric analysis of total T cells and of naïve and memory T-cell subsets is an essential test in the diagnosis of combined immunodeficiencies.
- Enumeration of T-cell receptor excision circles (TRECs) in dried blood spots collected at birth detects some, but not all, cases of combined immunodeficiency
- Functional assays, such as in vitro proliferation to mitogens and antigens, are valuable tools in the characterization of the severity of the disease. Other tests, such as cellular radiosensitivity, cytokine expression, regulatory T-cell function, and analysis of T-cell repertoire diversity, may contribute to the diagnosis in selected cases.
- Flow cytometry and Western blotting may be used to investigate expression of specific proteins associated with individual forms of T-cell immunodeficiency. However, while lack of protein expression may contribute to the diagnosis, demonstration of preserved protein expression cannot be used to rule out the diagnosis, because many cases of T-cell immunodeficiencies are due to hypomorphic mutations
- Ultimately, genetic diagnosis permits definitive diagnosis. T-cell immunodeficiency gene panels, whole exome sequencing, and whole genome sequencing are valuable strategies to achieve genetic diagnosis. However, the potential impact of the genetic variants detected must be critically assessed
- Many forms of combined immunodeficiency can be cured with hematopoietic stem cell transplantation. Use of a conditioning regimen is required to attain robust and durable donor stem cell engraftment and immune reconstitution

CMV, Cytomegalovirus; SCID, severe combined immune deficiency.

TABLE 34.3 Diagnostic Criteria of Combined Immune Deficiency (CID) Elaborated by the European Society for Immune Deficiencies (ESID)[39]

At least one of the following:
- At least one severe infection (requiring hospitalization)
- One manifestation of immune dysregulation (autoimmunity, IBD, severe eczema, lymphoproliferation, granuloma)
- Malignancy
- Affected family member

AND 2 of 4 T-cell criteria fulfilled:
- Reduced CD3 or CD4 or CD8 T-cell count (using age-related reference values)
- Reduced naïve CD4 and/or CD^+ T cells
- Elevated TCRγδ T cells
- Reduced proliferation to mitogen or TCR stimulation

AND HIV infection excluded

AND exclusion of a clinical diagnosis associated with CID (e.g., defined syndromic disease, such as dyskeratosis congenita, ataxia-telangiectasia, cartilage hair hypoplasia)

From: Seidel MG, Kindle G, Gathmann B, et al. The European Society for Immunodeficiencies (ESID) Registry Working Definitions for the Clinical Diagnosis of Inborn Errors of Immunity. *J Allergy Clin Immunol Pract.* 2019;7(6):1763–1770.

development of a low number of T cells, a growing number of gene defects that partially compromise T-cell differentiation and/or function, causing CID, have been described.[1]

CID DUE TO METABOLIC DEFECTS

Purine Nucleoside Phosphorylase Deficiency

Purine nucleoside phosphorylase (PNP), an enzyme of the purine salvage pathway, catalyzes the phosphorylation of inosine, guanosine, and deoxyguanosine.[40] In the absence of PNP, high intracellular levels of deoxyguanosine triphosphatase cause lymphoid and neuronal toxicity. Immature thymocytes are particularly susceptible to PNP deficiency. PNP deficiency (OMIM *613179) is inherited as an autosomal recessive trait. Its immunological phenotype is characterized by decreased T-cell counts, causing increased risk of infections. Compared to infants with ADA deficiency, patients with PNP deficiency tend to present after 1 year of age. Bacterial, fungal, and in particular viral infections are common. There is an increased risk of non-Hodgkin lymphoma. Although development of B and NK lymphocytes is often unaffected, there is an increased risk of severe autoimmune hemolytic anemia. Neurodevelopmental delay, hypotonia, and spasticity are frequent and may develop even before immune problems. HSCT represents the only curative option for the immune phenotype, but it is not expected to rescue the neurological phenotype.

Cytidine 5-Triphosphate Synthase 1 Deficiency

Cytidine 5-triphosphate synthase 1 (CTPS1) is involved in de novo synthesis of cytidine 5-triphosphate (CTP), a nucleotide required for DNA and RNA metabolism. CTPS1 expression is upregulated following TCR stimulation. *CTPS1* mutations (OMIM #615897) have been identified in several infants from Northwestern England, who manifested severe bacterial and viral infections since early in life, and an increased risk of EBV-driven non-Hodgkin lymphoma. CD4 T-cell lymphopenia, increased proportion of effector memory T cells, and reduced in vitro proliferation to mitogens and antigens have been reported.[41]

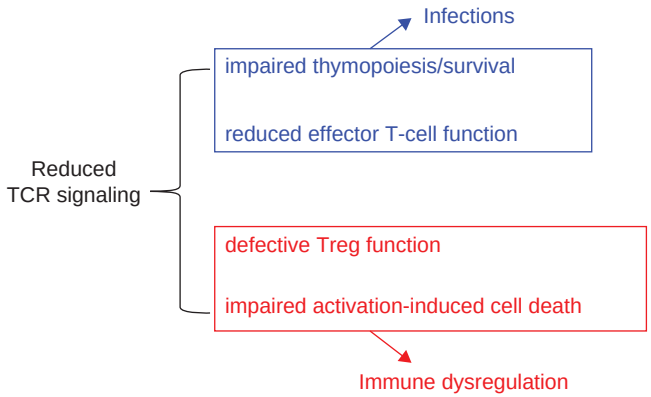

FIG. 34.5 Mechanisms of Increased Susceptibility to Infections and Autoimmunity in Patients with Defects of T-Cell Receptor Signaling.

CID Due to Defects of TCR-Mediated Signaling

Several forms of CID are due to genetic defects that impair intracellular signaling, and in particular signaling through the CD3/TCR complex (see Fig. 34.4). In these disorders, reduced signaling through the pre-TCR and the TCR may compromise generation of a diversified repertoire of T cells in the thymus and impair effector T-cell responses in the periphery, contributing to increased susceptibility to infections. Chronic viral infections (CMV, EBV) are particularly common and may cause lymphoproliferative disease and lymphoma. At the same time, reduced TCR signaling is also responsible for defective Treg function and impaired activation-induced cell death, which result in an increased rate of autoimmune manifestations (Fig. 34.5).

Deficiency of the Zeta-Associated Protein of 70 kDa (ZAP-70)

The ZAP-70 protein plays a critical role in TCR-mediated signaling.[42] Upon TCR ligation, ZAP-70 is recruited to the phosphorylated ITAM motifs of the CD3ζ chain and is itself phosphorylated by LCK. This process induces ZAP-70 kinase activity, permitting phosphorylation of various downstream molecules, including SLP-76, LAT, and PLC-γ1. ZAP-70 deficiency (OMIM *269840) is inherited as an autosomal recessive trait.[43] Clinical manifestations include life-threatening infections of bacterial, viral, and fungal origin beginning early in life, reminiscent of SCID. Some patients manifest with skin rash that may be severe, mirroring Omenn syndrome. A peculiar phenotype predominantly characterized by autoimmunity has been reported in patients in whom one of the alleles carried a gain-of-function mutation.

The typical immunological phenotype of ZAP-70 deficiency includes lack or markedly reduced number of CD8 T cells. CD4 T cells are present in normal number, but in vitro T-cell proliferation to mitogens and antigens is profoundly impaired. The differential diagnosis is with major histocompatibility complex (MHC) class I deficiency and CD8α deficiency, two conditions that are also characterized by a severe reduction of CD8 T cells. Treatment is based on HSCT.

LCK Deficiency

TCR ligation promotes activation of the p56Lck kinase, which mediates phosphorylation of components of the CD3 complex, initiating TCR-mediated signal transduction. LCK deficiency

(OMIM *615758) is a rare cause of CID manifesting with infections, autoimmune cytopenias, and vasculitis, associated with a low CD4 T-cell count and impaired T-cell function.

Deficiency of the IL-2 Inducible Tyrosine Kinase (ITK)

ITK participates in TCR signaling by inducing phosphorylation of PLC-γ1, thereby generating second messengers that activate protein kinase C (PKC), allowing Ca^{2+} release. ITK deficiency (OMIM *186973) is inherited as an autosomal recessive trait. The immunological phenotype is characterized by progressive CD4 T-cell lymphopenia and decreased T-cell function, contributing to a high rate of EBV infection and lymphoproliferative disease, including non-Hodgkin lymphoma in addition to respiratory tract infections. Hypogammaglobulinemia is common.[44]

STK4 Deficiency

STK4 is a kinase that activates various transcription factors, regulating cell survival and proliferation. STK4 deficiency (OMIM *614868) is an autosomal recessive form of CID characterized by recurrent bacterial and viral (Human Papilloma Virus (HPV), EBV, varicella-zoster virus [VZV], molluscum) infections, mucocutaneous candidiasis, lymphoproliferation, autoimmune cytopenias, and increased risk of lymphoma. Congenital heart disease and intermittent neutropenia are other common findings. Immunological abnormalities include CD4 T-cell lymphopenia with a low proportion of naïve T cells and impaired T-cell function.

RHOH Deficiency

RHOH is a small GTPase involved in signal transduction. RHOH deficiency (OMIM *602037) is characterized by increased susceptibility to HPV infection (causing epidermodysplasia verruciformis), recurrent pneumonia, and a higher risk of Burkitt lymphoma. Naïve T-cell lymphopenia, oligoclonal representation of the T-cell repertoire, and decreased T-cell function are typical immunological findings.[44]

T-Cell Receptor α Constant (TRAC) Chain Deficiency

Biallelic mutations of the T-cell receptor α constant chain gene (*TRAC*) cause TRAC deficiency (OMIM #615387), a rare form of SCID characterized by markedly reduced levels of the TCRαβ complex on the surface of T cells.[45] In addition to infections, immune dysregulation (with eczema, eosinophilia) and autoimmunity have been reported.

CID Due to Defects of Nuclear Factor-κB (NF-κB) Signaling

Following TCR signaling, the complex composed of caspase recruitment domain-containing protein (CARD)-11, BCL-10 and MALT1 proteins (CBM complex) is activated, permitting recruitment of TRAF6 and activation of IKK, leading to nuclear translocation of the p50 and p65 subunits of NF-κB and expression of NF-κB–dependent genes. Defects of the CBM complex due to biallelic loss-of function mutations of any one of the *MALT1*, *CARD11*, and *BCL10* genes (OMIM #615469, 615206, 616098) are associated with increased susceptibility to bacterial, viral and fungal infections.[46] Although the number of circulating T lymphocytes is normal, generation of memory T cells is impaired and proliferative responses to CD3 stimulation are decreased. Patients with *CARD11* mutations have a block in B-cell development at the transitional stage. Autosomal dominant CARD11 dominant negative mutations (OMIM #617638) are a cause of CID with bacterial and viral infections, early-onset atopic disease, and autoimmune cytopenias. Immunological abnormalities include skewing to Th2 cells and defective T-cell activation.[46] In contrast, autosomal dominant gain of function CARD11 mutations (OMIM #616452) cause hyperactivation of NF-κB, leading to a phenotype that is distinct from CID and is characterized by B-cell lymphocytosis, splenomegaly, and lymphadenopathy. In vitro T-cell activation through the TCR is reduced, and susceptibility to infections is variable.

The NF-κB family of proteins is composed of five members: NF-κB1 (p105), NF-κB2 (p100), RelA, RelB, and c-Rel.[47] Upon cleavage, the p105 and p100 proteins generate p50 and p52, which are involved in the canonical and noncanonical pathway of NF-kB activation, respectively, by forming a heterodimer with one of the Rel proteins. In the canonical pathway, the NF-κB heterodimer is kept in the cytoplasm by the IκBα protein. Following phosphorylation by the IKK kinase, IκBα is degraded upon phosphorylation by the IKK kinase, and NF-κB can translocate to the nucleus, inducing expression of target genes. The IKK complex is composed of two catalytic subunits (IKK-α and IKK-β, encoded by the *IKBKA* and *IKBKB* genes) and by the regulatory subunit IKK-γ (also known as NEMO), encoded by the *IKBKG* gene. Mutations of *IKBKG* cause an X-linked immunodeficiency characterized by recurrent infections, variable antibody responses, anhidrotic ectodermal dysplasia, and—in some cases—lymphedema or osteopetrosis (OMIM #300291).[48,49] The infections associated with this condition may be sustained by various pathogens, including pyogenic bacteria, viruses, and fungi. *Mycobacterium avium* and *M. kansasii* infections have been reported in up to 40% of the patients. Inflammatory manifestations are common, especially in the gastrointestinal tract.

Autosomal recessive IKBKB deficiency (OMIM #615592) manifests with early-onset severe infections sustained by various bacterial mycobacterial, viral, and fungal pathogens.[50] T and B cells exhibit uniquely a naïve phenotype. Low in vitro T-cell proliferation to mitogens and hypogammaglobulinemia are other typical features.

Autosomal dominant gain-of-function IKBKB mutations (OMIM #618204) cause increased phosphorylation of IKB-α, and therefore enhanced NF-κB activity. The clinical phenotype includes recurrent and severe infections, immune dysregulation, and signs of ectodermal dysplasia. T-cell lymphopenia, impaired generation of memory T and B cells, hypogammaglobulinemia, and defective antibody responses are the main immunological abnormalities.[51]

Heterozygous, gain-of-function mutations of the *IKBA* gene, that prevent phosphorylation and degradation of the protein, cause defective NF-κB activation and are responsible for a CID with ectodermal dystrophy and immune dysregulation (OMIM #612132).[52] Profound B-cell deficiency, hypogammaglobulinemia, and impaired in vitro T-cell proliferation to mitogens are common immunological abnormalities.

NFKB1 haploinsufficiency (OMIM #616576) is caused by heterozygous mutations that reduce levels and phosphorylation of p105, and therefore also of p50, affecting activation of the NF-κB canonical pathway. The phenotype is more often consistent with common variable immunodeficiency.[53] Autosomal

dominant NFKB2 deficiency (OMIM #615577) is caused by dominant negative mutations that impair processing of the p100 precursor, leading to reduced levels of p52 and defective activation of the NF-κB noncanonical pathway. In addition to a CVID-like phenotype, these patients also manifest adrenal insufficiency and alopecia.[53] Gain-of-function *NFKB2* mutations lead to constitutive activation of NF-κB and manifest with CID (recurrent pneumonia, severe EBV and CMV infections, warts), sclerosing cholangitis, and splenomegaly.[54] Low B-cell number, T-cell lymphocytosis, and hypogammaglobulinemia are the main immunological abnormalities.

Autosomal dominant RELA haploinsufficiency (OMIM #618287) is a rare disease characterized by CD4 T-cell lymphoproliferation (with low proportion of naïve T cells), autoimmune cytopenias, and mucocutaneous ulcers.[53] Autosomal recessive RELB (OMIM #617585) and c-REL deficiencies cause CID with recurrent infections and impaired T-cell diversity and function.[53] Decreased number of naïve T cells and low levels of TRECs have been demonstrated in RELB deficiency, and a low proportion of memory T and B cells and B-cell lymphopenia have been reported in c-REL deficiency.

Finally, NF-κB-inducing kinase (NIK) deficiency is caused by biallelic mutations of the *MAP3K14* gene. Patients suffer from recurrent bacterial, viral, and *Cryptosporidium* infections since childhood, associated with B-cell lymphopenia and decreased memory T cells.[53]

Clinical management of the defects of the NF-κB pathway varies depending on the underlying disease. Immunoglobulin replacement therapy and antimicrobial prophylaxis are required in most patients. However, HSCT is typically required to correct the profound immunodeficiency associated with IKBKB, RELB, and NIK deficiency and with gain-of function *IKBKA* mutations. A special case is represented by X-linked NEMO deficiency, because of the variable severity of the clinical phenotype. Moreover, persistence of inflammatory manifestations (especially of the gastrointestinal tract) has been observed in some of these patients, in spite of donor chimerism and immune reconstitution.

CID DUE TO DEFECTS OF MAJOR HISTOCOMPATIBILITY COMPLEX MOLECULE EXPRESSION

Expression of MHC class I and class II molecules is essential for positive selection of CD8 and CD4 cells, respectively, and for the development of adaptive immune responses.

MHC class I deficiency (OMIM *604571) is inherited as an autosomal recessive trait and may be caused by defects in the genes encoding the Transporter associated with Antigen Processing 1 (TAP1) and TAP2, the TAP-binding protein (TABP) TAPASIN, or in the β_2-microglobulin (*B2M*) gene.[55] These defects interfere with intracellular transport of peptide antigens, their loading onto MHC class I molecules, and with cell-surface expression of the complex. The clinical phenotype includes recurrent respiratory infections, chronic inflammatory lung disease, and ulcerative skin lesions with necrotizing granulomas. Glomerulonephritis and herpes zoster infections have been reported in TAPASIN deficiency. The number of circulating CD8 T cells is reduced, but in vitro T-cell proliferation is normal, which facilitates differential diagnosis with ZAP-70 deficiency. Treatment is largely based on supportive interventions. Treatment is supportive. Immunosuppressive drugs may worsen the disease manifestations and should be avoided.

MHC class II deficiency includes autosomal recessive conditions due to defects in genes (*CIITA, RFXANK, RFX5,* and *RFXAP*) that encode transcription factors and regulators that bind to the proximal promoters of the MHC class II genes, allowing their expression. The disease manifests early in life with increased susceptibility to bacterial, viral, and opportunistic respiratory tract infections. Chronic diarrhea and sclerosing cholangitis, often secondary to *Cryptosporidium* or CMV infection, are frequently observed.[55] The number of circulating CD4 T cells is markedly reduced. Hypogammaglobulinemia and poor antibody response to immunization antigens are common. Differential diagnoses include HIV infection and idiopathic CD4 lymphopenia; however, in these conditions, expression of MHC class II molecules is preserved. If untreated, most patients die in infancy or childhood. Antibiotic prophylaxis, immunoglobulin replacement therapy, and nutritional support are mainstays of treatment, but the only definitive cure is represented by HSCT. However, results are worse than in other forms of CID, and graft-versus-host disease is common, especially in patients with preexisting viral infections.[55]

CID Due to Defects of Co-Stimulatory Molecules

Several forms of CID are due to defects in genes that encode cell-surface molecules involved in the interaction of T cells with other cells types, including B lymphocytes, dendritic cells, and monocytes/macrophages.

Defects of CD40 Ligand and CD40

CD40 ligand (CD40LG) is predominantly expressed on the surface of activated CD4 T cells and interacts with CD40 expressed by B cells, monocytes, and dendritic cells, and various other cell types. CD40LG/CD40-mediated cross-talk between activated CD4 T cells and B cells promotes class-switch recombination and memory B-cell generation. In addition, interaction between $CD40LG^+$ T cells and monocytes and dendritic cells induces activation of these myeloid cells, promoting IL-12 production, which in turn acts upon T cells to induce expression of Interferon (IFN). CD40LG deficiency (OMIM *308230) is inherited as an X-linked trait. Affected males suffer from recurrent infections, including recurrent bacterial infections, *P. jirovecii, CMV, Cryptosporidium*, and *Cryptococcus*.[56] Chronic *Cryptosporidium* infections are often complicated by ascending cholangitis and sclerosing cholangitis. There is an increased risk of lymphomas, biliary tract tumors, and peripheral neuroectodermal tumors of the gastrointestinal tract. Chronic or intermittent neutropenia is common. Pure red cell aplasia secondary to parvovirus B19 infection has been reported. Immunological abnormalities include hypogammaglobulinemia with normal or elevated IgM, reduced proportion of switched memory B cells, and impaired T-cell proliferation to antigens. Flow cytometry may be used to document impaired expression of CD40LG, but mutation analysis is ultimately needed to confirm the diagnosis, especially in males expressing mutant forms of the molecule. Use of trimethoprim-sulfamethoxazole to prevent *P. jirovecii* pneumonia and regular immunoglobulin replacement therapy are the mainstays of treatment. Recombinant G-CSF may help in patients with severe neutropenia. Hygiene measures to prevent *Cryptosporidium* infection and laboratory and imaging studies to monitor liver and biliary tract status should be part of the monitoring plan. HSCT is indicated in patients with a more

severe clinical course and may be combined with liver transplantation for patients with liver failure.[56]

CD40 deficiency (OMIM *606843) is an autosomal recessive disease, whose clinical and immunological phenotype recapitulates that of CD40LG deficiency.

ICOS and ICOS Ligand (ICOSLG) Deficiency

The inducible T-cell co-stimulator (ICOS) is expressed on the surface of activated T cells; it promotes cytokine production, T-cell proliferation, and generation of follicular helper T cells.[57] These activities are mediated by ICOS interaction with ICOSL, which is expressed by B cells. Autosomal recessive ICOS and ICOSLG deficiencies are characterized by recurrent infections, autoimmunity, splenomegaly, granulomas, and increased risk of malignancies. In addition to respiratory tract infections, warts due to HPV infection and herpes simplex virus (HSV) and *Cryptococcus* infection have been also reported. Hypogammaglobulinemia with markedly reduced number of switched memory B cells are the main immunological defects in both conditions; however, ICOSLG deficiency is also characterized by T-cell lymphopenia.[58]

OX40 Deficiency

OX40 is a T-cell activation molecule that promotes cell survival. Autosomal recessive OX40 deficiency (OMIM *615593) has been described in a young adult with Kaposi sarcoma. Naïve and memory CD8 T cells were present in higher and lower than normal numbers, respectively. In vitro responses to antigens and IFN-γ production were reduced.

CD27 and CD70 Deficiency

CD27 and CD70 are counter-receptors expressed on the surface of T and B cells, respectively. Autosomal recessive defects of these molecules (OMIM #615122, 618261) are associated with EBV-driven lymphoproliferative disease, including Hodgkin lymphoma and diffuse large B-cell lymphoma.[59] Other manifestations include respiratory tract infections, severe varicella, autoimmunity, lymphadenopathy, hepatosplenomegaly, uveitis, and aphthous ulcers. Hypogammaglobulinemia has been frequently reported. HSCT can correct the disease phenotype.

CID DUE TO DEFECTS OF DNA REPAIR AND DNA REPLICATION

Ataxia-telangiectasia (A-T, OMIM *208900) is an autosomal recessive condition characterized by progressive neurodegeneration, development of telangiectasias, a variable degree of immunodeficiency, and increased risk of malignancies.[60] The disease is caused by mutations of the Ataxia-Telangiectasia Mutated (*ATM*) gene, which encodes a protein kinase that is recruited to sites of DNA double-strand breaks. ATM phosphorylates multiple substrates involved in DNA repair, cell cycle checkpoints, intracellular signaling, and gene transcription, and therefore controls multiple cellular processes. Increased cellular radiosensitivity is a prominent feature of the disease. Patients with A-T manifest oculocutaneous telangiectasias at around 2 to 3 years of age. Neurological problems (ataxia, dysarthria, oculomotor apraxia, hypotonia, tremors) appear a few years later, and progress, making these patients wheel-chair dependent by age 10 to15. The neurological features of the disease are associated with cerebellar involution and degeneration of Purkinje cells. The immunodeficiency of A-T manifests mainly with increased susceptibility to respiratory tract infections. A significant proportion of patients develop cutaneous granulomas. In some cases, presence of the rubella virus vaccine strain has been documented. Autoimmunity (in particular, diabetes mellitus) is also frequently observed. Other endocrinopathies include hypogonadism and growth hormone deficiency. There is accelerated aging, marked by development of progeric somatic changes. Up to 20% to 30% of A-T patients develop cancer in the course of their life. In most cases, malignancies are of lymphoid origin, and translocations involving chromosomes 7 and 14 (with breakpoints at the TCR and immunoglobulin loci) are frequently present in the malignant clones. Tumors of non-hematological origin are more frequently observed in older patients. The disease has a dismal prognosis, and death occurs in most cases by the fourth or fifth decade of life. Immunological abnormalities include a variable degree of T- and B-cell lymphopenia and hypogammaglobulinemia. Severe T-cell lymphopenia may already be present at birth, resulting in low TREC levels at newborn screening[61] but may worsen over time in other patients. The thymus is hypoplastic and lacks Hassall corpuscles. Low levels of IgA and IgG2, and high levels of serum IgM are the main abnormalities of humoral immunity. The high IgM also reflects the presence of monomeric IgM molecules. Elevated levels of serum alpha-fetoprotein (AFP) are a hallmark of the disease; however, this test cannot be used at birth because normal newborns also have elevated AFP levels. Therefore, for infants manifesting with T-cell lymphopenia at birth, mutation analysis at the *ATM* locus, and specific tests to assess ATM protein expression and phosphorylation are necessary to rule out A-T. Treatment is largely supportive. Administration of immunoglobulins and antimicrobial prophylaxis are beneficial in patients with recurrent infections. Exposure to ionizing radiation should be minimized. No definitive cure is currently available.

Nijmegen breakage syndrome (NBS, OMIM *251260) is an autosomal recessive disease due to mutations in the gene encoding nibrin, involved in DNA double-strand break, meiotic recombination, and telomere length maintenance.[60] Clinical manifestations include microcephaly, facial dysmorphisms, recurrent respiratory tract infections, cutaneous manifestations (granulomas, vitiligo, café-au-lait spots), and autoimmunity (cytopenias, thyroiditis, celiac disease, interstitial lung disease). More than 50% of the patients develop malignancies, in particular leukemias and lymphomas, by the third decade of life. Other solid tumors are more common in older patients. Immunological defects include T- and B-cell lymphopenia, reduced T-cell proliferative responses, and poor antibody responses. Treatment is largely supportive, but HSCT with reduced intensity conditioning has been successfully performed in patients with lymphoma.[62] Exposure to ionizing radiations should be avoided.

Bloom syndrome (OMIM *210900) is due to a defect in a helicase that regulates DNA replication and DNA double-strand break repair. Clinical manifestations include short stature, microcephaly, erythematous skin lesions, recurrent respiratory tract infections, autoimmunity, and increased risk of cancer (especially carcinomas, lymphomas, and leukemias) associated with cellular radiosensitivity. The immunodeficiency is rarely severe.

ERCC6L2 deficiency (OMIM *615715) is due to a defect of another helicase. Patients manifest short stature, microcephaly, variable degrees of developmental delay, and bone marrow failure. The number of B and T cells (especially of naïve $CD4^+$ cells) is reduced.

DNA ligase I deficiency is another autosomal recessive DNA repair defect, causing immunodeficiency of variable severity, ranging from hypogammaglobulinemia to profound CID (with severe lymphopenia) requiring HSCT. Learning disability may be present. Deficiency of NSMCE3 causes lung disease, Immunodeficiency, and Chromosomal breakage Syndrome (LICS, OMIM *617241), a condition with failure to thrive and severe viral infections leading to lung damage and early death. The number and function of T cells are reduced. RIDDLE syndrome (OMIM *611943) is a rare disorder characterized by Radiosensitivity, Immune Deficiency, facial Dysmorphisms, LEarning disability, and short stature. The disease is due to mutations in the *RNF168* gene encoding an E3 ubiquitin ligase involved in DNA double-strand break repair. Hypogammaglobulinemia with elevated IgM is a common immunological abnormality.

Several forms of immunodeficiency are due to defects of proteins involved in the initiation and progression of DNA replication. DNA polymerase δ (Polδ) deficiency is a CID due to biallelic loss-of-function mutations of the *POLD1* and *POLD2* genes, encoding two of the four subunits of Polδ, which plays an important role in DNA replication and maintenance of genomic stability. Clinical features include recurrent bacterial and viral infections and intellectual disability; short stature has also been observed in Polδ2 deficiency.[63,64] T-cell lymphopenia and hypogammaglobulinemia are the main immunological abnormalities.

DNA polymerase ε (POLE) deficiency includes defects of the POLE1 and the POLE2 subunits. Both disorders are inherited as autosomal recessive traits. POLE1 deficiency may manifest with facial dysmorphisms, immunodeficiency, livedo, and short stature (FILS syndrome, OMIM #615139) or with intrauterine growth retardation, metaphyseal dysplasia, congenital adrenal hypoplasia, genital anomalies, and immune deficiency (IMAGE-I, OMIM #618336) syndrome. A low number of naïve T cells and of memory B cells, decreased T-cell proliferation, reduced levels of serum IgM, and impaired antibody response to polysaccharide antigens have been frequently reported. POLE2 deficiency is characterized by dysmorphisms, microcephaly, growth retardation, and increased susceptibility to severe infections and autoimmunity, associated with severe T-cell lymphopenia, impaired proliferation to mitogens, and a reduced number of NK cells. GINS1 deficiency (OMIM *617827) is a rare disease characterized by growth retardation, mild skeletal and facial anomalies, and recurrent bacterial and viral infections associated with low T-cell count and profound NK-cell deficiency. Neutropenia with reduced number of mature granulocytes in the bone marrow is frequently observed. MCM4 deficiency (OMIM *602638) is characterized by growth retardation, adrenal insufficiency, severe viral infections, and a profound defect of NK lymphocytes. There is increased risk of malignancies associated with cellular radiosensitivity. Finally, Immune deficiency, Centromeric instability, and Facial anomalies (ICF syndrome) includes a group of disorders with mutations in the *DNMT3B (OMIM #242860)*, *ZBTB24 (OMIM #614069)*, or less frequently in the *CDCA7* (OMIM #616910) and *HELLS* (OMIM #616911) genes.[65] Infections are a prominent feature and a leading cause of death early in life. Besides facial dysmorphisms, neurodevelopmental and gross motor skill deficits, congenital malformations (macroglossia, hypospadias, cleft palate, syndactyly), and chronic diarrhea are common findings. Profound hypo-gammaglobulinemia with normal B-cell numbers is the main immunological abnormality, but progressive decline of T and B cells has been reported.

CID ASSOCIATED WITH CYTOSKELETAL DEFECTS

Several inborn errors of immunity are characterized by defects of the actin cytoskeleton that compromise the response to cell-surface receptor engagement, intracellular signaling, and cell motility.

Wiskott-Aldrich Syndrome and Related Disorders

Wiskott-Aldrich syndrome (WAS, OMIM *301000) is an X-linked disorder due to a defect in the gene encoding the WAS protein (*WASP*), which regulates actin polymerization in hematopoietic cells by interacting with the Arp2/3 complex.[66] Clinical manifestations include chronic thrombocytopenia, eczema, recurrent infections, immunodeficiency, and a high incidence of autoimmune diseases and malignancies The thrombocytopenia of WAS is associated with reduced platelet size, and is responsible for hemorrhagic manifestations of variable severity, ranging from petechiae and bruises to severe gastrointestinal and brain hemorrhages. Because of defective innate and adaptive immunity, patients with classic WAS are highly susceptible to bacterial, fungal, and viral infections. Autoimmune complications occur in 70% of WAS patients, most frequently presenting as cytopenias, arthritis, vasculitis, and inflammatory bowel disease. Lymphoma, often EBV-associated, and leukemias are common hematological malignancies in patients with WAS. A milder phenotype, X-linked thrombocytopenia (XLT), is associated with mutations that result in residual expression of mutated protein. Although XLT patients manifest only thrombocytopenia early in life (sometimes associated with mild eczema), severe infections, autoimmunity, and malignancy may occur at an older age. The immunological abnormalities of WAS include reduced T- and B-cell counts, impaired T-cell proliferation to anti-CD3, low serum IgM with elevated IgA and IgE, defective antibody responses to polysaccharide antigens, poor NK-cell and Treg function, and defective directional migration of lymphoid and myeloid cells. The T-cell lymphopenia is often progressive but may occasionally already be present at birth and be detected by low TREC levels at newborn screening. Flow-cytometric analysis of WASP expression may help in the diagnosis, which is ultimately confirmed by mutation analysis. Treatment includes antibiotic prophylaxis and IgG replacement therapy. Immunosuppressive therapy may be needed if autoimmune symptoms occur. Splenectomy ameliorates the bleeding tendency by increasing the number of circulating platelets. However, it substantially increases the risk of systemic infections due to encapsulated bacteria. HSCT is the treatment of choice, and excellent outcomes have been reported in recent years. After initial attempts with gene therapy based on use of gammaretroviral vectors was associated with a high rate of leukemias due to insertional mutagenesis, more promising results have been recently reported with use of self-inactivating lentiviral vectors.

The WASP-interacting protein (WIP) binds to and stabilizes WASP. WIP deficiency (OMIM *614493) is an autosomal recessive condition whose clinical and immunological phenotype mimics WAS.[67] Intracellular levels of WASP are reduced. HSCT can cure the disease.

ARPC1B deficiency (OMIM *617718) is an autosomal recessive disease due to mutations of the Arp2/3 complex component ARPC1B.[68] The clinical phenotype consists of eczema, food allergies, autoimmune complications, recurrent bacterial and viral infections, and mild bleeding tendency. The thrombocytopenia is less severe than in WAS. Abnormal chemotaxis, impaired NK- and Treg-cell function, and markedly increased IgA and IgE

levels are the main immunological abnormalities. Treatment is symptomatic, but HSCT has been successfully used in patients with severe manifestations. Autosomal dominant CDC42 deficiency (OMIM *616737) is characterized by growth dysregulation, facial dysmorphisms, recurrent infections, developmental delay, and macrothrombocytopenia. CDC42 encodes a small GTPase of the RHO family that modulates multiple signaling pathways controlling cell migration, endocytosis, and cell cycle.

Dedicator of Cytokinesis 8 (DOCK8) Deficiency

DOCK8 is a guanine nucleotide exchange factor (GEF) that regulates cytoskeleton reorganization and intracellular signaling in hematopoietic cells.[69] DOCK8 deficiency (OMIM #243700) is inherited as an autosomal recessive trait and is characterized by recurrent and severe bacterial, fungal, and viral infections, eczema, and immune dysregulation. Cutaneous viral infections (warts, molluscum contagiosum, herpes simplex) are especially common, and warts often progress to squamous cell carcinoma. Patients are also at increased risk of systemic infections due to VZV, CMV, and EBV. Vascular thrombosis in the central nervous system has been described in several patients. Lymphopenia affecting especially naïve T cells, increased proportion of CD8 T_{EMRA} cells, decreased in vitro proliferation to CD3 stimulation, and defects of NK cytolytic function are characteristic defects of cellular immunity. High IgE and low IgM serum levels are observed in most patients, and specific antibody responses are blunted.[69] If untreated, the disease has a poor prognosis but can be cured by allogeneic HSCT.[70,71]

DOCK2 Deficiency

DOCK2 is another GEF that regulates cytoskeleton reorganization in response to engagement of TCR, BCR, and various chemokine receptors. Autosomal recessive DOCK2 deficiency (OMIM #616433) is characterized by early-onset invasive bacterial and viral infections. Lymphopenia and defective function of T-, B-, and NK-cell responses are common findings.[72] Lymphocyte migration in response to chemokines is reduced,[72] and neutrophil production of reactive oxygen species is partially impaired.[73] Production of type 1 interferon by immune and nonimmune cells upon viral infections is markedly defective. HSCT is the only curative approach.

Moesin Deficiency

Moesin is a member of the ezrin-radixin-moesin family of proteins that link the cortical actin filaments to the cell membrane. Moesin deficiency (OMIM #300988) is inherited as an X-linked trait. Patients suffer from bacterial and viral infections. Severe VZV infection has been reported in several cases. Lymphopenia, hypogammaglobulinemia, and intermittent neutropenia are immunological findings.[74] Low levels of TRECs may be detected at birth. However, in most cases HSCT is not necessary, and the disease can be managed with immunoglobulin replacement therapy and prophylactic antibiotics.[75]

CID DUE TO DEFECTS OF CLATHRIN-MEDIATED ENDOCYTOSIS AND IRON INTERNALIZATION

Iron internalization plays an important role in promoting intracellular metabolism. Transferrin receptor deficiency (OMIM #616740) is an autosomal recessive CID due to a homozygous missense mutation in the transferrin receptor (*TFRC)* gene, impeding transferrin receptor and iron internalization. There are normal numbers, but reduced function of T and B cells, intermittent neutropenia and thrombocytopenia, and mild anemia. HSCT corrects the disease peneotype.[76]

The FCHO1 protein is involved in the early stages of clathrin-mediated endocytosis. Autosomal recessive FCHO1 deficiency (OMIM #619164) is a CID with low number and impaired function of T cells, and recurrent infections sustained by various pathogens. The disease can be cured by HSCT.[77]

CID With Immune-Osseous Dysplasia

Cartilage Hair Hypoplasia

CHH (OMIM *250250) is an autosomal recessive condition characterized by short-limbed dwarfism and light-colored, hypoplastic hair.[78] Bone marrow dysplasia, increased susceptibility to malignancies, Hirschsprung disease, defects of spermatogenesis, and a variable degree of immune deficiency are other typical features. The disease is more common in certain populations, such as the Amish and Finns, and is caused by mutations in the gene encoding an untranslated RNA component of the ribonuclease mitochondrial RNA processing (*RMRP*) complex, which is involved in cleavage of ribosomal RNA, processing of mitochondrial RNA, and cell-cycle control. T-cell lymphopenia in some patients may be so severe to manifest as SCID with low TREC levels at birth. Impaired in vitro proliferative responses to mitogens is another manifestation of impaired cellular immunity, which may cause increased susceptibility to severe varicella and other viral infections. Defects of humoral immunity may also be observed and contribute to recurrent respiratory tract infections and bronchiectasis. Autoimmune manifestations (hemolytic anemia, neutropenia, and thrombocytopenia) occur in about 10% of the patients. Bone marrow dysplasia may manifest with anemia, leukopenia, and thrombocytopenia. HSCT has been successfully used to correct CHH with severe immunodeficiency.

Schimke Syndrome

Schimke syndrome (OMIM *606622) is an autosomal recessive disorder characterized by short stature due to spondyloepiphyseal dysplasia, progressive renal impairment evolving to renal failure, facial dysmorphisms, micro/hypodontia, immunodeficiency (ranging from moderate T-cell lymphopenia to SCID), increased occurrence of marrow failure, and early onset of CNS vasculopathy and strokes.[79] The disease is caused by mutations of the *SMARCAL1* gene that encodes a chromatin remodeling protein. Recurrent infections of bacterial, viral, and fungal origin are seen in half of the patients. Severe presentations lead to death in the first decade of life, and development of renal failure is common among those who survive. Combined HSCT and renal transplantation may correct immune deficiency and renal problems.

Phosphoglucomutase 3 (PGM3) Deficiency

PGM3 deficiency (OMIM *615816) is a congenital disorder of glycosylation with a broad clinical phenotype that includes severe atopy, scoliosis, short stature, developmental delay, bone marrow failure, and recurrent bacterial, viral, and fungal infections.[80] Chronic lung disease and persistent EBV viremia have been reported in several patients. Markedly elevated IgE serum levels and eosinophilia are common findings. Some patients have severe T-cell lymphopenia causing a SCID phenotype.

Other Immuno-Osseous Dysplasias

Roifman syndrome (OMIM *616651) is an autosomal recessive spondyloepiphyseal dysplasia with extreme intrauterine growth retardation, retinal dystrophy, dysmorphisms, recurrent respiratory and cutaneous infections, and lymphadenopathy. Atopic and autoimmune manifestations are also frequently seen. The disease is due to mutations of the *RNU4ATAC* gene, encoding a small nuclear RNA (snRNA). Immunological abnormalities include hypogammaglobulinemia, low number of T and memory B cells, defective T-cell proliferation to antigens, and decreased NK cell function. Immunoglobulin replacement therapy is used to control infections.

The exosostin-like glycosyltransferase 3 (EXTL3) enzyme is involved in heparan sulfate biosynthesis. Autosomal recessive *EXTL3* deficiency (OMIM *605744) is characterized by syndromic manifestations, with immune deficiency ranging from SCID to moderate T-cell lymphopenia, associated with severe skeletal abnormalities, microcephaly, neurodevelopmental delay, and narrowing of the laryngotracheal tract.[81] *MYSM1* deficiency (OMIM *618116) manifests with postnatal short stature, neurodevelopmental delay, microcephaly, increased risk of bone marrow failure and myelodysplasia, and recurrent infections. Impaired B-cell development in the bone marrow, T-cell lymphopenia, and hypogammaglobulinemia are the main immunological abnormalities. Spondyloenchondrodysplasia with immune dysregulation (SPENCDI, OMIM *607944) is an autosomal recessive condition due to mutations of the *ACP5* gene, encoding tartrate-resistant acid phosphatase. Patients manifest bone abnormalities, mild developmental delay, spasticity, cerebral calcifications, and autoimmunity (lupus, vasculitis, pancytopenia). Cellular and humoral immune defects may be variably present.

CID ASSOCIATED WITH PROMINENT IMMUNE DYSREGULATION

Although CID is often associated with autoimmunity, in some forms of CID immune dysregulation represents a prominent feature and may even dominate the clinical picture.

IL-2 plays a critical role in immune homeostasis by promoting Treg fitness and function. CD25 deficiency (OMIM *606367), caused by mutations of the *IL2RA* gene, encoding the IL-2R α chain, is a CID manifesting with chronic diarrhea, eczema, endocrinopathies, autoimmune cytopenias, lymphocytic infiltrates in various organs, lymphadenopathy, hepatosplenomegaly, and increased risk of severe infections (CMV pneumonitis and colitis, other respiratory tract infections, chronic EBV viremia).[82] IL2RB deficiency (OMIM *618495), due to mutations of the gene encoding the IL-2R β chain, is characterized by a similar phenotype, with autoimmune colitis, hepatosplenomegaly, cytopenias, food allergy, and severe infections, in particular due to CMV and EBV. Downstream from the IL-2R and from other γ_c-containing receptors, STAT5B deficiency (OMIM *245590) manifests with autoimmunity (thyroiditis, thrombocytopenia, arthritis), eczema, viral infections, and pulmonary disease. Short stature with growth hormone insensitivity is a cardinal feature of this condition, reflecting the role of STAT5B in signaling also through the growth hormone receptor.

Signal transducer and activator of transcription 1 (STAT1) gain-of-function mutations cause an autosomal dominant disorder (OMIM #614162) that was initially reported to manifest with chronic mucocutaneous candidiasis (CMC). However, it was rapidly found that autoimmunity (cytopenias, enteropathy, type 1 diabetes, thyroiditis, alopecia, psoriasis), recurrent infections of bacterial, viral. and fungal origin, vascular aneurysms, eczema, and asthma are also common features.[83] Immunological abnormalities include a high number of circulating follicular helper-T (Tfh) cells and impaired generation of Th17 cells. Antifungals are used to treat CMC, and other infections require a targeted drug approach. JAK inhibitors have shown promising results in the treatment of autoimmunity but may aggravate viral and fungal infections. Results of HSCT remain unsatisfactory.

Upon cellular activation, the STIM1 molecule senses the Ca^{2+} concentration in the endoplasmic reticulum and activates Ca^{2+} release-activated channels (CRAC). ORAI1 constitutes the pore-forming subunits of the CRAC in the cell membrane. Mutations of *STIM1* and *ORAI1* genes (OMIM *612783 and 612782) cause an autosomal recessive immunodeficiency with increased susceptibility to severe infections, autoimmunity (cytopenia, hepatosplenomegaly), nonprogressive myopathy, and ectodermal dysplasia.[84] T cells are present in a normal number, but their proliferative capacity is decreased. Allogeneic HSCT can correct the immune defect.

X-linked immunodeficiency with magnesium defect, EBV infection, and neoplasia (XMEN disease, OMIM #300853) is an X-linked disorder due to mutations of the *MAGT1* gene that encodes for a magnesium transporter that also plays a role in protein glycosylation.[85] Patients suffer from chronic EBV infection, with high rate of progression to lymphoma. Recurrent infections due to other viruses have been also reported. Impaired T-cell activation and reduced expression of NKG2D on NK and CD8 T cells are the main immunological findings.

IL-21/IL-21R interaction plays a critical role in promoting B-cell maturation and plasmablast generation. Autosomal recessive IL-21 and IL-21R deficiencies (OMIM *615767 and 615207) are characterized by recurrent sinopulmonary infections.[86] In addition, *Cryptosporidium* infection and liver disease have been reported in IL-21R deficiency and severe early-onset colitis in IL-21 deficiency. Immunological abnormalities include B-cell lymphopenia, hypogammaglobulinemia with elevated IgE, and impaired T-cell proliferation to antigens.

OTHER FORMS OF CID DUE TO DEFECTS OF TRANSCRIPTION FACTORS

The IKAROS transcription factor, encoded by the *IKZF1* gene, regulates gene expression in hematopoietic cells via chromatin remodeling. Dominant negative *IKZF1* mutations cause a CID with increased susceptibility to bacterial and viral infections and *P. jirovecii* pneumonia, and to T-cell acute lymphoblastic leukemia.[87] Laboratory studies demonstrate a low number of T and B cells (with absence of memory cells), neutrophils, and eosinophils. HSCT can rescue the phenotype. A de novo, heterozygous, dominant-negative mutation in the transcription factor *BCL11B* has been identified in an infant with a profound numerical and functional T-cell deficiency and low TRECs at birth (OMIM #617237). Craniofacial and dental abnormalities, and absence of corpus callosum, were also present. The immune defects were reversed by HSCT.[88]

MANAGEMENT OF PATIENTS WITH CID

Irrespective of the nature of the underlying gene defect, all forms of T-cell immunodeficiency are characterized by significant morbidity, with increased susceptibility to infections, often associated with a high frequency of autoimmunity and malignancies. Careful review of the patient's medical and family history and evaluation of the immune status (with enumeration of lymphocyte subsets, distribution of naïve and memory subsets, and measurement of serum immunoglobulins and specific antibody responses) may facilitate recognition of immune deficiency. However because of the heterogeneity of CID and the overlapping clinical and laboratory features, genetic tests have become an essential step in the diagnostic approach to these disorders. Comprehensive gene panels, WES, and WGS represent valuable tools to identify the gene defect. Yet, because many mutations are private (i.e., not previously reported in other patients), functional validation with protein expression and functional studies are often necessary to demonstrate the disease-causing role of gene variants. Antimicrobial prophylaxis and immunoglobulin replacement therapy are beneficial in most forms of CID. Major caution should be used in the administration of live vaccines. Unless strictly necessary, exposure to ionizing radiation and to alkylating agents should be avoided in patients with possible defects in DNA repair. Regular follow-up visits with proper clinical, laboratory, and imaging studies should be planned for patients whose CID is associated with increased risk of malignancy. Finally, HLA typing and search for possible donors should be performed in patients whose CID may require HSCT.

THERAPEUTIC PRINCIPLES

Clinical Management of Patients With Severe Combined Immune Deficiency

- Strict hygiene and isolation measures, use of prophylactic antimicrobials, and immunoglobulin replacement therapy are the mainstay of treatment while preparing for definitive cure
- Immunization with live attenuated vaccines should be strictly avoided
- Breastfeeding is a potential source of cytomegalovirus (CMV) transmission to severe combined immune deficiency (SCID) babies and should be discontinued if the mother is CMV seropositive
- Blood products should be from CMV-negative donors and should be irradiated
- Some forms of T-cell immunodeficiency are associated with radiation sensitivity. In these patients, exposure to ionizing radiation and alkylating agents may cause severe, even fatal, consequences and should be avoided
- If untreated, SCID is inevitably fatal within the first years of life. However, hematopoietic stem cell transplantation (HSCT) can cure the disease. By identifying babies with SCID at birth, before the disease becomes clinically manifest, newborn screening permits prompt referral to HSCT, with improved outcome (>90% survival)

ON THE HORIZON

- Implementation of newborn screening will facilitate diagnosis and further improve clinical outcome of severe combined immune deficiency worldwide. Whole exome sequencing of DNA extracted by dried blood spots may permit newborn screening also of other congenital T-cell immunodeficiencies
- Databases of gene variants for which functional validation of the disease-causing effect has been obtained will help in the diagnostic approach
- Multicenter studies are needed to better define the natural history and the response to treatment of rare forms of combined immunodeficiency
- Development of novel drugs is needed to prevent and treat viral infections in patients with severe T-cell disorders
- Hematopoietic stem cell transplantation protocols tailored to treat individual gene defects may help further improve clinical outcome
- Gene therapy will likely be extended to treat a broader group of T-cell immunodeficiencies. Gene editing is a novel and attractive therapeutic approach, especially for disorders due to gain-of-function and dominant negative mutations

Genetic Disorders of Interferons-, Interleukin-17, Interleukin-18, and Nuclear Factor-κB-Mediated Immunity

Jacinta Bustamante, Shen-Ying Zhang, Bertrand Boisson, Vivien Béziat, Qian Zhang, Emmanuelle Jouanguy, Stéphanie Boisson-Dupuis, Anne Puel, and Jean-Laurent Casanova

In the last 25 years, primary immunodeficiencies (PIDs) or inborn errors of immunity (IEIs) affecting the immunity mediated by interferon (IFN)-γ, IFN-α/β-λ, Toll-like receptor (TLR) and interleukin (IL)-1 receptor (TIR) signaling, nuclear factor (NF)-κB pathway, TLR-3 pathway, IL-17, and IL-18 have been identified. Some of these genetic defects are "conventional" PIDs, associated with a broad range of infections, but others provide a molecular explanation for severe infectious diseases previously thought to be idiopathic (Table 35.1). These "non-conventional" PIDs may be associated with severe and/or recurrent infections caused by a single family of microorganisms, a situation strongly contrasting with that for "conventional" PIDs. Standard immunological explorations are generally normal in these patients, whether they are susceptible to one or several infectious agents.[1] Despite the lack of a clear immunological abnormality, infections in these patients are typically severe, and often fatal. Most IEIs affect leukocytes and other cell types.[2] This chapter is devoted to the description of these IEIs (see Table 35.1). They include disorders of the IFN-γ mediated immunity associated with the syndrome of Mendelian susceptibility to mycobacterial disease (MSMD) and tuberculosis (TB).[3–6] We also describe genetic defects affecting primarily the TLR-3 pathway. The predominant infectious phenotype of patients with these defects is herpes simplex virus (HSV)-1 encephalitis (HSE).[7] We include also the first genetic defects associated with severe isolated influenza, rhinovirus, human papillomaviruses (HPVs), fulminant hepatitis, and primary cytomegalovirus (CMV).[8–13] We describe IEIs associated with impaired signaling downstream from or via the TLR-IL-1R (TIR) pathway.[14–16] The main infectious phenotype of patients with any of these defects is the occurrence of pyogenic bacterial infections. Finally, we describe the group of defects affecting the IL-17A/F mediated immunity and conferring predisposition to chronic mucocutaneous candidiasis (CMC).[17,18]

KEY CONCEPTS

- New inborn errors of immunity (IEIs) should be considered in patients with unexplained serious infectious diseases.
- Children with severe infectious diseases should be actively investigated for a potential IEI.
- The exploration of idiopathic infections can lead to the discovery of new IEIs, which results in a better understanding of immunity to pathogens and new approaches to therapy.

GENETIC DISORDERS OF INTERFERON-γ-DEPENDENT IMMUNITY AND MENDELIAN SUSCEPTIBILITY TO MYCOBACTERIAL DISEASE

MSMD (OMIM#209950) is a rare group of genetic disorders associated with a selective susceptibility to weakly pathogenic mycobacteria, such as environmental mycobacteria (EM) and/or bacille Calmette–Guérin (BCG) vaccines, in otherwise healthy patients, normally resistant to other microbes (Fig. 35.1).[4] It occurs in about 1/50,000 individuals worldwide. The first clinical report of a probable idiopathic disseminated BCG (BCG-osis) infection following vaccination was in 1951. MSMD was the first IEI characterized by a selective predisposition to one or a few infectious agents. Various EM species have been isolated from MSMD patients.[3] The more virulent *Mycobacterium tuberculosis* has also been reported as disease-causing with these genetic disorders.[6] Patients with MSMD may have a wide range of clinical symptoms, from localized to persistent, disseminated infections and with impaired granuloma formation. Macrophage activation syndrome may occur in rare cases, probably because of uncontrolled infection.[4] Some patients spontaneously improve with age, or even remain clinically silent due to incomplete penetrance. About half of the patients are also particularly susceptible to non-typhoidal *Salmonella* and their spectrum of clinical diseases is broad, ranging from gastroenteritis to septicemia and disseminated infection.[3] A significant proportion of MSMD patients also suffer from CMC.[3] Occasionally other viral (caused by CMV, human herpes virus 8, parainfluenza virus type 3, respiratory syncytial virus [RSV] or varicella-zoster virus [VZV]), parasitic (leishmaniasis, toxoplasmosis), fungal (histoplasmosis, paracoccidioidomycosis, coccidioidomycosis) or bacterial (listeriosis, nocardiosis, klebsiellosis) infections have more rarely been reported.[3]

The first genetic etiology of MSMD was reported in 1996 with the discovery of autosomal recessive (AR) complete IFN-γR1 deficiency.[19,20] Since this initial description, mutations in 16 genes have been shown to be responsible for MSMD (Fig. 35.2).[4,21] The causal mutations in *IFNGR1* and *IFNGR2*, encoding the two chains of the receptor for IFN-γ, and some mutations in *STAT1*, encoding a transcription factor essential to the IFN-γR signaling pathway, result in defective cellular response to IFN-γ. MSMD-causing mutations in the genes encoding the p40 subunit of IL-12 *(IL12B)* and the β_1 chain of the receptor for IL-12 receptor *(IL12RB1)* affect the IL-12 and IL-23-dependent production of IFN-γ. MSMD-causing mutations in the genes encoding the β_2 chain of the IL-12 receptor *(IL12RB2)* affect the IL-12-dependent production by IFN-γ

TABLE 35.1 Genetic Disorders of Interferons-, Interleukin-17, Interleukin-18, and Nuclear Factor-κB-Mediated Immunity

[a]One AD IFN-γR1-deficient patient presented one episode of *Histoplasma capsulatum* infection, another patient presented coccidioidomycosis.
[b]One IL-12Rβ1-deficient patient presented one episode of *Paracoccidioides brasiliensis* infection and some patients display forms of chronic mucocutaneous candidiasis.
[c]POLR3A and POLR3C can be monogenic or digenic deficiencies.
AD, autosomal dominant; *AR*, autosomal recessive; *CMV*, cytomegalovirus; *EDA*, anhidrotic ectodermal dysplasia; *HPV*, human papillomavirus; *HSE*, herpes simplex encephalitis; *IAV*, influenza A virus; *IBV*, influenza B virus; *N*, normal; *RSV*, respiratory syncytial virus; *VZV*, varicella-zoster virus; *XR*, X-linked recessive.

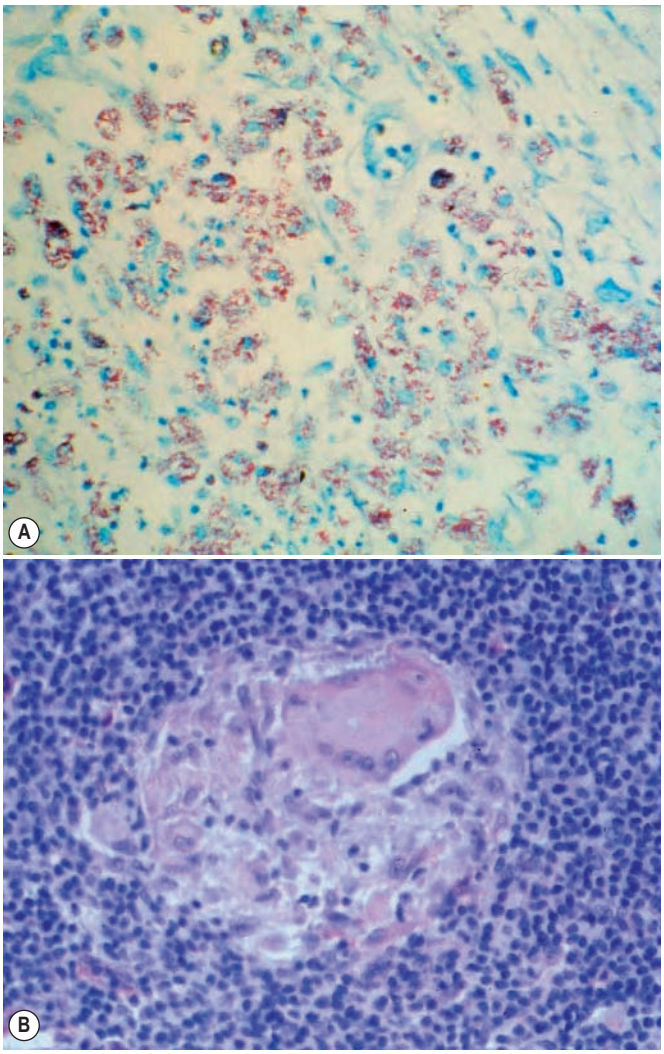

FIG. 35.1 Two Types of Granuloma in Patients With Mendelian Susceptibility to Mycobacterial Disease or Tuberculosis. (A) The lepromatous-like type consisted of poorly defined, poorly differentiated granulomas, with few, if any giant cells and lymphocytes, but widespread macrophages loaded with acid-fast bacilli. (B) The tuberculoid type consisted of well-circumscribed and differentiated granulomas, with epithelioid and multinucleated giant cells containing very few acid-fast rods, surrounded by lymphocytes and fibrosis, occasionally with central caseous necrosis.

and MSMD-causing mutations in the genes encoding the IL-23 receptor *(IL23R)* affect the IL-23-dependent production of IFN-γ. Bi-allelic mutations of *ISG15*, an IFN-γ-inducing molecule that acts in synergy with IL-12, have also been reported to cause MSMD, by impairing, but not abolishing IFN-γ production. Monoallelic mutations of *IRF8*, encoding an interferon regulator factor (IRF) inducible by IFN-γ, and homozygous mutations of *SPPL2A* impair IL-12 secretion by dendritic cells (DCs) interfering with the production of IFN-γ. Recently, a homozygous mutation in *IFNG* encoding IFN-γ has been described. MSMD can also be seen with hypomorphic defects in the X-linked gene encoding the NF-κB essential modulator (NEMO), which is involved in the CD40-dependent induction of IL-12, and in mutations affecting TYK2, which is involved in IL-12-dependent IFN-γ immunity. The MSMD-causing mutations in *CYBB*/gp91^{phox} affect the respiratory burst selectively in macrophages.[3,4] Some mutations of *STAT1* and most mutations of *NEMO* are associated with a broader range of infectious diseases (see below), and complete IRF8 deficiency is associated with a lack of circulating monocytes and DCs, as well as severe clinical disease, mimicking combined immunodeficiency (CID). The pathogenesis of MSMD in patients with these disorders results from impaired IFN-γ-mediated immunity. Among patients with MSMD, the level of IFN-γ mediated immunity determines the severity of mycobacterial disease.[4,21]

The high allelic heterogeneity at these 16 loci has led to the definition of 31 different genetic etiologies of MSMD, based on the mode of inheritance (recessive or dominant, autosomal or X-linked), mutant allele expression (e.g., presence or absence of encoded protein), the functional impact of the mutation (null or hypomorphic), and the mechanism underlying the dysfunction of expressed protein (e.g., phosphorylation, DNA-binding for transcription factors or both) (see Fig. 35.2).[3] In addition, mycobacteriosis has also been reported in patients with "syndromic MSMD" due to inherited AR TYK2, STAT1, or JAK1 deficiency, with susceptibility to mycobacterial and viral diseases due to impaired responses to IFN-γ (type II IFN) and IFN-α/β (type I IFN).[4] In addition, AR complete IRF8 deficiency, may present with mycobacterial, viral, and fungal infectious diseases due to impaired lymphoid and myeloid immunity; AR complete ROR-γ/ROR-γT deficiency, with susceptibility to mycobacterial and fungal diseases due to impaired IFN-γ and IL-17 immunities[22] and AR ISG15 associated with mycobacterial diseases plus type I interferonopathy. The identification of inborn errors of IL-12-, IL-23-, or ISG15-dependent induction of IFN-γ led to the successful, life-saving treatment of affected patients with recombinant IFN-γ.[3] Patients with MSMD are currently treated with antibiotics (ATB), but the prognosis for MSMD remains poor in some patients, while hematopoietic stem cell transplantation (HSCT) can be very difficult and is currently restricted to patients with complete deficiency of the IFN-γ receptor, STAT1, or IRF8.[3,4] Importantly, molecular diagnoses for siblings and offspring potentially carrying the MSMD-associated genotype may also lead to the selective prevention of mycobacterial disease with antimycobacterial antibiotics and/or recombinant IFN-γ[4] plus identification of individuals in whom vaccination with live BCG is absolutely contraindicated.[3]

THERAPEUTIC PRINCPLES

Treatment of Mendelian Susceptibility to Mycobacterial Disease Patients

- Vaccination with live bacille Calmette-Guerin (BCG) is contraindicated.
- Multiple antibiotics against the specific mycobacteria should be administered without interruption in patients with complete IFN-γR1 or IFN-γR2 deficiency.
- IFN-g therapy may be considered in addition to appropriate antimycobacterial antibiotics in patients with partial IFN-γR1, IFN-γR2, IRF8, gp91phox (or CYBB), or signal transducer and activator of transcription 1 (STAT1) deficiency as well as complete IL-12p40, IL-12Rβ1, or ISG15 deficiency.
- Hematopoietic stem cell transplantation (HSCT) should be considered in select patients with complete deficiency of IFN-γR1, IFN-γR2, STAT1, or IRF8.

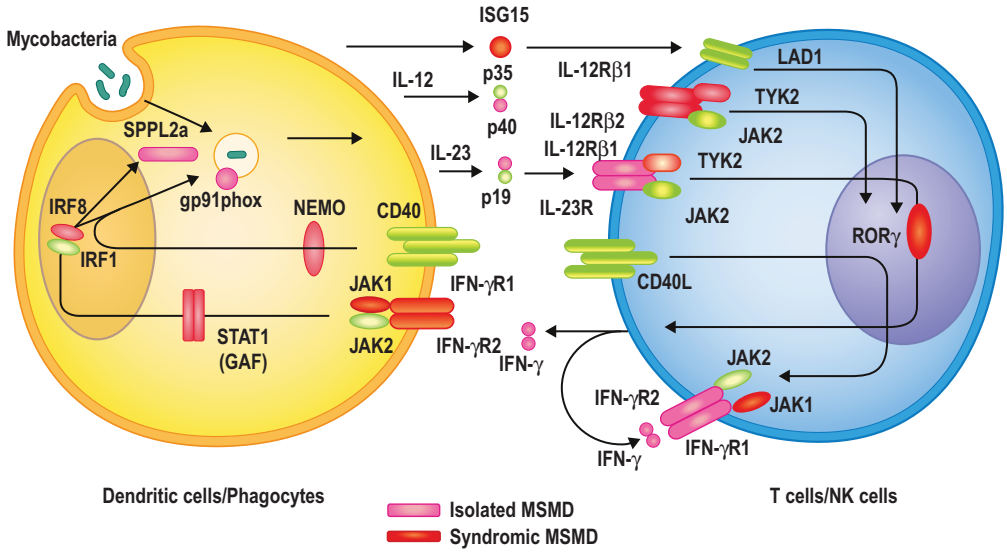

FIG. 35.2 Genetic Etiologies of Mendelian Susceptibility to Mycobacterial Infection. Cells involved in the production (T cells/NK cells) and response (dendritic cells, phagocytes) to interferon-γ (IFN-g). Proteins for which a mutation of the corresponding gene has been recognized to cause isolated Mendelian susceptibility to mycobacterial disease (MSMD) are shown in *pink* and those responsible for syndromic MSMD are shown in *red*. MSMD-causing mutations of *IL12B*, *IL12RB1*, *IL12RB2*, *IL23R*, *IFNG*, *ISG15*, *IRF8*, *SPPL2A*, *RORC*, *TYK2*, and *NEMO* impair the production of IFN-γ. MSMD-causing mutations of *IFNGR1*, *IFNGR2*, *STAT1*, *JAK1*, *CYBB*, and *IRF8* impair the action of IFN-γ.

GENETIC DISORDERS PREDISPOSING TO TUBERCULOSIS

TB caused by *M. tuberculosis* is still endemic in many countries (10 million new cases and 1.3 million deaths in 2017). However, only a minority of infected individuals (no more than 5% to 10%) develop clinical disease. Multiple experimental evidence has revealed a strong genetic basis for TB in humans.[6] However, classic association studies focusing on common variants of many candidate genes have not yielded consistent or reproducible results. Patient-based studies performed in parallel to these population-based studies yielded greater progress. Rare IEIs, including some of those linked to MSMD, were found to confer a predisposition to TB; these include IL-12Rβ1 and TYK2 deficiencies (found in no more than 1/600,000 individuals, hence representing a very small number of TB patients), and common IEI, such as homozygosity for P1104A TYK2 found in many more patients (this genotype is found in 1/600 Europeans and 1/5,000 other populations with the exception of sub-Saharan Africans and Eastern Asians).[23] Direct evidence includes the identification of siblings of MSMD probands carrying the same rare genetic defect but suffering from TB, with or without MSMD. Additional proof-of-concept was provided when several patients with TB but no family history of clinical MSMD were found to carry mutations in MSMD genes, including AR complete TYK2 deficiency found in two patients with isolated TB. These rare genetic etiologies underlying this common infectious disease provided proof-of-principle that TB susceptibility can be monogenic, but these situations are rare and do not account for TB as a global public health problem.[6]

Recently, a strong enrichment of individuals homozygous for a common TYK2 variant P1104A was found in a cohort of TB patients originating from countries outside Europe in which TB is currently endemic.[23] The minor allele frequency (MAF) of P1104A is 4.2% in the European population based on the Genome Aggregation Database (gnomAD), giving a frequency of homozygous individuals of approximately 1/600 in Europe. The P1104A mutant TYK2 protein catalytic activity is impaired such that it cannot phosphorylate itself or any other JAK or STAT substrate. Cells from patients homozygous for P1104A display impaired responses to IL-23, similar to cells from patients with complete TYK2 deficiency, whereas the other three TYK2-dependent cytokine pathways are unaffected. The role of P1104A homozygosity in TB was confirmed in a large cohort of European ancestry (United Kingdom [UK] Biobank).[6] Homozygosity for P1104A is the first common monogenic cause of TB susceptibility and the most common AR disorder in European population identified to date. It is estimated that TB has killed up to 1 billion people in Europe over the last 2000 years, suggesting that approximately 10 million people may have died due to TYK2 P1104A homozygosity. Interestingly, this homozygous variant was also found to have a strong protective effect against various inflammatory or autoimmune disorders, justifying the use of TYK2 inhibitors to treat some of these conditions.[6] Further understanding of genetic predisposition to TB is of clinical importance for new approaches to prevention and alternative approaches to therapy of the disease (e.g., recombinant IFN-γ).

GENETIC DISORDERS OF THE TLR3 PATHWAY IN HERPES SIMPLEX VIRUS-1 ENCEPHALITIS

This group of genetic disorders leads to impaired TLR3 signaling and susceptibility to HSE in childhood (Fig. 35.3).[7] The affected

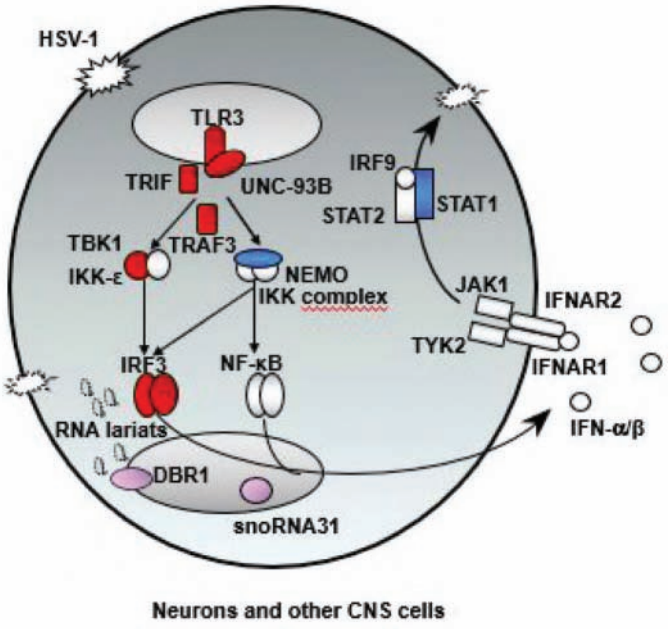

FIG. 35.3 Genetic Etiologies Underlying Herpes Simplex Encephalitis and Other Viral Encephalitis. Viruses enter the cells *(neurons, and other CNS cells)* and viral dsRNa is detected by TLR3. This recognition induces activation of IRF3 and nuclear factor-κB (NF-κB) pathway, leading the production of type I and type III interferons (IFNs). The binding of IFNs to their receptor induces the phosphorylation of JAK1 and TYK2 activating STAT1, STAT2, and IRF9. This complex is translocated as a heterotrimer to IFN-inducible genes. Proteins for which genetic mutations have been identified with susceptibility to herpes simplex virus (HSV)-1 encephalitis (HSE) andTLR3 signaling pathways are shown in *red*. Mutations in other genes of TLR3-IFNs pathway are shown in *blue*. Impaired TLR3 dependent, IFN-mediated cortical neuron and oligodendrocyte-autonomous anti-HSV-1 immunity underlie the pathogenesis of HSE in SnoRNA31 and DBR1 deficiencies (these deficiencies are shown in *pink*).

patients carry mutations of *TLR3*, *UNC93B1*, *TRIF*, *TRAF3*, *TBK1*, or *IRF3*. UNC-93B is a 12-transmembrane domain protein present in the endoplasmic reticulum (ER) that delivers the nucleotide-sensing receptors TLR3, 7, 8, and 9 from the ER to the endolysosomes. The TLR3 signaling pathway is exclusively mediated by the TRIF adapter and leads to activation of the transcription factors IRF3 and NF-κB. TRIF recruits TRAF6 and activates TAK1 in order for NF-κB to be activated. TRIF also recruits a signaling complex involving TBK1 and IKKε via TRAF3 for IRF3 activation.[7] This signaling pathway induces the production of type I and III IFNs (-α, -β, and -λ) as well as inflammatory cytokines that are important for antiviral immunity. TRAF3, TBK1, and IRF3 have functions downstream from multiple TNF family receptors as well as the receptors inducing IFN-α, -β, and -λ production, including TLR3. Genetic studies of isolated HSE of the forebrain led to the discovery of single-gene inborn errors of the TLR3-dependent pathway inducing IFN-α/β and -λ. These included mono- or biallelic mutations of the six TLR3 pathway genes (see Fig. 35.3).[7]

These findings, together with the previous observation of syndromic HSE in patients with X-linked recessive (XR) NEMO deficiency or AR complete STAT1 deficiency, suggested that TLR3-dependent IFN-α/β and/or -λ immunity is crucial for host defense against HSV-1 in the central nervous system (CNS). It has also been suggested that other mutations of these and other TLR3 or IFN pathway genes may underlie HSE in children or adults.[7] Interestingly, a few other patients with mutations of *TLR3* developed influenza A virus (IAV) pneumonitis or VZV ophthalmicus.[7] Importantly, TLR3-mediated responses to dsRNA and antiviral immunity seem to be redundant in most TLR3-expressing (non-CNS) cell types, including leukocytes in particular, which likely accounts for the lack of viral dissemination during the course of HSE.

The hypothesis that CNS-specific cell-intrinsic immunity rather than leukocyte-mediated immunity is crucial for host defense against HSV-1 was tested experimentally, initially with dermal fibroblasts as surrogate cells, and then with induced pluripotent stem cell (iPSC)-derived CNS- and peripheral nervous system (PNS)-resident cells from patients with forebrain HSE and mutations affecting TLR3 pathway genes. This work was consistent with studies showing that murine Tlr3 is required for responses to HSV in neurons and astrocytes. TLR3 pathway-deficient human fibroblasts[7,24,25] and iPSC-derived cortical neurons and oligodendrocytes[26] were found to be much more susceptible to HSV-1 infection than control cells. This phenotype was rescued by the addition of exogenous IFN-α/β. By contrast, in vitro differentiated human UNC-93B-deficient astrocytes or neural stem cells as well as TLR3-deficient peripheral trigeminal ganglia (TG) neurons did not show increased HSV-1 susceptibility compared to that of control cells.[26] Microglial cells, the CNS-resident macrophages that have been shown to rely on the cGAS/STING pathway to orchestrate anti-HSV-1 defense in mice, have not yet been tested in the human response to HSV-1 infection. Taken together, these data suggest that TLR3-dependent, IFN-mediated cortical neuron- and oligodendrocyte-autonomous anti-HSV-1 immunity appears to be crucial for host defense against HSV-1 infection in the human forebrain. These data provided a plausible cellular basis for the pathogenesis of genetically driven forebrain HSE, suggesting that cell-intrinsic immunity was crucial for host defense against HSV-1 in the human forebrain, as opposed to the innate and adaptive immunity mediated by leukocytes and related cells.[24,25] Treatment with recombinant IFN–α, in parallel with acyclovir, may

THERAPEUTIC PRINCPLES

Treatment of Patients With Genetic Susceptibility to Herpes Simplex Virus-1 Encephalitis

- In patients with TLR3 pathway deficiencies consideration can be given for adding interferon (IFN)-α to acyclovir therapy with the possibility of improving outcome.
- Serological monitoring for herpes simplex virus-1 (HSV-1) infection should be considered in individuals carrying mutations in TLR3 pathway genes with no detectable serum anti-HSV-1 antibody.
- In the absence of an effective vaccine against HSV-1, acyclovir may be considered an appropriate prophylactic treatment in individuals carrying mutations of TLR3 pathway genes, even if serologically negative for HSV-1.

help to improve disease outcomes in patients with TLR3 pathway deficiencies and HSE. With the exception of AR complete TLR3 deficiency and AR complete TRIF deficiency that have only been reported in a single patient, the other TLR3 pathway deficiencies displayed complete penetrance at the cellular level, but incomplete penetrance at the clinical level.

GENETIC DISORDERS OF OTHER INTERFERON-INDUCING PATHWAYS IN OTHER SEVERE VIRAL INFECTIONS

IEI affecting other virus-sensing, IFN-α-β-λ-inducing pathways have been reported recently, namely POL III deficiency underlying severe VZV infection, and MDA5 deficiency underlying severe pulmonary infections caused by various viruses including rhinovirus and RSV.[7,27] POL III is a protein complex comprising 17 subunits organized into different subcomplexes. It is a cytosolic DNA sensor recognizing and transcribing AT-rich DNA to RNA, and then triggering IFN induction through the RIG-I pathway. Four children with VZV pneumonitis or CNS infection have been found to have rare heterozygous missense Mutations of *POLR3A*, *POLR3C*, or both. Leukocytes from all patients displayed poor induction of IFN-α/β and -λ in response to synthetic or VZV-derived AT-rich DNA, or upon VZV infection resulting in poor control of VZV replication.[28] This work suggested an important contribution of type I and III IFNs to host defenses against VZV. Heterozygous *POLR3F* mutations were subsequently reported in monozygotic adult twins experiencing repeated CNS vasculitis presenting in a stroke-like manner with hemiparesis, sensory deficits, and headache, clinically diagnosed as being caused by recurrent VZV reactivation.[29] MDA5 is an IFN-α/β- and -λ-inducing cytosolic sensor of double-stranded (ds)RNA associated with viral byproducts and intermediates. Biallelic or monoallelic mutations of *IFIH1* encoding MDA5 have been reported in children with pulmonary rhinovirus, RSV, or EBV infection.[27] The *IFIH1* mutations are associated with impaired (ds)RNA sensing, reduced type I IFN induction, and increased cellular susceptibility to rhinovirus and RSV. Thus, human MDA5 deficiency is a novel inborn error of innate and/or intrinsic immunity that predisposes to respiratory viral infections. These new findings further highlighted the non-redundant role of type I and III IFNs in antiviral immunity in humans.

GENETIC ETIOLOGIES OF LIFE-THREATENING INFLUENZA PNEUMONITIS

Influenza viruses, including IAV and influenza B virus (IBV), have caused upper respiratory tract diseases throughout human history. Typically influenza virus infection causes a relatively mild disease of the upper respiratory tract that is readily cleared with little need for medical intervention.[27] However, infection with seasonal or more virulent pandemic influenza strains can cause life-threatening or fatal disease (e.g. acute respiratory distress syndrome [ARDS]). Four IEIs—GATA2, IRF7, IRF9, and TLR3 deficiencies—have been identified to be associated with life-threatening influenza pneumonitis (see Table 35.1).[8,27] Autosomal dominant (AD) GATA2 deficiency is the only one of these IEIs leading to a pleiotropic syndromic disorder that manifests as a lack of lymphoid and myeloid progenitors in the bone marrow, small numbers of DCs, monocytes, T, B, and NK cells, together with high susceptibility to viral, mycobacterial, and fungal infections. The deaths of four adults from severe IAV infection despite the presence of neutralizing antibodies in the serum have been reported. The lack of plasmacytoid DCs (pDCs) may contribute to susceptibility to IAV, because pDCs are known to produce a massive amount of type I IFN in response to viral infections. Type II IFN-mediated hypercytokinemia during infection was observed in two of the four patients, suggesting that immune dysregulation may also contribute to the severity of pneumonitis.[27]

Unlike patients with AD GATA2-deficiency, those with AR IRF7 or AR IRF9 deficiency have an essentially isolated susceptibility to influenza (see Table 35.1).[8,9,27,30] No overt immunological abnormality has been detected in these patients except for two recently reported IRF9-deficient siblings born to a consanguineous family.[27] Defects of IRF7 or IRF9 interrupt both type I and type III IFN signaling. IRF7 deficiency hinders the early production of type I IFNs by pDC. In contrast, IRF9 deficiency prevents IFN-stimulated gene factor 3 (ISGF3, a complex of STAT1, STAT2, and IRF9) formation that blocks downstream type I and III IFN responses. The cells of IRF7- and IRF9-deficient patients are susceptible to IAV infections in vitro, and to laboratory strains of other viruses.[27] Most recently, three unrelated, otherwise healthy, patients who carry heterozygous *TLR3* mutations have been reported to developed influenza pneumonitis but not HSE (see Table 35.1).[30] Two of these patients carried the same mutation as previously detected in four HSE patients.[30] Defects of TLR3 impair both type I and type III responses to IAV that can be rescued in vitro by exogenous type I and/or III IFNs, depending on the distribution of IFN receptors on the infected cell types. For example, either type I or type III IFNs can rescue defective TLR3 signaling in IAV-infected pulmonary epithelial cells (PECs) because both receptors are strongly expressed.[30] Observations in cases of TLR3 deficiency suggest that the tissue distribution of type I or type III IFN signaling molecules can determine the susceptibility to IAV. To date, no patient suffering from both HSE and IAV ARDS has been reported, indicating incomplete penetrance in both diseases' susceptibility. Recently, one adult Iranian patient has been reported with a CMV pneumonitis carrying a homozygous mutation in nitric oxidase synthase 2 (NOS2).[10] The mechanism connecting CMV infection and NOS2 deficiency has not yet been identified and requires further investigation.

GENETIC ETIOLOGIES IN HUMAN PAPILLOMAVIRUSES

HPVs are ubiquitous small DNA viruses with strict tropism for cutaneous or mucosal stratified epithelia. HPVs cause common, plantar, and flat warts on the skin, multifocal epithelial hyperplasia (MEH), mucosal condyloma, as well as cervical and oropharyngeal lesions. Persistent infections can lead to benign tumors and, in some cases, malignant transformation and progression to invasive cancer. Severe HPV infections are frequent in patients with HIV infection or on immunosuppressive treatment, indicating an important role for adaptive T-cell immunity in the control of HPV infection. In contrast to these syndromic HPV susceptibilities, some patients have isolated severe HPV infection

with milder T-cell deficiencies resulting mostly in decreased numbers or partially impaired function of CD4 T cells, as seen in patients with complete CD4 or IL-7 deficiency.[31–33] Among isolated susceptibilities to HPV infection, epidermodysplasia verruciformis is the best studied. The patients are specifically susceptible to β-HPVs that cause flat warts. AR amorphic mutations of *TMC6*, *TMC8*, and *CIB1*, encoding EVER1, EVER2, and calcium and integrin binding protein1 (CIB1), respectively, have been reported in these patients.[11,12,34] The EVER and CIB1 proteins have been shown to form a complex, and are thought to be viral restriction factors in skin keratinocytes.[12] Recently, juvenile recurrent respiratory papillomatosis, driven by certain α-HPVs, was shown to be due to biallelic gain of function (GOF) in *NLRP1*, suggesting an important role of cell intrinsic immunity against HPVs other than β-HPVs (α, γ, μ and ν).[11,34] Altogether, the studies of inherited susceptibility to HPVs reveal a central role of CD4 T cells and of keratinocyte intrinsic immunity for the control of the infection.

HUMAN GENETIC BASIS OF FULMINANT VIRAL HEPATITIS

Fulminant viral hepatitis (FVH) is a severe condition of liver function characterized by massive hepatocyte necrosis and an inflammatory infiltrate.[13] FVH is life-threatening, but the patients are typically otherwise healthy, and normally resistant to other microbes. Hepatitis A virus (HAV) and hepatitis B virus (HBV) are frequently involved in FVH. The actual prevalence and incidence of FVH worldwide are not precisely known, but previous studies have suggested that FVH develops in no more than 0.5% and 0.1% of individuals with symptomatic HAV and HBV infections, respectively. The outcome is poor, with fewer than 20% of patients surviving in the absence of liver transplantation. FVH is typically sporadic, but rare familial forms also exist, suggesting that there may be causal monogenic IEI. AR complete IL-18 binding protein (IL-18BP) deficiency was identified in 2019 as the first genetic etiology of FVH following HAV infection.[35] A girl born to a consanguineous family from Algeria but living in France died of FVH. The patient carried a homozygous private mutation in *IL18BP* gene, which encodes the IL-18B.[35] IL-18BP has a high affinity for IL-18 and blocks the binding of this cytokine to its membrane-bound receptor, IL-18R. It is known that IL-18 is hepatotoxic and was initially identified as the cytokine responsible for liver failure in a murine model. The mechanism is thought to involve enhanced IL-18- and IFN-γ-dependent killing of hepatocytes mediated by NK and CD8 T cytotoxic cells. Moreover, the FVH-causing *IL18BP* genotype suggests that excessive IL-18 immunity may be a general mechanism underlying FVH, perhaps through the enhancement of IFN-γ immunity. The elucidation of the genetic basis of FVH has important clinical implications (given the high mortality) for patients and their families, with the possibility of genetic diagnoses and counseling plus enabling the development of treatments based on the immunological mechanism involved.[13]

HYPOMORPHIC MUTATIONS OF *IKBKG*/NEMO

XR anhidrotic ectodermal dysplasia with immunodeficiency (XR-EDA-ID) is a rare IEI associated with a developmental disorder (Fig. 35.4) (OMIM# 300291). Patients with XR-EDA-ID carry hypomorphic mutations of *IKBKG*, which encodes IKK-γ/NEMO, a protein essential for NF-κB activation. More than 100 patients with such mutations have been reported.[36] The only immunological abnormality known to be common to all patients with NEMO deficiency is low levels of memory B cells, while an absence of serum antibodies generated to carbohydrate antigens has also been reported in the majority of patients. Some patients have high IgM levels, and a small number have NK-cell abnormalities.[36] The infectious phenotype of patients with *IKBKG* mutations patients is characterized by infections caused by encapsulated pyogenic bacteria, such as *Haemophilus influenzae* and *Streptococcus pneumoniae*. Infections caused by weakly pathogenic microorganisms, such as *M. avium* and *M. kansasii*, as well as other viral and bacterial infections have also been reported.[36] Infections are marked by a poor or delayed clinical and biological inflammatory response. Some patients (~20%) present with recurrent diarrhea and/or colitis. About 80% of the patients with *NEMO* mutations described have ectodermal dysplasia (EDA), which is characterized by hypohidrosis, widely spaced cone-shaped or peg-shaped teeth, and hypotrichosis (see Fig. 35.4).[36] These features result from defective signaling downstream from the ectodysplasin receptor. A small number of patients with more severe *IKBKG* mutations have been reported to display osteopetrosis and lymphedema associated with the EDA phenotype.[36] Some patients also have dysmorphia with mild frontal bossing. However, about 10% of patients with *IKBKG* mutations display none of the classic features of the EDA phenotype.[36,37]

FIG. 35.4 Ectodermal Dysplasia With Immunodeficiency Patients. Two patients with ectodermal dysplasia with immunodeficiency, one with widely spaced cone- or peg-shaped teeth, the other having conical incisors.

GENETIC DISORDERS OF IKKα/IKKβ

βAR complete IKKβ deficiency (OMIM#603258) was first reported in 2013, in four infants.[38] All patients presented with early-onset, life-threatening bacterial, mycobacterial, fungal, and viral infections as well as failure to thrive, conditions consistent with a clinical diagnosis of severe combined immunodeficiency (SCID).[38] Other patients with biallelic loss-of-function (LOF) mutations of *IKBKB* and a similar infectious phenotype have since been reported.[16] Immunological and functional investigations revealed abnormal T-cell differentiation (excess of naïve T cells), very low levels or absent regulatory T cells (Tregs), and low or absence of γ/δ T cells. The B-cell differentiation is also impacted with low levels of class-switched memory B cells.[16] IKKβ-deficient patients display no signs of EDA, developmental or gene regulatory defects in other organs, except for two patients with conical teeth.[16] A heterozygous GOF mutation of *IKBKB* has also been reported.[39] The patients presented with recurrent otitis media and sinusitis. EDA was considered possible only in the proband of one kindred. These patients have immune dysregulation, combined T-cell and B-cell deficiency, with low levels of naïve T cells and memory B cells associated with hypogammaglobulinemia.[39] Finally, AR complete IKKα deficiency is very rare and, like NEMO deficiency, seems to lead to a spectrum of phenotypes extending from fetal death to severe EDA-ID-like phenotypes in newborns. The presence of a heterozygous stop-gain mutation in a public database and the absence of a phenotype in the heterozygous parents in the initial report of the AR condition excluded the possibility of dominance by haploinsufficiency.

HYPERMORPHIC MUTATIONS OF NUCLEAR FACTOR-κB INHIBITOR ALPHA (NFKBIA/IκBα)

Heterozygosity for a hypermorphic or GOF *NFKBIA* mutation (OMIM#164008) encoding IκBα was first reported in 2003, in a European patient.[40] Other unrelated patients with seven different hypermorphic mutations of *NFKBIA* have since been reported.[40] IκBα GOF mutations lead to an impairment of T-cell receptor (TCR) signaling in 70% of patients, while all patients described with these mutations have impaired TNFR and IL-1R/TLR responses.[40] Patients with *NFKBIA* GOF mutations have low levels of memory B cells, dysgammaglobulinemia, and low levels of specific antibodies. Some also have low proportions of memory CD4 or CD8 T cells, or both, an excess of naïve T cells, or an absence of TCRγ/δ T cells. With the exception of two patients with IκBα disorder, one with complex mosaicism and one with S36Y mutation, all patients have been found to have the features of EDA.[36,40] Patients with IκBα GOF mutations have developed recurrent bacterial infections: pneumonia, sepsis or meningitis, and arthritis. They are also prone to opportunistic infections, such as *Pneumocystis jiroveci* pneumonia and CMC. Finally, some patients have presented with recurrent diarrhea and/or colitis.[16]

LUBAC DEFICIENCY: HOIL1/RBCK1 AND HOIP/RNF31 DEFICIENCIES

AR complete HOIL-1 deficiency (HOIL1/*RBCK1*, OMIM#610924) due to biallelic mutations of the HOIL-1 gene was first reported in 2012.[41] Patients had an autoinflammatory syndrome with pyogenic bacterial diseases, which led to their death.[41] LUBAC deficiency results in an impaired response to TNF and IL-1β in fibroblasts as well as an impaired response to CD40L in B cells, but it also leads to hyperresponsiveness to IL-1β in monocytes. Patients presented with recurrent systemic inflammatory symptoms starting during the first few months of life due to monocyte overactivation. They also developed recurrent pyogenic bacterial infections caused by *S. pneumoniae, H. influenzae, Escherichia coli, Staphylococcus* spp., and *Enterococcus*, at least in part because of their inability to produce anti-polysaccharide antibodies. One patient also had chronic CMV infection and another had *Giardia intestinalis* infection.[41] All patients also had amyotrophy, muscle weakness, and failure to thrive, probably due to muscular amylopectinosis complicated by peripheral myopathy and cardiomyopathy.[16] Interestingly, 14 patients with HOIL1 deficiency from 10 unrelated kindreds were identified on the basis of neuromuscular and cardiac involvement secondary to amylopectinosis. Partial AR HOIP deficiency (RNF31, OMIM# 612487) has been identified in two patients. The first patient displayed an autoinflammatory syndrome, pyogenic bacterial diseases, amylopectinosis, and lymphangiectasia.[42] There are reports of a second patient diagnosed with common variable immune deficiency (CVID) who displayed autoinflammation in the absence of lymphangiectasia or amylopectinosis. At the cellular level, HOIP deficiency is similar to AR HOIL-1 deficiency (see above), presenting with recurrent episodes of amyotrophy, muscle weakness, and failure to thrive, partly because of muscle amylopectinosis. These two cases of HOIP deficiency displayed similar clinical features of immune dysregulation.[16] Both suffered from severe bacterial infections due to the low level of memory B cells and impaired antibody production.

IRAK4 AND MYD88 DEFICIENCY

AR complete IRAK-4 deficiency (OMIM#607676) was first described in 2003.[14] These patients have normal basic immunophenotyping results, normal antigen-specific T-cell and B-cell responses with two notable exceptions.[16] First, the glycan-specific IgG and IgM antibody responses to pneumococcal and AB glycans (allohemagglutinins of the ABO system) are impaired in up to one third of the cases explored.[43] Second, serum IgE and IgG4 concentrations are high in up to two thirds and one third of the patients, respectively.[43] The IRAK-4-deficient patients were found to have a specific deficiency of unswitched memory B cells ($CD19^+$, IgD^+, $CD27^+$) but normal levels of switched memory B cells. IRAK-4 deficiency confers a selective predisposition to severe bacterial infection (*S. pneumoniae*, *S. aureus*, and *Pseudomonas aeruginosa*), with an impairment of the ability to increase plasma C-reactive protein (CRP) concentrations and to mount a fever at the beginning of an infection. Patients with IRAK-4 deficiency suffered from their first bacterial infection before the age of 2 years. However, the clinical phenotype of IRAK-4 deficiency seems to improve with age, as none of the patients had invasive bacterial infection after the onset of adolescence.[43] However, patients with IRAK-4 deficiency suffer from skin and respiratory infections even during and after adolescence.[43] AR complete MyD88 deficiency has been described in more than 20 patients (OMIM#612260).[15,43] The clinical and immunological features of these patients are similar to those with AR complete IRAK-4 deficiency.[15,16,43]

THERAPEUTIC PRINCPLES

Principles for the Treatment of Inherited Disorders of TIR-Mediated Immunity

- Patients should receive conjugated and nonconjugated vaccines against encapsulated bacteria (*S. pneumoniae*, *H. influenzae*, *N. meningitidis*). All live vaccines (BCG, poliovirus, MMR) are contraindicated.
- A preventive treatment, including antibiotic prophylaxis with trimethoprim-sulfamethoxazole and/or penicillin V, should be administered throughout the life of the patient.
- Monthly prophylactic administrations of intravenous or subcutaneous immunoglobulins should be considered in selected patients.
- Empiric parenteral antibiotic treatment against *S. pneumoniae*, *S. aureus*, and *P. aeruginosa* should be initiated as soon as an infection is suspected or if the patient develops a moderate fever, without taking inflammatory parameters into account.
- Hematopoietic stem cell transplantation should be considered in selected patients with genetic disorders of NEMO, IκBα, and complete deficiency of IKBKB.
- Patients with HOIL-1 and HOIP deficiencies should be followed for possible muscle weakness and cardiomyopathy. Heart transplants may need to be considered for these patients.

TIRAP Deficiency

AR complete TIRAP deficiency (OMIM#606252) has been identified in eight individuals of a large consanguineous family.[44] The homozygous mutation (R121W) of the Toll-IL-1 receptor domain-containing adapter protein (TIRAP) identified in this family affects the TIR domain and impairs the binding of TIRAP to both the receptor and MyD88. All but one of the individuals had no clinical phenotype and this patient suffered from pneumonia and sepsis caused by Panton-Valentine leukocidin (PVL)-producing *S. aureus*. Specific deficiency of unswitched memory B cells ($CD19^+$, IgD^+, $CD27^+$) but normal levels of switched memory B cells were observed.[44] Antibody production was normal in all carriers of the mutation, except for an absence of antibodies directed against lipoteichoic acid (anti-LTA) in the patient with clinical manifestations. In humans, the leukocyte response to LTA is mediated principally by TLR2/6 heterodimers acting in concert with CD36, but anti-LTA antibodies enhance this response through the recognition of their invariant IgG domain by CD32.[44]

Genetic Disorders of Interleukin-17-Mediated Immunity and Chronic Mucocutaneous Candidiasis

CMC is characterized by persistent or recurrent infections of the skin (intertrigo, angular cheilitis), mucous membranes (oral, esophageal, genital), and nails (onychomycosis) caused by *Candida* (*C. albicans* in particular).[18] CMC was first described in the 1960s, and was reported to display AD heritance. Soon after, cases with a possible AR inheritance were reported. Inherited CMC usually begins early in infancy and can affect either otherwise healthy individuals (isolated CMC) or be associated with other clinical features (syndromic CMC). Superficial dermatophytosis, invasive fungal diseases, bacterial infections of the skin and respiratory tract, and viral cutaneous infections have been reported in some patients. In rare cases, cerebral aneurysms, oral/esophageal squamous cell carcinoma, or autoimmunity have also been described. These IEIs are caused by mutations of *IL17F*, *IL17RA*, *IL17RC*, *ACT1/TRAF3IP2*, *MAPK8*, *CARD9*, *STAT3*, *ZNF341*, *RORC*, *STAT1*, and *AIRE*, representing genes that disrupt the production of or the response to IL-17A and IL-17F (Fig. 35.5).[18] Some patients with invasive fungal diseases (e.g., CNS candidiasis) carry biallelic mutations of the *CARD9* gene.[18] The molecular and clinical features of CMC have been reviewed elsewhere.[18] An exception to these IEIs is the AR autoimmune polyendocrinopathy syndrome type 1 (APS-1 or autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy [APECED]) (OMIM 240300). APS-1 is caused by mutations of the *AIRE* gene resulting in impaired T-cell tolerance, with 88% of patients developing CMC. High levels of neutralizing autoantibodies against IL-17A, IL-17F, and/or IL-22 have been detected in the serum of many APS-1 patients possibly responsible for the CMC.[45]

AR complete IL-17RA deficiency (OMIM 613953) was first identified in 2011 and additional patients were reported later (see Fig. 35.5).[17,18] CMC was present in all patients, but some may also have developed staphylococcal cutaneous lesions and recurrent bacterial infections of respiratory tract.[18] The cellular phenotype was characterized by an absence of response to IL-17A and IL-17F homo- and heterodimers in the patients' fibroblasts, and to IL-17E (IL-25) in the patients' peripheral blood mononuclear cells.[18] AD IL-17F deficiency (OMIM 613956) was also first described in 2011 in a multiplex kindred from Argentina with isolated CMC.[17] A monoallelic private missense mutation of *IL17F* was detected and found to have no impact on protein production. However, this mutation greatly decreased the activity of homo- and heterodimers (IL-17F/IL-17F or IL-17A/IL-17F) containing the mutant protein, by affecting their binding to the receptor. Another patient with a monoallelic mutation of *IL-17F* has been reported, but no cellular characterization was carried out.[17] AR complete IL-17RC deficiency has been reported in three unrelated patients from Turkey and Argentina.[46] All patients suffered from CMC, and none presented invasive or recurrent bacterial infections. The clinical manifestations of infectious diseases in this group of patients resembled those in patients with AD IL-17 deficiency.[46] The homozygous mutations identified confer a loss of IL-17RC protein expression in transfected HEK293T cells, with complete abolition of the response to IL-17A and IL-17 homo- and heterodimers of patients' fibroblasts.[46] AR complete ACT1 deficiency has been reported in two patients from a consanguineous family from Algeria.[47] These two siblings developed CMC. However, one of them presented recurrent episodes of folliculitis decalvans and bilateral blepharitis caused by *S. aureus*. Their cellular phenotypes were characterized by impaired responses to IL-17A and IL-17F homo- and heterodimers in patients' fibroblasts, and impaired responses to IL-17E in T cells.[47] Recently, an AD deficiency of JNK1 has been identified in three patients from a French multiplex family. Patients presented with syndromic CMC that also included mucocutaneous infections with *S. aureus* and a connective tissue disorder. JNK1 is involved in several pathways, including the IL-17 signaling pathway. Patients' fibroblasts displayed impaired cellular responses to IL-17A and IL-17F homo- and heterodimers. In humans, JNK1 also acts downstream from transforming growth factor-β1 (TGF-β1), involved in Th17 differentiation in vitro, and, as expected, patients' peripheral blood mononuclear cells (PBMCs) displayed reduced proportions of Th17 cells.[48]

Genome-wide approaches led to the discovery of heterozygous *STAT1* missense mutations in patients with CMC (OMIM 614162).[49,50] These mutations, unlike the previously reported mono- or biallelic *STAT1* LOF mutations associated with susceptibility to mycobacterial, intracellular bacterial,

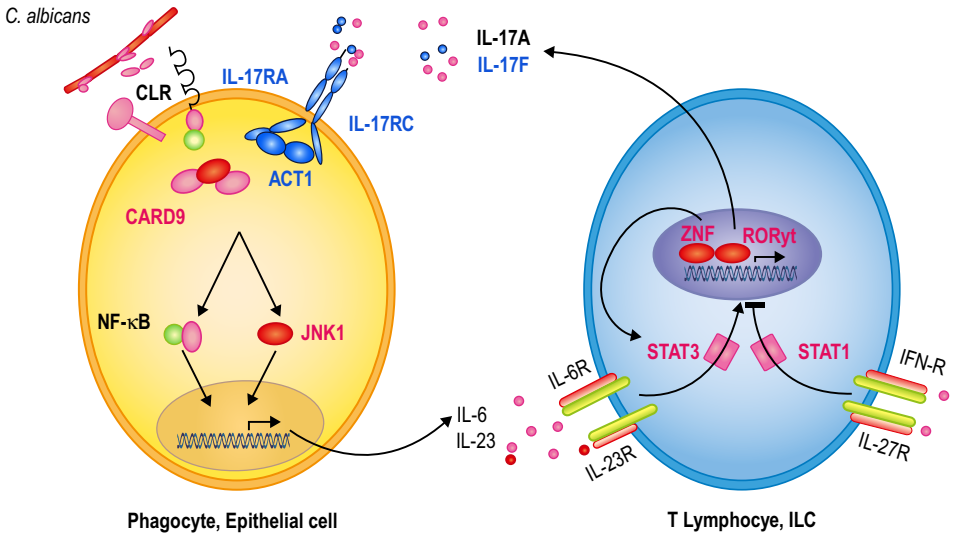

FIG. 35.5 Genetic Etiologies Affecting the Interleukin-17-Mediated Immunity. Schematic representation of interleukin-17 *(IL-17F)*-mediated immunity and cooperation between cells recognizing *Candida albicans* (phagocytes and epithelial cells) and cells producing IL-17 cytokines (T and innate lymphoid cells *[ILC]*). Proteins for which a mutation of the corresponding gene has been recognized to cause isolated chronic mucocutaneous candidiasis (CMC) are shown in *blue*, and those responsible for syndromic CMC are shown in *red*. CMC causing mutations of *IL17F*, *IL17RA*, *IL17RC*, *ACT1*, and *MAPK8* (encoding JNK1) impair responses to IL-17A/F response. CMC causing mutations of *IL12B*, *IL12RB1*, *STAT1* (GOF), *STAT3*, *ZNF341*, *RORC*, and *CARD9* genes impair the development of IL-17-producing T cells.

and viral infections, were shown to be GOF (see Fig. 35.5).[18] CMCD-causing *STAT1* mutations enhance the responses of STAT1 to IFN-α/β, IFN-γ, and IL-27, thereby repressing IL-17 T-cell development, likely accounting for the low IL-17 T-cell counts in these patients, resulting in CMCD.[18] Presently over 400 patients with STAT1 GOF have been identified worldwide. AR complete ROR-γ/ROR-γT deficiency has recently been identified in three unrelated consanguineous families (see Fig. 35.5).[22] RORC is a DNA-binding transcription factor that plays an important role in thymopoiesis. The patients suffered from an unusual combination of BCG-osis and mild CMC.[22] Mutations identified affect both IL-17 and IFN-γ immunity. The lack of functional ROR-γT protein, a transcription factor, prevents the development of IL-17-producing T cells, accounting for the CMC observed in these patients. Surprisingly, the patients also lacked mucosal-associated invariant T (MAIT) cells and invariant natural killer T cells (iNKT), which normally produce IFN-γ, and can inhibit intracellular mycobacterial replication. Moreover, their conventional CD8 α/β and γ/δ T cells, unlike their CD4 α/β T and NK cells, produced only very small amounts of IFN-γ. ROR-γ/ROR-γT, thus plays a critical role in MAIT and iNKT development, and in the capacity of γ/δ T cells and $CCR6^{+}CXCR3^{+}CD4^{+}$ α/β Th1 cells to make IFN-γ. This results in a profound impairment of IFN-γ production by lymphocytes, leading to susceptibility to mycobacterial disease and making vaccination with BCG contraindicated.[22] Antibiotic treatment can be combined with recombinant IFN-γ in cases of disseminated mycobacterial infection. Finally, patients with hyper-IgE syndrome (HIES), whether AD or AR, caused by monoallelic dominant negative mutations of *STAT3*[51,52] or biallelic loss of function mutations of *ZNF341* (see Fig. 35.5),[53,54] respectively, display syndromic CMC, with severe skin and pulmonary staphylococcal disease, severe eczema, high serum IgE levels, and some developmental abnormalities.[18] These patients were shown to display abnormally low proportions of ex vivo and in vitro differentiated Th17 cells, due to impaired signaling downstream of cytokines important in their development (e.g., IL-6, IL-23) for STAT3, or to the disruption of ZNF341-dependent STAT3 transcription and activity.[53,54] Overall, these studies strongly suggest that IL-17 immunity plays a crucial role in defense against CMC in humans. The careful clinical description of a large series of patients would be required to determine the role of these cytokines more precisely.

THERAPEUTIC PRINCIPLES

Management of Patients With Chronic Mucocutaneous Candidiasis

- Patients with *chronic mucocutaneous candidiasis* should be managed with preventive long-term antifungal therapy, principally fluconazole followed by other antifungal drugs such as itraconazole or posaconazole.
- Antibiotic prophylaxis should be considered in select patients with cutaneous staphylococcal disease.
- Immunoglobulin replacement therapy should be considered in patients with recurrent pneumonia.
- Genetically defining the defect can lead to specific immunomodulatory therapy, such as using a Janus kinase (JAK) inhibitor in patients with STAT1 gain of function mutation.

CONCLUSION

An understanding of the molecular basis of the IEIs affecting the innate and adaptive immune responses has provided detailed insight into the pathogenesis of infections in affected patients, paving the way for genetic counseling and rational treatment

design. These IEIs should be considered in patients with unexplained infectious diseases, whether caused by single or multiple infectious agents, even if all standard immunological testing has been unrevealing. Interestingly, even common infectious diseases, such as TB, invasive pneumococcal disease, and HSE, may be associated with monogenic immune disorders. The discovery of many novel IEIs opens up exciting new perspectives, not only in increasing our understanding of immunity to pathogens but also benefiting patients. It is thought that most patients with severe infectious diseases likely suffer from an underlying IEI, and they should therefore be investigated for known and potentially unknown immunodeficiency conditions.

ON THE HORIZON

- Unexplained infectious diseases occur in patients, particularly in children, as a result of an inborn error of immunity.
- Patients with severe infectious disease should be repeatedly investigated even if all standard immunological testing has been unrevealing.
- The exploration of these defects, by application of next-generation deep-sequencing technologies, provides tools for molecular diagnosis and genetic counseling and opens up exciting new perspectives benefiting patients.
- The identification of associated genetic defects will also guide rational treatment based on improvements in our understanding of specific disease pathogenesis.

ACKNOWLEDGMENTS

We thank our collaborators, our patients, and families for their assistance in making possible the studies contained in this chapter. We thank all the members of the Human Genetics of Infectious Diseases Laboratory for helpful discussions. The Laboratory of Human Genetics of Infectious Diseases is supported by grants from The Rockefeller University Center for Clinical and The Rockefeller University. The Laboratory of Human Genetics of Infectious Diseases is supported by ANR, ANRS, NIH grants; the INSERM and the Fondation pour la Recherche Médicale (FRM).

KEY CONCEPTS

- New IEIs should be sought in patients with unexplained infectious diseases.
- Children with severe infectious diseases should be repeatedly investigated for known and unknown immunodeficiency conditions.
- The exploration of idiopathic infections leads to the discovery of new IEIs and to a better understanding of immunity to pathogens.

Principles for the Treatment of Mendelian Susceptibility to Mycobacterial Disease Patients

- Vaccination with live BCG is contraindicated.
- Multiple ATBs against mycobacteria should be administered without interruption in patients with complete IFN-γR1, IFN-γR2, IRF8 or STAT1 deficiency.
- Prolonged and aggressive antimycobacterial ATBs may be associated with subcutaneous recombinant IFN-γ in selected patients with partial IFN-γR1, IFN-γR2, IRF8, CYBB, JAK1 or STAT1 deficiency, complete IL-12p40, IL12Rβ1, IL12Rβ2, IL-23R, SPPL2A, IFN-γ or ISG15 deficiency.
- HSCT should be considered in patients with complete IFN-γR1, IFN-γR2, IRF8, or STAT1 deficiency.

Principles for the Treatment of Herpes Simplex Virus-1 Encephalitis

- Treatment with IFN-α, in parallel with acyclovir, may help to improve disease outcome in patients with TLR3 pathway deficiencies, in particular.
- Serological monitoring for HSV-1 infection should be considered in individuals carrying mutations of TLR3 pathway genes but with no anti-HSV-1 antibody detectable in serum.
- In the absence of an effective vaccine against HSV-1, acyclovir may be considered an appropriate prophylactic treatment in individuals carrying mutations of TLR3 pathway genes, even if serologically negative for HSV-1.

Principles for the Treatment of Inherited Disorders of TIR-Mediated Immunity

- Patients should receive conjugated and nonconjugated vaccines against encapsulated bacteria (pneumococcus, *H. influenzae*, meningococcus). Live vaccines (BCG, poliovirus) are contraindicated.
- A preventive treatment, including ATB prophylaxis with trimethoprim-sulfamethoxazole and/or penicillin V, should be administered throughout the life of the patient.
- Monthly prophylactic administrations of intravenous or subcutaneous immunoglobulins should be considered in selected patients.
- Empiric parenteral ATB treatment against *S. pneumoniae*, *S. aureus*, and *P. aeruginosa* should be initiated as soon as an infection is suspected or if the patient develops a moderate fever, without taking inflammatory parameters into account.
- HSCT should be considered in selected patients with genetic disorders of NEMO, IκBα, and complete deficiency of IKBKB.
- Patients with HOIL1 and HOIP deficiencies should be followed for possible muscular weakness and cardiomyopathy. Heart transplants should be considered for these patients.

Principles for the Treatment of Chronic Mucocutaneous Candidiasis

- A preventive antifungal treatment, (principally fluconazole) should be administered in the long term, followed by other antifungal drugs, such as itraconazole or posaconazole.
- ATB prophylaxis should be considered in selected patients with cutaneous staphylococcal disease.
- Monthly prophylactic administrations of intravenous immunoglobulins should be considered in selected patients with recurrent pneumonia.
- G-CSF, the JAK inhibitor ruxolitinib or HSCT may also be considered.

Hemophagocytic Lymphohistiocytosis

Michael B. Jordan and Adi Zoref Lorenz

Hemophagocytic lymphohistiocytosis (HLH) is an increasingly recognized life-threatening hyperinflammatory syndrome. The syndrome of HLH describes both patients with familial HLH (due to a variety of genetic lesions) as well as patients without clear genetic causes, many of whom have other medical conditions, including infection, malignancy, and rheumatologic disorders that are thought to contribute to its development.

KEY CONCEPTS

- A hyperactive immune response, characterized by excessive activation of T cells, which recruit innate effector cells, leading to severe, often fatal, immune-mediated pathology
- Tissue damage is due to the toxic effects of immune activation, not self-reactivity ("collateral damage" instead of autoimmunity)
- "Hemophagocytosis" refers to the appearance of macrophages eating other cells in an apparent nonspecific fashion
- Although hemophagocytic lymphohistiocytosis (HLH) has been historically divided into familial (or "primary") forms and "secondary" forms, it should be viewed as a singular syndrome that is associated with a continuum of genetic and environmental risk factors.
- The syndrome of HLH encompasses HLH diseases (requiring immune suppression for treatment) and HLH disease mimickers—diseases that create the same clinical picture but do not involve immune activation or require immune suppression

HLH may present in a variety of clinical contexts. Patients in the familial HLH (fHLH) category are usually infants or young children with a positive family history or known genetic causes. These patients have a clear risk of HLH recurrence and will generally not survive long term without hematopoietic cell transplantation (HCT). Although HLH in these patients can be associated with infections or vaccination, the immunologic activator is often not apparent.

Older children or adults who present without a family history or a known genetic cause typically have concurrent infections or medical conditions that appear to activate their HLH. These patients have historically been referred to as "secondary HLH," as opposed to "primary" (familial) HLH. However, a variety of data indicate that this dichotomy is a false one; "triggers" are seen in many patients with fHLH. Experimental studies demonstrate that even severe genetic lesions still require a trigger—suggesting that some patients have unrecognized triggers. Finally, the range of identified genetic lesions now includes milder ones, which typically present at older ages.

In certain cases the term "secondary" is still apt, due to their distinctive features and treatments: malignancy (a unique sort of "acquired genetic lesion") and rheumatologic disorders, such as systemic onset juvenile idiopathic arthritis (SJIA). Although the clinical contexts and triggers for HLH are diverse, the immunopathologic syndrome that develops in response to excessive or poorly regulated adaptive immune responses is similar in all patients. Indeed, the severity of mutations appears to underlie an individual's risk for developing HLH in response to mild or extreme immune stimuli.[1]

EPIDEMIOLOGY

The exact incidence and prevalence of HLH are unknown and remain challenging to ascertain accurately. The diagnosis of HLH is challenging because of its variable presentation and the many nonspecific clinical features it shares with other disease processes. HLH is considered to be rare, but increasing awareness and recognition of the syndrome is leading to more frequent diagnoses.

Infants are most commonly affected, with the highest incidence in those less than 3 months of age. A report estimated the prevalence of fHLH in tertiary care pediatric hospitals as 1 case per 3000 inpatient admissions.[2] A comprehensive, population-based study in Sweden reported an incidence of 1.2/1,000,000 children per year. One child per 50,000 live born developed fHLH during the 15 years study period.[3] Although HLH is primarily a pediatric disease, it is diagnosed in patients of all ages. In a large cohort from Japan, 40% of the HLH patients were adults.[4,5] The incidence may be as high as 1 in 2000 adult admissions at tertiary medical centers.[6]

PATHOPHYSIOLOGY OF HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

- In genetic forms, a disorder of intrinsic immune regulation
- In syndromic forms not well understood
- T cells are the keys driver of disease
- Interferon gamma (IFN-γ) is the main mediator in genetic forms

PATHOPHYSIOLOGY

HLH is a syndrome of excessive inflammation and tissue destruction due to abnormal immune activation. For fHLH at least, experimental studies in animal models have demonstrated that HLH results from excessive activation of a normal CD8 T-cell reaction (an otherwise physiologic response to infection) (Chapter 12).[7] The lack of normal cytotoxic function deregulates antigen presentation, leading to excessive T-cell activation. Several key concepts are apparent from these studies. First, the immune response itself, not the infectious or other environmental activators, drives disease pathology. Second, unlike many other

immune disorders, immune activation, not self-reactivity (or autoimmunity), is the cause of disease pathology. Third, while macrophages are clearly involved in disease development, T cells (specifically CD8 T cells) are key upstream drivers of HLH disease.[8] Finally, across multiple genetic models, interferon gamma (IFN-γ) (Chapter 14) is a key mediator of disease development and is likely the principal connector between activated T cells and activation of macrophages. Furthermore, the clinical testing of anti-IFN-γ antibody (emapalumab) has proven that IFN-γ is a key driver of disease.[9]

GENETICS

A widening spectrum of genetic lesions associated with HLH is now recognized, in which the most severe ones inevitably lead to HLH at an early age, and milder ones are associated with older onset age and more potent environmental activators. Single allele mutations typically thought of as conferring only carrier status are frequently seen in patients with HLH associated with rheumatologic disorders or malignancy.[10] Thus, genetic contribution/risk does not fit neatly into the familial/nonfamilial dichotomy.

A nonexhaustive list of genetic lesions leading to HLH is described in Table 36.1. A recent whole-exome based study has expanded the list of potentially HLH-associated genes to include other genes associated with immune function and regulation, albeit with less clear causality. However, the overall theme of all of these genetic findings is that fHLH is caused by defective immune regulation, leading to excessive activation of T cells and macrophages (Fig. 36.1).

TABLE 36.1 Genetic Mutations Associated With Hemophagocytic Lymphohistiocytosis

Gene	Disease	Apparent Mechanism of HLH Predisposition
PRF1	FHL2	Defective granule-mediated cytotoxicity
UNC13D	FHL3	
STX11	FHL4	
STXBP2	FHL5	
RAB27A	Griscelli syndrome	
LYST	Chediak-Higashi syndrome	
AP3B1	Hermanski-Pudlak syndrome	
XIAP	XLP2/ X-linked HLH	Disorders of inflammasome activation
NLRC4	Auto-inflammation with infantile enterocolitis	
CDC42	NOCARH syndrome	
SH2D1A	Lymphoproliferative syndrome, X-linked, 1 (XLP1)	Disorders of T-cell signaling
ITK	Lymphoproliferative syndrome 1	
CD27	Lymphoproliferative syndrome 2	
MAGT1	Immunodeficiency, X-linked, with magnesium defect, Epstein-Barr virus infection, and neoplasia (X-MEN)	
SLC7A7	Lysinuric protein intolerance	Disorders of macrophage inflammatory signaling
HMOX1	Heme oxygenase deficiency	

HLH, Hemophagocytic lymphohistiocytosis.

DIAGNOSIS

HLH was defined in the HLH-2004 study as fulfilling five of eight criteria: fever, splenomegaly, cytopenias in two or more lineages (platelets <100 K/mL, hemoglobin <9 g/dL, neutrophils <1000 /mL), ferritin >500 ng/mL, sCD25 >2400 U/mL, low NK cell function, hemophagocytosis on biopsy, and either fibrinogen <150 mg/dL or triglycerides >265 mg/dL. Initial symptoms of HLH are nonspecific and may overlap with other inflammatory or hematopoietic diseases. Conditions fulfilling

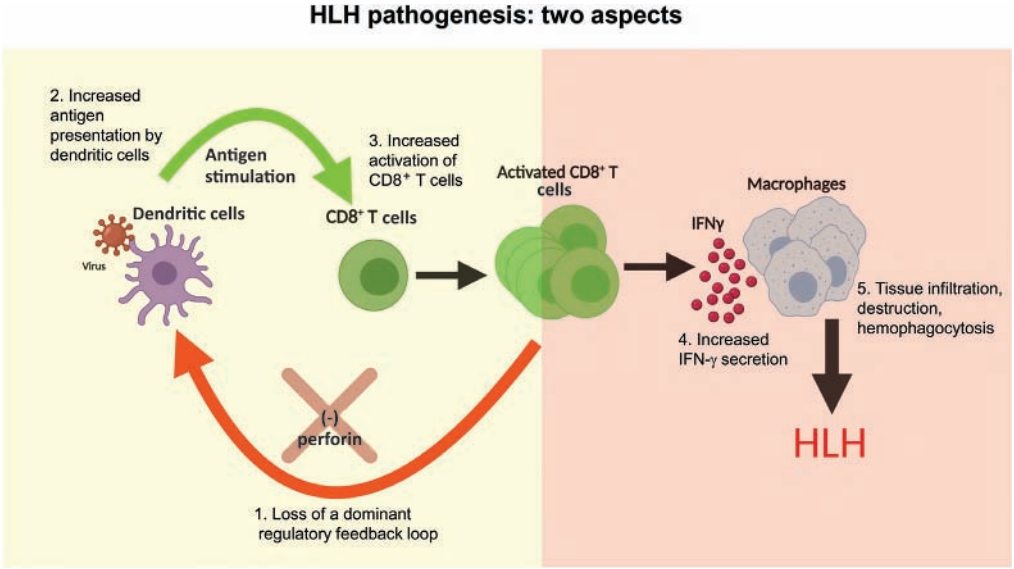

FIG. 36.1 The Pathogenesis of Familial Hemophagocytic Lymphohistiocytosis (*HLH*). T-cell responses are normally shaped by negative feedback involving the perforin pathway in which cytotoxic T cells (Chapter 12) eliminate antigen-presenting cells (Chapter 6). Patients with familial HLH (fHLH) often have defects of the perforin pathway. Experimental studies have demonstrated that defects of this feedback regulation result in excessive antigen presentation by dendritic cells, leading to excessive T-cell activation (Chapter 10), and overproduction of interferon-gamma (*IFN-γ*) (Chapter 14), leading to pathologic macrophage activation. Thus, clinical HLH results from a primary defect of immune regulation leading to severe immunopathology, which is largely driven by IFN-γ.

this syndromic definition may be conceptually split into *HLH disease* (fHLH and others) and *mimickers* of HLH disease. This distinction is important as HLH disease requires prompt and aggressive immune suppression, while other conditions may require different therapies or may be worsened by immune suppression. For example, a patient with a visceral *Leishmania* infection could present with this clinical pattern without having "inappropriate" immune activation and would be harmed by immune suppression.

Why is this concept valuable? HLH typically requires prompt recognition and treatment, often before all data can be gathered. However, this aggressive stance should be balanced by a cautious and careful exclusion of conditions that look like HLH but would not benefit from or even be harmed by immune suppression and may require different specific treatments. Undiagnosed malignancy is especially problematic as HLH-directed therapy often obscures diagnosis.[11] Moreover, the cases should be divided by the HLH activator because each has its characteristics and treatment.[12]

Since T-cell activation is central to HLH pathogenesis, sCD25 should always be elevated in untreated HLH.[13] If not elevated, then one should doubt a diagnosis of HLH. Similarly, though not as well established, because HLH appears to be primarily driven by IFN-γ, elevations of CXCL9 (Chapter 15) (a sensitive indicator of IFN-γ bioactivity) should be seen in untreated cases of HLH disease).[14] Ferritin levels above 10,000 ng/mL appear to be relatively specific for HLH in children but are not very sensitive.[15] While specialized immunologic testing may facilitate diagnosis, if a diagnosis can be made without them, then treatment should not be delayed pending these results. Likewise, treatment should not be delayed for assessment of central nervous system (CNS) involvement, though this should always be conducted (once a lumbar puncture can be safely performed).

Most features of HLH are unexpected in either their high levels (ferritin, sCD25, triglycerides), distinctiveness (splenomegaly and hemophagocytosis), or acute appearance (anemia). There are also "ironic" features that are the opposite of what we expect to see in a state of inflammation such as neutropenia, thrombocytopenia, low NK function, and fibrinogen level. Though many HLH diagnostic features are unique, their presence or absence should not automatically determine the diagnosis. Moreover, they have not been validated for secondary HLH and efforts to determine specific diagnostic criteria are ongoing.

OTHER MANIFESTATIONS

HLH may present in many forms, including fever of unknown origin (FUO); hepatitis or acute liver failure; and sepsis-like, Kawasaki-like, and familial neurologic abnormalities. Not all of the HLH diagnostic criteria may be present initially, so it is vital to follow clinical signs and laboratory markers of pathologic inflammation repeatedly to identify the trends. Typical clinical features seen in patients with HLH, grouped by organ system, are described below.

Prolonged Fever is a common manifestation. In patients with FUO, cytopenia, highly elevated ferritin (>3000 g/dL), or sCD25 significantly above age-adjusted normal ranges generally suggest that a complete HLH diagnostic evaluation should be pursued.

Liver Disease and Coagulopathy. Most patients with HLH have variable evidence of hepatitis at presentation. HLH should be considered in the differential diagnosis of acute liver failure, mainly if lymphocytic infiltrates are noted on biopsy. Most patients have evidence of disseminated intravascular coagulation (DIC) and are at high risk for acute bleeding.

Blood Lineages Cytopenia. Anemia and thrombocytopenia occur in more than 80% of patients at the time of presentation with HLH. Although hemophagocytosis in bone marrow is associated with HLH, the morphologic phenomenon may also be induced by blood transfusions, infection, an autoimmune disease, or other events. Despite the terminology of HLH, the diagnosis of HLH should never be made or excluded solely on the presence or absence of hemophagocytosis.

Neurologic Symptoms. More than one-third of patients present with neurologic symptoms. These include seizures, meningismus, decreased level of consciousness, cranial nerve palsy, psychomotor retardation, ataxia, irritability, and hypotonia. The cerebrospinal fluid (CSF) is abnormal in more than 50% of fHLH patients with findings of pleocytosis, elevated protein, or hemophagocytosis. Magnetic resonance imaging (MRI) findings are highly variable and include discrete lesions, leptomeningeal enhancement, or global edema, and images that correlate with neurologic symptoms.[12]

DISTINCTIVE CLINICAL CONTEXTS

Hemophagocytic Lymphohistiocytosis in the Context of a Rheumatologic Disease (R-HLH)

Macrophage activation syndrome (MAS) is the term most commonly used to refer to an HLH or HLH-like syndrome occurring in the context of rheumatologic disorders (Chapter 52 and 54). R-HLH is most commonly associated with juvenile idiopathic arthritis (SJIA) (Chapter 54), systemic lupus erythematosus (SLE) (Chapter 52), or adult-onset Still disease. While MAS and HLH are very similar and should be viewed as the same disease, there are notable differences in presentation. Consensus criteria for recognizing MAS in the context of SJIA have been developed, and, in general, these MAS patients are older than fHLH patients and present with substantially higher platelet and neutrophil counts as well as higher fibrinogen levels. These laboratory values are typically elevated in patients with SJIA, so normal levels may be viewed as "abnormally normal" in MAS.[16]

Hemophagocytic Lymphohistiocytosis in the Context of Malignancy (M-HLH)

The association of HLH with malignancy has been recognized for decades. Patients may present with the clinical syndrome of HLH associated with undiagnosed underlying malignancy or transformation of an indolent hematologic malignancy, or they may develop HLH during treatment for known malignancy, usually in the context of infection. The pathophysiology of M-HLH is not well defined, and the tumor itself may "mimic" the HLH diagnostic criteria. However, the prognosis of these patients is abysmal and significantly worse than other HLH etiologies.

Lymphoma deserves special mention (Chapter 78), as it is the most common malignancy associated with HLH at its initial presentation. Because of the difficulty of distinguishing lymphoma from fHLH or R-HLH, thorough imaging and aggressive biopsy, often guided by positron emission tomography/computed tomography (PET/CT), should be pursued or at least considered before starting corticosteroids and other therapies that may obscure diagnosis.[11] Malignancy may present with HLH at all ages (including infancy), but is increasingly likely at older ages and is associated

with perhaps a majority of cases in adults.[5,17] When considering M-HLH, it is essential to note that the presence of Epstein-Barr virus (EBV) viremia does not rule out malignancy (including B- or T-cell lymphomas), and sCD25 may be disproportionately elevated compared to other features of HLH in patients with occult lymphoma.[18]

CLINICAL PEARLS

Differential Diagnosis—an Hemophagocytic Lymphohistiocytosis Trigger or a Mimic of Hemophagocytic Lymphohistiocytosis Disease?

Infections

- Most atypical infections should be considered a "mimic" as hyperinflammation is not the central problem.
- Infection-specific therapy is needed, and immunosuppressive therapy is likely to be harmful.
- Common infections include visceral leishmaniasis, atypical/tuberculous mycobacteria, histoplasmosis, ehrlichia, bartonella and Brucella species, disseminated adenovirus, and disseminated herpes simplex.
- Many other (mostly viral) infections may be viewed as "triggers" of hemophagocytic lymphohistiocytosis (HLH) disease, including EBV and Cytomegalovirus CMV (which may also require infection-specific therapies).

Other Hematologic Disorders

- Mimics include Langerhans cell histiocytosis involving the marrow and/or visceral organs and multicentric Castleman disease, especially the TAFRO (thrombocytopenia, anasarca, myelofibrosis, renal dysfunction, and organomegaly) variant.
- Therapy should be directed towards the underlying disorder, +/– additional corticosteroids.

Drug Reactions

- Drug Rash with Eosinophilia and Systemic Symptoms, or DRESS syndrome, may present as HLH.
- It may be considered as both trigger and mimic as treatment requires both withdrawal of the offending agent and prolonged corticosteroids.

Storage Diseases

- Mimics include Wolman disease (infantile lysosomal acid lipase deficiency) and Gaucher disease.
- These disorders develop features of HLH (e.g., splenomegaly, cytopenias) due to processes not involving immune hyperactivation.

Metabolic Disorders

- Lysinuric protein intolerance (LPI) and others may be considered as mimics of HLH disease, as they require different, specific treatment.
- The inflammatory features of LPI in particular are notable and may be viewed as overlapping with fHLH.

Hemophagocytic Lymphohistiocytosis in the Context of Immune Compromise (IC-HLH)

HLH can occur in a variety of immune compromised patients, including primary immune deficiency (PID) or patients receiving immunosuppressive therapy, mostly in the context of unresolved infection. For instance, patients with inflammatory bowel disease (IBD) (Chapter 75)—usually treated with azathioprine or mercaptopurine—have been reported to develop (usually relatively mild) HLH after infection with EBV or cytomegalovirus (CMV). In these contexts, the pathophysiology is not well understood. While it may be related to the underlying disease, HLH appears to be a dysregulated response to infection in the context of immunosuppression. It is difficult to generalize about whether IC-HLH may benefit from significant immune suppression. For IBD patients, withdrawal of mercaptopurine, treatment of infection, supportive care, and moderate-dose corticosteroids often suffice. Thus, IC-HLH ambiguously straddles the categories of HLH disease and HLH disease mimics.

A variety of PIDs have been reported to present with HLH.[19] These include combined or selective T-cell disorders (Chapter 34), such as severe combined immunodeficiency (SCID), Omenns syndrome, severe DiGeorge syndrome, Wiskott-Aldrich syndrome, and autoimmune lymphoproliferative syndrome; selective B-cell disorders such as X-linked agammaglobulinemia (Chapter 33); and neutrophil disorders such as chronic granulomatous disease (CGD) (Chapter 39).

Patients with PID and HLH often have unresolved, severe infections. Patients with SCID most often have viral infections, while those with CGD present with bacterial infections. Thus, the presence of HLH associated with unusual or unusually severe infection should suggest undiagnosed immune deficiency.

For patients with SCID and infection, immunosuppressive therapy is generally not helpful, and this condition should be considered to be a mimic of HLH disease. HLH in CGD patients is less clear, though typical treatment for HLH beyond corticosteroids is usually not indicated. Thus, the constellation of HLH symptoms in the context of PID should typically be considered a mimic of HLH disease, though some patients may require immunosuppressive therapy.

Hemophagocytic Lymphohistiocytosis in the Context of Immune-activating Therapies (Rx-HLH)

The HLH syndrome develops in some patients receiving immune-activating therapies, such as T-cell engaging antibodies, CAR T cells (Chapter 81), or immune checkpoint inhibitors (Chapter 80). In this context, this syndrome is usually referred to as cytokine release syndrome (CRS). However, its pathophysiology appears quite similar to fHLH and should be recognized as iatrogenic HLH, or Rx-HLH.

TREATMENT

Prompt and aggressive initiation of treatment may be lifesaving.

HLH-94 Protocol

Currently, the standard of care for HLH should be considered to be treatment with etoposide and dexamethasone as per a slightly modified HLH-94 protocol.[20] In general, immediate treatment of HLH is warranted once a diagnosis is made. At the same time, it is essential to rule out HLH disease mimics or malignancies before starting therapy to avoid inappropriate treatment and obscuring the underlying diagnosis. The risk of patients deteriorating during prolonged diagnostic evaluation must be balanced against these concerns, especially in the face of limited data.

If treatment is initiated before a firm diagnosis is established, the uncertainty of the diagnosis should be revisited once the patient is stable. Though aggressive treatment is needed for most patients, initial treatment with dexamethasone alone with close inpatient monitoring may be appropriate in patients who are not infants and not severely ill.

Salvage Therapy

Emapalumab, an interferon-gamma (IFN-γ) blocking monoclonal antibody, was approved by the US Food and Drug Administration for refractory or recurrent HLH.[9] Another well-supported salvage therapy is alemtuzumab (anti CD52), which can be used as a bridge to bone marrow transplant (BMT).

Targeted Therapy

As mentioned, anti IFN-γ (emapalumab) was the first targeted therapy approved and is now being examined for frontline use in HLH and in specific subsets (R-HLH, M-HLH). A JAK1/2 inhibitor (ruxolitinib) (Chapter 86) is being investigated currently in several clinical trials. Anti-cytokine treatment is common in R-HLH (IL-1 or IL-6 blocking agents), though these patients are increasingly diagnosed with chronic complications, such as lung disease. Blockade of IL-18 (Chapter 14) is being investigated for patients with HLH driven by the inflammasome.[21]

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic hematopoietic stem cell transplantation (HSCT) is performed to prevent potentially fatal HLH disease recurrence. Patients with clear family histories and/or genetic etiologies for HLH, as well as those with significant CNS involvement or who have recurrent disease, should proceed to BMT as soon as the disease is reasonably well controlled. Moreover, patients with a hematologic malignancy that cannot be cured with conventional agents (but may be treated with HSCT) should also proceed to transplant (Chapter 92).

Relapsing HLH, however, does not always reflect an underlying genetic predisposition; sometimes, it may indicate undiagnosed underlying infection or malignancy rather than a genetic etiology. Since genetic risks are usually not known when patients present, HLA typing (Chapter 5), and preliminary donor searches should be performed early after diagnosis. Sibling donors should be screened for HLH-associated genetic lesions. Decisions regarding whether or not to proceed to transplantation hinge upon an assessment of HLH recurrence risk, balanced against the risks of transplantation.

ON THE HORIZON

- Clarification of the cellular and molecular mechanisms underlying nonfamilial hemophagocytic lymphohistiocytosis (HLH) types, development of new diagnostic tools, and improvement of therapeutic strategies.
- Use of large cohorts to validate and optimize diagnostic criteria for both familial and secondary forms of HLH.
- Clinical trials of novel therapeutic agents. Examples at the time this chapter was written include:
  - Emapalumab for fHLH, for adults with HLH, or in SJIA-MAS/HLH.
  - Recombinant IL-18-binding protein (tadekinig α) for HLH driven by XIAP or NLRC4 (see Table 36.1).
  - Ruxolitinib for HLH.

HLH, Hemophagocytic lymphohistiocytosis; *MAS*, macrophage activation syndrome; *SJIA*, systemic onset juvenile idiopathic arthritis.

SUMMARY

HLH has many forms, but it is always a disorder of excessive immune activation. fHLH is a unique PID involving excessive T-cell activation and recruitment of innate effector cells. Without prompt diagnosis and treatment, the natural history of HLH is almost uniformly fatal. Rising awareness of HLH in recent years has improved recognition, but also increased the risk of misdiagnosis and inappropriate treatment of HLH-mimicking conditions. An evolving understanding of HLH pathophysiology is beginning to alter therapy for this disease (e.g., emapalumab for second-line treatment of HLH). The recognition of clinical patterns is essential for diagnosis. However, because of the nonspecific nature of the clinical symptoms, the differential diagnoses of other inflammatory conditions must be considered to avoid unnecessary or harmful immune suppression induced by HLH therapy.

Autoinflammatory Syndromes

Catharina M. Mulders-Manders, Jeroen C.H. van der Hilst, Jos W.M. van der Meer and Anna Simon

Autoinflammatory diseases, which are also known as *periodic fever syndromes*, encompass a group of rare disorders characterized by recurrent or persistent inflammation. *Autoinflammation* is a term that has been used since the late 1990s to illustrate the difference between autoimmune disorders and diseases characterized by exuberant inflammation. Typically, autoinflammatory diseases do not show features of excess adaptive immune system activation, and autoantigens or autoantigen-specific T cells are not present in these diseases. It is now recognized that autoinflammation and autoimmunity form two ends of a spectrum of inappropriate immune system activation and share several common features.

Located at the autoinflammatory end of this spectrum are the classic monogenic autoinflammatory diseases: familial Mediterranean fever (FMF), cryopyrin-associated periodic syndrome (CAPS), mevalonate kinase deficiency (MKD; also known as *hyperimmunoglobulin D and periodic fever syndrome* [HIDS]), and tumor necrosis factor (TNF) receptor–associated periodic syndrome (TRAPS). The number of autoinflammatory diseases is increasing rapidly. New monogenic autoinflammatory diseases, as well as new autoinflammatory diseases without a clear genetic background, have been identified in the past decades. It has also become clear that autoinflammation is at least partially involved in the pathogenesis of other, more common diseases, such as gout, Crohn disease, and ulcerative colitis.

Because it is impossible to discuss all autoinflammatory diseases in detail here, the classic monogenic diseases FMF, CAPS, TRAPS, and MKD have been selected as the main focus of this chapter. Their pathophysiologic mechanisms are understood to a much higher degree than in many newer autoinflammatory diseases, and their clinical presentations have been described precisely.

In addition, two other autoinflammatory diseases are discussed, one with relatively high prevalence and the other because of its interesting pathophysiologic mechanism: (i) periodic fever, aphthous stomatitis, pharyngitis, and adenitis (PFAPA) syndrome and (ii) Schnitzler syndrome.

The cornerstone of diagnosing an autoinflammatory disease is the clinical assessment of the patient. This includes a detailed medical and family history and direct observation of an inflammatory episode. The first step in the diagnostic process is to exclude other more common causes of recurrent inflammation, including infections, malignancy and paraneoplastic phenomena, and autoimmune disease.[1] A first differential diagnosis can be made on the basis of age of onset, associated signs and symptoms, duration of inflammation, family history, and ethnic background, (Table 37.1), and this can guide targeted diagnostic testing.

KEY CONCEPTS

Autoinflammation Versus Autoimmunity

- Common features:
  - Inflammation due to excessive immune activation
  - Phenotypes characterized by exacerbations and remissions.
- Distinctive features:
  - Autoinflammation: dysregulation of innate immunity, no high-titer autoantibodies or autoantigen-specific T cells
  - Autoimmunity: dysregulation of adaptive immunity, defect in lymphocyte function, autoantibodies may be present.
- Autoinflammation and autoimmunity form two ends of a continuous spectrum of excessive immune system activation.
- A number of diseases show overlapping features between autoinflammation and autoimmunity.

EPIDEMIOLOGY

It is important to realize that the incidence of specific diseases varies widely among ethnic groups. With more than 100,000 patients worldwide, FMF is the most prevalent monogenic autoinflammatory disease. It is most common in individuals originating from around the Mediterranean basin, such as Turks, Jews (primarily non-Ashkenazi), Arabs, and Armenians. In these selected populations, the carrier frequency of mutations in the Mediterranean fever gene *(MEFV)* can be as high as one in three individuals.[1] This may indicate a survival benefit for carriers of heterozygous mutations, possibly through protection against infectious agents.

The first patients with MKD were described in 1984 in the Netherlands[2] (then referred to as HIDS). More than 200 patients have now been identified, most of Western European and Caucasian ancestry. This could be partly explained by increased awareness for this disease among physicians in that part of the world. An alternative explanation is a common founder effect with clustering of carriers, illustrated by a carrier rate of 1:153 for the most common mutation in the mevalonate kinase gene *(MVK)* (V377I) in Dutch newborns.[3,4]

TRAPS is seen in patients from around the world, although most patients originate from northwestern Europe. A few dozen families and more than 200 sporadic cases have been reported.

The exact prevalence of the CAPS is unknown, but more than 200 cases have been reported. Disease awareness and recognition among clinicians have improved because of the availability of effective treatment for this disease.

PFAPA syndrome was first reported at the end of the 1980s.[5] It is difficult to estimate the incidence of PFAPA, because the level

TABLE 37.1 Classic Monogenetic Autoinflammatory Diseases

	FMF	CAPS	TRAPS	MKD
Mode of inheritance	Autosomal recessive	Autosomal dominant	Autosomal dominant	Autosomal recessive
Age of onset (years)	<20	Generally <1, in MWS/FCAS <20 possible	Variable, most <10	<1
Main ethnic distribution	Turks, Arabs, Jews, Armenians	Europeans	All	Northwestern Europeans (Dutch, French)
Gene involved	*MEFV*	*NLRP3*	*TNFRSF1A*	*MVK*
Protein involved	Pyrin	NLRP3	TNF receptor type 1	Mevalonate kinase
Duration of typical attack	2–3 days	Variable; hours–days or continuous inflammation	Days–weeks	HIDS: 4–6 days; MA: continuous, flares possible
Distinguishing symptoms	Peritonitis, pleuritis, erysipelas-like skin lesions	Aseptic meningitis; sensorineural deafness; bone lesions, dysmorphic features May be cold induced	Severe myalgia, periorbital edema	HIDS: lymphadenopathy, attacks induced by vaccination MA: joint contractions, growth and developmental delay
Risk of amyloidosis[a]	Up to 75%	Up to 33%	25%	<5%
Treatment	Colchicine, combination with IL-1 inhibition when resistant	IL-1 inhibition	Mild disease: NSAIDs; Severe disease: IL-1 inhibition	IL-1 inhibition

[a]In patients with long-term uncontrolled inflammation.

of awareness of this disease seems to vary among clinicians. A single pediatric center in the United States reported 122 patients fulfilling the criteria for PFAPA in 10 years,[6] making it more common than any of the monogenic autoinflammatory diseases (with the exception of FMF in certain populations). In most patients with PFAPA, symptoms cease before or during adolescence. The cause of this spontaneous resolution is unknown. The characteristic combination of symptoms of PFAPA has been described in adults, but it remains a matter of debate whether these patients suffer from true PFAPA syndrome.

Schnitzler syndrome, first described by the French dermatologist Schnitzler in 1972,[7] is an acquired autoinflammatory disorder with a median age of onset of 51 years. More than 160 cases have been reported worldwide.

SIGNS AND SYMPTOMS

Familial Mediterranean Fever

FMF is an autosomal recessive disease. More than 90% of patients become symptomatic within the first two decades of life. Typical attacks are characterized by abrupt onset of high fever, peaking soon after onset and lasting for 12 hours to 3 days. Subsequently, the fever subsides rapidly. Painful serositis accompanies the fever. Serositis can also be present without fever. More than 95% of patients experience abdominal pain, which lasts up to 3 days. The pain, which is caused by sterile peritonitis, may initially be focal and then progresses to more diffuse pain. Before being diagnosed with FMF, a significant proportion of patients will have undergone exploratory abdominal surgery under suspicion of appendicitis. At surgery, intra-abdominal adhesions, a result of recurrent peritonitis, may be found. Pelvic adhesions can reduce fertility in female patients. Pleuritis, presenting as thoracic pain, is experienced by approximately 40% of patients. Synovitis with monoarthritis of knee, ankle, or wrist occurs in one-half to three-quarters of patients. An arthritic attack may have a more protracted course compared with nonarthritic FMF, with fever lasting up to a week. Joint pain may persist when fever has already subsided. Synovitis usually resolves completely without joint destruction. The skin can be affected. Erysipelas-like skin lesions overlying the shins are very characteristic of FMF but are seen only in 30% of patients. Less frequent symptoms of FMF include vasculitis, orchitis, aseptic meningitis, and myalgia. Pericarditis is rare in FMF.

There are no consistent triggers for FMF attacks. Emotional stress or menstruation may increase the frequency of attacks; some patients are able to report specific triggers for their attacks. Attack frequency varies greatly among patients and during an individual patient's life. Some patients suffer from continuous inflammation, whereas others have attacks once a year or even less frequently.

The literature on FMF is replete with genotype-phenotype studies. The most consistent finding is that carriers of the M694V/M694V genotype have more severe disease, with earlier onset and higher frequency of arthritis and long-term complications.

Life expectancy of patients with FMF depends on timely initiation of appropriate treatment to prevent amyloidosis. Without amyloidosis, FMF patients have normal life expectancy.

Cryopyrin-Associated Periodic Syndrome

CAPS is autosomal dominantly inherited. Originally, three separate clinical syndromes, all with their own clinical features, were distinguished: familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and neonatal-onset multisystem inflammatory disease (NOMID), which is also known as chronic infantile neurologic, cutaneous, and articular (CINCA) syndrome. With the discovery of *NLRP3* mutations in all three diseases, it has become clear that the clinical phenotype of CAPS is a continuous spectrum of severity, instead of distinct diseases. There is no genotype-phenotype association, suggesting a role for other yet undiscovered disease-modifying factors.

CAPS often manifests clinically soon after birth or in early childhood. It is characterized by recurrent urticaria-like rash, arthralgias, myalgias, headaches, and fever. Ocular symptoms, including conjunctivitis and uveitis, are common. Some

patients develop sensorineural hearing loss during adolescence or adulthood. At the severe end of the clinical spectrum, central nervous system (CNS) symptoms, including chronic aseptic meningitis that is characterized by chronic headache, increased intracranial pressure, hydrocephalus, mental retardation, and seizures, are common. Papilledema with optic nerve atrophy can lead to loss of vision. In severely affected patients, arthropathy, with distinct radiographic findings of premature patellar and epiphyseal long-bone ossification and osseous overgrowth, develops early in life. If left untreated, this leads to growth retardation, severe joint contractures, and persisting disability.

The duration of attacks is variable and ranges from hours to days. At the severe end of the spectrum, patients have continuous inflammation. Attacks may be triggered by exposure to cold, minor trauma, or emotional stress.

In the past, patients with severe CAPS often died in childhood. This changed after the introduction of anti–interleukin-1 (IL-1) therapy, which is very effective in treating CAPS. Overall, patients without neurologic involvement are now believed to have a normal life expectancy.

Tumor Necrosis Factor Receptor–Associated Periodic Syndrome

TRAPS is inherited in an autosomal dominant fashion. Age of onset varies widely. Many patients become symptomatic within the first years of life, with a median age of onset of 3 years, but adult onset is also possible. The usual duration of fever in TRAPS is considerably longer than in the other classic autoinflammatory syndromes: attacks persist for a minimum of 3 days but can last for several weeks. The interval between attacks in a single patient can vary substantially.

Localized myalgia, a deep cramping, and often severely disabling pain in a single limb resulting from monocytic fasciitis and associated with fever are found in virtually all patients. The affected limb may show local erythema, which may migrate to the distal part of the extremity (Fig. 37.1). Almost all patients have abdominal pain, often accompanied by vomiting, constipation, and bowel obstruction. Arthralgia and monoarthritis involving hips, knees, or ankles are present in 25% of patients at some point. Chest pain is frequent and can be caused by pleuritis or may be musculoskeletal in origin. Ocular symptoms range from conjunctivitis and periorbital pain to severe uveitis and iritis. Periorbital edema with conjunctival injection is a distinctive, but infrequent, feature of TRAPS. Other less frequently observed symptoms are pericarditis and lymphadenopathy.

FIG. 37.1 Migratory erythematous macular rash during an inflammatory attack in a patient with tumor necrosis factor receptor–associated periodic syndrome.

Mevalonate Kinase Deficiency

Before the discovery of the underlying genetic defect in MVK, two distinct autosomal recessive diseases were distinguished, which are now known to form two ends of a continuous spectrum: HIDS at the less severe end and mevalonic aciduria (MA) at the most severe end.

HIDS is characterized by recurrent fever attacks that last for 4 to 6 days, starting in early childhood. The inflammatory attacks occur on average every 4 to 6 weeks. Attack frequency varies in a single patient and among patients and tends to decrease later in life. Attacks often start with chills, followed by a rapid rise in temperature. Factors that can provoke an attack are infections, trauma, vaccination, and both physical and emotional stress, although a clear trigger is often absent. Characteristic for HIDS is the first attack being triggered by childhood vaccination.

Fever is accompanied by cervical lymphadenopathy and abdominal pain with vomiting and diarrhea. The skin may show erythema, papules, urticarial rash, or exanthema. The majority of patients suffer from large-joint arthralgia or arthritis. Oral or genital aphthous ulcers may be present during attacks. Hepatosplenomegaly has been reported. Patients with HIDS appear to have normal life expectancy and experience no complications.

MA is located at the severe end of the MKD spectrum. This severe disease is present from birth and is characterized by psychomotor retardation, ataxia, failure to thrive, cataracts, and facial dysmorphia. Episodic fever or inflammation are present in MA. Many patients die in early childhood.

In recent years, it has become clear that the spectrum of MKD comprises more than only these two diseases. Mutations in *MVK* have been found in the absence of typical MKD features in patients with retinitis pigmentosa and early-onset ulcerative colitis. Mutations in *MVK* have also been found in patients with the skin diseases disseminated superficial actinic porokeratosis and porokeratosis of Mibelli, cyclic neutropenia, and macrophage activation syndrome, but there is no evidence of decreased mevalonate kinase activity in these patients. Mutations in these diseases may overlap with mutations that may cause MA and HIDS.

Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Adenitis Syndrome

PFAPA is primarily a childhood disease with a usual onset before the age of 5 years. Patients suffer from recurring episodes of fever that generally last for 3 to 6 days and recur with great regularity. Additional symptoms include pharyngitis, cervical adenitis, and aphthous stomatitis. Other symptoms may include headache, vomiting and mild abdominal pain, arthralgia, and myalgia. Between fever episodes, patients are symptom free. In most patients, attacks cease after several years, often before or during adolescence.

Schnitzler Syndrome

A typical feature of Schnitzler syndrome is its late onset, at a median age of 51 years. Patients typically present with chronic

TABLE 37.2 Diagnostic Criteria for Schnitzler Syndrome[a] and PFAPA[a]

Schnitzler Syndrome

Major Criteria (≥1 present)

(Chronic) urticarial rash

Monoclonal immunoglobulin M (IgM; or IgG: variant type)

Minor Criteria (≥2 present)

Intermittent fever

Arthralgia or arthritis

Bone pain

Lymphadenopathy

Hepatomegaly and/or splenomegaly

Elevated erythrocyte sedimentation rate (ESR) and/or leukocytosis

Bone abnormalities (on radiologic or histologic examination)

Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Adenitis Syndrome

I Regularly recurring fevers with an early age of onset (<5 years of age)

II Constitutional symptoms in the absence of upper respiratory infection, which include at least one of the following:
- (a) Aphthous stomatitis
- (b) Cervical lymphadenitis
- (c) Pharyngitis

III Exclusion of cyclic neutropenia

IV Completely asymptomatic interval between episodes

V Normal growth and development

[a]Schnitzler syndrome and PFAPA can be diagnosed only after exclusion of other causes.

PFAPA, Periodic fever, aphthous ulcers, pharyngitis, and adenitis syndrome.

de Koning HD, Bodar EJ, van der Meer JW, et al. Schnitzler syndrome: beyond the case reports: review and follow-up of 94 patients with an emphasis on prognosis and treatment. Semin Arthritis Rheum. 2007 Dec;37(3):137–48 and Thomas KT, Feder jr HM, Lawton AR et al. Periodic fever syndrome in children. J Pediatr. 1999 Jul;135(1):15–21

recurrent and mostly nonpruritic urticarial rash. This can be accompanied by fever, arthralgia or arthritis, and bone pain (Table 37.2). Symptoms progress over years. The presence of monoclonal paraproteinemia, typically of immunoglobulin M (IgM), is characteristic for Schnitzler syndrome. Presence of monoclonal IgG is less common and is sometimes referred to as *variant Schnitzler syndrome*. Onset of symptoms can precede paraproteinemia for years, but only little is known about this. Symptom severity is unrelated to the level and type of paraproteinemia.

An important long-term complication of Schnitzler syndrome is Waldenström macroglobulinemia, which, in a single study, had an incidence of 15% 10 years after diagnosis. Patients with Schnitzler syndrome have a normal life expectancy.

PATHOGENESIS

The common pathophysiologic feature of most autoinflammatory diseases is overproduction of the proinflammatory cytokine IL-1β. This protein is produced as an inactive proform (pro–IL-1β), which must be cleaved to become activated. The most common pathway of cleavage is by caspase-1. Like IL-1β, caspase-1 is transcribed as an inactive proform (procaspase-1), and it, too, must be cleaved by a multiprotein complex called the *inflammasome*. Several inflammasomes have been identified, of which the nucleotide-binding oligomerization domain (NOD)-like receptor P3 (NLRP3) inflammasome has been studied in greatest detail.

The NLRP3 inflammasome consists of the central protein NLRP3, the adapter protein apoptosis-associated speck-like protein containing a C-terminal caspase recruitment domain (ASC), and the effector protein procaspase-1. Upon activation of the inflammasome, procaspase-1 is converted into mature caspase-1, which is then able to cleave inactive pro–IL-1β to its active form (Fig. 37.2A).

Familial Mediterranean Fever

FMF is caused by mutations in *MEFV*, which encodes the protein pyrin, primarily expressed in peripheral blood leukocytes, especially neutrophils and monocytes. Pyrin is a member of the pyrin-domain (PYD)-containing proteins, which are able to bind to the PYD domain of other proteins, including apoptosis-associated speck-like protein containing a C-terminal caspase recruitment domain. Binding of pyrin to ASC leads to activation of ASC, with consequent recruitment and activation of procaspase-1. Pyrin can also bind to the PYD domains of other proteins that are able to initiate apoptosis or activate nuclear factor (NF)-κB, including caspase-8 (Fig. 37.2B). These complexes are called *pyrin inflammasomes*.

So far, more than 370 sequence variants in the *MEFV* gene have been reported in the central online Infevers registry (https://infevers.umai-montpellier.fr/web/), most of which are clustered in exon 10 of the gene. The six most prevalent mutations (M694V, V726A, M680I, M694I, V694I, E148Q) cause approximately 80% of cases. Changes in *MEFV* can also be found in other inflammatory diseases including periodic fever with autoinflammation and neutrophilic dermatosis, chronic nonbacterial osteomyelitis, and livedoid ulcerative dermatitis. It has been proposed that *pyrin-associated autoinflammatory diseases* may be used as the common term to refer to all *MEFV*-related diseases.[8]

Cryopyrin-Associated Periodic Syndrome

CAPS is caused by mutations in the gene encoding NLRP3. Previous to its discovery at the beginning of this century, the protein was unknown. It was named *cryopyrin*, in analogy with pyrin in FMF and to illustrate the influence of cold exposure in some patients with CAPS. Literature on this gene can be confusing because the gene previously has also been referred to as *NALP3, PYPAF1*, and *CIAS1*. Mutations associated with CAPS are gain-of-function (GOF) mutations, leading to increased NLRP3 activity. To better reflect the current genetic nomenclature and because periodic fever may not always be present, an international expert group has proposed to rename CAPS to *NLRP3-associated autoinflammatory disease* (NLRP3-AID).[8]

Tumor Necrosis Factor Receptor–Associated Periodic Syndrome

Mutations in the gene *TNFRSF1A* are responsible for TRAPS. This gene encodes the TNF-receptor superfamily 1A (TNFRSF1A), the main cell surface receptor for TNF. This receptor consists of three domains: an extracellular ligand-binding domain, a transmembrane domain, and an intracellular effector domain. So far, more than 170 TNFRSF1A sequence variants have been described, and all TRAPS-associated mutations are located within the extracellular domain of the protein. Upon ligand binding by the extracellular receptor domain, the TNFR forms trimers, triggering the recruitment of intracellular adaptor proteins, which initiate a downstream signaling cascade, leading to NF-κB and mitogen-activated protein kinase (MAPK) activation and caspase-induced apoptosis. When the receptor is activated, the extracellular domain of the TNFR is shed from the membrane. These shed receptors form

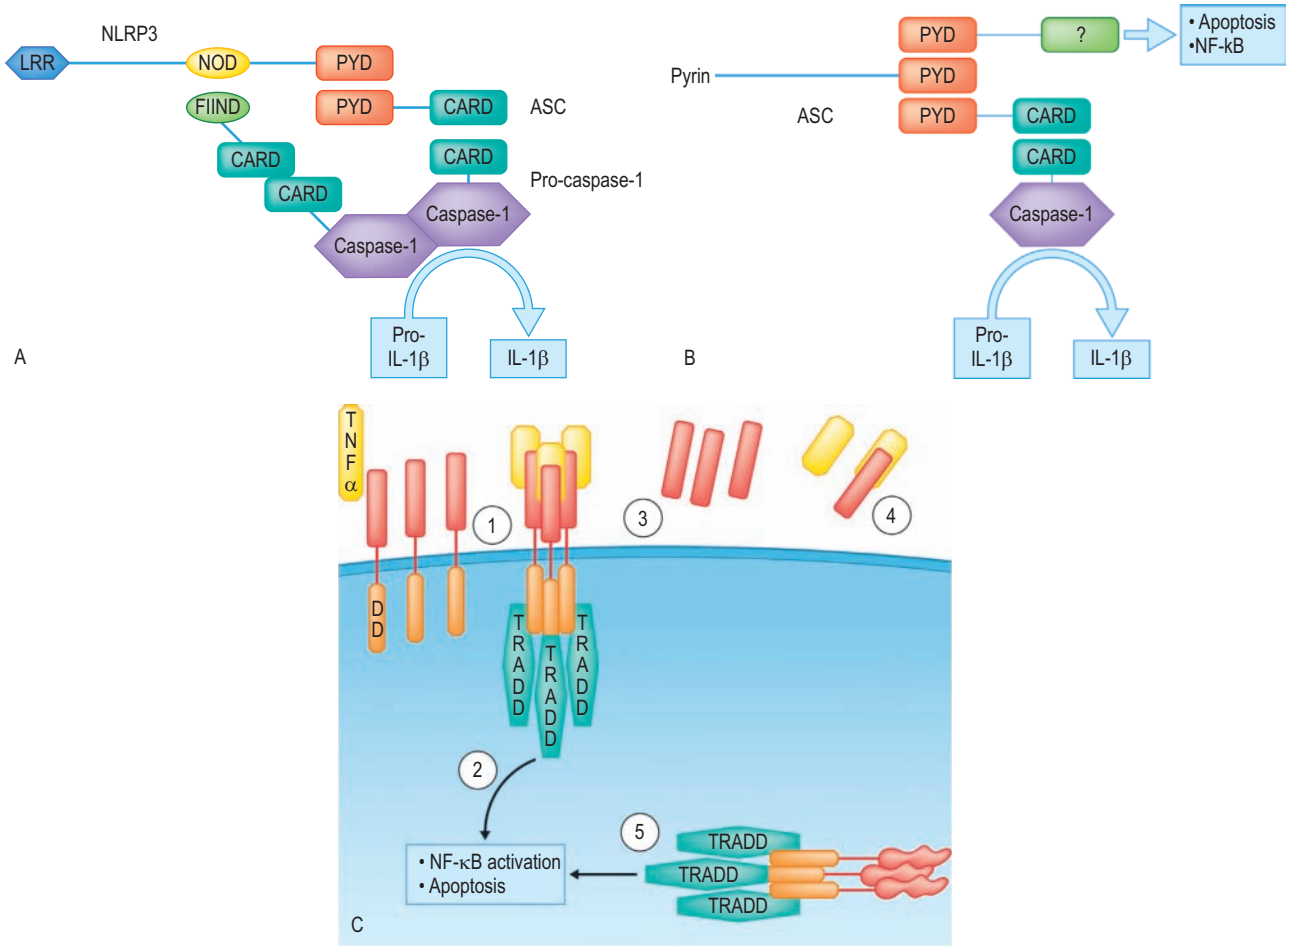

FIG. 37.2 (A) Pathophysiologic mechanisms of classic monogenic autoinflammatory diseases. The nucleotide-binding oligomerization domain *(NOD)*-like receptor P3 *(NLRP3)* Inflammasome. NLRP3 is the central component of this inflammasome. NLRP3 contains three domains: a pyrin domain *(PYD)*, NOD, and a domain of leucine-rich repeats *(LRR)*. Cryopyrin binds apoptosis-associated speck-like protein containing a C-terminal caspase recruitment domain *(ASC)* through its PYD domain and through the NOD domain. The association of these proteins ultimately leads to the release of active caspase-1, which, in turn, activates interleukin-1β *(IL-1β)* through the cleavage of pro–IL-1β. (B) Mechanism of action of pyrin. Pyrin contains a pyrin domain *(PYD)* that is able to bind to apoptosis-associated speck-like protein containing a C-terminal caspase recruitment domain *(ASC)*. ASC can recruit caspase-1 via its *CARD* domain, leading to production of mature interleukin-1β *(IL-1β)*. Pyrin is also able to bind to the PYD domain of other proteins involved in inflammation and apoptosis. (C) Pathophysiology of tumor necrosis factor (*TNF)* receptor–associated periodic syndrome (TRAPS). (1) TNF binds to the TNF receptor on the surface of inflammatory cells (2). After receptor triggering, TNF receptor type 1–associated DEATH domain *(TRADD)* is recruited, inducing a signaling cascade leading to apoptosis and production of proinflammatory cytokines (3). Receptors are shed from the surface, leading to a pool of receptors that dampen immune responses (4). Mutated TNF receptors form aggregates and are retained intracellularly. These aggregated receptors are capable of binding TRADD (5) and stimulate ligand-independent cytokine production.

an extracellular pool of soluble TNFRs, retain their affinity for binding TNF, and are therefore able to mitigate the immune response. Initially, it was hypothesized that TRAPS-associated mutations would lead to defective shedding of TNFR1 receptors, but this hypothesis was discarded because the major pathogenetic mechanism for TRAPS after in vitro experiments showed misfolding and intracellular accumulation of mutated proteins. These aggregated receptors retain their normal signaling function and can induce ligand-independent MAPK signaling and production of reactive oxygen species (ROS), resulting in inflammation (Fig. 37.2C).

There are two exceptional *TNFRSF1A* mutations: R121Q (previously referred to as R92Q) and P75L (previously P46L). These mutations do not lead to receptor misfolding and are present in low frequency in the general population. They may cause a mild inflammatory phenotype.

Mevalonate Kinase Deficiency

The genetic defect in MKD is located in *MVK*. Mevalonate kinase is a key enzyme in the isoprenoid pathway and is located directly downstream from 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMG-CoA-reductase). The end products of the mevalonate kinase pathway are cholesterol and a number of nonsterol isoprenoids, which are essential compounds in various cellular functions. Mutations in *MVK* lead to reduced mevalonate kinase enzyme activity. In patients with mild disease, residual mevalonate kinase activity is generally 5% to 15% of healthy controls and is even lower in patients with the severe phenotypes.

The mechanistic link between reduced mevalonate kinase activity and autoinflammation is thought to be defective protein prenylation. Prenylation is a posttranscriptional modification, in which nonsterol isoprenoids are coupled to proteins, influencing protein-protein and protein-membrane interactions. Several hypotheses on the effect of defective prenylation in the pathogenesis of MKD exist. Defective prenylation of RhoA, with consequent activation of Rac1 and PKB, may lead to IL-1β secretion with formation of an NLRP3-dependent inflammasome, or to instable mitochondria, which are inadequately cleared from the cytosol with consequent production of ROS, activating NLRP3.[9–11] The MVK pathway is involved in the metabolic introduction of trained immunity and this may explain, at least in part, the constitutively enhanced cytokine production by monocytes of these patients.[12]

Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Adenitis Syndrome

Little is known about the pathophysiology of PFAPA. No genetic defect for PFAPA has been discovered, and this is in agreement with the absence of a clear hereditary pattern. It may be linked to a complex genetic trait. A positive family history has been described, although not all of the patients with a family history were screened for other autoinflammatory diseases.

During PFAPA flare-ups, upregulation of complement genes and genes in the interferon (IFN)–IL-1 pathway are seen. Isolated peripheral blood mononuclear cells and monocytes of patients with PFAPA show increased IL-1β production without induction of transcription of IL-1β RNA or caspase-1 induction upon lipopolysaccharide stimulation. This increased inflammatory response can be abolished by a pan-caspase inhibitor, indicating the important role of the inflammasome in this disease.[13]

Schnitzler Syndrome

The etiology of Schnitzler syndrome remains unknown. A central role for IL-1β is illustrated by the high efficacy of anti–IL-1β therapy in patients with Schnitzler syndrome.[14] No causative genetic defect for Schnitzler syndrome has been found. Somatic mosaicism may be an explanation for the late onset of Schnitzler syndrome, and low-grade mosaicism may not be picked up by routine gene sequencing.[15] Several genetic defects have also been described in very small numbers of patients, but their role in the pathogenesis of Schnitzler syndrome remains unclear.

LABORATORY TESTS

In classic monogenetic autoinflammatory diseases, an explicit acute phase response, with elevated inflammatory markers (C-reactive protein [CRP], erythrocyte sedimentation rate [ESR], serum amyloid A [SAA]) and leukocytosis, is invariably present during symptomatic periods. In other autoinflammatory diseases, this may be less evident.

During clinical disease remission, persistent subclinical inflammation can be found. Cold agglutinins, antinuclear autoantibodies (ANAs), or cryoglobulins are usually not present but may be found in low titers. Proteinuria (>0.5 g of protein per 24 hours) is highly suggestive for secondary amyloid A (AA) amyloidosis.

Elevated serum IgD can be present in MKD. It is discussed in detail in the respective section on the diagnosis of this disease. Similarly, the paraproteins encountered in Schnitzler syndrome are discussed in the section on the symptoms of Schnitzler syndrome.

TABLE 37.3 Tel Hashomer Criteria for the Diagnosis of Familial Mediterranean Fever

Major Criteria (≥1 present)
Typical attack[a] with abdominal symptoms
Typical attack[a] with pleural symptoms
Typical attack[a] with monoarthritis
Typical attack[a] with only fever
Incomplete attack[b] with abdominal symptoms
Minor Criteria (≥2 present)
Favorable response to colchicine
Incomplete attack with monoarthritis
Exertional leg pain

[a]Typical attacks are defined as at least three attacks with fever greater than 38°C.
[b]Incomplete attacks are painful and recurrent attacks not meeting the criteria for typical.
The sensitivity and specificity of these criteria for the diagnosis of FMF are greater than 95% and greater than 97%, respectively.
From Livneh A, Langevitz P, Zemer D, et al. Criteria for the diagnosis of familial Mediterranean fever. *Arthritis Rheum.* 1997;40:1879–1885.

DIAGNOSIS

Familial Mediterranean Fever

FMF is a clinical diagnosis. A validated set of clinical criteria for the diagnosis of FMF has been called: the Tel Hashomer criteria (Table 37.3). These criteria have high positive predictive value and negative predictive value in populations with high pretest probability, but their diagnostic accuracy is lower in other populations. In 2015 it was proposed to replace these criteria, which have been in use since 1997, by a new set of criteria (Eurofever criteria, Table 37.4).

For experienced physicians, it is not difficult to diagnose FMF in patients who have a medical history compatible with FMF and who come from an ethnic group with high prevalence of FMF. In countries with a low incidence of FMF, several years of diagnostic delay are not unusual, as typical attacks remain unrecognized.

When FMF is suspected on clinical grounds, treatment with colchicine should be initiated immediately. A positive effect of colchicine is confirmatory for the diagnosis FMF.

In populations with a low prevalence of FMF and in atypical cases, sequencing of the *MEFV* gene can be helpful in the diagnostic work-up.

Cryopyrin-Associated Periodic Syndrome

CAPS is diagnosed on the basis of typical clinical features (Table 37.5), sometimes supported by a positive family history reflecting autosomal dominant inheritance. Detection of mutations in the *NLRP3* gene will confirm the diagnosis in most cases, but cases with "mutation-negative" CAPS have been described. Some of these patients may have somatic mosaicism. Reaction to treatment is the same for these patients as for patients with a proven *NLRP3* mutation.

Tumor Necrosis Factor Receptor–Associated Periodic Syndrome

A new set of clinical criteria for TRAPS has recently been proposed (see Table 37.4). The cornerstone of the diagnosis of TRAPS is detection of mutations in the *TNFRSF1A* gene.

TABLE 37.4 Diagnostic Criteria for Familial Mediterranean Fever, Tumor Necrosis Factor–Associated Periodic Syndrome, and Mevalonate Kinase Deficiency

FMF		TRAPS		MKD	
Presence	**Score**	**Presence**	**Score**	**Presence**	**Score**
Episode duration <2 days	9	Periorbital edema	21	Age <2 years at onset	10
Chest pain	13	Duration of episodes >6 days	19	Aphthous stomatitis	11
Abdominal pain	9	Centrifugal migratory erythematous patches, most typically overlying a local area of myalgia, usually on limbs of trunk	18	Generalized lymphadenopathy or splenomegaly	8
Turkish, Armenian, non-Ashkenazi Jewish, Arabian ancestry	22	Myalgia	6	Painful lymph nodes	13
Spanish, Italian or Greek ancestry	7	Relatives affected	7	Intermittent diarrhea (sometimes/often)	20
				Persistent diarrhea (always)	37
Absence	**Score**	**Absence**	**Score**	**Absence**	**Score**
Aphthous stomatitis	9	Vomiting	14	Chest pain	11
Urticarial rash	15	Aphthous stomatitis	15		
Cervical lymphadenopathy	10				
Episode duration >6 days	13				
Cutoff value	≥60	Cutoff value	≥43	Cutoff value	≥42

For FMF: A cutoff of ≥60 points using these criteria has a sensitivity of 94% to 97% and a specificity of 91% to 98%.
For TRAPS: A cutoff of ≥43 has a sensitivity of 80% to 85% and a specificity of 87% to 91%.
For MKD: A cutoff of ≥42 has a sensitivity of 89% to 93% and a specificity of 89% to 92%.

Mevalonate Kinase Deficiency

MKD can be suspected when characteristic clinical findings are present (see Table 37.4) in combination with persistent elevated serum levels of IgD greater than 100 international unit per milliliter (IU/mL). Elevation of serum IgD is not pathognomonic for MKD because it may also occur in other inflammatory conditions, including FMF and PFAPA. Furthermore, in the very young, IgD may be normal, and in some of the affected individuals, IgD is never elevated. Elevated IgD is accompanied by elevated IgA in 80% of patients. The serum level of IgD does not correlate with disease severity, and elevated concentrations are present during asymptomatic periods.

During attacks, traces of mevalonic acid may be found both in urine and serum and can be measured with special techniques, which are, however, not commonly available. Measurement of mevalonate kinase enzyme activity is usually only done in the research setting and requires cell cultures.

Clinical suspicion of MKD can be confirmed by sequencing of the *MVK* gene.

Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Adenitis Syndrome

There is currently no diagnostic test to prove PFAPA. It is diagnosed based on clinical signs and symptoms. The modified criteria by Thomas et al. are used (see Table 37.2) and may be supplemented by numeric limits, such as minimum number of attacks and duration of fever. Exclusion of other causes, including other autoinflammatory syndromes, is important.

Schnitzler Syndrome

Schnitzler syndrome is diagnosed on the basis of clinical criteria (see Table 37.2). Exclusion of other causes, particularly monoclonal gammopathy of undetermined significance (MGUS) and chronic idiopathic urticaria, is of paramount importance.

Autoinflammation of Unknown Origin

Regardless of the increasing number of autoinflammatory diseases recognized and the increasing insights into the mechanisms of autoinflammation, an increasing number of patients presenting with an autoinflammatory phenotype cannot be assigned to one of the known autoinflammatory diseases. These patients are considered to suffer from *autoinflammation of unknown origin*. It is likely that further research and newly developed diagnostic techniques will identify new proteins, genetic defects, and pathways in these patients, leading to recognition of new diseases. In patients with autoinflammation of unknown origin, anti–IL-1 therapy can be tried both diagnostically and therapeutically.[16]

TREATMENT

Colchicine

Colchicine is the treatment of first choice for FMF. Although it has been used since the 1970s, the mechanism of action of colchicine in FMF is still unknown. It is highly effective in

preventing attacks. Response to colchicine has been used as a diagnostic criterion for FMF.

The average dose used is 1.0 to 1.5 mg/day. If tolerated, the dose can be increased up to 3 mg/day in patients with insufficient response. There are few patients with FMF who are unresponsive to colchicine. Others may not be able to tolerate an effective dose of colchicine because of side effects. These patients may benefit from IL-1 inhibition.[17]

All patients with FMF should be prescribed colchicine, regardless of disease severity and attack frequency. When anti–IL-1 treatment is started, expert opinion recommends continuation of colchicine in the highest tolerable dose for the prevention of amyloidosis, as it has not been proven that anti–IL-1 monotherapy fully protects against secondary amyloidosis, even when there is complete suppression of inflammation.

The most common side effects of colchicine are diarrhea and abdominal pain. These are dose dependent. In patients with persistent diarrhea, dose reduction can be tried to reduce severity. Myopathy, neuropathy, and leukopenia are very rare, with severe side effects occurring primarily in patients with abnormal kidney or liver function or because of interaction with other drugs (*e.g.*, CYP3A4 inhibitors).

High-dose colchicine has been shown to be teratogenic in animals. However, multiple cohort studies have shown that colchicine can be used safely during pregnancy and breastfeeding. In therapeutic doses, colchicine does not have a negative effect on sperm number and quality, and it has no negative effect on male or female fertility.

As a general rule, there is no place for colchicine in the treatment of autoinflammatory syndromes other than FMF. As an exception to this rule, patients with autoinflammation of unknown origin may experience a favorable effect, especially if their disease shares characteristics with FMF or Behçet disease. A small trial has demonstrated decreased attack frequency during colchicine treatment for PFAPA.[18]

Inhibition of Interleukin-1

KEY CONCEPTS

Interleukin-1β

- Interleukin-1β (IL-1β) is a very potent proinflammatory cytokine.
- Many autoinflammatory diseases are caused by dysregulation of IL-1β.
- Measurement of IL-1 β serum levels has no value in the diagnosis of autoinflammation or in assessing disease severity.
- IL-1 inhibition is the treatment of first choice for many autoinflammatory diseases, and it has greatly improved quality of life in patients.

The detection of *NLRP3* mutations in CAPS has illustrated the importance of IL-1β in the pathogenesis of autoinflammation.

The first inhibitor of IL-1 developed was the recombinant human IL-1 receptor antagonist anakinra, which is still the most commonly available IL-1 inhibitor. It competitively binds to the IL-1 receptor, completely inhibiting the actions of both IL-1α and IL-1β. Anakinra has a short half-life and needs to be given as a once-daily subcutaneous injection.

The selective anti–IL-1β monoclonal antibody canakinumab has a longer half-life and is also injected subcutaneously. Standard injection frequency is once per 8 weeks, but shorter intervals may be necessary in severe disease. In cases with adequate disease control, longer intervals may suffice.

Rilonacept is a construct of two extracellular chains of the IL-1 receptor complex fused to the Fc-portion of IgG. It is given as a weekly subcutaneous injection.

Currently, there is evidence for the effectiveness of anti–IL-1 therapy in many autoinflammatory diseases, including FMF, CAPS, TRAPS, MKD, PFAPA, and Schnitzler syndrome. Typically, anti–IL-1 treatment leads to instant abortion of inflammation with clinical response within the first hours to days after the first injection. This vivid response to treatment is so characteristic that IL-1 inhibition can serve as a diagnostic tool in the diagnosis of these autoinflammatory disorders. Anakinra and canakinumab have both been approved for the treatment of CAPS by the US Food and Drug Administration (FDA) and the European Medical Association (EMA). These agents were given "orphan" status for the treatment of TRAPS by the EMA. Canakinumab is effective in HIDS, TRAPS, and colchicine-resistant FMF.[19] In 2016 the FDA and EMA approved the use of canakinumab in patients with these diseases. Canakinumab is also effective in, but not approved for, the treatment of Schnitzler syndrome.[20] Rilonacept is approved for the treatment of CAPS by the FDA but is not commonly used in Europe.

In patients with mild MKD and periodic symptoms with long symptom-free intervals, anakinra can be used on demand. In these cases it can be started at the first signs of an attack and only be continued for a few days.[21]

Side effects of IL-1 inhibition include painful injection-site reactions, which are most commonly seen with anakinra, and increased frequency of infections, mostly mild upper respiratory tract infections. More severe infections are rarely seen.

Inhibition of Interleukin-6

Tocilizumab, a monoclonal antibody against the IL-6 receptor, has been registered by the FDA and EMA for the treatment of rheumatoid arthritis and systemic-onset juvenile idiopathic arthritis (SoJIA), giant cell arteritis, and chimeric antigen receptor (CAR)-T-cell–induced cytokine release syndrome and is used with increasing frequency in autoinflammatory diseases. It is available as an intravenous infusion or subcutaneous injection. The most common dose is 8 mg/kg in children and adults, or 10 to 12 mg/kg in children with body weight less than 30 kg, with an interval of 2 to 4 weeks. Side effects of tocilizumab are increased susceptibility to infections, most commonly upper respiratory tract infections, elevated liver enzymes, and hematologic abnormalities. Bowel perforations have been reported. As IL-6 induces the production of CRP in the liver, anti–IL-6 therapy always normalizes CRP, making it impossible to use it as a marker for disease activity. Tocilizumab has been shown to be effective in patients with anakinra-resistant Schnitzler syndrome, MKD, and TRAPS.

Inhibition of Tumor Necrosis Factor

Three widely used inhibitors of TNF are infliximab, adalimumab, and etanercept. The most common side effect of TNF inhibition is increased risk of serious infections.

Originally, TNF inhibition was regarded the treatment of first choice in patients with TRAPS unresponsive to nonsteroidal antiinflammatory drugs (NSAIDs). However, TNF inhibition induces complete response only in a minority of patients with TRAPS and is therefore far less effective than anti–IL-1 treatment.[22]

Anti-TNF treatment may also be effective in MKD, but responses are mostly partial. It may be tried in patients who show unsatisfactory response to anti–IL-1 treatment.[22]

Corticosteroids

Corticosteroids are very effective in PFAPA when initiated early in an attack. Prednisone 1 mg/kg is most commonly used during attacks, although lower doses may also be effective. Use of corticosteroids may increase attack frequency in PFAPA.[23] Mild TRAPS can be treated with a short course of steroids (30 mg daily for 7 days), and patients experiencing more severe attacks may respond to higher doses. The beneficial effect of corticosteroids may decrease over time, necessitating dose escalation.[22] Short-term corticosteroids may also be effective in patients with mild MKD.[22]

Simvastatin

The finding of dysregulation of the mevalonate kinase pathway, with cholesterol as its major end product, has led to the hypothesis that blockage of this pathway by HMG-CoA reductase inhibitors (statins) would possible be beneficial in patients with MKD. Small trials and case reports showed a statistically significant, but clinically negligible, effect in some patients. Therefore statins have been abandoned as treatment for MKD in clinical practice.

Other Immunosuppressive Drugs

In the past, numerous immunosuppressive drugs were tried in a trial-and-error approach to find an effective treatment for the disabling symptoms of autoinflammation. The results have been mostly disappointing, and there is no strong evidence to support the use of other immunosuppressants in autoinflammation. When other treatments are ineffective, some patients may, however, benefit from immunosuppressive drugs.

Other Treatments

It remains a matter of debate whether adenotonsillectomy effectively resolves symptoms in PFAPA. A Cochrane review of two unblinded randomized controlled trials showed that children with PFAPA undergoing adenotonsillectomy had a four-time higher chance of becoming symptom free.[24]

Several case reports on the positive effects of hematopoietic stem cell transplantation (HSCT) in patients with severe MKD have been published.[25] Because of the severe side effects, HSCT should be considered the last resort.

AMYLOIDOSIS

Secondary or type AA amyloidosis is a serious complication of all autoinflammatory syndromes. It is caused by tissue deposition of insoluble degradation products of the inflammatory protein SAA. Kidneys are most commonly affected. Because SAA is an acute phase reactant, there is a close relationship between the duration and level of inflammation and the development of amyloidosis. The incidence of AA amyloidosis varies among autoinflammatory diseases. Patients with FMF are at highest risk, with an incidence of up to 75% before the introduction of colchicine treatment for this disease. There is a strong correlation between ethnicity and risk of amyloidosis in FMF, with increased risk among Sephardic Jews.

Up to 25% of patients with TRAPS will develop amyloidosis if left untreated. There seems to be a strong familial predilection. In CAPS, approximately one-third of patients develop amyloidosis in the absence of treatment. Patients with MKD and Schnitzler syndrome have a relatively small risk of amyloidosis, with only a few patients with these diseases and amyloidosis known worldwide.[26]

It is unclear why some patients with the same level of inflammation may develop or never develop amyloidosis. This may be related to single nucleotide polymorphisms (SNPs) in the *SAA* gene or other genotypes.

As proteinuria is often the first sign of AA amyloidosis, patients with autoinflammation should be screened for it with regular urine sampling. Amyloidosis can be confirmed by Congo red staining of the biopsy specimen of affected tissue. This will show an apple-green birefringence under polarized light microscopy (Fig. 37.3). Progression of amyloidosis is strongly dependent on the ability to control the underlying inflammation. If the SAA concentration can be maintained less than 10 mg/L, progression of amyloidosis can be halted in many cases. Some patients even show regression of amyloidosis during treatment.[27] A cohort mainly consisting of patients

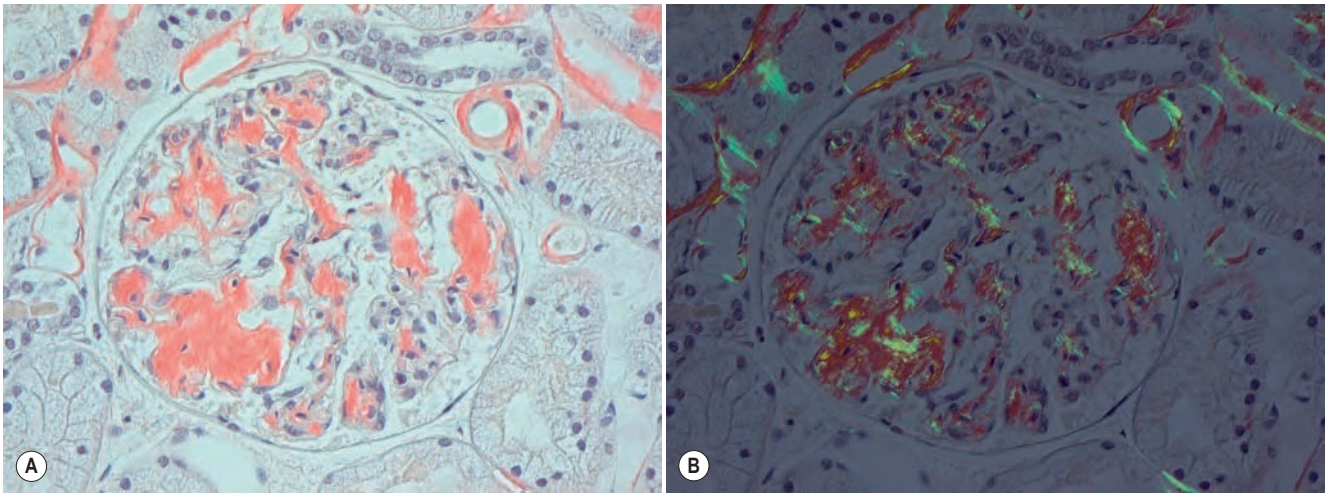

FIG. 37.3 Renal Biopsy from a Patient With Amyloid A Amyloidosis. Amyloid deposits are visualized by staining with Congo *red* (A). Under polarized light microscopy amyloid deposits show typical *apple-green* birefringence (B).

diagnosed with amyloidosis before the availability of targeted therapy showed a median survival of 19 years after the diagnosis of amyloidosis.[28]

CLINICAL PEARLS

A Typical Case of Autoinflammation

- An 18-year-old Western European woman was seen because of recurrent episodes of fever and skin rash. These attacks started 2 hours after birth when a systemic maculopapular skin rash appeared. The rash remained present on a daily basis but was not triggered or exacerbated by cold exposure.
- At the age of 2 years, the patient developed episodes of fever, approximately 3 days each week. Typically, she had a single daily fever spike up to 39°C, which usually occurred in the evening. There was no hearing loss, and arthralgia/arthritis, dysmorphia, meningitis, myalgias, abdominal pain, and lymphadenopathy were also absent. The family history was negative for autoinflammatory diseases.
- On the basis of the clinical presentation, cryopyrin-associated periodic syndrome (CAPS) was suspected as a cause, and targeted gene analysis was performed. This showed an R260W mutation of the *NLRP3* gene. Thus this patient was diagnosed with CAPS.
- After the diagnosis was made, the patient was successfully treated with anakinra, 100 mg once daily. When canakinumab, the long-acting interleukin-1 (IL-1) inhibitor, became available, she was switched to 150 mg canakinumab once every 2 months; she remains symptom-free.

CONCLUSIONS

ON THE HORIZON

- Identification of new (hereditary) autoinflammatory syndromes in patients with episodic inflammation of unknown origin
- Wider availability and application of interleukin-1 (IL-1) inhibitors and development of new drugs to improve treatment.

Since the introduction of the term *autoinflammation* at the end of the 20th century, the clinical characteristics of the classic monogenic autoinflammatory diseases FMF, CAPS, MKD, and TRAPS have been described in more detail. Many new diseases have been identified. Research focused on their pathophysiologic mechanism has revealed new genes and pathways and provided further insight into the mechanism of inflammation in general. The development of IL-1–targeting drugs has led to better quality of life for patients and to increased life expectancy in some of these diseases by prevention of complications, such as secondary amyloidosis. Nevertheless, many patients with autoinflammation remain undiagnosed.

For the near future, further study of the mechanisms of inflammation in patients with autoinflammatory diseases will likely provide a deeper insight into the workings of innate immunity and will lead to the identification of even more diseases in the autoinflammatory spectrum. The search for new therapies, preferably oral drugs, for the treatment of autoinflammation will continue.

Immune Regulatory Disorders

Troy R. Torgerson and Alice Y. Chan

Normal immunity requires a delicate balance between immune effector mechanisms and immune regulatory mechanisms. Effector mechanisms are required to prevent, control, and eradicate external threats to the body, while regulatory mechanisms are required to modulate and control the establishment, initiation, intensity, and longevity of those immune effector responses. The first identified inborn errors of immunity (IEI) were associated principally with susceptibility to recurrent, severe, or unusual infections; the genes mutated in these disorders play key roles in the development or function of essential immune effector mechanisms. In contrast, approximately 20 years ago, a second major class of IEI was described in which patients suffer primarily from severe autoimmunity, inflammatory disease, or nonmalignant lymphoproliferation. Some of these patients have recurrent or unusual infections, but most of their clinical features were the result of immune-mediated pathology. Defective genes identified in these patients typically encode proteins that play key roles in immune regulatory mechanisms; consequently, these are considered to be disorders of immune regulation.

There are now over 430 genes that have been associated with IEI.[1] Of these, approximately 30% have clinical features that would classify them predominantly as immune regulatory disorders. These disorders cluster into groups characterized by similar clinical presentations and, in most cases, by genetic defects that often impact one or more related immune regulatory proteins or signaling pathways (see Table 38.1 for a list of these groups and specific examples). Among the disease groups listed in Table 38.1, hemophagocytic lymphohistiocytosis (HLH) and autoinflammatory disorders are covered in Chapters 36 and 37, respectively.

CLINICAL FEATURES OF IMMUNE REGULATORY DISORDERS

Autoimmunity, inflammatory disease, and nonmalignant lymphoproliferation are common clinical features of immune regulatory disorders. Each genetic disorder tends to have a characteristic combination of clinical symptoms affecting particular organ systems, but there are common types of organ-specific manifestations that tend to occur in multiple disorders. By organ system, clinical symptoms that are frequently observed, beginning with the most common, are: (i) *hematologic*—autoimmune cytopenias, anemia, thrombocytopenia, and neutropenia, often with detectable autoantibodies; (ii) *gastrointestinal* (GI; autoantibodies directed toward gut or liver antigens may or may not be present)—autoimmune or inflammatory enteropathy, lymphoproliferation in the gastrointestinal (GI) tract (nodular lymphoid hyperplasia or lymphocytic colitis), and autoimmune or inflammatory hepatitis; (iii) *skin*—various types of dermatitis, most commonly eczema and psoriasis; (iv) *lungs*—interstitial lung disease, follicular bronchiolitis, and non-caseating granulomas; (v) *endocrine*—thyroiditis, type 1 diabetes, adrenal insufficiency, gonadal insufficiency, and other endocrine disorders, commonly with autoantibodies against thyroid (thyroglobulin, thyroid peroxidase), pancreas (GAD65, insulin, ZnT8, islet cells), adrenal (21-hydroxylase), with other endocrine autoantibodies often present and even detectable well before development of clinical disease; (vi) *renal*—nephritic, nephrotic, or tubulointerstitial disease; (vii) *cardiovascular*—vasculitis; and (vii) *musculoskeletal*—arthritis or myositis.

Many of these clinical manifestations may be present in more common autoimmune or inflammatory diseases like systemic lupus or inflammatory bowel disease (IBD). There are, however, features that should raise suspicion that a patient may have an IEI with immune dysregulation, including: (1) *Early-onset disease*. Onset of clinically significant autoimmune, inflammatory, or lymphoproliferative disease early in life (i.e., under the age of 5 years) should raise suspicion for an IEI disorder. (2) *Unusual combinations of clinical features*: for example, type 1 diabetes or interstitial lung disease paired with IBD. While the incidence of type 1 diabetes is modestly higher in patients with IBD, this combination is not common so should raise suspicion for a potential underlying IEI disorder. Similarly, the combination of infections with unusual pathogens or atypically severe infections in a patient with immune dysregulation, particularly one not receiving significant immunosuppressive therapy, should raise suspicion for an underlying IEI. (3) *Disease that is unusually extensive*: for example, the presence of interstitial lung disease with follicular bronchiolitis, enteropathy with nodular lymphoid hyperplasia throughout the bowel, type 1 diabetes, psoriasis, psoriatic arthritis, and hypogammaglobulinemia in a single patient.

THE GENETICS OF IMMUNE REGULATORY DISORDERS

The number of different gene defects associated with immune regulatory disorders has grown steadily since 2010. All modes of inheritance, including X-linked recessive, autosomal recessive, and autosomal dominant have been observed, but many of the single gene disorders identified since 2015 demonstrate autosomal dominant inheritance. Despite segregating as dominant traits, the mechanisms of disease among these autosomal

TABLE 38.1 Immune Regulatory Disease Phenotypes and Genes

Disease Class	Disease Entities	Common Clinical Manifestations	Example Genes (Protein)[a]
Treg/Teff Cell Axis	IPEX IPEX-like APECED	Enteropathy (diarrhea) Dermatitis (eczema, psoriasis) Cytopenias Endocrinopathies (T1DM, thyroiditis, etc.)	FOXP3, CD25, CTLA4, LRBA, DEF6, IL2RB, STAT1(GOF), STAT3(GOF), STAT5B (LOF or GOF)
Nonmalignant Lymphoproliferation	ALPS ALPS-like ALPS-U RALD	Lymphadenopathy Splenomegaly Recurrent cytopenias Leukoproliferation Fever Malignancy (lymphoma)	FAS, FASL, CTLA4, LRBA, DEF6, PIK3CD, PIK3R1 STAT3(GOF), TNFRSF9, TET2, CASP10, KRAS, NRAS
Autoinflammatory Syndromes	TRAPS CAPS FMF DADA2 DIRA CRIA	Recurrent fevers Rash (various types) Abdominal and/or chest pain Joint/muscle pain and/or swelling	TNFRSF1A, TNFRSF11A, CDC42, NLRP3, MEFV, ADA2, IL1RN, RIPK1
Debris Defects	Complement deficiency Interferonopathies PRAAS	Glomerulonephritis Lupus (systemic, chilblain. etc.) Aicardi-Goutieres syndrome (basal ganglia calcifications) Vasculitis	C1q, C2, COPA, DNASE1, IFIH1, STING, TREX1, PSMB8
Hyperinflammatory Disorders	fHLH	Fever Cytopenias Hepatosplenomegaly, lymphadenopathy Rash Elevated ferritin, triglycerides, and sCD25 Low fibrinogen, DIC	LYST, PRF1, RAB27A, UNC13D, CDC42, ITK, MAGT1, SH2D1A, STAT1(GOF), NLRC4, XIAP
Hematopoietic Malignancies	SPTCL LGL DLBCL AML / MDS	Susceptibility to malignancy (various)	HAVCR2 (TIM3) STAT3-GOF CARD11, BCL10, MALT1 PIK3CD GATA2 TET2
Congenital Atopic Hypersensitivity		Allergic disease	JAK1(GOF), PGM3, STAT5B(GOF)
Inflammatory Bowel Disease (IBD)	Infantile-onset IBD VEO-IBD		CYBB, IL10, IL10RA, IL10RB, SKIV2L, TTC7A, CYBB, RIPK1, NEMO

[a]Genes listed together function in the same pathway or complex.

ALPS, Autoimmune lymphoproliferative syndrome, *AML*, acute myeloid leukemia, *CAPS*, cryopyrin-associated autoinflammatory syndromes, *CRIA*, cleavage-resistant RIPK1-induced autoinflammatory, *DADA2*, deficiency of adenosine deaminase 2, *DIRA*, deficiency of the interleukin-1 receptor antagonist, *DLBCL*, diffuse large B-cell lymphoma, *Fhlh*, familial hemophagocytic lymphohistiocytosis, *FMF*, familial Mediterranean fever, *GOF*, gain of function, *IPEX*, immune dysregulation, polyendocrinopathy, enteropathy, X-linked, *JIA*, juvenile idiopathic arthritis, *LGL*, large granular lymphocytic leukemia, *LOF*, loss-of-function, *MDS*, myelodysplastic syndrome, *PRAAS*, proteasome-associated autoinflammatory syndrome, *RALD*, RAS-associated autoimmune leukoproliferative disease, *SPTCL*, subcutaneous panniculitis-like T-cell lymphoma, *TRAPS*, tumor necrosis factor receptor associated periodic syndrome, *VEO-IBD*, very early onset inflammatory bowel disease.

dominant disorders vary from haploinsufficiency to dominant loss-of-function (LOF) to dominant gain-of-function (GOF). To complicate matters more, many autosomal dominant immune dysregulation disorders exhibit variable expressivity of the associated clinical phenotype, meaning that some patients with the same mutation may have little to no clinical disease while others have severe disease. This creates challenges when trying to counsel individuals carrying disease-associated mutations about their risks of the disease when making decisions about treatment.

Somatic or Mosaic Genetic Defects and Immune Dysregulation

One unique aspect of immune dysregulation disorders is that acquired (somatic) mutations can cause clinical disease due to the fact that these mutations often activate or enhance the growth, survival, or reactivity of the cells in which they occur. In many cases, these somatic mutations occur in only a subset of cells but can lead to the same phenotype and disease severity as when the mutation is present in the germ line. A growing number of disorders have been described in which a somatic mutation in as few as 5% of cells of a particular cell subset can lead to disease.[1] Depending on when the mutation occurs, the somatic variant can cause either germline or somatic mosaicism. *Germline mosaicism* usually occurs as a result of a mutation arising de novo in one or more cells relatively early after fertilization. As a result, most or all cells arising from that initial cell (including germ cells/gametes) carry the mutation, meaning that the mutation can be passed down to offspring. *Somatic mosaicism* typically occurs in a terminally differentiated cell type at any time during its life span.

Often, somatic mutations lead to a selective growth advantage for the cells that harbor the mutation, leading to their expansion. Mutations that lead to abnormal immune cell function, abnormal growth, resistance to apoptosis, resistance to regulation, etc., can lead to those cells secreting large amounts

of cytokine, growing in an unregulated manner, or inappropriately attacking cellular or protein targets. Because cells that acquire somatic mutations tend to gain enhanced or altered function, they lead almost exclusively to immune dysregulation and almost never to immune deficiency. A growing number of gene defects cause similar clinical disease, regardless of whether they occur as germline or somatic mutations (e.g., *FAS*, *NLRP3*, *NLRC4*, *TNFRSF1A*, *NOD2*, *TMEM173*, *TLR8*).[2,3] Some disorders, such as the RAS-associated autoimmune leukoproliferative disorder (RALD), are caused by mutations in the *NRAS* or *KRAS* genes, and the inflammatory disorder caused by mutations in *STAT5B* have been described exclusively in the setting of somatic mutations. Finally, immune regulatory disorders can also arise when mutations take place in only a subset of immune cells, including cryopyrin-associated periodic syndrome (CAPS) occurring when somatic *NLRP3* mutations arise in only a subset of myeloid cells, or pure red cell aplasia occurring when somatic *STAT3-GOF* mutations take place only in CD8 T cells.[4,5] Unfortunately, identification of somatic mutations can be very difficult, particularly when the mutation is present in only a subset of cells. In these cases, either ultra-deep next-generation sequencing (i.e., sequencing to a depth of 500× coverage or higher) or enrichment of the affected cell subset prior to sequencing may be required.

GENERAL DIAGNOSTIC TESTING APPROACH TO IMMUNE REGULATORY DISORDERS

One of the most challenging aspects of immune regulatory disorders is that there is often significant phenotypic overlap between patients with different genetic defects. Similarities tend to be highest among disorders in the same disease group; the underlying molecular defects often involve related immune mechanisms or signaling pathways (see Table 38.1), but there can also be significant overlap of clinical phenotypes between different disease groups. Previously, the approach to diagnosis varied, but typically depended on clinical laboratory testing paired with flow-cytometry-based testing in order to define an immunophenotype before embarking on targeted genetic testing to try to confirm a diagnosis. Because of the dramatic decline in the cost of genetic sequencing, the most direct way to obtain a definitive diagnosis in most cases is to perform broad-based genetic testing using a large gene panel, whole exome sequencing, or whole genome sequencing. Depending on the cohort, published data suggests that this "genetics first" approach can yield an answer in 30% to 50% of cases.[6–8]

Adjunctive Diagnostic Tests

At the present time, the most useful application of adjunctive diagnostic testing is to supplement or confirm pathogenicity of a genetic variant. Adjunctive testing generally falls into two major categories: protein expression studies and functional assays. A variety of tests have been developed to evaluate the presence and phenotype of various immune cell subsets or the expression of key proteins in cells; examples include B-cell immunophenotyping to assess naïve and memory B-cell populations or tests to evaluate FOXP3 or CTLA4 protein expression in regulatory T cells. Functional tests can be useful to determine whether novel gene variants identified by genetic testing have a functional consequence that may suggest pathogenicity. Examples include evaluation of STAT1 phosphorylation in patients with a suspected STAT1-GOF mutation, evaluation of CD80 transendocytosis/uptake in patients with suspected CTLA4 haploinsufficiency or LRBA deficiency, or assessment of muramyl dipeptide—stimulated TNF production by monocytes in patients with suspected XIAP deficiency.[9,10] Only a handful of these tests are available in clinical labs, while others are available only as research assays. Consequently, these tests are generally not good for screening patients for the presence of disease, but instead are used for follow-up assessments after genetic testing.

Additional Workup

In addition to genetic and adjunctive testing performed to arrive at a definitive diagnosis, assessments to screen for organ involvement are recommended. These include assessments of the hematopoietic system, immune system, GI tract and liver, endocrine organs, lungs, and kidneys. In each case, the goal is to screen for active organ-specific autoimmune disease, which should be considered in all patients with immune regulatory disorders. These should be tailored to each patient's clinical presentation.

A variety of autoantibodies have been identified in patients with immune regulatory disorders; some of these may be pathogenic, so screening should be considered in all cases. Autoantibodies against endocrine organs are quite common, making screening for thyroid autoantibodies recommended; screening for diabetes-associated autoantibodies should be considered, particularly if there are any signs of glucose instability. Investigation of autoantibodies targeting other organs may be guided by the organ-specific clinical manifestations in each patient.

SPECIFIC IMMUNE REGULATORY DISORDERS

Regulatory-T-Cell (Treg)/Effector-T-Cell (Teff) Axis Defects

Regulatory T cells (Tregs) play a major role in maintaining immune tolerance and returning the immune system to homeostasis after an immune activation event. Thymically derived regulatory T cells (tTregs) constitute the majority of Tregs in the resting state. Cells with a tTreg phenotype are first identifiable in the thymic medulla after progenitor T cells have undergone the initial rounds of positive selection in response to engagement of their T-cell receptor by antigen. The developing Tregs are exposed to tissue-specific antigens presented on AIRE-expressing thymic medullary epithelial cells, and their characteristic genetic program is set in place (although the precise mechanisms by which this happens is unknown) (Fig. 38.1). It is known that the transcription factor FOXP3 is required for the development of functional Treg cells. tTregs eventually leave the thymus and enter the periphery, where they require persistent interleukin (IL)-2 stimulation to maintain their FOXP3 expression, expand, and acquire maximal regulatory function. tTregs utilize a variety of mechanisms to regulate target cells, including direct cell-cell interactions via key regulatory molecules like CTLA4, secretion of regulatory cytokines like transforming growth factor-β (TGF-β) and IL-10, competition for IL-2 in the local microenvironment, and others (see Fig. 38.1). Absence of key molecules required for the development or function of Tregs can lead to an imbalance between regulatory and effector T-cell function, thereby causing immune dysregulation and autoimmunity.

Autoimmune regulator (AIRE) deficiency (autosomal recessive/autosomal dominant) causes the syndrome of autoimmune

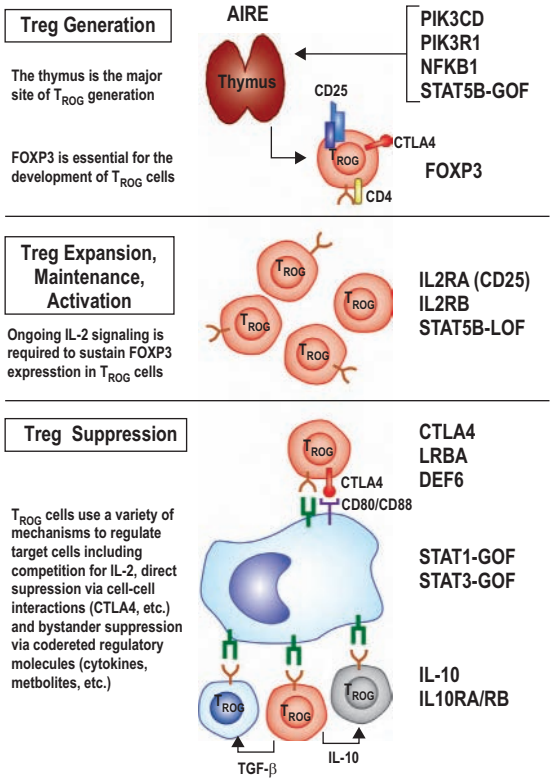

FIG. 38.1 The Normal Life Cycle of Thymically Derived Regulatory T Cells. Cells initially require selection in the thymus and expression of FOXP3 to become functional regulatory T cells (*Tregs*). In the periphery, they require ongoing interleukin (*IL*)-2 stimulation to sustain FOXP3 expression; they expand and become activated to suppress target cells. Functionally active Tregs exert suppressive function on target cells in various ways, including direct cell-cell interaction and secretion of immunoregulatory cytokines. Certain activating mutations in key immune signaling pathways (STAT1, STAT3, etc.) may cause effector cells to be resistant to the suppressive activity of Tregs. *AIRE*, Autoimmune regulator; *TGF-β*, transforming growth factor-β.

polyendocrinopathy, candidiasis, and ectodermal dystrophy (APECED), which is characterized by extensive organ-specific autoimmunity mediated by both cellular and humoral immune mechanisms. Key target tissues include endocrine organs (parathyroid dysfunction, adrenal insufficiency, gonadal failure, type 1 diabetes, etc.), lung (interstitial lung disease), GI tract (enteropathy, pernicious anemia), liver, and skin. Many patients also have chronic mucocutaneous candidiasis (CMC). Recent studies have shown that the CMC is caused primarily by dysregulated type 1 immunity with overexpression of interferon-gamma, leading to compromised mucosal barrier function.[11] Since AIRE is primarily expressed in thymic medullary epithelial cells where it plays a role in thymic T-cell selection, this may be related to defective negative selection of autoreactive T cells. Decreased Treg function may also contribute to the excessive type 1 immunity, as APECED patients demonstrate both a decreased percentage of $CD4^+CD25^{high}$ tTreg cells as well as decreased FOXP3 protein expression in these cells compared to normal individuals.[12] Furthermore, isolated tTreg cells from APECED patients have a decreased ability to suppress proliferation of effector T cells in vitro compared to those from healthy controls.[12] Murine studies suggest that Janus kinase (JAK) inhibitors may be effective in controlling the excessive type 1 immunity in APECED.[11] Since AIRE is expressed primarily in the thymus, hematopoietic cell transplant (HCT) is unlikely to yield significant benefit.

FOXP3 deficiency (X-linked recessive) causes the syndrome of immune dysregulation, polyendocrinopathy, enteropathy, and X-linked (IPEX). This occurs in males with a single mutated X chromosome. Most patients with IPEX present with a basic triad of clinical features, including autoimmune enteropathy (watery diarrhea), dermatitis (usually eczema), and endocrinopathy (type I diabetes and thyroiditis). In addition, most patients have other autoimmune features, including cytopenias, liver disease, nephritis/nephropathy, etc. Since FOXP3 is required for the development of functional Tregs, deficiency causes a lack of effective peripheral immune tolerance. Murine studies have demonstrated that in this setting, effector T cells act as the primary drivers of autoimmunity. The most effective therapies have therefore been those directed toward controlling effector T-cell function, including tacrolimus (FK506), cyclosporine, and sirolimus (rapapmycin). HCT has been shown to be an effective therapy for IPEX, but no particular transplant regimen has proven definitively to be superior as long as the chosen transplant regimen leads to stable donor cell engraftment.[13,14]

IL2RA, IL2RB, and STAT5B deficiency (autosomal recessive) cause defects in IL-2 signaling, either as a result of absent IL-2 receptor chains (IL2RA and IL2RB) or absence of the dominant IL-2 driven transcription factor, STAT5B. Ongoing IL-2 stimulation of Tregs is required to sustain FOXP3 expression, thereby preserving their suppressive function and maintaining their competitive fitness. As a result of Treg dysfunction, humans with defects in IL-2 signaling develop immune dysregulation with autoimmune enteropathy (diarrhea), dermatitis (eczema, pemphigus nodularis, psoriasiform dermatitis), and early-onset endocrinopathies (type 1 diabetes, thyroiditis). Patients with STAT5B deficiency also develop severe, interstitial pneumonitis that can be life threatening, and due to the separate role of STAT5B in signaling from the human growth hormone receptor, patients also exhibit dwarfism. Development of pathogenic autoantibodies is common, and many patients also have hepatosplenomegaly, lymphadenopathy, and lymphocytic infiltrates in various organs. Because IL-2 is essential for expansion of effector T cells, patients with defects in this signaling pathway often have moderate T-cell lymphopenia, and in cases of IL2RB and STAT5B deficiency, may also have low NK cell numbers due to the role that these molecules play in IL-15 signaling. As a result, patients are typically susceptible to viral and fungal pathogens, with cytomegalovirus (CMV) pneumonitis being reported in several patients and thrush and *candida* esophagitis being common. Various immunosuppressive therapies have been tried in patients with IL-2 signaling defects, but treatment with aggressive immunosuppression is complicated due to infectious susceptibilities. HCT has been successful in both IL2RA and IL2RB deficiency, has not been reported in STAT5B deficiency.[15–18]

STAT1-GOF defects (autosomal dominant) are most commonly associated with CMC, but there is a wide range of phenotypic heterogeneity among patients, with some having only intermittent CMC episodes and others with extensive immune dysregulation and autoimmunity. Common features among patients with more extensive autoimmunity include enteropathy (diarrhea), dermatitis (eczema, psoriasiform dermatitis), endocrinopathy

(thyroiditis, type 1 diabetes), and cytopenias. From an infection standpoint, some STAT1-GOF patients have susceptibility to recurrent or severe herpes viral infections, and a subset have hypogammaglobulinemia, poor vaccine responses, and recurrent bacterial sinopulmonary infections, sometimes misdiagnosed as common variable immune deficiency (CVID) before a molecular diagnosis is obtained. Vascular aneurysms have been described in a small number of patients, and many patients with a severe immune dysregulation phenotype have failure to thrive with growth delay. A growing number of case reports have described significant clinical improvement in response to JAK kinase inhibitors (JAKinibs), although there have also been reports of invasive fungal and herpes viral infections in patients receiving this treatment. HCT can be successful, but in the largest published case series, survival was only 40%, with high rates of primary and secondary donor graft failure, suggesting that transplant should be approached with caution until more data are available regarding the best HCT approach.[15]

STAT3-GOF defects (autosomal dominant) are characterized by severe, systemic autoimmunity and marked growth failure in at least 50% of patients. Common autoimmune features include autoimmune enteropathy (diarrhea), early-onset type 1 diabetes, cytopenias, inflammatory liver disease, splenomegaly, and lymphadenopathy, sometimes mistaken for autoimmune lymphoproliferative syndrome (ALPS) prior to obtaining a molecular diagnosis. Other findings that are less common but still serious include hypogammaglobulinemia and recurrent infections, arthritis, and vasculitis. Like patients with STAT1-GOF disease, there are case reports describing significant clinical improvement with the use of JAKinib therapy. Since IL-6 is a major driver of STAT3 activation, IL-6 blockade using monoclonal antibody therapy has also been used, although the clinical effectiveness of this is less clear. HCT has been used successfully, but an early case series suggests that survival may be just over 50%, with many patients dying of severe graft-versus-host disease or infections after transplant.[15]

CTLA4 haploinsufficiency (autosomal dominant) is usually associated with both an immune deficiency (hypogammaglobulinemia and recurrent infections) and profound, systemic autoimmunity. The most common autoimmune features include recurrent, autoimmune cytopenias (hemolytic anemia, thrombocytopenia, neutropenia) and nonmalignant lymphoproliferation in nonlymphoid organs. The most common sites of lymphoid proliferation are the GI tract (nodular lymphoid hyperplasia) and lungs (follicular bronchiolitis, granulomatous lymphocytic interstitial lung disease [GLILD], etc.). Nonmalignant lymphoproliferative lesions in the central nervous system occur in 25% to 30% of patients and are quite likely to involve CTLA4 pathway defects. Less common autoimmune features include endocrinopathies (thyroiditis, type 1 diabetes, etc.), arthritis, and aplastic anemia. In patients with lymphoproliferation and autoimmunity, sirolimus (rapamycin) has been used successfully but may not fully control symptoms. Targeted treatment with CTLA4-Ig (immunoglobulin) fusion protein to "add back" functional CTLA4 has been used in an increasing number of cases and has shown significant therapeutic benefit, although questions remain about how long patients can be maintained on this therapy. HCT has shown encouraging results in patients who still have severe or progressive disease despite treatment.[19]

LRBA deficiency (autosomal recessive) has many features that overlap with CTLA4 haploinsufficiency, and early therapeutic attempts demonstrated an excellent disease response to CTLA4-Ig fusion protein. This observation led to the finding that LRBA is involved in recycling of CTLA4 back to the surface of T cells so that in its absence, T cells are partially deficient in their expression of CTLA4. *LRBA* is a large gene, and a substantial number of identified mutations are copy number variants of various sizes that can be missed by traditional next-generation sequencing approaches, which can make confirmation of a diagnosis difficult. Like CTLA4 haploinsufficiency, HCT has also been successful in patients with LRBA deficiency, although some patients do not achieve a complete remission of symptoms. LRBA is broadly expressed, and given its role in recycling CTLA4, it is likely that LRBA carries out additional cellular functions that may not be corrected by transplantation of only the hematopoietic cells.[20]

NONMALIGNANT LYMPHOPROLIFERATION

The best-described clinical disorder associated with nonmalignant lymphoproliferation is ALPS. ALPS typically becomes manifest within the first 5 years of life with nonmalignant, chronic peripheral lymphadenopathy and/or splenomegaly. Hepatomegaly develops in approximately 50% of cases. Patients typically have recurrent episodes of autoimmune cytopenias (hemolytic anemia and thrombocytopenia) and may develop more extensive autoimmunity, including autoimmune liver disease, glomerulonephritis, aplastic anemia, alopecia areata, and other features. Over time the lymphoproliferation tends to lessen, but often the autoimmune issues persist long term. ALPS patients have a high lifetime risk of lymphoma.

FAS deficiency (autosomal dominant) can occur as either a germline or somatically acquired defect. In addition to the clinical autoimmune features noted above, patients can have hypergammaglobulinemia with autoantibodies targeting hematopoietic cells (red cells, platelets, and neutrophils) as well as anti-phospholipid antibodies. Patients were found to have elevated α/β double-negative ($CD4^{neg}CD8^{neg}$) T cells in the peripheral circulation, although a number of other useful biomarkers have been identified which can aid in confirming a diagnosis of FAS deficiency. These include increased circulating levels of soluble FAS ligand (FASLG), vitamin B_{12}, IL-10, and IL-18. Because of the increased risk of lymphoma (most highly associated with mutations in the intracellular domain of FAS), patients should be counseled to watch for changes in the degree or character of their lymphadenopathy and for "B symptoms" (fever, night sweats, weight loss). Positron emission tomography (PET) scans and biopsies may be required to evaluate suspicious cases. Traditionally, first-line treatment to manage the lymphoproliferation and autoimmunity has been steroids, but steroid-sparing agents, including mycophenolate mofetil (MMF) and sirolimus (rapamycin), have been used for long-term therapy. Among these, sirolimus has proven to have a particularly beneficial effect on the lymphoproliferation, which has encouraged some to use this as a first-line therapy for FAS deficient ALPS. In patients who fail pharmacologic therapy, splenectomy was often considered, but the risks and benefits should be carefully weighed since post-splenectomy infection and sepsis are the most lethal complication of the disease. Since the disease of FAS-deficient patients tends to improve with age, HCT is not usually considered; there are, however, a small number of patients who have been treated with HCT with reportedly good survival and disease response.[21]

CASP10 deficiency (autosomal recessive/autosomal dominant) is associated with diffuse lymphadenopathy, splenomegaly,

autoimmune cytopenias, hypergammaglobulinemia, and development of pathogenic autoantibodies. Patients may have expanded double-negative T cells in peripheral blood.

PIK3CD and PIK3R1–related defects (autosomal dominant) lead to hyperactivity of a key phosphatidyl inositol-3 kinase (PI-3 kinase Δ) that is present in hematopoietic cells. Mutations cause either a GOF in the kinase subunit (PIK3CD) or a LOF in the regulatory subunit (PIK3R1) of this kinase, leading to an overall increase in activity. The resultant dysregulated growth of B and T cells is associated with lymphoproliferation manifested by lymphadenopathy, splenomegaly, and lymphocytic infiltrates in the lung and GI tract, causing interstitial pneumonitis and enteropathy. Most patients have hypogammaglobulinemia with recurrent bacterial sinopulmonary infections and a susceptibility to herpes group viruses, particularly Epstein-Barr virus (EBV), which often leads to persistent EBV viremia. Some patients develop autoimmune cytopenias and other organ-specific autoimmunity (kidney, liver, etc.). The combination of lymphoproliferative drive paired with a particular susceptibility to EBV leads to a high rate of malignant transformation (>10%) in these patients, with Hodgkin or non-Hodgkin lymphomas being the most common.

Treatment of PIK3CD and PIK3R1 disease typically involves a combination of immunoglobulin replacement therapy and antibiotics to control the recurrent bacterial infections as well as immunomodulatory therapy to control the lymphoproliferative and autoimmune aspects of the disease. Sirolimus (rapamycin) and B-cell-depletion therapy (rituximab, etc.) have shown significant benefits in treating the lymphoproliferative aspects of disease, and phase I/II clinical trials of targeted PI-3 kinase inhibitors (e.g., leniolisib) have shown promise as potential future treatment options. Patients who develop malignancies often undergo HCT as part of their treatment regimen, and their overall outcomes have been reasonably good but are confounded by the underlying malignancy and risks for disease relapse. HCT has not yet been broadly employed prophylactically in patients with PIK3CD or PIK3R1 defects, but is a consideration.[22,23]

NRAS and KRAS GOF defects (autosomal dominant) are somatic mutations that cause hematopoietic cells to become resistant to apoptosis. As a result, patients typically have leukocytosis with a persistent monocytosis that can be difficult to differentiate from juvenile myelomonocytic leukemia (JMML). As a group, these disorders are often referred to as RALD. Most patients have persistent splenomegaly, modest lymphadenopathy, and autoantibodies to a variety of targets, some of which may be pathogenic. These can cause cytopenias and other autoimmune disorders, including systemic lupus, which has been reported in a small number of cases. Like patients with PI-3 kinase pathway defects, patients with RALD are at higher risk of developing hematopoietic malignancies, particularly JMML, and should be counseled accordingly. Despite having a clinical phenotype that overlaps with FAS deficiency, RALD patients typically have normal to mildly elevated double-negative T cells and normal serum FAS ligand and vitamin B_{12} levels. A variety of immunomodulatory therapies have been tried for RALD, but responses vary. For patients who develop JMML, HCT has become standard of care; HCT is not typically considered prophylactically in patients with RALD.[24]

PRKCD deficiency (autosomal recessive) has only been described in a handful of patients. Lymphadenopathy, splenomegaly, hypergammaglobulinemia, and the presence of autoantibodies were common features. In addition, some patients developed lupus with nephritis, rash, serositis, and arthritis. These patients were treated with steroids and MMF, while another patient without lupus was reported to have a good clinical response to sirolimus (rapamycin) with a decrease in splenomegaly and hypergammaglobulinemia.[25]

CONCLUSIONS

There are a growing number of IEI characterized by immune dysregulation. In general, these have been linked either to activating mutations in molecules or pathways that promote immune effector cell growth, activation, or survival or to a loss of regulatory molecules or cells that control these processes. Patients with IEI defects generally present with autoimmunity, inflammatory disease, or lymphoproliferation. Since these processes may target multiple organs, patients often seek care in a variety of different subspecialty clinics. As a consequence, it is important for providers in virtually all medical subspecialties to have an awareness of these disorders and the fact that genetic testing can provide both a diagnosis and significant insight into potential targeted therapies that may be particularly effective in treating these patients.

KEY CONCEPTS

- Immune regulatory disorders should be suspected in the setting of autoimmune, inflammatory, or nonmalignant lymphoproliferative disease that is:
  - **Too much**—Multiple organ systems involved, multiple cell lines affected, multiple autoantibodies to diverse targets.
  - **Too severe**—Immune dysregulation is unusually severe and/or life-threatening.
  - **Too weird**—Unusual autoimmune disease, unusual or severe infections in addition to immune dysregulation.
  - **Too young**—Onset of disease in infancy or early childhood.
- Immune regulatory disorders have significant phenotypic overlap, so making a specific diagnosis can be challenging.
- Broad-based genetic testing (i.e., whole exome or whole genome sequencing, large gene panel) is the diagnostic approach most likely to lead to a specific diagnosis.

CLINICAL PEARLS

Common autoimmune, inflammatory, and lymphoproliferative disease manifestations:

- **Hematologic**—autoimmune cytopenias (anemia, thrombocytopenia, neutropenia)
- **GI tract**—autoimmune or inflammatory enteropathy, nodular lymphoid hyperplasia, autoimmune hepatitis, nodular regenerative hyperplasia (liver)
- **Lungs**—**interstitial** lung disease, follicular bronchiolitis, non-caseating granulomas
- **Skin**—**eczema**, psoriasis, other dermatitides
- **Endocrine**—autoimmune thyroiditis, type I diabetes, gonadal insufficiency, etc.
- **Cardiovascular**—vasculitis

Less common autoimmune, inflammatory, and lymphoproliferative disease manifestations:

- **Musculoskeletal**—arthritis, myositis
- **Cardiovascular**—vasculitis
- **Neurologic**—lymphoproliferation, strokes

THERAPEUTIC PRINCIPLES

- The primary goal of treatment is to control autoimmunity, inflammation, or nonmalignant lymphoproliferation in order to ameliorate acute symptoms and prevent permanent tissue and organ damage.
- Broadly active immunomodulators (e.g., corticosteroids) may be required acutely to stabilize acute illness, but for long-term therapy, efforts should be made to target treatment as much as possible to avoid undesired side effects.
- Identification of a genetic cause of disease can often provide guidance for targeted treatment (e.g., CTLA4-Ig in CTLA4 haploinsufficiency, JAK inhibitors in JAK or STAT gain-of-function disorders).
- Biopsies of affected tissue followed by staining of biopsies for immune cells (B cells, T cells, eosinophils, etc.) or immune proteins (complement, IgA, etc.) can provide useful information about the components of the immune system mediating disease at the level of the tissue, allowing therapy to be targeted accordingly.
- Use of immunomodulators may cause increased risk for infection, so antimicrobial prophylaxis should be considered in all cases, taking into consideration the patient's underlying infectious susceptibilities.
- In patients with pre-existing infections, treatment needs to address both immune dysregulation and infections in order to optimize outcomes.

JAK, Janus kinase.

ON THE HORIZON

- The number of genetically defined immune dysregulation disorders is likely to increase in the coming years.
- Newly identified genetic defects associated with a phenotype of immune dysregulation will highlight molecular pathways and molecules that play key roles in regulating immunity.
- A growing number of targeted therapies will increase opportunities to provide precision treatments to patients with a genetic diagnosis.
- There is a significant need for development of new tools and approaches to identify disease causing somatic variants in patients.

Neutrophils and Neutrophil Disorders

Steven M. Holland and Gülbü Uzel

We have learned a great deal about phagocytes since their discovery by Metchnikoff in 1905: neutrophils, monocytes, macrophages, and eosinophils traffic to sites of infection or inflammation and engulf microorganisms and apoptotic cells as the lead players in the innate immune response.

NEUTROPHILS

Neutrophils, also known as *granulocytes* because of their numerous cytoplasmic granules, are crucial for the host defense against bacteria and fungi. They are bone marrow–derived, terminally differentiated cells incapable of further cellular division. They have a short life span in the circulation ($t_{1/2}$ ≈7 hours) but survive an additional 1 to 2 days in tissue. In peripheral blood, they are normally maintained at 3000–6000 cells/mm^3 and represent 30% to 50% of the circulating leukocytes. There are four pools of neutrophils in vivo: (i) the bone marrow pool (≈90% of the total); (ii) the circulating pool (≈3% of the total); (iii) the marginated pool (adherent to the endothelium, ≈4% of the total); and (iv) those located in the tissues as extravasated or exudative neutrophils. About 55% to 60% of bone marrow is dedicated to the production of neutrophils, producing around 10^{11} cells daily, but production increases in times of stress.

Myeloid cell differentiation is a complex process that typically extends over 2 weeks in bone marrow. The pluripotent stem cell, the precursor for all hematopoiesis, develops into lineage-committed progenitors, which proceed to terminally differentiated distinct cells, all the while preserving and regenerating more pluripotent stem cells.[1]

PRODUCTION OF MACROPHAGES AND GRANULOCYTES

The pluripotent stem cell gives rise to the myeloid stem cell from which the colony-forming unit granulocyte/erythrocyte/macrophage/megakaryocyte (CFU-GEMM) is derived. Among the growth factors that are influential at this step are stem cell factor (SCF), interleukin-3 (IL-3), and granulocyte/macrophage–colony-stimulating factor (GM-CSF).[2] The CFU-GEMM further differentiates into the colony-forming unit–granulocyte/macrophage (CFU-GM) under the continuing influence of these growth factors. The colony-forming unit–granulocyte (CFU-G), a neutrophil lineage committed precursor, is derived from CFU-GM under the control of IL-3, GM-CSF, and granulocyte–colony-stimulating factor (G-CSF). The myeloblast is formed from the CFU-G under the influence of GM-CSF and G-CSF and is the first morphologically distinct cell of the neutrophil lineage. Promyelocyte, myelocyte, metamyelocyte, band form, and mature neutrophil formation follow consecutively under the ongoing control of G-CSF and GM-CSF. The maturation process from stem cell to myelocyte takes 4 to 6 days, with an additional 5 to 7 days for the myelocyte to form the mature neutrophil, all in bone marrow.

Macrophage differentiation is similar to granulocyte differentiation in many respects. The CFU-GM differentiates into the colony-forming unit–macrophage (CFU-M) followed by the formation of the monoblast, promonocyte, and monocyte under the influence of macrophage colony-stimulating factor (M-CSF).[3] After monocytes are released into blood, they circulate for 1 to 4 days before entering tissues, where they further differentiate into macrophages.

EVOLUTION OF NEUTROPHIL GRANULES

During myelopoiesis in bone marrow, the first granules forming at the promyelocyte stage, stain blue with the Wright or Romanowsky stain, and are called *primary granules* or *azurophilic granules*. Their formation ceases at the myelocyte stage, and they are distributed among the daughter cells. These primary granules contain microbicidal enzymes, including defensins, hydrolases, and proteases (Table 39.1). As the granulocyte precursors mature and divide, the number of primary granules per cell decreases. After the promyelocyte stage, secondary or specific granules form. In the mature neutrophil, they comprise about two-thirds of the granules. The secondary granules are less dense and contain cytochrome b_{558}, lysozyme, lactoferrin, and collagenase. The gelatinase-containing tertiary granule forms after the metamyelocyte stage and can be detected in the band form and the mature granulocyte.

DISORDERS OF NEUTROPHIL PRODUCTION

Chronic neutropenia refers to conditions lasting more than 6 months with an absolute neutrophil count (ANC) of less than 500 cells/μL. Chronic neutropenia has many etiologies, as listed in Table 39.2.

Severe Congenital Neutropenia and Cyclic Neutropenia

Kostmann originally described an extensive northern Swedish kindred with both recessive and dominant neutropenia, but subsequently sporadic cases were added, making Kostmann neutropenia a confusing mélange of syndromes.[4] Severe congenital neutropenia (SCN) is now known to be a heterogeneous

TABLE 39.1 Neutrophil Granule Components

Granule	Contents	Properties
Primary (azurophilic) granules	*Lysosomal hydrolases* Myeloperoxidase Defensins Lysozyme Elastase Cathepsin G Azurocidin Proteinase 3 Bacterial—permeability increasing protein (BPI) *Acid hydrolases* Cathepsin B Cathepsin D β-Glycerophosphatase granulocyte β-Glucuronidase *N*-acetyl-β-glucosaminidase α-Mannosidase *Other* Collagenase	• First formed during myelopoiesis at promyelocyte stage • Appearing blue when stained with Wright stain • Least mobilizable of all granules • Measuring ≈ 0.8 μm in diameter • Containing defensins making up 30%–50% of granule contents • Augmenting the microbial damage initiated by reactive oxidants • Helping to digest dead microbes and host cells • Neutralizing gram-negative bacteria by means of BPI
Secondary (specific) granules	*Lysosomal hydrolases* Lysozyme *Other* Collagenase Gelatinase Lactoferrin Vitamin B_{12}–binding proteins Cytochrome b_{558} Histaminidase FMLF receptors C3bi receptors	• First formed at the myelocyte stage • Specifically found specific in phagocytes • Measuring ≈0.5 μm in diameter • Binding proteins to deprive microorganisms of nutrients • Having positively charged, enhancing cell surface
Tertiary (smaller) granules	*Acid hydrolases* Cathepsin B Cathepsin D β-Glycerophosphatase granulocyte β-Glucuronidase *N*-acetyl-β-glucosaminidase α-Mannosidase *Other* Gelatinase	• Heterogeneous population of organelles, including C-particles and secretory vesicles • Detected in the band form and mature neutrophils

TABLE 39.2 Causes of Neutropenia

Classification	Etiology
Hematological	Kostmann syndrome Severe congenital neutropenia Cyclic neutropenia Myelodysplastic syndrome Aplastic anemia Leukemia
Immunological/inflammatory disorders	Severe combined immunodeficiency (SCID), certain types Hyper-IgM syndrome (CD40L deficiency) Chediak-Higashi syndrome Cartilage–hair hypoplasia Reticular dysgenesis Dyskeratosis congenita Autoimmune neutropenia Isoimmune neutropenia
Infections	Human immunodeficiency virus (HIV) Parvovirus Epstein-Barr virus Malaria Cytomegalovirus
Inborn errors of metabolism/nutritional disorders	Gaucher disease Glycogen storage disease, type Ib Transcobalamin deficiency Vitamin B_{12}, folate deficiency
Other	Schwachman-Bodian-Diamond syndrome Idiopathic neutropenia Chemotherapy Radiation therapy Drugs (e.g., vancomycin, chloramphenicol, sulfamethoxazole, clozapine) Toxins (e.g., benzene) Dialysis Reticuloendothelial sequestration

group of disorders that present similarly. The genes recognized as mendelian causes of neutropenia are neutrophil elastase (*ELANE* or *ELA2*), *HAX1*, *G6PC3*, *GFI1*, *GATA2, JAGN1*, *VPS45* genes, and activating mutations in the Wiskott–Aldrich syndrome (*WAS*) gene.

SCN is usually diagnosed in early infancy because of the occurrence of life-threatening pyogenic infections, cellulitis, stomatitis, peritonitis, perirectal abscess, or meningitis. The most common bacteria isolated are *Staphylococcus aureus, Escherichia coli*, and *Pseudomonas aeruginosa*. Patients usually have an ANC ≤200 cells/μL, mild anemia, and hypergammaglobulinemia, sometimes with eosinophilia and monocytosis. SCN represents a maturational arrest of neutrophil precursors at the level of promyelocytes or myelocytes in bone marrow. A subset of patients with SCN (7.5% to 10%) subsequently develops a myelodysplastic syndrome (MDS) or acute myeloid leukemia (AML), which has been associated with acquired truncation mutations of the G-CSF receptor (G-CSFR).

The majority of patients with SCN have heterozygous mutations in the neutrophil elastase (*ELANE*).[5] The fascinating cyclic form of this disorder has neutrophil counts oscillating with 21-day cycles: hence the name cyclic neutropenia (CN). These typically missense mutations are transmitted as autosomal dominant mutations but also occur spontaneously. There is no clear genotype–phenotype correlation between specific *ELANE* mutations that lead to CN as opposed to SCN. They lead to intracellular accumulation of mutant proteins that are inappropriately trafficked into azurophilic granules.[5] The mutated, aberrantly folded elastase is thought to contribute to neutrophil precursor apoptosis and the clinical phenotype of neutropenia, but the mechanisms by which this occurs are still obscure. Treatment with subcutaneous G-CSF can increase the ANC above 1000 cells/μL, with a decrease in the frequency of infections and significant clinical improvement.[6] However, patients with SCN who have received long-term G-CSF therapy are at an increased risk of developing AML or MDS, which correlates with overall G-CSF responsiveness.

Homozygous loss-of-function mutations in *HAX1* account for the majority of recessive cases of SCN,[7] some of which were in original pedigree described by Kostmann. Patients may have isolated SCN or associated neurological problems (cognitive impairment, developmental delay, or epilepsy), depending on which isoform of *HAX1* is mutated. Patients with mutations affecting isoform A have only SCN as opposed to patients with

mutations affecting both isoforms (A and B), who develop neurological problems in addition.[8]

Dominant zinc finger mutations disabling transcriptional repressor activity of the *growth factor independent 1* (*GFI1*) gene have been described in a few patients with SCN.[4] *GFI1* encodes a transcriptional repressor prooncogene controlling normal hematopoietic cell differentiation and also regulating *ELANE* as well as several genes encoding CAAT enhancer binding proteins (C/EBP). Mutations in *GFI1* are also associated with aberrations in lymphoid and myeloid cells, leading to a circulating population of immature myeloid cells. *Gfi1* knock-out mice have impaired regulation of T-helper type 2 (Th2) cells and differentiation of B, Th17, and dendritic cells (DC).

Mutations in the glucose-6-phosphatase catalytic subunit 3 (*G6PC3*) complex cause another form of SCN along with developmental and somatic problems.[9] *G6PC3* encodes glucose-6-phosphatase-β, which hydrolyzes glucose-6-phosphate (G6P) in the final step of gluconeogenesis and glycogenolysis. It is coupled to a glucose transporter (G6PT) that facilitates G6P transport from the cytoplasm to the endoplasmic reticulum. Mutations in the *G6PT* gene lead to glycogen storage disease type Ib, which has variable neutropenia and infections and other complications, such as liver adenomas, growth retardation, osteoporosis, polycystic ovaries, and inflammatory bowel disease (IBD). Children with these complications have increased susceptibility to bacterial infections and cardiovascular abnormalities, including prominent ectatic superficial veins.

Shwachman-Bodian-Diamond Syndrome

Shwachman-Bodian-Diamond syndrome (SBDS) was first described in 1964 as a disorder with pancreatic exocrine insufficiency and bone marrow dysfunction. Currently, it is recognized as the second most common cause of inherited exocrine pancreatic insufficiency after cystic fibrosis. It is autosomal recessive with an estimated incidence of 0.5 to 1/100,000.[10] The SDBS protein belongs to a highly conserved protein family involved in RNA metabolism. Mutations cause defects in the development of the exocrine pancreas, hematopoiesis, and chondrogenesis. Recurring mutations result from gene conversion caused by recombination with a pseudogene in 89% of unrelated patients; 60% carry two converted alleles. (Pseudogene conversion is also the cause of the majority of cases of $p47^{phox}$-deficient chronic granulomatous disease [CGD].)

Patients present with recurrent infections, failure to thrive, hematopoietic dysfunction, metaphyseal dysostosis, growth retardation, and fatty replacement of the pancreas. Most patients have mild neutropenia, and a few have intermittent or chronic neutrophil counts ≤500 cells/μL.[11] Anemia and thrombocytopenia are associated with neutropenia. Congenital aplastic anemia with anemia, thrombocytopenia, and neutropenia is an unusual presentation of SBDS. Upper and lower respiratory tract pyogenic infections are common and related to neutropenia. Short ribs with broadened anterior ends are common radiological findings, along with metaphyseal dyschondroplasia of the femoral head. The diagnosis is suggested by neutropenia, radiological findings, and abnormal pancreatic exocrine function. It is confirmed by gene sequencing.

Autoimmune Neutropenia

Autoimmune neutropenia (AIN) is caused by peripheral destruction of neutrophils as a result of granulocyte-specific autoantibodies.[12]

Primary Autoimmune Neutropenia

Primary AIN is seen in infancy unassociated with other systemic immune-mediated disorders and is the most common form of neutropenia, equally affecting boys and girls at around 1/100,000.[12] The average age at diagnosis is 8 months. The majority present with mild skin and upper respiratory tract infections; some patients remain asymptomatic despite low ANCs. The majority of patients have a neutrophil count ≥500 cells/μL at diagnosis, but ANCs may transiently increase two- to threefold during severe infection. Bone marrow shows normal to increased cellularity. Myeloid precursors typically reach the myelocyte/metamyelocyte stage. Phagocytosed granulocytes in bone marrow may indicate removal of sensitized granulocytes there. Granulocyte-specific antibodies are detected by direct granulocyte immunofluorescence testing (D-GIFT), the vast majority of which are immunoglobulin G (IgG) against glycoproteins of the granulocyte membrane designated neutrophil antigens (NAs). NAs are located on IgG receptor IIA or IIIB (FcγRIIa and FcγRIIIb).

AIN is generally self-limiting. Disappearance of the antibodies from the circulation precedes normalization of neutrophil counts. Prophylactic antibiotic treatment should be reserved for those with recurrent infections. Alternative treatment strategies for severe infections and in the setting of emergency surgical interventions include high-dose intravenous immunoglobulin (IVIG), corticosteroids, and G-CSF—with the latter being the most effective at increasing the ANC.

Secondary Autoimmune Neutropenia

Secondary AIN can be seen at any age and has a more variable clinical course. Hepatitis, systemic lupus erythematosus (SLE), or Hodgkin disease may underlie it and cause other autoimmune problems as well. These antineutrophil antibodies (ANAs) have pan-FcγRIII specificity. CD18/CD11b antibodies have been detected in a subset of patients with secondary AIN that responds poorly to most therapies.

Alloimmune Neonatal Neutropenia

First described by Lalezari in 1966, alloimmune neonatal neutropenia (ANN) is caused by the transplacental transfer of maternal antibodies against the fetal NAs NA1, NA2, and NB1, leading to immune destruction of neonatal neutrophils.[13] These complement-activating antineutrophil IgG antibodies can be detected in about 1/500 live births. Antibody-coated neutrophils in ANN are phagocytosed by the reticuloendothelial system and removed from the circulation, leaving the neutropenic neonate at risk for infections. Omphalitis, cellulitis, and pneumonia typically occur within the first 2 weeks of life in association with neutropenia. Diagnosis can be made by detection of neutrophil-specific alloantibodies in the maternal serum. ANN responds to G-CSF or high-dose IVIG, but most infants improve without specific treatment in a few weeks to 6 months with waning of maternal antibody.

DEFECTS OF LEUKOCYTE ADHESION

Migration of circulating leukocytes from the bloodstream into tissues depends on complex bidirectional interactions between leukocytes and endothelial cells (Chapter 16). The initial steps involve the activation of circulating leukocytes by signal molecules released from inflamed tissues or from the bacteria

themselves. After activation by chemotactic factors—such as the complement fragment C5a, IL-8, leukotriene B4 (LTB4), or the bacterial product formyl-methionyl-leucyl-phenylalanine (fMLF)—leukocytes rapidly become adhesive to the endothelium, other leukocytes, or laboratory surfaces. The activation process involves translocation of subcellular granules containing adhesion molecules (CD18/CD11b) to the polymorphonuclear leukocyte (PMN) surface and qualitative alterations in the adhesion molecules constitutively expressed on the plasma membrane. Adhesion and transmigration of leukocytes occur as a result of interactions between three groups of molecules: leukocyte integrins, endothelial intercellular adhesion molecules (ICAMs, members of the immunoglobulin supergene family), and glycosaminoglycans or selectins (Fig. 39.1). The first step in targeting PMNs to inflamed tissues is the rolling or tethering of PMNs on the endothelium of postcapillary venules.[14] This is attributed to the interactions between CD15s (sialyl Lewis^X or SLe^X) expressed on the leukocyte surface and P-selectin or E-selectin, members of the selectin family of adhesion molecules expressed on the vascular endothelium. In addition, L-selectin on the leukocyte surface interacts with its counterligands P-selectin, CD34, glyCAM-1, and other glycoproteins located on the endothelial surface. *Rolling*—a relatively low-affinity interaction mediated by selectins—is followed by *firm adhesion*, which is a high-affinity interaction between integrins on the neutrophil and ICAMs on the endothelium. Adhesion is followed by the transmigration of neutrophils between endothelial cells out to the extracellular matrix (ECM).

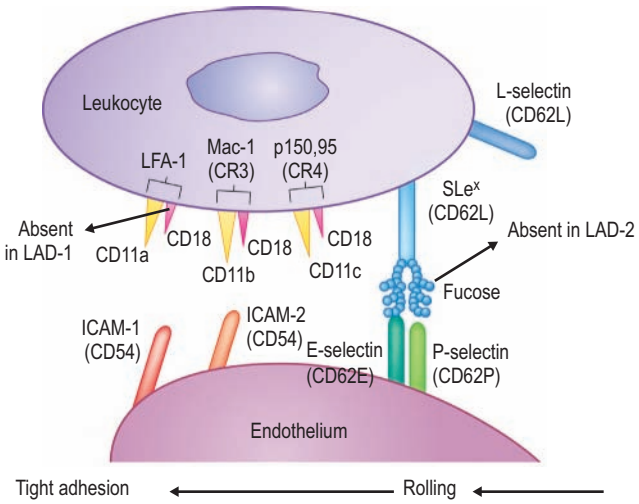

FIG. 39.1 Leukocyte Adhesion to Nonlymphoid Endothelium. Selectins (*L-selectin/CD62L, P-selectin/CD62P,* and *E-selectin/CD62E*), integrins (*CD18/CD11a* or *LFA-1, CD18/CD11b* or *Mac-1*, and *CD18/CD11c* or *p150,95*), and intercellular adhesion molecules (*ICAMs*) are involved in leukocyte adhesion to the nonlymphoid endothelium. Rolling or low-affinity tethering, the initial step of leukocyte adhesion, is mediated by the interactions of E- and P-selectin on endothelial surfaces with the sialyl Lewis^x (*SLe^x* or CD15s) of leukocytes as well as L-selectin on the leukocyte surfaces with its counterligands CD34 or glyCAM-1. Rolling facilitates tight adhesion as a result of the interactions of leukocyte function–associated antigen-1 (*LFA-1*) with ICAM-1 or ICAM-2 and Mac-1 with ICAM-2. CD18 is missing or dysfunctional in leukocyte adhesion defect-1 (*LAD-1*); SLe^x is missing in LAD-2.

Leukocyte Adhesion Defect-1

In the 1970s, infants and children were recognized with severe, recurrent life-threatening bacterial infections affecting the skin, gingiva, and lungs, often with delayed separation of the umbilical stump with severe omphalitis. These patients were shown to have defects in membrane expression of the leukocyte adhesion glycoproteins of the integrin superfamily.[15,16]

Integrins are noncovalently associated, heterodimeric cell surface receptors, comprising one α subunit (CD11a, CD11b, or CD11c) and a common β chain (CD18), the latter required for surface expression of the CD11 chains. These proteins mediate leukocyte adhesion to the endothelium and other leukocytes. Leukocyte adhesion defect-1 (LAD-1) results from mutations in the CD18 gene (*ITGB2*), located on chromosome 21q22. Patients with LAD-1 have defective polymorphonuclear cell adherence, leading to defective chemotaxis and trafficking as well as low natural killer (NK) and cytotoxic T-lymphocyte (CTL) activity. The absence of CR3 leads to loss of complement-mediated phagocytosis and bacterial killing. LAD-1 is often manifested by delayed umbilical cord separation, omphalitis, persistent leukocytosis, destructive periodontitis, and recurrent infections with *S. aureus*, *P. aeruginosa*, and *Klebsiella* spp. Patients with some residual CD18 expression and function (i.e., hypomorphic mutations) live beyond childhood with less frequent or severe infections and do not typically have delayed umbilical cord separation. Persistent neutrophil leukocytosis (usually >15.000 cells/μL) in the absence of infection is common in all patients, driven by both low-level ongoing infection and impaired exit of neutrophils from the circulation. Oral ulcers, severe periodontitis, gingivitis with apical bone loss (Fig. 39.2), and eventual loss of permanent teeth are major problems in LAD-1 and reflect excessive IL-17 expression by CD4 T cells as a result of uninhibited IL-23 production by tissue macrophages.[17] Necrotizing cutaneous ulcers with delayed wound healing and lingering eschar formation are common (Fig. 39.3). Defective chemotaxis and adhesion mean that leukocytes fail to migrate to sites of infection, accounting for the inability to form pus and erythema at the site of infection. Biopsies of the ulcers characteristically show poorly formed granulation tissue and scant fibrinous exudate without neutrophils. Ulcerative gastrointestinal (GI) disorders resembling IBD are also recognized in LAD-1, especially as patients grow older.

FIG. 39.2 Oral Pathology in Leukocyte Adhesion Defect-1 (LAD-1). Gingivitis and severe periodontitis are hallmarks of LAD-1.

FIG. 39.3 Skin Infection in Leukocyte Adhesion Defect-1 (LAD-1). Failure to form pus, inability to demarcate the fibrotic skin debris, and limited inflammation.

Although most cases of CD18 deficiency are homozygous, compound heterozygotes also occur.[18] The diagnosis is usually made by flow cytometric analysis of neutrophils showing decreased or absent CD18 and its associated heterodimers—CD11a, CD11b, and CD11c—and confirmed by mutational analysis of *ITGB2*. More subtle phenotypes can be detected by testing for mobilization of CD18 complexes, such as CD18/CD11b from neutrophils upon cellular stimulation. Definitive therapy of LAD-1 is bone marrow transplantation. Infections must be managed aggressively, since inflammatory responses and clinical signs are unreliable in these patients with profoundly impaired innate immune responses. Surgery is often essential for debridement of nonhealing ulcers, which frequently need tissue grafts, but immunomodulation of the affected cytokine pathways may also be helpful. Although not correcting the underlying gene defect, but reflecting the excessive production of IL-23 and IL-17 at sites of inflammation that is associated with severe oral ulcers, periodontitis and bone loss, a patient with moderate LAD-1 (34% of control CD18 activity) was treated with ustekinumab, which blocks IL-23-dependent production of IL-17. After 1 year of treatment the patient's severe chronic periodontitis and a deep sacral ulcer had resolved without serious infections or adverse reaction. This approach to therapy offers additional insight into the complex pathophysiology of LAD-1 inflammation and suggests the possibility of novel therapeutic approaches to symptomatic management.[19]

KEY CONCEPTS

Leukocyte Adhesion Defect

- Three types of adhesion defect are known: leukocyte adhesion defect (LAD)-1, -2, and -3. There are two phenotypes for LAD-1: moderate and severe.
- LAD-1 results from mutations in CD18; LAD-2 is caused by mutations in sialyl Lewis^x (CD15s); LAD-3 results from mutations in *FERMT3*.
- High white blood cell count, delayed umbilical cord separation, recurrent bacterial infections, skin ulcers, defective wound healing, gingivitis, and periodontitis are the hallmarks of LAD-1.

Leukocyte Adhesion Defect-2

A distinct defect of leukocyte adhesion with susceptibility to infection was described by Etzioni et al. in 1992 and named LAD-2.[15,20] It is characterized by growth retardation and cognitive impairment, hypotonia, seizures, dysmorphic features, strabismus, and persistent periodontitis. In contrast to LAD-1, wound healing is not impaired, nor is the susceptibility to bacterial infections as severe. Hypofucosylation of the protein (SLe^X) on neutrophils impairs the rolling step of neutrophil adhesion. The underlying defect is in guanosine diphosphate (GDP)–fucose biosynthesis, resulting from mutations in the GDP–fucose transporter-1 (*FUCT1* or *SLC35C1*), hence the designation of this disease as a congenital disorder of glycosylation IIc (CDGIIc). In addition to severe impairment in neutrophil migration as in LAD-1, lymphocyte homing to skin is also defective. Patients with LAD-2 have had relatively mild courses of infections with several pneumonias and superinfection of varicella lesions,[20] and some have reportedly improved with fucose supplementation. In addition to SLe^X, fucosylated blood group antigens are also affected, leading to the Bombay blood group phenotype (lack of the H antigen) and Lewis a^-b^- in these patients. Absence of CD15 on patient neutrophils can be detected by flow cytometry. Effective and prompt treatment of infections is central to the management of LAD-2.

Leukocyte Adhesion Defect-3

A third leukocyte adhesion deficiency was recognized, LAD-3, initially named LAD-1/variant (LAD-1v), has a distinct infantile bleeding diathesis similar to Glanzmann-type thrombasthenia along with defective leukocyte adhesion.[21] Although CD18/CD11a (lymphocyte function–associated antigen-1 [LFA-1] or $\alpha_1\beta_2$) is the main integrin on leukocytes, $\alpha_{IIb}\beta_3$ (also called *GPIb-IIIa*) allows platelets to bind fibrinogen to promote clotting. This was initially described in Turkish patients and ascribed to the fermitin (kindlin) family member 3 gene *FERMT3*, which encodes KINDLIN3, an adaptor protein expressed in hematopoietic cells that regulates integrin activation.[22,23] KINDLIN3 activates integrins through binding to distinct motifs on the short tails of the integrin β subunits. Phenotypically, leukocytes and platelets in LAD-3 have defective β_3, β_2, and β_1 integrin activation as a result of loss of "inside out" or chemokine-mediated LFA-1 activation and intrinsic LFA-1/$\alpha_1\beta_2$ adhesiveness. In addition, these cells have decreased adherence to endothelial cells and reduced expression of the Rap-1 guanine nucleotide exchange factor, CalDAG-GEFI (CDGI). Based on the location and severity of mutation, LAD-3 leukocytes may also display loss of adhesion to vascular cell adhesion molecule-1 (VCAM-1). LAD-3 platelets have decreased binding to soluble fibrinogen, respond poorly to thrombin via thrombin receptors (PARs), and therefore have poor platelet granule secretion through integrin activation. Bone marrow transplantation is necessary and can be curative.

CHRONIC GRANULOMATOUS DISEASE

CGD, first described in 1954, is characterized by recurrent infections and hypergammaglobulinemia. It results from defective phagocyte superoxide production leading to impaired microbial killing. CGD comprises six genotypes with a relatively consistent phenotype (Table 39.3) of recurrent severe bacterial and fungal infections and tissue granuloma formation.[24] CGD occurs at around 0.5 to 1/100,000 births. It is inherited in X-linked and autosomal recessive patterns, with the relative frequencies of recessive disease depending on the rates of local consanguinity. In the United States, the X-linked form accounts for about

TABLE 39.3 Genotype–Phenotype Correlations in X-Linked Chronic Granulomatous Disease

	X91⁰	X91⁻	X91⁺
gp91^{phox} protein levels	Undetectable	Normal to low	Normal
Residual superoxide production	Undetectable	Undetectable	Low

Type of mutations in *CYBB*	Deletions, insertions, splice site mutations, missense mutations, nonsense mutations	Missense mutation, especially involving amino acids 310–587	Missense mutations, especially involving amino acids 1–309

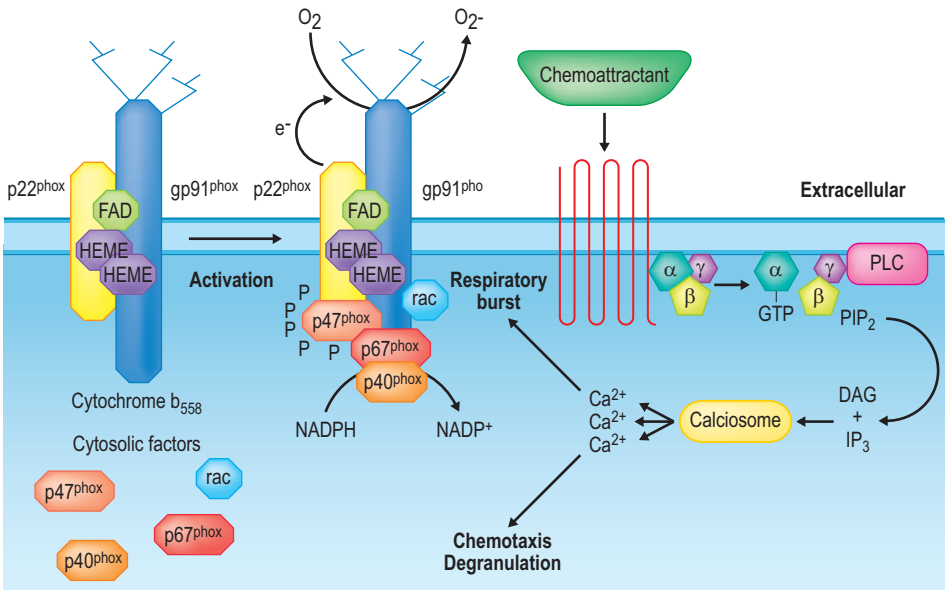

FIG. 39.4 Schematic Representation of the Nicotinamide Adenine Dinucleotide Phosphate (*NADPH*) Oxidase System. Chemoattractants interact with their receptors on the neutrophil surface, leading to an increase in intracellular calcium concentration. This activation results in the assembly of the NADPH oxidase complex following phosphorylation of cytosolic factors. This, in turn, leads to superoxide production. *DAG*, diacylglycerol; *FAD*, flavin adenine dinucleotide; *PIP_2*, phosphatidylinositol bisphosphate; *IP_3*, inositol triphosphate; *α, β, γ*, subunits of the guanosine triphosphate (*GTP*)–coupled receptors.

65% of cases and the autosomal recessive p47^{phox} (*ph*agocyte *ox*idase) deficiency for about 25%.

Patients with CGD often present with pneumonia, liver abscess, skin infections, lymphadenitis, or osteomyelitis; bacteremia is relatively uncommon. Initial presentation with immune dysregulation, particularly IBD, is not unusual. Exuberant tissue granuloma formation at the sites of infection, at surgical wounds, and in hollow viscera is a frequent problem seen primarily in patients with X-linked CGD.

The NADPH Oxidase and Its Activity

The nicotinamide adenine dinucleotide phosphate (NADPH) oxidase is a multicomponent system that transfers an electron to molecular oxygen by way of flavin adenine dinucleotide (FAD) and heme to form superoxide (O_2^-) (Fig. 39.4). Cytochrome b_{558} is a membrane-bound heterodimer lodged in the wall of the secondary granules; the large glycosylated β subunit is gp91^{phox} and the small nonglycosylated α subunit is p22^{phox}. The cytoplasmic tail of gp91^{phox} binds FAD, heme, and NADPH, which are required for electron transfer to oxygen (O_2). Neutrophil stimulation leads to aggregation and phosphorylation of p47^{phox}, p67^{phox}, p40^{phox}, and the small guanosine triphosphate (GTP)–binding proteins RAC1/RAC2, which dock with the cytochrome at the membrane through binding of p47^{phox} and p22^{phox}.

Much of the killing effect of neutrophils is, in fact, carried out by proteases enhanced by NADPH oxidase activity.[25] Charge created by electron flux across the membrane is compensated mostly by K^+ flux, which enhances microbial killing. Papayannopoulos and Zychlinksy identified neutrophil extracellular traps (NETs; extruded DNA with attached antimicrobial peptides), which depend on superoxide generation and are deficient in CGD.[26]

Mutations Leading to CGD

X-Linked CGD

The most common form of CGD is caused by mutations in *CYBB*, which encodes gp91^{phox} (located at Xp21.1) (see Table 39.3). Mutation types include deletions (22.2%), insertions (7%), deletion/insertion (1.5%), nonsense (29.8%), missense (19.4%), splice sites (19.5%), and promoters (0.6%).[27] The sporadic mutation rate is approximately 11%. Large interstitial deletions may include adjacent telomeric genes as well, leading to complex phenotypes, such as CGD along with McLeod syndrome (*KX*, or Kell antigen deletion), Duchenne muscular dystrophy (*DMD*), and X-linked retinitis pigmentosa (*RPGR*).[27] McLeod syndrome includes absent erythrocyte Kx protein and diminished levels of Kell blood group antigens. In patients with

McLeod syndrome, anti-Kx antibodies are formed when transfusions are given, making future transfusions extremely difficult. Patients with these large deletions may eventually develop progressive neurodegenerative symptoms, such as areflexia, dystonia, and choreiform movements. Deletions centromeric to *CYBB* may cause ornithine decarboxylase deficiency along with CGD.[28]

Autosomal Recessive CGD

Mutations in p47^{phox} (*NCF1*, located at 7q11.23) cause the majority of the recessive cases of CGD, around 25%, usually caused by homozygous deletions of the canonical GT splice site at the start of exon 2.[29] p22^{phox} (*CYBA*, located at 16q24) and p67^{phox} (*NCF2*, located at 1q25) are responsible for less than 5% of CGD cases each. p40^{phox} (*NCF4*, located at 22q13.1) deficiency has been reported in a boy with early-onset severe granulomatous fistulizing colitis without a significant infectious phenotype.[30] Essential for reactive oxygen species (EROS) is encoded by *CYBC1* and is required for transport of the gp91^{phox}/p22^{phox} complex to the cell surface; recessive defects in CYCB1 also result in CGD[30a]. No autosomal dominant cases of CGD have been identified.

Clinical Manifestations of CGD

The first severe infection usually occurs in infancy or childhood but can also occur in adulthood. Later diagnoses usually are seen in patients with residual superoxide production, either hypomorphic gp91^{phox} or p47^{phox} deficiency.[27,31] The constellation of signs and symptoms that suggest CGD range from failure to thrive, to IBD, visceral abscesses, recurrent sinopulmonary infections, and characteristic infections—most commonly pneumonia, lymphadenitis, liver abscess, skin abscess, perianal abscess, and osteomyelitis.[32] As in other neutrophil defects, the most common pathogen is *S. aureus*. Characteristic infections are caused by catalase-positive organisms such as *S. aureus, Burkholderia cepacia* complex*, Serratia marcescens, Nocardia* spp., and *Aspergillus* spp. (Fig. 39.5).

Staphylococcal liver abscesses in CGD are dense and necrotic and cause significant morbidity. Their fibrocaseous consistency makes percutaneous drainage difficult, and open surgery was formerly often performed. However, combined steroid and antibiotic therapy of CGD liver abscess has now become the preferred approach in many centers.[33] Liver involvement leading to portal hypertension is the likely cause of the splenomegaly commonly seen in CGD and is also closely tied to mortality.[34]

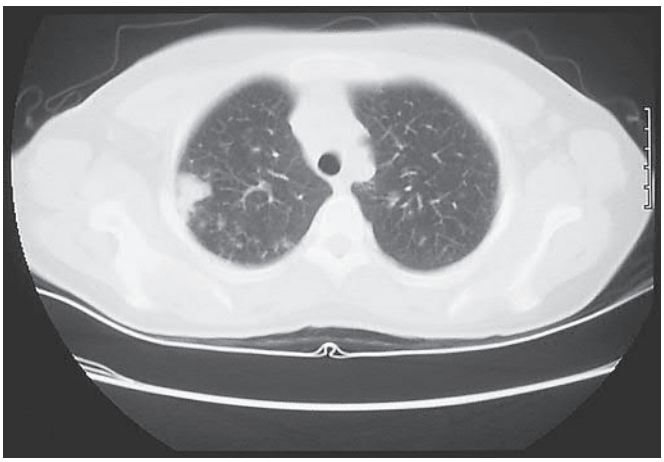

FIG. 39.5 Computed Tomography (CT) Scan of the Lungs of a Patient with Chronic Granulomatous Disease (CGD) and *Aspergillus* Pneumonia. *Aspergillus* pneumonia is often a peripheral consolidation in the lung parenchyma.

Pulmonary aspergillosis remains a major cause of death in CGD.[35] *Aspergillus fumigatus* is the most commonly isolated fungus, but it is successfully treated with azole antifungals. In contrast, severe disease in CGD is caused by *Aspergillus nidulans*, *Aspergillus viridinutans*, and other *Aspergillus* non-*fumigatus* species with low pathogenicity in the normal host.[35,36] Surgical resection of these infections is often required. *Aspergillus* infections in CGD are often unaccompanied by fever and leukocytosis.[35] Acute diffuse pulmonary fungal infection in CGD is referred to as "mulch pneumonitis," characterized by fever, hypoxia, and diffuse pulmonary infiltrates caused by inhalation of fungi, typically during mulching, leaf raking, or gardening.[37] This syndrome can be the initial presentation of CGD in older children and adults and is important to recognize, since it best responds to a combination of antifungals and steroids.

Septicemia is relatively uncommon but may occur with *B. cepacia* complex and *Chromobacterium violaceum. Granulibacter bethesdensis* is a gram-negative rod that causes chronic necrotic lymph node and spleen involvement pathognomonic for CGD.[38]

Inflammatory granulomata are a hallmark of CGD. Pyloric outlet obstruction, bladder outlet obstruction, and ureteral obstruction are common. Crohn-like IBD affects between 30% and 50% of patients, predominantly those with the X-linked form, and may involve the esophagus (Fig. 39.6), jejunum, ileum, cecum, rectum, and perirectal area.[39] GI manifestations can include diarrhea, malabsorption, abdominal pain, growth delay, and hypoalbuminemia. The median age of initial GI manifestations is 5 years, and abdominal pain is common. Interestingly, GI involvement has no effect on mortality, is not associated with liver disease, and is unaffected by the use of interferon-γ (IFN-γ).[32,39]

Granulomata respond very well to steroids and often require a slow taper over several weeks to months. Exuberant formation of granulation tissue and dysregulated cutaneous inflammatory responses lead to wound dehiscence and impaired wound healing (Fig. 39.7). Autoimmune and rheumatological problems have been reported at high rates in patients with CGD as compared to the general population.[40]

A comprehensive study of 287 patients with CGD from 244 kindred correlated the production of reactive oxygen intermediates with survival.[32] Patients with residual superoxide production had better long-term survival compared than those without residual superoxide production. Confirming the importance of this association, there was a direct correlation between the degree of superoxide and survival. Consistent with their previously recognized milder disease and better survival, patients with mutations in p47^{phox} had significant residual superoxide production. For those with gp91^{phox} mutations, the findings were more surprising. Patients with X-linked CGD with residual superoxide production were those with missense or splice mutations in the first 309 amino acids of gp91^{phox}. Those with missense mutations involving amino acids 310 to 587 had no residual superoxide production, regardless of protein levels. Therefore, identification of the specific molecular subtype of CGD and specific mutation has important implications for morbidity and survival. Interestingly, mortality curves

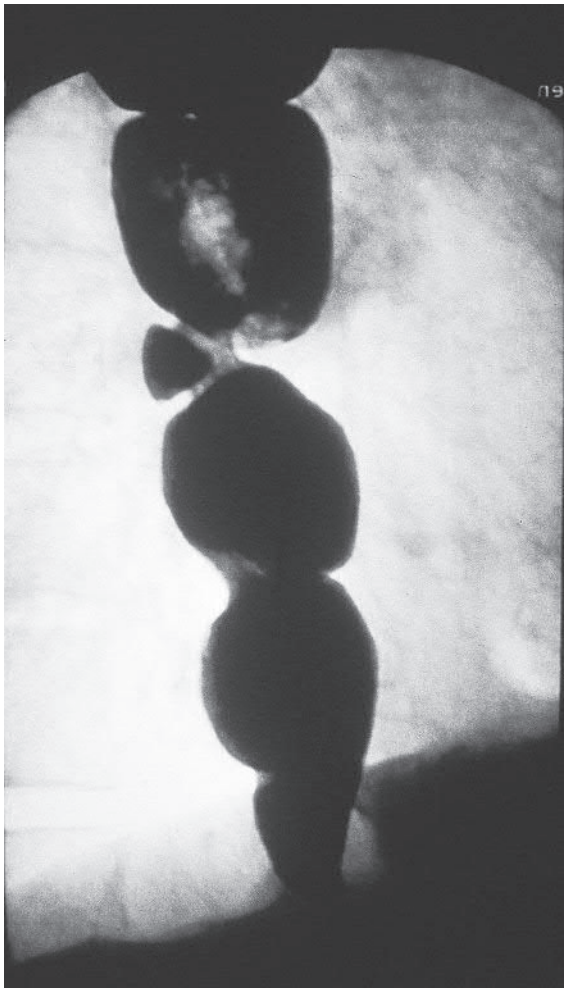

FIG. 39.6 Esophageal Involvement in Chronic Granulomatous Disease (CGD). Esophageal strictures caused by granuloma formation, as shown by barium swallow.

did not diverge until after age 20 years, suggesting that residual superoxide production determines later toxicities, such as liver dysfunction, rather than early childhood mortality from infection. It is critical to keep in mind that this comprehensive study included data from patients followed for up to 30 years—that is, a significant number of patients were born before the advent of modern antimicrobials. Therefore, survival of a child born today who receives ideal management will probably exceed that in the study population above.

CLINICAL PEARLS

Chronic Granulomatous Disease

- Chronic granulomatous disease (CGD) comprises six inherited disorders with a relatively consistent phenotype.
- Major problems in CGD are infections with catalase-positive bacteria and fungi and formation of granulomata in the gastrointestinal and urinary tract.
- Oral prophylactic antibiotics and subcutaneous interferon (IFN)-γ injections three times a week are currently recommended for CGD.
- Diagnosis can be made via nitroblue tetrazolium (NBT) test or dihydrorhodamine (DHR) assay, the latter being a more sensitive diagnostic tool.
- Bone marrow transplantation is highly effective and can be curative.

Diagnosis of CGD

The diagnosis of CGD is most easily established by the dihydrorhodamine (DHR) assay, which measures the hydrogen peroxide–dependent conversion of DHR 123 to rhodamine 123, which is accompanied by fluorescence. This test is relatively reproducible, and a quantitative DHR index, obtained using flow cytometry that with residual superoxide production capacity. Other assays include nitroblue tetrazolium (NBT) reduction and dichlorofluorescein (DCF), but these older methods are more complicated and subjective (Fig. 39.8). One important false positive to keep in mind in DHR testing is myeloperoxidase (MPO) deficiency, which gives a DHR result consistent with CGD; however, superoxide production measured by NBT or the more specific ferricytochrome c reduction is normal to increased.

Treatment of CGD

Prophylactic trimethoprim–sulfamethoxazole (TMP-SMX) significantly reduces the frequency of bacterial infections in CGD, especially those caused by *S. aureus*. TMP-SMX prophylaxis is ineffective against fungal infections but does not encourage them. Prophylactic itraconazole prevents fungal infections. IFN-γ is beneficial as a prophylactic treatment in

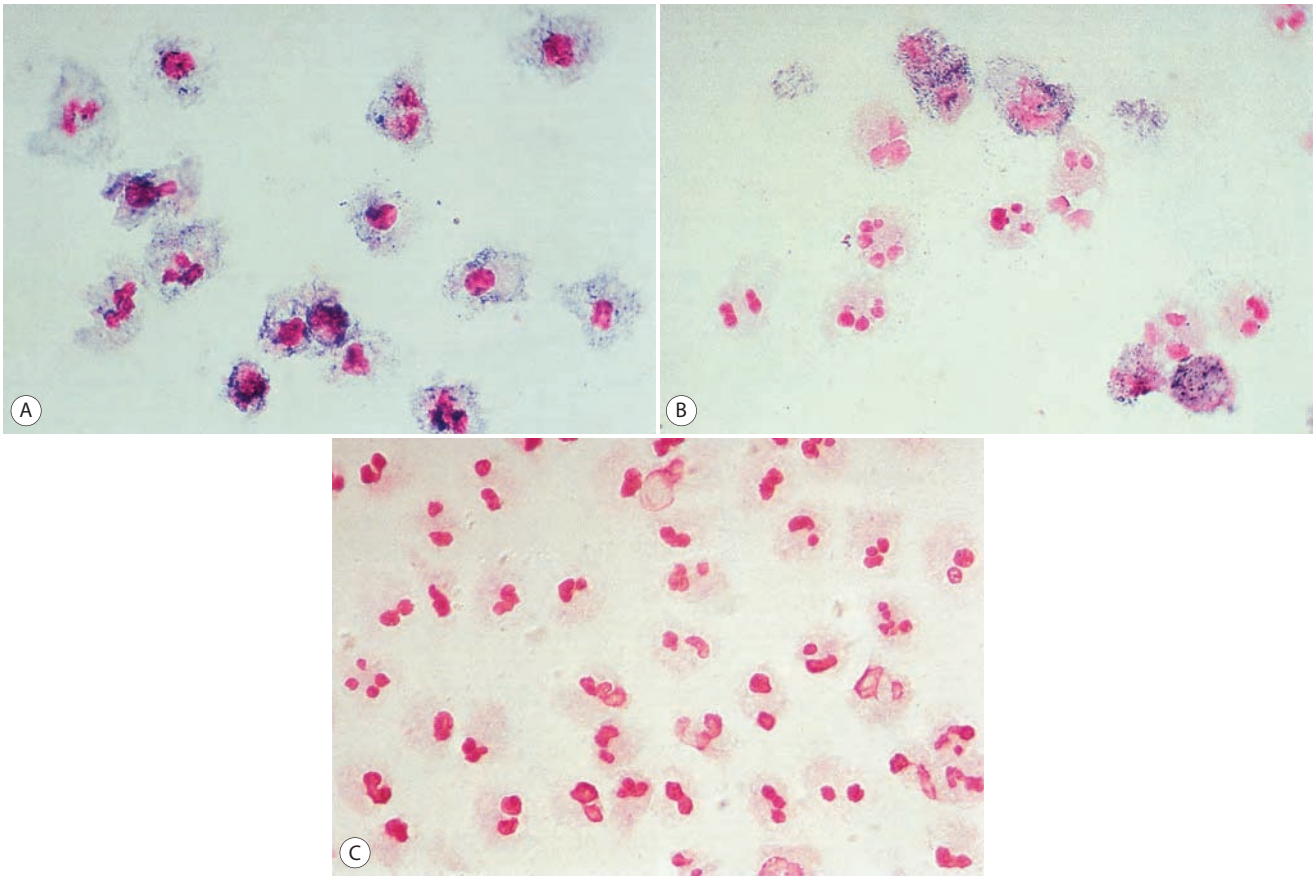

FIG. 39.8 Laboratory Diagnosis of Chronic Granulomatous Disease (CGD) with the Nitroblue Tetrazolium (NBT) Test. (A) Nitroblue tetrazolium reduction (NBTR) by purified normal neutrophils following stimulation with phorbol esters and calcium ionophore. NBT is reduced by all neutrophils, showing a *blue/purple deposit*. (B) NBTR by purified neutrophils from an X-linked CGD carrier; two different populations of cells are seen. Normal (unaffected cells) reduce the NBT dye and stain *blue/purple*, whereas affected cells fail to reduce the NBT dye and appear *clear*. (C) Neutrophils from a patient with CGD fail to reduce the NBT dye and appear *clear*. (Courtesy of Dr. Douglas B. Kuhns, Leidos, Frederick, MD.)

CGD. In a multicenter, placebo-controlled trial of IFN-γ, the number and severity of infections were significantly reduced by IFN-γ. The exact mechanism of action of IFN-γ is not known, but it has multiple effects, including stimulation of components of NADPH oxidase in partial deficiencies, increased bactericidal activity through neutrophil granule components, and Fc receptor expression. Subcutaneous administration of recombinant IFN-γ three times a week at a dose of 50 μg/m^2 (for those with body surface area >0.5 m^2) is recommended. Adverse effects of recombinant IFN-γ in patients with CGD include fever, chills, headache, flu-like symptoms, and diarrhea. During severe infections, leukocyte transfusions are sometimes used in addition to antibiotics, but this approach may lead to alloimmunization, compromising future bone marrow transplantation opportunities.

Because CGD is predominantly a hematopoietic disorder, bone marrow transplantation can cure CGD and has been successfully performed even in the setting of active infection.[41] The type of transplant that is used in patients with CGD varies among centers, but transplants using either fully myeloablative or partially myeloablative (reduced-intensity) conditioning have been effective. Although active infection is a relative contraindication for bone marrow transplantation overall, there are certain infections in CGD, especially those caused by atypical *Aspergillus* spp. infections, that are not curable with standard antifungal therapy. Bone marrow transplantation prevents not only recurrent life-threatening infections but also GI disease and growth retardation and is currently successful in about 90% of cases. Gene therapy for CGD appears to be effective but is still limited by the need for a preparative regimen to make space in the bone marrow for gene-corrected stem cells. Durability of the transduced cells remains to be demonstrated, and this treatment is not yet widely available.

MYELOPEROXIDASE DEFICIENCY

MPO is a heme-containing enzyme necessary for the conversion of hydrogen peroxide (H_2O_2) to hypochlorous acid (HOCl). MPO is expressed early in myeloid differentiation and resides in the azurophilic granules of neutrophils and the lysosomes of monocytes.[42] Mature MPO is a symmetrical molecule of four peptides, with each half consisting of a heavy–light chain heterodimer. Neutrophils of individuals with MPO deficiency fail to produce HOCl upon stimulation, whereas the NADPH oxidase system remains unaffected. Prolonged supranormal levels of superoxide and H_2O_2 production follow stimulation in MPO-deficient neutrophils. This may result from lack of negative feedback regulation of HOCl on the NADPH oxidase, although

the exact mechanism is unknown. MPO deficiency can be primary (congenital) or secondary (acquired).

Primary MPO Deficiency

Primary MPO deficiency is the most common phagocyte defect with a frequency of 1/4000 births. Both total and partial MPO deficiencies have been described. Patients with primary MPO deficiency do not usually have increased infections, probably because MPO-independent mechanisms compensate for the lack of MPO-dependent microbicidal activity. Visceral candidiasis occurring with concurrent diabetes has been reported in some patients. However, the frequency of such cases is very low. Affected individuals may develop nonfungal infections, malignancies, and certain skin disorders. In several cohorts of patients with complete MPO deficiency, an increased incidence of solid or hematological tumors has been observed.[42] MPO-deficient neutrophils have no apparent defect in the phagocytosis of bacteria or fungi, but microbicidal activity is slower than normal. MPO-deficient neutrophils are severely impaired in killing *Candida* spp. or *Aspergillus* spp. in vitro despite the fact that most patients with MPO deficiency do not develop significant fungal infections. This suggests that the mucosal barrier to fungal infection is independent of MPO activity and is able to prevent invasive infection.

The most common mutation is a missense replacement of arginine 569 with tryptophan (R569W), causing maturational arrest of the MPO precursor and preventing heme incorporation. Most patients are compound heterozygotes. The diagnosis of MPO deficiency is made by using anti-MPO monoclonal antibodies (mAbs) in flow cytometric analysis of neutrophils. No MPO expression is seen in congenital deficiency, whereas near-normal antigenic reactivity may be seen with the acquired form. Maintenance antibiotic or antifungal therapy is not routinely recommended. Prompt and prolonged therapy is advised in patients with diabetes mellitus and congenital MPO deficiency, as they may develop localized or systemic infections.

Secondary or Acquired MPO Deficiency

In the majority of patients, MPO deficiency is partial and transient. Secondary MPO deficiency can be seen in some hematological malignancies or disseminated cancers, exposure to cytotoxic agents or antiinflammatory medications, iron deficiency, lead intoxication, thrombotic diseases, renal transplantation, and pregnancy. MPO activity in bone marrow myeloid precursors as well as peripheral blood cells may vary from cell to cell. Successful treatment of the underlying condition typically corrects the defect. Secondary MPO deficiency is most likely linked to somatic mutations in the case of malignancy or toxic–metabolic effects on MPO activity.

Specific Granule Deficiency

Neutrophil-specific granule deficiency (SGD) is a rare disorder of leukocyte maturation in which neutrophil secondary granules and some primary granule proteins are absent as a result of mutations in CCAAT/enhancer binding protein epsilon C/EBPε (encoded by *CEBPE* located at 14q11.2), a member of the leucine zipper family of transcription factors. SGD is characterized by frequent, severe pyogenic infections, a paucity or absence of neutrophil-specific granule proteins and defensins, and atypical neutrophil nuclear structure with mostly bilobed nuclei. In vitro, these patients' cells show diminished neutrophil migration, reduced staphylococcal killing, reduced phagocytosis, and increased cell surface-to-volume ratio. Eosinophils and platelets are also affected. Platelets lack high-molecular-weight (HMW) von Willebrand factor multimers and have reduced platelet fibrinogen and fibronectin due to diminished platelet α granules. Bleeding diatheses and neutrophil phagocytosis of platelets are seen in SGD. In addition, SGD eosinophils are deficient in the eosinophil-specific granule proteins eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN), and major basic protein (MBP) despite the presence of messenger RNA (mRNA) transcripts for these proteins. An autosomal dominant form of SGD is caused by heterozygous mutations in *CEPPE*. Few patients have been reported to have survived beyond adolescence except for those with milder disease. SMARCE2 controls the expression of *CEBPE* mRNA, and mutations in the *SMARCD2* gene also cause SGD.[43] Few patients have been reported to have survived beyond adolescence except for those with a milder dominant form. Bone marrow transplantation should be considered early in the course of the disease.

KEY CONCEPTS

Specific Granule Deficiency

Specific granule deficiency (SGD) is caused by promyelocyte–myelocyte transition block as a result of a mutation in the *C/EBPε* gene.

- Pathological findings in SGD granulocytes include absence of secondary granule proteins and selective loss of the primary granule defensins.
- The prognosis is very poor in recessive forms of SGD.

CHEDIAK-HIGASHI SYNDROME

Chediak-Higashi syndrome (CHS) is a rare autosomal recessive disorder characterized by partial oculocutaneous albinism, increased susceptibility to infections, deficient NK-cell activity, and abnormal giant primary granules in neutrophils.[43] This immunodeficiency was first reported by Beguez-Cesar in 1943 and then further elaborated by Chediak and Higashi a decade later. The hallmark of CHS is giant abnormal granules in all granule-containing cells, including melanocytes (melanosomes are members of the lysosomal lineage of organelles), neutrophils, central and peripheral neural tissues, fibroblasts, and hair. The underlying defect is the inability to form appropriate lysosomes and cytoplasmic granules. CHS granulocytes lack cathepsin G and elastase, but the defensin content is normal. The giant granules of CHS are derived predominantly from azurophilic granules. CHS is classically a biphasic immunodeficiency in which the first phase is susceptibility to infection and the second is an accelerated lymphoproliferative syndrome with histiocytic infiltration of various tissues. Rarely, the accelerated phase may be the initial presentation. The giant organelles are derived from the late compartments of the endocytic pathway, affecting specifically late endosomes and lysosomes with minimal or no effect on early endosomes. *CHS1* encodes a 3801 amino acid lysosomal transporter (LYST), which has a vital role in lysosomal trafficking. Lysosomal exocytosis triggered by membrane wounding is impaired in Chediak-Higashi fibroblasts. The reduced survival of fibroblasts after wounding indicates that impaired lysosomal exocytosis inhibits membrane resealing. Inability of cells to repair plasma membrane lesions may contribute to the pathology of CHS. The degree of albinism can

vary from a slightly diluted skin pigment to hypopigmented skin and hair, photophobia, nystagmus, strabismus, macular hypoplasia, and reduced visual acuity. Skin biopsy shows large irregular melanin granules in melanocytes. Microscopic analysis of hair also shows poor distribution of melanin. Pancytopenia, neutropenia, and lack of NK-cell cytotoxicity result in frequent pyogenic infections, usually caused by staphylococci or streptococci. Hepatosplenomegaly and lymphadenopathy are common. A mild bleeding diathesis results from platelet storage pool deficiency. Neurological findings, including intellectual disability, seizures, cranial nerve palsies, and progressive peripheral neuropathy, have been noted in CHS.

The lymphoma-like lymphohistiocytic accelerated phase is characterized by increased hepatosplenomegaly, lymphadenopathy, and worsened pancytopenia, which may resemble the virus-associated hemophagocytic syndromes or familial hemophagocytic lymphohistiocytosis. Although chemotherapy can induce transient remissions, relapses are common. Bone marrow transplantation prevents the accelerated phase and restores NK-cell function, but it does not resolve the central or peripheral nervous system abnormalities. Demonstration of giant azurophilic cytoplasmic inclusions on peripheral blood smear is very suggestive of the diagnosis of CHS; mutation analysis confirms the diagnosis.

HYPER-IgE RECURRENT INFECTION, OR JOB SYNDROME

This syndrome was first published as hypoinflammatory recurrent infections with severe eczema and called "Job syndrome" by Ralph Wedgewood and colleagues in 1966. In 1972, Rebecca Buckley and coworkers recognized the IgE elevation that is characteristic of this disease. This multisystem autosomal dominant disorder is caused by heterozygous mutations in the gene encoding signal transducer and activator of transcription 3 (*STAT3*, located at 17q21).[44] Mutations in *STAT3* are mostly missense and are clustered in either the DNA-binding domain or Src homology 2 (SH2) domains of STAT3 Hyper-IgE recurrent infection syndrome (HIES, or Job syndrome) is characterized by recurrent infections of the lower respiratory tract and skin, chronic eczema, arterial anomalies, including coronary arterial tortuosity and aneurysms, extremely elevated IgE levels, and eosinophilia (Table 39.4). HIES occurs in all racial and ethnic groups.

TABLE 39.4 Clinical and Laboratory Findings in Patients With the Hyper-IgE Syndrome

Findings	Incidence (%)
Eczema	100
High IgE levels (>2000 IU/mL)	97
Eosinophilia (>2 SD above the mean for normals)	93
Boils	87
Pneumonia	87
Mucocutaneous candidiasis	83
Characteristic facies (in those ≥16 years)	83
Lung cysts	77
Scoliosis (for those ≥16 years)	76
Hyperextensible joints	68
Delayed shedding of primary teeth	72
Bone fractures	57

Facial, Skeletal, and Dental Abnormalities

Facial differences seen in the majority of the patients are a protruding, prominent mandible and forehead, apparent ocular hypertelorism, a broad nasal bridge, and a wide, fleshy nasal tip with increased interalar distance (Fig. 39.9). A high-arched palate is also common, as are skeletal abnormalities. Grimbacher et al. noted pathological bone fractures in 57% and scoliosis in 76% (Fig. 39.10). Low bone density and cortical bone loss are also seen, but not clearly correlated with the rate of bone fracture. Other infrequent skeletal abnormalities in HIES are craniosynostosis, spina bifida, bifid rib, wedge-shaped lumbar vertebra, hemivertebra, and pseudoarthritis of the hip. Joints are hyperextensible. A unique dental abnormality in HIES is retention of primary teeth, causing delayed eruption of permanent teeth.

KEY CONCEPTS

Hyper-IgE Recurrent Infection Syndrome or Job Syndrome

- Recurrent pneumonias and skin infections, chronic eczema, extremely elevated immunoglobulin E (IgE) levels, and eosinophilia are the hallmarks of the syndrome.
- Facial, skeletal, and dental abnormalities are very common.
- Lung abscesses and pneumatoceles following pneumonias caused by *Staphylococcus aureus* and *Haemophilus influenzae* cause major morbidity.

Infections and Immunological Characteristics

Moderate to severe eczema presenting within the first hours to weeks of life is almost universal in HIES. Mucocutaneous candidiasis involving fingernails and toenails, mouth, vagina, and intertriginous areas is seen in most patients. Primary pulmonary infections are caused by *S. aureus, Haemophilus influenzae*, and *Streptococcus pneumoniae*. These pneumonias are

FIG. 39.9 Facial Abnormalities Seen in Patients with Hyper-IgE Recurrent Infection Syndrome (HIES). Prominent mandible and forehead, apparent hypertelorism, broad nasal bridge with a wide nasal tip, and increased interalar distance are commonly seen facial features of HIES. (With permission from Grimbacher B, Holland SM, Gallin JI, et al. Hyper-IgE syndrome with recurrent infections—an autosomal dominant multisystem disorder. *N Engl J Med.* 1999;340:692.)

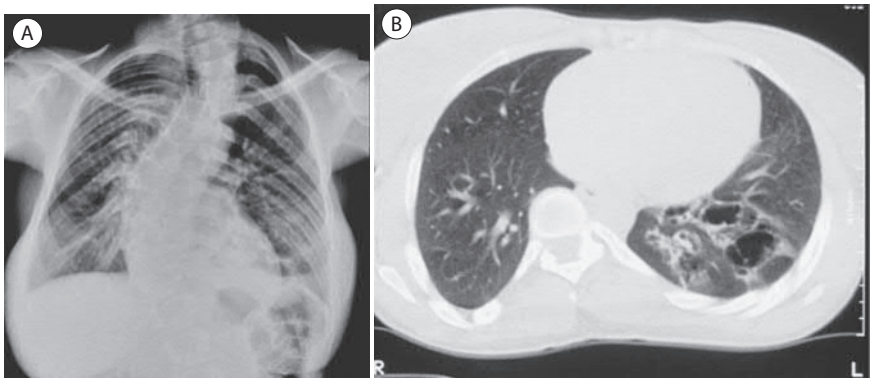

FIG. 39.10 Thoracic Pathology in Hyper-IgE Recurrent Infection Syndrome (HIES). (A) Chest X-ray of a patient with scoliosis. (B) Computed tomography (CT) scan of the lungs in the same patient demonstrates multiple pneumatoceles caused by prior infections.

often associated with abscess formation and usually lead to the development of pneumatoceles (see Fig. 39.10). Once lung cavities are formed, they provide an attractive environment for superinfection with *Pseudomonas* or *Aspergillus* spp. The clinical morphotype suggests abnormal tissue remodeling. *Pneumocystis jiroveci* pneumonia, cryptococcosis, histoplasmosis, and coccidioidomycosis have been reported. IgE levels are usually above 2000 IU/mL, but substantial fluctuations in IgE levels have been recorded over time, and the IgE levels do not correlate with disease activity or eosinophilia. Total serum IgG levels are usually within the normal range. Eosinophilia is common; the white blood cell (WBC) count is usually normal to low.

Mutations in *STAT3* lead to disruption of cytokine signaling, including IL-6, -10, -11, and -17 and -23. STAT3 deficiency leads to elevated tumor necrosis factor (TNF) and IFN-γ, but reduced IL-17 producing T cells (Th17 cells). This latter defect may explain the predisposition to mucocutaneous candidiasis.[45] Numbers of memory B and T cells are low. Shingles vesicles are increased despite normal recovery from primary varicella-zoster virus (VZV) infections. Frequency of lymphomas, but not epithelial malignancies, are increased.

In contrast to the dominant negative STAT3 mutations causing HIES gain-of-function mutations in STAT3 associated with high IL-6 response have recently been identified in children with failure to thrive, arthritis, livedo, and lung disease.

DOCK8 Deficiency (Autosomal Recessive Hyper-IgE Syndrome)

Several distinct diseases have elevated IgE, eczema, and eosinophilia. Deficiency of dedicator cytokinesis 8 (encoded by the gene *DOCK8*, located at 9p24) includes food allergies, asthma, herpesvirus infections, human papilloma virus (HPV), and molluscum contagiosum infections, which are not part of dominant negative STAT3 deficiency. In addition to the infection susceptibility, patients with DOCK8 deficiency are predisposed to cutaneous and lymphoid malignancies.[46] Although Th17 cells are markedly diminished in patients with STAT3 deficiency, they are less severely reduced in those with DOCK8 deficiency (patients with HIES-like disease[45]). Transplantation in highly effective in DOCK8 deficiency and should be considered early in life.

GATA2 Deficiency (Monomac Syndrome)

The *GATA2* gene (located at 3q21.3) encodes an early hematopoietic transcription factor most active in myeloid development.[47] There are five disease names associated with defects in *GSTS2: mpnp<AC (*monocytopenia and mycobacterial disease). DCML (dendritic cell, monocyte, B and NK deficiency), familial AML/MDS, Emberger syndrome, and NK-cell deficiency. In general, affected individuals develop late-childhood or adult-onset disseminated nontuberculous mycobacterial disease or disseminated fungal disease. Patients have absolute circulating monocytopenia, NK-cell cytopenia, and B-cell lymphopenia. Despite these circulating cytopenias, there are tissue macrophages and plasma cells, and Ig levels are normal to elevated. Neutrophils are variably affected, but persistent neutropenia is not uncommon. Other infections include HPV, molluscum contagiosum, histoplasmosis, and aspergillosis. Progressive pulmonary alveolar proteinosis is common, as are cytogenetic abnormalities of bone marrow, such as trisomy 8 and monosomy 7. Lymphedema develops in a minority and may have onset in late childhood. Pediatric myelodysplasia is another common manifestation. Diagnosis is suspected on the basis of the infections and hematological abnormalities. Since most routine hematological laboratory studies allow quite low ranges of normal monocyte percentages, it is necessary to look at absolute no the abnormal results on hemography. Since most routine hematological laboratory studies allow quite low ranges of normal monocyte percentages, it is necessary to look at absolute monocyte numbers, which are often ≤10% of normal. Other presentations of this syndrome include aplastic anemia, acute myelogenous leukemia, lymphedema, and chronic myelomonocytic leukemia. Sequencing of *GATA2* is required for diagnosis. Transplantation is highly effective if done before leukemia has developed.[47]

ASSESSMENT OF NEUTROPHIL FUNCTION

Discrete abnormalities in neutrophil function lead to recurrent bacterial or fungal infections. Assays have been developed to interrogate those functions.[48] However, since neutrophils cannot be viably stored or frozen, samples are usually examined fresh with simultaneous normal volunteer controls. The techniques discussed here are reviewed in Chapter 39.

Isolation of Neutrophils

Most assays require neutrophils to be purified from other blood components. Blood is usually anticoagulated using either citrate or heparin (10 units/mL) tubes and maintained at 20°C to 25°C in polypropylene containers. Typically, 1 to 2 × 10^6 neutrophils can be isolated per milliliter of whole blood.

Neutrophil Adherence

The adhesive function of phagocytes is commonly assessed by passage of 1 mL of whole blood through a column filled with nylon wool. Adherence is measured as the difference in the ANC of the precolumn sample and of the sample after passage through nylon wool. Alternatively, isolated neutrophils can be induced to bind to plastic using a 96-well plate either uncoated or coated with fetal bovine serum, a ligand like ICAM-1, or a specific ECM protein, such as fibrinogen or fibronectin. Endothelial cell monolayers harvested from human umbilical veins can serve as a more physiological substrate for the measurement of cell adhesion. Isolated neutrophils are preloaded with the cell permeant, acetoxymethyl ester derivative of the fluorescent dye, calcein (calcein-AM). Nonspecific esterases in the cytosol cleave the ester linkage, trapping the fluorescent probe in the cytosol. The labeled neutrophils are added to each well and incubated in the absence or presence of phorbol myristate acetate (PMA) to promote adherence through activated integrins. At the end of the incubation, the wells are washed to remove nonadherent cells. The fluorescence of each well is determined with a fluorescent microplate reader and compared with the fluorescence of a control well with a fixed number of fluorescent cells. Under control conditions, fewer than 10% of the neutrophils adhere to plastic or to plastic coated with fetal bovine serum. Slightly more neutrophil adherence is observed on wells coated with fibrinogen. Treatment of normal neutrophils with PMA for 30 minutes results in the adherence of 100% of the neutrophils under all conditions. Adherence is abnormal in patients with LAD. Neutrophils isolated from patients with typical LAD-1 generally exhibit markedly reduced adherence under both unstimulated and PMA conditions.

Neutrophil Chemotaxis

Neutrophil chemotaxis in vivo can be evaluated by using skin windows. Skin blisters are gently raised on the volar surface of the forearm using a vacuum pump and a blister device, with little hemorrhage or vascular damage. The roof of the blister is removed, and the exposed dermis is bathed with autologous serum with the use of a skin window chamber. In 24 hours, exudative neutrophils accumulate in the autologous serum bathing the skin lesion. The skin chamber provides a mechanism for characterizing the immune cells as well as the soluble immune mediators that accumulate during the evolution of the inflammatory response. Chemotaxis *in vitro* is generally measured by using a Boyden chamber. The Boyden chamber includes three components: a lower (chemoattractant) chamber, a nitrocellulose or polycarbonate filter layer, and an upper cell chamber. The lower compartments are filled with a chemoattractant, such as fMLF; 10^{-8} M) or IL-8 (10 ng/mL). Rapid fluorescence-based assays of neutrophil chemotaxis uses a 96-well chemotaxis chamber and a fluorescence microplate reader.

Expression of Surface Antigens

The expression of cell surface antigens on neutrophils relies on labeled mAbs analyzed by flow cytometry. The panel may include the β_2 integrins (CD11a, CD11b, CD11c, and CD18), selectins (CD62L), Fcγ receptors I, II, and III (CD64, CD32, and CD16), leukosialin (CD43), the common leukocyte antigen (CD45), and markers for the specific granules (CD67), and azurophilic granules (CD63). The expression of surface antigens can be used to assess the responsiveness of neutrophils to particular ligands, such as fMLF and lipopolysaccharide (LPS).

Neutrophil Degranulation

The proteases, acid hydrolases, and inflammatory mediators released from storage granules in neutrophils can mediate bacterial killing, tissue damage, healing, and immune regulation. Lactoferrin from specific granules can chelate iron, resulting in a bactericidal or bacteriostatic effect. Stimulation of neutrophils with various secretagogues can release granular enzymes into the extracellular fluid. Treatment of the neutrophils with cytochalasin b (5 μg/mL) disrupts microfilament assembly and facilitates the release of both specific and azurophilic enzymes. To differentiate degranulation from cell lysis, release of the cytosolic enzyme lactate dehydrogenase should be monitored simultaneously. The release of azurophilic granules can be assessed by determination of β-glucuronidase activity. Supernatant fluids or cell extracts obtained from stimulated neutrophils are incubated with 4-methylumbelliferyl-β-D-glucuronide. Alternatively, MPO can be determined by using commercially available enzyme-linked immunoassays. CD63 is also found in the membrane of azurophilic granules and migrates to the neutrophil surface after stimulation with fMLF in the presence of cytochalasin b. The release of specific granules can be assessed by determination of lactoferrin levels using an enzyme-linked immunoassay. The carcinoembryonic antigen CD66b (formerly CD67) is found on the neutrophil surface and in the specific granules, and its expression on the surface of the neutrophils is increased after stimulation with fMLF or LPS. Detection of the constituents of secretory granules can be assessed by flow cytometric analysis of the change in expression of surface proteins, such as adhesion molecules, and cytochrome b_{558} of the NADPH oxidase. Neutrophil NET formation can also be measured in vivo and in vitro.

Generation of Reactive Oxygen Species

The production of O_2^- can be detected by using the reduction of cytochrome c. Because O_2^- causes a one-to-one stoichiometric reduction of ferricytochrome c to ferrocytochrome c, the resultant increase in the absorption spectrum at 550 nM can be used to quantitate the production of O_2^-. Superoxide dismutase is added to an identical tube to control for the nonspecific reduction of cytochrome c. However, since cytochrome is not permeable to the cells, the detection of O_2^- is limited to that released into the extracellular milieu. Neutrophils isolated from patients with CGD produce little O_2^- in response to PMA in 10 minutes. However, some patients with forms of CGD associated with residual superoxide production have low but detectable O_2^- production in 60 minutes. Neutrophils from X-linked heterozygous carriers of X-linked CGD can yield a full spectrum of O_2^- production, whereas neutrophils from autosomal recessive carriers of CGD generally yield a normal response. Although the detection of O_2^- by reduction of cytochrome c is useful in the diagnosis of patients with CGD, it cannot be used in the diagnosis of carriers because of the wide spectrum of responses that result from the random process of degree of X-chromosome inactivation or lyonization.

The extracellular release of H_2O_2 can be measured by using horseradish peroxidase–induced oxidation of either phenol red or Amplex red. Neutrophil suspensions in the presence of horseradish peroxidase and a chromophore are exposed to either PMA or buffer alone. Changes in optical density of phenol red at 600 nm can be determined with a standard microplate reader. With Amplex red—a much more sensitive fluorescent chromophore—H_2O_2-dependent changes in fluorescence can be determined with a fluorescence microplate reader.

The NBT test is a qualitative assay of O_2^- production and yields a visual record of the reduction of the NBT dye to insoluble, blue-black deposits of formazan. Whole blood or isolated neutrophils are mixed with NBT in a chamber slide and stimulated with PMA for 15 to 30 minutes at 37°C. The slide is counterstained with 0.1% safranin and examined under a microscope. Normal neutrophils, but not neutrophils from patients with CGD, reduce the yellow dye to black-brown-blue aggregates in the cells (see Fig. 39.8, A–C). The NBT test can be used to diagnose X-linked carriers of CGD but cannot differentiate autosomal carriers from normal subjects.

An alternative to the NBT test is a flow cytometric assay, using dihydrorhodamine-1,2,3 (DHR). Neutrophils are loaded with the nonfluorescent dye and then stimulated with PMA for 15 minutes at 37°C. H_2O_2 produced upon PMA stimulation oxidizes the DHR and results in increased fluorescence, detectable with a flow cytometer. Catalase is added to prevent cell-to-cell diffusion of H_2O_2. Since DHR is localized to the cytoplasm, and catalase is present in the extracellular fluid, the assay detects the intracellular production of reactive oxygen metabolites. Stimulation of normal neutrophils with PMA results in a two-log increase in the fluorescence intensity. The major advantages of the DHR assay are the sensitivity, the high signal-to-noise ratio, and ease of recording data from a large number of cells.

Western Blot for Measuring NADPH Oxidase

Determination of the protein expression in CGD by Western blot analysis provides direction for the genetic defect. A validated healthy control and a typical gp91^{phox} CGD sample are included on each blot to ensure adequate visualization of p22^{phox}. Patients with p47^{phox} CGD are Western blot negative. Patients with p67^{phox} CGD are generally Western blot negative. Because p22^{phox} and gp91^{phox} exist as a membrane complex, patients with a defect are p22^{phox}, in general, Western blot negative for both p22^{phox} and gp91^{phox}. In contrast, defects in gp91^{phox} yield more variable results. Neutrophils from patients with nonsense defects in gp91^{phox} exhibit low but detectable levels of p22^{phox}. Patients with missense mutations in gp91^{phox} that yield detectable gp91^{phox} protein exhibit proportionately higher levels of p22^{phox} and EROS proteins that can also be detected by Western blotting.

TRANSLATIONAL RESEARCH

The progress made over the past 60 years in understanding and managing phagocyte defects has been remarkable, spanning initial identification, phenotyping, and molecular characterization. The last 20 years have seen the advent of oral antifungals, potent oral antibiotics, oral antivirals, reduced intensity conditioning for bone marrow transplantation, and gene therapy. These advances have transformed the quality of life and longevity of all patients with immune deficiencies. We now need further in-depth study of the mechanisms that drive disease pathophysiology to gain novel insights. The advent of therapeutic cytokines, small molecule inhibitors and agonists, RNA inhibitors, and effective means of gene transfer should make directed approaches to disease modification a reality. However, we must be sure we know exactly what functions need addressing. The downstream effects of genetic defects are surprisingly complex and not always as straightforward as has been anticipated. More detailed clinical and functional phenotyping, careful examination of developmental and gene expression effects, and continued longitudinal studies of large cohorts will convert these severe diseases punctuated by acute, life-threatening infections into chronic conditions that are successfully treated medically or successfully managed until successful bone marrow transplantation becomes available.

ON THE HORIZON

- Early recognition and molecular diagnosis of all phagocyte defects, leading to prophylactic antimicrobial treatment, where indicated
- Improvement in bone marrow transplantation technology to allow for early, safe, successful, fertility-preserving transplantation in all cases
- Understanding the mechanisms of the hepatic complications of chronic granulomatous disease (CGD) that correlate with mortality

Complement and Complement Disorders

John P. Atkinson, M. Kathryn Liszewski, Anuja Java, and Hrishikesh S. Kulkarni

OVERVIEW: AN EVOLUTIONARY AND HISTORICAL PERSPECTIVE

The complement system arose early in evolution, possibly even in single-cell organisms. In vertebrates, it features a proteolytic cascade to coat microorganisms with cleavage fragments that are recognized by receptors on phagocytic cells.[1,2] This phenomenon, known as *opsonization*, leads to immune adherence followed by internalization. A related strategy employed by primates is to express a complement receptor on erythrocytes. In blood, the opsonized pathogen becomes adherent to a cluster of abundant erythrocytes, which, like a taxi, delivers them to the liver and/or the spleen for transfer to monocytes and macrophages to be neutralized. In this manner, bacteria are both immobilized and prevented from traveling free in the circulation to such sites as the brain.

To mediate opsonization, the complement system needed to develop a system to transfer a plasma component onto the pathogen. Lectins and, subsequently in evolution, antibodies (Abs) faced this same challenge. Of note, both of the latter eventually utilized the complement system (lectin pathway and classical pathway [CP]) to "complement" their attachment strategies. In contrast to lectins and antibodies, the alternative pathway (AP) earlier solved this problem through development of a thioester bond in C3. C3's homologous cousin, α_2-macroglobulin, also utilizes cleavage of a thioester bond to covalently attach to and thereby inactivate proteases. The parallels are apparent—upon its generation following C3 activation, C3b can transiently (within microseconds) attach to nearby hydroxyl or amino groups to form an ester or amide linkage, respectively. This mechanism creates essentially an almost unbreakable bond and places the complement fragment irreversibly on the pathogen's surface. The components of the complement system are listed by category in Table 40.1.

The major function of the complement system is to modulate the membrane of a microbial target, leading to immune adherence and internalization of the opsonized antigen. The target is selected by lectins in the lectin pathway and predominantly by antibodies in the CP. However, the ancient AP does not feature selective or specific recognition. Instead, 1% to 2% of C3 "ticks over" each hour, serving as a surveillance system. The activated C3 has a few microseconds to bind to a target, such as a bacterium, or it will be inactivated by water [now termed "C3(H_2O)"]. If it lands on a pathogen, the AP feedback loop engages and C3b is quickly generated. For example, this rapid amplification can deposit several million copies of C3b on a single *Escherichia coli* bacterium in 2 to 3 minutes. If C3b remains in the fluid phase, it is promptly inactivated by plasma regulators. If it binds to healthy self-tissues, it is inactivated by ubiquitously expressed membrane complement inhibitors. Thus, the AP initially comprised the original complement system and likely consisted of three elemental proteins (C3 and two proteases known as *factor B* and *factor D*). These three were sufficient to generate a C3 convertase (splitting) enzyme and also to form a feedback loop. The positive regulator of this remarkable enzymatic feedback/amplification loop, known as *properdin*, probably came later in evolution, as did lectins and antibodies.

Still later to develop was the membrane attack complex (MAC, often called the *terminal pathway*) that is common to all three cascades. The goal of its five sequentially interacting, nonenzymatic proteins (C5b, C6, C7, C8, and C9) is also to attach to and then alter the surface of a pathogen by membrane perturbation, often ending in lysis. In humans, a deficiency of any one of these five proteins leads to meningococcal infections. Interestingly, properdin deficiency also predisposes to recurrent meningococcemia. Thus, such infections likely drove specialization of this terminal wing of the complement system.

In contrast to the rapidly acting AP, an initial limitation with the lectin and Ab systems is that their triggers are present in limited quantities. It takes several days to ramp up synthesis of a particular lectin (acute phase type response) and at least a week to develop a specific immunoglobulin M (IgM) and even longer for an IgG immune response. For a host with an opportunistic pathogen invading the bloodstream, this time delay for an adaptive humoral immune response is far from adequate. Consequently, the complement system is often called the "guardian of the intravascular space." Once a "pumped" circulation of blood developed in evolution, a rapidly acting, abundant, and highly efficient system to prevent pathogens from entering, traveling, and reproducing in plasma was mandatory.

The second function of the complement system is to promote the inflammatory response. This is primarily accomplished by the anaphylatoxins C3a and C5a. Upon cleavage of C3 to C3b (the major complement opsonin) and C5 to C5b (the trigger of the MAC), the ~10 kilodalton (kDa) C3a and C5a fragments are released, and these can engage their respective receptors to initiate vascular and cellular changes, rapidly leading to a proinflammatory state. These receptors are expressed on many cell types, including endothelial, epithelial, and immune cells. Upon receptor engagement, defensive strategies are initiated and result in increased blood flow and stimulated phagocytes that are now more efficient at binding and ingesting C3 fragment-coated antigens.

Through these same interactions, the complement system instructs the adaptive immune response. Antigens decorated by complement proteins are taken up by monocytes, follicular-dendritic cells (FDCs), B lymphocytes, and other antigen-presenting cells (APCs), resulting in an adaptive immune response (the complement system is often called "nature's

TABLE 40.1 Proteins of the Complement System

Component	Function
Classical Pathway (CP)	
C1q	Part of C1. Binds to immunoglobulin M (IgM), IgG, pentraxins, and ligands on apoptotic cells to initiate CP activation.
C1r	Part of C1. After auto-activation, cleaves C1s.
C1s	Part of C1. After activation by C1r, cleaves C4 and C2.
C4	Cleaved by C1s to form C4a and C4b. C4b is an opsonin and part of the CP and LP C3 and C5 convertases. C4a is an untethered agonist for protease-activated receptor (PAR1) and PAR4.
C2	Binds to C4b and then cleaved by C1s to form C2a and C2b; C2b becomes part of the enzymatic component of the CP and LP C3 and C5 convertases. C2a is released.[a]
Lectin Pathway (LP)	
MBL	Recognition component for LP activation. Binds to mannose-rich glycans through C-type lectin domains.
MASP-1 and MASP-3	Associated with MBL and ficolins. Cleaves C2, but not C4. Cleaves profactor D.
MASP-2	Associated with MBL and ficolins. Cleaves C2 and C4.
Ficolins 1–3	Recognition components for LP activation. Bind to glycans through fibrinogen-like recognition domains.
Alternative Pathway (AP)	
C3	Cleaved by C3 convertases to form C3b and C3a. C3b is opsonic. A small fraction becomes part of the AP C3 convertase and part of all C5 convertases. C3b is further cleaved to opsonic iC3b and the CR2 ligands C3dg and C3d. C3a is an anaphylatoxin.
Factor B	Binds to C3b and then cleaved by factor D to form Bb, the enzymatic component of the AP C3 and C5 convertases. Ba is released.[b]
Factor D	Cleaves factor B bound to C3b to form AP convertases.
Properdin	Stabilizes AP convertases. Binds to microbial ligands to initiate AP activation.
Membrane Attack Complex (MAC)	
C5	Cleaved by C5 convertases to form C5b and C5a. C5b initiates MAC formation. C5a is an anaphylatoxin.
C6	Part of the MAC. Binds membranes.
C7	Part of the MAC. Binds membranes.
C8	Part of the MAC. Initiates pore formation.
C9	Part of the MAC. Polymerizes to form lytic pores.
Soluble Regulatory Proteins	
C1-INH	Serine protease inhibitor of C1r, C1s, MASP-1, MASP-2, kallikrein, factor XII.
C4BP	Binds C4b and prevents interaction with C2. Decay accelerating and cofactor activities for C4b-containing convertases.
FH	Binds C3b and polyanions. Prevents factor B binding. Has decay-accelerating and cofactor activities for C3b-containing convertases.
FI	Cleaves C3b and C4b bound to a cofactor protein.
Vitronectin	Binds C5b-7, prevents membrane insertion and lysis.
Clusterin	Binds C8 and C9, prevents MAC assembly and lysis.
Membrane Regulatory Proteins	
CD55 (DAF)	Accelerates decay of C3 and C5 convertases.
CD46 (MCP)	Cofactor for FI cleavage of C3b and C4b.
CD59	Binds to C8 and C9, prevents MAC assembly and lysis.
Receptors	
CD35 (CR1)	Opsonic receptor for C3b and C4b. Has decay-accelerating and cofactor activity for C4b and C3b and convertases containing these fragments.
CD21 (CR2)	Receptor for C3dg and C3d. Enhances B-cell activation.
CD11b/CD18 (CR3)	Opsonic receptor for iC3b. Leukocyte adhesion integrin.
CD11c/CD18 (CR4)	Opsonic receptor for iC3b. Leukocyte adhesion integrin.
CRIg	Opsonic receptor for iC3b and C3c. Inhibits C5 convertases.
C5aR (CD88)	Proinflammatory and chemotactic receptor for C5a.
C5L2	Receptor for C5a. Function not fully defined.
C3aR	Proinflammatory and chemotactic receptor for C3a.
C4aR	Cell activation; endothelial cell permeability.

[a]No defined function upon release.
[b]Several putative functions reported but requires further study.

adjuvant.") Thus, complement activation is required for optimal Ab responses to most foreign antigens. Individuals lacking C3 are predisposed at an early age to bacterial infections, predominantly by encapsulated bacteria.

Complement deficiencies are instructive anomalies of nature. Surprisingly, a complete deficiency in an early component of the classical complement pathway predisposes to autoimmune diseases, particularly systemic lupus erythematosus (SLE) (Chapter 52). Greater than 80% of patients with C1q or C4 deficiency present with SLE. This association indicates that the complement system is required not only for host defense against foreign agents but also to identify and safely

clear self-materials (debris or garbage removal), particularly RNA and DNA species.

Much complement-mediated pathology revolves around disturbances of the AP and thus its potent amplification loop. It must be rigorously regulated to prevent activation on normal self and excessive activation on injured self. Even haploinsufficiency of its major inhibitors predisposes to endothelial damage in atypical hemolytic–uremic syndrome (aHUS) and retinal damage in age-related macular degeneration (AMD).

Genetically based deficiencies have taught us that individuals lacking in a complement activating component present with recurrent infections and/or autoimmunity. While those lacking proper regulation of the system have an excessive response to tissue injury.

Knowledge of how complement is activated and how it can be controlled points to opportunities for the development of therapeutic agents. One such example is anti-C5 monoclonal antibody (mAb) therapy, which has been recently approved to treat several complement-dependent pathogenic disorders. Other new complement therapeutics and diagnostics are on the horizon as genetic evaluations are increasingly utilized to define diseases in which the complement system is involved, and biotechnology companies are pursuing development of novel complement inhibitors.

COMPLEMENT PATHWAYS

The three pathways of complement activation are the CP, lectin pathway (LP), and AP (Fig. 40.1).[1,2] The CP is initiated by IgM or IgG Ab binding to an antigen. The CP can also be activated by innate pattern recognition molecules, such as the pentraxins and C-reactive protein (CRP). They participate with natural antibodies in early host defense and provide a mechanism for clearance of cells via immune complexes and apoptosis. The LP uses most of the CP components but is activated by mannan-binding lectin (MBL) and the ficolins, which are lectins that recognize repeating carbohydrate patterns on microorganisms.[3] The AP is the most ancient pathway and also has the broadest recognition ability. The AP is engaged by surface components of all types of microorganisms, including bacteria, fungi, parasites, and viruses.[4] It is continuously turning over and autoactivates if its inhibitors are lacking. Activation of the AP can also be initiated by properdin (P), a molecule that binds to pathogens and apoptotic cells. This mechanism further promotes its function as an innate and rapid responder to infection. The AP is an important amplification mechanism for CP or LP activation, resulting in greater opsonization and generation of the terminal lytic pathway. For example, the initial trigger on a pathogen surface may be IgM or a lectin, but the majority of the C3b deposited is via AP's amplification or feedback loop that is engaged by just having C3b on a target.

The cleavage of C3 to C3a and C3b is central to all three pathways of complement activation. This enzymatic step exposes a highly reactive thioester bond through which C3b covalently attaches to nearby molecules (Fig. 40.2). Activation of C3 to C3b also exposes sites for interactions with other complement proteins, inhibitors, and receptors. Recent results have shed new light on the structural basis for C3 activation. In 2006, several studies reported the first x-ray structure of C3b, the activated product C3.[5,6] The results revealed a major conformational change in C3 upon cleavage to C3b that exposes the reactive thioester group as well as cryptic binding sites for complement receptors and regulatory proteins. Moreover, the crystal structures of five binding proteins in complex with C3b have now been solved.[7]

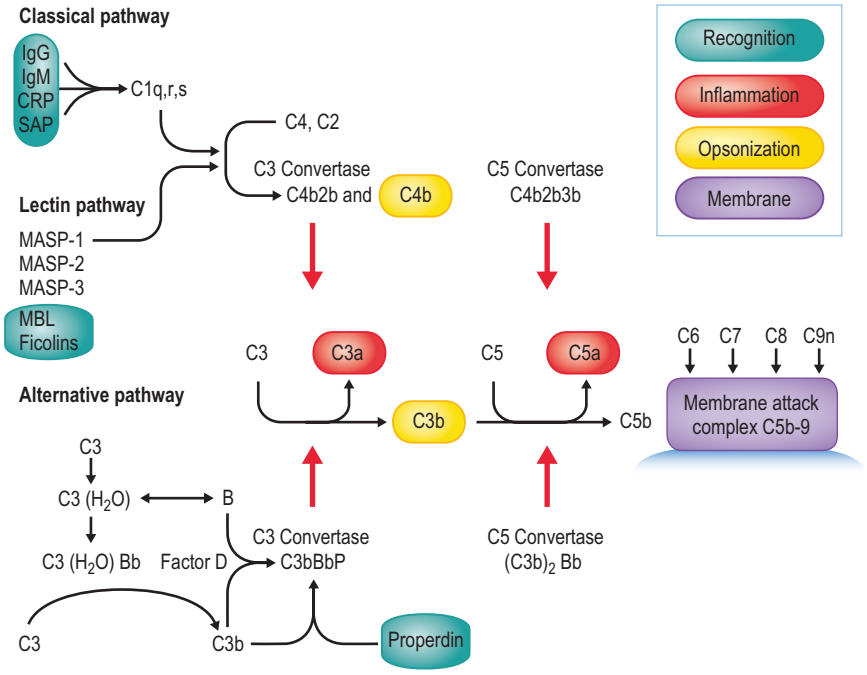

FIG. 40.1 Overview of the Complement Pathways Indicating Components Required for Recognition, the Enzymatically Active Fragments and Complexes and the Major Opsonic, Inflammatory, and Membranolytic Products. Note: not shown are the released fragments of C4 (C4a), C2 (C2b), and factor B (Ba). *MASP*, mannan-binding lectin–associated serum proteases.

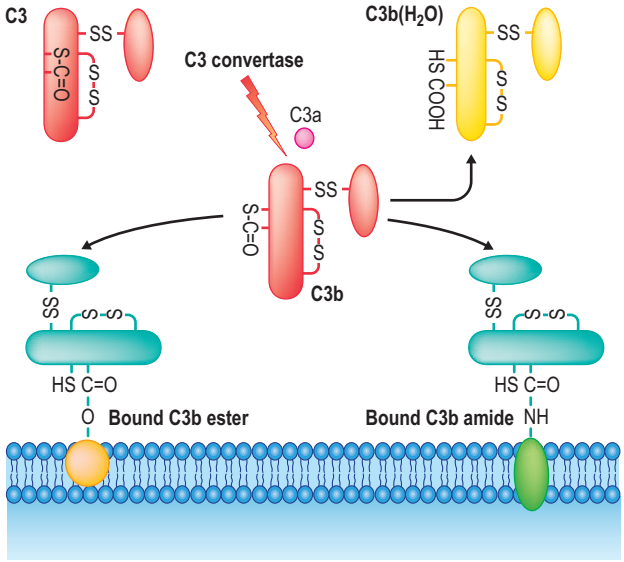

FIG. 40.2 Exposure and Reactivity of the C3 Thioester Bond. C3 cleavage by a C3 convertase generates metastable C3b with a reactive thioester. Metastable C3b may be hydrolyzed to form C3b(H_2O) or may react with hydroxyl (ester linkage) or amino (amide linkage) groups to become covalently bound to a surface. Note: C3 is composed of two disulfide-linked chains, the α-chain (110 kDa) and the β-chain (75 kDa).

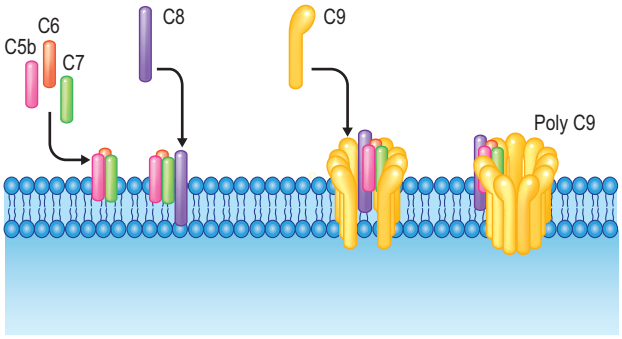

FIG. 40.3 Sequence of Protein Interactions in the Assembly of the Membrane Attack Complex (MAC). C5b, generated by a convertase cleaving C5, combines with C6 and C7 to form a hydrophobic complex capable of a membrane interaction. Binding of C8 allows the complex to insert further into the membrane and forms a site for C9 polymerization. C9 (~18 monomers) polymerizes to form a transmembrane pore to mediate cell lysis.

Classical Pathway

KEY CONCEPTS

Structural and Functional Homologies in Complement Pathways

Recognition: C1q, MBL, ficolins, CRP
Initiating enzymes: C1r, C1s, MASP-1, MASP-2, FD
C3 convertases: C4b2b, C3bBb
C5 convertases: C4b2b3b, (C3b)2Bb
Enzyme subunits of convertases: C2a, Bb
Assembly subunits: C3b, C4b (both covalently bound to target)
Anaphylatoxins: C3a, C5a
MAC subunits: C5b, C6, C7, C8, C9
Regulatory proteins: C4BP, FH, CR1, MCP, DAF, CSMD1
Receptor proteins: CR1 and CR2; CR3 and CR4, CRIg
Major opsonins: C3b and C4b

The CP is initiated primarily by Ab binding to a target antigen. In general, the ability of Ab to activate complement is ranked as follows: IgM > IgG3 > IgG1 > IgG2 > IgG4. Binding of these Abs exposes sites in the Fc region for attachment of the first subcomponent of complement, C1q.[8,9] C1 is a large calcium-dependent complex composed of C1q and two molecules each of the proenzymes, C1r and C1s. C1q is a 410-kDa protein with six globular heads connected by a collagen-like tail. IgM, IgG, and CRP bind C1q through its globular head groups. For IgM, which is pentameric, binding to antigen creates a conformational change that exposes the C1q binding site. For IgG, at least two closely bound molecules are required to provide multiple attachment points for C1q binding.

Once C1q binds to an activator, C1r is cleaved by an autocatalytic process. Activated C1r then cleaves and activates C1s, which, in turn, cleaves circulating C4. Note that there are two isotypes of C4: C4A and C4B. These differ in their preference for acceptor nucleophiles, amino groups for C4A and hydroxyl groups for C4B.

C4 and C3 are highly homologous proteins that share an unusual posttranslational modification known as an *internal thioester bond* (see Fig. 40.2).[5] Cleavage of C4 releases the C4a fragment and exposes the reactive thioester bond in the larger C4b fragment. This allows C4b to attach covalently to nearby target structures through hydroxyl or amino groups to form an ester or amide bond, respectively. The exposed thioester bond is highly but transiently reactive as it is susceptible to rapid hydrolysis. For example, within microseconds, about 5% of the generated C4b typically becomes attached to the target. Bound C4b provides an anchor site for C2 attachment, which is then also cleaved by C1s, releasing the smaller fragment C2a and leading to the formation of C4b2b.

The complex C4b2b is termed the *CP C3 convertase* because it cleaves C3 to C3b, releasing C3a. The C2b component of the complex contains the active enzymatic site. C3 cleavage is similar to C4 cleavage in that the larger fragment, C3b, contains a thioester site (see Fig. 40.2) that mediates covalent attachment to nearby surface structures. C3 is found at a three- to fourfold higher concentration in serum compared with C4, and its cleavage is amplified by the AP. Thus, efficient complement activation will result in clusters of multiple bound C3b molecules that can be recognized by cellular receptors. C3b that attaches to C4b within the C3 convertase produces the trimolecular complex C4b2b3b, which is a C5 convertase. Cleavage of C5 produces C5a, which has potent inflammatory activity, and C5b, which initiates the formation of the MAC or, as it is also known, the *terminal complement complex* (TCC) (Fig. 40.3).

Lectin Pathway

The LP is similar to the CP, except that it uses pattern recognition molecules, MBL, and ficolins-1, -2, and -3, instead of Ab to target activation.[3,10] MBL is structurally similar to C1q, with a collagen-like region and globular heads. The globular heads of MBL are C-type lectin domains specific for repeating carbohydrate structures found on microorganisms. Like C1q, MBL and ficolins are in complex with serine proteases, MBL-associated

serum proteases (MASPs), which are structurally and functionally similar to C1r and C1s. MASP-1 and -2 are active proteases, but only MASP-2 cleaves both C4 and C2 to generate C4b2a, the same C3 convertase as the CP. MASP-1 can supplement activation by cleaving C2 but not C4. Two nonproteolytic splice products of the *MASP2* and *MASP1/3* genes, sMAP and MAP-1, compete with MASP-1 and -2 for binding to MBL to regulate the LP. Subsequent steps in the LP are identical to those in the CP. Interestingly, MASP-3 bridges the LP and AP since it is the main enzyme that cleaves profactor D to mature factor D.[11,12]

Alternative Pathway

The AP uses proteins that are structurally and functionally homologous to those of the CP, but this pathway has unique features that play three important roles in the complement cascade. First, the surveillance role of the AP is mediated by a continuous low level of spontaneous activation that results from the hydrolysis of the C3 thioester bond.[4] Hydrolyzed C3, C3(H_2O), assumes a conformation similar to that of C3b and can bind factor B (homologous to C2), which is cleaved by factor D (homologous to C1s) to form a fluid-phase C3 convertase. This convertase cleaves C3 to generate C3b, which can covalently bind to nearby structures and provide the basis for a bound C3 convertase (C3bBb). Because C3b is both a part of this enzyme and a product of the reaction, a positive feedback loop that rapidly deposits more C3b is formed. This "idling-like" activation process is tightly regulated on host cells and tissues by plasma and membrane-bound complement regulatory proteins. The plasma protein factor H (FH) is particularly important in controlling AP activation, both in the fluid phase and on "nonactivating" surfaces. The latter recruits FH through its binding sites for polyanions, including sialic acid and glycosaminoglycans. "Activating" surfaces, such as microbial polysaccharides, lipopolysaccharides, and foreign glycoproteins, provide C3b attachment sites that are protected from regulatory proteins. Similar to the CP, the AP C5 convertase (C3bBb3b) is formed when a second C3b attaches to the C3 convertase. The AP C3 and C5 convertases are stabilized by P (factor P or P), for which this pathway was originally named.

Second, an additional role for properdin (P) in initiating AP activation was rediscovered.[4,13,14] P is a pattern-recognition molecule with specificity for microbes and damaged cells. Once bound, P can recruit C3b and thereby provide a platform for the assembly of the AP convertase. Thus, P binding can direct AP activation, similar to MBL in the LP. P binding to certain *Neisseria* species potently activates the AP, and this may account for the susceptibility of P-deficient individuals to infection with *N. meningitidis*.

The third important role of the AP is the amplification of C3b deposition and C5 convertase generation that is initiated by the CP or the LP.[4] This function of the AP is critical in complement-mediated pathology, as it increases the generation of C5a and the MAC, the most inflammatory components of the system. It is this amplification role of the AP that makes it an attractive therapeutic target.

MEMBRANE ATTACK COMPLEX

All three complement pathways merge with the cleavage of C5 into C5a and C5b. Although C5 is structurally homologous to C3 and C4, it lacks an internal thioester bond that allows covalent attachment to surfaces. C3a and C5a are also structurally homologous and, as described below, are the most potent proinflammatory mediators of the complement system. C5b initiates the formation of the MAC (see Fig. 40.3). The membrane-bound MAC precursor complex that is composed of C5b, C6, C7, and C8 recruits C9 from plasma. Unfolding of the initial C9 exposes binding sites for the next C9 molecule sequentially until a ring is formed with 18 copies of C9.[15] This complex, as indicated by its name, penetrates membrane bilayers to form pores that disrupt the osmotic barrier, leading to swelling and lysis of susceptible cells. Lysis of Ab-sensitized erythrocytes by the MAC is the basis of the total hemolytic complement (THC) assay or CH_{50}. C5b initiates the formation of the MAC. Without further proteolytic steps, C5b binds to C6 and this complex binds to C7. The C5b67 complex is lipophilic and associates with cell membranes, if available, or with serum lipoproteins. Once bound to a membrane, C5b67 recruits C8, and the complex penetrates more deeply into the membrane. However, efficient lysis requires C9, a pore-forming molecule with homology to perforin, a protein used by cytotoxic T cells and natural killer (NK) cells for killing virus-infected targets. The complex of C5b678 forms a nidus for C9 binding and polymerization. Although complement-dependent lysis of bacteria can be observed in vitro, many pathogens have evolved mechanisms to circumvent this activity of complement.[16] Opsonization by C3b is therefore the most potent mechanism for destruction (adherence followed by ingestion) of bacteria by the complement system. The sublytic MAC is proinflammatory because of its membrane-perturbing capabilities for host cells, and it contributes to the deleterious effects of complement activation in inflammatory diseases.

REGULATION OF COMPLEMENT ACTIVATION

The complement cascade is rapidly activated and highly amplified by the generation of C3 and C5 convertases. Control mechanisms exist at three main levels that limit the potential harm that uncontrolled complement activation might cause: (1) the initiation step in the CP and the LP; (2) the C3 and C5 convertases of all three pathways; and (3) the assembly of the MAC. Both soluble and membrane-bound regulatory proteins serve these functions, which direct it to the appropriate targets and then terminate complement activation.[17]

C1 Esterase Inhibitor

C1 esterase inhibitor (C1-INH) is a plasma serine proteinase inhibitor (serpin) that covalently binds to activated C1r and C1s, irreversibly inhibiting their activity and thereby limiting CP activation. C1-INH inactivation of C1r and C1s also removes them from the C1 complex, exposing sites on the collagen-like region of C1q. Likewise, C1-INH inhibits MASP-1 and MASP-2, kallikrein, factor XIa, factor XIIa, and plasmin of the LP and the contact, coagulation, and fibrinolytic systems. Inherited deficiency of C1-INH is the basis of hereditary angioedema, a disease characterized by recurrent attacks of subcutaneous or submucosal edema (Chapter 46).[18]

Regulators of the C3 and C5 Convertases

The C3 and C5 convertases are central to the generation of the inflammatory and opsonic products of complement activation and are highly regulated by fluid-phase and membrane-bound regulatory proteins. First, the membrane-deposited C4b and C3b may be bound by the regulator to prevent convertase formation with C2 or FB. Second, the convertases themselves are complexes

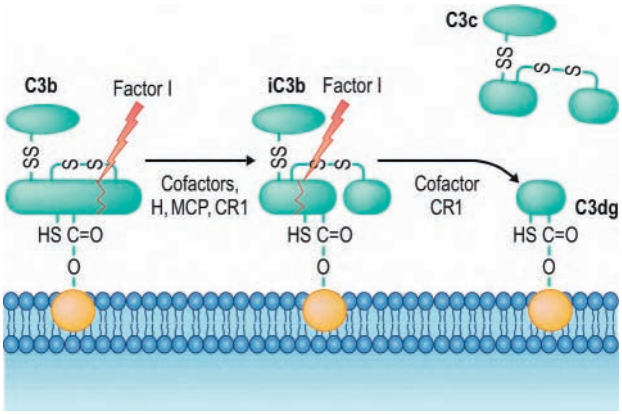

FIG. 40.4 Factor I *(FI)*–Dependent Cleavage of C3 Showing the Structures of the Products and the Required Cofactors. The cofactor protein binds first and then the serine protease factor I cleaves the C3b at two sites in two locations on its α-chain. *MCP,* Membrane cofactor protein.

of two or three components, and one mechanism of regulation is the dissociation of these complexes. This type of regulation is termed *decay acceleration*. A third mechanism of regulation is the enzymatic inactivation of the C4b and C3b components of the convertases (Fig. 40.4). This is accomplished by the plasma serine protease factor I (FI), which, however, only acts on C4b or C3b in association with one of several regulatory proteins. The binding of regulatory proteins to C4b or C3b to enable FI cleavage is termed *cofactor activity*.

Factor I

Factor I (C3b inactivator, C3bINA) cleaves C4b and C3b into products that are recognized by specific cellular receptors (as discussed below). The sequential cleavages of C3b by FI to iC3b and C3dg are depicted in Fig. 40.4. C4b is cleaved in an analogous manner to C4d. (The iC4b intermediate is found only transiently.) The regulatory proteins that facilitate this cleavage by cofactor activity and those that inactivate C3 and C5 convertases by decay-accelerating activity are members of a family of structurally related proteins encoded within the regulators of complement activation (RCA) genetic locus.[19–21] This family is characterized by a repeating structure that consists of subunits, termed *complement control protein repeats* (CCP) or sushi domains, of about 60 amino acids with a conserved pattern of two disulfide bonds per repeat, and are usually encoded by a single exon.

Soluble Regulatory Proteins, C4b-Binding Protein, and FH

C4b-binding protein (C4BP) and FH are fluid-phase regulatory proteins with both decay-accelerating and cofactor activities. C4BP is multimeric, being composed of seven identical subunits, each containing eight CCPs. FH is a single-chain protein composed entirely of 20 CCPs. C4BP is specific for C4b and the C4b-containing convertases of the CP (C4b2b, C4b2b3b), whereas FH regulates C3b and C3b-containing convertases (C3bBb, C3bBb3b, C4b2b3b). FH is essential for regulation of C3 "tickover," and FH deficiency results in an acquired deficiency of C3. Additional binding sites on FH that recognize polyanions, such as sialic acid and glycosaminoglycans, provide targeted regulation of AP activation on surfaces.[17,22,23]

Membrane Regulatory Proteins

The RCA family includes the membrane regulatory proteins decay-accelerating factor (CD55, DAF), membrane cofactor protein (CD46, MCP), and complement receptors CR1 (CD35) and CR2 (CD21).[19,21,24,25] Additionally, other recently identified membrane regulators are the CUB (for C1r/C1s Bmp1, Uegf, Bmpf) and sushi multiple domains protein 1 (CSMD1) and complement receptor of the immunoglobulin superfamily (CRIg).

CD55 (DAF) and CD46 (MCP), as their names imply, have decay-accelerating and/or cofactor activity, respectively, that inhibits complement activation on cell membranes.[19] Each has an extracellular domain composed exclusively of four CCPs. CD55, a glycosylphosphatidylinositol (GPI)–anchored protein, and CD46, a transmembrane protein, are widely distributed on cells in contact with blood, with the notable exception of erythrocytes that lack CD46. Soluble CD55 is also found in most biological fluids. Both protect cells from complement-mediated lysis. CD35 (CR1) has decay-accelerating and cofactor activity and is a receptor for bound C4b and C3b. The function of CD35 as a complement receptor is discussed later in the chapter.

Two more recently described regulators are CSDM1 and CRIg. CSDM1 is a type 1 transmembrane protein that is widely expressed and contains 28 CCPs and 14 CUB domains. It inhibits the classical pathway and serves as a cofactor for cleavage of C3b.[26,27] CRIg binds C3b and iC3b and functions to inhibit the alternative pathway, clear systemic pathogens, and regulate the adaptive immune response. CRIg is widely expressed on macrophages in many tissues, being highly prevalent in the Kupffer cells in the liver.[6]

Properdin

In contrast to the regulatory proteins discussed above, the plasma protein P (factor P) stabilizes C3 and C5 convertases of the AP, increasing their activity.[4,13,14] This enhancer of AP activation is found as noncovalently linked dimers, trimers, tetramers, and larger species composed of identical 56-kDa chains. The majority of this plasma protein consists of a series of six thrombospondin type 1 modules. P binds to C3b and to Bb, preventing the spontaneous or induced decay of the AP C3 and C5 convertases. Its multimeric structure promotes interaction with clustered C3b. As discussed above, bound P can also recruit C3b to provide a site of assembly for the AP C3 convertase.

Regulators of the Membrane Attack Complex

The MAC is also regulated by both fluid-phase and membrane regulatory proteins.[1,17,25,28]

Soluble Membrane Attack Complex Inhibitors: Vitronectin and Clusterin

Soluble hydrophobic proteins block the incorporation of the MAC into membranes. Two well-characterized proteins with this activity are vitronectin (S protein) and clusterin (SP-40,40, apolipoprotein J).[17,25] Vitronectin is in plasma and the extracellular matrix and binds to C5b-7. C8 and C9 can still bind to the complex, but membrane insertion and C9 polymerization are prevented. Soluble complexes of vitronectin and C5b-9 are in plasma during complement activation, and an enzyme-linked immunosorbent assay (ELISA) specific for this complex has been used to monitor activation of the MAC. Clusterin forms

a complex with C5b-9, preventing membrane insertion. It is found in plasma, in the male reproductive tract, and on endothelial cells of normal arteries.

Membrane Attack Complex Inhibitor CD59

The primary membrane-bound inhibitor of the MAC is CD59.[17,25] CD59 is a GPI-anchored protein expressed by most cells. CD59 binds to C8 and C9, preventing their incorporation and thus blocking polymerization of C9.

COMPLEMENT RECEPTORS

Many of the biological effects of complement activation are mediated by cellular receptors for fragments of complement proteins. These include receptors for the small soluble complement fragments C5a and C3a and receptors for bound complement fragments C1q, C4b, and C3b as well as their cleaved fragments. Receptors are specific for C3b and for its further breakdown products generated by the enzymatic processing by FI in conjunction with the cofactor proteins mentioned above. The breakdown of C3b and its intermediate products are shown in Fig. 40.4 and the receptors for these components in Fig. 40.5.

C1q Receptors

C1q is one of a family of proteins termed *soluble defense collagens* that includes the "collectins" (MBL, surfactant proteins A and D, conglutinins, and the ficolins). Each of these proteins is composed of a collagen-like linear stem region terminated by multiple globular recognition domains or head groups. The collectins recognize carbohydrates with their C-type lectin head groups, and the ficolins recognize acetyl groups on carbohydrates and other molecules with fibrinogen-like recognition domains. In contrast, the globular head groups of C1q do not recognize carbohydrates but, rather, bind to amino acid motifs on IgG, IgM, and pentraxins. In general, the soluble defense collagens broadly recognize pathogen-associated carbohydrate patterns and damaged or apoptotic cells. Reported direct effects of this group on leukocytes include the enhancement of phagocytosis, triggering of the respiratory burst, and regulation of cytokine responses. Several cell-surface proteins have been proposed to facilitate these activities, including CD93 (C1qRp), CD35 (CR1), $\alpha_2\beta_1$ integrin, calreticulin in complex with CD91, gC1q-binding protein, and SIPRα. However, none has been definitively established as a receptor in the classic sense.[1,10,29,30]

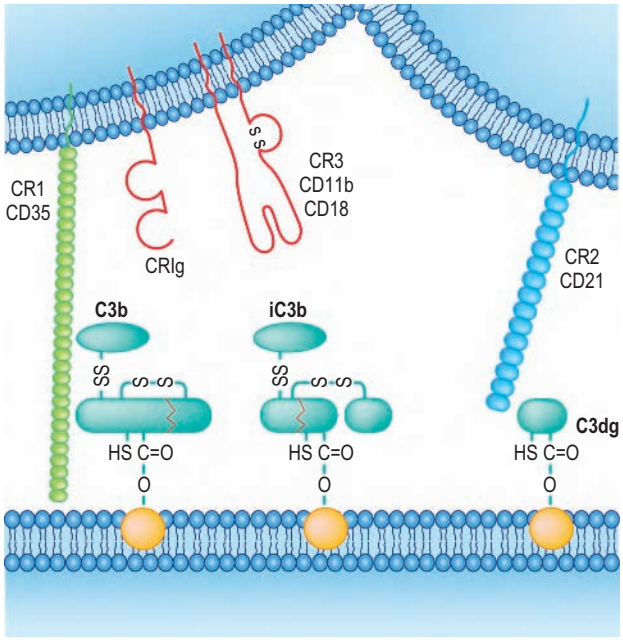

FIG. 40.5 Receptors for Bound C3b and Its Cleavage Products. Receptors shown are CD35 and CD21 composed of CCP (SCR) subunits; CD11b/CD18 (CR3), a β_2 integrin; and CRIg with one or two immunoglobulin domains. The specificities of the receptors are CD35 for C4b and C3b (C4b > C3b), CRIg for iC3b > C3b; CD11b/CD18 for iC3b; CD21 for C3dg and C3d. CD11c/CD18 (CR4) is similar to CD11b/CD18 and is not shown. Receptors are not drawn to scale. Their molecular weights are listed in Table 40.1.

Complement Receptor 1 (CR1, CD35)

There are five identified receptors for bound fragments of C3 and/or C4. CD35 is a large protein composed of a linear string of CCPs, a transmembrane region, and a short intracytoplasmic domain. Different allelic forms of CD35 are found, the most common being composed of 30 CCPs with a molecular weight of 190 kDa. These CCPs are organized into groups of seven, creating structures termed *long homologous repeats* (LHRs), each of which contains a single binding site. The predominant allele of CD35 contains two binding sites for C3b, three for C4b, and one for C1q. CR1 is expressed on human erythrocytes, monocytes and macrophages, neutrophils, B lymphocytes, a small percentage of T lymphocytes, eosinophils, FDCs, and glomerular podocytes.

CD35 on primate erythrocytes provides a mechanism for clearing immune complexes from the circulation. Although the number of receptors on each erythrocyte is low, the large number of erythrocytes provides the major pool of CR1 in the circulation. Soluble immune complexes that fix complement attach quickly to erythrocytes in the circulation, bypassing monocytes and neutrophils. These erythrocyte-bound complexes are taken to the liver and spleen, where they are transferred to tissue-specific macrophages such as hepatic Kupffer cells expressing Fc and complement receptors. The erythrocytes exit into the circulation to pick up more immune complexes. This clearance pathway is impaired in patients with SLE because of decreased complement in the circulation, decreased CD35 on erythrocytes, and saturated Fc receptors in the liver and spleen.

CD35 on monocytes and neutrophils promotes binding of microbes carrying C3b and C4b on their surface (immune adherence reaction), facilitating their phagocytosis through Fc receptors. CD35 can directly mediate the uptake of microbes when phagocytic cells have been activated by chemokines or integrin interactions with matrix proteins. CD35 is a member of the RCA family and has decay-accelerating and cofactor activity in addition to its function as a receptor. It differs from the membrane regulatory proteins DAF (CD55) and MCP (CD46) in its ability to also bind to C3b and C4b extrinsically (on targets other than the cell expressing it) and in its cofactor activity for iC3b processing. CD35 is the most effective cofactor for FI cleavage of C3b and iC3b to the smallest covalently bound fragment C3dg. C3dg is the major ligand for CR2 on B lymphocytes (described below). The cofactor activity of CD35 on B lymphocytes processes bound C3b to C3dg, facilitating binding to CR2 and lowering the threshold for B-cell activation.[21,25,31]

Complement Receptor 2 (CR2, CD21)

CD21 is also an RCA family protein composed of 15 to 16 CCPs. CD21 has a limited range of expression that includes B lymphocytes, FDCs, and some epithelial cells. CD21 is specific for the smallest covalently bound C3 fragments, C3dg and C3d, and has weaker binding to iC3b. CD21 is also the Epstein-Barr virus (EBV) receptor on B cells and nasopharyngeal epithelial cells and binds to CD23, a low-affinity IgE receptor.[21,31]

CD21 on B lymphocytes serves a costimulatory role. It is expressed on mature B cells as a complex with CD19 and CD81 (TAPA-1). Coligation of CD21 and the B-cell antigen receptor induces the phosphorylation of CD19, activating several signaling pathways and strongly amplifying B-cell responses to antigen. This role of CD21 is believed to contribute to the strong adjuvant effect produced by attaching C3d to antigen.[21,31]

Complement Receptors 3 and 4

CR3 and CR4 are the β_2 integrins commonly known as CD11b/CD18 (Mac-1) and CD11c/CD18.[21] β_2 integrins are large heterodimers found on neutrophils and monocytes with multiple roles in adhesion to endothelium and matrix molecules as well as direct recognition of microbial pathogens. The binding activities of β_2 integrins are regulated by cellular activation often through chemokine receptors. Both CD11b/CD18 and CD11c/CD18 are expressed primarily on neutrophils, monocytes, and NK cells and bind to iC3b and, to a lesser extent, C3b. CD11b/CD18 has been studied more extensively than CD11c/CD18. CD11b/CD18 expression, clustering, and conformation are all rapidly upregulated by chemokine activation of neutrophils, leading to increased responses to ligand. CR3 plays an essential role in neutrophil attachment to and migration through activated endothelium to sites in inflammation and in the regulation of neutrophil apoptosis. Deficiency of the β_2 chain (CD18) results in leukocyte adhesion deficiency, characterized by recurrent pyogenic infections, and defects in inflammatory and phagocytic responses. Complement receptors CD11b/CD18 and CD11c/CD18 provide an essential function for the removal of microbial pathogens following complement activation, since C3b processing to iC3b often occurs rapidly after deposition.

Complement Receptor of the Immunoglobulin Superfamily (CRIg)

CRIg is a receptor for iC3b and C3b present on Kupffer cells in the liver as well as other tissue macrophages but is absent from splenic macrophages, peripheral blood cells, bone marrow–derived macrophages, and monocyte/macrophage cell lines.[32] Two alternatively spliced forms of human CRIg were identified with one and two Ig domains. The mouse receptor has a single Ig domain. CRIg removes C3b or iC3b-opsonized particles from the circulation by the liver.

C5a and C3a Receptors

During complement activation, the homologous proteins C3 and C5 are each cleaved near the amino-terminus of the α chains to release a soluble peptide fragment of approximately 8 kDa. These fragments are designated C3a and C5a. C5a may also be generated locally by direct cleavage of C5 by thrombin or leukocyte proteases.[33] C3a and C5a are termed *anaphylatoxins* because of their ability to increase vascular permeability, contract smooth muscle, and trigger the release of vasoactive amines from mast cells and basophils.[34,35] C5a is 10- to 100-fold more active than C3a. These peptides are also chemotactic: C5a is specific for neutrophils, monocytes, and macrophages, whereas C3a is specific for mast cells and eosinophils. Biological activities of complement anaphylatoxins are summarized in Table 40.2.

TABLE 40.2 Cellular Targets and Effects of Complement Anaphylatoxins

	Targets Bearing Receptors	Effects
C3a, C5a	Mast cells, basophils	Degranulation, release of vasoactive amines: contraction of smooth muscle, increased vascular permeability
C3a	Eosinophils	Chemotaxis, degranulation
C5a	Endothelium	Increased adhesion of leukocytes; augmented chemokinesis and cytokine synthesis
C5a	Neutrophils, monocytes/ macrophages, eosinophils, basophils, astrocytes	Chemotaxis
C5a	Neutrophils, monocytes/macrophages	Priming: activation of receptors, assembly of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase; activation: degranulation, respiratory burst
C5a	Resident macrophages	Regulation of FcγR expression (↑activating, ↓inhibitory)
C5a	Hepatocytes	Acute phase protein synthesis
C3a, C5a	Lymphocytes (antigen-presenting cells)	Regulation of T-cell responses to antigen

Structurally, anaphylatoxins are compact structures consisting of multiple helices cross-linked by disulfide bonds with more flexible carboxy-terminal regions. The C-terminal peptide of C3a interacts with the C3aR and can reproduce C3a agonist activity. In contrast, C5a interacts with the C5aR at multiple sites. Plasma carboxypeptidases cleave the C-terminal arginine from C3a and C5a, producing the des-Arg forms. This inactivates C3a; however, C5a-desArg retains much of its biological activity. The C5aR (CD88 and C5L2) and the C3aR are rhodopsin-type receptors with seven transmembrane-spanning domains coupled to G-protein signaling pathways. C5aR is expressed at high levels on neutrophils and is also expressed by macrophages, mast cells, basophils, smooth muscle cells, and endothelial cells. If C5a is generated locally, for example, at an extravascular site of infection, it helps induce an acute local inflammatory response, including vasodilation, edema, neutrophil chemotaxis, and activation of neutrophils and macrophages for enhanced phagocytosis and killing. The inflammatory activities of C5a can also contribute to complement-mediated pathology in some conditions, such as sepsis, acute respiratory distress syndrome, and ischemia/reperfusion (I/R) injury, making the C5a–C5aR interaction an attractive therapeutic target.

The C5L2 receptor binds to both C5a and C5a-desArg. C5L2 was initially believed to be a default or decoy receptor for C5a because it is uncoupled from G proteins. Genetic deletion of C5L2 (*Gpr77*$^{-/-}$) in mice resulted in enhanced neutrophil infiltration and cytokine production in the pulmonary Arthus

reaction, supporting an antiinflammatory role for C5L2 in immune complex disease, where genetic deletion of C5aR is fully protective. However, studies in a cecal ligation and puncture (CLP) model of sepsis found increased survival in mice lacking either C5aR or C5L2. The results suggest an active proinflammatory role for C5L2 that requires C5a and results in the release of the inflammatory signal, high-mobility group box-1 protein (HMGB1) from phagocytic cells. Thus, both C5aR and C5L2 may contribute synergistically to harmful inflammatory events during sepsis.

COMPLEMENT IN HOST DEFENSE AND IMMUNITY

Complement in Host Defense

Complement activation provides a coordinated response to infection that results in the opsonization of microbial pathogens and the attraction and activation of phagocytic cells to kill them. Complement-dependent opsonization is of greatest importance in infections with encapsulated extracellular bacteria, and individuals with deficiencies in Ab production, neutrophil function, or C3 share increased susceptibility to these organisms, including *Streptococcus pneumoniae* and *Haemophilus influenzae*. MBL deficiency is also associated with recurrent pyogenic infections in young children. In general, activation of complement by natural Ab or MBL results in C3b and iC3b deposition on these pathogens, overcoming the antiphagocytic effects of the capsule. Phagocytic cells ingest and kill the organisms using CD35, CD11b/CD18, and CD11c/CD18 receptors in conjunction with other innate and Fc receptors. C5aR signaling activates these receptors, leading to increased phagocytosis. Gram-negative bacteria are also susceptible to complement-dependent lysis. This is evident in the increased incidence of disseminated neisserial infection in individuals deficient in C3, any of the MAC components, or P, as discussed below.

Complement in Inflammation

An essential function of complement in host defense is the coordination of the local inflammatory response. C5a is the most potent complement product in this activity.[35] Sublytic deposition of the MAC on endothelial cells and platelets and C3a interaction with the C3aR also contribute to the proinflammatory effects of complement activation. As discussed below, these potent inflammatory fragments of complement, when generated in high amounts or targeted inappropriately, result in many of the disease-related deleterious effects of complement. Local production of C5a at a site of infection occurs either through local complement activation or through direct cleavage of C5 by tissue macrophages or thrombin.[33,34] This C5a is released and sets up a chemotactic gradient for neutrophils and macrophages. In addition, C5a activates endothelial cells to express P-selectin and synthesize chemokines, including interleukin-8 (IL-8). Interaction of C5a with mast cells releases vasoactive amines, increasing endothelial permeability. Neutrophils and macrophages are "primed" by interaction of C5a with its receptor. Priming includes enhancement of chemotaxis, activation of complement receptors for phagocytosis increased expression of activating FcγR, and assembly of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase that is required for effective killing of microbes after phagocytosis. C5a also prevents neutrophil apoptosis, prolonging survival and contributing to local accumulation. Together, these actions result in the attraction and activation of potent antimicrobial cells and resolution of infection.

Pathogen Evasion of Complement

Further evidence of the host defense function of complement is the association of complement evasion strategies with virulence. Pathogenic gram-negative bacteria, such as *Salmonella*, have lipopolysaccharides with long O-polysaccharide side chains that promote rapid shedding of the MAC and prevent its insertion into the cell membrane. *Neisseria* species have several FH-binding components that help restrict AP activation and protect against lysis. Group A and B streptococci and *S. pneumoniae* have cell-surface components (M protein, Bac or beta, PspC, Hic) that bind to FH and/or C4BP, restricting complement activation. Other organisms, including type 3 group B streptococci, elaborate sialic acid–containing capsules or cell walls to limit AP activation.

Although complement deficiencies are not generally associated with viral infections, the importance of complement in host defense against viruses is suggested by the multiple strategies used by viruses to evade complement.[16,36] Several viruses

KEY CONCEPTS

How Pathogens Abuse and Evade the Complement System: Some Examples

1. Bacteria
Block C1, C3b deposition
Streptococcus pneumoniae
Block MAC access to plasma membrane
Salmonella
Limit access of C3b, iC3b to complement receptors by capsule
Streptococcus pneumoniae
Haemophilus influenzae
Block AP activation by sialylation
Streptococcus agalactiae (GBS) type III
Neisseria
Bind (highjack) FH, C4BP to inhibit complement activation
Streptococcus pneumoniae (Hic)
Streptococcus pyogenes (GAS) (M protein)
Neisseria
Use CD55 (DAF), CD46 (MCP) for attachment to cells
Streptococcus pyogenes (GAS) (M protein)
Neisseria
Escherichia coli
Use complement receptors for entry
Mycobacterium tuberculosis (CR3)
Bacillus anthracis spores (CR3)

2. Viruses
Express complement regulatory proteins homologous to those synthesized by the host
Herpes simplex virus (glycoprotein C)
Poxviruses (SPICE/VICE)
Express unique complement regulatory proteins
Flaviviruses (Dengue, West Nile)
Use CD55 (DAF), CD46 (MCP) for attachment to cells
Measles virus, adenovirus, herpes virus 6 (CD46)
Picornaviruses, hantavirus (CD55)
Use complement receptors for entry
Epstein-Barr virus (CD21)
Human immunodeficiency virus (CD35, CR3)

3. Parasites
Express complement regulatory proteins
Schistosoma (CRIT)
Acquire complement regulatory proteins from host
Schistosoma (CD55)
Use complement receptors for entry
Leishmania (CR1, CR3)

produce complement regulatory proteins, including vaccinia virus complement control protein and herpes virus glycoprotein C, which facilitate breakdown of C3b and C4b. Some viruses, such as human immunodeficiency virus (HIV), incorporate complement regulatory proteins into the viral envelope, a strategy that is also used by other pathogens, such as *Schistosoma*.[16,36,37]

There are also many examples of complement receptors and membrane regulatory proteins being exploited as receptors for pathogens to invade cells. Examples of these include strategies of direct pathogen binding to receptors as well as deposition of C3 fragments followed by invasion through host C3 receptors.[16]

Role of Complement in Adaptive Immunity

Over the past 10 years there has been renewed interest in the role of the innate immune system in adaptive immune responses.[4] The importance of complement in humoral immunity has been recognized since the observation that complement depletion of mice before immunization decreased Ab responses to thymus-dependent antigens. Further studies have shown that complement receptors CR1 (CD35) and CR2 (CD21) are also essential for immunomodulation.[21,31] In humans, these receptors are found together on B cells and FDCs. CD35 is also expressed on a number of other cell types (described above), including erythrocytes and phagocytic cells.

Effects of Complement on the Humoral Immune Response

Results obtained by experimental manipulation of C3, C4, and their receptors in mouse models indicate roles for these complement components at multiple levels in the humoral immune response.[21,31] One caveat regarding these studies is that in the mouse CD35 and CD21 are alternative splice products of the same gene, and genetically deficient animals lack both receptors.[21] In humans, CD35 and CD21 are encoded by separate genes. The first role of CD35/CD21 is in B-cell development, indicated by a pronounced defect in B-1-cell development in CD35/CD21–deficient mice. B-1 cells are generally found outside lymphoid follicles, have a restricted repertoire, and are essential in the production of natural Ab to pathogens, such as *S. pneumoniae*, and to self-antigens exposed on damaged cells, such as phosphatidylcholine and DNA. Although the mechanism of this defect in CD35/CD21–deficient mice is not fully understood, these mice have an altered repertoire of natural Ab and B-1 cells.[21,31] Decreased natural Ab may contribute to susceptibility to infection and autoimmune disease in hereditary complement deficiency (discussed below).

A second role for complement in the Ab response is the well-described function of CD21 as a coreceptor for the mature B-cell response to antigen.[21,31,38] As described above, CD21 is associated with the signaling complex of CD19 and CD81 (TAPA-1) in the B-cell membrane. Coligation of CD21 with the B-cell antigen receptor occurs naturally when the antigen activates complement and covalently binds C3dg. This coligation of the B-cell receptor with CD21 greatly decreases the threshold for B-cell activation and blocks Fas-initiated apoptosis of B cells. B cells activated by complement-opsonized antigen have increased ability to present antigen as well as survival and proliferation during encounters with T-dependent antigens.

The expression of CD35 and CD21 on FDCs is also important in the Ab response. FDCs trap antigen in the germinal centers and provide selection of somatically mutated high-affinity B-cell clones. Antigen trapped on FDCs also provides a source of long-term stimulation for maintenance of memory B cells. FDCs use complement receptors (CD35 and CD21) and FcγR to trap and retain antigen for these functions. Expression of CD21 on both FDCs and B cells is required for effective affinity maturation of the Ab response and for the development and maintenance of memory B cells.

Complement and T-Cell Biology

For many years, T cells were thought to express only a limited repertoire of complement proteins. However, we now know that T cells express many complement components, although at lower amounts relative to APCs.[39] Complement proteins can exert both a direct and indirect effect on T cells. For example, CR1 is expressed by ~12% of blood-circulating $CD4^+$ and $CD8^+$ T cells and is upregulated upon TCR engagement. However, CR1 is considered to be a negative controller of T-cell activity since CR1 stimulation during $CD4^+$ T-cell in vitro activation inhibits proliferation and IL-2 production and induces IL-10 secretion.[39] Further, CR1 may have additional signaling roles in T cells.

The first evidence that complement indirectly influences T-cell protective responses was shown by studies in primary pulmonary infection with influenza in which C3-deficient mice have a defect in influenza-specific $CD4^+$ and $CD8^+$ T-cell priming.[38] The mechanism may be more efficient uptake and presentation of C3-opsonized virus by APC through CR3 and CR4 or stimulation of T-cell responses through the C3aR.

Other complement components may directly impact T-cell function. For example, C1q-opsonized immune complexes (ICs) bind to T cells via C1qR and can induce cell activation. Additionally, the anaphylatoxin receptors can directly regulate T-cell responses as indicated by studies of *C3ar* and *C5ar1* double-knockout mice that demonstrated reduced ability to generate Th1 responses.

Further, costimulation of human T cells in vitro through CD3 and CD46 leads to the development of T cells with a regulatory phenotype characterized by synthesis of IL-10 in the absence of other Th2 cytokines (IL-2, IL-4) (Chapter 14). The induction of regulatory T cells (Tregs) was seen in response to both anti-CD46 cross-linking and natural ligands (C3b dimers, streptococcal M protein).

CD55-deficient mice showed enhanced T-cell responses to immunization and increased T cell–dependent autoimmune disease. These effects were complement dependent and apparently involved the loss of CD55 regulation of local complement synthesis by APCs during cognate interactions with T cells. One postulated mechanism is that CD55 inhibits the generation of C3a and C5a by APCs, preventing their interactions with C3aR and C5aR on T cells.[40]

The Intracellular Complement System (Complosome)

For many years, the complement system was considered a serum-centric system. However, a growing number of new studies are revealing that complement also has an intracellular arsenal of components that provide not only immune defense but also key interactions for host cell functioning (reviewed by Liszewski et al.[41] and Arbore et al.[42]). While early work has centered primarily on T cells, the intracellular complement system (the complosome) likely functions in most, if not all, cells. Some of these functions may trace their origin to the ancient complement system that likely began with a primitive form of C3 responsible for protection from intracellular pathogens. With continuing

evolution and creation of more components, this system expanded to the extracellular space as C3 became secreted to guard the vasculature from infectious agents. It is no surprise, then, that contemporary cells retain elements of this vestigial system.

Thus, current evolving understandings of this system recognize the following functions: (1) C3 serves as a damage-associated molecular pattern that, in particular, coats intracellular pathogens; (2) most cells contain intracellular stores of C3 and recycle C3(H2O); (3) intracellular C3 assists in cellular survival and metabolic reprogramming; (4) other components of the complosome include C5, factor B, properdin, and complement receptors and regulators (e.g., CD46, FH, C3aR, C5aR). As the complosome becomes better elucidated, new targets for the next generation of complement therapeutics may emerge.

Role of Complement in Clearance of Apoptotic Cells

Damaged tissue and dead and dying cells activate complement through several pathways. This can increase local inflammation and cellular damage, as in I/R injury, AMD, and hemolytic–uremic syndrome (HUS) (discussed below). Complement activation by apoptotic cells contributes to their opsonization and clearance and may prevent the development of autoimmunity. The deleterious consequences of complement activation following tissue damage are mainly attributable to AP-dependent generation of C5a and the MAC, whereas the beneficial effects are dependent on early CP components and innate recognition molecules.[43,44]

Necrosis, as occurs following ischemic tissue injury, exposes phospholipids and mitochondrial proteins that activate complement directly or indirectly. The pathways are different depending on the tissue involved.[43] For example, renal reperfusion injury appears to be initiated by the AP, possibly secondary to the loss of regulatory proteins on tubular epithelial cells. Intestinal (I/R) injury is initiated by natural IgM Ab and requires both the CP for initiation and the AP for injury. MBL and CRP-initiated complement activation have been proposed to contribute to myocardial reperfusion injury after coronary artery ligation.

Apoptotic cells are recognized by multiple receptors and opsonins.[44,45] The association between early CP deficiencies and SLE (see below and Chapter 52) has been attributed to a failure of complement-dependent opsonization, resulting in accumulation of apoptotic cells and released autoantigens. Support for this hypothesis is provided by studies of mice deficient in C1q, IgM, or serum amyloid P (SAP), all of which develop autoantibodies against phospholipid and nuclear antigens characteristic of SLE, and by the therapeutic effect of CRP in mouse models of SLE.[29] The role of complement in apoptotic cell recognition and uptake by macrophages is depicted in Fig. 40.6. MBL, C1q, and surfactant protein-D (SP-D) bind to apoptotic cells and facilitate clearance through direct binding to cellular receptors as well as complement activation.[45] Natural IgM Ab, CRP, and SAP bind to phospholipids exposed on late apoptotic cells. All three proteins can also activate the CP generating C1q, C4b, C3b, and iC3b ligands for complement receptors. CRP and SAP also directly opsonize apoptotic cells for uptake through Fcγ receptors.[46] Phagocytosis of apoptotic cells generally induces antiinflammatory cytokines transforming growth factor-β (TGF-β) and IL-10.

Targeted and Restricted Activation of the Complement System

Interestingly, CRP and SAP also bind complement regulatory proteins FH and C4BP, which helps limit complement activation to the deposition of opsonic components with little or no lysis or generation of C5a.[47] This type of targeted complement activation was also observed on acrosome-activated spermatozoa. In this case, the CP was activated by CRP from follicular fluid, resulting in bound C3b and iC3b, which are proposed to bind complement receptors on the egg and facilitate fertilization. Such engagement of the complement systems is likely a physiological (normal) mechanism for handling intracellular and extracellular debris that is continually produced in the body. For example, complement fragments are almost universally observed at sites of tissue injury in conditions such as atherosclerosis and Alzheimer disease. Whether such deposition is helpful or harmful (or both, depending on timing, duration, and magnitude) remains to be defined.

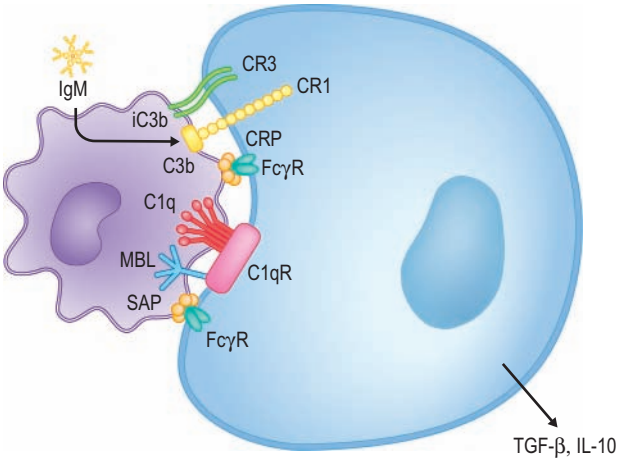

FIG. 40.6 Pathways of Opsonization of Apoptotic Cells by Complement. Innate recognition of apoptotic cells by natural immunoglobulin M *(IgM)*, cross-reactive protein *(CRP)*, serum amyloid P *(SAP)*, C1q, and mannose-binding lectin *(MBL)* is shown. Each reaction activates complement, leading to opsonization by C3b and iC3b. In addition, C1q and MBL bind to collectin receptors, and CRP and SAP bind to FcγR on macrophages. Cytokine responses to apoptotic cells opsonized by complement include the antiinflammatory cytokines transforming growth factor-β *(TGF-β)*, and interleukin-10 *(IL-10)*.

COMPLEMENT DEFICIENCIES

Genetics and Incidence

Complete genetic deficiencies of complement proteins are rare, with an estimated combined prevalence of 0.03% for any inherited complete deficiency (excluding MBL deficiency) in the general population.[2,48–50] For most components, inheritance is autosomal and expression is codominant, so complete deficiency is homozygous recessive and heterozygotes express half levels. There are two C4 genes (*C4A* and *C4B*), so a range of partial deficiencies can be observed. All cases of C1-INH deficiency have been heterozygous, and P deficiency is X-linked. MBL is found in multiple allelic forms with different levels of expression ranging from 5 nanograms per milliliter (ng/mL) to more than 5 micrograms per milliliter (μg/mL) in plasma. Deficiencies specific to the LP are not detected by the screening assays described below but can be determined by specific assays.[51]

The most common clinical presentations of patients with complement deficiencies are recurrent infections with encapsulated bacteria, neisserial infections, and systemic autoimmune disease

TABLE 40.3 Clinical Effects of Genetic Complement Deficiency

Deficient Component	Resulting Defect	Clinical Associations
C1q, C1r, C1s, C4, or C2	Inability to activate the CP	Systemic lupus erythematosus, bacterial infections
Factor D (FD), factor B (FB)	Inability to activate the AP	Infections (encapsulated bacteria)
MBL, MASP-2	Decreased or absent ability to activate the LP	Recurrent childhood infections, pyogenic bacteria
Properdin	Reduced efficiency of AP activation	Neisserial infections
C3	Decreased opsonization. No MAC. No activation of AP. Decreased inflammation (no C3a).	Recurrent childhood infections, *N. meningitidis, Streptococcus pneumoniae*, other encapsulated bacteria; autoimmune disease (uncommon)
FH, FI,	Lack of regulation of fluid-phase C3 convertases, severe acquired C3 deficiency (C3NeFs)	Infections, membranoproli ferative glomerulonephritis, C3G
C5, C6, C7, C8, C9	Inability to form the MAC	Infection—recurrent, disseminated neisserial
Serum carboxypeptidase-N	Failure to control C3a, C5a, bradykinin	Recurrent angioedema
C1-INH	Loss of regulation of C1 and bradykinin	Recurrent angioedema (HAE)
FH, FI, CD46 (haploinsufficiency)	Decreased regulation of C3 convertases	Atypical hemolytic–uremic syndrome, age-related macular degeneration[a]
DAF, CD59	Failure to regulate complement activation on autologous cells (especially red blood cells)	Paroxysmal nocturnal hemoglobinuria (PNH), early-onset protein-losing enteropathy and thrombosis, PLE (DAF)

[a]Heterozygous C3 and factor B variants that lead to a gain of function cause atypical hemolytic–uremic syndrome (aHUS), age-related macular degeneration (AMD), and C3G.
C1 INH, C1 esterase inhibitor; *C3G*, C3 glomerulopathy; *DAF*, decay-accelerating factor; *HAE*, hereditary angioedema; *MAC*, membrane attack complex; *MASP*, MBL-associated serine protease; *MBL*, mannan-binding lectin; *NeF*, nephritic factor (stabilizing autoAb to convertase).

(Table 40.3). Populations with these disease manifestations have a much higher incidence of complement deficiency. For example, in Caucasian patients with SLE, the incidence of C2 deficiency is nearly 1%, 100-fold higher than in the general population. Screening of patients with autoimmune disease for complement deficiencies is useful, as these individuals are at higher risk for certain disease manifestations and may be at greater risk for infectious complications. Complement deficiency is found in as many as 20% of patients with recurrent disseminated neisserial infections. Evaluation of complement function is highly recommended in patients with systemic neisserial infections so that appropriate immunization and antibiotic prophylaxis can be initiated.

Complement deficiencies are most readily detected by hemolytic screening assays (the CH_{50} and AH_{50}), which determine the dilution of patient's serum needed to lyse 50% of erythrocytes sensitive to the CP (CH_{50}) or the AP (AH_{50}).[52] Deficiency of any C1 subcomponent, or any of the other CP components (C2 to C8), will result in little or no lysis in the CH_{50} (CH_{50} values <5%). C9-deficient patients may have residual activity in this assay (CH_{50} values <30%). Little or no lysis is observed in the AH_{50} assay if factor D, P, or any of the components C3 to C9 are deficient. By comparing the results of the two assays, it is possible to narrow down the search for the deficient component.

Hemolytic and antigenic assays may be done for each individual component to confirm the deficiency.

CLINICAL PEARLS

Value of Screening for Complement Deficiencies

1. Patients with recurrent bacterial infections and normal white blood cells and immunoglobulins should be analyzed for a complement deficiency (obtain CH_{50} and AP_{50}).
2. Patients with recurrent or disseminated neisserial infection should be evaluated for deficiency of C3–C9 by CH_{50} and for properdin by AP_{50}.
3. Prophylactic antibiotics and immunization should be considered in complement-deficient individuals, especially for pneumococcus and neisserial species.
4. Patients with systemic lupus erythematosus (SLE) (especially young children and those with familial lupus, and recurrent bacterial infections) should be screened with CH_{50}.

Classical Pathway Deficiencies

Patients with deficiencies of early CP components (C1, C4, or C2) are most commonly identified as having systemic autoimmune disease but are also at increased risk of infection.[48–50] The primary infectious agents in these patients are encapsulated bacteria, *S. pneumoniae, H. influenzae, N. meningitidis*, and *S. agalactiae*, which are cleared by Ab and CP opsonization.

C1 Deficiency

C1-deficient patients most commonly lack C1q, but C1r or C1s deficiency also results in nonfunctional C1 and no CP activity. Absence of C1q is highly associated with the development of SLE, with an incidence of 90%.[48–50,52] It has been proposed that this association is related to defective clearance of apoptotic cells.[53] Apoptotic cells may be opsonized by IgM, or pentraxins, leading to activation of the CP, which may be initiated by IgM or pentraxin (CRP and SAP). Cells can also be cleared by direct C1q binding, leading to attachment and uptake through other phagocytic receptors (e.g., phosphatidylserine receptor). Other proposed mechanisms to account for the strong association between C1 and C4 deficiency (see below) and SLE include defective immune complex clearance and defective development and maintenance of B-cell tolerance.

C4 Deficiency

There are two C4 genes, *C4A* and *C4B*, located within the major histocompatibility complex (MHC) on chromosome 6.[50] The two forms of C4 protein have similar function, but different substrate preferences for the covalent binding reaction that occurs on activation to C4b. C4A is more efficient in attaching to amino groups on proteins, such as immune complexes, whereas C4B is more efficient in attaching to carbohydrates. Complete C4 deficiency requires four null alleles and is rarely found but is highly associated with SLE (75% incidence). Partial C4 deficiencies with one to three null alleles, however, are relatively common, found in up to 25% of individuals. Complete C4A deficiency is greatly overrepresented in the SLE population. C4A deficiencies are found in about 1% of the general population and 10% to 15% of patients with SLE. Complete C4B deficiencies are more commonly associated with bacterial infections, suggesting

that the functionally different C4 genes contribute differently to host defense and autoimmunity.

C2 Deficiency

The gene encoding C2 is also located within the MHC. C2 deficiency is the most common complete complement deficiency, with about a 0.01% incidence in the population.[48–50] About half of C2-deficient individuals are clinically healthy. The remaining individuals have recurrent pyogenic infections and/or rheumatological diseases. The most common infectious agents are *S. pneumoniae, H. influenzae, N. meningitidis*, and *S. agalactiae*. Infections are invasive and mainly occur in childhood, suggesting that the defect may be partially overcome by development of acquired immune defenses. Rheumatological diseases associated with C2 deficiency include SLE (15%), vasculitis, polymyositis, and Henoch-Schönlein purpura. SLE associated with C2 deficiency has some features that distinguish it from other types of SLE; these features include equal expression in males and females, early onset, increased photosensitivity, decreased incidence of renal disease, lower frequency of anti-dsDNA Ab, and higher frequency of anti-SSA/Ro and anti-C1q Ab.[48–50]

Lectin Pathway Deficiencies

MBL deficiency was originally found as a serum defect in the opsonization of yeast in pediatric patients with recurrent infections. There are multiple MBL polymorphisms in the population, in both the promoter and coding regions of the gene, and MBL deficiency is common (estimated to be 14% in the normal Swedish population).[48] In addition to the association of MBL deficiency in children with recurrent infections, there is a two- to threefold increased frequency of MBL deficiency in SLE, and these individuals have more frequent and more severe infections during the course of their disease. Serious infectious complications are also more frequent in the subgroups of patients with cystic fibrosis and rheumatoid arthritis (RA) with MBL deficiency.

Although rare, in one reported homozygous MASP-2 deficiency,[51] the patient was asymptomatic until the age of 13 years when he was diagnosed with ulcerative colitis. Additional autoimmune manifestations developed along with recurrent severe infections with *S. pneumoniae*.

Alternative Pathway Deficiencies

Individuals with complete deficiencies of factor D or P have been reported. Patients with factor D deficiency have presented with recurrent infections by *Neisseria* and other organisms. Properdin deficiency is X-linked, and patients most commonly have severe childhood infections with *N. meningitidis*.[13,48,52]

C3 Deficiency

C3 is central to all three complement activation pathways. Nineteen families with primary inherited deficiency of C3 have been reported. The most common presentation is recurrent life-threatening infections before the age of 2 years, sometimes followed by immune complex disease. The infections observed are primarily respiratory tract infections (48%) and meningitis (34%) with a variety of pathogens, especially encapsulated bacteria. The organisms most often involved are *N. meningitidis* and *S. pneumoniae*, but other encapsulated gram-negative and gram-positive bacteria have also been observed. Recurrent infections are seen in more than 50% of patients with C3 deficiency. This clinical presentation is similar to that seen in hypogammaglobulinemia.

Acquired C3 Deficiency: Genetic Deficiencies of FH and FI and C3 and C4 Nephritic Factors

Factors H and I are required to control C3 convertase in the fluid phase of the AP. Complete deficiency of either protein results in C3 cleavage and depletion to very low levels. C5, factor B, and P levels may also be reduced. The clinical presentation of patients with FH or FI deficiency resembles that of patients with primary C3 deficiency. The highest disease association is recurrent infection with *N. meningitidis* and *S. pneumoniae*, and there is also an increased incidence of SLE. FH deficiency is more commonly associated with renal disease compared with C3 or FI deficiency (73% of individuals with FH deficiency compared with 13% of individuals with FI deficiency and 26% of those with C3 deficiency).

Nephritic factors (NeFs) are autoantibodies specific to the CP or the AP C3 convertase (C4b2a or C3bBb) or the AP C5 convertase that stabilizes these enzyme complexes and prevents normal regulatory control. The AP C3Nef induces unregulated complement activation, resulting in acquired C3 deficiency. NeFs are often associated with C3 glomerulopathy and with partial lipodystrophy.

Deficiencies of Complement Receptors

Deficiencies of CR1 (CD35) and CR2 (CD21)

Complete genetic deficiencies of CR1 or CR2 have not been reported. However, partial deficiencies of CR1 on erythrocytes, B lymphocytes, and polymorphonuclear leukocytes and of CR2 on B lymphocytes have been reported in patients with SLE. Decreased CR1 on erythrocytes may be acquired as a result of immune complex clearance.[48,52]

Leukocyte Adhesion Deficiency: CR3 and CR4 Deficiency

Leukocyte adhesion deficiency (LAD; Chapter 39) is a syndrome caused by mutations of the common β_2-integrin chain, CD18, found in LFA-1, CR3, and CR4. Defects are related to adhesion and activation of phagocytic cells, and the clinical presentation includes childhood infections with pyogenic bacteria.

Deficiencies of Regulatory Proteins

Hereditary Angioedema: C1-INH Deficiency

Hereditary angioedema (HAE) is found in individuals with heterozygous (autosomal dominant pattern of inheritance) deficiency of C1-INH.[18] C1-INH is a serine protease inhibitor (serpin) with regulatory activity for C1r, C1s, MASP-1, and MASP-2 of the complement system; factor XII (Hageman factor) and kallikrein of the contact system; factor XI and thrombin of the coagulation system; and plasmin and tissue plasminogen activator (tPA) of the fibrinolytic system. Although previous studies implicated a C2 product (C2 kinin) as a mediator, more recent data, including studies in a C1-INH–deficient mouse model, indicate that bradykinin is the primary biological mediator of angioedema in HAE.[18] In the more common form of HAE (type I, 85% of patients), reduced synthesis of C1-INH is found (5% to 30% of normal), along with decreased serum C4 and C2. In type II HAE, an abnormal C1-INH is synthesized, making antigenic levels normal or elevated with reduced functional activity and decreased C4 and C2. Clinically, type I and type II HAE are indistinguishable.

HAE presents in childhood or adolescence as recurrent episodes of nonpainful, nonpruritic, and nonpitting swelling that

are subcutaneous and/or submucosal. Urticaria is not present. Episodes are self-limiting, usually peaking at 24 hours and resolving over 2 to 5 days. Attacks are variable in frequency, severity, duration, and location, and initiating factors are poorly understood. The most common areas involved are the extremities, face, genitals, and respiratory and gastrointestinal tracts. Intestinal attacks are often associated with vomiting and diarrhea and are extremely painful (partial obstruction from the bowel wall edema). Laryngeal attacks may result in life-threatening respiratory tract narrowing. Recurrent attacks continue throughout the life of the patient and may involve multiple sites or progress from one site to another. Diagnosis of HAE is suggested by family history and clinical findings. Confirmation is based on decreased C1-INH functional activity (<10% to 35% of normal). It is important to note that although C1-INH protein is decreased in type I HAE, it can be normal or even elevated in type II HAE. C4 levels are below normal in 95% of patients with HAE. Acquired forms of C1-INH deficiency have been described, usually in older patients with lymphoproliferative diseases. These are usually caused by autoantibodies to C1-INH and are distinguished from HAE by a lack of family history and decreased C1q as well as C4. The management and treatment of HAE are discussed in Chapter 46.

Paroxysmal Nocturnal Hemoglobinuria: Decay-Accelerating Factor and CD59 Deficiency

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare acquired disorder in which a somatic mutation in the *PIGA* gene in a clone of bone marrow stem cell results in defective synthesis of GPI-anchored proteins. PNH is characterized clinically by intravascular hemolysis and venous thrombosis. DAF and CD59 are GPI-anchored complement regulatory proteins expressed on erythrocytes, and PNH erythrocytes are highly susceptible to lysis. Studies of individuals with isolated DAF and CD59 deficiencies indicate that hemolysis is more highly associated with CD59 deficiency. The basis for thrombosis in PNH is poorly understood. A mAb to C5 has been approved by the US Food and Drug Administration (FDA) to treat PNH.

Control of Localized Complement Activation: Atypical Hemolytic–Uremic Syndrome, Age-Related Macular Degeneration

Hemolytic–uremic syndrome (HUS) is a rare disease characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. "Typical" HUS occurs in children and is caused by *E. coli*, mainly O157:H7, producing a shiga-like toxin. Atypical HUS (aHUS) affects primarily older children and adults and is associated with either loss-of-function mutations in complement regulators FH, FI, or CD46 or gain-of-function mutations in C3 or FB. Mutations in complement proteins are identified in approximately 50% of patients. FH mutations associated with aHUS are predominantly clustered in the C-terminal end of the molecule in CCP19–20, a region that is required for FH binding to polyanions and endothelial cells. The ability of FH to regulate fluid-phase AP activation is therefore not affected, and C3 levels are normal. These findings have led to the hypothesis that local complement regulation is essential for preventing renal disease following endothelial cell injury and that FH acts locally after binding to exposed matrix or damaged endothelium.

Genetic variants in *CFI* and *CFH* have also been associated with age-related macular degeneration (AMD), a major cause of blindness in older adults. These variants range from common polymorphisms, conferring relatively low to moderate risk, to rare variants with nearly complete penetrance and high risk. FH polymorphism (Tyr/His402) is commonly associated with AMD[54] and is located in CCP7 (in a region of FH that binds heparin and CRP).[23,55,56] As is the case for the mutations associated with aHUS , this region of FH is not required for regulation of the fluid-phase AP convertase. AMD develops when abnormal deposits of a protein, termed drusen, form in the retina. Recent findings support the view that the local inflammatory response, including complement activation with MAC deposition, damages the retina, leading to vision loss. Although complement factors are not the only genes linked to AMD, common variants are estimated to account for more than 50% of cases and rare variants commonly lead to haploinsufficiency in about 10% of cases. These findings are driving the development of new complement-based therapeutics that could provide protection from a very significant form of age-related visual loss.

COMPLEMENT IN DISEASE

Measurement of Complement in a Clinical Setting

Laboratory tests for complement include functional assays for the CP (CH_{50}), the AP (AH_{50}), and the LP (LP_{50}) as well as antigenic levels and functional assays for each of the individual components. The CH_{50} is a hemolytic assay in which sheep erythrocytes sensitized with rabbit anti-sheep RBC Ab are incubated with serial dilutions of the patient's serum. The titer is the reciprocal of the dilution of serum at which 50% of the sheep erythrocytes are lysed. The CH_{50} requires all of the CP and terminal components (C1 to C9). Diseases associated with CP activation result in decreased CH_{50}, C4, and C3 levels. These are primarily immune complex–associated diseases, both autoimmune and infectious, and are listed in Table 40.4.

Another cause of selective CP activation is essentially a laboratory artifact, in which clotting of the blood sample in the cold is associated with consumption of the early CP. Plasma CH_{50} is often normal, but the serum CH_{50} value is markedly decreased. C3 and C4 antigenic tests may be normal or moderately reduced, but their functional activity is lost. In these situations, the clinician should consider diseases associated with cold reactive Ab: namely, cryoglobulinemias and cold agglutinin syndrome.

A comparable assay for the AP (AH_{50}) uses a buffer that blocks CP activation and employs rabbit erythrocytes in place of sensitized sheep erythrocytes. Rabbit erythrocytes spontaneously activate the human AP and are lysed in the assay. The AH_{50} requires all of the AP and terminal components (factor B, D, and P and C3 to C9). The combined use of the CH_{50} and AH_{50} is the most effective screening method for genetic deficiencies of complement components. Complete deficiency will generally result in titers of < 5% in one or both assays. Because C3 to C9 are common to both pathways, the combined results of the two assays can rapidly determine whether the deficiency is one of these shared components, one of the CP components (C1, C2, C4), or one of the AP components (factors B, D, P).

Properdin deficiency results in low, but not absent, lysis in the AH_{50}, and patients with C9 deficiency may have values up to 30% of normal in the CH_{50}. The AP is activated in gram-negative sepsis, aHUS, AMD, C3 glomerulopathy, IgA nephropathy, and PNH. As described above, the majority of these conditions are associated with genetic variants in complement proteins. Screening for complement genetic mutations that includes

a multigene panel is available in many laboratories. The gene panel offered may vary slightly among the different laboratories conducting these tests. All variants are usually reported according to Human Genome Variation Society (HGVS) nomenclature and classified based on the guidelines established by the joint consensus of the American College of Medical Genetics (ACMG) and the Association of Molecular Pathology. Laboratories that specialize in functional analysis of genetic variants can further assist in defining the significance of the variants. Laboratory values may show decreased C3 with decreased or normal CH_{50}, and normal C4 levels (see Table 40.4). However, normal C3 levels do not exclude the presence of mutations in complement regulatory proteins, because C3 is an acute-phase reactant with elevated synthesis during disease states. Also, rarely is the predisease value known and, furthermore, there is a rather wide normal range.

Evaluation of AP function also includes measurement of serum concentrations of FH, FI, anti-FH Ab, and CD46/MCP expression on leukocytes by flow cytometry. Since most patients carry a heterozygous mutation in a complement protein, patients in whom the mutant protein is not expressed or is dysfunctional would be expected to have a 50% functional level. Measurement of serum antigenic levels will detect ~25% of patients with mutations in *CFH* and ~40% of mutations in *CFI*. Flow cytometry to measure CD46/MCP expression will detect ~75% of the mutations.

LP function (and MBL deficiency) is determined by using a specific ELISA, in which the patient's serum is placed into wells coated with mannan. Binding MBL and activation of the LP results in the deposition of C4b and C4d, which are detected with mAbs. MBL levels may also be determined antigenically.

Heterozygous C1-INH deficiency, as described above, is associated with the clinical syndrome of HAE.[18] The diagnosis can be made on the basis of clinical findings and family history. C1-INH activity is reduced in these patients, and C4 protein is also low in 95% of patients, especially during attacks of edema. In type I HAE (85% of cases), C1-INH protein levels are low, but in type II HAE (15% of cases), an abnormal C1-INH protein is made, and antigenic levels are normal or elevated. There is an acquired form of C1-INH deficiency associated with autoantibodies to the inhibitor commonly seen in patients with lymphoma. In this case, low C1-INH is usually accompanied by decreased C1q as well as C4 and C2.

In clinical practice, evaluation of complement levels and genetic variants may be useful in a variety of circumstances. Initial consideration of complement deficiency may be appropriate in patients presenting with autoimmune conditions or repetitive pyogenic infections in the setting of a normal white blood cell (WBC) count and normal quantitative immunoglobulin levels (see Table 40.3). The complement profile can also be helpful in differential diagnoses of SLE and its look-alikes (see Table 40.4). Monitoring complement levels is frequently used to follow disease activity and response to therapy in a variety of conditions. In addition, identification and characterization of genetic variants helps to predict the risk of recurrence of a disease.

Role of Complement in Specific Immunological Diseases

Complement activation is involved in the pathogenesis of many immunological diseases. A general concept emerging from current research in this area is that most of the pathogenic effects of complement depend on the generation of C5a and the MAC. Further, it is becoming recognized that regardless of the initial activation mechanism, AP amplification is often needed to produce sufficient quantities of these mediators to cause disease. Finally, systems biology approaches increasingly reveal that members of the complement cascade interact with other inflammatory mediators, resulting in diseases that are a product of complex gene–environment interactions, such as asthma and Alzheimer disease.

Systemic Lupus Erythematosus (Chapter 52)

CLINICAL PEARLS

Complement Tests for Diagnosis and Monitoring of Systemic Lupus Erythematosus

- A low C4 and C3 assist in the diagnosis of systemic lupus erythematosus (SLE).
- Decreased C3 and C4 are associated with increased severity of disease, and especially with lupus nephritis.
- On serial observations, decreasing C3 and C4 levels predict and help to establish an SLE flare-up.
- Note: Decreases in C4 may precede decreases in C3.
- Remission after treatment of lupus often shows return toward normal levels of C4, followed by increases in C3.
- Note: Patients with SLE who have partial C4 deficiency may have persistently low C4 levels.
- Complete absence of CH_{50} implies the existence of a hereditary deficiency of one of the classical complement pathway components, usually C1q, C4, or C2.

Complement plays a dual role in SLE.[48,49,57,58] There is a strong association of genetic deficiencies of C1q, C1r, C1s, C4, C2, and, to a lesser degree, C3 with SLE, indicating a protective role. Three main complement-dependent mechanisms have been proposed: (1) complement-dependent clearance of immune complexes; (2) modulating the adaptive immune system, particularly through the development and maintenance of self-tolerance in B lymphocytes; and (3) a requirement for complement in the clearance of apoptotic cells and potential autoantigens released from damaged cells. The pathogenesis of SLE results, in large part, from an inflammatory response to immune complexes formed by autoantibodies (e.g., Ab to double-stranded DNA [anti-dsDNA]) binding to antigens from dead and dying cells. However, complement activation is believed to play a pathogenic role in tissue damage induced by autoantibodies in SLE. There is evidence for complement activation in skin and renal lesions of patients with SLE, as well as in autoantibody-mediated hemolytic anemia and thrombocytopenia.

Antiphospholipid Syndrome (Chapter 61)

Antiphospholipid syndrome is characterized by antiphospholipid Ab, recurrent fetal loss, vascular thrombosis, and thrombocytopenia. Antiphospholipid Abs are found in 50% of patients with SLE, and thrombotic events occur in about 50% of them. Antiphospholipid Abs identified in patients without SLE have similar clinical consequences. Disease pathogenesis has been attributed to the procoagulant effects of antiphospholipid Abs. A mouse model of antiphospholipid Ab syndrome has been used to demonstrate that injection of pregnant mice with human IgG antiphospholipid Ab results in fetal loss and wasting. In this model, complement is required for pathogenesis, and treatment with complement inhibitors is protective. Studies in the mouse model are consistent with initial complement activation by antiphospholipid Ab bound to the decidua, followed by C5a

generation and recruitment of neutrophils. The AP as well as the CP was required for pathology. Interestingly, C3 deposition in the decidua was decreased if neutrophils were depleted, suggesting an amplification pathway mediated either by tissue damage or by neutrophil release of complement components.

Rheumatoid Arthritis (Chapter 53)

Patients with RA generally have normal or elevated complement values systemically.[58,59] There is, however, evidence for local complement activation in joint fluid, in synovia, and in rheumatoid nodules. In addition to being elevated in the joints of patients with RA, complement activation products are also found in patients with osteoarthritis, SLE, Reiter syndrome, and gout. Concentrations of C3a and C5a in joint fluid are higher in RA than in other types of arthritis. An important role for complement activation in the pathogenesis of RA is suggested by studies in two animal models—collagen-induced arthritis and the K/BxN-derived Ab transfer model. In the first model, inflammatory joint disease was ameliorated by treatment with an Ab to C5 that blocks its cleavage, preventing generation of C5a and the MAC. In the second model, disease was prevented by genetic deficiency of factor B, but not C4, indicating an essential involvement of the AP.

Vasculitis (Chapters 59 and 60)

Human vasculitides encompass a spectrum of disease mechanisms and clinical manifestations. Some, such as giant-cell arteritis and the antineutrophil cytoplasmic Ab (ANCA)–associated vasculitides, granulomatosis with microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis, are not usually associated with local complement deposition or evidence of systemic complement depletion. Despite that, a "self-fueling inflammatory amplification loop," as a result of the generation of C5a by activated neutrophils and neutrophil priming by C5a, appears to be able to drive necrotizing vascular injury. Additionally, in vasculitides associated with circulating immune complexes, C3b, MAC, and/or AP components are deposited in lesions, and complement profiles consistent with CP and/or AP activation are found (see Table 40.4).

Immunological Renal Diseases (Chapter 68)

Complement activation is evident in most types of glomerulonephritis, with the site and pathway of activation dependent on the location of immune complex or autoantibody deposition. AP activation has been identified in IgA nephropathy, poststreptococcal glomerulonephritis, and C3 glomerulopathy (C3G). More recent results have implicated activation of the LP in IgA nephropathy. Glomerular deposition of MBL has been associated with greater histological damage and higher proteinuria.

C3 glomerulopathy is a chronic progressive form of glomerulonephritis characterized by complement dysregulation, which results in prominent C3 deposition in kidney biopsies on immunofluorescence. C3 glomerulopathy has been historically called MPGN and was divided into three histological groups, designated type I, II, and III based on electron microscopy findings. Given that the historical classification of MPGN did not help delineate disease pathogenesis and as MPGN was increasingly being viewed as immunoglobulin-mediated (associated with CP activation) and non–immunoglobulin-mediated (associated with AP activation), the term C3 glomerulopathy was introduced in 2010. *C3 glomerulopathy* is used to describe those cases of glomerular involvement secondary to the AP activation, with an emphasis on immunofluorescence microscopy findings. The two major subgroups of C3 glomerulopathy are dense deposit disease (DDD) and C3 glomerulonephritis (C3GN) based on the location of the deposits on electron microscopy. DDD was previously classified as MPGN type II.

In glomerulonephritis secondary to immune complex disease (immunoglobulin-mediated, such as SLE and forms of MPGN), complement activation is primarily by the CP, and C4 is detected along with C3 and IgG in glomerular deposits. Complement activation contributes to renal disease by attracting and activating inflammatory cells through the anaphylatoxin C5a and by direct damage to cells through the MAC. Pathology caused by inflammatory cell infiltration is predominant when subendothelial immune complex deposition and complement activation occur.

In contrast, in non–immunoglobulin-mediated glomerulonephritis (current C3G), defects in the tightly regulated AP are believed to result in excessive activity of the C3 convertase. This can occur either in the presence of the C3 nephritic factor (C3Nef), which is a stabilizing autoantibody, or in the setting of deficient functional FH activity, either through mutations or acquired defects. C3NeF is a pathogenic autoantibody that binds to the AP C3 convertase (C3bBb), preventing its decay and regulation by FH and FI. Absence of functional FH results in unregulated C3 convertase activity, resulting in uncontrolled glomerular inflammation and renal disease. Understandably, such reclassification has helped target treatment, for example, by using plasma infusion or exchange and even the anti-C5 mAb eculizumab in certain cases.

Asthma (Chapters 43)

Asthma is a chronic inflammatory disease of the lung, in which Th2 responses to environmental allergens frequently play a critical role. The development of mice deficient in receptors for C3a and C5a has led to a new understanding of the roles of

TABLE 40.4 Complement Test Interpretation

Pathway	CH_{50}	C4	C3	Related Diseases
CP	↓	↓	↓	SLE, serum sickness, vasculitis, subacute bacterial endocarditis, MPGN (type I)
AP	↓	N	↓	Poststreptococcal glomerulonephritis, MPGN (type II)
Fluid-phase activation of the CP	↓	↓	N	C4NeF, HAE, cryoglobulinemia
Fluid-phase activation of the AP	↓	N	↓	FH or FI deficiency, C3NeF, MPGN (type II)
Acute-phase response	↑	↑	↑	Acute and chronic inflammation
Decreased CH_{50} (sample collection problems)	↓	N	N	Cryoglobulins, cold activation, sample mishandling; coagulation-associated activation
Decreased CH_{50} (biosynthetic)	↓	N	↓	Severe liver disease; decreased C3, C6, C9

the complement anaphylatoxins in asthma. Several studies have demonstrated a correlation between C3a and C5a release in asthmatic lungs and the influx of eosinophils and neutrophils. C3-deficient and C3aR-deficient mice were protected from development of acute bronchoconstriction, airway inflammation, and airway hyper-responsiveness. C5a inhibition had similar effects on the response to challenge in an established allergic environment. However, in contradiction to these findings, C5 deficiency was genetically linked to susceptibility to experimental allergic asthma. Further studies found that C5a signaling (most likely through the C5aR on pulmonary DCs) during initial pulmonary exposure to allergen decreased Th2 cytokine and IgE production, thereby preventing the initiation of the allergic response. Thus, it appears that both the C3a–C3aR and C5a-C5aR axes contribute to asthma pathogenesis. However, how disruption of their homeostatic roles on different immune cells versus the bronchial epithelium contributes to asthma pathogenesis remains to be understood.

Neurological Disease

Proteins from the complement system are normally found in the central nervous system (CNS) and the peripheral nervous systems. Low levels of hemolytic complement (0.25% of serum levels) can be measured in the cerebrospinal fluid if care is taken to stabilize it with gelatin during storage. Levels of anaphylatoxins are increased in the CNS when the blood–brain barrier is impaired. Complement proteins and regulatory proteins are synthesized by glial cells and astrocytes, and their synthesis is enhanced by inflammatory cytokines, such as IL-6. There is evidence both from human multiple sclerosis (MS) (Chapter 65) and the animal model, experimental allergic encephalitis (EAE), that complement activation with the generation of the MAC contributes to the demyelination in these diseases. Generation of the MAC can lead to oligodendrocyte death, generation of inflammatory mediators, or a repair process in which myelin synthesis is decreased. Complement activation on myelin and oligodendrocytes is initiated by antimyelin Ab or directly by myelin through the CP. There is evidence of MAC formation in the cerebrospinal fluid of patients with MS, and complement depletion, inhibition, and genetic deficiency are protective in rat and mouse models of EAE.

In any disease in which the host synthesizes an autoantibody, it may bind to its target antigen and fix complement. In turn, the complement system could then contribute to tissue injury and thereby disease pathogenesis and thus be a therapeutic target. Neuromyelitis optica (NMO) and myasthenia gravis (MG) are two such examples in which the target antigen is known, autoantibodies are made, and complement activation occurs at the disease site. Moreover, in both diseases a mAb to C5 has been approved for treatment by the FDA.

There is also evidence of complement activation in degenerative neurological conditions such as Alzheimer disease. In Alzheimer disease, neurofibrillary tangles and senile plaques composed of β-amyloid and other proteins develop, resulting in neuronal loss and dementia with progressive loss of cognitive function. Complement activation products C1q, C4, C3, and MAC components, as well as clusterin (ApoJ) and vitronectin (S40), are found deposited in areas of β-amyloid, suggesting CP activation. Peptides derived from β-amyloid were shown to activate C1 directly by binding to the collagen-like domain. SAP, a component of all types of amyloid, including β-amyloid, activates the CP as well. There are limited data on the role of complement in the pathogenesis of Alzheimer disease, with some studies reporting enhanced disease following complement inhibition and another finding decreased inflammatory changes and neuronal degeneration in C1q deficiency. Finally, excessive complement activity, notably C4, has been implicated in the development of schizophrenia and has been associated with reduced numbers of synapses. This suggests that the role of complement proteins in neuropsychiatric illness extends beyond inflammation-mediated tissue damage.[60,61]

Ischemia/Reperfusion Injury

I/R injury refers to injury induced by inflammatory mediators, such as reactive oxygen intermediates produced by activated neutrophils, following the reperfusion of hypoxic tissue. Different pathways of complement activation may be important in different sites of injury, probably because of differences in expression of complement regulatory proteins and the nature of the tissue damage and the antigens exposed to the innate immune system. The primary complement mediators of tissue injury are C5a and the MAC acting locally and, in some cases, C5a acting systemically. In experimental renal I/R injury and in human tubular necrosis, the AP appears to be directly activated and neither Ab nor the CP is required. However, in intestinal I/R injury, the CP as well as the AP are required, and a natural IgM Ab to a newly exposed antigen on damaged endothelium initiates complement activation. In coronary artery ligation/reperfusion models, innate recognition of epitopes of ischemic tissue by MBL and CRP leads to lectin and CP activation, respectively.

ON THE HORIZON

Future Directions in Complement Research

- Functional analysis of polymorphisms and rare variants in complement proteins identified in genome-wide association studies (GWAS) and by next-generation sequencing of inflammatory and autoimmune diseases will be functionally characterized to provide insight into pathogenesis and treatment.
- Genetic sequencing of entire complement activation pathways and their regulators and receptors in patients with inflammatory and autoimmune diseases will reveal novel pathogenic mechanisms and approaches to diagnosis and therapy.
- RNA sequence analysis will identify "up and down" regulation of complement proteins in human disease.
- Structural analysis of complement protein complexes will lead to targeted small molecules to inhibit or enhance complement activation.
- Therapeutic trials of existing agents and those in development will dramatically refine therapy of complement-mediated diseases.
- Proteome studies in patients with infectious, inflammatory, and autoimmune diseases will reveal patterns of complement activation and biomarkers for diagnosis, disease activity, and monitoring responses to therapy.

COMPLEMENT-BASED THERAPEUTICS

The multiple roles of complement in inflammatory and autoimmune diseases make it an attractive target for therapeutic intervention. Recombinant complement inhibitors, inhibitory mAb, and peptide-based receptor inhibitors have been developed to block the detrimental effects of the complement activation fragments.[61] As described above, products of the complement cascade have many beneficial effects in host defense and the adaptive immune response. The detrimental effects of complement

activation are commonly associated with C5a and the MAC. Thus, targeting either the generation of C5a or its association with C5aR might be expected to control inflammation while maintaining other important functions, such as opsonization. An anti-C5 mAb that prevents C5 cleavage (eculizumab) has been approved for human use in the treatment of PNH,[61] atypical HUS, NMO, and MG. Other drugs targeting the C5 pathway, as well as mAb directed to components of the AP (e.g., factor B, factor D), are under investigation for C3G and AMD. Peptides and mAb directed at the C5aR, as well as upstream of C3 convertase production, have shown promise in a number of inflammatory models in animals and are being evaluated for the treatment of sepsis, reperfusion injury, asthma, and IgA nephropathy. Other approaches that are being developed will target complement regulatory proteins to specific cell or tissue targets. As the importance of this system is clarified in a variety of inflammatory diseases, it is likely that further research will establish new complement-based therapeutic agents for additional applications.

Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

Susan L. Gillespie, Javier Chinen and Mary E. Paul

There is much to celebrate when considering the quest to end the human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) epidemic worldwide. World Health Organization (WHO) initiatives, including the scale-up of HIV testing, early initiation of treatment, more efficacious antiretroviral (ARV) medications, and improvements in disease monitoring, have resulted in people infected with HIV now living longer and healthier lives with fewer AIDS-related deaths. The number of new infections has also declined due in part to multipronged HIV prevention strategies including pre-exposure prophylaxis (PrEP), improvements in interventions to prevent mother-to-child transmission (PMTCT), and early infant diagnosis and treatment.

According to the Joint United Nations Programme on HIV/AIDS (UNAIDS), at the end of 2018, an estimated 37.9 million people worldwide were living with HIV or AIDS (Fig. 41.1).[1] The annual number of deaths from AIDS-related illness globally has fallen from a peak of 1.7 million in 2004 to 770,000 deaths in 2018. Also encouraging is the decline in new infections. Since peaking at 2.9 million infections in 1997, year by year the number of new HIV infections has continued to decline, down to 1.7 million new infections in 2018.

KEY CONCEPTS

Trends in HIV Infection

- Global rates of HIV infection have shown a slow but steady decline, but there is great heterogeneity in disease incidence among countries and regions.
- Despite progress made in adoption and implementation of HIV policies, certain populations are lagging behind in the global response, including infants, girls, and women, and members of key populations such as men who have sex with men (MSM), transgender individuals, those who inject drugs, and sex workers.
- The age demographic most affected in the developing world—that is, those aged 25–44 years—includes men and women who are economically productive and women of childbearing potential.
- Worldwide, most infections are acquired through heterosexual contact.
- In the United States, African Americans and MSM are disproportionately infected.
- The numbers of infections transmitted from mother to child are declining as access to prophylactic medications to prevent infection improves.

Similar encouraging statistics exist for children and adolescents with HIV infection. Of the 37.9 million people living with HIV worldwide, 2.8 million are children and adolescents age 0 to 19. There were 360,000 new infections in 2018 with 160,000 infections occurring in children age 0 to 9 and 190,000 in adolescents age 10 to 19. AIDS-related deaths occurred in 120,000 children and adolescents.[1]

Despite these encouraging improvements in global statistics, however, there is great heterogeneity in the progress made among individual countries and regions and among specific demographic groups. For example, although new HIV infections are declining in most countries, particularly those in sub-Saharan Africa that had been most affected by HIV, there has been an increase in the annual number of new infections in other regions of the world such as Eastern Europe, central Asia, the Middle East, and North Africa.

Certain populations are also lagging behind in the HIV response. For example, early infant diagnosis and access to antiretroviral therapy (ART) for children has fallen short of international goals, with only 58.8% of infants born to women living with HIV being tested in a timely manner and only 54.2% of children age 0 to 14 receiving ARV treatment. Girls account for 75% of new infections among adolescents. Additionally, members of specific demographic groups referred to as key populations remain at extremely high risk for acquiring HIV. Key populations and their sexual partners represent more than half of new infections. For example, gay men and other men who have sex with men (MSM), people who inject drugs, and sex workers are each more than 20 times more likely to acquire HIV compared to the general population. Transgender people are 12 times more likely.[1]

US PERSPECTIVE

The United States Centers for Disease Control and Prevention (CDC) estimate that approximately 1.2 million adults and adolescents older than age 13 were living with HIV in the US at the end of 2018, including 161,800 (13.8%) whose infection was undiagnosed. Despite ongoing prevention efforts designed to reduce the number of new cases of HIV infection, the number of new infections annually in the United States has remained stable, with an estimated 36,400 new infections in 2018.

Within the United States, there is great variability in both the geographical and demographic distribution of the disease, with more people living with HIV residing in states in the south and northeast. Certain segments of the population are disproportionately affected, specifically MSM and ethnic and racial minorities, including African Americans and Hispanic Americans (Fig. 41.2).[2]

In the United States and other developed countries, the number of children newly infected with HIV has decreased dramatically as a consequence of successful interventions against perinatal mother-to-child transmission. Among children born during 2017, 39 children were diagnosed with perinatally acquired HIV. At the same time, new pediatric AIDS cases and AIDS deaths also have plummeted, in large part as a result of powerful combinations of ARV drugs.[2]

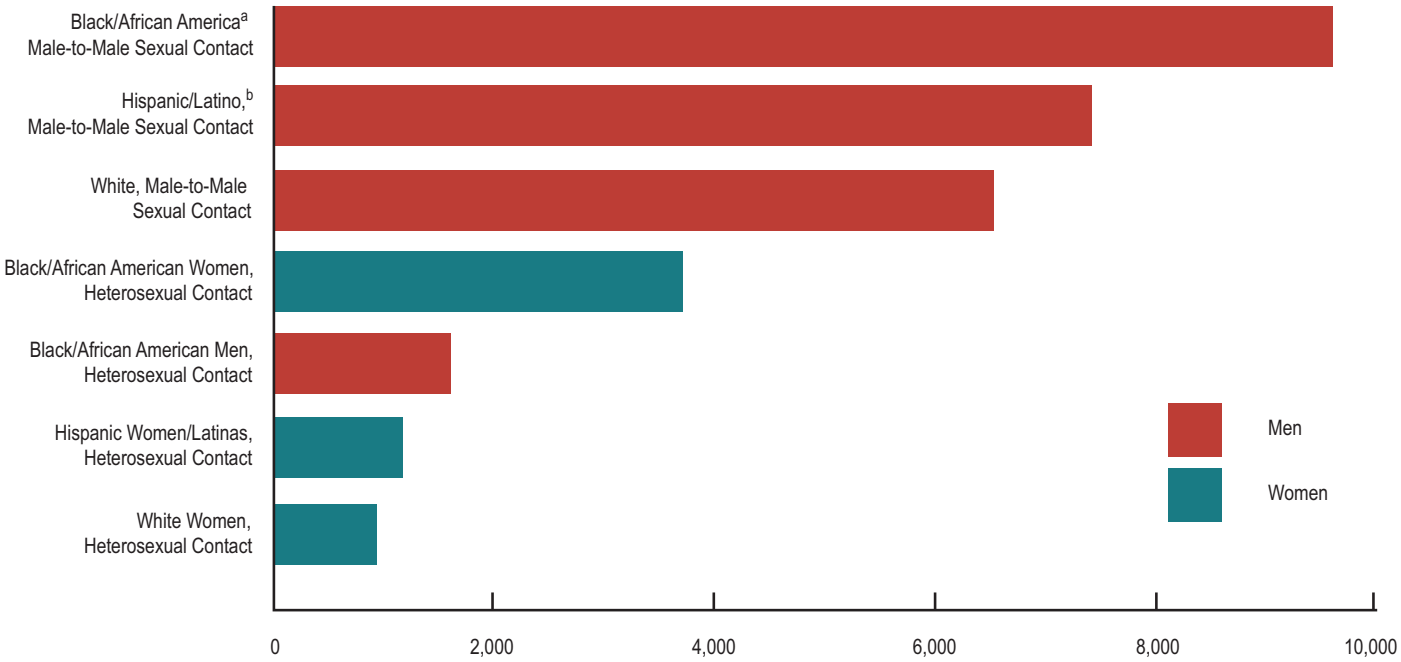

FIG. 41.2 New Diagnoses in the United States and Dependent Areas for the Most Affected Subpopulations, 2018. (https://www.cdc.gov/hiv/statistics/overview/ataglance.html.)

[a]Black refers to people having origins in any of the Black racial groups of Africa. African American is a term often used for people of African descent with ancestry in North America.

[b]Hispanic/Latino people can be of any race.

HIV IMMUNOPATHOGENESIS

HIV Life Cycle

HIV is a lentivirus that preferentially targets CD4 T cells by binding the viral glycoprotein (gp) 120 glycoproteins to two cell surface proteins, the CD4 receptor and either the CCR5 or the CXCR4 chemokine receptor (Fig. 41.3).

Other cell targets for HIV are monocytes and dendritic cells, which can be infected even though they present with significantly less expression of these receptors than CD4 T cells.

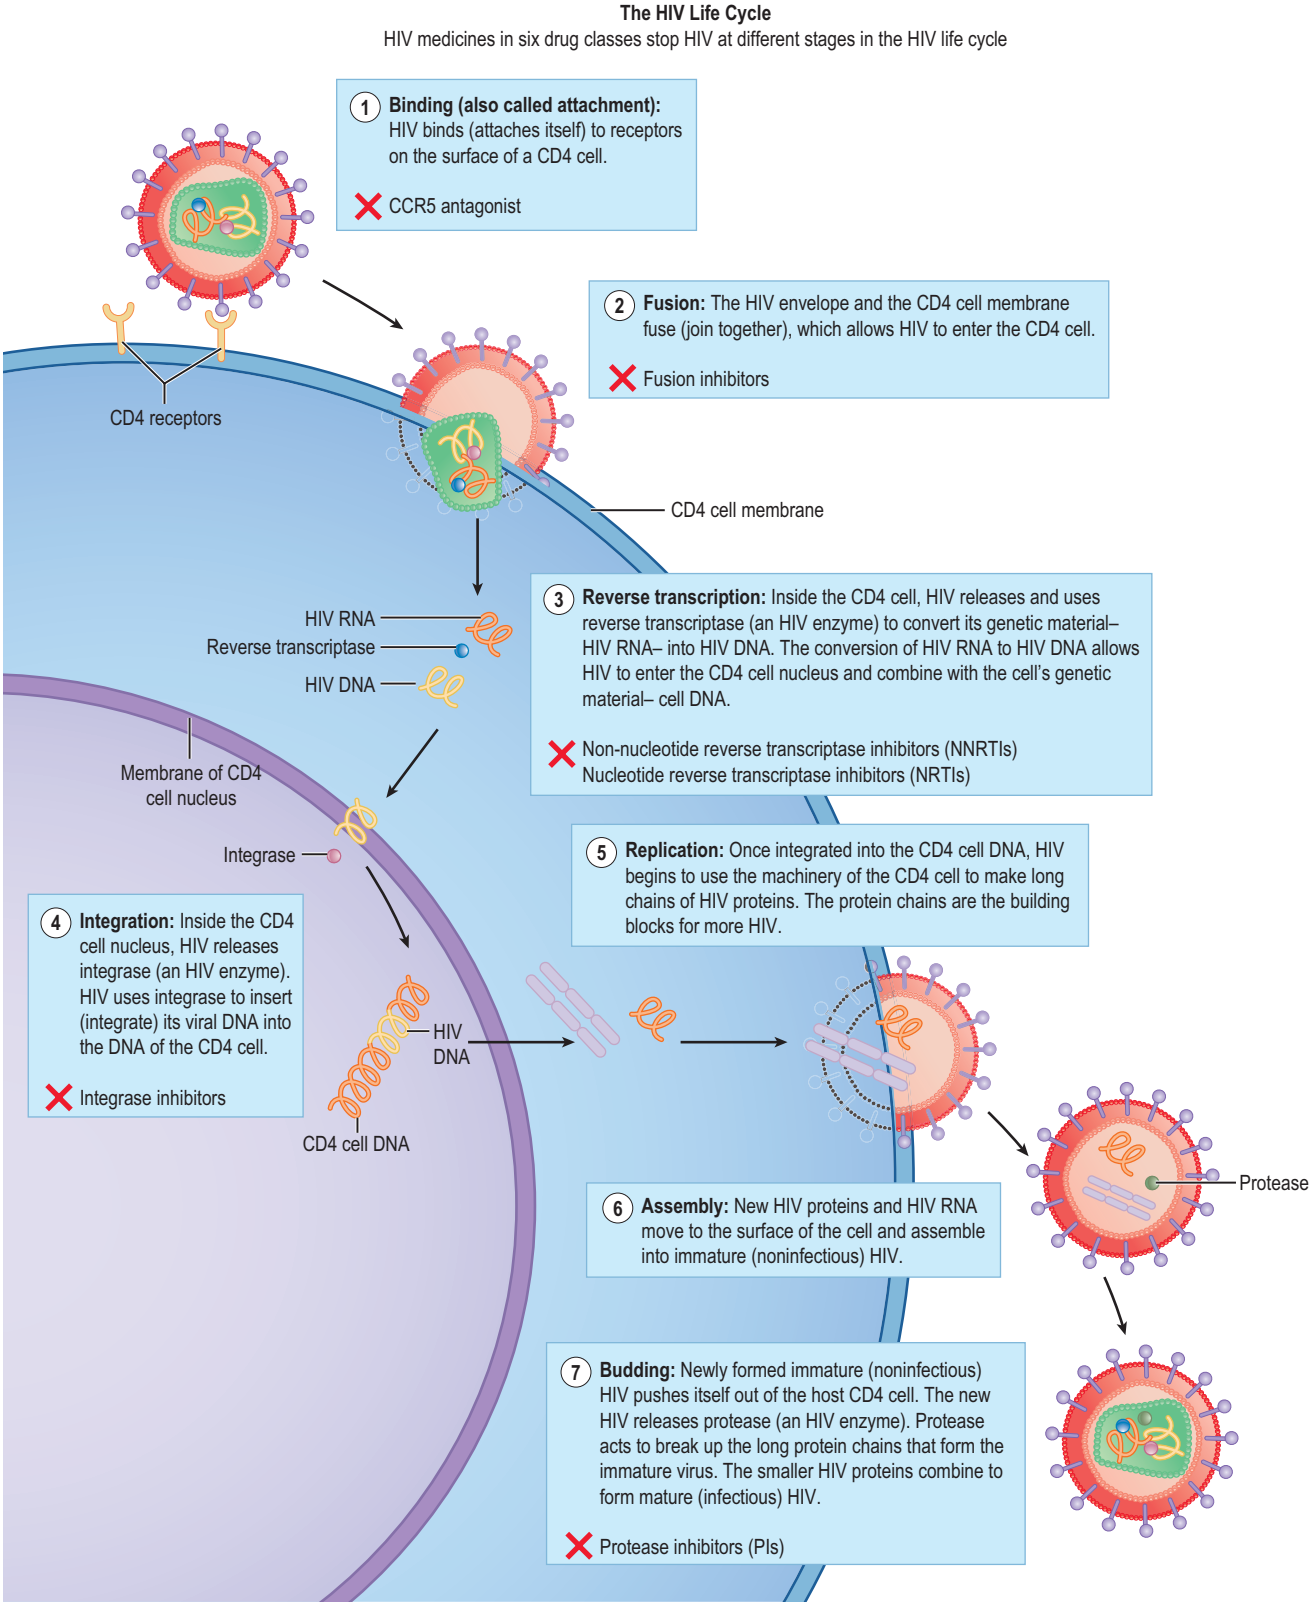

FIG. 41.3 The Human Immunodeficiency Virus *(HIV)* Life Cycle and Stage Susceptibility to Antiretroviral Therapy. (From https://www.info.nih.gov/education-materials/fact-sheets/19/73/the-hiv-life-cycle.)

After the virus is attached to the cell, the viral membrane fuses with the cell membrane and viral RNA enters the cytoplasm. It is transcribed by the viral reverse transcriptase (RT) into double-stranded DNA, which is translocated to the cell nucleus and is subsequently integrated into the cell genome as a provirus, mediated by virus integrase enzyme. Viral proteins Tat and Nef, in addition to intrinsic T-cell activation factors, induce active transcription and expression of viral RNA and proteins to produce new virus particles that exit the host cell to infect other target cells. CD4-independent viral entry has been demonstrated in B cells, astrocytes, and kidney epithelial cells; however, efficient viral replication is not likely to occur in these cells.

HIV Infection Through Mucosa

The mucosa of the gastrointestinal tract and the genital tract are the most significant ports of entry of HIV,[3] with viral infections occurring through the anorectal mucosa more efficiently than through the female genital tract, most likely due to anatomical differences in these tissues. The mucosa in the cervix and vagina has a multilayered epidermis and is covered with thick mucosa. In contrast, the anorectal mucosa has a monolayer of cylindrical epithelial cells. The diversity of HIV virion mutations within an individual shortly after anorectal infection is larger in number than after vaginal infection, supporting the protective role of the mucus and the multilayered epithelia of the female lower genital tract. HIV infection might be favored with mucosal damage due to trauma or due to inflammation secondary to other sexually transmitted diseases (Fig. 41.4).

Cells of the innate and adaptive immune system are found in mucosal tissues developing immune responses, immune tolerance, and/or inflammation when in contact with microbes or foreign substances. Anti-HIV–specific CD4 T cells and CD8 T cells are found in the cervical and vaginal mucosa of women with chronic HIV infection, although simultaneous significant viral shedding suggests that the presence of these T cells is not sufficient to control the spread of the virus.

The gastrointestinal tract contains the largest amount of lymphoid tissue in the body. HIV replication can be detected in the germinal centers of lymph nodes within a week, and viremia is found within 21 days of infection. Activation and destruction of CD4 T cells lead to massive depletion of CD4 T cells, and an increase of serum inflammatory cytokines, which might explain the flu-like syndrome that patients experience during acute HIV infection.[4] Simultaneously, HIV reservoirs get established with viral infection and integration of viral DNA in resting cells. Studies in people with chronic HIV with different degrees of viremia suggest that the presence of HIV-specific cytotoxic T cells in the gastrointestinal mucosa is the immune parameter most associated with preservation of mucosal HIV-specific CD4 T cells and viremia control. Mucosal Th17 cells are particularly susceptible to HIV infection and their depletion is associated with reduced secretion of interleukin (IL)-21, interleukin-11 (IL-11) an interleukin needed for the integrity of the mucosal barrier.[5] Natural killer (NK) cells, γδ T cells, and innate lymphoid cells in the mucosa are activated, contributing to persistent inflammation. In chronic HIV infection, these cells are eventually depleted from tissues.[6]

Chronic Immune Activation

Progressive T-cell depletion in HIV infection is induced in part by a state of chronic immune activation, which also contributes to noninfectious inflammatory complications such as cardiovascular disease.[4,7] In individuals with HIV, immune activation is caused by increased microbial translocation in the gut, direct Toll-like receptor (TLR) stimulation by HIV, and coinfection with other pathogens, resulting in high serum and tissue levels of inflammatory cytokines, such as IL-6. Lipopolysaccharide levels are also increased in peripheral blood, which in turn can activate the coagulation cascade and promote thrombosis. Low or normal levels of regulatory T cells are observed in long-term non-progressors (LTNPs), suggesting that these cells play a role in anti-HIV immunity, most specifically in modulating CD8 T-cell immunity. It has also been suggested that regulatory T cells may play a beneficial role by reducing chronic immune activation.[8]

HIV Latency and HIV Reservoirs

The most difficult challenge in the efforts to achieving cure of HIV infection is the presence of HIV reservoirs, defined as resting or nonreplicating cells infected with HIV.[9,10] Anti-HIV

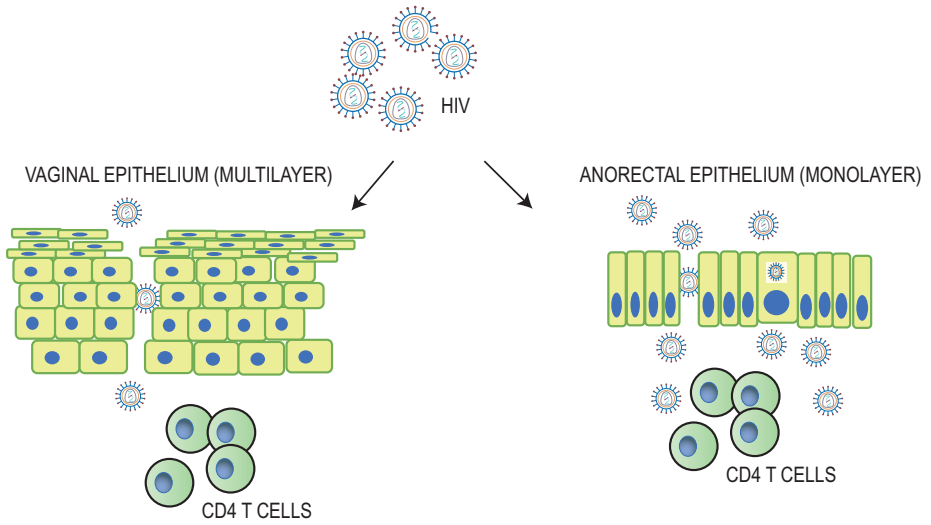

FIG. 41.4 Anorectal and Vaginal Epithelium Are Ports of Human Immunodeficiency Virus *(HIV)* Entry.

drugs are able to efficiently suppress HIV replication; however, when these drugs are stopped, activation of resting cells results in production of new virus.[11] Most proviral DNA is detected in memory CD4 T cells in lymphoid tissues and in peripheral blood. Infected T cells producing very low levels of viral RNA and proteins are most likely to avoid immunosurveillance. Molecular mechanisms resulting in reduced or near absent HIV transcription include the balance of negative and positive transcription factors, transcription interference, and DNA methylation or other epigenetic modifications. T-cell activation leads to HIV replication by changing the dynamics of transcription factors, such as Nuclear Factor Kappa B (NFκB), promoting gene expression, including expression of HIV genes. HIV reservoirs are established during the acute phase of the infection: thus the recommendation of early intensive treatment to reduce the population of latently infected CD4 T cells.[9] The reservoir increases in size with persistent HIV replication; and even though viremia decreases after successful antiretroviral treatment, HIV genetic diversity studies suggest that the number of T cells harboring proviruses remains large.[12] Based on the natural decay of HIV infected, resting T cells, which have a half-life of 44 months, it is estimated that it would take a lifetime to eliminate the HIV reservoir in a patient receiving an optimal ARV regimen.[13] Nonreplicating monocytes, astrocytes, and glial cells are other latently infected cells that form part of the HIV reservoir.

KEY CONCEPTS

HIV Reservoirs

- HIV reservoirs are groups of cells that are infected by the virus, and remain inactive for a period of months or years. When these cells are activated, viral replication occurs.
- HIV reservoirs have been difficult to target due to reduced or absent viral expression.
- HIV reservoirs are established during the early stages of infection.
- The size of HIV reservoirs is proportional to the degree of HIV viremia.

ANTI-HIV IMMUNITY

Immunity against HIV depends mostly on specific cytotoxic CD8 T cells, which recognize infected cells by their expression of viral proteins in the context of human leukocyte antigen (HLA) class I molecules (Fig. 41.5). This interaction results in CD8 T-cell activation with release of cytokines, enzymes, and cytotoxic granules, leading to death of the infected cell.[4,14] These antiviral cells are most efficient when certain combinations of HLA and virus strain occur in the host, such as the presence of cells bearing the HLA-B27 allele and infected with a clade B viral strain.

However, HIV infection almost always results in global T-cell destruction and exhaustion, unless ARV therapy is administered. HIV reservoirs remain practically ignored by CD8 T cells, in part due to the low level of viral protein expression, and pharmacological agents are being investigated to activate quiescent cells with integrated proviral DNA.[10] Of note, the presence of anti-HIV CD8 T cells decreases after the start of ARV therapy, presumably due to the reduced viremia and the low viral protein expression of HIV-infected resting cells. In addition, viral escape mutants not recognized by CD8 T cells become predominant in individuals with chronic HIV infection.

Characterization of the anti-HIV antibody response is of priority to optimize the design of vaccines and monoclonal antibodies for active and passive immunization, respectively. These vaccines are aimed to induce an immune response that reduces or prevents HIV infection at the mucosa by interfering with cell infection, as well as helping to reduce viral load at infected tissues. Non-human primate models of HIV infection have proven that this protective effect of anti-HIV antibodies can be achieved; however, it has yet to be demonstrated in humans.[15] Antibody responses are initially directed against the gp41 portion of the Env protein, and over time develop against other HIV proteins. Several studies in individuals with HIV have identified antibodies that target epitopes common to several HIV strains, known as broadly neutralizing antibodies (Fig. 41.6).[16]

Similarly important antibody functions are mediating antibody-dependent cytotoxicity and enhancing phagocytosis. These responses and subsequent anti-HIV antibodies might

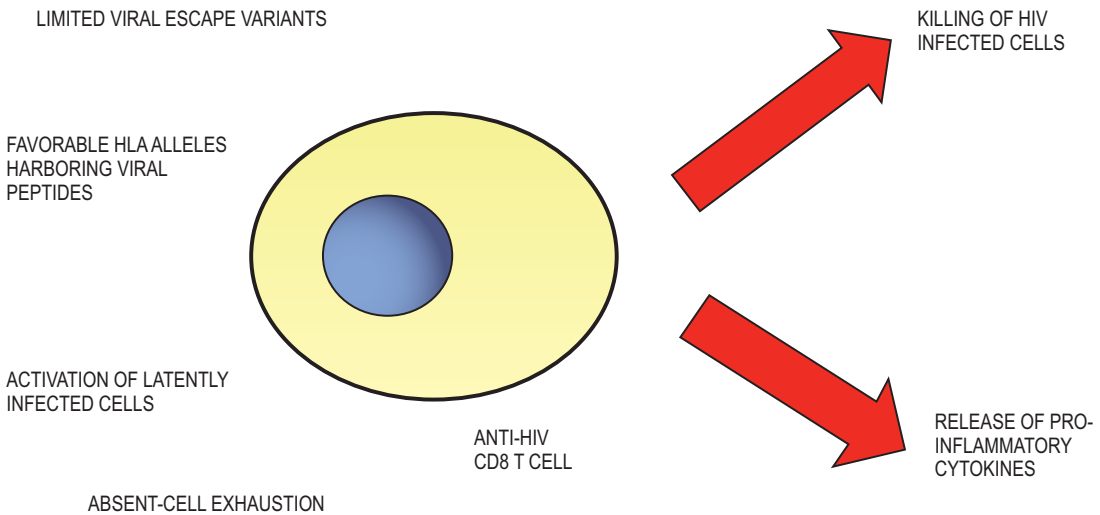

FIG. 41.5 Anti-Human Immunodeficiency Virus CTL Function (Factors Affecting CD8 T-Cell Activity). *CTL,* Cytotoxic T lymphocyte; *HIV,* human leukocyte antigen.

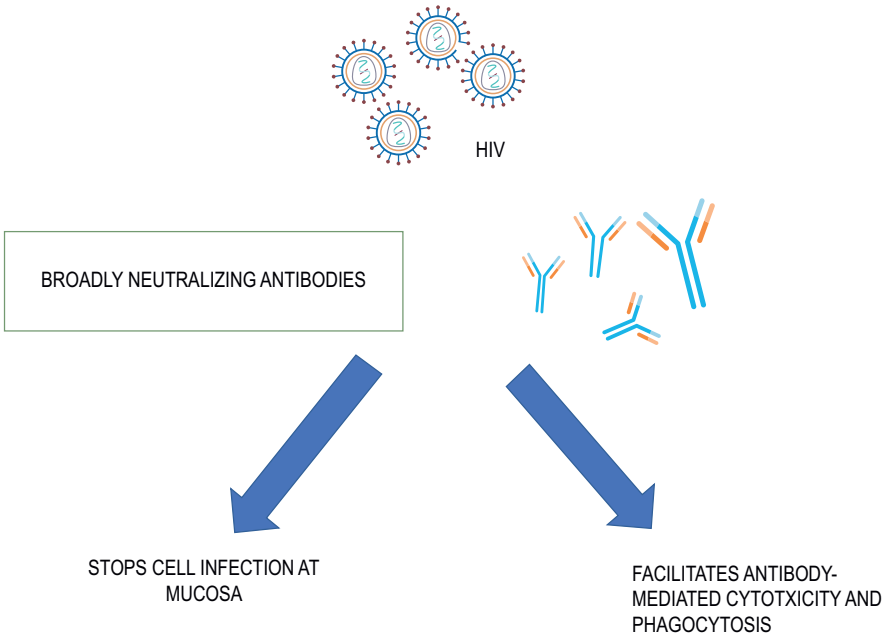

FIG. 41.6 Broadly Neutralizing Antibodies. *HIV,* Human immunodeficiency virus.

have reduced efficacy because of the rapid production of escape mutants, with subsequent generation of new antibody specificities. This is the most compelling argument explaining why antibody-based approaches are not likely to influence chronic infections. Clinical trials to test the protection against HIV infection conferred by a cocktail of broadly neutralizing antibodies are currently under way.

INNATE IMMUNITY IN HIV INFECTION

Innate immunity mechanisms are active in HIV infection with a significant role in controlling HIV viremia and optimizing the adaptive anti-HIV immunity. Pattern recognition receptors, such as TLR and retinoic acid-inducible gene I (RIG-I)-like receptors, recognize viral proteins and nucleic acids leading to the activation of immune cells, most significantly induced by type I and type II interferon pathways, through interferon regulatory factor (IRF)3 and IRF7 (Fig. 41.7).[17]

One of these proteins is interferon-inducible protein 6 (IFI6), which binds HIV DNA after reverse transcription, activating the inflammasome and inducing cell death. Cyclic GMP-AMP synthase (cGAS) is another DNA-binding protein that signals activation of innate immunity cells.

KEY CONCEPTS

Innate Immunity in HIV Infection

- Anti-HIV innate immunity mechanisms play a significant role in the control of viremia, and the optimization of antiviral adaptive immunity.
- Innate immunity includes the expression of several antiviral proteins, some of which have been linked to long-term viremia control.
- NK cells, monocytes, macrophages, and epithelia are innate immunity cells that respond to HIV infection with inducing cell death and increasing secretion of cytokines, leading to activation of the adaptive immune response and inflammation pathways.

The HIV gp120 protein can activate TLR2 and TLR4 in epithelial cells, triggering local inflammatory responses and recruiting lymphocytes to the infection site. TLR7, TLR8, and RIG-I are intracellular proteins that recognize HIV RNA and activate antiviral mechanisms. TLR8 activates the NLRP3 inflammasome and the release of IL-1β. Anti-HIV proteins that are expressed after activation of pattern recognition receptors include apolipoprotein B mRNA-editing enzyme catalytic subunit-like 3G (APOBEC3G), tripartite motif (TRIM) 5a, sterile alpha motif and histidine aspartate domain containing protein 1 (SAMHD1), tetherin, schlafen 11 (SLF11), interferon-inducible transmembrane protein (IFITM), and myxovirus-resistance protein 2 (MX2). These proteins are also called restriction factors and are the first line of defense against HIV, with inhibitory molecular mechanisms ranging from uncoating, to inhibition of reverse transcription, to interfering with viral release. Cells of the innate immune system, such as monocytes, macrophages, and NK cells, are activated as a result of cytokine release. These cytokines mediate the complex interplay of the innate immunity with the adaptive immunity, increasing viral peptide expression for immune surveillance recognition, and favoring Th1 polarization of CD4 T cells, among other responses.[18]

CLINICAL FEATURES

If HIV infection is left untreated, its natural history involves the progression through three clinical phases: acute retroviral syndrome, chronic or latent infection, and finally AIDS. Each clinical phase correlates with specific events in the interaction between HIV and the host immune system. A small percentage of patients become long term nonprogessors (LTNP), and an even smaller percentage become elite controllers (see Long-Term Non-Progressors/Elite Controllers).

Acute HIV Infection

Soon after infection, unopposed by effective host immune responses, HIV rapidly replicates and disseminates to lymphoid tissues (see Immunopathogenesis: Gastrointestinal System). During this time, HIV virus cannot be detected in plasma. As virus rapidly expands in gut-associated lymphoid tissue and

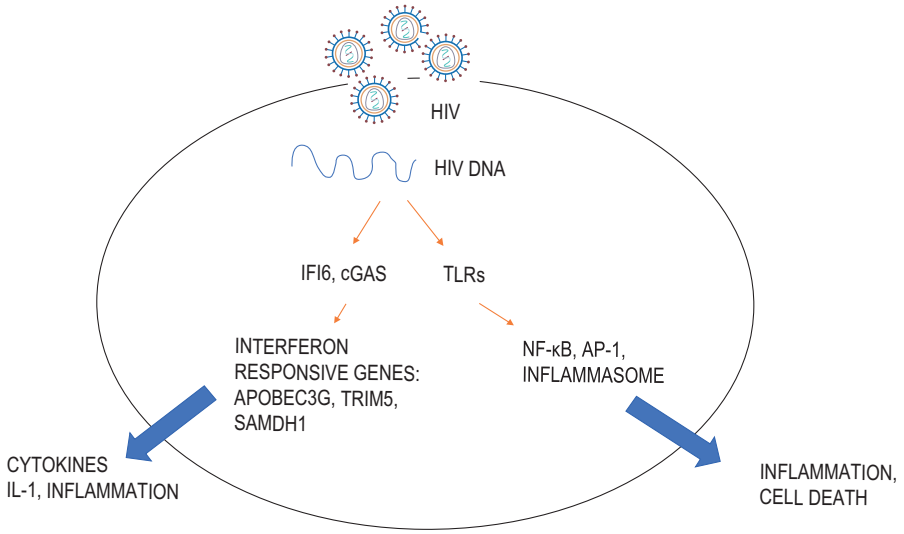

FIG. 41.7 Activation of Innate Immunity Mechanisms. *cGAS*, Cyclic GMP-AMP synthase; *HIV*, human immunodeficiency virus; *IFI6*, interferon-inducible protein 6; *IL-1*, interleukin-1; *NF-kB*, nuclear factor kappa B; *TLRs*, Toll-like receptors. For other abbreviations see text.

then spreads into the systemic circulation, there is a sharp rise in plasma viral RNA, reaching as high as 10 million copies per milliliter. This high level of viremia causes irreversible destruction of reservoirs of helper T cells and establishes viral latency, the silent integration of HIV-1 DNA into the genomes of resting T cells. Plasma viremia typically peaks 3 to 4 weeks after transmission, and then, as a result of the depletion of susceptible CD4 T cells and HIV-specific immune responses, the virus load precipitously declines, followed by more gradual decline for several weeks before reaching a set point.

The presentation of the acute retroviral syndrome associated with acute HIV infection can be highly variable, ranging from asymptomatic to severe illness requiring hospital admission. The most commonly described signs and symptoms of acute infection are nonspecific and resemble an influenza or mononucleosis-like illness, with associated fever, fatigue, myalgia, rash, and headache (Table 41.1).[19]

CLINICAL PEARLS

Acute Infection Is an Opportunity for Early HIV Diagnosis

- Acute HIV infection often causes a nonspecific viral syndrome, often described as being similar to influenza or infectious mononucleosis.
- Many patients present to a clinician at this stage, but most are not recognized as HIV infection.
- Irreparable damage to the host immune system occurs during this stage of HIV infection, resulting in chronic immune activation and the eventual collapse of the immune system.
- HIV viral latency is established during the acute infection as HIV DNA integrates with the host genome. Integrated viral genetic material makes cure of HIV impossible even after prolonged viral suppression with antiretroviral therapy (ART).
- ART initiated during the acute infection can halt the destruction of the body's memory T cells in the gut-associated lymphoid tissue (GALT) and lead to better long-term outcomes for the patient.
- Acute and early HIV infection is associated with high viral loads and increased infectiousness. ART initiated during the acute infection can lead to suppression of viral replication, lowering the viral load and decreasing the risk of onward infection.

The onset of symptoms typically occurs 2 to 4 weeks after transmission, coinciding with the period of high plasma viremia, and dissemination of virus and a burst of inflammatory cytokines. As the host develops HIV-specific immunity and the virus load decreases, CD4 and CD8 T cells recover, and the symptoms of the acute infection resolve. Although up to 90% of patients seek medical care for this illness, the nonspecific nature of the symptoms makes diagnosis of acute infection difficult. And absent a high index of suspicion, most newly infected individuals are not diagnosed until much later. Diagnosis of HIV in the acute or early phase enables the initiation of ART. Early treatment has many potential benefits including decreasing the severity of the acute infection, lowering the viral set point, and slowing disease progression. The public health implications of the acute HIV infection are enormous because the risk of transmission from individuals with acute infection appears to be much higher than that from those with established infection, in part because of the high viral load in blood and genital secretions during the acute phase.

Chronic HIV Infection

The acute infection is followed by a prolonged latent period that may last 8 to 10 years in adults but is much shorter in children. During this time, the HIV viral load fluctuates around a relatively stable set point.[20] The viral set point is a major determinant of infectivity and risk of disease progression, with higher viral loads being associated with more likely viral transmission, more rapid disease progression, and greater risk of death. The host immune response is insufficient to eradicate the infection but may be enough to contain viral replication for many years. Although commonly thought to represent a stalemate between viral replication and CD4 T-cell production, this period is actually characterized by a steady and inexorable decline of CD4 T cells (50 to 75 cells/μL of peripheral blood per year). As the infection progresses, most individuals develop clinical symptoms. The ability of the immune system to contain viral replication is overcome, and the viral load begins to increase. There is usually an inflection point in the CD4 T-cell curve marking the start of a period of more rapid decline in CD4 T-cell counts. As these counts fall, immunodeficiency, symptomatic disease, and AIDS eventually occur (Fig. 41.8).

TABLE 41.1 Clinical Signs and Symptoms of Acute HIV Infection

Features	Overall ($n = 375$) %	SEX		ROUTE OF TRANSMISSION	
		Male ($n = 355$) %	Female ($n = 23$) %	Sexual ($n = 324$) %	Injection Drug Use ($n = 34$) %
Fever	75	74	83	77	50

End-Stage HIV Infection: AIDS

As the peripheral blood CD4 T-cell count drops to less than 200 cells/μL, the immune system's ability to fight infection is compromised to the extent that AIDS-defining illnesses begin to appear. On the basis of the CD4 T-cell count, prophylaxis for opportunistic infections is administered (Table 41.2). Without treatment, most patients will succumb to opportunistic infections within 2 years of developing AIDS.

Long-Term Non-Progressors/Elite Controllers

A minority of individuals with HIV infection are called LTNPs because they do not progress to AIDS after a defined period in the absence of ARV therapy. A subset of these individuals are elite controllers because in addition to non-progression of disease, they are able to maintain undetectable viral loads throughout infection. Understanding the mechanisms involved in their ability to control the infection may be helpful in elucidating factors required for a functional cure of HIV.[20]

DIAGNOSIS AND MONITORING OF HIV INFECTION

Diagnostic Tests

The diagnosis of HIV infection depends on the detection of viral and host biological markers, which appear in a chronology that is typically consistent among individuals.[21] After infection there is an "eclipse period" during which no available diagnostic test is capable of detecting HIV. The earliest diagnostic markers, HIV RNA and HIV p24, can be measured 9 to 12 days and 14 to 19 days after infection, respectively (Fig. 41.9). HIV immunoglobulin is detectable approximately 3 weeks after and persists throughout infection. The time between infection and detection of HIV immunoglobulin is referred to as the seroconversion window period. Serological assays for HIV have historically been categorized as first-, second-, third-, and fourth-generation tests with improvement in assay sensitivity resulting in earlier detection of infection with each successive generation. More recently, the use of HIV test "generation" nomenclature is no longer recommended, and tests are now categorized based on the identified marker. First- and second-generation antibody tests are now referred to as IgG-sensitive tests, third-generation assays as IgM/IgG-sensitive tests, and fourth-generation as antigen-antibody immunoassays.

In 2014, the CDC and the Association of Public Health Laboratories (APHL) released an HIV laboratory testing algorithm designed to better detect acute infections and differentiate between HIV-1 and HIV-2.[21] This algorithm was updated in 2018 (Fig. 41.10).[22]

HIV Immunoassays

The CDC testing algorithm starts with an antigen-antibody immunoassay. These tests detect p24 antigen, and anti-HIV-1/HIV-2 IgM and IgG. A negative result is conclusive and generally requires no follow-up testing. The assay will be reactive if either p24 or HIV antibodies are present. Further testing is required to determine which combination of markers have been detected.

TABLE 41.2 Opportunistic Infection Prophylaxis and Treatment in Adolescents and Adults

Risk Factor	Agent	Prophylactic Medication
CD4 cell count <200 cells/μL	*Pneumocystis jiroveci*	Trimethoprim–sulfamethoxazole (TMP-SMX) or dapsone plus or minus pyrimethamine and leucovorin or aerosolized pentamidine or atovaquone
	Coccidioidomycosis	In endemic areas: fluconazole or itraconazole
CD4 T-cell count <100 cells/μL	*Toxoplasma gondii*	TMP-SMX or dapsone plus pyrimethamine plus leucovorin or atovaquone plus pyrimethamine plus leucovorin
	Histoplasmosis	In endemic areas: itraconazole
CD4 T-cell count <50 cells/μL	*Mycobacterium avium* complex (MAC)	Macrolide (clarithromycin or azithromycin) or rifabutin
	Cryptococcosis	In endemic areas: fluconazole or itraconazole
Purified protein derivative (PPD) >5 mm induration or recent tuberculosis (TB) contact but no active TB and no history of treatment for active or latent TB	*Mycobacterium tuberculosis*	Isoniazid (INH) + pyridoxine for 9 months. If unlikely to complete 9-month course and on highly active antiretroviral therapy (HAART): rifabutin plus pyrazinamide for 2 months
Contact with chickenpox or shingles in varicella-zoster seronegative individuals	Varicella-zoster	Varicella-zoster immunoglobulins (VZIGs)
Human immunodeficiency virus (HIV)–infected	*Streptococcus pneumoniae*	Pneumovax
	Meningococcus—for youth attending the military or college and consider for unvaccinated adults	Menactra
Negative anti-hepatitis B core antibodies (HBc) and previously unimmunized or underimmunized to hepatitis B	Hepatitis B	Recombivax-HB or Engerix-B
Negative anti-hepatitis A serology	Hepatitis A	Havrix

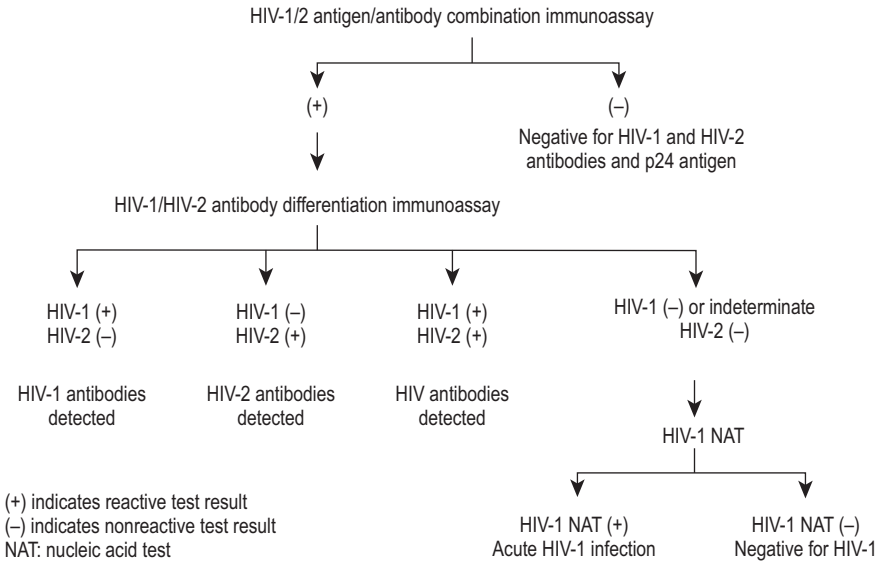

FIG. 41.10 Recommended Laboratory Human Immunodeficiency Virus *(HIV)* Testing Algorithm for Serum or Plasma Specimens. (From https://www.cdc.gov/hiv/pdf/guidelines testing recommendedlabtestingalgorithm.pdf)

To determine whether HIV-1, HIV-2, or both HIV-1 and HIV-2 antibodies are present, an HIV-1/HIV-2 differentiation assay is performed. Detection of either HIV-1 or HIV-2 antibodies confirms HIV-1 or HIV-2 monoinfection. Detection of both HIV-1 and HIV-2 antibodies confirms HIV-1/HIV-2 dual infection. If the assay is unable to confirm presence of antibodies to either HIV-1 or HIV-2 then there is a possibility of acute HIV infection and sample is then tested for HIV-1 nucleic acid. If HIV-1 nucleic acid is not detected, then HIV infection is excluded. If HIV-1 nucleic acid is detected, HIV infection in the acute stage has been diagnosed. HIV RNA detection plays a valuable role in identifying early infection before seroconversion and in confirming reactive screening tests.

HIV Nucleic Acid Amplification Tests

Nucleic acid amplification tests are used to detect HIV RNA or DNA in biological samples. HIV RNA polymerase chain reaction (PCR) is used to identify the presence of HIV RNA using qualitative assays or to quantify the virus load or the extracellular viral RNA in plasma and serum. The HIV viral load is used to monitor the effectiveness of ART in suppressing viral replication. HIV DNA PCR is a qualitative assay used to detect HIV viral DNA in peripheral blood mononuclear cells. Detecting HIV DNA often from whole blood samples collected on filter paper as dried blood spots (DBS) has allowed the early diagnosis of HIV in perinatally exposed infants and is still used for this purpose in international settings. HIV DNA PCR is not typically available for HIV diagnosis in the United States, having been largely replaced by qualitative HIV RNA PCR.

Point-of-Care Diagnostic Tests

Point-of-care (POC) HIV diagnostic tests, often described as "rapid" tests, are the most commonly used HIV screening tests. POC HIV tests are self-contained enzyme immunoassays that detect HIV antibodies in whole blood or oral fluid specimens and can be used at the POC, able to be performed by non-laboratory staff, and yield results within 30 minutes. Because results of rapid tests are available quickly, individuals can learn of their results in a single encounter. POC tests are slightly less sensitive but are as specific as laboratory assays. POC tests, often performed by lay counselors, have enabled widespread testing in resource-limited settings, such that, in 2017, 75% of people living with HIV knew their HIV status.[23]

Monitoring Tests

Once infection is confirmed, specific laboratory tests are performed at baseline and then periodically to monitor efficacy of ART, HIV disease status, and progression, to inform treatment decisions, and to identify end-organ toxicity.[24] CD4 T-lymphocyte (CD4) cell count and HIV RNA (viral load) are the two markers of ART responses and HIV disease progression.

CD4 T-Cell Count

The CD4 T-cell count is used to assess immune function, is essential for identifying those with severe immunosuppression, and is predictive of potential for disease progression and mortality. The CD4 T-cell count determines whether prophylactic medications for opportunistic infections are needed. Once a patient is on ART, an increasing CD4 T-cell count also helps confirm the efficacy of the therapy.[24] In children younger than 5 years of age, CD4 percentage is preferred because it typically remains stable in the setting of age-related changes in absolute CD4 count in this age group.[25]

HIV Viral Load

Particularly for patients on ART, plasma HIV RNA (viral load) is the most important indicator of response to therapy. Optimal viral suppression is generally defined as a viral load persistently below the level of detection (<20 to 75 copies/mL, depending on the assay used) and is usually achieved within 12 to 24 weeks of effective ART.[24] Failure to achieve maximal viral suppression or detectable virus after a period of maximal suppression may indicate virological failure attributable to drug resistance or nonadherence to ART. Higher HIV viral loads also correlate with greater risk for onward infection.

Drug Resistance: HIV Genotype Versus Phenotype

Viral resistance to ARV agents can be assessed by either HIV genotypic or phenotypic assays. Genotypic testing involves sequencing of the protease, RT, and integrase regions of the HIV genome to identify the presence of key mutations that confer anti-HIV drug resistance. Genotype testing is the preferred method of resistance testing to guide initial therapy and also to inform regimen changes in patients with suboptimal virological responses to ART.[24]

Phenotype assays assess the ability of HIV to replicate in vitro in the presence of various concentrations of ARV agents. The assay is performed by isolating certain key regulatory genes from HIV, usually protease, RT, and integrase, inserting them into standardized viral constructs containing an indicator cassette, and infecting cell lines in the presence of ARV agents. The results are compared against control viral isolates and expressed as a fold-change in viral susceptibility. Phenotyping assays remain very expensive, and large studies have failed to conclusively prove a clinical advantage of phenotype assays over genotype assays. The phenotype assay quantifies susceptibility and is typically used by experts evaluating individuals who have accumulated resistance and failed multiple regimens.[24]

KEY CONCEPTS

Other HIV Tests

- Genotyping: helps to guide the choice of antiretroviral medications in patients with resistant virus by sequencing the viral genetic code and identifying mutations that confer resistance to specific agents or classes of agents.
- Phenotyping: similar information to genotyping but not widely used; based on growing engineered viruses with a patient's virus' genes in the presence of antiretrovirals to determine their resistance.

These assays present data as if there is only one virus strain in the body; in reality, there are numerous viral strains at any one time, with many more archived in cells; these assays detect the dominant strain in the circulation, neglecting the other strains, which may account for up to 20% of the circulating viral particles. Given this limitation, when genotyping results are utilized for changing therapy, old treatment regimens and previous genotype results must be taken into consideration.

Testing for Viral Tropism and Abacavir Hypersensitivity

Additional assays should be performed before the initiation of specific ARV medications. A viral tropism assay should be performed before initiation of a CCR5 antagonist. HLA-B*57:01 testing is indicated before initiation of abacavir, as this HLA phenotype is associated with abacavir hypersensitivity in 5% to 8% of patients early in the course of treatment.

TREATMENT

Antiretroviral Therapy: Attacking the Life Cycle of HIV

Combinations of ARV medications are used to maximally inhibit HIV replication and to reduce HIV-associated morbidity and mortality. Combination ART refers specifically to a combination of at least three ARV medications inhibiting the HIV life cycle (Figs. 41.3 and 41.11).

Current US guidelines recommend initiation of ART-naïve persons with a combination of ARV medications that includes drugs from at least two classes and often involves the use of two nucleoside reverse transcriptase inhibitors (NRTIs) plus an integrase strand transfer inhibitor (INSTI), a nonnucleoside reverse transcriptase inhibitor (NNRTI), or a protease inhibitor (PI) with a pharmacokinetic enhancer (cobicistat or ritonavir). In ART-experienced patients, modification of ARV regimens and use of other classes of ARVs is guided, in part, by consideration of a number of factors, including viral resistance patterns, potential side effects, available medication formulations, pill burden, frequency of dosing, tolerability, short-term and long-term adverse event profiles, desire for pregnancy, and desire to preserve subsequent treatment options.[24]

When to Start Therapy

There are significant data to support treating all individuals with HIV infection with ART and starting treatment as soon as possible after diagnosis to reduce morbidity and mortality and to prevent transmission of HIV (see also HIV Prevention). Randomized controlled trials have demonstrated that ART should be initiated in all patients with HIV infection, regardless of disease stage. The urgency to initiate ART is greatest for patients with lower CD4 counts, in whom the absolute risk of opportunistic infections, non-AIDS morbidity, and death is highest. Standard of care suggests that rapid initiation of ART, defined as initiating immediately or within days of diagnosis, is indicated to improve survival, reduce reservoirs, and decrease long-term morbidity caused by persistent inflammation. Trials have shown that risk of development of cardiovascular, kidney and liver disease, and malignancy may be reduced by reducing viral replication and inflammation.[26–29] Earlier ART initiation appears to increase the probability of restoring normal CD4 counts, a normal CD4/CD8 ratio, and lower levels of immune activation and inflammation, as summarized in the US adult treatment guidelines.[24]

Recommendations for initiating therapy in infants and children have always been aggressive due to rapid disease progression in infants born with HIV.[25] In children less than 1 year of age, the health and survival benefit of rapid ART initiation has been demonstrated by clinical trials. Growth and development, including neurodevelopment, have been shown in trials to be significantly better in children who initiated treatment early.

Antiretroviral Agents

There are more than 20 approved ARV drugs, which are classified into six classes based on their chemical structure or the viral life-cycle step that they inhibit (see Fig. 41.11). The classes of ARV agents currently available include NRTIs, NNRTIs, PIs, fusion inhibitors, integrase inhibitors, attachment inhibitor, post-attachment inhibitors, and CCR5 antagonists.

Reverse Transcriptase Inhibitors, Protease Inhibitors, and Integrase Inhibitors

Modified versions of cellular nucleosides, NRTIs, once triphosphorylated in vivo, are incorporated into the proviral DNA by HIV RT and induce premature chain termination, thereby inhibiting successful conversion of the viral RNA to DNA. NNRTIs bind to RT and induce a conformational change such that RT is unable to bind with nucleotides. PIs act on viral protease, preventing the cleaving of the posttranslational viral polyproteins necessary for the maturation and infectivity of viral particles. Integrase inhibitors prevent strand transfer of

viral DNA and thus block the incorporation of the completed HIV DNA copy into the host-cell DNA. A long-acting, injectable formulation combining an NNRTI and an integrase inhibitor is being studied.

Entry Inhibitors: Fusion Inhibitors, CCR5 Blockers, Attachment and Post-Attachment Inhibitors

Fusion inhibitors and CCR5 antagonists inhibit HIV entry into host cells. Fusion inhibitors bind to viral gp41 and block the conformational changes necessary to induce fusion of the viral particle with the host cell. CCR5 antagonists bind to the CCR5 chemokine co-receptor on host cells, inducing a conformational change that impedes CCR5 interaction with HIV gp120, thereby preventing HIV entry into host cells. Fostemsavir is a first-in-class HIV attachment inhibitor that works by attaching directly to HIV gp120 and, as a result, blocking HIV from attaching to CD4 on the host cell. Ibalizumab is a CD4-directed post-attachment inhibitor. Use of agents in this class of medications is typically limited to treatment of individuals with multidrug resistant infection.

IMMUNORECONSTITUTION AFTER THERAPY

Return of T Cells: Memory T Cells, Then Naïve T Cells

To varying degrees, the immune system is able to recover following initiation of therapy, a process called immunoreconstitution.[30] Upon start of ART in patients who are compliant and able to tolerate the regimen, the initial CD4 T-cell count is the best predictor of a successful outcome. Rapid reduction in the viral load, often to an undetectable level, is one of the earliest changes following initiation of ART, reflecting the ability of combination ART to rapidly suppress viral replication. Lagging behind the drop in viral load is the rise in CD4 T-cell concentration. An initial increase in circulating CD4 T cells occurs in 3 to 6 months as a result of a decrease in immune activation and subsequent migration of memory T cells ($CD4^+$, $CD45RO^+$) out of the lymphoid compartment. A more gradual rise in total CD4 T cells occurs over the course of 3 to 5 years with the appearance of new, naïve ($CD4^+$, $CD45RA^+$, $CD62L^+$) and memory T cells. Interestingly, a substantial minority of patients never reach a normal level of CD4 T cells, but, instead, reach a plateau at lower levels. Primary drug prophylaxis and some secondary drug prophylaxis for opportunistic infections may be discontinued in patients once the CD4 T-cell count reaches greater than 200 cells/μL and is maintained for more than 3 to 6 months. Cellular and humoral responses to most pathogens also recover with rising CD4 T-cell counts. Of interest, a low CD4 T-cell count at the time of initiating therapy predicts a poor response to bacterial vaccines even after recovery of CD4 T-cell levels, suggesting a lag in the return of naïve CD4 T cells.

Immune Reconstitution Inflammatory Syndrome

Immune reconstitution inflammatory syndrome (IRIS) is a well-known, if incompletely understood, response in patients with AIDS after initiating ART.[30] IRIS is characterized by an acute paradoxical worsening of inflammatory symptoms of treated opportunistic infections or the unmasking of previously subclinical, untreated infections related to the recovery of immune responses to opportunistic pathogens. IRIS occurs within weeks of ART initiation as the memory and effector antigen-activated

CD4 T-cell population recovers. A recent systematic review found that IRIS developed in 13% of patients after initiation of ART.[30] The most predictive risk factor for the development of IRIS was a low CD4 T-cell count at the start of ART, with the incidence of IRIS increasing exponentially as the CD4 T-cell count declined. IRIS develops more commonly in patients with cytomegalovirus (CMV) retinitis, cryptococcal meningitis, progressive multifocal leukoencephalopathy, and tuberculosis. Studies reported that as many as 4% of patients with IRIS died, but the proportion was much higher if the syndrome was associated with cryptococcal meningitis.[30] Fig. 41.12 shows the several models of inflammation that could result in IRIS as the immune system improves when AIDS is treated with ARV medications.[30]

Hyperallergenic State Associated With Immunoreconstitution

Another complication possibly associated with IRIS is the appearance of asthma in children who were perinatally infected with HIV and received combination ART since infancy.[31] This condition may be mediated by CD4 T-cell activation, release of Th2-type cytokines, and loss of regulatory T cells (Tregs) and tolerance. In support of this concept, Gingo et al. reported at least a 20% prevalence of asthma in adults with HIV infection compared with that of 8.8% in the general population.[32] In a subsequent pediatric study in which pulmonary function testing was objectively measured by spirometry, the following findings emerged: nonreversible obstructive pulmonary disease was present in youths who had been perinatally infected with HIV and possibly in those exposed to HIV but who were uninfected. This pulmonary disorder contains elements of asthma and chronic obstructive pulmonary disease (COPD) and closely resembles the asthma-COPD overlap syndrome. Chronic infections and immune dysregulation appear to play a significant role in this complication of HIV infection.[33,34]

PREVENTION

Prevention of Mother-to-Child Transmission

More than 90% of children living with HIV worldwide were infected through mother-to-child transmission during pregnancy, around the time of birth, or through breastfeeding.[1] Efforts to prevent this transmission hold the most promise in reducing the number of children infected with HIV, and these efforts include (i) early identification of HIV infection in pregnant women through routine antenatal testing; (ii) provision of ARV medications to both the pregnant woman and her infant; (iii) delivery by elective cesarean section, when indicated; (iv) complete avoidance of breastfeeding when safe and sustainable alternatives are available; (v) widespread availability of educational programs addressing HIV infection; and (vi) HIV counseling and testing services.[35]

Prevention of Sexual Transmission

Several biomedical interventions have the potential for radically changing the patterns and rates of HIV transmission. These include male circumcision and expanded use of ART in infected individuals to prevent ongoing infection (treatment as prevention) or prophylactically in uninfected individuals either before or after potential exposure to HIV to prevent acquisition of infection (PrEP and postexposure prophylaxis).

Male Medical Circumcision

The penile foreskin contains HIV-susceptible cells and is a potential portal of viral entry. Randomized controlled trials

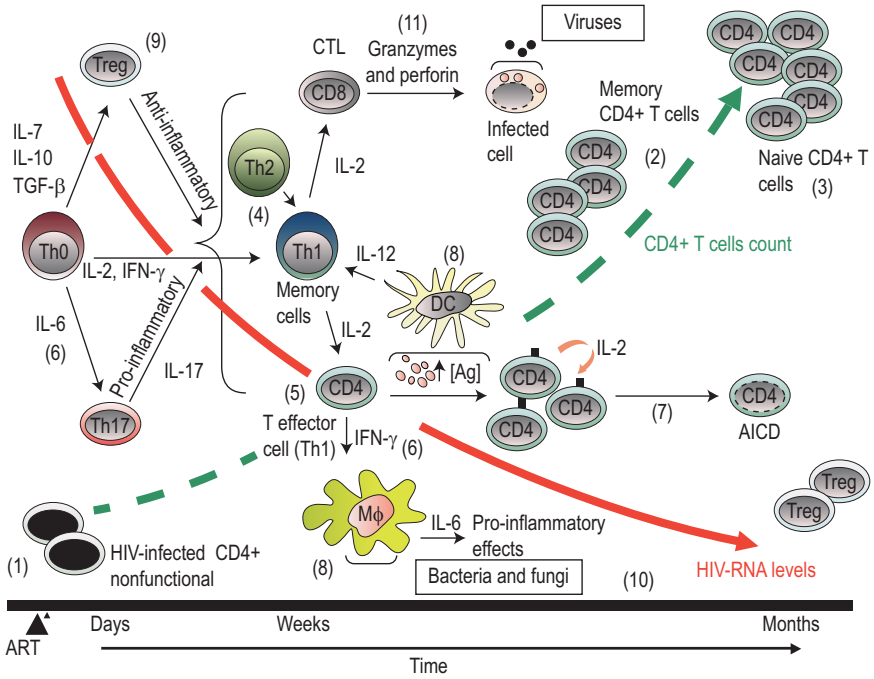

FIG. 41.12 Classical model of immunopathogenesis of immune reconstitution inflammatory syndrome. *ART*, Antiretroviral therapy. (From Manzardo C, Guardo AC, Letang E, et al. Opportunistic infections and immune reconstitution inflammatory syndrome in HIV-1-infected adults in the combined antiretroviral therapy era: a comprehensive review. *Expert Rev Anti Infect Ther*. 2015;13[6]:751–767.)

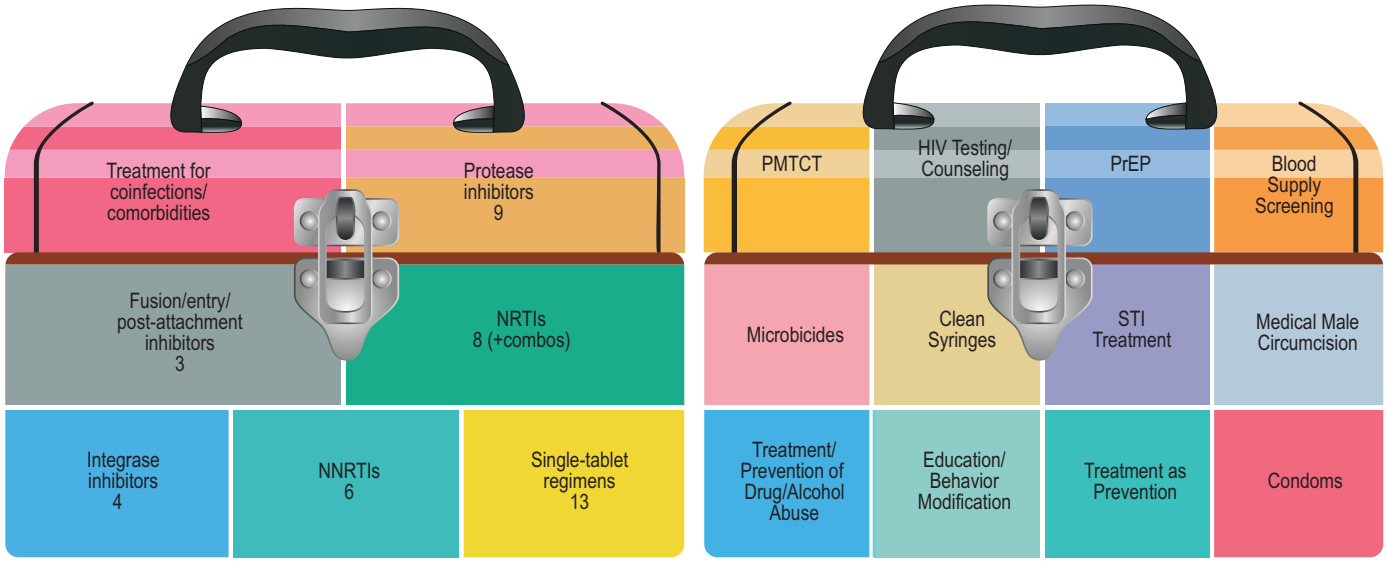

FIG. 41.13 Human Immunodeficiency Virus Treatment and Prevention Toolkits. *NNRTI*, Nonnucleoside reverse transcriptase inhibitor; *NRTI*, nucleoside reverse transcriptase inhibitor; *PMTCT*, prevent mother-to-child transmission; *PrEP*, pre-exposure prophylaxis. in several African countries have indicated that male medical circumcision reduces the risk of heterosexually acquiring HIV infection by 50% to 60%.[36] The WHO recommends male circumcision as part of a comprehensive HIV prevention package; however, condom use and other prevention modalities also remain important in HIV prevention. There was only a modest benefit for the female partners of the circumcised men. In fact, in some circumstances, the risk of transmission to women from men with HIV infection who have undergone circumcision may be increased, perhaps through exposure to infected blood attributed to resumption of sexual activity before the circumcision site had fully healed.[36]

Pre-Exposure Prophylaxis

PrEP is the use of an ARV medication to prevent the acquisition of HIV infection by uninfected persons. PrEP can either be taken orally, using an ARV drug available for treatment of HIV infection (tenofovir plus emtricitabine), or topically as a vaginal gel containing tenofovir. The efficacy of oral PrEP has been shown in randomized controlled trials and is high when the drug is used as directed. Moderate efficacy of a PrEP gel has been shown in one trial. The European Medicines Agency recently approved the use of an ARV-containing vaginal ring for prevention for women in high HIV burden settings. People at substantial risk of HIV infection should be offered PrEP as an additional prevention choice, as part of comprehensive prevention. Other formulations of ART are being studied for use as PrEP. A long-acting injectable integrase inhibitor shows promise in preventing HIV.

Expanded Treatment With Antiretroviral Therapy

The expanded use of ART in individuals with HIV infection has been shown to reduce HIV transmission to uninfected partners. Both "Treatment as Prevention" and "Test and Treat" strategies involve the use of ART in individuals with the express purpose of treating HIV early and reducing transmission to others. In both approaches, ART is initiated regardless of CD4 count or viral load to reduce the viral load in the genital secretions of individuals who have HIV infection and thereby reduce HIV transmission to partners. The efficacy of the "Treatment as Prevention" model is demonstrated in the multinational HIV Prevention Trials Network (HPTN 052) clinical trial that examined the effectiveness of ART to prevent the sexual transmission of HIV in serodiscordant couples.[37] Serodiscordant couples (1763 in number) were randomly assigned to have the individual with HIV either start ART immediately upon enrollment or to defer ART until immunological or clinical criteria were met. Of 28 genetically linked infections that occurred during the trial, only 1 infection occurred in couples assigned to receive immediate treatment, representing a 96% reduction in the risk of HIV transmission. There were also fewer morbidity and mortality events in the early-treatment group, suggesting a therapeutic benefit from early treatment as well. Subsequent studies have found no linked transmissions in a total of more than 150,000 condomless sex acts when the partner with HIV was on ART and viral load was below detectable levels.[38] HIV treatment and prevention tools are illustrated in Fig. 41.13.

HIV VACCINES: CLINICAL TRIALS

Preventive Vaccines

The production of an effective HIV vaccine has been thwarted by the genetic variability of HIV, extreme rate of mutation in the virion, and the sequestration of the virus in impenetrable reservoirs, predominantly the nonreplicating CD4 T cell. Also, glycan shielding may occur. HIV shields its envelope proteins with a blanket of molecules called glycans, which resist penetration by antibodies. More than 30 HIV vaccines have been tested in human trials, including those with recombinant env gp120 proteins with adjuvants, HIV DNA plasmids, viral vectors,

and prime-boost designs.[39] Most vaccines work by inducing the B cells to make antibodies against the infection that the vaccine mimics. Antibodies attack pathogens and either destroy them directly, or "tag" infected cells so they can be destroyed by other parts of the immune system. Broadly neutralizing antibodies (bNAbs) overcome the genetic variability and glycan shield in that they are active against a wide number of different viral strains and react to and attach to the most conserved parts of HIV by penetrating the glycan shield.

So far, however, the results for HIV vaccines have been disappointing. Some HIV vaccines can induce anti-HIV antibody responses, but they have proved to be either ineffective (e.g., the HVTN 702 study) or only marginally effective (e.g., the RV 144 vaccine study). The phase III trial RV 144 in Thailand (ALVAC-HIV vCP1521 + AIDSVAX gp120 B/E) showed possible protection against HIV infection in heterosexual men and women.[39]

In addition to the goal of developing an HIV vaccine that elicits neutralizing antibodies, the search for a vaccine that stimulates a protective CD8 cytotoxic T-cell response continues. Association of certain major histocompatibility complex (MHC) molecules with HIV disease progression is clearly linked to the cytotoxic T-cell responses. Unfortunately, the HIV vaccine-induced cytotoxic CD8 T-cell response is insufficient to halt the progression of acute or chronic HIV disease. This was clearly indicated in the STEP clinical trial, in which the CD8 T-cell effects were the same between HIV-infected vaccinees and sham HIV-infected vaccinee controls. Qualities of effector and central memory CD8 T cells that would be protective include (i) production of cytotoxic cytokines (e.g., interferon gamma (IFN)-γ and IL-2); (ii) rapidly replicating capacity; (iii) cytotoxic potential; (iv) high affinity for HIV antigens; (v) inhibition of HIV replication; (vi) recognition of specific HIV epitopes restricted by protective HLA-B antigens; (vii) central memory cells with long life spans; and (viii) rapid-attack memory cells at mucosal HIV entry sites. A collaboration of scientists has proposed the modification of the partially successful RV 144 vaccine with the goal of producing a new HIV vaccine that will broadly neutralize HIV and variants of HIV that emerge under selective pressure.[40] These modifications include changes in the viral epitopes, vaccine adjuvants, and use of a different clade as the construct of the virus. The goal of this new proposal is to use the information of many previous HIV trials to produce an ideal HIV vaccine that will prevent the spread of HIV infection in children and adults.

Several large-scale trials of vaccines in late-phase development are ongoing in southern Africa: HIV Vaccine Trials Network (HVTN) 702 (Uhambo; NCT02968849) is a phase 2b/3 trial of safety and efficacy of the prime-boost ALVAC HIV vaccine plus bivalent gp120 protein adjuvanted with MF59 regimen in 5400 adult men and women in South Africa; HVTN 705 (Janssen; NCT03060629) is a phase 2b/3 trial of safety and efficacy of the prime-boost Ad26-mosaic vaccine plus gp140 protein vaccine in 2600 adult women in southern Africa and a second study of this strategy in MSM (HVTN 706; NCT03964415); and PrEPVacc (NCT04066881) is a phase 2b trial to assess the combination of an HIV vaccine (DNA, modified Vaccinia Ankara Virus, and Env protein plus adjuvant) and PrEP using an adaptive trial design.[41] A small phase I safety trial of a gene-transfer protocol using a DNA vector vaccine coding for the production of the bNAb VRCO7, a bNAb targeting the CD4 binding site of the HIV-1 envelope glycoprotein, showed promising results.[42]

Therapeutic Vaccines

A therapeutic vaccine is one in which the vaccine is used after infection occurs, aiming to induce antiviral immunity to alter the course of disease. This would be accomplished by controlling viremia or reducing the viral set point in infected patients. Primate models suggest that just such a result is possible, especially with cellular immunity–inducing vaccines. To date, however, data from human studies have not shown any conclusive benefit in using therapeutic vaccines alone. Using a therapeutic vaccine in combination with ART is another approach currently under investigation. A small study of a therapeutic vaccine randomized 15 subjects to receive vaccine and 16 to receive placebo. The intervention consisted of priming with a plasmid DNA (pDNA) vaccine containing genes encoding multiple HIV proteins, followed by boosting with an attenuated viral vector expressing a single HIV gene.[43] All participants had viral rebound and immune responses to HIV were only marginally enhanced.

Future for HIV Vaccines

There is general belief that more basic research exploring vaccine design and trials in animals will lead to important clues for human study, but newer approaches have been employed as well (Fig. 41.14). Illustration of clinical trials in ARV-treated macaques may be applied to humans in future by Byrareddy et al.[44] and Nishimura et al.[45] Monoclonal antibody specific for CD4 T-cell-surface integrin ($\alpha_4\beta_7$) disrupts cellular trafficking of CD4 T cells with gastrointestinal tissue mucosal vascular addressing cell adhesion molecule (MAdCAM1). The CD4 T-cell counts remained steady, CD8 T-cell immunity sharply increased, and HIV replication became undetectable for up to 2 years.[44,45] As illustrated by these HIV vaccine studies in animals, understanding the immune correlates of vaccine efficacy is the usual approach for judging the success of an HIV vaccine. However, broadly neutralizing antibodies (bNAbs) are being explored in another way. Investigators are hypothesizing that bNAb formation will correlate with immunity and are attempting to design a vaccine to induce the correlate. Large passive transfer studies of bNAbs for prevention will inform the feasibility of this approach. The challenge is to take an epitope on the viral envelope that might induce a broadly neutralizing antibody, clone the antibody, and show binding to the epitope, then make an immunogen that induces the bNAb.

ON THE HORIZON

- Production of newer antiretroviral drugs, including those used for post-exposure prophylaxis with greater specificity for interrupting events in the viral life cycle and with fewer side effects for patients.
- Investigation of new microbicidal drugs that can be safely applied before exposure for protection against human immunodeficiency virus (HIV) transfer.
- Development of preventive and therapeutic vaccines for HIV/acquired immunodeficiency syndrome (AIDS) that induce strong viral neutralizing antibody power and strong CD8 T-cell cytotoxic responses.
- Testing of gene construct–modified autologous hematopoietic stem cells capable of halting HIV replication.

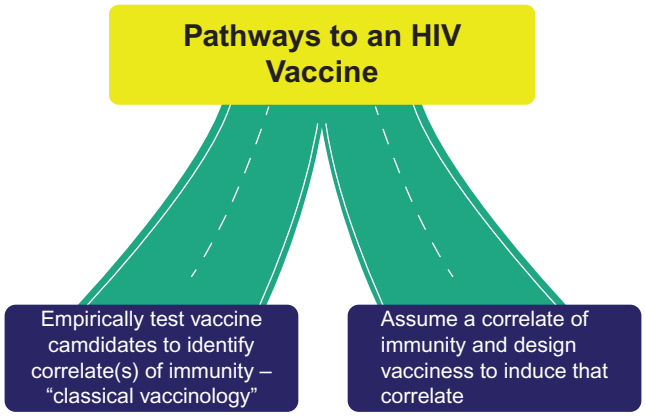

FIG. 41.14 Pathways to an Human Immunodeficiency Virus (HIV) Vaccine; Classical Vaccinology Versus a Newer Approach Being Used to Study Vaccines Designed to Induce Broadly Neutralizing Antibodies. The newer approach assumes a correlate of immunity and involves designing vaccines to induce that correlate. (From Eisinger, RW, Folkers GK, Fauci AS. Ending the human immunodeficiency virus pandemic: optimizing the prevention and treatment toolkits. *Clin Infect Dis*. 2019;69[12]:2212–2217.)

TRANSLATIONAL RESEARCH NEEDS AND CONCLUSIONS

Current ARV therapeutic agents for treatment of HIV are usually administered in simplified regimens of one pill per day, and these regimens are potent with minimal toxicity. When taking these ARVs regularly, people living with HIV can expect a near-normal life expectancy. However, the eradication of HIV/AIDS can be approached practically only with an effective preventive vaccine. The approach to cure with gene therapy is perhaps the most sophisticated translational research venture. Using viral vectors to place gene constructs within nuclear DNA to prevent HIV replication is the goal of such research. Arguably, the most advanced form of this genetic engineering to halt HIV replication is the zinc finger endonuclease approach to disrupt specific genes necessary for the life cycle of HIV. Adoptive transfer of autologous zinc finger–treated stem cells with infinite replication capacity may be an attractive future for individuals already infected with HIV. The extraordinary experiment of HLA-matched and CCR5-δ35 deletion of hematopoietic stem cell immunoreconstitution of a patient with HIV infection ("Berlin Man") is a proof of concept of molecular and genetic engineering to cure HIV infection, but is a technique totally impractical for the millions of patients with HIV infection worldwide. Nevertheless, this "one in a million" chance experiment has demonstrated the survival advantage of lymphocytes that cannot become infected with HIV.

HIV, a type 1 retrovirus, contains merely nine genes, but those nine genes have so far thwarted all scientific efforts toward finding a cure of its infection in humans. Optimism is warranted, however, because of the enormous knowledge base the study of HIV has generated in understanding the many arms of innate and adaptive immunity protecting humans and the promise of a curative treatment or vaccine for HIV. Perhaps no other disease has caused so much to be learned so fast. In much of the world, HIV causes chronic infection, rather than certain death, thanks, in large part, to the use of ARV drugs. More novel drugs are in development as a result of the new-found understanding of the molecular biology of HIV.

The HIV/AIDS pandemic has also brought the sobering realization that other new and potentially deadly pathogens could yet emerge to strike at humanity. Severe acute respiratory syndrome (SARS) coronavirus-2 (CoV-2), which causes the novel coronavirus disease that emerged in 2019 (COVID-19), has caused over 20 million infections worldwide and resulted in hundreds of thousands of deaths. The SARS CoV-2 pandemic has wreaked havoc on economies, interrupted supply chains of goods and services, and brought health services in the United States to the brink of failure. The novel pathogen will bring untold morbidity among survivors of severe disease. Regarding HIV prevention and treatment, the new pandemic has disrupted HIV treatment and prevention programs worldwide and has brought to the forefront health and healthcare disparities and inequalities reminiscent of the early days of the HIV pandemic.

Autoantibody-Mediated Phenocopies of Primary Immunodeficiency Diseases

Jennifer D. Treat, Sarah K. Browne, and Christa S. Zerbe

Anticytokine autoantibodies have been identified in health and disease, with their role in pathogenesis ranging from none to directly causal. It is becoming increasingly recognized that neutralizing, high-titer autoantibodies cause a variety of potentially life-threatening illnesses. Their manifestations are diverse, and their clinical presentation is generally a reflection of the cytokine pathways that are rendered functionally deficient.

Examples include pulmonary alveolar proteinosis (PAP) caused by anti-granulocyte macrophage-colony-stimulating factor (GM-CSF) autoantibodies;[1] disseminated nontuberculous mycobacterial (NTM) and other opportunistic infections caused by anti-interferon-γ (IFN-γ) autoantibodies;[2] chronic mucocutaneous candidiasis (CMC) caused by anti–interleukin (IL)-17A, anti-IL-17F, or anti-IL-22 autoantibodies;[3,4] and bacterial infection caused by anti-IL-6 autoantibodies[5] (Table 42.1). In each of these cases a high-titer, biologically active autoantibody has been identified in association with a unique clinical syndrome. Although this list is not exhaustive, these diseases are of particular interest in that the clinical manifestations are often similar to those in patients with genetic defects in the same cytokine-associated pathways. The Mendelian defects that confer a similar phenotype to their anti-cytokine autoantibody counterpart also provide a strong biological rationale for establishing the autoantibodies as causal. Although a number of other anticytokine-autoantibody associated syndromes such as pure red-cell aplasia (antierythropoietin autoantibodies)[6] and severe osteoporosis in celiac disease (antiosteoprotegerin autoantibodies)[7] have been described, this chapter focuses on those that increase susceptibility to infection.

There are numerous commonalities and distinctions worth highlighting among anticytokine autoantibody-associated immune deficiency. Shared in common is the presence of high-titer, neutralizing anticytokine autoantibodies of the immunoglobulin G (IgG) isotype. PAP caused by anti-GM-CSF autoantibodies appears to be primarily a lung disease largely resulting from disruption of GM-CSF-dependent pulmonary surfactant catabolism. *In vitro* studies using primary human cells and mouse work have demonstrated that anti-GM-CSF autoantibodies cause immune dysfunction largely through transcription factor PU.1, which may explain pulmonary and extrapulmonary infections observed in PAP, particularly those opportunists known to be controlled by neutrophils or macrophages.[1] PAP caused by anti-GM-CSF autoantibodies is similar to severe immune deficiency caused by anti-IFN-γ autoantibodies in that both diseases have adult onset. On the basis of broad screening for other autoantibodies, it appears affected patients make high-titer neutralizing autoantibody against only one cytokine and do not demonstrate an increased frequency of other autoantibodies or forms of autoimmunity.[1,2] Patients with autoantibodies against IL-17A, IL-17F, IL-22 who also have chronic mucocutaneous candidiasis (CMC) are different in that, so far, all have had an underlying primary diagnosis of either autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia (APECED, also known as autoimmune polyendocrinopathy syndrome type 1 [APS-1]) or thymic neoplasia.[3,4] Thus in patients with APECED, a mendelian defect in the gene *AIRE*, which is responsible for negative selection for autoreactive T cells in the thymus, the onset of anti-cytokine autoantibodies and CMC occurs earlier in life. Occasionally, CMC is the initial presentation of thymoma (just as myasthenia gravis caused by anti-acetylcholine receptor autoantibodies must prompt evaluation for thymoma), highlighting the fact that for all anticytokine autoantibody-associated syndromes, the timeline for development of anticytokine autoantibodies relative to the observation of clinical disease is largely unknown. Additionally, patients with thymoma and APECED can develop multiple anti-cytokine autoantibodies, although they have a proclivity for certain ones, including type I IFNs, IL-17A, IL-17F, IL-22, and, in the case of thymoma (but not APECED), IL-12. Given the presence of multiple neutralizing autoantibodies, and the fact that T-cell intrinsic defects or thymic insufficiency can also confer infection susceptibility, it is challenging to prove that a particular anticytokine autoantibody is the necessary and sufficient agent of disease pathogenesis. In the case of anti-IL-6, four patients have

KEY CONCEPTS

Anticytokine Autoantibody-Associated Primary Immunodeficiency Diseases

- Anticytokine autoantibodies have been identified in a group of patients with immunodeficiency diseases characterized by the development of high-titer, neutralizing autoantibodies to cytokines.
- The clinical manifestations in patients with anticytokine autoantibodies are similar to those seen in patients with genetic defects in the pathway of the target cytokine.
- Immunodeficiency syndromes described include those associated with anti-granulocyte macrophage-colony-stimulating factor (GM-CSF) autoantibodies and pulmonary alveolar proteinosis (PAP); anti-interferon (IFN)-γ autoantibodies and severe immunodeficiency; anti-interleukin (IL)-17A, anti-IL-17F, and anti-IL-22 autoantibodies and chronic mucocutaneous candidiasis (CMC); and anti-IL-6 autoantibodies and bacterial infection.
- Management of these syndromes involves treating the consequences of the autoantibody (*e.g.*, infectious manifestations, lung disease) or targeting the autoantibody itself.

TABLE 42.1 Anticytokine Autoantibody–Associated Syndromes and Their Phenotypically Similar Genetic Counterparts

Cytokine Target	Genetic Phenocopies	Clinical Manifestations	Laboratory and Radiological Manifestations	*In vitro* Evidence for Biological Activity	Infections	Comments
GM-CSF	GM-CSF receptor α or β subunits	PAP Insidious and progressive respiratory failure Newly described cases of isolated cryptococcal meningitis and *Nocardia* infection in individuals without human immunodeficiency virus (HIV) infection[17–19]	BAL fluid contains large foamy macrophages or monocyte-like macrophages and elevated levels of surfactant proteins Characteristic computed tomography (CT) of chest demonstrates ground-glass opacities with thickening of intralobular septae, "crazy paving." PFTs demonstrate restrictive and diffusion defects[1]	Anti-GM-cerebrospinal fluid autoantibodies inhibit pSTAT-5 production,[17] PU.1 expression, Macrophage inflammatory protein 1α (MIP-1α) production	Pulmonary and extrapulmonary infections with *Nocardia, Aspergillus, Proteus, Histoplasmosis*, and *Cryptococcosis*[1]	Mutations in surfactant proteins have also been described SP-B, Surfactant protein C (SP-C), or ATP-binding cassette subfamily A-3 (ABCA3), but are considered clinically distinct
IFN-γ[h]	Mutations in IFN-γR1; IFN-γR2; STAT1; IL-12Rβ1; IL-12Rβ2; IL-12p40; NEMO; IRF8; ISG15	Chronic infections with intracellular pathogens, particularly lymphadenitis, skin, soft tissue, and bone infections; can be multiple organisms simultaneously or sequentially; reactive dermatoses; constitutional symptoms common	Elevated erythrocyte sedimentation rate, C-reactive protein-reactive protein (CRP), β_2 microglobulin, anemia, hypergammaglobulinemia. CT imaging may demonstrate abscess formation or osteomyelitis	Anti-IFN-γ autoantibodies inhibit phospho-STAT1 production(2, 11), IFN-γ inducible gene expression[29] and IL-12p70 and TNF-α protein production[2,11]	Nontuberculous mycobacteria, tuberculosis, nontyphoidal *Salmonella, Histoplasma, Penicillium, Cryptococcus, Burkholderia pseudomallei*, varicella-zoster virus[2]	Functional testing to evaluate downstream inhibitory effects of autoantibody important, (*i.e.*, plasma inhibition of IFN-γ–induced phospho-STAT1 production)
IL-17A IL-17F IL-22	IL-17RA IL-17F	Recurrent candidal infections of mucosal surfaces, nails, and skin Infection may become resistant to antifungals	(APECED patients only) In patients with pneumonitis, common CT findings include bronchiectasis, ground glass opacities or mosaicism.	Anti–IL-17 autoantibodies inhibit IL-17–induced IL-6[4]	*Candida* spp.	Reported only in the context of APECED and thymoma so far
IL-6	STAT3	Recurrent bacterial infections.	Undetectable CRP	Anti–IL-6 autoantibodies prevent IL-6–induced CRP mRNA[5]	*Staphylococcus aureus, Escherichia coli* and *Streptococcus intermedius*	Four cases reported to date

GM-CSF, Granulocyte macrophage–colony stimulating factor; *PAP,* pulmonary alveolar proteinosis; *BAL,* bronchoalveolar lavage; *PFT,* pulmonary function test; *pSTAT,* phosphorylated signal transducer and activator of transcription test; *MIP,* macrophage inflammatory protein; *SP,* surfactant protein; *ABC,* adenosine triphosphate-binding cassette; *IFN,* interferon; *NEMO,* nuclear factor (NF)-κB essential modulator; *IRF,* interferon regulatory factor; *TNF,* tumor necrosis factor; *APECED,* autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia.

been identified with neutralizing anti-IL-6 IgG antibodies. All four presented with severe bacterial infections but had low C-reactive protein (CRP), an IL-6-driven inflammatory marker.[5,8,9]

OVERVIEW OF PATHOPHYSIOLOGY

The pathophysiology of infection susceptibility is generally thought to involve a functional deficiency in the cytokine that is being neutralized (Chapter 14). It is believed that a high-titer autoantibody binds its respective cytokine target, thereby blocking downstream signaling and biological activity. For each anticytokine–autoantibody pair, it has been demonstrated that plasma or purified IgG from a patient with the anticytokine autoantibody prevents the activity of the targeted cytokine at the levels of signal transduction, gene transcription, and/or protein expression. In the case of anti–IFN-γ autoantibodies, it has been demonstrated that antibody levels track with disease activity;[10,11] however, for anti-GM-CSF autoantibodies, the results have been conflicting. It is also possible, but not yet proven, that antibody-binding avidity may influence the degree of disease severity as well. Thus, it may be possible to have high-titer, lower avidity anti-cytokine autoantibody leading to a similar disease phenotype to low-titer, high-avidity anti-cytokine autoantibody.

The events that lead to the generation of anti-cytokine autoantibodies are poorly understood and are likely disease specific. Nonetheless, by comparing and contrasting these diseases, we may begin to understand some key factors. Although a large cohort of patients with PAP have been described in Japan, this disease is seen worldwide across all ethnicities and not within families, suggesting that if there is a genetic component, it is a complex one. No familial clustering has been identified in over 130 reported cases of anti–IFN-γ autoantibodies and opportunistic infection;[2,12–15] however, the disease is mostly seen in Asian-born Asians, suggesting that there may be an environmental trigger in the context of a common genetic background.

The fact that anti-cytokine autoantibodies are both IgG and high-affinity implicates the T-helper (Th) lymphocyte-dependent processes of class switching and affinity maturation. Interestingly, anti-IL-17A, -IL-17F, and -IL-22 autoantibodies appear directly linked to either the genetic *AIRE* deficiency of APECED or the acquired *AIRE* deficiency observed in patients with thymoma.[16] In both cases, thymic-driven disease appears to be leading to extensive B-lymphocyte dysregulation in the form of many autoantibodies beyond just anti-cytokine autoantibodies. However, given that B cells may play a primary role in the development of autoimmunity in *AIRE* deficiency, the mechanisms underlying B-cell autoreactivity are likely complex.[16] Furthermore, evidence in mouse models of rheumatologic disease suggests that peripheral B-lymphocyte lineages leading to autoantibodies may fundamentally differ from those leading to development of protective antibodies.[17] Thus a common phenomenon of anticytokine autoantibody production may, in fact, be a reflection of a convergence of multiple differing mechanisms.

ANTI-GM-CSF AUTOANTIBODIES AND PULMONARY ALVEOLAR PROTEINOSIS

GM-CSF is a hematopoietic stem cell (HSC) growth factor that binds the GM-CSF receptor, which is widely expressed on many cell lineages, including neutrophils, macrophage precursors, dendritic cells (DCs), erythrocyte progenitors, and megakaryocytes. The GM-CSF receptor is composed of two α and two β subunits, which together bind two GM-CSF molecules with high affinity and induce signal transduction and activator of transcription (STAT)5 phosphorylation, nuclear translocation, and induction of expression of the master transcription factor PU.1. PAP was first described in 1958 by Rosen et al. as an idiopathic syndrome of respiratory failure, histopathologically characterized by alveoli filled with acellular periodic acid-Schiff-positive proteinaceous material.[1] The pathogenesis of PAP has since been linked to congenital or acquired defects in the GM-CSF signaling pathway.

The first clues to the etiological mechanism of PAP surfaced in 1994 and 1995 when GM-CSF$^{-/-}$ and GM-CSF receptor β$^{-/-}$ mice, respectively, demonstrated pulmonary disease that was virtually identical to human PAP. Shortly thereafter, mechanisms involving disruption of GM-CSF signaling were linked to PAP in humans.[1] Primary PAP results from mutations in either the GM-CSF receptor subunits α or β and generally leads to severe respiratory failure and usually presents early in life. Autoimmune PAP results from neutralizing anti-GM-CSF autoantibodies, can also cause respiratory failure, and shares the same pulmonary histopathology as the primary form (Fig. 42.1). In contrast to primary PAP, the autoimmune form is typically diagnosed in adulthood,[1] and its clinical course and severity are highly variable, ranging from progressive respiratory decline to spontaneous resolution. A secondary form of PAP caused by qualitative or quantitative deficiency of alveolar macrophages, generally in the context of hematologic malignancies, iatrogenic immunosuppression, or inhaled toxins, has also been recognized.

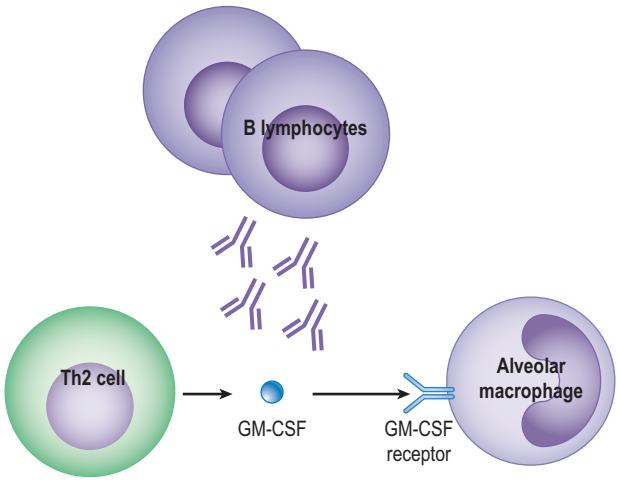

FIG. 42.1 Anti-Granulocyte Macrophage-Colony-Stimulating Factor (GM-CSF) Autoantibody Associated Pulmonary Alveolar Proteinosis (PAP). Autoimmune PAP results from impairment of GM-CSF dependent catabolism of surfactant and its subsequent overaccumulation in pulmonary alveoli due to neutralizing anti-GM-CSF autoantibodies, leading to respiratory failure. Th2 cell, type 2 T-helper cell.

Although the primary pathological process relates to impairment of GM-CSF-dependent catabolism of surfactant and its subsequent overaccumulation in pulmonary alveoli, there has long been an association with opportunistic infections.[1] Beyond its role in pulmonary surfactant homeostasis, the GM-CSF receptor is widely expressed on immune cells, including neutrophils, monocytes, DCs, megakaryocytes, and erythrocyte progenitor cells, and influences cell differentiation, proliferation, and immune activation. GM-CSF has been shown in both humans and mice to facilitate not only terminal differentiation of monocytes to alveolar macrophages but also innate immune responses, primarily via induction of transcription factor PU.1. Cells isolated from bronchoalveolar lavage (BAL) fluid from patients with autoimmune PAP show decreased PU.1 messenger RNA (mRNA), which is thought to be central to the pathogenesis of PAP. PU.1 has been shown to regulate Toll-like receptor (TLR) signaling, adhesion, phagocytosis, and microbicidal activity, thus providing a mechanism for the increased infection susceptibility that is observed in PAP. Beyond the macrophage, defects have also been shown in neutrophil adhesion, phagocytosis, oxidative burst, and bacterial killing from both the blood of human patients with PAP and GM-CSF$^{-/-}$ mouse bone marrow.[18]

Patients with acquired PAP are vulnerable to typical respiratory pathogens as well as opportunistic infections. Although the high incidence of respiratory infections may be partially attributable to their underlying chronic lung disease, the opportunistic infections are generally caused by organisms controlled by macrophages, including *Nocardia, Histoplasma*,[1] nontuberculous mycobacteria,[19] and *Cryptococcus*.[20] Although Witty et al. reported eight cases of PAP and *Mycobacterium avium* complex cultured from BAL fluid,[19] these patients did not receive antimycobacterial drugs and appeared to fare no worse than uninfected patients. Furthermore, most of these infections were described before the recognition of anti-GM-CSF autoantibodies as being causal, so these reports may be confounded by heterogeneity within the underlying diagnosis.

Extrapulmonary infections have been observed with some frequency, which could be ascribed to the systemic effects of anti-GM-CSF autoantibodies identified in the circulation. In support of this systemic effect, several case reports describe patients with PAP who had extrapulmonary infections, including cases of central nervous system (CNS) *Nocardia* infection, septic arthritis, perinephric abscess, and *Nocardia* dissemination to skin; CNS *Aspergillus* and *Proteus;* and disseminated histoplasmosis.[1] A few case series have also reported opportunistic infections associated with high-titer neutralizing anti-GM-CSF autoantibodies without concurrent PAP. Anti-GM-CSF antibodies have been reported in previously healthy adults uninfected by HIV who had cryptococcal meningitis specifically caused by *Cryptococcus gattii*.[20,21] Neutralizing anti-GM-CSF autoantibodies were also found in five of seven patients with disseminated/extrapulmonary *Nocardia* infections.[22] However, it remains to be seen if these infections are the only manifestations in these patients, or if they may eventually develop PAP, as seen in the two of seven cases of cryptococcal meningitis associated with anti-GM-CSF autoantibodies.[20] Why the same autoantibody may produce different clinical phenotypes is unknown. Opportunistic infections have not been reported as a complication of congenital PAP. Reasons for this could include the extreme rarity of this condition or limited opportunity for exposure to environmental opportunists as a result of medical debilitation.

Treatment includes whole lung lavage (WLL) to evacuate the proteinaceous material contained in the alveoli. Unfortunately, WLL is an invasive procedure that only temporizes the symptoms of PAP without treating the underlying cause, often resulting in the need for repeat procedures. Alternatively, inhaled or subcutaneous GM-CSF has been effective, either by saturating the antibody or by inducing tolerance.[23,24] In two large studies, one using subcutaneous GM-CSF and one using inhaled GM-CSF, a clinical response was not associated with a reduction in plasma or BAL concentrations of anti-GM-CSF autoantibodies, thereby providing possible support for the former mechanism.[23,24] B-cell targeted therapy using the anti-CD20 chimeric monoclonal antibody (mAb) rituximab has been used to treat a small number of patients and has shown encouraging clinical results.[25]

ANTI IFN-Γ AUTOANTIBODIES AND SUSCEPTIBILITY TO INTRACELLULAR PATHOGENS

Interferon gamma, produced predominantly by activated Th1 cells and natural killer (NK) cells, is central to host defense against intracellular pathogens (Chapter 26). The IFN-γ receptor (IFN-γR), expressed primarily on monocytes, is composed of two subunits in duplicate, IFN-γR1 and IFN-γR2. Binding of IFN-γ to its receptor leads to Janus kinase 2 (JAK2) and then JAK1 phosphorylation on the intracellular portions of IFN-γR2 and IFN-γR1, respectively. Subsequent STAT1 docking, phosphorylation, homodimerization, and nuclear translocation lead to transcription of IFN-γ responsive genes. Macrophage activation, differentiation, and elaboration of inflammatory mediators, such as tumor necrosis factor-α (TNF-α) and IL-12, ensue. Defects in the IFN-γ–IL-12 axis lead to mendelian susceptibility to mycobacterial disease as well as those caused by other intracellular pathogens, including listeriosis, salmonellosis, histoplasmosis, melioidosis, and penicilliosis.[26] The list of genetic mutations involving this pathway that result in increased susceptibility to mycobacteria or other intracellular pathogens continues to expand and, to date, includes mutations in IFN-γR1, IFN-γR2, STAT1, IL-12p40, IL-12Rb1, nuclear factor-κB (NF-κB) essential modulator (NEMO), IFN regulatory factor (IRF) 8, and IFN-stimulated gene (ISG) 15.[26] Neutralizing autoantibodies against IFN-γ represent an alternative mechanism by which the IFN-γ–IL-12 metabolic pathway is disrupted, with the first cases described in 2004[12] (Fig. 42.2). We reported 85 patients identified in a 6-month period,[2] and the number of patients is still growing,[10–15] suggesting that immunodeficiency caused by anti–IFN-γ autoantibodies is probably underappreciated.

The infections in patients with anti-IFN-γ autoantibodies mimic many of those seen in patients with inborn errors in the IL-12–IFN-γ signaling pathways and include mycobacterial, particularly nontuberculous environmental mycobacteria, nontyphoidal *Salmonella, Penicillium, Histoplasma, Cryptococcus, Burkholderia pseudomallei*, and additionally varicella-zoster virus (VZV), both dermatomal and disseminated.[2] Infections have been noted in all organ systems, although lymph nodes, skin, soft tissue, and bone appear to be preferentially affected. Up to 50% of patients develop sterile reactive dermatoses, most commonly neutrophilic dermatosis, but also erythema nodosum, pustular psoriasis, and exanthematous pustulosis.

Although patients with Mendelian defects tend to present in childhood, all reported cases of patients with anti–IFN-γ were

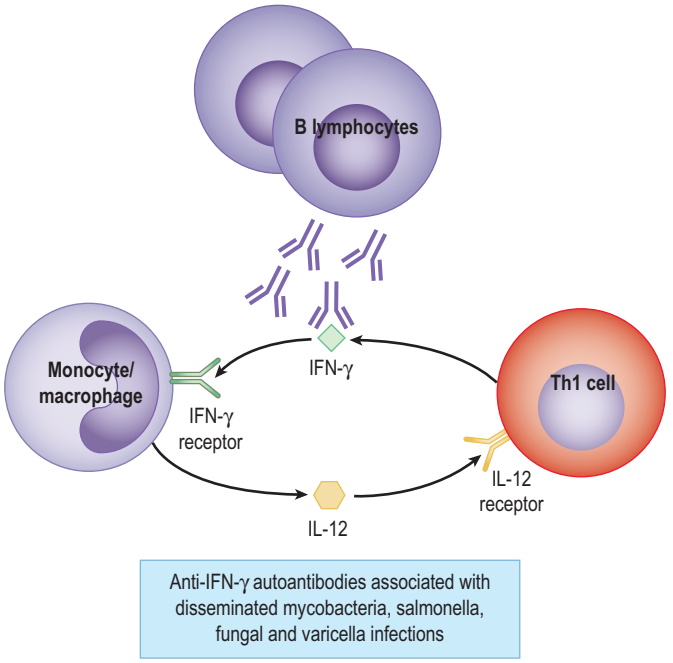

FIG. 42.2 Anti-Interferon (IFN)γ Autoantibody Associated Susceptibility to Intracellular Pathogens. Neutralizing autoantibodies against IFN-γ disrupt the IFN-γ-IL-12 metabolic pathway. Infections in patients with anti-IFN-γ autoantibodies mimic many of the infections seen in patients with inborn errors in the interleukin (IL)-12-IFN-γ signaling pathways and include mycobacterial, nontyphoidal *Salmonella, Penicillium, Histoplasma, Cryptococcus, Burkholderia pseudomallei*, and varicella zoster virus. Th1 cell, type 1 T-helper cell.

previously healthy adults, the vast majority of whom were Asian-born Asians. There is now a single case report in a juvenile diagnosed with disseminated NTM in the presence of anti-IFN-γ autoantibodies.[27] A recent association with human leukocyte antigen–antigen D related (HLA-DR)*15:02/16:02 and HLA-DQ*05:01/05:02 was shown in 78 patients with anti–IFN-γ autoantibodies,[28] further implicating a genetic predisposition to development of disease. However, no familial clustering has been observed, and Asians born outside of Asia have yet to be reported with this syndrome, suggesting complex genetics and possibly an environmental contribution to autoantibody pathogenesis. The publication of an American-born, Caucasian female with this syndrome also adds to the complexity of its pathogenesis.[15]

A recent study compared 74 Thai patients with anti-IFN-γ autoantibodies to an existing US cohort of 19 patients and found several distinctions. *Mycobacterium abscessus* was the most commonly isolated NTM species in the Thai group while in the US, *Mycobacterium avium* complex was most commonly identified. The most commonly involved sites also varied amongst the groups with lymph nodes and skin being common in the Thai cohort while bone, lung and central nervous system involvement was more common in the US cohort. Sweet syndrome was a common disease-associated condition at presentation in Thailand, a condition uncommonly seen in the US, but which should nevertheless trigger consideration for autoantibodies. In both groups, tracking of autoantibody titers suggested that the largest decrease in titers over time portends a better prognosis.[11]

Notable laboratory features include anemia of chronic disease and elevation in inflammatory markers, such as erythrocyte sedimentation rate (ESR), CRP, and β_2 microglobulin. Immunologically, patients commonly demonstrate polyclonal hypergammaglobulinemia, but they otherwise have normal lymphocyte phenotyping, including CD4 T lymphocytes, monocyte numbers, and IFN-γR1 expression.

Treatment has focused mainly on managing the infections with targeted antimicrobials. Interestingly, a severe paradoxical inflammatory reaction similar to immune reconstitution syndrome, manifesting as lymphadenopathy, cavitary lung lesions, and lytic bone lesions during antituberculosis treatment, has been reported and should be distinguished from true failure of antimicrobial treatment.[29] In cases refractory to anti-infective agents, some have attempted to overcome the antibody with IFN-γ administration or to drive down antibody levels with plasmapheresis and cyclophosphamide[30] or rituximab.[10] There are anecdotal cases of treatment with bortezomib, a proteasome inhibitor, and daratumumab, a CD38-directed monoclonal antibody, however there are not enough data on these newer treatment modalities. It is unclear what factors predict response to antimicrobials alone *versus* a need for further immunomodulation; the efficacy of these immune modulatory approaches remains to be evaluated formally in clinical trials.

ANTI-IL-17 AND ANTI-IL-22 AUTOANTIBODIES AND CHRONIC MUCOCUTANEOUS CANDIDIASIS

IL-17A and IL-17F are proinflammatory cytokines that can combine as either homodimers or heterodimers with each other (Chapter 14). These dimerized combinations signal via IL-17RA and IL-17RC heterodimeric receptor complexes, ultimately activating NF-κB. IL-22, produced by T lymphocytes and NK cells, also signals via a heterodimeric receptor composed of IL-22R1 and IL-10R2 subunits, expressed mainly on epithelial and other nonimmune cells. IL-17A/F and IL-22 cooperate to induce proinflammatory cytokines involved in granulopoiesis and neutrophil recruitment as well as antimicrobial peptides, such as β defensins and S100 proteins, which are thought to be important in mucosal immunity. Clinical evidence for a protective role of IL-17 in CMC arose from the observation of this infectious complication in diseases with varying degrees of Th17 impairment, including *STAT3*-deficient hyper-IgE syndrome (HIES, or Job's syndrome), dectin-1 deficiency, CARD9 deficiency, and, to a lesser degree, IL-12 receptor β_1 deficiency.[32] Strong support of this hypothesis came via instances of two families that demonstrated inherited susceptibility to mucosal candidiasis: one with an autosomal recessive mutation in IL-17RA, and another with an autosomal dominant negative mutation in IL-17F.[31]

APECED leads to a clinical triad of hypoparathyroidism, adrenal insufficiency, and CMC.[16] Other endocrine glands, including gonads, thyroid, endocrine cells in the gut, and pancreatic islet cells, are variably affected. Many other autoimmune phenomena, including Sjögren syndrome, rheumatoid arthritis, hepatitis, keratitis, vitiligo, pernicious anemia, and alopecia, as well as autoantibodies to type I IFNs, have been described.[16] The biological consequences of these anti–IFN-α autoantibodies are unclear, but autoantibodies to other tissue antigens in APECED, such as autoantibodies to glutamic acid decarboxylase, thyroid peroxidase, and 21-hydroxylase, are clearly pathological. Another important consideration in patients with APECED is the association of autoimmune pneumonitis. A recent study found that up to 40% of APECED patients, especially those with

autoantibodies against BPIFB1 (BPI fold containing family B member 1) and KCNRG (potassium channel regulator), have clinical and/or radiographic findings associated with pneumonitis. If left untreated, these patients may develop further complications such as hypoxemic respiratory failure and death. However, if discovered early enough, these patients respond well to treatment with T and B lymphocyte-directed immunomodulation.[32] Providing an explanation for the preponderance of autoimmunity seen in APECED was the observation that the transcriptional activity of *AIRE* in medullary thymic epithelial cells (mTECs) promotes expression of tissue-specific genes, thereby facilitating intrathymic destruction of autoreactive T cells and fostering self-tolerance.[16]

Unlike the above-described Mendelian disorders, the mechanism of CMC in APECED is not directly linked to the genetic deficiency itself but, rather, to the strong genetic predisposition to autoimmunity, which, in this case, includes production of neutralizing anti-IL-17A, anti-IL-17F and anti-IL-22 autoantibodies[3,4] (Fig. 42.3). Puel et al. identified antibodies to IL-17A, IL-17F, or IL-22 in 33 patients with APECED, 29 of whom also had CMC, compared with healthy controls who had neither autoantibodies nor CMC.[4] Kisand et al. found autoantibodies against IL-17A, IL-17F, or IL-22 in up to 90% of 162 cases of APECED, also strongly associated with CMC.[3] They also identified anti-IL-17 and anti-IL-22 autoantibodies in two patients with thymoma and CMC, but in none of the 33 patients with thymoma who did not have CMC. There were a few instances of autoantibodies without CMC, and many examples of CMC independent of APECED, suggesting that autoantibodies to IL-17 and IL-22 are not absolutely necessary for development of CMC. However, their identification, particularly in light of the CMC disease seen in patients with IL-17RA and IL-17F mutations, provides support for a causal relationship. Interestingly, thymoma tissue also demonstrates decreased *AIRE* expression, further linking these diseases beyond a shared tendency toward autoimmunity and anti-cytokine autoantibody production. What is less clear however, is the exact role *AIRE* is playing in pathogenesis of organ-specific autoimmunity (including anti-cytokine autoantibody formation), since the syndromes diverge considerably in this regard.[16]

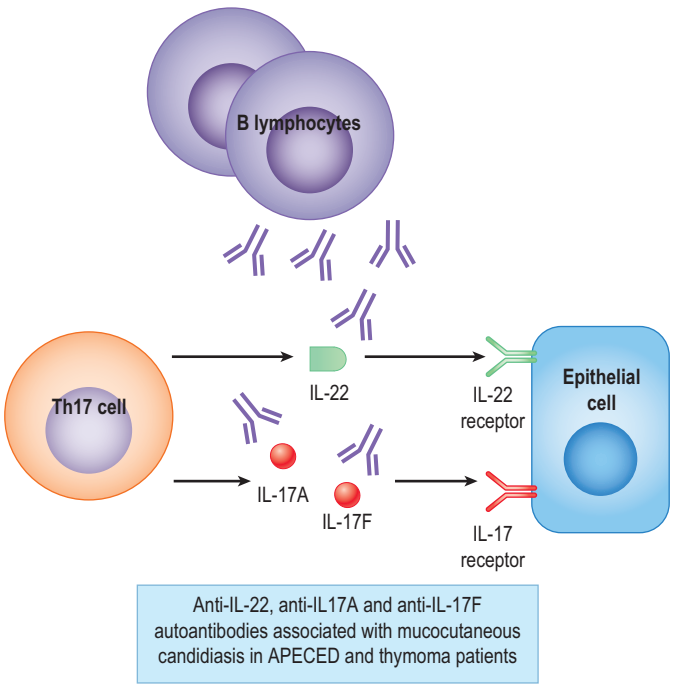

FIG. 42.3 Anti-Interleukin (IL)-17 and Anti-IL-22 Autoantibodies Associated Chronic Mucocutaneous Candidiasis (CMC). IL-17A/F and IL-22 induce proinflammatory cytokines involved in granulopoiesis and neutrophil recruitment as well as important mucosal antimicrobial peptides, such as β defensins and S100 proteins. Neutralizing antibodies against IL-17A, IL-17F, and IL-22 in autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia (APECED) syndrome constitute the likely mechanism of CMC in these patients.

ANTI-IL-6 AUTOANTIBODIES AND BACTERIAL INFECTIONS

IL-6 is produced by many immune and nonimmune cells, including B cells, T cells, macrophages, synovial cells, endothelial cells, and hepatocytes, and is involved in both acute and chronic inflammation, ranging from sepsis to rheumatoid arthritis. IL-6 binds a heterodimeric receptor composed of IL-6Rα and a shared receptor chain gp130. IL-6Rα confers ligand specificity, whereas gp130 mediates signal transduction. IL-6 regulates the acute phase response in the liver, with its hallmark induction of CRP and elevated ESR. Anti-IL-6 autoantibodies were first identified in a Haitian boy who had two episodes of severe staphylococcal cellulitis, one complicating chickenpox infection, the other following mosquito bites.[5] Treatment included supportive care and anti-infective agents. Undetectable CRP, despite severe infection, suggested impairment in IL-6 activity. Since that time, there have been three other reported cases of anti-IL-6 autoantibodies in patients with severe bacterial infections without elevation in CRP: a 67-year-old man with thoracic empyema with *Escherichia coli* and *Streptococcus intermedius*, a 56-year-old woman with multiple subcutaneous abscesses with *Staphylococcus aureus*, and a 20-month-old female with septic shock presumed to be caused by *Staphylococcus aureus*.[8,9] All three cases demonstrated low levels of CRP despite the severity of their respective infections, prompting the search for anti-IL-6 autoantibodies. *STAT3* is the critical signal transduction molecule for IL-6 and IL-10, and autosomal dominant mutations in *STAT3* also lead to recurrent infections due to staphylococcus, streptococcus and hemophilus,[33] suggesting a common potential mechanism for this phenotypic profile of infection susceptibility. The limitations to this association are that the infections in the first reported case resolved without any apparent change in the anti-IL-6 autoantibody titers, and there are still a very limited number of reported cases to date.

MANAGEMENT

Therapies directed at the syndromes of pathogenic autoantibodies have focused either on treating the disease consequences or targeting the autoantibody itself. Therapeutic BAL removes proteinaceous alveolar material from the lungs of patients with PAP,[1] and anti-mycobacterials treat the disseminated NTM infection in patients with autoantibodies to IFN-γ.[12,34] Approaches ranging from physical removal of the antibody, to immunomodulatory therapy, to induction of immune tolerance or suppression of the population of cells that produce the pathogenic autoantibodies have also been employed.

PAP and disseminated NTM associated with anti–IFN-γ autoantibodies have been treated with exogenous GM-CSF[23,24] and IFN-γ,[35] respectively, resulting in clinical improvement, although PAP has been studied more rigorously in this regard. Autoantibody levels after therapy were not routinely evaluated across diseases, nor were they measured in a standardized fashion, although, at least in the PAP cohorts, it appears they did not change in response to exogenous cytokine administration.[23,24]

In cases that were refractory to treatment, attempts have been made to alleviate the blockade by reducing anti-cytokine autoantibody levels. One patient with anti-IFN-γ autoantibodies underwent plasmapheresis and cyclophosphamide therapy in addition to receiving antimycobacterials.[31] Rituximab, the mouse-human chimeric mAb that targets the human B-cell marker CD20, is currently approved for treatment of B-cell lymphoma and rheumatoid arthritis. Since B cells ultimately differentiate into antibody-producing cells, it has been applied to a number of autoantibody-mediated diseases, such as myasthenia gravis (Chapter 65) and pemphigus vulgaris (a blistering skin disease caused by autoantibodies that recognize desmoglein 3, a keratinocyte cell-surface protein; Chapter 63). Successful rituximab therapy has also been reported in PAP[25] and immunodeficiency caused by anti-IFN-γ autoantibodies[10] with a specific reduction of anticytokine–autoantibody titers.

A new approach in pure red blood cell (RBC) aplasia caused by anti-erythropoietin autoantibodies is to bypass the autoantibody with a erythropoietin receptor synthetic peptide agonist peginesatide (Hematide; Affymax) that does not share homology with the eosinophil peroxidase (EPO) ligand.[35] Although this approach has not been used in cases of anti-cytokine autoantibodies causing immune deficiency, it underscores the range of novel treatment approaches that might be explored for anti-cytokine autoantibody associated syndromes.

ON THE HORIZON

- Anti-cytokine autoantibodies are an emerging mechanism underlying the pathogenesis of immune deficiency in previously "healthy" adults, and perhaps children.
- The clinical manifestations of these diseases, like pulmonary involvement in anti-granulocyte macrophage-colony-stimulating factor (GM-CSF) associated pulmonary alveolar proteinosis (PAP), may provide insight to signaling pathways and target cells of the involved cytokine.
- Recent discovery of many anti-cytokine autoantibody associated diseases suggests that other idiopathic immunodeficiency diseases may be the result of an autoantibody affecting an as-yet unknown signaling pathway or cell type.
- Much research needs to be done on the management of patients with these syndromes, since besides just treating the symptomatic consequences of the autoantibody, targets to control disease may include the autoantibody itself or cells or pathways leading to its generation.
- Profiling anti-cytokine autoantibodies in patients with immunodeficiency could help personalize their management by potentially predicting disease manifestations and optimizing treatment options.

CONCLUSIONS

Anti-cytokine autoantibodies have been identified in healthy adults as well as in those with different diseases, suggesting that their occurrence may range from a normal homeostatic mechanism, to epiphenomena, to being directly pathogenic. In PAP, the identification of anti-GM-CSF autoantibodies came over 40 years after the initial description of the syndrome, suggesting that other currently idiopathic diseases may someday be explained by the identification of neutralizing or agonizing autoantibodies. Furthermore, it was not intuitive that systemic autoantibodies to a hematopoietic growth factor should result in disease confined mainly to the lung. The identification of anti-GM-CSF autoantibodies in cryptococcal meningitis implicates the GM-CSF pathway in host defense of this infection, much as Mendelian disorders have done for NTM and the IFN-γ–IL-12 pathway. The observation of high-titer, neutralizing anti-cytokine autoantibodies in an expanding number of diseases, beyond those characterized only by immune deficiency,[7] combined with the opportunity for novel therapeutic approaches to their diagnoses, mandates that their presence be not merely considered but rigorously sought.

Allergic Airway Diseases

David B. Corry, Evan Li, and Amber U. Luong

The allergic airway diseases comprise a large and disparate group of respiratory disorders that are characterized by airway and parenchymal inflammation that impairs sinus and lung function. The physiologic importance of the airways combined with the need to respond immunologically to an extremely broad range of infectious and irritant particulates, aerosols, and gases explains the diverse nature of airway immune disorders and their disproportionately large effect on human health. The allergic respiratory tract immune disorders covered in this chapter are among the most common of human afflictions. Non-allergic lung disorders are considered in Chapters 72 and 73.

Allergic disorders have a common immune phenotype of characteristic cellular, humoral, biochemical, and molecular components. Eosinophils, neutrophils, and tissue mast cells are easily seen on conventional hematoxylin and eosin staining of pathologic specimens. Less obvious on histochemical staining, but equally important to allergic diseases, are B cells that secrete the antibody isotypes immunoglobulin E (IgE) and IgG4, and T helper 2 (Th2) and Th17 cells that secrete a repertoire of cytokines, including interleukin-4 (IL-4), IL-5, IL-9, IL-10, IL-13, and IL-17A that coordinate and activate other allergic effector cells such as eosinophils, mast cells, B cells, and innate lymphoid cells (ILCs) in addition to target cells of the airway such as airway epithelium. The allergic airway diseases are typically chronic and occasionally fatal; although spontaneous remissions are not uncommon, they are rarely curable. However, recent insights have vastly improved prospects for improved therapy.

CLINICAL PRESENTATION OF ALLERGIC AIRWAY DISEASE

Although the diverse effector cells and molecules that characterize allergic inflammatory exudates can be seen anywhere along the respiratory tract, the functional impact of allergic disease is quite different in the upper and lower airways.

Chronic Rhinitis and Rhinosinusitis

Epidemiology and Clinical Presentation

The major upper airway inflammatory disorders are rhinitis and chronic rhinosinusitis (CRS). Rhinitis involves inflammation of the nasal mucosa categorized as either allergic, an IgE-mediated inflammation, or non-allergic rhinitis. Typical rhinitis symptoms include clear rhinorrhea, postnasal drip, and nasal congestion with sneezing and nasal pruritus, often associated with ocular symptoms such as conjunctivitis and tearing, differentiating allergic rhinitis (AR) from non-allergic rhinitis. Based on symptom duration, AR is currently classified as "intermittent" or "persistent" with severity of symptoms noted as "mild" or "moderate-severe."

KEY CONCEPTS

Classification of Allergic Rhinitis

Frequency of Symptoms	Severity of Symptoms
Intermittent	**Mild**
Symptoms present for less than 4 days to a week Or for less than 4 weeks	No presence of sleep disturbance Or impairment of daily activities, leisure and/or sport Or impairment of school or work Or troublesome symptoms
Persistent	**Moderate-Severe**
Symptoms present for more than 4 days to a week Or for more than 4 weeks	Presence of sleep disturbance And/or impairment of daily activities, leisure and/or sport And/or impairment of school or work And/or troublesome symptoms

In contrast to rhinitis, rhinosinusitis affects both the sinuses and nasal mucosa. Rhinosinusitis can be subdivided into acute and CRS based on duration of symptoms. CRS is reported to affect approximately 29 million Americans and is defined by symptoms persisting longer than 12 weeks. Clinically, CRS is broadly categorized based on the absence or presence of nasal polyps. Within CRS with nasal polyps (CRSwNP), there are several subtypes, including allergic fungal rhinosinusitis (AFRS), aspirin-exacerbated respiratory disease (AERD), and cystic fibrosis.

Signs and symptoms associated with rhinosinusitis in adults include facial pain and pressure, headaches, nasal congestion with or without obstruction, frontal or postnasal drainage, generalized malaise, and cough. In contrast, symptoms in children are age related and require the caretaker to recognize them. Young children often present with a chronic cough, and irritability rather than facial pain. The prevalence of rhinosinusitis in children is inversely related to age.[1]

Diagnosis

The diagnosis of AR is based on a history of typical symptoms and common physical exam findings. Several physical findings include "allergic shiners," a darkening of the infraorbital

skin resulting from chronic venous pooling, and a persistent horizontal crease across the nasal bridge resulting from constantly wiping the front of the nose. Bilateral conjunctivitis may be present in patients with ocular involvement.

On anterior rhinoscopy, engorged, boggy, and pale inferior turbinates with clear discharge coating the nasal cavity are supportive of AR. Examination of the oropharynx often reveals cobblestoning of the mucosa, indicating chronic postnasal drainage.

Although not necessary to make the diagnosis of AR, two tests commonly used to demonstrate IgE-mediated allergic reactions are immediate-hypersensitivity skin testing and measurement of serum allergen-specific IgE.

The diagnosis of CRS requires the presence of at least two major or one major and at least two minor clinical symptoms persisting for longer than 12 weeks in conjunction with evidence of inflammation within the sinus cavity. Major symptoms include facial pain/pressure, nasal obstruction, nasal drainage, and hyponosmia or anosmia. Minor symptoms are headaches, halitosis, fatigue, dental pain, cough, and ear pain or pressure. The most specific symptom for rhinosinusitis is the presence of discolored rhinorrhea. Evidence of inflammation on nasal endoscopy or imaging is also necessary to make a CRS diagnosis. On nasal endoscopy, inflammation is suggested by edema and/or drainage from the middle meatus; a diagnosis of CRSwNP is made when nasal polyps are visualized (Fig. 43.1). In patients with a history of CRS but normal nasal endoscopy, computed topography (CT) scanning of the sinuses is necessary to evaluate for mucosal thickening and/or fluid within the sinuses (Fig. 43.2).

Clinical CRSwNP subtypes are defined by additional criteria. For AFRS, the widely accepted criteria include five characteristics: nasal polyps; type I (immediate) hypersensitivity to fungi; radiographic imaging consistent with AFRS; eosinophilic mucin with evidence of fungi; and a lack of evidence of fungal invasion into the surrounding tissue.

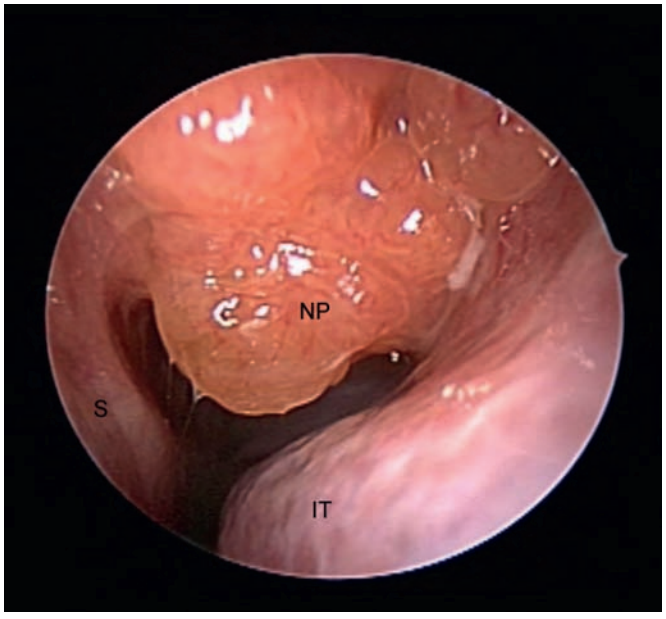

FIG. 43.1 Nasal Polyposis. Seen on this nasal endoscopy are nasal polyps *(NP)* emanating from the sinus cavity into the nasal cavity between the septum *(S)* and the inferior turbinate *(IT)* of a patient with chronic rhinosinusitis.

FIG. 43.2 Coronal Sinus Computed Tomography Image From a Patient With Chronic Rhinosinusitis. The maxillary sinuses (lateral to the nasal cavity) and ethmoid sinuses (medial to the orbital cavities) exhibit mucosal thickening and accumulation of obstructed secretions consistent with inflammatory changes within the paranasal sinuses.

KEY CONCEPTS

Diagnosis of Chronic Rhinosinusitis

Chronic Rhinosinusitis

- Presence of at least two of the following symptoms
  - Facial pressure or pain
  - Nasal obstruction or congestion
  - Anterior or posterior nasal drainage
  - Hyposmia or anosomia
- Edema or discolored drainage within the sinus cavity or middle meatus
- *Or* CT sinus showing fluid or mucosal thickening within sinus cavities

Chronic Rhinosinusitis Wthout Nasal Polyps	Chronic Rhinosinusitis With Nasal Polyps
No evidence of nasal polyps within the middle meatus as noted on nasal endoscopy in a patient with no history of previous sinus surgery	Presence of nasal polyps within the middle meatus as noted on nasal endoscopy History of nasal polyps within sinus cavity in a previously operated patient with CRS diagnosis

The diagnosis of AERD requires a history of respiratory symptoms exacerbated by oral intake of aspirin or other cyclooxygenase-1 (COX-1) inhibitors on at least two occasions or a positive reaction on aspirin challenge.[2]

Cystic fibrosis is typically diagnosed in early childhood as a result of pulmonary symptoms. However, nasal polyps in anyone younger than 18 should prompt evaluation for cystic fibrosis, confirmed by either a sweat test or a genetic test evaluation for a mutation in the cystic fibrosis transmembrane conductance regulator gene.[2]

Therapy

The most effective and widely used pharmaceutical approaches to controlling nasal and ocular symptoms of AR are intranasal

glucocorticosteroids and antihistamines. Other drugs potentially useful in rhinitis management include oral steroids, oral leukotriene (LT) receptor antagonists, intranasal chromones, and intranasal ipratropium bromide.

Unlike drugs, allergen immunotherapy is offered to change the immunologic response to antigens with chronic controlled exposure. This therapy typically requires 3 to 5 years of treatment. Two types of immunotherapy are available: subcutaneous immunotherapy (SCIT) and sublingual immunotherapy (SLIT). A concern associated with SCIT is anaphylaxis; this risk is much lower with SLIT.[3]

The treatment of CRS is more controversial than that of AR. In general, treatment consists of medical and/or surgical therapy. CRS is primarily considered to be an inflammatory rather than infectious disorder; as such, antibiotics are less frequently advocated and usually replaced with intranasal and oral steroids. In addition, daily sinus irrigations with physiologic saline represents a critical therapeutic component to counteract mucociliary dysfunction and promote antigen clearance.[4]

Patients with persistent symptoms despite medical therapy are candidates for functional endoscopic sinus surgery (FESS). In AFRS and AERD with sinuses impacted with thick eosinophilic mucus or with serious complications such as acute vision loss from expanded sinus cavities, endoscopic sinus surgery is mandatory and may be followed by medical therapy.

In those undergoing FESS, revision sinus surgery for recurrent disease despite medical therapy occurs in 16% to 25% of CRS patients. Asthma, elevated serum and/or tissue eosinophils, and noncompliance with postoperative medical therapy are associated with higher risk of nasal polyp recurrence and need for revision sinus surgeries. The newest advance in CRS treatment is anti–IL-4/IL-13 receptor antibody (dupilumab) for CRSwNP (Table 43.1). Several other biologics are undergoing clinical evaluation for management of CRS.[4]

Asthma

Epidemiology and Clinical Presentation

After several decades of rising incidence, asthma is the most common chronic disease of childhood and one of the most common disorders of children and adults in the United States. Although most frequently diagnosed initially in childhood, asthma can be first diagnosed at any age. The prevalent and incurable nature of asthma will continue to ensure it as one of the most expensive of medical afflictions both in terms of medical expenditure and time lost from work and school. Asthma is a lower respiratory tract disease characterized by dyspnea and other symptoms including cough, chest tightness, chest pain, and wheezing. Persons with mild disease often present only with a chronic cough. Symptoms are usually intermittent and are characteristically relieved by bronchodilator and antiinflammatory therapy.

Asthma patients are classified into distinct subtypes according to characteristic environmental or occupational exposures that elicit symptoms, the presence or absence of concomitant atopy, temporal expression of symptoms, and responsiveness to antiinflammatory therapy. Respiratory viruses are the most frequently implicated causes of attacks, especially in children, while tobacco smoke, ozone, and particulate air pollution are other major inciting agents. Many, but not all, asthma patients are atopic, with up to 60% of severe asthmatics showing no evidence of environmental sensitization. If atopy is present, patients are referred to as extrinsic, atopic, or allergic asthmatics, whereas those who lack atopy are referred to as having intrinsic or non-allergic asthma. In general, airway constriction occurs and symptoms are provoked when triggering agents are inhaled, representing the clinical expression of airway hyperresponsiveness, the exaggerated tendency of the airway to constrict in response to exposure to provocative agents. Some of these agents (e.g., viruses and pollens) are only intermittently present, causing seasonal asthma. Other agents are encountered continuously (e.g., fungi, dust mites) and cause persistent (or perennial) asthma. Occupational asthma is defined as asthma acquired in the workplace, where dozens of potentially toxic agents have been identified. Numerous additional asthma subsets can be defined according to the factor or factors that commonly elicit attacks of dyspnea. A final category of asthma, steroid-resistant, refers to patients relatively unresponsive to antiinflammatory steroid therapy.

Diagnosis

Asthma is often recognized on clinical grounds alone, with acute attacks marked by obvious dyspnea, wheezing, cough, and use of accessory muscles of respiration. Confirmation of the diagnosis is ensured if attacks reliably resolve with bronchodilator therapy. Spirometry can provide objective evidence of airway obstruction as assessed by reversible decrements in the forced expiratory volume in 1 second (FEV_1) and other measures of airflow such as peak airflow. When the clinical presentation is uncertain, bronchial provocation tests can determine the

TABLE 43.1 Biologic Agents Approved for Use in Allergic Airway Disease Therapy

Biologic Agent	Chemistry	Immune Target	Approved Use	Administration (Adults only)
Omalizumab	IgG1 kappa monoclonal antibody	IgE	Moderate to severe persistent asthma in patients with a positive skin test or in vitro reactivity to a perennial aeroallergen	75–375 mg every 2–4 weeks based on serum IgE level and body weight, subcutaneous
Benralizumab	IgG1 kappa monoclonal antibody	Alpha chain of the IL-5 receptor	Eosinophilic asthma	30 mg every 4 weeks for 3 weeks, then every 8 weeks, subcutaneous
Mepolizumab	IgG1 kappa monoclonal antibody	IL-5	Eosinophilic asthma	100 mg every 4 weeks, subcutaneous
Reslizumab	IgG4 kappa monoclonal antibody	IL-5	Eosinophilic asthma	3 mg/kg every 4 weeks, intravenous
Dupilumab	IgG4 kappa monoclonal antibody	Alpha chain of the IL-4/IL-13 receptor	Eosinophilic or steroid-dependent asthma; CRS with nasal polyps	400 mg followed by 200 mg every other week or 600 mg followed by 300 mg every other week

CRS, Chronic rhinosinusitis; *Ig*, immunoglobulin; *IL*, interleukin.

presence of airway hyperresponsiveness and thereby establish the diagnosis.[5] Additional laboratory data supporting a diagnosis of allergic asthma include peripheral blood eosinophilia, elevated serum total and antigen-specific IgE levels, and positive skin prick test results against one or more allergens.

Therapy

As with rhinitis and rhinosinusitis, asthma therapy is generally nonspecific and directed at improving airflow through bronchodilation and reducing inflammation. Immediate relief of bronchoconstriction and dyspnea is achieved with bronchodilating agents that activate the β_2 adrenergic receptor on airway smooth muscle beta agonists. For long-term asthma control, the most effective agent class is steroids, often combined with long-acting beta agonists (LABAs), which reduce inflammation and suppress airway constriction and dyspnea. For mild to moderate disease, bronchodilating agents and steroids are typically administered by inhalation, which significantly reduces systemic side effects. A secondary agent class used for controlling bronchospasm is anticholinergics that antagonize the muscarinic acetylcholine receptor. Severe disease may also require high-dose treatment with oral or intravenous steroids and high-dose inhaled beta agonists given by nebulizer.

Additional antiinflammatory agents for asthma treatment include LT receptor antagonists, chromones, theophylline, omalizumab (a monoclonal antibody that reduces circulating and mast cell–bound IgE), and more recently anti–IL-5, anti–IL-5 receptor, and anti–IL-4/IL-13 receptor antibodies (see Table 43.1).

Bronchial thermoplasty (BT) is a relatively new bronchoscopic technique in which heat is applied to the airways via a radiofrequency catheter to ablate airway contractile cells. Clinical trials indicate that this technique reduces exacerbation rates long term, but the risk of initially enhancing exacerbations suggests that BT should be reserved for severe asthmatics with refractory disease.

OTHER AIRWAY ALLERGIC DISEASE SYNDROMES

In addition to CRS and asthma, several other allergic airway diseases involving prominent airway and eosinophilia can cause profound morbidity. These disorders are clinically heterogeneous but are believed to share a similar pathophysiology related to inhalation of antigens that provoke airway eosinophil and Th2 responses.

Eosinophilic disorders are organized according to whether there is an *extrinsic* or *intrinsic* cause of the eosinophilia (Table 43.2). Inhaled or ingested extrinsic factors, including medications and infectious agents (e.g., parasites, fungi, mycobacteria) can trigger an eosinophilic response. This may be mild and self-limited, as in Loeffler syndrome. Intrinsic pulmonary eosinophilic syndromes are either idiopathic, malignant, or premalignant diseases, often systemic in nature.

Extrinsic Eosinophilic Syndromes

Tropical Eosinophilic Pneumonias

The tropical eosinophilic pneumonias comprise a group of clinically similar eosinophil-predominant inflammatory disorders characterized by chest pain, wheezing, cough, and airway hyperresponsiveness, often during a debilitating, but transient, febrile illness. Migrating parasites from the genera *Dirofilaria*, *Strongyloides*, *Wuchereria*, and *Brugia* traversing the lungs are considered responsible for most cases of tropical eosinophilic pneumonia. However, in the United States, *Strongyloides* spp. are the most common cause of parasitic infection and tropical eosinophilic pneumonia. Immunocompromised patients, including those taking systemic steroids, may develop *Strongyloides* hyperinfection syndrome, in which recently hatched larvae burrow through the intestine and migrate to the lungs, causing a severe and potentially fatal lung disease that is frequently complicated by sepsis (Fig. 43.3). Therapy of parasite-related pulmonary eosinophilia syndromes is directed at relieving symptoms and eliminating the parasites and other offending agents.

TABLE 43.2 Eosinophilic Lung Disorders

Disease	Causative Agent	Proposed Immune Mechanism
Loeffler syndrome	Inhaled food, infection, or medication	T cell–mediated hypersensitivity reaction
Drug rash with eosinophilia and systemic symptoms (DRESS) syndrome	Drugs: sulfonamides, phenobarbital, sulfasalazine, carbamazepine, and phenytoin	Hypersensitivity reaction to drug
Parasitic infections	*Strongyloides* spp., *Wuchereria bancrofti*, *Brugia malayi*	T-cell and B-cell clonal activation in response to parasite antigens and adjuvant factors.
Allergic bronchopulmonary aspergillosis	*Aspergillus*	IgE and immune complex deposition
Acute eosinophilic pneumonia	Fungal infections, cigarette smoking, post–stem cell transplant	Hypersensitivity response to inhaled antigen (infectious or otherwise)
Chronic eosinophilic pneumonia	Unknown systemic-mediated process	Unknown, but chronic nature evident with T cell–mediated granuloma production
Idiopathic hypereosinophilic syndrome	Infections, systemic diseases and drugs that drive peripheral eosinophilia	Systemic responses caused in part due to excess interleukin (IL)-5 production from clonal expansion of T helper 2 (Th2) cells as well as fusion gene *FIP1L1–PDGFR*
Churg-Strauss syndrome	Autoimmune vasculitis to unknown antigen, associated with asthma	Decreased T-regulatory cell function with diminished IL-10 production

Allergic Bronchopulmonary Aspergillosis

ABPA is a severe pulmonary allergic reaction to *Aspergillus* antigens seen almost exclusively in the setting of preexisting asthma or cystic fibrosis.[6] Diagnostic criteria include asthma with wheezing, peripheral blood eosinophilia, detection of precipitating anti-*Aspergillus* antibodies, elevated serum total IgE, and radiographic evidence of fleeting pulmonary infiltrates often with central bronchiectasis. *Aspergillus* spp. and other fungi can frequently be isolated from airway secretions of ABPA patients, suggesting active fungal growth within the airways, or

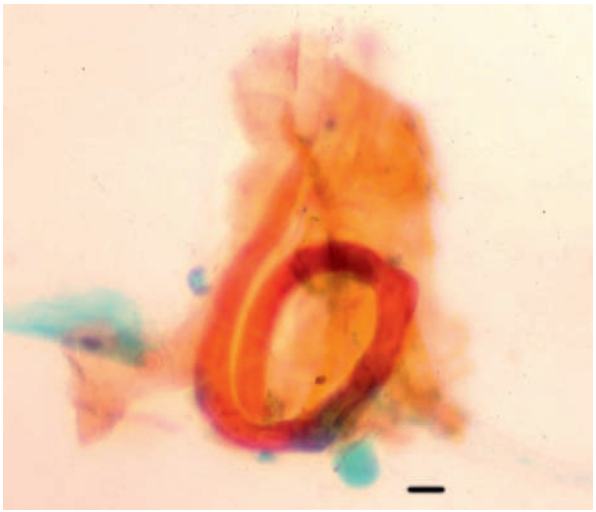

FIG. 43.3 Strongyloidiasis. The coiled larva of *Strongyloides stercoralis* is seen on this Papanicolaou stain of a bronchoalveolar lavage sample from a patient with *Strongyloides* hyperinfection. Original magnification 400×; bar=10 μm.

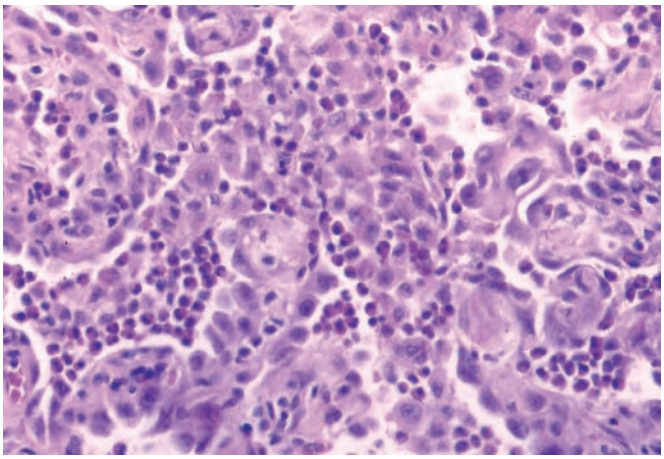

FIG. 43.4 Histology of Chronic Eosinophilic Pneumonia. Lung biopsy specimen from a patient with chronic eosinophilic pneumonia demonstrates a confluent infiltrate with eosinophils filling alveoli together with large, multinucleate macrophages. Original magnification, 200×, hematoxylin and eosin stain.

airway mycosis. Complications of chronic ABPA include severe airway hyperresponsiveness, bronchiectasis, eosinophilic pneumonia, pulmonary fibrosis, and invasive fungal disease. Treatment of ABPA aims to suppress the inflammatory response to the fungus and to control bronchospasm with steroid therapy, the duration of which may be shortened by concomitant use of oral antifungal agents such as itraconazole.[6]

Acute and Chronic Eosinophilic Pneumonia

AEP is an acute, often debilitating eosinophilic inflammatory syndrome exclusively involving the lungs and marked by pulmonary infiltrates, dyspnea progressing to frank respiratory failure, and fever. The diagnosis is dependent on eosinophils exceeding 25% of all inflammatory cells within bronchoalveolar lavage fluid. Increasing evidence suggests association between AEP and respiratory fungal infections and new-onset cigarette smoking.[7,8] AEP has also been reported following allogeneic hematopoietic stem cell transplantation in the setting of graft-versus-host disease (GVHD).[9] Prompt recognition and treatment of GVHD with steroids usually results in rapid improvement.

In contrast, CEP presents more chronically (>6 weeks' duration); although it can occur in isolation, it more frequently presents in association with autoimmune and malignant diseases. Like AEP, CEP can present with striking eosinophilic inflammation of the lung (Fig. 43.4). Granulomas are occasionally seen on biopsy, suggesting an antigen-driven, T cell–mediated process in the chronicity of the disease. Treatment, as for CEP, is centered on steroids, but unlike AEP, relapse occurs frequently after treatment discontinuation.[10]

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (HP), also termed extrinsic allergic alveolitis, is a pleiotropic acute, subacute, or chronic pulmonary inflammatory disorder marked by cough, chest tightness, malaise, and, in acute disease, fever and chills. Wheezing is uncommon, as are allergic features such as peripheral blood eosinophilia and atopy. Subacute and chronic disease typically lack fever and malaise, but dyspnea can be debilitating, progressing to hypoxemia and death due to end-stage pulmonary fibrosis if untreated. Histologically, HP presents acutely with interstitial and alveolar neutrophilia that evolves in subacute disease as lymphocytic interstitial lung inflammation often including poorly formed granulomas. Chronic disease is marked by progressively more interstitial fibrosis replacing the lymphocytic inflammation.

HP is caused by inhalation of a variety of microbes, including thermophilic actinomycetes, fungi, and protozoans, often in combination with antigens derived from plants and animals (e.g., soybean proteins; bird dander). Uncommonly, low-molecular-weight chemicals such as isocyanates can also elicit HP. Treatment is directed at removing offending inhalants and administration of steroids and bronchodilators.[11,12]

Intrinsic Eosinophilic Syndromes

Hypereosinophilic Syndrome

This multisystem disease is marked by the massive accumulation of eosinophils in many tissues and almost universally involves the lungs. Expansion of Th2 cells and local and systemic release of IL-4 and IL-5 are frequently seen. The myeloid variant of hypereosinophilic syndrome (HES) results in the clonal expansion of Th2 cells in the absence of known antigen. A deletion on chromosome 4 resulting in a *FIP1L1-PDGFRA* fusion along with a variety of other chromosomal aberrations strongly support the concept that HES is a myeloproliferative disorder involving Th2 cells, although aberrant secretion of IL-5 by both solid and liquid tumors can produce similar syndromes. The presence of $CD3^{-}CD4^{+}$ T cells is the hallmark of the lymphocytic variant of HES; the molecular mechanisms of this variant are largely unknown. When neither a mutation nor aberrant T cells can account for the aberrant eosinophilia, as is seen in approximately 75% of all cases, HES is considered idiopathic. Many organs can be affected, resulting in dysfunction or failure of the gastrointestinal tract, skeletal muscles (leading potentially to respiratory failure), endomyocardial fibrosis, myocarditis, and congestive heart failure. Pulmonary involvement manifests as obstructive

airway disease, pulmonary edema, or pulmonary emboli due to a hypercoagulability. Diagnosis is based on discovery of peripheral blood eosinophilia in the setting of a multisystem disorder, with evidence of aberrant Th2 responses or elevated IL-5 secretion, a defined mutation in the case of the myeloid variant of HES, and the presence of $CD3^{-}CD4^{+}$ T cells in the lymphocytic variant. The most effective therapy for HES is based on tyrosine kinase inhibition using agents such as imatinib mesylate for myeloid variant HES. For lymphocytic and idiopathic variants of HES, the goal is to reduce peripheral eosinophilia with steroids, hydroxyurea, or anti–IL-5 antibodies (see Table 43.1).[13]

Eosinophilic Granulomatosis and Polyangiitis

Eosinophilic granulomatosis and polyangiitis (EGPA), also termed Churg-Strauss syndrome (CSS), is an idiopathic necrotizing vasculitis of medium- and small-caliber vessels characterized by airway obstruction and eosinophilia. The disease has an autoimmune nature, with circulating antimyeloperoxidase and antineutrophil cytoplasmic antibodies (p-ANCA) in 60% to 70% of affected individuals. Because EGPA is usually seen in patients with a history of asthma and allergies and the prominent pathologic feature is necrotizing vascular and tissue granulomas, the term "allergic granulomatosis and angiitis" is used synonymously. Reports linking EGPA with the LT inhibitors zafirlukast and montelukast associated with steroid withdrawal suggest that these agents unmask preexisting EGPA rather than directly causing the disorder. Similar observations have been made with omalizumab treatment. The vasculitis of CSS can affect the sinuses, central and peripheral nervous systems, gastrointestinal tract, kidneys, and heart. Treatment of CSS is based on reinstituting systemic steroids, leading to disease resolution in most patients. Severe steroid-resistant disease may require cyclophosphamide and other immunosuppressants.[14]

IMMUNOLOGIC MECHANISMS OF ALLERGIC AIRWAY DISEASE

The immune mechanisms of disease proposed by Gell and Coombs in the 1960s remain essential to understanding the pathogenesis of allergic airway diseases. Although such mechanisms probably operate in all allergic diseases, their relative importance depends on whether the disease process predominantly affects the upper or lower respiratory tract (Fig. 43.5).

KEY CONCEPTS

Immunopathogenesis of Allergic Airway Disease

- Gell and Coombs type 1 and type 4 hypersensitivity mechanisms contribute to disease expression, especially airway obstruction.
- Innate immune pathways involving interleukin (IL)-33, thymic stromal lymphopoietin (TSLP), IL-25, and complement proteins critically contribute to the development of allergic airway inflammation.
- Environmental agents that are now established as important initiation factors for allergic airway inflammation include proteases, and endotoxin derived from fungi and bacteria.
- Fungi and viruses are established infectious causes of allergic disease of the upper and lower airways.

Type I (Immediate) Hypersensitivity

This form of hypersensitivity involves the activation of basophils and mast cells that release histamine and other inflammatory mediators. Antigen recognition is via IgE antibodies binding to high-affinity receptors (FcεRI) to arm effector cells. Th2 cells

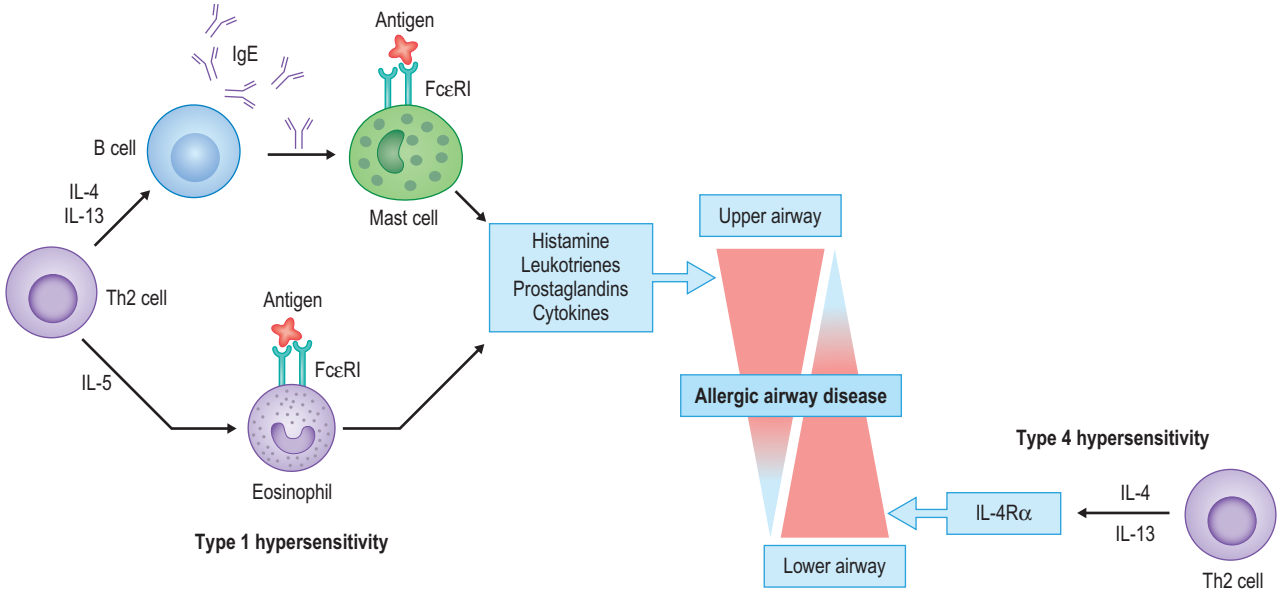

FIG. 43.5 Differential Importance of Allergic Immune Mechanisms According to Airway Level. Type I hypersensitivity *(left)*, mediated by immunoglobulin E *(IgE)*-primed mast cells and eosinophils, is ultimately driven indirectly by the cytokines secreted by T helper 2 *(Th2)* cells. In contrast, type IV hypersensitivity *(right)* is mediated directly by Th2 cytokines, especially interleukin *(IL)*-4 and IL-13, acting through a similar receptor that includes IL-4Rα. Both immune mechanisms are important to the expression of allergic disease at all airway levels, but type I hypersensitivity predominates in the upper airway, whereas type IV hypersensitivity likely assumes a more important role in the lower airway.

coordinate both production of IgE antibodies and activation and recruitment of allergic effector cells to the airway. Antigen-specific IgE bound to the surface of mast cells and basophils is cross-linked upon exposure to relevant antigens, causing cellular activation and release of preformed mediators of inflammation such as histamine, proteases, LTs, numerous cytokines, and other substances. IL-4 released primarily by Th2 cells is an important regulator of type I hypersensitivity reactions because it is required for B-cell maturation and IgE secretion.

There is evidence that IL-4 and IL-13 can mediate distinct effector phenotypes in airway and tissue macrophages and dendritic cells. Two major effector macrophage subtypes include conventionally activated (M1) macrophages that arise under the predominant influence of type I cytokines, especially interferon (IFN)-γ, and alternatively activated macrophages (M2) that arise under the influence of IL-4 and IL-13 in the relative absence of IFN-γ. M2 macrophages express a distinct gene profile including high-level expression *of arginase 1, Ym1, Fizz1 (RELM)*, and *PD-L2*. Current evidence suggests that M2 macrophages promote allergic responses and that redirecting them to the M1 phenotype might be useful.[15] Type I hypersensitivity is most prominently activated during anaphylaxis and AR.

Cell-Mediated Features of Immediate Hypersensitivity

Airway obstruction in allergen-sensitized asthma evolves over several hours after allergen exposure and is seen in two distinct phases. The early phase response is marked by airway constriction that becomes maximal approximately 30 minutes after allergen exposure and is fully relieved after approximately 2 hours (Fig. 43.6). Approximately 50% of asthmatic subjects tested develop a late-phase response in which airway obstruction again develops 4 to 6 hours after allergen exposure. Late-phase reactions are linked to airways infiltration with Th2 cells and eosinophils. The accompanying bronchoconstriction is reversible with bronchodilating agents.[16]

Airway hyperresponsiveness is neurologically mediated through parasympathetic nerves such as the vagus and is fully reversible with bronchodilating agents that either interrupt muscarinic parasympathetic signaling directly (e.g., ipratropium bromide) or activate receptors (e.g., β_2-adrenergic) that antagonize muscarinic bronchoconstrictive pathways. Airway hyperresponsiveness is recognized as episodic bronchoconstriction that is reversed with bronchodilating agents. Late-phase responses after antigen challenge therefore represent a form of airway hyperresponsiveness.

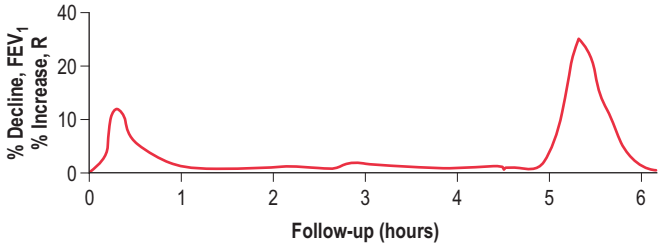

FIG. 43.6 Early- and Late-Phase Airway Changes Following Allergen Challenge. This graph shows the two phases of bronchoconstriction typically seen after allergen inhalation in sensitized, asthmatic subjects. Within 20 to 30 minutes after allergen inhalation, the first (early) phase of bronchoconstriction is seen, as assessed by either a decline in forced expiratory volume in 1 second *(FEV_1)* or increase in airway resistance *(R)*. After quickly subsiding, approximately 4 to 6 hours (h) later, a second (late) phase of bronchoconstriction occurs.

Studies from many species have demonstrated that airway hyperresponsiveness in the setting of allergic inflammation is critically dependent on Th2 cells and type 2 ILCs (ILC2) that have specifically been recruited to the lung. Moreover, it is now clear that IL-13 is the major Th2 and ILC2 cytokine that mediates airway hyperresponsiveness by acting on constitutive airway cells, such as airway smooth muscle cells, that express the IL-13 receptor. However, IL-13 does not directly induce bronchoconstriction. Bronchoconstriction in asthmatics is triggered by diverse exogenous factors in addition to allergens (e.g., altered temperature and humidity, pungent odors, irritating aerosols) and endogenous stimuli (e.g., extreme emotional states) with little apparent connection to immunologic mechanisms. Thus, rather than directly mediating airway obstruction, IL-13 establishes the basis for responding broadly to diverse agents with neurologically mediated bronchoconstriction.[17]

A second and more insidious form of airway obstruction is physical obstruction of the airways due to mucus and fibrin clots accumulating in the airways as tenacious plugs, a phenomenon currently termed plastic bronchitis. Airway obstruction due to plastic bronchitis is not immediately reversible with bronchodilators or other pharmacologic agents and is consequently the major cause of asthma death due to asphyxiation.[18]

Finally, IL-4 and IL-13 further coordinate the recruitment and retention of allergic effector cells to airway epithelium and submucosa, which facilitates rapid responses to inhaled allergens. Acting through a similar receptor that includes the alpha chain of the IL-4 receptor (IL-4Rα), IL-4, and IL-13 signal constitutive airway cells such as airway epithelial cells to induce secretion of a restricted repertoire of chemoattractants that promote the immigration of allergic cells expressing specific cognate receptors from the lung and airway microcirculation (Table 43.3).[19]

Contributing Immune Mechanisms in Allergic Airway Disease

IL-5 contributes to both immediate and cell-mediated hypersensitivity reactions by promoting the growth and differentiation of eosinophils. Although widely viewed as pathogenic and contributing to expression of allergic airway diseases, more recent studies indicate that eosinophils are important in tissue remodeling and in controlling allergic inflammation induced by pathogens such as fungi.

In addition to Th2 cells, mast cells, and eosinophils, ILCs including ILC2, natural killer cells (NK cells; a type of ILC1) and γδ T cells may also contribute to allergic disease expression through their ability to rapidly secrete type 2 and other cytokines.[20]

TABLE 43.3 Chemoattractants Linked to the Recruitment of Allergic Inflammatory Cells

Chemokine	Receptor
CCL1	CCR8
CCL11	CCR3
CCL17, CCL22	CCR4
CX_3CL1	CX_3CR1
Prostaglandin D_2	CRTh2
Leukotriene B_4	BLT1

Numerous additional mediators contribute to the expression of allergic disease. The complement system is especially important; complement proteins C3a and C5a, the major anaphylatoxins, are both essential for the expression and regulation of experimental asthma. C3a signaling through the C3a receptor (C3aR) is required for robust Th2 responses, allergic inflammation, and airway hyper-responsiveness in response to airway allergens. In contrast, C5a, which can signal through two receptors, C5aR and C5L2, appears to inhibit Th2 responses, perhaps acting as a physiologic antagonist of the allergic disease–promoting activity of C3a.[21]

Inflammatory lipid mediators important to allergic airway disease include the LTs and prostaglandins (PGs). The cysteinyl LTs (CysLTC4, CysLTD4, and CysLTE4) signal through at least two receptors to mediate similar allergic features as IL-13, including airway inflammation and hyperresponsiveness. Full expression of experimental allergic disease, in fact, appears to require the concomitant expression of both IL-13 and the CysLTs. However, IL-13 appears to be the dominant allergic mediator, perhaps partly accounting for why LT antagonism alone is less effective than inhaled steroids in treating asthma. Noncysteinyl LTs such as LTB_4 also contribute to the expression of allergic airway inflammation by controlling recruitment of allergic effector cells, including Th2 cells.[22]

Environmental Factors and Allergic Disease Initiation

Formerly, asthma, rhinosinusitis, and rhinitis were believed to result from aberrant immunologic responses to innocuous inhaled antigens, including allergens derived from dust mites, cats, dogs, and plants. More recently, a major exception to the intrinsically innocuous nature of allergens was recognized. Specifically, the allergenic fungi such as *Aspergillus* spp. and other molds, but also yeasts such as *Candida albicans*, are now recognized as ubiquitous respirable agents that can actively infect and grow within the respiratory tract, producing airway mycosis.[23]

A fungal infectious basis for allergic airway disease is demonstrated by (1) the high rate of isolation of filamentous fungi from the airways in CRS, especially AFRS, asthma and ABPA; (2) the almost universal presence of fungus-specific Th2 immunity and fungi isolated from airway mucus in subjects with allergic CRS (Fig. 43.7); (3) the efficacy of antifungal antibiotics when given to fungus-sensitized asthmatics; and (4) experimental validation that filamentous fungi are infectious for the mouse airway and produce allergic airway disease comparable with asthma. Moreover, fungal airway infection is sufficient to induce atopy to innocuous bystander antigens, suggesting that fungal infection could underlie both atopy and respiratory tract allergic disease.[23]

Respiratory viruses and particulate matter are also prominently linked to allergic airway disease. Approximately 70% to 80% of children and adults test positive for human rhinovirus (HRV) during acute disease exacerbations. Other respiratory viruses likely contribute to allergic disease pathogenesis, although the mechanisms remain obscure.[24] Particulate matter such as tobacco smoke, diesel exhaust particles, and other forms of smoke are strongly linked to asthma exacerbation and enhanced atopy, as is exposure to ozone (O_3). A common link tying these various forms of air pollution to allergic disease may be induction of oxidative stress, ultimately leading to enhanced activation of nuclear factor kappa B (NF-κB), enhanced Th2 cytokine release, and increased allergic inflammation.[25]

Research from experimental systems has shed additional light on how allergens initiate inflammation and disease. Although structural features of allergens are not linked to their allergic character, a common biochemical feature strongly associated with allergic disease is protease activity. Proteases as single molecules are as effective as any complex allergen or fungal infection in inducing allergic airway inflammation and hyperresponsiveness when administered to rodents or inhaled by humans. Household proteases that retain enzymatic activity are derived largely from fungi, suggesting again that airway infection due to these organisms, resulting in in situ protease production, may be an important mechanism underlying allergic disease induction. Irritation of the airways through viral infection, ozone exposure and other mechanisms further increases endogenous airway protease activity, especially through induction of thrombin activity.[23]

Analyses of diverse allergenic proteases suggest that they initiate a complex, airway epithelial-centered mechanism in which the cytokines thymic stromal lymphopoietin (TSLP), IL-33, and IL-25 are induced and lead to robust allergic responses. In part, this sequence is initiated by the action of exogenous and endogenous proteinases on fibrinogen. Cleavage of fibrinogen by

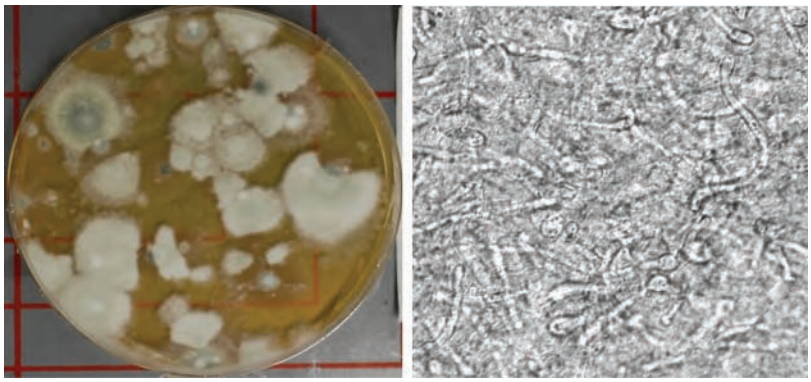

FIG. 43.7 Respiratory Tract Fungi in Allergic Airway Disease. (A) Representative Sabouraud's plate fungal cultures of sinus lavage fluid from a representative subject with chronic rhinosinusitis and asthma. (B) Photomicrograph of unstained sinus lavage mucus from a representative patient with allergic fungal rhinosinusitis showing extensive hyphal network (400× original magnification). (Modified from Porter, P.C., Lim, D.J., Maskatia, Z.K., et al., Airway surface mycosis in chronic T_H2-associated airway disease, *J Allergy Clin Immunol*. 2014;134:327.)

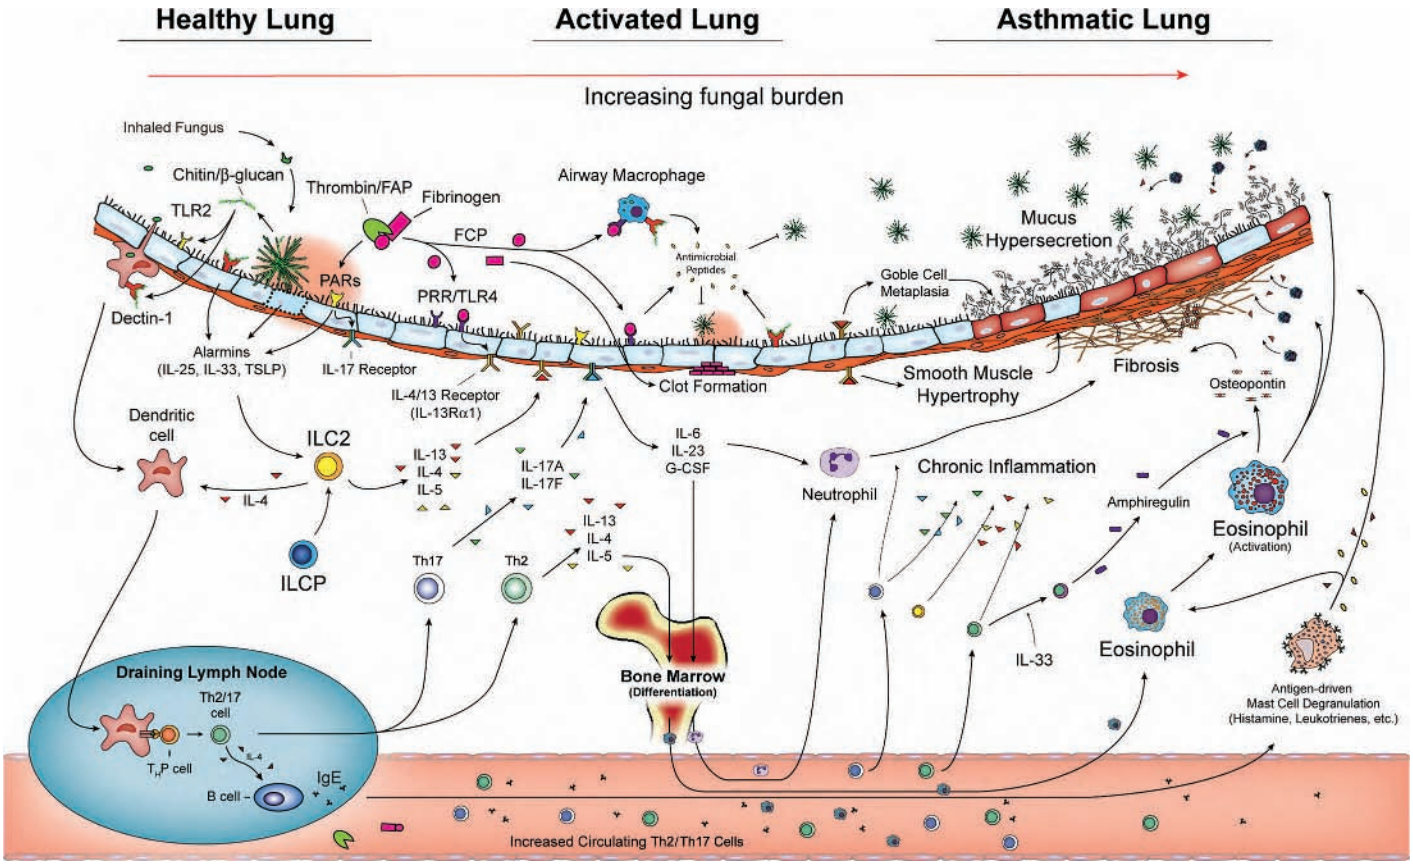

FIG. 43.8 Immune Pathogenesis of Asthma Due to Airway Mycosis. All initially healthy individuals are exposed to inhaled fungi that can produce at least transient airway mycosis. Depending on host and environmental factors, the airway mycosis can lead to airway inflammation that characterizes the activated, but not necessarily diseased, lung, and eventually progresses to clinically significant asthma with attendant immune and structural sequelae. The initial wave of airway mycosis triggers innate allergic responses by activating pattern recognition receptors (*PRRs*) including Toll-like receptor 2 *(TLR2)* and Dectin-1 expressed on airway epithelial and immune cells that detect fungal sugars such as chitin and β-glucan. Epithelial cells then secrete cytokines such as interleukin-25 *(IL-25), IL-33*, and thymic stromal lymphopoietin (TSLP) into the subepithelial space to promote the development of innate lymphoid cells type 2 *(ILC2)* and dendritic cells that migrate to draining lymph nodes and promote development of T helper type 2 (*Th2*) and *Th17* cells and IgE-secreting B cells. At the same time, endogenous proteinases, and potentially fungal proteinases, promote the breakdown of fibrinogen into fibrinogen cleavage products *(FCP)* that signal through TLR4 to initiate airway hyperreactivity, eosinophilia, and mucous hypersecretion. Proteinases, fungal and endogenous, may also interact with protease-activated receptor 2 (PAR2) to either promote or attenuate asthma-like disease. With greater degrees of airway mycosis, the low-grade, innate allergic inflammation that characterizes healthy and activated lungs converts to a chronic lung (asthma) phenotype characterized by more persistent and intense allergic inflammation that includes prominent T helper 2 (Th2) cells and Th17 cells, eosinophils (under the direction of *IL-5*), and mast cells (under the direction of *IL-4* and immunoglobulin E *[IgE]*), and neutrophils (under the direction of *IL-17A* and related cytokines), which promote severe allergic inflammation, airway hyperreactivity, and mucous hypersecretion that characterize various asthma endotypes. Most of these immune elements, including highly activated neutrophils, eosinophils, and antimicrobial peptide-secreting epithelial cells, have an antifungal role. Nonetheless, failure to resolve airway mycosis can result in permanent airway damage including airway fibrosis and bronchiectasis. (Reproduced from Li, E., Knight, J.M., Wu, Y., et al., Airway mycosis in allergic airway disease *Adv Immunol.* 2019;142:106.)

proteases yields fibrinogen-cleaved products (FCPs) that signal through Toll-like receptor 4 (TLR4) to initiate both antifungal responses and innate allergic inflammation, including ILC2 responses (Fig. 43.8).[23]

NOVEL PATHWAYS TO THERAPY IN INFLAMMATORY AIRWAY DISEASE

Intensive research conducted over several decades has markedly improved understanding of the immune and environmental basis of allergic and non-allergic airway diseases. However, currently available therapies for these diseases have failed to match this level of sophistication. Allergic disease is immunologically complex and likely to involve multiple hypersensitivity mechanisms operating in parallel. Recent studies also show that factors other than allergens likely critically influence the airway immune response to inhaled antigens and particulate matter. These adjuvant factors include cell wall products of bacteria and fungi, secreted factors such as proteases, and endogenous factors that result from cells damaged through exposure to allergens and smoke. Evidence further suggests that asthma

and rhinosinusitis may be linked to respiratory tract infections involving viruses, especially HRV, and fungi. Future therapies are therefore likely to focus on both the endogenous factors that coordinate allergic inflammation (e.g., cytokines) and etiologic environmental factors.

Once considered primarily a physical barrier, the respiratory epithelium is now known to actively coordinate immunity to allergens and other environmental challenges. Through release of IL-33, IL-25, and/or TSLP, respiratory epithelial cells can initiate and coordinate the innate and adaptive type 2 immune response (see Fig. 43.8). In addition, respiratory epithelial cells produce several chemokines in response to environmental triggers recruiting dendritic cells, ILC2s, basophils, eosinophils, and mast cell progenitors.[26] A number of triggers listed earlier as well as trauma to airway cells can activate the release of these type 2 cytokines and chemokines.

The epithelial cell cytokines, IL-25, IL-33, and TSLP share many overlapping functions supporting a local type 2 inflammatory response but also possess unique functions. For example, IL-33 and IL-25 activate different types of ILCs, with IL-33 primarily activating ILC2 while IL-25 preferentially stimulates a novel population of type 2 innate cells. TSLP is associated more with activation of the adaptive type 2 inflammatory response via dendritic cells and uniquely supports the hematopoiesis of basophils. Together, these epithelial cell–derived cytokines orchestrate a robust innate and adaptive type 2 inflammatory response in addition to initiating repairs needed for the epithelial barrier (see Fig. 43.8).[26]

ON THE HORIZON

- Clinical trials focused on interrupting key innate immunologic pathways (*i.e.*, IL-33, thymic stromal lymphopoietin [TSLP]) in allergic disease.
- Focused research on the importance of infectious pathogens, especially fungi, in asthma and chronic rhinosinusitis.
- Accelerated development of biomarkers for asthma, chronic rhinosinusitis, and possibly other allergic airway disorders.
- Emergence of clinical trials focusing on antiinflammatory small molecules.

Recent studies have verified the importance of Th2- and ILC-derived cytokines, including IL-5 and IL-13, to the pathogenesis of human allergic disease. The anti–IL-5 antibody mepolizumab and anti–IL-4/IL-13 receptor (dupilumab) antibodies were recently approved for use in eosinophilic asthma and appear to offer substantial benefit (see Table 43.1). In addition to defining diseases that are most likely to benefit from them, a major challenge with all biologic agents is overcoming their prohibitive costs. Therefore the therapy of allergic airway diseases is likely to evolve toward the development of small, relatively easily manufactured and relatively inexpensive molecules that antagonize disease-related pathways established through biologics as essential to disease expression.

The central role that proteases and the proteolytic activation of complement (e.g., C3) and coagulation-related inflammatory pathways (e.g., fibrinogen) play in allergic diseases support targeting of these molecules as part of future clinical trials in allergic airway disease. However, the discovery that severe, life-threatening forms of asthma and severe CRS are ultimately due to fungal infections suggests that novel anti-inflammatory therapies must be combined with antifungal approaches if patients are to derive maximum benefit. Although several positive trials involving antifungals for allergic airway disease have been reported, future studies are likely to involve improved clinical trial designs combined with superior antifungal agents and improved means of delivery, including by aerosol.

Mast Cells and Mast Cell Disorders

Cem Akin, Michelle Al-Hosni and Dilawar Singh Khokar

Mast cells (MCs) are granular innate immune cells that are widely distributed in tissue and are best recognized as the primary effector cell of allergic disease. While there is still much to learn about human MCs, significant advancements have been made in our understanding of human MCs including their functions independent of allergic disease as well as the origin and development of MCs and their progenitors. In this chapter, we will review the origin, development, and functions of MCs, as well as their roles in human health and disease. Basophils are circulating cells containing granules staining similarly to MCs (Fig. 44.1), attributed with overlapping pathogenic roles in allergic disease, although their physiologic function is less understood.

MAST CELL BIOLOGY

Mast Cell Origin and Early Development

MCs are of hematopoietic origin. One proposed model of MC development is that hematopoietic stem cells in the bone marrow give rise to different types of progenitor cells including multipotent and common myeloid progenitors that progress to a mast cell progenitor (MCp), which exits the bone marrow and migrates to different tissue sites to complete differentiation and maturation.[1] Tissue resident MCs persist for extended periods of time and are exposed to a host of stimuli, which allows further differentiation and maturation.[1,2] MC development occurs along a myeloid pathway in distinct stages characterized by various cell surface markers as well as variable expression in transcription factors. In humans, the MCp population exists as CD34/CD117/CD13 positive cells.[3]

Although multiple cytokines influence MC growth and development, stem cell factor (SCF) is considered the most important.[4] SCF is the ligand for the c-kit receptor (CD117), which is a transmembrane receptor with intrinsic tyrosine kinase activity.[4] SCF is best known for facilitating MC survival that is thought to occur via its inhibition of apoptotic proteins.[4] It has also been linked to other MC functions including proliferation, differentiation, maturation, cellular adhesion, and MC chemotaxis.[4] In addition, SCF has been implicated in the augmentation of mast cell activation (MCA) via different receptors including FcεR1 as well as TLR4, and c-kit signaling enhances MC degranulation via calcium influx and induction of changes in transcriptional activity.[4] Gain of function mutations in the c-kit receptor gene are central to the pathogenesis of mastocytosis.[5] Mice with hypofunctioning KIT/SCF pathway have a profound MC deficiency. These findings demonstrate that SCF/KIT is a key signaling pathway for MCs, although there are likely additional factors contributing to progenitor development.[6] *In vitro*, MCs can be cultured from $CD34^+$ sorted progenitors in hematopoietic stem cell media supplemented with SCF alone.[4] It has been generally thought that MCs share a common progenitor with myeloid cells, although a MC specific unique progenitor directly branching from the multipotential progenitor cell has also been demonstrated.[7]

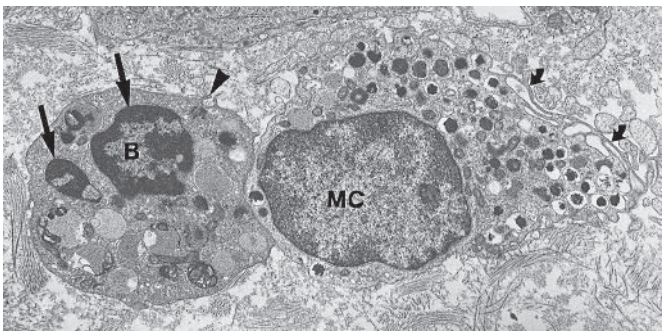

FIG. 44.1 Ultrastructures of Mast Cell and Basophil. A basophil *(B)* adjacent to a mast cell *(MC)* in the ileal submucosa of a patient with Crohn disease. The basophil exhibits a bilobed nucleus *(solid arrows)* whose chromatin is strikingly condensed beneath the nuclear membrane. The basophil surface is relatively smooth with a few blunt processes *(arrowhead)*. The mast cell nucleus is larger and its chromatin less condensed than that of the basophil. The mast cell's granules are smaller, more numerous, and more variable in shape and content than those of the basophil. The mast cell surface has numerous elongated, thin folds *(curved arrows)* (original magnification approximately ×9000). (From Dvorak AM, Monahan RA, Osage JE, Dickersin GR. Crohn's disease: transmission electron microscopical studies. *Hum Pathol*. 1980;11:606–619, with permission from Ann M. Dvorak.)

KEY CONCEPTS

Mast Cell Origin and Development

- MCs originate from the bone marrow and belong to a myeloid lineage.
- MCps migrate to different tissues where they complete differentiation/maturation and may reside for long periods of time.
- Stem cell factor and c-KIT signaling are central to MC survival and function as well as development of mastocytosis.
- MC progenitors reside in a CD34/CD117/CD13 positive progenitor pool.

Mast Cell Homing

Tissue-specific homing of MCps is a critical portion of MC development as it enables maturation and differentiation in unique microenvironments. Integrins and cell adhesion mole-

cules help mediate the process by which MCps localize to different tissues. Human MCps express α4β1 integrin and this regulates adhesion to activated endothelial cells, which in turn helps facilitate migration of MCps from circulation to tissue. Integrin expression also varies by target tissue. For example, mucosal MCs require β7 to mediate homing to the gut; the integrin α4β7 mediates homing to the gut by binding MadCAM1 (mucosal address in cell adhesion molecule 1) and VCAM-1 (vascular cell adhesion molecule 1). MCps express a number of different chemokine receptors including CCR1, CXCR2, CCR3, CXCR4, and CCR5.[8] In humans, expression of CCR1 and CCR5 has been linked to MCp retention in the bone marrow as compared to circulating precursors.[8] CXCR2 is involved in the homing of MC precursors to the intestine.

Mast Cell Heterogeneity

There is substantial heterogeneity among MCs in regard to protease content, receptor expression, mediator content, and responsiveness to immunologic and nonimmunologic stimuli. MC heterogeneity can occur between different tissues and within the same tissue. Historically, MCs have been classified based on their protease content with two major subtypes: MCt (tryptase only) and MCtc (tryptase and chymase). Classically, MCts are found predominantly at mucosal surfaces while MCtcs are found in connective tissue. Recent studies suggest that MCs are far more heterogeneous than their protease content would suggest. Transcriptional analysis of MCs isolated from different tissue sites has revealed significant variance in genes encoding serine proteases, metalloproteases, adhesion molecules, mediator production, and cytokine production.[9,10] Differential transcriptional expression has also been noted to occur in MCA with different stimuli such as in immunoglobulin E (IgE) cross-linking versus interleukin (IL)-33 stimulation.[11] Different disease states are also associated with specific changes in MCs. For example, in eczema, MCs in the skin display increased substance P and neurokinin receptor expression as compared to MCs in the gastrointestinal (GI) tract where chymase expression is increased in response to parasitic infection. In murine models of food allergy, activation of connective tissue MCs was linked to systemic anaphylaxis and activation mucosal mast cell protease-1 (MMCP-1) MCs was linked to GI-predominant reactions.[12] Collectively, these findings support the concept that MCs express different gene profiles in response to environmental stimuli resulting in inter- and intra-tissue–specific variability that contribute to both MC-mediated disease and homeostatic function.

KEY CONCEPTS

Mast Cell Homing and Heterogeneity

- MC homing to tissue is mediated by adhesion molecules such as integrins and also by chemokines. For homing to the gut, α4β7 binding to MadCAM1 is critical.
- There is substantial heterogeneity among MC populations with variances in protease content, receptor expression, mediator content, and responsiveness to stimuli.
- MC heterogeneity and phenotype play important roles in both normal MC function and disease pathogenesis.

MAST CELL ACTIVATION

A characteristic feature of MCs is their ability to be activated by multiple stimuli in complex environments. This functionality is central to their role in homeostasis and a number of disease states. Table 44.1 summarizes key ligands and receptors in MCA. The most extensively studied MC receptor is FcεR1 (high affinity IgE receptor). FcεR1 is a tetrameric receptor (composed of α, β, and 2 γ subunits) lacking intrinsic kinase activity, where α subunit binds IgE, and γ subunit mediates signal transduction. Crosslinking of FcεR1 via IgE-antigen complexes results in receptor aggregation that initiates a tyrosine phosphorylation cascade stimulated by lyn/syk, fyn, and hck kinases leading to a multiphasic cell response.[4] This response is characterized by MC degranulation with immediate release of preformed mediators (such as histamine), followed by rapid production of lipid mediators (prostaglandins such as PGD_2 and cysteinyl leukotrienes [LT]), and cytokine production.[4]

MCA response coincides with the biphasic early and late phase symptoms of allergic diseases such as allergic rhinitis. Activation of FcεR1 by IgE also has effects independent of degranulation including promotion of MC survival and increasing cell expression of FcεR1.[4] Whether or not IgE *independent* of antigen is able to activate MCs has been an area of controversy. Monomeric IgE bound to FcεR1 without antigen has been shown to trigger MC degranulation, amplify migratory response, and enhance MC survival.[13–16] Histamine-releasing-factor (HRF) has also been implicated in antigen-independent IgE activation of MCs by facilitating crosslinking of IgE bound to FcεR1.[17] These findings support a role of MCA in allergic disease independent of sensitization status and also highlights the importance of IgE-FcεR1 binding interaction as a therapeutic target for MC-mediated processes.

Non–IgE-mediated MCA is an area of active investigation as it provides insight into disease processes where symptoms mediated by MC degranulation are present, but there is no clear IgE-mediated sensitization. MCA by a variety of different triggers has been described including IgG (through FcγR1, RIIa, and RIII), complement receptors, PAMPs (pathogen associated molecular patterns) via toll-like receptors (TLRs), MRGPRX2 (Mas-related G-protein-coupled receptor-X2) through various ligands, alarmins, chemokines, and cytokines.[4,18] IgG-mediated MCA occurs via IgG binding to FcγR and provides a mechanism by which MCA may occur in autoimmune diseases as many autoimmune conditions are characterized by IgG immune complex formation. Likewise, complement activation in autoimmune and infectious disease may contribute to MCA via C3a and C5a receptors. MRGPRX2 is a G protein coupled receptor thought to be involved in several MC functions including innate immune responses, wound repair, and induction of MC degranulation in a manner independent of IgE.[19] *In vitro* experimentation using small molecule drugs such as fluoroquinolone antibiotics and neuromuscular blocking agents have demonstrated that such medications are capable of eliciting MC degranulation via MRGPRX2.[20] This would suggest that a subset of immediate drug hypersensitivity reactions may be non–IgE-mediated and potentially explains how a patient without prior exposure or sensitization to a drug could display an allergic reaction to that drug on first exposure. Recently, there has been an increased focus on MC neural interactions given the close proximity of MCs to nerve fibers in peripheral tissue. Many neuropeptides, such as substance P (also acting through MRGPRX2 receptor), have been demonstrated to cause MC degranulation, and neurologic symptoms such as itch and sometimes pain are often present in MC mediated processes.[18]

TABLE 44.1 Mast Cell Activation

Ligand/Receptor	Biologic Effect	Clinical Significance
SCF/c-kit	Enhances MC survival, migration, and adhesion as well as stimulation of IL-6 production.	Mutations in c-kit are associated with mastocytosis, and kit inhibitors are emerging as therapy for MC disease.
IgE/FcεR1	Causes MC degranulation, lipid mediator, and cytokine production.	Mechanism of IgE-mediated allergic disease.
IgG/FcγR1, RIIa and RIII	Causes MC degranulation, proinflammatory cytokine production, and lipid mediator production.	Contribution of MC to immune response to pathogens; possible role of MC activation in autoimmune disease.
C3a, C5a/C3aR, C5aR	Enhances IgG/FcγR-induced MC degranulation; promotes MC migration, adhesion, and mediator production.	Contribution of MC to immune response to pathogens; possible role of MC activation in autoimmune disease.
PAMPs/TLR-1, 2, 4, 5, 6	Increases cytokine production from MCs; depending on context can inhibit IgE/FcεR1 activation.	Contribution of MC to immune response to pathogens; possible role in regulation of IgE allergic responses.
Neuropeptides and drugs/ MRGPRX2	Cause MC degranulation in response to different stimuli including substance P and small molecule drugs	Possible mechanism of pseudo-allergic reactions and of allergic reactions upon first exposure to a drug.
IL-4/IL-4R	Enhances FcεR1 expression, increases release of MC mediators, and enhances MC production of other Th2 cytokines.	Possible mechanism of anti-IL4 therapies in allergic disease.
IL-33/ST2	Promotes MC activation, survival, maturation, adhesion, and cytokine production.	IL-33 is an alarmin and is released in response to cellular damage or inflammation, thus highlighting the role of MCs in immune responses to tissue damage and inflammatory diseases.
TSLP/TSLP-R	Promotes MC survival, but with little MC activation or stimulation of cytokine production.	TSLP is released by barrier/epithelial cells in response to a number of stimuli and is one mechanism by which MCs interact with their local environment.

IL, Interleukin; *MCs*, mast cells; *MRGPRX*, Mas related G protein coupled receptor X; *PAMP*, pathogen associated molecular pattern; *SCF*, stem cell factor; *TSLP*, Thymic stromal lymphopoietin.

MCA is regulated by inhibitory receptors containing tyrosine-based inhibitory motifs (ITIMs) intracellularly. Siglec 6 and 8, CD300a, and FcγRIIb are examples of such inhibitory receptors in humans.

MAST CELL MEDIATORS

MC and basophils express a myriad of potent biologically active mediators. These mediators are either stored preformed in cytoplasmic secretory granules or synthesized *de novo* upon cellular activation and help to orchestrate various functions in inflammation and host defense (Table 44.2).

Preformed Mediators

Preformed mediators, such as histamine, proteases (*e.g.*, tryptase, chymase, and carboxypeptidase A), and proteoglycans (*e.g.*, heparin) are stored in cytoplasmic granules and rapidly released within seconds to minutes upon cell activation. The specific profile of preformed mediators is influenced by MC subtype and the surrounding microenvironment. Degranulation can occur by several mechanisms, generally involving the fusion of membrane granules with the plasma membrane, resulting in the release of granular contents into the extracellular environment. Similar to lysosomes, MC granules are stabilized by a low pH and contain lysosomal enzymes. One such enzyme is β-hexosaminidase, found in all MC subtypes. Quantification of released β-hexosaminidase activity has been used as a measure of MC degranulation *in vitro*.[2] Uniquely, MCs are able to re-granulate and therefore remain functional following activation and subsequent degranulation.[2] Histamine, tryptase and proteoglycans are discussed more detail below due to their clinical significance.

Histamine

Histamine is derived by the decarboxylation of the amino acid histidine. The main source of histamine in humans are MCs and, to a lesser extent, basophils.[21] However, histamine is also produced by neurons, enterochromaffin-like cells in the stomach, and bacteria including those in the gut.[21] Circulating histamine interacts with target cells via four types of receptors (H1-4) and ultimately contributes to the increased vascular permeability, vasodilation, smooth muscle contraction, bronchoconstriction, mucus production, increased heart rate and cardiac output, gastric acid secretion, and pruritus associated with allergic and inflammatory reactions.[21] In clinical practice, H1 receptor antagonists (*e.g.*, cetirizine, levocetirizine, fexofenadine, loratadine, desloratadine) are frequently used in the management of allergic diseases such as rhinitis and chronic urticaria.

Mast Cell Proteases

MC proteases (*e.g.*, tryptases, chymases, and carboxypeptidase A), like other preformed mediators, are stored as active enzymes within secretory granules. A wide range of non–mast-cell–specific proteases can also be found within MC secretory granules including granzyme B, lysosomal cathepsins, active caspase 3, kallikreins, matrix metalloproteinase-9, and renin.

Tryptase

Tryptase isoforms. Tryptase is the most abundant preformed granular enzyme found in all human MCs and is frequently used as a marker for MC activation. Of the four isoforms of tryptase (α, β, γ, δ), β-tryptase, and to a lesser extent α-tryptase, are considered the most biologically significant.[21] The γ and δ forms of tryptase are believed to have little, if any, catalytic activity. Tryptase-encoding genes are clustered together on chromosome 16 (TPSAB1, TPSB2, TPSG1, TPSD1). Notably, α-tryptase and β1-tryptase alleles are co-allelic at the *TPSAB1* gene locus,[22] while *TPSB2* only encodes β-tryptase. In human MCs, β-tryptase undergoes conformational change from an inactive monomer to its biologically active tetrameric form comprised of identical subunits. However, the stability of the β-tryptase tetramer relies upon the presence of heparin and

TABLE 44.2 Selected Mast Cell Mediators

Mediator Ligand/Receptor	Pathophysiologic Effects	Commonly Used Targeted Therapy in Allergic Disease
Preformed		
Histamine/H1, H2, H3, H4R	Increased vascular permeability, vasodilation, smooth muscle contraction, bronchoconstriction, mucus production, increased heart rate and cardiac output, gastric acid secretion, pruritus	H1-receptor antagonists (cetirizine, levocetirizine, fexofenadine, loratadine, rupatadine); H2-receptor antagonists (ranitidine, famotidine)
Proteases		
Tryptase (α, β, γ, δ)/PAR (protease activated receptors)	Allergy, inflammation, tissue remodeling, immune response; defective in hereditary α-tryptasemia (HAT)	
Chymase	Tissue remodeling and injury; potent enzymatic conversion of angiotensin I to angiotensin II	
Carboxypeptidase A (CPA3)	Vasoprotective neutralization of endotoxin I; neutralizes sarafoxtoxin (snake venom)	
Proteoglycans		
Heparin	B-tryptase tetramer stabilizer; vascular permeability, smooth muscle contraction;	
Newly formed		
Lipid mediators		
PGD2/DP1, CRTH2 (DP2); TXA2	vasodilation (DP1), bronchoconstriction (CRTH2/DP2); basophil, eosinophil, Th2 and ILC2 cell chemoattractant (PGD2); aspirin-exacerbated respiratory disease (AERD)	Cyclooxygenase (COX) inhibitors, other nonsteroidal antiinflammatory drugs (NSAIDs), aspirin
CysLTs (LTC4, LD4, LTE4), LTB4/CysLT1R, CysLT2R, GPR99	Bacterial defense; neutrophil chemoattractant (LTB_4); bronchoconstriction (LTD4); smooth muscle contraction; increased microvascular permeability; amplified Th2 response	CysLT1R-antagonists (montelukast, zafirlukast); 5-LO inhibitor (zileuton)
PAF/PAF-R	Platelet aggregation, vasodilation, potent bronchoconstriction	Platelet-activating factor receptor (PAFR) antagonist (rupatadine); epinephrine
Cytokines		
IL-1β, IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-9, IL-10, IL-11, IL-13, IL-15, IL-16, IL-17A, IL-18, IL-22, IL-24, IL-25, IL-33, TNF-α, SF, NGF, TGF-β, FGF-2, VEGF, IFN-α, GM-CSF, TSLP	Cell signaling, growth, proliferation and migration	
Chemokines		
CCL5, CXCL8	Immune cell recruitment to sites of infection	Anti-IL-4, IL-13/IL-4Rα antagonist (dupilumab); anti-IL-5 (mepolizumab, reslizumab); IL-5R antagonist (benralizumab)

only occurs in pH values under 6.5. Therefore it follows that either heparin depolymerization or increasing intragranular pH may result in decreased tryptase enzyme activity. In contrast to β-tryptase stored in granules, α-tryptase is a protryptase lacking enzyme activity that is secreted constitutively outside of the cell; as such, its levels may correlate with total body MC burden. This, in turn, is useful in assessing MC burden and monitoring response to cytoreductive therapy in mastocytosis.

Pathophysiology and diagnostic function. The pathologic and physiologic effects of tryptase after MC degranulation may play a role in the development of allergy, inflammation, tissue remodeling, and the immune response. Baseline serum levels (median around 5 ng/mL, normally ranging from 1 to 11 ng/mL) reflect the constitutive secretion of immature monomeric tryptases (mainly α tryptase) by resting MCs, and are therefore reflective of total body MC burden.[21] The heparin-bound, highly active tetrameric form of β-tryptase is released by MCs only upon activation and represents the increase in serum tryptase during an allergic response.[21] In contrast, an increase in serum level of α-tryptase is not seen following allergen-induced MC degranulation.[21] In clinical practice, the measurement of serum tryptase is used to diagnose and monitor mastocytosis and disorders of MCA.[21] Currently, commercially available tryptase assays measure only total tryptase (*i.e.*, α and β). A transient and rapid increase of total serum tryptase (>2 + 1.2*baseline level) within 4 hours of an anaphylactic event is generally considered laboratory evidence of MCA.[21] In the evaluation of systemic mastocytosis, a baseline serum tryptase level of greater than 20 ng/mL is considered a minor diagnostic criterion.[21] Tryptase levels may also be useful in monitoring response to cytoreductive therapy in mastocytosis.

Hereditary α-tryptasemia. Hereditary α-tryptasemia (HAT) is a recently described autosomal dominant condition caused by increased monoallelic α-tryptase copy number at TPSAB1,[22,23] where serum tryptase levels (generally above 8 ng/mL) correlate with the copy number of the α-tryptase allele. It is estimated to be present in 6% of general population. Whether HAT is associated with a distinct clinical phenotype is a matter of active investigation. Patients with HAT appear to be more prone to severe hymenoptera allergy reactions if they also have an IgE-mediated sensitization. While it is tempting to suggest that persistent symptoms of otherwise undetermined etiology may be due to excess α-tryptase, many patients with this condition are asymptomatic and there remains no conclusive evidence associating HAT with a common set of specific symptoms or other disease states.

Proteoglycans and Heparin

Chondroitin sulfate and heparin are proteoglycans stored in preformed MC granules and render the metachromatic staining properties of the cells. In addition to its anticoagulant effect, heparin contributes to vascular permeability and smooth muscle contraction.[21] In maculopapular lesions of cutaneous mastocytosis, heparin is associated with clusters of MCs within the lesions.[24]

Newly Formed Mediators

Lipid mediators (*e.g.*, prostaglandins, LT, platelet activating factor [PAF]), cytokines, chemokines, and growth factors are produced *de novo* upon MC activation.[2]

Lipid Mediators

Lipid mediator synthesis occurs shortly after degranulation and begins with the production of arachidonic acid and lysophosphatidylcholine from membrane phosphatidylcholine by phospholipase A_2.[25] The eicosanoids, prostaglandins (PG), and LT are generated by the metabolism of arachidonic acid through the cyclooxygenase (COX) and lipoxygenase pathways, respectively.[2] PAF is synthesized from lysophosphatidylcholine.[2,25] These lipid mediators go on to participate in the regulation of vascular permeability, smooth muscle contraction, and the recruitment of immune effector cells.[2,25]

Prostaglandins

Prostaglandin synthesis via the COX pathway begins with conversion of arachidonic acid to PGH_2, the bioactive precursor of all PGs, by the COX enzyme.[2] PGD_2 synthase subsequently converts PGH_2 to PGD_2, arguably the most important PG in MCs.[2] Liberated PGD_2 can elicit vasodilation and bronchoconstriction when bound to its receptors, DP_1 and CRTH2 (DP_2), respectively.[21] A strong chemoattractant for basophils, eosinophils, Th2 cells, and group 2 innate lymphoid cells (ILC2), all of which express CRTH2 (DP_2) receptors, PGD_2 can thereby amplify type 2 inflammation by inducing cytokine generation (IL-4, IL-5, IL-13).[21] In contrast to the large quantities generated by MCs, PGD_2 is not produced by basophils.[21] PGD_2 is, however, made by other immune cells including eosinophils, Th2 cells, DCs, and by nonhematopoietic tissues such as brain, heart, lungs, and kidney.[21] Clinically, the COX pathway plays a role in aspirin-exacerbated respiratory disease (AERD), which is discussed in more detail later in this chapter.

Leukotrienes

In activated MCs and basophils, the lipoxygenase (LO) pathway of LT synthesis begins with oxidation of arachidonic acid by 5-LO and 5-LO-activating protein (FLAP) into unstable metabolites, 5-HpETE and LTA_4.[2,26] LTA_4 hydrolase converts LTA_4 to LTB_4, which undergoes conjugation by LTC_4 synthase to form LTC_4, the precursor for all cysteinyl-leukotrienes (CysLT).[2,26] LTC_4 is released by an energy-dependent mechanism involving multi-drug resistance protein (MRP-1), converted extracellularly to LTD4, a potent bronchoconstrictor, and finally to the stable metabolite LTE_4.[2,26] In addition to MCs and basophils, myeloid dendritic cells (DC), eosinophils, and macrophages also release CysLTs (LTC4, LTD4, LTE4).[21] Generally, LTs contribute to host defense against bacterial infections by influencing local vascular endothelium to promote rolling and recruitment of neutrophils and eosinophils.[2] Specifically, the small quantity of LTB_4 produced acts as a potent neutrophil chemoattractant.[2] However, despite their beneficial effects in bacterial defense, CysLTs play a significant role in allergic inflammation by inducing smooth muscle contraction and airway constriction, and increasing microvascular permeability.[21] Mouse models suggest CysLT amplifies Th2 responses through three distinct receptors ($CysLT_1R$, $CysLT_2R$, GPR99), with effects achieved at concentrations up to 1000-fold lower than histamine.[21] In clinical practice, $CysLT_1R$ antagonists (*e.g.*, montelukast, zafirlukast) and 5-LO inhibitors (*e.g.*, zileuton) are used in the management of asthma.[4] Notably, a recent study demonstrated montelukast-sensitive MC activation by LTE4 through $CysLT_1R$, inducing production of PGD_2 and thromboxane A_2 (TXA_2).[26]

Platelet-Activating Factor

PAF is synthesized *de novo* from membrane lysophosphatidylcholine by several cell types including MCs, eosinophils, platelets, neutrophils, monocytes, basophils, epithelial and endothelial cells in response to stress and other stimuli.[25] Effects attributed to PAF include platelet aggregation, vasodilation, and potent bronchoconstriction.[25] PAF is rapidly hydrolyzed and degraded to its inactive metabolite, lysoPAF, by intracellular and plasma types of the PAF acetylhydrolase (PAF-AH) enzyme.[21,25] Many of the cells that produce PAF are also targets for its bioactivity through G protein-linked receptors (PAF-r). PAF receptor binding leads to mobilization of intracellular calcium and activation of kinases, resulting in release of arachidonic acid.[25] In human lung MCs and peripheral blood-derived MCs, PAF induces histamine and PGD2 release following receptor binding.[25] In human airways, PAF is also a potent mediator of eosinophil chemotaxis.[25] Notably, PAF has no effect on skin MCs which lack PAF-r expression.[25] However, increased serum PAF levels and decreased PAF-AH have been linked to the development of allergic diseases such as rhinitis, asthma, and chronic urticaria. PAF is produced during the early and late phases of the allergic response, contributes to nasal congestion and rhinorrhea in allergic rhinitis, and is among many proinflammatory mediators involved in asthma pathogenesis.[25] PAF also plays a role in IgE-dependent and IgE-independent anaphylaxis; higher PAF levels may correlate with more severe reactions.[25] PAF has been implicated as a mediator in sepsis, atherosclerosis, and malignancy.[25]

Cytokines and Chemokines

Cytokines are small secreted proteins essential for cell signaling, growth, proliferation, and migration. Via autocrine secretion, MCs themselves can be affected by a number of cytokines including SCF, IL-4, IL-6, IL-10, transforming growth factor (TGF)-β, IL-33, and thymic stromal lymphopoietin (TSLP). The unique responses elicited influence the heterogeneity and phenotype variation seen among MC populations. The central role of SCF in MC growth and differentiation was discussed above. IL-6 is critical for human MC maturation.[4] TGF-β, classically immunosuppressive, enhances early MCp differentiation, but reduces survival of late-stage precursors. TGF-β also elicits MC chemotaxis, reduces FcεR1 expression IgE-induced cytokine production, and inhibits IL-33 production.[4] IL-33 is produced by barrier cells in response cell damage or inflammation and can activate MCs, as well as promote their survival, maturation, adhesion, and cytokine production.[4] TSLP is also expressed by barrier cells and promotes MC proliferation.[4] Much research has focused on MC-derived IL-4 as a major contributor to symptom development in allergy and asthma.[4] IL-4 elicits Th2 differentiation of naïve T cells, and amplifies type 2 inflammatory responses via a positive feedback loop between MCs, Th2, and ILC2 cells.[4] The effect of MC cytokine production in food allergy has also been suggested by a recent study demonstrating MCps in the intestinal mucosa as an important source of IL-9 and IL-13.[12] Conversely, MCs can express antiinflammatory cytokines TGF-β and IL-10.[4] As a part of the innate immune response to microbial infection, MCs generate TNF-α, IL-6, and IL-1β.[2] In addition to an array of cytokines, MCs produce chemokines, notably CCL5 and CXCL8, which help recruit immune cells to sites of infection.[5] Chemokines were previously discussed in the context of MC homing.

NORMAL MAST CELL FUNCTION

As previously discussed, MC development, migration, and survival are influenced by growth factors, most notably SCF.[4] In healthy individuals, tissue-resident MCs are maintained in constant numbers at baseline and their numbers are upregulated after allergic or inflammatory triggers. MCs are involved in host

immune defenses, immune tolerance, tissue repair, neutralization of venoms, and homeostasis.[2]

Immune Response to Infection

MCs contribute to both innate and adaptive immune responses. Although found in most tissues, the strategic distribution of MCs at surfaces with environmental exposure, such as skin and mucosal surfaces,[2] supports a role in pathogen recognition and host defense.

Innate Immunity

MCs contribute to the innate immune response through toll-like receptors (TLRs), NOD-like receptor (NLR), RIG-like receptor (RIG), and complement receptor recognition of various antigens, toxins, and pathogens,[4] resulting in the release of inflammatory mediators help to contain and clear infection and aid in the recruitment of effector cells (*e.g.*, neutrophils and macrophages). TLR-2 recognizes peptidoglycans from gram-positive bacteria, gram-negative bacteria, and mycobacteria, resulting in cytokine release (TNF-α, IL-1β, IL-4, IL-5, IL-6, IL-13), production of LTC4, and MC degranulation.[2,4] Similarly, TLR-4 binds lipopolysaccharides (LPSs) from gram-negative bacteria, lipid A, fibrinogen, and *Mycobacterium tuberculosis*, to induce cytokine release (TNF-α, IL-1β, IL-6, IL-13) without degranulation.[2,4] MCs are able to directly eliminate microbes through intracellular and extracellular antimicrobial mechanisms. MCs release peptides with direct bactericidal effects (*e.g.*, cathelicidins, defensins, and psidins), and are also capable of phagocytosis and production of reactive oxygen species to aid in bacterial killing.[2] To help ensnare and kill extracellular bacteria that may have evaded phagocytosis, activated MCs can produce aptly named MC extracellular traps (MCETs).[2] MC proteases can also degrade endogenous peptides and venoms, thereby limiting their toxicity.[2] In early parasitic infections, MCs and basophils release IL-4 and IL-13 to promote IgE production, immune cell recruitment, and regulation of gastrointestinal permeability which, in addition to growth factors IL-3, SCF, and IL-9 effects, promote the expulsion of the parasite and containment of a chronic infection.[2] The role of MCs in viral infections is less well defined. In response to viral products, activated MCs express IL-1β, IL-6, CCL3, CCL4, CCL5, and CCL8.[2] MC viral recognition is also thought to incite cellular responses, specifically, the recruitment of CD8 T lymphocytes to the site of infection and the production of IFN-1 to promote viral clearance.[2]

Adaptive Immunity

In addition to their interaction with adaptive immune systems through involvement in allergic reactions through high affinity receptor for IgE, studies on the role of MCs in adaptive immunity have shown that MCs, like DC, are capable of antigen processing and presenting via MHCI and MHCII complexes.[2] MC mediators promote DC function, phenotypical maturation, and migration to lymph nodes.[2] MCs can also directly activate T lymphocytes through the release of TNF.[2] In contrast to their significant role in the propagation of adaptive immunity, MCs can also temper the duration and magnitude of the immune response via expression of antiinflammatory cytokines such as IL-10 and TGF-β.[2]

Immune Tolerance

Although long considered mediators of inflammation and immediate hypersensitivity, MCs can also act as modulators of the immune response. MC-derived IL-10 and TGF-β, for example, can downregulate the expression of the IgE-receptor FcεRI to limit IgE-mediated MC degranulation.[2,5]

Mast Cell Homeostasis

Several studies have demonstrated the importance of proinflammatory and antiinflammatory effects of IL-4, IL-10, and TGF-β on pathways of MC homeostasis.[4] In an effort to balance cell growth, MCs have pathways for both apoptosis and autophagy.[4] While MCs are susceptible to Fas- or TNF-related apoptosis-inducing ligand (TRAIL)-mediated apoptosis via caspase activation, SCF can inactivate pro-apoptotic proteins and increase expression of pro-survival proteins.[4] A separate process, autophagy, involves the degradation and reuse of intracellular organelles and proteins. Dysregulation of MC autophagy has been implicated in chronic rhinosinusitis, asthma, and systemic sclerosis.[4]

KEY CONCEPTS

Normal Mast Cell Function

- Mast cells have roles in both innate and adaptive immune responses, and are strategically distributed at environmental interfaces to optimize pathogen recognition and host defense.
- Mast cells mediate inflammation and immediate hypersensitivity, but can also act as response modulators to promote immune tolerance.
- Pathways for both apoptosis and autophagy help maintain mast cell homeostasis.
- Mast cells also produce growth factors to promote tissue repair.

MAST CELL RELATED DISEASE

Role of Mast Cells in Allergic Disease

MCs are perhaps best known for their pathogenic role in allergic diseases such as asthma and allergic rhinitis. In most cases, clinical signs of allergic response (*e.g.*, increased vascular permeability, bronchospasm, erythema, smooth muscle contraction, augmented mucus production) result from localized effects of MC mediators released in response to allergen recognition and activation of the IgE-bound FcεR1 receptor in sensitized individuals.[2,4,25]

Anaphylaxis

Anaphylaxis is an acute, potentially life-threatening, multisystem clinical reaction caused by immunological or nonimmunological activation of MCs and basophils leading to precipitous release of mediators into the circulation.[25] In the clinical setting, triggers of anaphylaxis can include food allergies, drug allergies, venom, exercise, or idiopathic etiology. Systemic mediator release can lead to rapid development of urticaria, gastrointestinal upset, respiratory distress, and cardiovascular collapse, the hallmarks of anaphylaxis. Although histamine and β-tryptase are released together, histamine is a less reliable clinical biomarker of MC degranulation due to its short half-life and other non-MC sources.[21] An acute rise in serum β-tryptase levels therefore remains the best marker of systemic MC activation in anaphylaxis.[21] The classic mechanism of anaphylaxis can be considered a severe form of IgE-mediated type I hypersensitivity, although anaphylaxis can also be independent of IgE-mediated activation.[25] Recent studies have also suggested PAF may amplify the physiologic manifestations of both IgE- and IgG-mediated anaphylaxis.[25,27] PAF response is partially dependent on calcium influx, and therefore downregulation of signal-

ing through PAF-r occurs with epinephrine and other vasoactive agents that activate adenylate cyclase, thereby increasing intracellular calcium.[25,27] In drug-induced anaphylaxis, both immunological and nonimmunological mechanisms have been proposed, including immune-complex–mediated and immune-complex–independent complement activation.[19,25] Opiates and vancomycin have been shown to directly activate MCs, and some drugs (*e.g.*, muscle relaxants) are thought to mediate anaphylaxis through activation of MRGPRX2 or other related surface receptors.[19,20]

Asthma

Asthma is a disease of chronic airway inflammation defined by the presence of variable obstruction and airway hyperresponsiveness (Chapter 43). MCs release numerous proinflammatory mediators that contribute to bronchoconstriction, impaired gas exchange, increased mucus secretion, inflammatory cell infiltration, and airway remodeling seen in asthma. Abnormal localization of MCs to airway smooth muscle bundles may be seen in bronchial biopsies of asthmatic subjects, and studies demonstrate a strong correlation between smooth muscle MC density and airway hyper-responsiveness.[28] A substantially higher proportion of (Mast cell tryptase and chymase) MC tissue culture cells was also noted on biopsy samples from subjects with severe asthma, as compared to those with mild asthma.[27,28] In clinical practice, the efficacy of anti-IgE monoclonal antibodies (*e.g.*, omalizumab), LT antagonists, and MC stabilizers (*e.g.*, cromolyn), as well as improvements with allergen immunotherapy, emphasizes MC involvement in early- and late-phase asthma responses.[17,21]

Aspirin-Exacerbated Respiratory Disease

MCs play a significant role in AERD, a triad disorder of asthma, severe rhinosinusitis, and nasal polyposis associated with distinct respiratory reactions to aspirin and other COX-1 inhibitors.[29] Notably, AERD is associated with elevated baseline levels of MCA products, including tryptase, PGD2 and LTE_4, which further increase with aspirin or COX-1 inhibitor challenge.[29] COX-1 inhibitors are thought to cause reactions by depleting homeostatic PGE_2 from surrounding tissue.[29] The role of MCs in AERD is also implied by the attenuating effects of MC stabilizers (*e.g.*, cromolyn and nedocromil) on bronchoconstriction.[30] In clinical practice, high-dose daily aspirin therapy, following successful desensitization, has been used in an effort to suppress AERD-associated nasal polyp growth. The 5-LO inhibitor zileuton may reduce baseline respiratory symptoms in AERD.[29] The novel anti-IL-4 and IL-13 monoclonal antibody dupilumab has been shown to reduce urinary PGD_2 metabolites and LTE_4[29] and is now approved for the treatment of chronic rhinosinusitis with nasal polyposis, asthma, and atopic dermatitis.

Allergic Rhinitis

Allergic rhinitis is characterized by the inflammatory response of nasal mucosa to seasonal and perennial airborne allergens (Chapter 88). Classic symptoms include sneezing, rhinorrhea, nasal and palatal itch, and nasal congestion. Increased numbers of activated MCs can be found in the nasal epithelium of patients with both seasonal and perennial allergic rhinitis.[27] Currently, intranasal corticosteroids, oral antihistamines, and oral LT inhibitors remain mainstays of therapy for allergic rhinitis. Allergen immunotherapy is beneficial in selected patients as a second-line therapy.

Food Allergy

Type 1 hypersensitivity reactions are the most widely studied mechanism of food allergy. Food allergens cross-link IgE bound to the FcεR1 receptors of MCs, with subsequent MCA and release of mediators, most notably histamine. Peanut-induced anaphylaxis in mice and humans is thought to be influenced by MC release of histamine and PAF, specifically[12] FcεR1 receptor expression is positively regulated by increased IgE concentration.[2] Symptoms of allergic reaction can involve a single or multiple organ system, generally manifesting within 2 hours of food allergen ingestion. As previously discussed, tissue microenvironment can influence differentiation of MC subpopulations. MC_T dominate in the normal lung and intestinal mucosa, while (Mast cell tryptase and chymase) MC_{tC} dominate within deep connective tissue. A recent study by Benedé and Berin suggested MC heterogeneity as an important contributor to the range of food allergy symptoms.[12] Murine model of food allergy implied that the connective tissue MC subset, specifically, is key in the development of severe systemic anaphylaxis.[12]

Role of Mast Cells in Nonallergic Disease

MCs may contribute to the pathogenesis of other nonallergic diseases, and have been implicated in cardiovascular disease, several autoimmune diseases, and even cancer. In coronary artery disease, cardiac MCs may contribute to the development of coronary inflammation and cardiac ischemia, while increased numbers of MCs can be found in atherosclerotic plaques.[2] MC–derived tryptase and chymase induce proteolytic changes in HDL particles and thereby are thought to promote formation of foam cells.[2] Notably, chymase is also a potent angiotensin converting enzyme and main producer of the coronary constrictor angiotensin II in humans.[2] MCs have been implicated in multiple autoimmune diseases including Crohn disease, rheumatoid arthritis, psoriasis, multiple sclerosis (MS), rheumatoid arthritis, Type 1 diabetes mellitus, Guillain-Barre syndrome, allergic encephalitis, bullous pemphigoid, and Sjögren syndrome.[4] However, the precise role of MCs in autoimmune pathophysiology remains mostly unclear and remains the focus of continued debate and research.

KEY CONCEPTS

Mast Cells in Allergic and Nonallergic Disease

- Mast cells significantly contribute to the pathogenesis of allergic diseases like asthma and allergic rhinitis, as well as anaphylaxis.
- An acute rise in serum β-tryptase levels therefore remains the best marker of systemic MC activation in anaphylaxis.
- Aspirin-exacerbated respiratory disease (AERD) is a triad disorder of asthma, severe rhinosinusitis with nasal polyposis, and distinct respiratory reactions to aspirin and other COX-1 inhibitors, in which mast cell activation can be demonstrated at baseline and after induction with COX-1 inhibitors.
- Mast cells have also been implicated in cardiovascular disease, several autoimmune diseases, and even cancer.

MAST CELL DISORDERS

Disorders in which MCs are involved (MCDs) can be globally classified as primary, secondary, or idiopathic. In a primary MCD, there is an inherent defect within the MC or its progenitor resulting in pathology. Primary MCDs are typically clonal disorders as is the case in mastocytosis.[5,31] In secondary MCDs,

there is a primary disease process, such as an IgE-mediated allergy that results in nonclonal MCA. In idiopathic MCDs, MCA occurs in the absence of a clearly identifiable MC abnormality or systemic disease triggering secondary MCA (examples of this include idiopathic anaphylaxis and idiopathic mast cell activation syndrome or iMCAS).[23]

Mastocytosis

Mastocytosis is characterized by abnormal clonal MC expansion driven by D816V KIT mutation and neoplastic MC accumulation in one or more organ systems.[5,31] Mastocytosis can be broadly categorized as cutaneous (CM) or systemic (SM) and then further subcategorized based on additional features.[31] CM is most commonly diagnosed in children while SM is the predominant category in adults (Fig. 44.2).

WHO classification and diagnostic criteria for mastocytosis are listed in Table 44.3. Monoclonal mast cell activation syndrome (MCAS) is diagnosed when the patient does not meet full criteria for SM but only D816V KIT mutation or $CD25^+$ MCs are detectable. Appropriate classification of mastocytosis is critical as treatment and prognosis varies by type. For example, patients with cutaneous mastocytosis who do not meet criteria

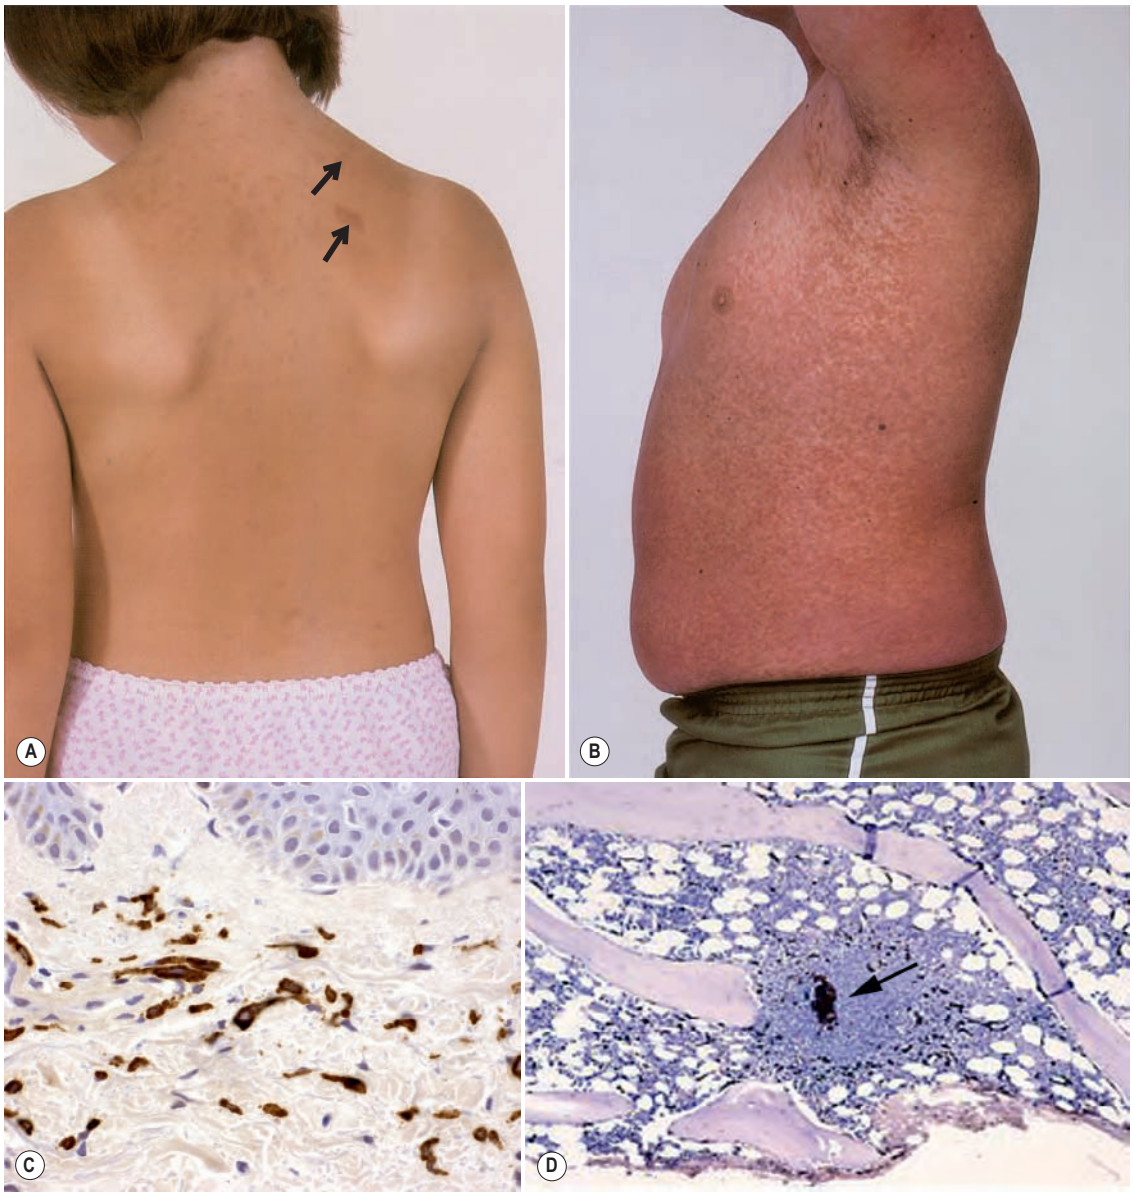

FIG. 44.2 Cutaneous Mastocytosis and Histopathology. Urticaria pigmentosa is the most common form of cutaneous mastocytosis. In childhood, lesions are disseminated and consist of well-demarcated hyperpigmented macules (*e.g.*, *arrows*) (A). In adults, lesions may be numerous with less well-demarcated brownish-red macules and papules (B). Histopathology of cutaneous mastocytosis shows many mast cells containing abundant tryptase immunoreactive cytoplasmic granules in the papillary dermis (antitryptase, AA1 clone, Dako; original magnification approximately ×400) (C). Bone marrow pathology of indolent mastocytosis is characterized by paratrabecular lymphoid nodule containing small, well-differentiated lymphoid cells around substantial numbers of fusiform cells with prominent granules in the tryptase stain *(arrow)* (antitryptase, AA1 clone, Dako; original magnification approximately ×250) (D). (Courtesy of Cem Akin.)

TABLE 44.3 Mastocytosis

Type	Diagnostic Criteria	Subtypes/Variants	Clinical Pearls
Cutaneous mastocytosis	Typical skin findings on exam. Typical infiltrates of MCs in a multifocal or diffuse pattern on skin biopsy. Does not meet diagnostic criteria for SM.	Urticaria pigmentosa (UP)/Maculopapular cutaneous mastocytosis (MPCM) Diffuse cutaneous mastocytosis (DCM) Mastocytoma of the skin	UP/MPCM is the most common skin manifestation of mastocytosis. CM is the most common form of mastocytosis in children and typically resolves by puberty. Adults w/skin findings have a higher likelihood of having SM and thus should be evaluated for SM. Patients with CM w/o evidence of SM have the best prognosis.
Systemic mastocytosis	Major criterion – multifocal, dense infiltrates of MCs (≥15 in aggregates) detected in biopsy (bone marrow and/or an extra cutaneous organ). Minor criteria • 25% MCs in infiltrate (on biopsy) are spindle shaped, have atypical morphology, or are immature. • Detection of an activating point mutation (codon 816/D816V) in biopsy or blood. • MCs in biopsy or blood express CD25 (w/ or w/o CD2). • Serum total tryptase greater than 20 ng/mL (unless there is an associated myeloid neoplasm). Diagnosis is made if one major and one minor criterion are met or if three minor criteria are met.	Indolent systemic mastocytosis (ISM) Smoldering systemic mastocytosis (SSM) = SM + "B findings"[a] Systemic mastocytosis associated with a hematologic neoplasm (SM-AHN) Aggressive systemic mastocytosis (ASM) = SM + "C findings"[b] Mast cell leukemia (MCL)	Patients w/elevated tryptase and a hx of anaphylaxis and/or negative HAT testing should be evaluated for SM. On biopsy, it is important to assess for abnormalities in other hematopoietic cell lines. After CM, ISM and SSM have the best prognosis. Skin lesions are present in most cases of ISM & frequently absent in ASM & MCL.
Mast cell sarcoma	Unifocal mast cell tumor with a destructive growth pattern. Does not meet criteria for SM.	N/A	Poor prognosis. May transform to MCL.

*B findings—30% MC infiltration on bone marrow biopsy, dysplasia, and/or proliferation of other marrow cell lines, but not enough to meet criteria for another diagnosis, and hepatosplenomegaly and/or lymphadenopathy without signs of dysfunction.
**C findings—Bone marrow dysfunction caused by MC infiltration, hepatosplenomegaly with dysfunction, osteolytic lesions (with or without fracture), and malabsorption and/or weight loss (presumably due to gastrointestinal MC infiltration).

for systemic mastocytosis have the best disease prognosis and typically require minimal therapy.[5,31] Patients with indolent systemic mastocytosis also have good prognosis with life expectancy similar to that of the general population and typically can be managed by symptomatic therapy.[5] The signs and symptoms of mastocytosis are due to MC mediator release and include pruritus, flushing, nausea, vomiting, diarrhea, abdominal pain, and hypotension. In addition, signs of tissue dysfunction (such as cytopenias, liver failure, malabsorption, pathologic fractures) due to MC burden and co-existing hematologic disorders are observed in advanced cases.

For this reason, therapy is often directed toward either mast cell mediators (avoidance of triggers to reduce mediator release as well as direct anti-mediator therapy) or reducing mast cell burden in advanced cases (cytoreductive therapy) (Table 44.4). Approximately 80% of patients with SM have a somatic gain of function mutation in KIT with the most common being in codon 816 (D816V).[5] This mutation causes KIT to be continuously active and leads to uncontrolled MC differentiation and survival that results in pathology. Given these findings, KIT inhibitors have become an area of active investigation as treatment for mastocytosis.[31] Other forms of mastocytosis such as aggressive systemic mastocytosis (ASM), mast cell leukemia (MCL), and systemic mastocytosis with associated hematologic neoplasm (SM-AHN) often have more rapid and complex disease courses that require multidisciplinary care including a referral to hematology as well as antineoplastic therapies.[31] SM-AHN is frequently associated with myeloid neoplasms which often negatively affects prognosis. SM and AHN components are treated separately. Conversion between different forms of mastocytosis is rare, but does occur; thus these patients require regular follow-up for monitoring of disease progression and complications.[5,31]

Mast Cell Activation Syndrome

MCAS is heterogeneous disorder characterized by (1) severe, multisystem, and episodic symptoms of MC mediator release; (2) improvement or resolution of symptoms with anti-mediator therapy; and (3) laboratory evidence of MCA.[23] Diagnostic testing for MCAS includes serum tryptase and urinary metabolites of MC mediators.[23] As a number of different processes can mimic MCA symptoms, the differential diagnosis can be overwhelming; thus it is essential that all three consensus criteria be fulfilled before the diagnosis is established. It has been proposed that idiopathic anaphylaxis be viewed as the quintessential presentation of MCAS, thus establishing the paradigm that MCAS is a severe systemic reaction resulting from mast cell mediator release.[23] As such, therapy for MCAS should be focused on reducing MCA (avoiding triggers, use of MC stabilizers, *etc.*) and pharmacologically counteracting MC mediators. As our

TABLE 44.4 Treatment of Mastocytosis

Target	Drug/Intervention	Clinical Pearls
MC mediator symptoms	H1 blockers	Most patients with mastocytosis require at least an H1 blocker.
	H2 blockers	H2 blockers are often used an adjunct to H1 blockers for cutaneous symptoms and also to target GI symptoms.
	Leukotriene antagonists	
	Mast cell stabilizers	Cromolyn (mast cell stabilizer) can be used as an adjunct to H1 blockers and may help with GI symptoms.
	Epinephrine	
	Corticosteroids (oral and topical)	Patients with diarrhea tend to respond well to oral steroids. An alternative to consider are anticholinergics.
	Anticholinergics	
	Light therapy	Topical steroids can improve lesions and symptoms in patients with UP or DCM.
		8-Methoxypsoralen in conjunction with ultraviolet phototherapy can be used for adults with refractory cutaneous disease and symptoms
Osteoporosis	Calcium supplementation	All patients with SM should be screened for osteoporosis.
	Estrogen replacement	
	Bisphosphonates	Radiotherapy can be used in a palliative setting for management of isolated bone lesions in aggressive disease.
	Denosumab	
	Radiotherapy	
Cytoreductive therapies	Interferon alpha2b (IFN-α2b)2-chloro-2-deoxyadenosine (cladribine, 2-CdA)	Typically used in advance disease.
	Tyrosine kinase inhibitors (TKI)	IFN-α2b is historically first line therapy for ASM, but has poor tolerance and relapse is common after discontinuation.
	• Imatinib (Gleevec)	Cladribine/2-CdA is also historically a first-line therapy for ASM, but is associated with many toxicities (myelosuppression, opportunistic infection, *etc.*).
	• Midostaurin	
	• Investigational TKIs (including avapritinib (D816V selective KIT inhibitor and ripretinib (switch pocket inhibitor)Hematologic stem cell transplant	Efficacy of imatinib is limited by its lack of activity against D816V KIT mutation, the most common mutation in mastocytosis. Imatinib is effective for patients with juxtamembrane or transmembrane *KIT* mutations, wild-type *KIT*, or *FIP1L1-PDGFRA* fusion oncogene (all rare findings in systemic mastocytosis).
		Midostaurin is a multikinase inhibitor with activity against wild type and D816V mutated KIT, and avapritinib is a D816V selective tyrosine kinase inhibitor, both of which are FDA approved is FDA approved for treatment of ASM, SMAHN, and MCL.
		Stem-cell transplant may be considered for select patients (ASM, SMAHN, and MCL); survival benefit seems to be greatest in SMAHN.

understanding of mast cell biology evolves we may be better able to identify aberrancies that lead to MCAS as well as future targets for therapy.

BASOPHILS AND RELATED DISORDERS

Basophils are granulocytic cells that share many morphologic and biochemical features with MCs. In contrast to MCs, basophils complete maturation in the bone marrow and are released into peripheral circulation as mature end-stage cells. Basophil development and maturation is regulated by a number of cytokines. One of the most critical cytokines for human basophil growth is IL-3. Granulocyte/macrophage colony stimulating factor (GM-CSF), IL-5, TGF-β, and TSLP are also thought to play a role in basophil development.

Basophils share many of the same mediators (*e.g.*, histamine and CysLTs) as well as mechanisms of activation (*e.g.*, IgE/FcεR1) with MCs.[21] For this reason, basophils may also contribute to pathology involving IgE-mediated MC activation and degranulation. Basophils are an important source of IL-4 and IL-13 after antigen exposure,[32] suggesting that they play an important role in Th2-mediated allergic disease. Several studies have shown that basophils in allergic individuals undergo a process known as *priming* whereby phenotypic and functional changes increase basophil propensity for stimulation by allergen exposure.[33] Basophils also migrate to sites of inflammation in allergic disease such as the nose as well as the lung and play an important role in the generation of the late phase allergic response.[34,35] While basophils and MCs share many similarities, basophils do not produce significant amounts of PGD2 and have a limited cytokine profile after activation (predominantly Th2). Collectively, these findings suggest that basophils are a critical component of Th2- and IgE-mediated disease processes.

Given the role basophils play in allergic disease, flow cytometry–based tests of basophil activation have been developed for the assessment of immediate hypersensitivity. Two of the most common markers used in the basophil activation test (BAT) are CD63 and CD203c which are induced on the basophil surface after an allergen-IgE complex binds to FcεR1.[21] The BAT has the potential to be used both for the detection of immediate hypersensitivity as well as monitoring for the induction of a hyposensitized state (Fig. 44.3).

Basophils are found to be decreased in blood and have alterations in their IgE-receptor–mediated activation in patients with chronic spontaneous urticaria (CSU). This is thought to reflect their migration to tissue from blood and their possible involvement in symptomatology of CSU. In addition to diseases in which basophils are co-activated with MCs, basophils can be increased in hematologic neoplasias. Basophilic leukemia (defined by >40% circulating basophils) can be classified as *acute* (>20% blasts) or *chronic* (<20% blasts), *primary* (where there is an inherent basophil issue), or *secondary* (where another hematopoietic disorder such as chronic myeloid leukemia results in a secondary basophilia). The treatment of basophil-mediated symptomatology is similar to that of MC disease and dependent upon presence of cell activation and total cell burden. In the case of activation, treatment is focused on avoidance of triggers, and counteracting released mediators. In the case of increased basophil cell burden, antineoplastic or cytoreductive therapy may be sought.

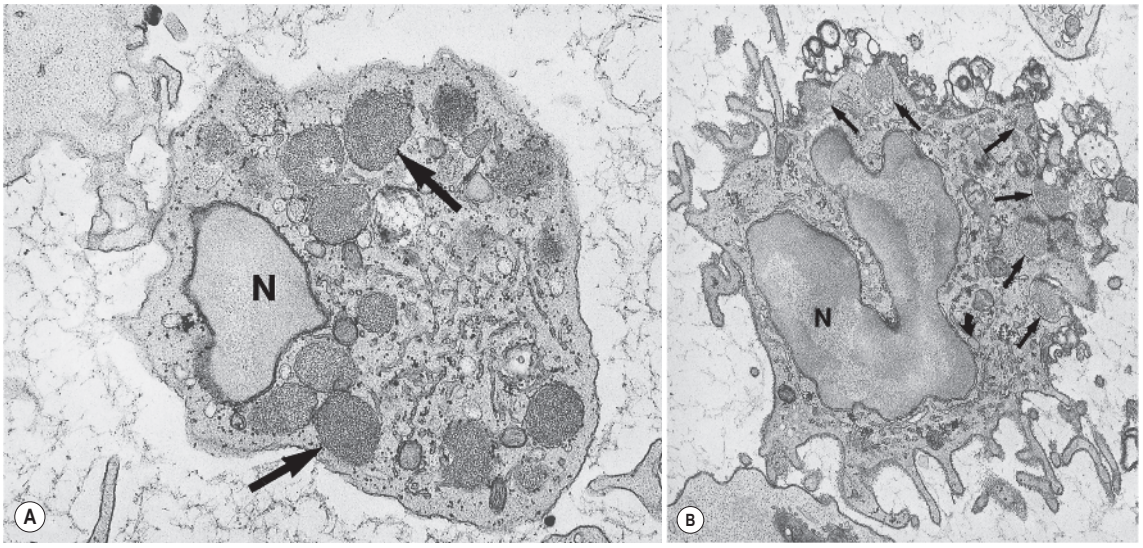

FIG. 44.3 (A) Transmission electron micrograph of a human basophil in a preparation of peripheral blood leukocytes obtained by separation over Ficoll-Hypaque. All of the cytoplasmic granules (some indicated by *solid arrows*) contain particulate electron-dense material. *N*, Nucleus. (Original magnification approximately ×19,800.) (B) A human basophil 2 minutes after exposure to antigen *in vitro*. The cell exhibits extrusion of granules from six separate sites on the plasma membrane *(small arrows)*. At this time after cell stimulation, particle-filled granules retain their shape and characteristic structure even after exposure to extracellular milieu. Cationized ferritin coats the cell surface and enters culs-de-sac that contain exteriorized granules. The cell exhibits no fully intracytoplasmic typical basophilic granules, but one of the smaller kind of granules *(curved arrow)* can be observed in the perinuclear region. *N*, Nucleus. (Original magnification approximately ×19,200.) (From Dvorak AM, Newball HH, Dvorak HF, Lichtenstein LM. Antigen-induced IgE-mediated degranulation of human basophils. *Lab Invest*. 1980;43:126–139, with permission from Nature Publishing Group Ltd.)

KEY CONCEPTS

Basophils

- Basophils originate from the bone marrow and are of myeloid lineage, but, unlike MCs, complete their maturation in the marrow before being released into the peripheral circulation as mature cells.
- Basophil development occurs in various stages and is regulated by multiple factors with one of the most important being IL-3.
- The basophil activation test (BAT) is a flow cytometry–based test that looks for expression of CD63 and CD203c on the basophil surface in response to allergen-IgE complex stimulation to assess immediate hypersensitivity.
- Basophil-related disease is due to either basophil activation, increased basophil number, or a combination of both. Treatment is similar to that of mast cell disorders and includes foiling cell activation and reducing cell number.

Eosinophils and Eosinophilic Disorders

Amy D. Klion and Paneez Khoury

First described in the 1800s by Paul Ehrlich, eosinophils are rare cells of the myeloid lineage that are characterized by a bilobed nucleus and abundant secondary granules that bind the acidic red dye, eosin. Best known for their role as innate effector cells in allergic inflammation and helminth infection, eosinophils or eosinophil-like cells have been found in all vertebrates examined to date, including fish and even invertebrate cockroaches.[1] Conservation of eosinophils across species over millions of years combined with the lack of evidence for congenital eosinophil deficiency in humans[2] suggest that eosinophils play important biologic roles. Despite the viability of genetically engineered "eosinophil-less" murine models and the lack of safety signals in clinical trials of eosinophil-depleting therapies, recent data from murine and human studies support this hypothesis and are beginning to delineate roles for eosinophils in a wide variety of homeostatic processes. This is of particular interest as the number of therapeutic agents targeting eosinophils increases. After a brief summary of the basic biology of eosinophils and eosinophil activation, this chapter focuses primarily on the role of eosinophils in health and disease, including novel therapeutic approaches and their contribution to our understanding of the role that eosinophils play in homeostasis and pathogenesis.

EOSINOPHIL BIOLOGY

Eosinophil Life Cycle

The relative numbers of eosinophils in the bone marrow, blood, and tissue at any one time depend on the balance between eosinophilopoiesis, migration to and from the bloodstream, and apoptosis. Eosinophils develop from pluripotent $CD34^+$ hematopoietic stem cells in the bone marrow through the complex interplay of transcription factors, cytokines, and growth factors (reviewed in Fulkerson and Rothenberg[3]). A key step in this process is the generation of lineage-committed eosinophil precursors (EoPs) from a common eosinophil/mast cell progenitor that expresses the transcription factor GATA-1. *Gata1* gene expression is essential for eosinophil development in mice and humans and occurs via an eosinophil-lineage-specific enhancer in the gene itself. This double palindromic enhancer is also present in genes encoding other characteristic eosinophil proteins, such as eosinophil peroxidase *(EPX)*, interleukin-5 receptor α *(IL-5RA)*, and the eotaxin receptor gene *CCR3*; targeted deletion of the enhancer led to the creation of one of the first mouse strains completely lacking eosinophils.[4] Additional events in early eosinophil lineage differentiation include downregulation of friend of GATA-1 *(FOG1)* in the context of expression of CCAAT/enhancer binding protein (C/EBP)α C/EBPε, interferon regulatory factor (IRF8), PU.1, and tribbles homolog 1 (TRIB1).

EoPs are blastic cells that have fine intracytoplasmic granules and express both CD34 and IL-5RA on their surface.[5] As they differentiate into mature eosinophils, they lose expression of CD34 and acquire the characteristic morphologic features of mature eosinophils. Although EoPs are programmed to become eosinophils even in the absence of IL5, increased IL5 levels, as seen in helminth infection and allergic reactions, stimulate their proliferation and terminal differentiation. Other cytokines and chemokines, including IL33, IL3, granulocyte–macrophage colony-stimulating factor (GM-CSF), and members of the eotaxin family, can induce eosinophil differentiation in vitro in the absence of IL5, adding to the complexity of the process.

Mature eosinophils (and small numbers of EoPs) exit the bone marrow into the peripheral circulation, where, under homeostatic conditions, they remain for approximately 1 day before migrating to the tissue.[6] As is true for other circulating leukocytes, eosinophil egress from the bloodstream involves multiple steps and surface expression of various selectins and integrins important in endothelial interactions, including tethering, rolling, and transendothelial migration (reviewed in Klion et al.[7]; Fig. 45.1). Whereas eotaxin-1 (CCL11) appears to be the major driver of eosinophil trafficking to the thymus, lymph nodes, spleen, stomach, and intestine in healthy individuals, local production of additional mediators, including eotaxin-3 (CCL26) and prostaglandin D_2, in response to allergen stimulation, tissue damage, or other factors, can attract eosinophils to almost any tissue in the setting of eosinophilic disease. This has clinical implications since therapeutic agents that affect expression or block function of these molecules, such as natalizumab (anti-CD49d), vedolizumab (anti-α4β7), and dupilumab (anti-IL4 receptor α), can cause impaired eosinophil tracking to affected tissues resulting in increased blood eosinophilia.

The life span of eosinophils in the tissue under homeostatic conditions is generally believed to be less than a week. In the setting of inflammation and local secretion of anti-apoptotic cytokines, including IL5, eosinophils likely persist longer. Moreover, in situ eosinophilopoiesis from EoPs in response to local production of IL5 and other mediators may contribute to tissue eosinophilia in some cases.[8]

Eosinophil Structure

Mature resting eosinophils are characterized by a bilobed nucleus and a cytoplasm containing abundant specific granules (Fig. 45.2). These granules are composed of an electron-dense core of major basic protein (MBP) and a matrix, containing the highly cationic eosinophil granule proteins (MBP, EPX,

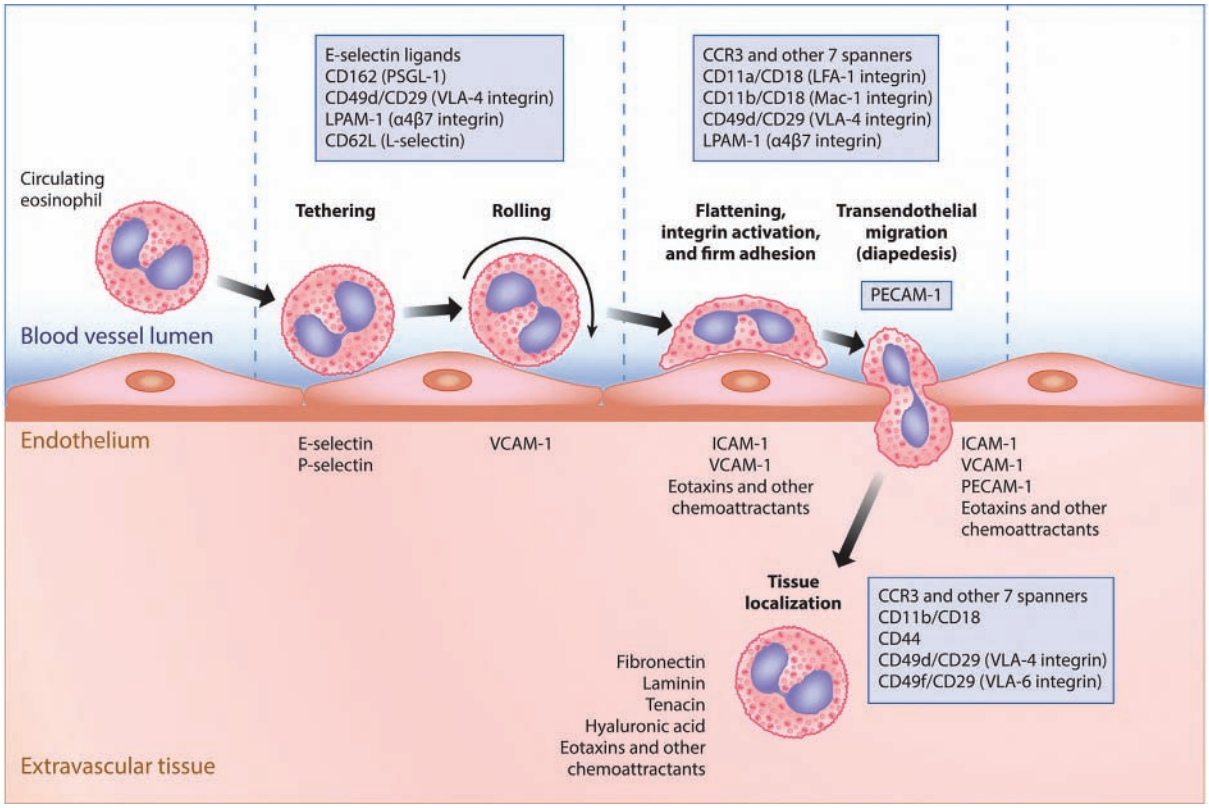

FIG. 45.1 **Eosinophil life cycle** (from Klion, Ackerman and Bochner (artist: Jacqueline Schaffer). Annu Rev Pathol; PMID 31977298).

eosinophil-derived neurotoxin [EDN], and eosinophil cationic protein [ECP]), as well as a multitude of preformed cytokines, chemokines, growth factors, and receptors.[9] In addition to the cellular machinery typical of any blood cell, the cytoplasm of eosinophils contains a complex vesiculotubular network and galectin-10 (Charcot-Leyden crystal protein). Galectin-10, one of the most abundant eosinophil proteins, appears to play an essential role in specific granule formation.[10] Although not present in resting eosinophils, lipid bodies, cytoplasmic organelles rich in arachidonic acid that synthesize inflammatory lipid mediators, including leukotriene C4 and prostaglandin D_2, are rapidly formed following eosinophil activation.[11]

Eosinophil Activation and Degranulation

Eosinophil activation can be intrinsic (i.e., due to activating mutations in the myeloid lineage) or in response to external stimuli, including cytokines, chemokines, and alarmins. Depending on the stimulus, activation can lead to degranulation by one of several mechanisms: (1) exocytosis (fusion of one or multiple granules creating a channel for extracellular release of mediators), (2) piecemeal degranulation (shuttling of selected granule contents to the cell surface through the tubulovesicular network via specific receptors), and (3) cytolysis (granule release during cell death with or without the release of nuclear DNA in the form of eosinophil extracellular traps [EETs]).[12] Activation-induced rapid release of mitochondrial DNA nets containing granule proteins has also been described in the absence of cytolysis.

Another prominent feature of eosinophil activation is altered surface receptor expression. In addition to upregulation of adhesion molecules involved in egress from the bloodstream, changes in expression levels of chemokine receptors, immunoglobulin receptors, vesicle-associated membrane proteins (e.g., CD63), and activation markers (e.g., CD69, CD25) have been described.[7] Other events accompanying eosinophil activation include the secretion of lipid mediators and reactive oxygen species and the formation and release of Charcot-Leyden crystals, characteristic birefringent crystals found at sites of eosinophilic inflammation in tissues and in association with EETs.

Irrespective of the mechanism of activation, deposition of eosinophil granule protein contents and release of inflammatory mediators contribute to the effector functions of eosinophils but can also cause tissue damage, hypercoagulability, and fibrosis. Although the factors that determine the outcome of eosinophilic inflammation in a given tissue or individual are poorly understood and remain a topic of investigation, the generation of murine models lacking eosinophils and the availability of therapies specifically targeting eosinophils in humans have led to recent advances in our understanding of eosinophil function in health and disease.

ROLE OF EOSINOPHILS IN HOMEOSTASIS

Whereas eosinophil-deficient mice have no apparent developmental defects and normal life spans, an expanding number of abnormalities in basic homeostatic functions have been reported, including reduced body fat mass, glucose intolerance, impaired vaccine recall responses, and alterations in immune responses and microbiome composition in the gut.[12] Most of these functions have been attributed to eosinophil secretion of mediators that modulate the development and function of other

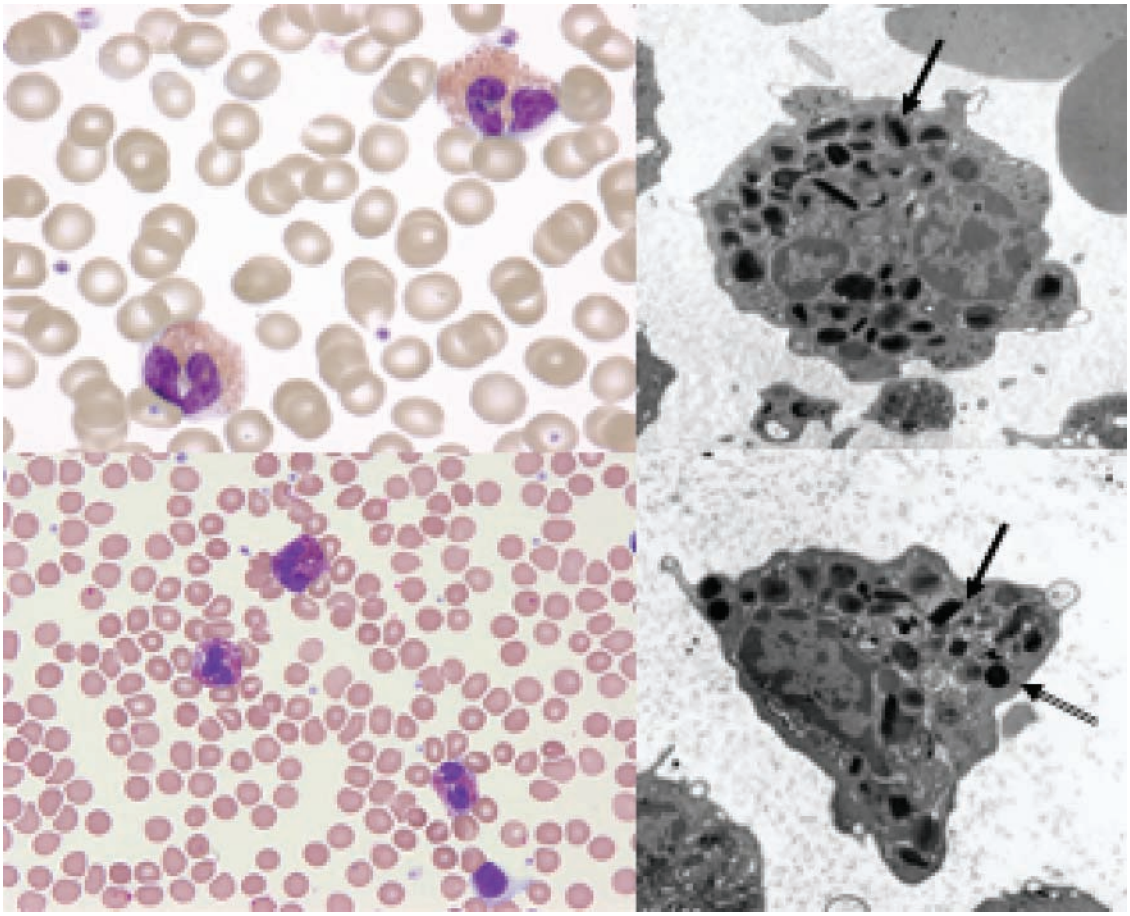

FIG. 45.2 Eosinophil Structure. Resting *(upper panels)* and activated *(lower panels)* eosinophils are shown by light and electron microscopy. Specific granules are indicated by *solid arrows* and lipid bodies by an *open arrow*. (Adapted from Klion et al. Blood 2004 PMID 14988154.)

immune cells, although eosinophils likely play a more direct role in some processes, including tumor surveillance.

The applicability of these findings to humans has been more difficult to unravel. Many of the relationships between numbers of eosinophils and other cell types have been confirmed in humans; however, the functional consequences of these associations remain unclear. Congenital absence of eosinophils has not been reported to date, and although rare cases of acquired eosinophil deficiency have been described, they do not appear to be associated with consistent abnormalities related to eosinophil deficiency. More recently, the availability of therapeutics that target eosinophils has begun to directly address the consequences of eosinophil depletion in humans. Although studies to date have failed to confirm many of the murine findings (e.g., impaired responses to immunization, glucose intolerance, predisposition to malignancy), additional studies over longer time frames are needed. Moreover, subclinical effects of eosinophil reduction may be potentiated when the function of other cell types is compromised, either as a result of the underlying disease process or therapeutic intervention.

Recent data from murine models have convincingly demonstrated the existence of a distinct subset of lung-resident eosinophils (rEOs) that play a regulatory role in the absence of inflammation.[13] These rEOs are functionally IL-5-independent (but express IL-5Rα) and have a distinct surface immunophenotype and RNA expression profile compared to eosinophils that enter the tissue following allergen challenge and steady-state eosinophils in the small intestine in mice. Whereas human eosinophils exhibit phenotypic heterogeneity in different microenvironments, the existence of a distinct terminally differentiated regulatory eosinophil subset in humans remains controversial.

EOSINOPHILIA AND EOSINOPHILIC DISORDERS

Definition of Eosinophilia

Eosinophilia is defined as an absolute eosinophil count (AEC) of approximately greater than 500/mm^3 and hypereosinophilia (HE) as an AEC at least 1500/mm^3 in the peripheral blood, or markedly increased tissue eosinophilia. Whereas the prevalence of eosinophilia ranges from approximately 5% in healthy military recruits to more than 30% in selected immigrant groups, HE is much less common and more likely to be associated with clinical manifestations. Hypereosinophilic syndromes (HES) are a rare group of heterogeneous conditions characterized by HE and confirmed or presumed eosinophil-driven clinical manifestations. Whereas the level of blood eosinophilia can be helpful in monitoring disease activity, especially in an individual patient with HES, this does not always reflect the extent and severity of organ or tissue damage involvement. The use of targeted therapeutics with differing effects on blood and tissue

eosinophils has further complicated the interpretation of blood eosinophil levels.

Diagnostic Approach to the Patient With Eosinophilia

The causes of eosinophilia and eosinophil-associated disease are myriad (Table 45.1) and range from disorders with relatively benign manifestations and only minimal peripheral eosinophilia, such as allergic rhinitis and chronic rhinosinusitis, to more severe conditions with marked eosinophilia and severe end-organ manifestations, including eosinophilic granulomatosis with polyangiitis (EGPA) and eosinophilic myeloid malignancies. Although helminth infections likely still account for the highest percentage of mild to moderate eosinophilia worldwide, their prevalence is decreasing. In contrast, the prevalence of atopic conditions associated with eosinophilia, including asthma, chronic rhinosinusitis, atopic dermatitis, and drug-related eosinophilia, continues to rise.

The urgency of evaluation and need for treatment depend on the degree of eosinophilia, clinical context, and potential underlying causes. In this regard, a comprehensive history, including onset of the eosinophilia, travel and potential exposures, current and recently discontinued medications, prior medical history, and current symptoms, is essential. A complete physical examination with assessment of lymphadenopathy, splenomegaly, and skin findings, complete blood count with differential and routine biochemical testing should be performed in all patients with additional laboratory and diagnostic studies dictated by the preliminary clinical findings. Of note, intact eosinophils may be absent in biopsies despite immunohistochemical evidence of eosinophil degranulation. Although an in-depth discussion of all of the potential causes of eosinophilia is beyond the scope of this chapter, the following section provides a system-based discussion of some of the more common eosinophil-associated disorders. Clinically distinct syndromes and hypereosinophilic disorders restricted to a single organ system (*i.e.*, overlap HES) are included in the system-based section. Multisystem eosinophilic disorders, including rare clinical subtypes of HE/HES, are discussed separately.

TABLE 45.1 Eosinophil-Associated Disorders and Clinical Syndromes

Broad Categories	Examples (not exhaustive)
Allergic and atopic skin and soft tissue	Atopic dermatitis, eosinophilic asthma, chronic rhinosinusitis
	Atopic dermatitis — allergic and in the setting of immune dysregulatory disorders
	Bullous diseases (pemphigoid and pemphigus)
	Eosinophilic folliculitis
	Eosinophilic cellulitis (Wells syndrome)
	Eosinophilic fasciitis
	Episodic angioedema with eosinophilia
	Cutaneous manifestations of parasitic infection, such as cutaneous larva migrans and onchocercal dermatitis
	Drug hypersensitivity reactions
	Cutaneous T-cell lymphoma
Pulmonary	Acute and chronic eosinophilic pneumonia
	Allergic bronchopulmonary aspergillosis
	Helminth infection, including Loeffler syndrome (transpulmonary migration of helminth parasites) and tropical pulmonary eosinophilia
	Fungal infection, including coccidiomycosis, cryptococcosis, and histoplasmosis
	Drug hypersensitivity pneumonitis
	EGPA
Gastrointestinal	Eosinophilic gastrointestinal disorders (EGIDs)
	Eosinophilic hepatitis — idiopathic, autoimmune, drug, or helminth-associated
	Eosinophilic cholecystitis
	Inflammatory bowel disease
Renal or urinary	Acute interstitial nephritis, often medication-induced
	Eosinophilic vasculitis
	Eosinophilic cystitis, including primary and secondary (*e.g.*, to urinary schistosomiasis)
Cardiac	Endomyocardial fibrosis, eosinophilic myocarditis, or eosinophilic pericarditis, typically in the setting of EGPA or rare HES variants
Neuromuscular	Mononeuritis multiplex, typically in the setting of EGPA or rare HES variants
	Eosinophilic meningitis due to medication, fungal or parasite infection, and rarely lymphoma
	Eosinophilic myositis, including calpain-3 associated, autoimmune, and infectious (*e.g.*, trichinosis and sarcocystosis)
Drug and toxin-related	Drug hypersensitivity reactions, including DRESS
	Drug effects, such as those due to IL-2, GM-CSF infusion
	Eosinophilia-myalgia syndrome
Infectious	Helminth infection, ectoparasites (scabies, myiasis), various fungal infections, human immunodeficiency virus
immune	Rheumatologic disorders, including EGPA, IgG4-related disease and rheumatoid arthritis
	Sarcoidosis
	Primary immunodeficiency disorders, such as DOCK8 deficiency, and Omenn syndrome
	Transplant rejection
Hematologic and neoplastic	Myeloid HESs, including those associated with abnormalities in *PDGFRA, PDGFRB, JAK2*, and *FGFR1* and chronic eosinophilic leukemia-not otherwise specified
	Systemic mastocytosis
	Lymphocytic leukemias, especially T-cell leukemia and pre-B-cell ALL, and varied lymphomas
	Solid tumors, especially adenocarcinoma
Other	Rare HESs, hypoadrenalism, cholesterol embolism, serosal surface irritation, familial hypereosinophilia

ALL, Acute lymphocytic leukemia; *GM-CSF*, granulocyte–macrophage colony-stimulating factor; *DOCK8*, dedicator of cytokinesis 8; DRESS, drug rash with eosinophilia and systemic symptoms; *EGPA*, eosinophilic granulomatosis with polyangiitis; *GM-CSF*, granulocyte–macrophage colony-stimulating factor;*HES*, hypereosinophilic syndrome; *IgG4*, immunoglobulin G4; *IL-2*, interleukin-2.

Eosinophilia by Organ System

Dermatologic and Soft Tissue Disorders

Eosinophilic skin infiltration is extremely common and can occur in the context of a wide variety of diagnoses with or without concomitant peripheral eosinophilia (reviewed in Leiferman and Peters[14]). The clinical manifestations of skin and soft tissue eosinophilia are protean and include pruritus, urticaria, angioedema, maculopapular eruptions, bullae, ulcers, and fibrosis. Although clinical findings are sometimes pathognomonic (e.g., the "groove sign" in eosinophilic fasciitis or the serpiginous pruritic track of cutaneous larva migrans), this is the exception rather than the rule. Common conditions, such as atopic dermatitis, can present with moderate to marked blood eosinophilia and can be particularly difficult to differentiate from the initial presentation of a systemic HES. In addition, eosinophilic dermatologic conditions can sometimes be a clue to an underlying non-eosinophilic diagnosis, as in the case of eosinophilic pustular folliculitis and human immunodeficiency virus (HIV) infection.

Parasitic infections, infestations (e.g., scabies), and environmental or drug hypersensitivity reactions, which can include drug reaction with eosinophilia and systemic symptoms (DRESS), are among the most frequent secondary causes of eosinophilia, and dermatologic involvement should be considered in the setting of an appropriate exposure history. Autoimmune blistering disorders (e.g., pemphigoid and pemphigus), immunoglobulin G4 (IgG4)-related diseases, vasculitic disorders (not limited to EGPA), and various lymphoproliferative and myeloproliferative disorders, including T-cell lymphoma and systemic mastocytosis, commonly present with eosinophilic infiltration of the skin and mild to marked peripheral eosinophilia. Extensive skin involvement and significant eosinophilia in a young child or in the context of recurrent or unusual infections should prompt consideration of a primary immunodeficiency, such as dedicator of cytokinesis 8 (DOCK8) deficiency.

Rare idiopathic eosinophilic conditions that predominantly involve the skin and soft tissues include eosinophilic cellulitis (Wells syndrome) and eosinophilic fasciitis. Although varied triggers have been reported, the pathogenesis of eosinophilic cellulitis remains unknown. It can occur in the absence of other clinical manifestations or as part of a systemic eosinophilic disorder. Dermal involvement is common, and typical histopathologic findings include superficial and deep dermal inflammation with histiocytes, lymphocytes, and eosinophils. Eosinophil granule deposition in the dermis can result in characteristic "flame figures" on histopathology. Eosinophilic fasciitis is primarily a disease of the fascia and perimysium, although skin involvement can be present. Antecedent dermal edema followed by skin tightening, induration, and eventual sclerosis is typical. Fascial involvement and fibrosis may result in the characteristic "groove sign," skin tightening, muscle atrophy, and potentially irreversible contractures. Both eosinophilic cellulitis and eosinophilic fasciitis can occur as paraneoplastic syndromes.

Pulmonary Disorders

Eosinophilic conditions affecting the upper and lower airways include various allergic and immunologic disorders, of which eosinophilic asthma and chronic rhinosinusitis with and without nasal polyposis are the most common. Although each of these conditions can occur in isolation, they can also be the presenting symptom of another allergic or immunologic diagnosis, such as aspirin-exacerbated respiratory disease, allergic bronchopulmonary aspergillosis/mycosis, hypersensitivity pneumonitis, or EGPA. Features suggestive (but not diagnostic) of the latter include HE and failure to respond to standard or low-dose topical therapies. Although the role of eosinophils in the pathogenesis of chronic obstructive pulmonary disease is controversial, sputum and blood eosinophilia occur and biologics that target eosinophils have shown efficacy in some clinical trials.

The differential diagnosis of eosinophilia and pulmonary parenchymal disease is very broad and includes allergic, infectious, rheumatologic, neoplastic, and idiopathic disorders. A careful history and routine laboratory testing are useful in narrowing the differential, and computed tomography (CT) imaging of the chest can provide valuable information, especially when characteristic features are present. Nevertheless, bronchoalveolar lavage (BAL) and/or lung biopsy are often necessary for definitive diagnosis. Acute eosinophilic pneumonia (AEP) is a diagnosis of exclusion in a previously healthy patient presenting with fever, cough, and dyspnea of less than 7 days' duration and radiologic evidence of pulmonary infiltrates. There is frequently a history of recent initiation of cigarette smoking or significant smoke, sand, or dust exposure. BAL reveals greater than 25% eosinophils and no evidence of an underlying cause. Although hypoxemia and need for intubation are common, most patients recover, and recurrent episodes are extremely rare. In contrast, chronic eosinophilic pneumonia is a chronic illness most commonly diagnosed in women with a history of asthma. Symptoms are subacute and include cough, fever, weight loss, and dyspnea. Bilateral pleural-based or peripheral infiltrates are characteristic radiologic findings. Moderate blood eosinophilia is frequent, and BAL shows greater than 25% eosinophils.

Pleural fluid eosinophilia is defined by the presence of greater than 10% eosinophils and is a normal response to air or blood in the pleural space in the context of both accidental or iatrogenic trauma (e.g., following thoracotomy or repeated thoracentesis). Other causes include malignancy, especially lung cancer, drug hypersensitivity, pulmonary embolism, and a wide range of infectious pathogens, including helminths, fungi, viruses, and mycobacteria and bacteria (reviewed in Kalomenidis and Light[15]). Rarely, eosinophilic pleural effusions occur in the setting of immunologic disorders, including rheumatoid arthritis, EPGA, and sarcoidosis. The cause of pleural eosinophilia is not identified in up to 25% of cases.

Gastrointestinal Disorders

Gastrointestinal (GI) disorders associated with blood and/or tissue eosinophilia include those where eosinophils play a key role in pathogenesis (e.g., eosinophilic GI disorders [EGIDs], eosinophilic hepatitis, eosinophilic cholecystitis, eosinophilic pancreatitis) and those where eosinophilia is common but of unknown clinical significance (e.g., inflammatory bowel disease [IBD], celiac disease, autoimmune hepatitis). Moreover, eosinophilic infiltration of the GI tract can occur in isolation or as part of a multisystem disorder, including EGPA, *PDGFRA*-associated myeloid neoplasm, and other rare HES variants. Secondary causes of GI eosinophilia are many and include helminth infection, drug hypersensitivity reactions, and immune dysregulatory disorders.

EGIDs are rare disorders with characteristic symptoms and histopathologic evidence of eosinophils in the GI tract in the absence of a secondary etiology.[16] Although eosinophils are believed to play a key role in the pathogenesis of EGIDs, additional cell types, including mast cells, T cells, and fibroblasts, have also been implicated. The nomenclature of EGIDs continues to evolve as diagnostic criteria are developed for EGID involving different segments of the GI tract and/or layers of tissue involvement (e.g., mucosal vs. serosal).

KEY CONCEPTS

- Eosinophilic GI disorders (EGIDs) are rare, chronic/relapsing atopic conditions of the gastrointestinal tract that are diagnosed using a combination of clinical and pathologic features.
- Pediatric EGIDs may be more complex in presentation owing to nutritional deficiencies, growth delay, and need for feeding tubes for enteral nutrition. Developmental delay and behavioral disturbances have been described.
- Uncommon in isolated eosinophilic esophagitis (EoE), marked peripheral eosinophilia frequently accompanies EGID involving the stomach, small bowel, and/or colon, blurring the lines between EGID and systemic hypereosinophilic syndrome (HES) with GI involvement.
- Histologic features of EoE include eosinophilic inflammation with disruption of the epithelial architecture, basal zone hyperplasia, dilated intracellular spaces, and lamina propria fibrosis.
- Although the pathogenesis of EGIDs is incompletely understood, non-IgE-mediated reactions to food antigens play a role in the pathogenesis of EoE and EG in many patients.
- Treatment is generally indicated in EoE irrespective of symptom severity as chronic inflammation in the esophagus can lead to fibrosis, stricture formation, and food impactions. Choice of treatment of non-EoE EGIDs is generally guided by the severity of symptoms and presence of complications.
- Current therapeutic options for EGIDs include dietary interventions and swallowed and systemic glucocorticoids. Several promising biologic therapies are currently in clinical trials.

Eosinophilic esophagitis (EoE) is a chronic, immune-mediated disorder defined by the presence of greater than 15 eosinophils per high power field (hpf) in the mucosa of the esophagus and food-related symptoms. The current incidence of EoE is estimated at 5 to 10 cases per 100,000 individuals with a prevalence of 0.5 to 1 case per 1000 individuals in the United States and a male predominance. The prevalence of EoE is increased in family members of affected patients, and monogenic causes have been described (e.g., Loeys-Dietz syndrome [LDS] and DOCK8). Children commonly present with food refusal, failure to thrive, abdominal pain, and vomiting or regurgitation, whereas adults are more likely to complain of nausea, vomiting, dysphagia, food impaction, and chest pain. IgE-mediated food allergy and atopic disease are frequent concomitant diagnoses and peripheral eosinophilia, when present, is generally mild unless other GI segments are also involved. Endoscopy may reveal normal-appearing mucosa, edema, erythema, longitudinal furrows, plaques, and exudates, or a "crepe paper" appearance (Fig. 45.3). Trachealization and strictures can be seen in more advanced stages of the disease. Histologic assessment with adequate sampling is recommended even when the mucosa appears grossly normal. Tissue eosinophilia and other histologic features (EoEHSS) are useful for diagnosis.[17] Esophageal eosinophilia due to gastroesophageal reflux, achalasia, Crohn disease, connective tissue disorders, helminth

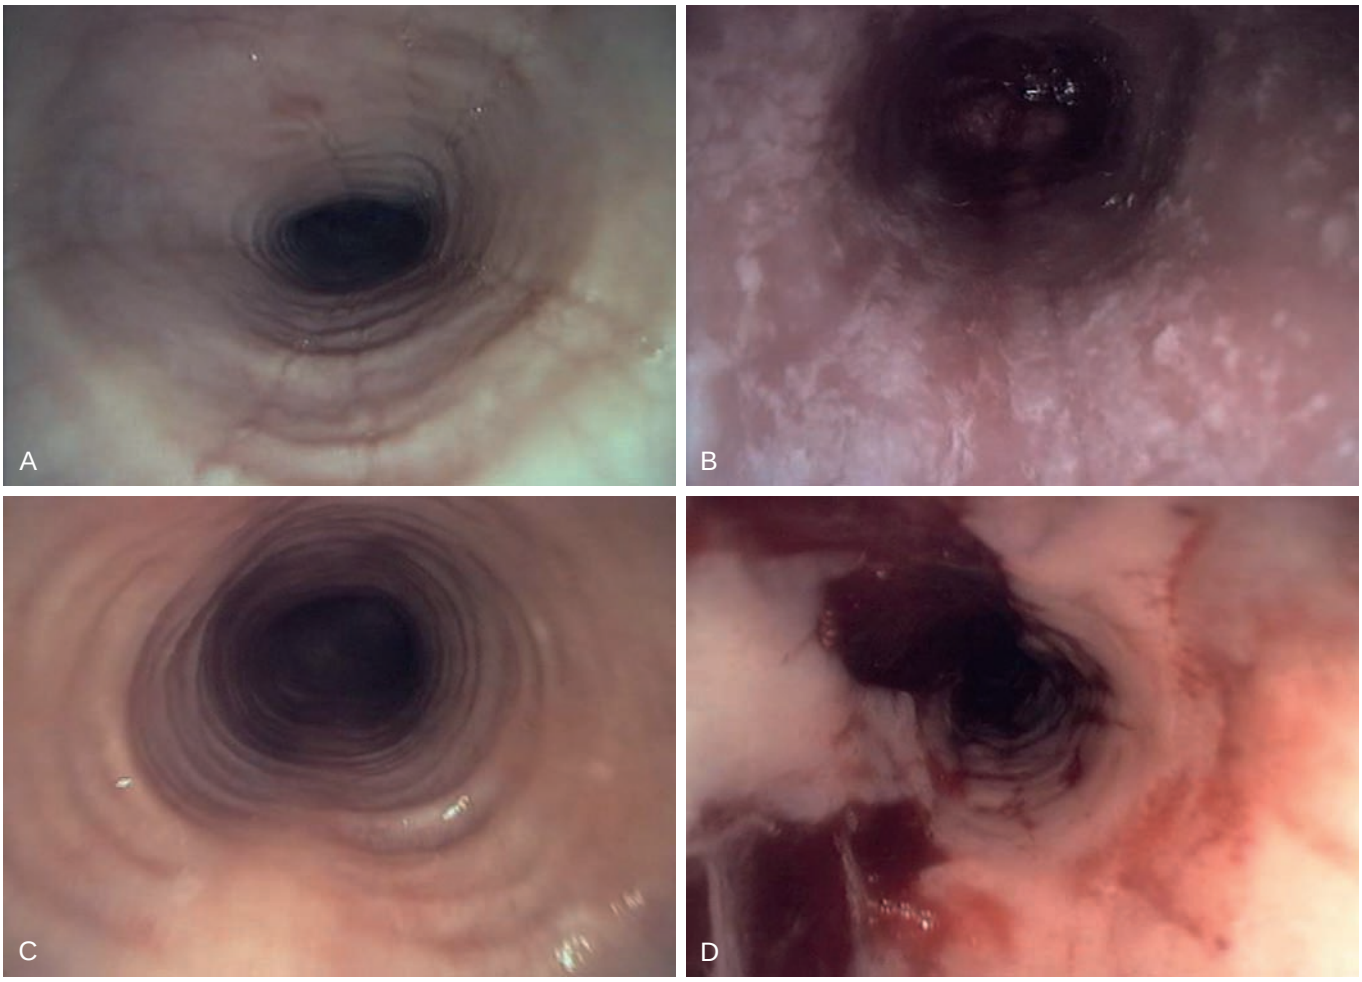

FIG. 45.3 Endoscopic Findings in Eosinophilic Esophagitis. Representative endoscopic pictures of active eosinophilic esophagitis showing loss of vascularity and red furrows (A), whitish exudates (B), corrugated rings (C), and a long-distance stricture with a deep laceration after dilatation (D).

infections, and drug hypersensitivity reactions must be excluded to make a diagnosis of EoE.

Non-EoE EGIDs (*i.e.*, eosinophilic gastritis, enteritis, and colitis) have been less well studied. Estimated prevalences range from 3.3 to 8.4 per 100,000 individuals but are confounded by the lack of consensus diagnostic criteria. Tissue eosinophilia (30 or more eosinophils/hpf in 5 high powered fields in the stomach, greater than 30/hpf in the small bowel, and greater than 60/hpf in the colon) in the absence of IBD or a known secondary cause supports the diagnosis but may be absent in patients with disease restricted to the deep submucosal, muscularis, or serosal layers. Males and females appear to be equally affected. Symptoms reflect the location and extent of intestinal involvement and can include early satiety, nausea, vomiting, abdominal pain, bloating, and diarrhea. Complications include iron deficiency anemia, protein-losing enteropathy, malabsorption, ascites (with serosal involvement), ulceration, and, rarely, perforation. Extraintestinal eosinophilic involvement of the liver, gallbladder, or pancreas has also been reported.

Renal and Genitourinary Disorders

The most common cause of eosinophilic infiltration of the kidney is acute interstitial nephritis (AIN) as a manifestation of drug hypersensitivity or a systemic eosinophilic disorder, such as EGPA or IgG4-related disease. Patients with AIN typically present with renal dysfunction accompanied by eosinophilia, rash, and/or fever. The presence of eosinophiluria was previously considered pathognomonic for this syndrome; however, eosinophils and their granule proteins can also be present in the urine of patients with systemic eosinophilic disease with and without renal abnormalities and in patients with eosinophilic cystitis. Renal vein thrombosis should be considered in hypereosinophilic patients with reduced creatinine clearance in the absence of an active urinary sediment.

Idiopathic eosinophilic cystitis is a rare disorder of unknown etiology that affects all ages, with approximately 20% of cases in children. Patients typically present with frequency, urgency, suprapubic pain, urinary incontinence, and/or retention. Peripheral eosinophilia and elevated IgE are common. This and an association with EGID in some cases suggest that idiopathic eosinophilic cystitis may be allergen-driven. Secondary causes of eosinophilic cystitis include drug hypersensitivity reactions, especially to medications delivered intravesically, urinary schistosomiasis, and bladder cancer. Rarely, eosinophilic cystitis occurs as a manifestation of idiopathic HES.

Cardiac Disorders

Eosinophilic cardiac involvement[18] is most commonly a manifestation of HES, where it occurs in up to 20% of patients and is an important cause of mortality. Etiologies of particular concern, because of the therapeutic implications, are eosinophilic myeloid neoplasms, especially those associated with mutations in *PDGFRA* and *JAK2*, helminth infection, EGPA, and DRESS. Although endomyocardial fibrosis (EMF) with valvular involvement, apical thrombus formation, and a high risk of thromboembolic events is characteristic (Fig. 45.4), additional manifestations include eosinophilic myocarditis, eosinophilic pericarditis, and eosinophilic coronary arteritis (in EGPA). Myocardial disease can be patchy, and tissue biopsies may not demonstrate intact eosinophils, especially in EMF. Immunohistochemical staining for granule proteins can be helpful in this regard. Eosinophilic infiltration of cardiac tissues has been described in other conditions, including viral myocarditis, sarcoid, and amyloid, but the role of eosinophils in the pathogenesis of these conditions remains controversial.

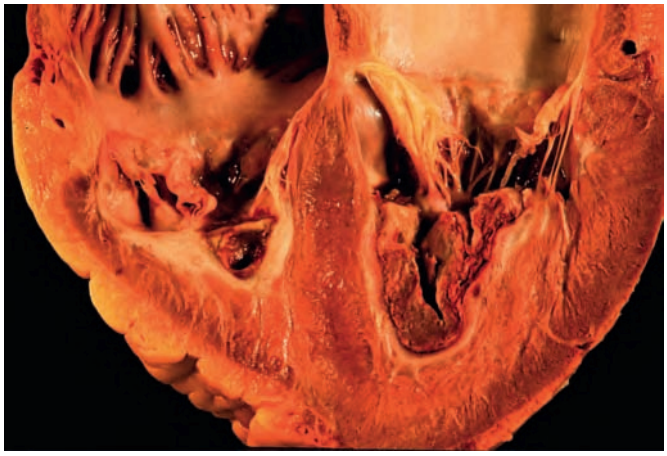

FIG. 45.4 Eosinophilic Endomyocardial Disease.

Neuromuscular Disorders

Eosinophilic involvement of the nervous system can manifest as peripheral neuropathy, meningitis, or central nervous complications. Eosinophil-related peripheral neuropathy is most frequently seen in the context of HES, including EGPA. Clinical manifestations range from mild sensory abnormalities to severe sensorimotor impairment involving multiple nerves (*i.e.*, mononeuritis multiplex). Eosinophilic meningitis may be due to drug hypersensitivity, infection (e.g., angiostrongyliasis, schistosomiasis, and cryptococcosis), or hematologic malignancy. Diagnosis requires the presence of greater than 10 eosinophils/μL (or 10% or more eosinophils) in the cerebrospinal fluid in a patient with clinical signs of meningitis. The most common central nervous complications of eosinophilia are thromboembolic, although rare cases of encephalitis have been reported.

The differential diagnosis of inflammatory eosinophilic myositis is broad and includes drug-induced myopathy, infectious (typically parasitic) or toxin-associated myositis, autoimmune (e.g., dermatomyositis or polymyositis), and genetic causes (e.g., calpain-3-associated limb-girdle myopathies). When no cause is identified, primary eosinophilic myositis should be considered. There are several clinically defined phenotypes of primary eosinophilic myositis that can be differentiated using a combination of clinical, histopathologic, and radiologic findings (reviewed in Selva-O'Callaghan et al.[19]); however, classical eosinophilic myositis presents with pain, overlying erythema, weakness, and tenderness with muscle biopsies demonstrating myonecrosis and endomysial inflammation. Eosinophilic fasciitis may be associated with myopathy and perimyositis with elevated aldolase but does not typically cause true myositis or muscle atrophy (except as a result of disuse in the setting of contractures).

Drug and Toxin-Related Eosinophilia

Drug-related eosinophilia is one of the most common causes of peripheral eosinophilia and can occur in response to any

prescription or over-the-counter medication, nutritional supplement, or herbal remedy. Manifestations of drug hypersensitivity range in severity from asymptomatic eosinophilia to the potentially life-threatening systemic involvement seen in DRESS, a nonimmediate hypersensitivity that typically presents with fever greater than 38°C, skin rash, lymphadenopathy, organ involvement, atypical lymphocytosis, and eosinophilia at least 3 weeks after drug initiation. Whereas many drugs can cause DRESS, the most common offending agents include anti-epileptics, reverse transcriptase inhibitors, dapsone, minocycline, and allopurinol. Skin, liver, and kidneys are most often affected, but lung and heart abnormalities are reported. Drug-specific T effector cells, viral reactivation, especially human herpes virus-6 (HHV-6), and decreased regulatory T cells have all been implicated in the pathogenesis of DRESS. Long-term-sequelae can include autoimmune disorders, such as thyroiditis, lupus, and diabetes.

CLINICAL PEARLS

Drug Hypersensitivity

- Eosinophilia and eosinophil-related complications can occur in response to any drug (prescription or over-the-counter) or dietary supplement.
- The clinical manifestations of drug hypersensitivity range from asymptomatic eosinophilia to severe life-threatening complications.
- Some clinical presentations may suggest a particular class of offending agent (e.g., DRESS and anti-epileptic medications, eosinophilia-myalgia syndrome, and tryptophan), whereas others (e.g., rash, pulmonary infiltrates) are less specific.
- Eosinophilia may not resolve for many months after the causative drug is discontinued and glucocorticoids or other immunosuppressive therapy may be needed to treat eosinophil-associated clinical manifestations.

Some drugs are associated with characteristic clinical syndromes (e.g., tetracyclines and eosinophilic hepatitis, L-tryptophan, and eosinophilia-myalgia syndrome); whereas others cause pleiomorphic clinical manifestations (*e.g.*, checkpoint inhibitors, cephalosporins). Yet others drive eosinophilia as a consequence of their mechanism of action, including some cytokine therapies (IL-2, GM-CSF) and monoclonal antibodies (e.g., dupilumab and vedolizumab).

Infectious and Immune Causes of Eosinophilia

A wide range of infectious agents, including parasites, fungi, viruses, and bacteria, can cause peripheral and/or tissue eosinophilia (reviewed in O'Connell and Nutman[20]). Since many of these are geographically or environmentally restricted, an appropriate exposure history and assessment of endemicity and travel is essential. The clinical picture is sometimes strongly suggestive of a particular diagnosis (e.g., periorbital edema and myositis in a patient with trichinosis or a subconjunctival worm in an African patient with loiasis). More commonly, clinical manifestations are nonspecific but can help narrow the differential diagnosis. The pattern of organ involvement and duration and degree of eosinophilia are particularly helpful in this regard.

Helminths are the most common cause of infection-related eosinophilia worldwide and can be broadly categorized into those that cause acute eosinophilia and those that cause persistent or chronic eosinophilia. Acute eosinophilia is a common early feature of infection with parasites that migrate through the lungs, including *Ascaris*, hookworm, and schistosomes. Acute marked eosinophilia can also be seen with serosal membrane involvement (*i.e.*, echinococcal cyst rupture, eosinophilic meningitis due to *Angiostrongylus* infection) and in hyperresponsive syndromes, such as tropical pulmonary eosinophilia (a rare presentation of lymphatic filariasis) and eosinophilic enteritis due to *Anisakis*. Among the multitude of helminths that cause chronic eosinophilia, *Strongyloides* is of particular concern due to its worldwide distribution, ability to persist for decades in an infected host, and propensity to disseminate with glucocorticoid administration. Hypersensitivity reactions to ectoparasite infestations, such as scabies and myiasis, can present with varying degrees of peripheral eosinophilia and should be considered in patients with consistent skin findings. Conversely, protozoan infections are almost never the cause of eosinophilia with the exception of acute watery diarrhea due to *Cystoisospora belli* infection and eosinophilic myositis due to *Sarcocystis* infection (restricted to southeast Asia). Whereas mild to moderate peripheral and/or tissue eosinophilia is frequently seen in a variety of cutaneous and systemic fungal infections, marked eosinophilia is characteristic of only a few, of which coccidioidomycosis is most common. Viral infections cause eosinopenia with rare exceptions, of which the most notable is HIV infection.

Primary disorders of immune dysregulation or immunodeficiency can present with peripheral eosinophilia that may or may not be associated with eosinophil-related clinical manifestations (reviewed in Williams et al.[21]). Onset at birth or in early childhood, characteristic features, and/or recurrent or atypical infections should prompt consideration of an underlying genetic cause. Some immunodeficiencies typically present very early in life with peripheral eosinophilia and eosinophilic manifestations, such as the exfoliative dermatitis seen in Ommen syndrome; others, such as autosomal dominant hyper-IgE syndromes (HIES) and DOCK8 deficiency, are more often diagnosed later in childhood in the setting of recurrent infections, elevated IgE levels, and HE with eosinophilic skin and GI involvement. Other disorders characterized by peripheral eosinophilia and eosinophilic tissue involvement include phosphoglucomutase 3 deficiency (PGM3); adenosine deaminase-severe combined immunodeficiency (ADA-SCID); immunodysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX), and IPEX-like disorders; LDS; severe dermatitis, multiple allergies and metabolic wasting (SAM); and Wiskott-Aldrich syndrome (WAS). Asymptomatic peripheral eosinophilia has also been reported in up to 10% of patients with autoimmune lymphoproliferative syndrome (ALPS) and is associated with increased mortality.

Eosinophilia is common following immune reconstitution after hematopoietic cell or solid organ transplantation. Causes include drug reactions, infections, acute severe graft-versus-host disease, and in the case of hematopoietic cell transplantation, immune reconstitution itself.

Finally, eosinophilia can be associated with a wide range of rheumatologic and idiopathic inflammatory conditions. In some cases, eosinophils are implicated in the pathogenesis of the clinical manifestations, such as eosinophil-associated myopathies, eosinophilic synovitis, eosinophilic panniculitis, EGPA, and IgG4-associated disease. In others, mild to moderate peripheral eosinophilia of uncertain clinical significance has been reported with some frequency (e.g., sarcoidosis, rheumatoid arthritis, dermatomyositis, and Sjögren syndrome).

GENETIC IMMUNE DISORDERS ASSOCIATED WITH HYPEREOSINOPHILIA

- A wide variety of inherited immune disorders are associated with blood and/or tissue eosinophilia
- Presentation in infancy, recurrent or atypical infections, and syndromic features are clues to an underlying inherited immune cause of eosinophilia
- Disorders commonly associated with eosinophilia include
  - IL6 pathway disorders: autosomal dominant hyper-IgE syndromes (HIES)-STAT3 deficiency
  - Actin dysregulatory disorders: DOCK8 deficiency
  - CID with T-cell receptor abnormalities or associated syndromic features: ARPC1B deficiency (small series), Omenn syndrome, ADA-SCID, ZAP-70 deficiency, TCR α or γ deficiency
  - Conditions of immune dysregulation: STAT5b gain of function
- Disorders in which eosinophilia has been reported in a subset of affected individuals include
  - Autoinflammatory disorders: neonatal-onset multisystem inflammatory disease (NOMID), chronic infantile neurological cutaneous and articular (CINCA), Blau syndrome
  - IL6 pathway disorders: IL6 receptor mutations, autosomal recessive HIES (e.g., ZNF341-deficiency)
  - Actin dysregulatory disorders: Wiskott-Aldrich syndrome, CARMIL2 deficiency syndrome (small series)
  - CID with T-cell receptor abnormalities or associated syndromic features: immunoskeletal dysplasia with neurodevelopmental abnormalities (EXTL3; small series), Comel-Netherton syndrome (*SPINK5* deficiency) and EPHKE syndrome (small series or case reports), ataxia-telangiectasia (rare), PGM3 deficiency (up to 50%)
  - Disorders associated with CARD11 variants
  - Loeys-Dietz syndrome
  - SAM syndrome
  - Combined immunodeficiencies and disorders of T-cell receptor generation: CD40/CD40L deficiency (case reports), CARD9 deficiency
  - Conditions of immune dysregulation: autoimmune lymphoproliferative syndrome (ALPS), JAK1 gain of function, IPEX and IPEX-like syndromes (seen in many affected individuals, counts frequently not reported)

ADA-SCID, Adenosine deaminase-severe combined immunodeficiency; *CADINS*, CID with early-onset asthma, eczema and food allergies, autoimmunity ID with atopic dermatitis; *CARD*, caspase recruitment domain family member; *CARMIL2*, capping protein, Arp2/3, myosin-I linker 2; *DOCK8*, dedicator of cytokinesis 8; *IPEX*, Immunodysregulation, polyendocrinopathy, enteropathy, X-linked syndrome; *PGM3*, phosphoglucomutase 3; *SAM*, severe dermatitis, multiple allergies, and metabolic wasting; *STAT3*, signal transducer and activator of transcription 3; *SPINK5*, serine peptidase inhibitor Kazal type 5; *TCR*, T-cell receptor; *ZAP-70*, zeta-chain-associated protein kinase 70.[21,33]

EGPA, previously known as Churg-Strauss syndrome, is a systemic vasculitic disorder defined in part by blood and/or tissue eosinophilia in the setting of preceding asthma and/or sinus disease.[22] Clinical complications are related primarily to eosinophilic infiltration and vasculitis and include myocarditis and/or pericarditis with resultant cardiomyopathy, peripheral neuropathy and thromboembolic events, migratory pulmonary infiltrates, skin involvement including purpuric and necrotic lesions, renal involvement, and, rarely, tracheal stenosis or optic neuritis. Anti-neutrophil cytoplasmic antibody (ANCA) positivity is often considered a hallmark of the disease; however, there are likely multiple phenotypes of EGPA and greater than 50% of patients with profound eosinophilia and characteristic clinical manifestations are ANCA-negative. Although eosinophil-rich inflammatory infiltrates and granulomatous inflammation in small to medium-sized vessels with vasculitis are diagnostic, these features may be absent in patients receiving glucocorticoid or other systemic therapies.

Hematologic and Neoplastic Causes of Eosinophilia

Eosinophilia can be the presenting manifestation of many acute and chronic lymphocytic neoplasms, including Hodgkin lymphoma, T-cell leukemia/lymphoma, and pre-B-cell acute lymphoblastic leukemia, and is a frequent feature of myeloid neoplasms and myeloproliferative disorders, including acute and chronic eosinophilic leukemia, chronic myelomonocytic leukemia, and systemic mastocytosis. The 2016 WHO classification of myeloid/lymphoid neoplasms with eosinophilia defines the following molecular abnormalities as the most common culprits: *PDGFRA, PDGFRB, FGFR1*, and *PCM1-JAK2*; however, other fusion partners (e.g., *ETV6)* and molecular abnormalities associated with a myeloid picture with eosinophilia (e.g., *JAK2* V16F, and *JAK2* exon 13 mutations, particularly V617F) have also been described.[23] Whereas peripheral eosinophilia is relatively uncommon in solid tumors, eosinophils are frequently present in the tumor microenvironment where they may play a role in the antitumor response.[24] Solid tumors, especially adenocarcinomas, are a rare cause of HES.

Hypereosinophilic Syndromes

HES are a heterogeneous group of disorders defined by AEC greater than or equal to 1500/mm^3 and evidence of eosinophil-mediated clinical manifestations. Although any organ can be affected, dermatologic, GI, and pulmonary manifestations are most common. Life-threatening cardiac and neurologic complications develop in up to 20% of patients over time. Following the landmark paper by Chusid and colleagues in 1984, describing 14 patients with "idiopathic" HES, a number of classification schemes have been proposed in an attempt to incorporate advances in our understanding of the drivers and pathogenesis of eosinophilic disease. The following categories are based on the consensus classification developed by the International Cooperative Working Group on Eosinophil Disorders (ICOG-EO) in 2012 and have proven useful in predicting treatment responses to a number of agents, including glucocorticoids, imatinib, and targeted biologics.[25]

Myeloid Hypereosinophilic Syndromes

Myeloid HES (MHES) is defined as HES due to definite or presumed clonal eosinophilia. Clinical features suggestive of MHES include markedly increased dysplastic eosinophils and EoP on peripheral smear, anemia or erythrocytosis, thrombocytopenia, increased serum vitamin B_{12} and/or tryptase levels, splenomegaly, and characteristic findings on bone marrow examination. The most common etiology of MHES, accounting for greater than 80% of cases in most series, is an interstitial deletion in chromosome 4 leading to the imatinib-sensitive fusion gene *FIP1L1-PDGFRA*. This mutation is almost exclusively seen in males and likely accounts for the male predominance and poor prognosis of "idiopathic" HES in early series. Clonal abnormalities involving *PDGFRB, JAK2, FGFR1*, and *KIT*, and chromosomal deletions and translocations account for most of the remaining cases of MHES with an identified cause.

Lymphoid Hypereosinophilic Syndromes

Lymphoid or "lymphocytic" HES (LHES) is defined by the presence of a phenotypically aberrant or clonal T-cell population

producing Type 2 cytokines that drive reactive HE. The most commonly identified aberrant T-cell population is $CD3^-$ $CD4^+$, followed by $CD3^+$ $CD4^+$ $CD8^+$ and $CD3^+$ $CD4^-$ $CD8^-$. Clonality can frequently, but not always, be demonstrated by assessment of the γ chain of the T-cell receptor by polymerase chain reaction (PCR) and/or Vβ chain assessment by flow cytometry. Although patients with LHES can present with a wide range of clinical manifestations, skin involvement (e.g., erythroderma, pruritic dermatitis, poikiloderma), lymphadenopathy, and elevated IgE are characteristic. Exclusion of lymphoma is important at presentation and periodically thereafter since progression to lymphoma has been reported in 5% to 30% of patients, sometimes decades after the initial diagnosis of LHES. Aberrant $CD3^-$ $CD4^+$ T-cell populations have been described in patients with asymptomatic hypereosinophilia (HEus) and episodic angioedema with eosinophilia (Gleich syndrome), although their contribution to the underlying disease process is unknown.

Overlap Hypereosinophilic Syndromes

By far the most confusing clinical category is overlap HES, which includes single-organ hypereosinophilic disorders (e.g., eosinophilic pneumonia, EGID, eosinophilic fasciitis) and defined syndromes associated with HE and eosinophilic manifestations (e.g., EGPA). These disorders overlap in presentation with idiopathic HES but are considered separately due to differences in treatment approaches (see below).

Associated Hypereosinophilic Syndromes

Associated HES is the term used for HES secondary to a known cause, such as drug hypersensitivity, infection, neoplasia, or immunodeficiency, where definitive treatment is directed at the underlying cause.

Familial Hypereosinophilic Syndromes. Hereditary cases of HES are extremely uncommon. Dominant mutations of STAT3 underlie the rare multisystem disorder characterized by recurrent boils, cyst-forming pneumonias, eosinophilia, and extreme elevations of IgE. Autosomal dominant transmission of HES has been mapped to chromosome 5q31-33 in one large kindred with dysregulation of IL5 expression. Familial clustering has been described in EoE; however, with the exception of EoE as part of a Mendelian syndrome (e.g., Loeys-Dietz, SAM), the underlying mechanism of inheritance appears complex. Rare cases of EGPA occurring in two members of the same family have also been reported.

Idiopathic Hypereosinophilic Syndromes. Idiopathic HES is the term used to describe patients with HES who do not fit into any of the categories above. In some cases, patients present with persistent asymptomatic HE without evidence of end-organ manifestations or tissue involvement in the absence of therapy (HEus). Although rare, HEus presents a unique problem as the risk of progression to HES is unknown.

THERAPY OF EOSINOPHIL-ASSOCIATED DISORDERS

General Treatment Approach

The approach to treatment of eosinophilic disorders depends on a variety of factors, including the severity of clinical manifestations, most likely diagnosis, and role of eosinophils in disease pathogenesis.[26] As such, the initial approach to the patient with mild to moderate eosinophilia does not differ from the approach to the patient with HE. In a patient with presumed eosinophil-related manifestations requiring urgent intervention (e.g., active cardiac involvement or thromboembolic events), glucocorticoid therapy is considered first-line therapy unless there is clear evidence of a hematologic malignancy or another disorder that requires rapid therapy directed at the underlying cause. Ivermectin therapy should be administered concurrently if there is a potential history of exposure to *Strongyloides* to prevent glucocorticoid-induced hyperinfection syndrome. Early initiation of other agents (e.g., cytotoxic therapy in EGPA or imatinib in *PDGFR*-associated myeloid neoplasms) depends on the level of suspicion for a particular underlying etiology.

Once the patient is stabilized, and in cases where treatment is not urgently needed, evaluation should focus on assessment of end-organ manifestations and the most likely etiology of the eosinophilia (Table 45.2). If a secondary cause, such as a helminth infection, drug hypersensitivity, or primary immunodeficiency, is identified, this should be treated, and resolution of the eosinophilia confirmed (if appropriate). In some cases, concomitant therapy directed at the eosinophilia may be necessary to manage clinical manifestations prior to definitive treatment (for example, glucocorticoid therapy to treat severe eczema prior to stem cell transplant in a patient with DOCK8 deficiency or pulmonary manifestations in a patient with tropical pulmonary eosinophilia prior to definitive therapy with diethylcarbamazine). At the opposite end of the spectrum, mild to moderate eosinophilia in an asymptomatic patient without evidence of end-organ manifestations can be observed without treatment. The decision to withhold therapy in the setting of HE is more complex and requires additional evaluation.

Whereas the optimal treatment for symptomatic patients with mild to moderate eosinophilia has not been systematically studied (necessitating an individualized approach), the treatment approach for patients with blood and/or tissue HE (*i.e.*, HES) has evolved considerably in recent years due in large part to the availability of new diagnostic tests and novel targeted agents. The most dramatic example of this is certainly the discovery of *FIP1L1-PDGFRA* as a driver of myeloid HES and the dramatic response of these patients to imatinib.

Historically, the most common agents used to treat all forms of HES were, in order of frequency, glucocorticoids, hydroxyurea, and interferon-α. Although these agents have been used for decades, and in the case of glucocorticoids, are highly effective in the short term, many patients become refractory over time and long-term toxicity is significant.[27] Consequently, a wide variety of cytotoxic, immunomodulatory, and immunosuppressive drugs have been tried with varying success. The development of imatinib and its ultimate approval in 2006 for the treatment of HES marked a major shift in approach by providing a targeted therapy for a defined subset of HES patients. More recently, regulatory approval of biologics that target eosinophils for the treatment of asthma, atopic dermatitis, EGPA, and, in the case of mepolizumab (anti-IL5 antibody), HES, is beginning to alter conventional approaches to therapy of many eosinophilic disorders.

Approach to Therapy of Hypereosinophilic Syndromes

There are considerable data to support a role for clinical subtype in determining therapeutic responses in HES as outlined below. Additional factors to consider include medication side effects, comorbid conditions, concomitant medications, and cost and convenience of therapy.

TABLE 45.2 Evaluation of the Patient With Hypereosinophilia

Test	Comment
All Patients with HES	
Complete blood count[a]	
Routine chemistries, including liver function tests[a]	
Quantitative serum immunoglobulin levels, including IgE	
Serum troponin,[a] echocardiogram	If abnormal, cardiac MRI should be considered as this may show characteristic features of eosinophilic involvement; tissue involvement may be patchy limiting the utility of biopsy
Pulmonary function tests[a]	
Chest/abdomen/pelvis CT[a]	To assess for splenomegaly, lymphadenopathy, and occult neoplasms
Bone marrow biopsy, including cytogenetics[a]	Recommended in all patients with AEC >5.0 × 10^9/L and features of M-HES or L-HES. Should be considered in other patients
Biopsies of affected tissues (if possible)[a]	
Other testing as indicated by history, signs, and symptoms	Including parasitic serologies, anti-neutrophil cytoplasmic antibodies, and HIV
Serum tryptase and vitamin B_{12} levels	
FIP1L1/PDGFRA analysis by FISH or RT-PCR	Testing of peripheral blood is sufficient
T- and B-cell receptor rearrangement studies	
Lymphocyte phenotyping by flow cytometry[a]	At a minimum CD3, CD4, and CD8 and CD19 or 20 staining should be performed to assess for aberrant $CD3^-CD4^+$, $CD3^+$ $CD4^+$ $CD8^+$, and $CD3^+CD4^-CD8^-$ populations and B-cell lymphoproliferative disorders
Patients with Features of M-HES	
Additional testing for *BCR-ABL1, PDGFRB, JAK2, FGFR1*, and *KIT* mutations by PCR, FISH, or other methods, as appropriate	Testing should be guided by bone marrow findings
Patients with Evidence of L-HES	
Consider PET scan,[a] lymph node biopsy[a]	
EBV viral load	

AEC, Absolute eosinophil count; *CT*, computed tomography; *EBV*, Epstein–Barr virus; *FISH*, fluorescence in situ hybridization; *HES*, hypereosinophilic syndromes; *HIV*, human immunodeficiency virus *L-HES*, lymphoid HES; *M-HES*, myeloid HES; *MRI*, magnetic resonance imaging: *PET*, positron emission tomography; *RT-PCR*, reverse transcription polymerase chain reaction.

[a]Substantially affected by corticosteroid therapy.

Myeloid Hypereosinophilic Syndromes

Prior to the recognition of *FIP1L1-PDGFRA* as a major cause of glucocorticoid-resistant HES, 5-year mortality in patients presenting with HE and myeloid features exceeded 30%. With the availability of imatinib, outcomes have dramatically improved in this group of patients due, in large part, to the near-universal imatinib responsiveness in patients with molecular abnormalities involving *PDGFRA* or *PDGFRB*. Imatinib responses in the absence of a detectable *PDGFR* abnormality vary depending on the series but features suggestive of a primary myeloid disorder (*i.e.*, MHES) strongly predicted response in one series. Side effects of imatinib include transient cytopenias, elevated transaminases, swelling, diarrhea, and muscle cramps. Pre-treatment with glucocorticoids is recommended for patients with evidence of eosinophilic cardiac involvement due to rare reports of cardiac necrosis in this population. Second-generation tyrosine kinase inhibitors, such as nilotinib, have shown efficacy in the setting of imatinib intolerance. Although there are relatively little data addressing treatment duration, cures have been reported and a large retrospective study of *PDGFRA*-positive patients found that length of therapy-induced remission prior to drug discontinuation was a major predictor of relapse-free survival.[28]

Whereas therapies targeting other molecular abnormalities, including mutations and translocations in *JAK2*, *FGFR1*, and *KIT*, are currently available or in development, data in patients presenting with HES are limited. Other therapies that have shown some efficacy in MHES include hydroxyurea, interferon-α, cytarabine, and stem cell transplantation.

Idiopathic Hypereosinophilic Syndromes

Systemic glucocorticoids remain first-line treatment for IHES, although rare patients do not respond, and many patients require moderate to high doses and ultimately require steroid-sparing therapies. Until recently, hydroxyurea and interferon-α were the preferred second-line steroid-sparing agents, with efficacy rates in the 30% to 40% range, followed by a wide range of cytotoxic and immunosuppressive agents that have been tried with varied success and considerable toxicity. The recent approval of mepolizumab for HES treatment and promising data from a phase 2 trial of benralizumab have already begun to change this paradigm. Although a number of questions remain, including the predictors of response and relapse, available data suggest that biologics targeting IL-5 or its receptor are safe, well-tolerated, and effective in a majority of patients with IHES.

Lymphoid Hypereosinophilic Syndromes

The general approach to LHES is similar to that for IHES, although patients with LHES are more likely to require higher doses of glucocorticoids. Second-line therapies are typically directed at suppression of T lymphocytes and/or IL-5 with interferon-α at the top of the list due to its multifaceted effects on clonal T-cell numbers and cytokine production. Other agents that have shown some efficacy in case reports and small series include cyclosporine, mycophenolate mofetil, alemtuzumab, and *JAK* inhibitors. Although mepolizumab is effective in controlling symptoms in LHES patients, it was significantly less effective in suppressing AEC to the normal range in LHES patients in the phase 2 study and does not have a direct effect on the clonal population.

OVERLAP HYPEREOSINOPHILIC SYNDROMES

A general guide to the treatment of overlap HES is precluded by the number and diversity of conditions included in this category, each of which requires an individualized approach. Consequently, for the purpose of this chapter, discussion is limited to two of the more common diagnoses encountered by subspecialists in allergy and immunology: namely. EGID and EGPA.

Eosinophilic Gastrointestinal Disorders

Current treatment modalities for EoE include dietary approaches, pharmacologic therapy, and endoscopic management (*i.e.*, food disimpaction and dilation of strictures).[29] Consequently, an interdisciplinary approach involving allergists, gastroenterologists, registered dieticians, and in some cases psychologists with experience in food-related disorders, is most effective. Since clinical and histologic improvement may be discordant in EoE and persistent inflammation can lead to long-term sequelae, including fibrosis and stricture formation, endoscopy remains the gold standard for evaluation of treatment response. Less-invasive assessment tools, such as the Esophageal String Test™, have been used in research settings and are in clinical development.

Dietary elimination using a hypoallergenic formula has been shown to induce histopathologic remission and symptomatic improvement in both children and adults. Consequently, dietary interventions are frequently initiated as first-line treatment. Empiric approaches include six-food elimination diets (SFED; milk, gluten, egg, soy, peanut, tree-nut, fish, and shellfish) and single- or step-up elimination approaches starting with the most common culprits (2-FED; milk and gluten) with extension to four foods (4-FED; milk, gluten, egg, and legumes) if the 2-FED diet is unsuccessful.[30] Data directly comparing the different dietary approaches are not currently available, and targeted testing with specific IgE is not helpful in identifying culprit foods in the absence of IgE-mediated food allergy in this patient population. Since the feasibility of an initial dietary approach and continuation as maintenance therapy requires significant resources and effort, shared decision making with the patient and family should be implemented when appropriate.

Pharmacologic interventions include acid suppression with proton pump inhibitors, topical (swallowed) steroids, and novel biologics. Acid suppression with proton-pump inhibitors leads to clinical improvement in some patients but frequently fails to induce histologic remission in EoE. In contrast, fluticasone and off-label modification of preparations of standard delayed release or liquid preparations of glucocorticoids used in asthma or IBD have shown efficacy in reducing dysphagia scores and peak eosinophil counts. Inhaled fluticasone can be swallowed or delayed-release capsules (e.g., Entecort) can be opened and enteric-coated granules crushed, made into a slurry or liquid preparation in thickeners of various sorts (e.g., sucralose or honey), and swallowed on an empty stomach. New delivery methods for oral suspensions and ready-to-use dispersible tablets for direct delivery to the esophagus are under investigation.

Although biologic therapies that target eosinophil-active cytokines, their receptors, or eosinophils themselves are in development for EoE, none are currently Food and Drug Administration (FDA)-approved for this indication.

Clinical trials using anti-IL-5 antibodies (mepolizumab and reslizumab) have been generally disappointing despite reduction in tissue eosinophil levels. The reasons for this are likely multifactorial and include study design, incomplete tissue depletion, and irreversible structural changes. A number of other biologics, including benralizumab, an afucosylated antibody to IL-5 receptor that efficiently depletes eosinophils in the blood and tissue through antibody-dependent cell cytotoxicity; dupilumab, an antibody to IL-4 receptor α that reduces eosinophil tracking to the tissue; and lirentelimab (AK002), an afucosylated antibody to Siglec-8 that both depletes eosinophils and inhibits mast cell degranulation, are currently in phase 3 trials after promising results in smaller studies.

There are currently no consensus guidelines for treatment of non-EoE EGIDs. Solitary gastric involvement is frequently treated in the same way as EoE. Patients with severe disease or more extensive GI involvement often require treatment with systemic glucocorticoids or other immunosuppressive agents. Phase 3 clinical trials of benralizumab and lirentelimab for eosinophilic gastritis and duodenitis are in progress. Treatment options for eosinophilic colitis remain largely unexplored.

Eosinophilic Granulomatosis with Polyangiitis

Whereas EGPA treatment guidelines have been established by the EGPA Consensus Task Force,[31] the importance of suppressing eosinophil counts to normal ranges and the most appropriate monitoring parameters for EGPA remain controversial. Glucocorticoids are recommended as first-line treatment and can be used as monotherapy to induce remission in patients with mild disease. When life-threatening or severe clinical manifestations are present, additional immunosuppressive agents (e.g., cyclophosphamide) are recommended to induce remission. This has typically been followed by maintenance therapy with azathioprine or methotrexate, although this is likely to change with the recent regulatory approval of mepolizumab (300 mg subcutaneously) for EGPA treatment.[32] Phase 3 trials are ongoing with rituximab (anti-CD20 antibody) and benralizumab, both of which have shown efficacy in preventing relapse in case reports and small open-label studies in EGPA.

Familial Eosinophilia

Familial EGID, EGPA, or symptomatic HES should be treated no differently than sporadic cases. The role for preemptive treatment in asymptomatic patients with familial eosinophilia has not been established. These patients should, however, be monitored for development of clinical manifestations.

HEus

The most appropriate approach to the asymptomatic patient with HE without clinical manifestations remains unclear, as predictors of progression have not been identified. At a minimum, such patients should undergo evaluation, including bone marrow examination, to exclude an occult myeloid neoplasm (MHES) requiring treatment. A number of factors, including the level of the AEC, potential side effects of treatment, and comfort level of the patient and physician should be considered in deciding whether to treat empirically.

ON THE HORIZON

- A better understanding of the underlying mechanisms that drive eosinophilia in varied eosinophilic disorders is needed for more accurate diagnosis and treatment of eosinophil-associated disorders.
- With the increasing availability of therapeutic agents that target eosinophilia, biomarkers and patient-reported outcome tools that correlate with eosinophilic disease activity are paramount in assessing the comparative efficacy of different treatments.
- Elucidating the role of eosinophils in homeostatic processes is a key factor in predicting the long-term effects of eosinophil-depleting therapies in humans.

Urticaria, Angioedema, and Anaphylaxis

Elena Borzova and Clive E.H. Grattan

Urticaria is a common skin disease that may be associated with a substantial disease burden.[1] Recent advances in our knowledge and understanding of its pathophysiology offer new diagnostic and treatment approaches for many patients.

DEFINITION

Urticaria is characterized by itchy wheals, angioedema, or both.[2] Urticarial lesions resulting from localized edema of the upper dermis are called *wheals* (Fig. 46.1), whereas acute reversible swelling of the lower dermis, subcutaneous and submucosal tissues is known as *angioedema* (Fig. 46.2).

KEY CONCEPTS

Definition of Urticaria

- Urticaria is an illness characterized by wheals, angioedema, or both.
- Wheals are superficial swellings of the skin: they are pale and itchy with surrounding redness when they appear and then become pink before fading.
- Angioedema is a deeper swelling below the skin or mucosa that usually lasts longer than wheals and may be painful rather than itchy.
- Wheals may occur with or without angioedema in urticaria.
- Acute urticaria lasts less than 6 weeks.[2] It is common and often precipitated by viral infections. Urticaria caused by drugs and foods falls in this category and here the cause is usually clear from the history.
- Chronic urticaria lasts 6 or more weeks with continuous disease activity.[2] A cause may not be found.
- When angioedema occurs without wheals, C1 esterase inhibitor deficiency should be excluded.
- Neonatal urticarial rash raises the possibility of a hereditary autoinflammatory disease or other rare genetic syndromes.

EPIDEMIOLOGY

Urticaria is common, affecting up to 20% of the general population at least once over their lifetime. The lifetime prevalence of chronic urticaria (CU) of all types is estimated at 1.4% and point prevalence at 0.7%.[3]

Acute urticaria mainly affects young adults, patients with atopic diseases, and has an obvious female preponderance, whereas CU is more common in adults, affecting mainly middle-aged women.[2,3] By definition, acute urticaria resolves within 6 weeks, whereas CU may last for years, rarely for more than 10 years. In adults, CU resolves spontaneously in 35% to 57% of patients within 1 to 1.2 years from the onset of the symptoms. In children, annual resolution rate of CU is approximately 10%.[4]

GENETICS

Although there is no indication of Mendelian inheritance, the frequency of chronic spontaneous urticaria (CSU) is higher in first-degree relatives of patients. CSU was linked to several HLA risk alleles including HLA class I (e.g., Bw4, B14, B44) and HLA class II (e.g., DRB1*01, DRB1*04, DRB1*0901, DRB1*12, DQ1, DQB1*0302).[5] Genetic variation in histamine-related genes, including *FCERI* and *HNMT*, and leukotriene-related genes, such as *ALOX5*, *LTC4S* and the PGE2 receptor gene *PTGER4*, were reported to be linked to CU. Additionally, variation in genes associated with autoimmunity such as *PTPN22* appeared to be relevant to CSU.[6]

Rarely, cold-induced urticarial lesions can be a cutaneous manifestation of several monogenic disorders such as *PLCG2*-associated antibody deficiency and immune dysregulation (PLAID) syndrome[7] and cryopyrin-associated periodic syndromes (CAPS),[8] including newly described FXII-associated cold autoinflammatory syndrome (FACAS).[9]

CLINICAL PATTERNS

Urticaria is classified by the duration of continuous activity into acute (less than 6 weeks) or chronic (6 weeks or more).[2] It may be spontaneous and/or inducible. Inducible urticarias may be triggered by mechanical, thermal, or other stimuli.

ETIOPATHOPHYSIOLOGY

Although many aspects of the pathophysiology of urticaria remain unclear, our understanding has advanced considerably over the last two decades (Table 46.1).

Mast Cell–Dependent Mechanisms

Skin mast cells (MCs) are key players in the pathogenesis of urticaria. They are predominantly located around the small blood vessels and lymphatic vessels, as well as around peripheral nerves. The MC density is greatest at distal body areas, including the face, hands, and feet. A threefold increase in the density of cutaneous MCs in the lesional skin of CSU patients has been reported.[10]

Human skin MCs contain preformed mediators in their granules, including histamine, proteases (tryptase, chymase), and heparin. They express many membrane receptors, including high-affinity immunoglobulin E (IgE), low-affinity IgG receptors (FcγRIII), and the inhibitory receptor Siglec-8. Unlike MCs elsewhere (e.g., lung and gastrointestinal [GI] tract), skin

MCs have high expression of complement C5a receptors and the neuropeptide receptors MRGPRX2.[11]

Skin MC activation is central to the pathophysiology of CU. MCs can be activated by a variety of immunological and nonimmunological triggers (Fig. 46.3). Immunological and nonimmunological pathways of MC activation are characterized by distinct patterns of mediator release. In CSU, immunological activation of MCs is thought to occur by cross-linking of high-affinity IgE receptors (FcεRI) by autoantigens binding specific IgE[12] or by MC activating autoantibodies (anti-FcεRIα or anti-IgE antibodies). Histamine release (HR) peaks at 5 to 10 minutes, followed by de novo synthesis of lipid-derived mediators (leukotriene C_4 [LTC_4] and prostaglandin D_2 [PGD_2]) and cytokines/chemokines. In contrast, nonimmunological stimulation of MCs by neuropeptides, opiates, or C5a leads to rapid HR within 15 to 20 seconds, without generation of eicosanoids or cytokines.[12]

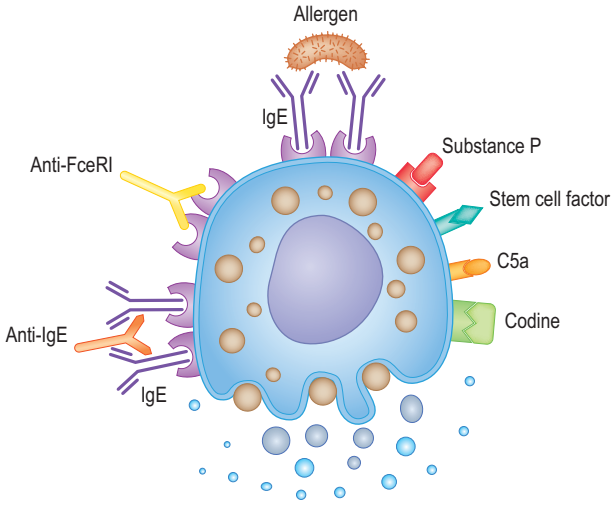

FIG. 46.3 Schematic Representation of a Mast Cell or Basophil. Activation of the immunoglobulin E (*IgE*) receptor by cross-linking with immunological stimuli (allergen/specific IgE binding, anti-IgE, or anti-FcεRI autoantibodies) or independent activation by nonimmunological stimuli (substance P, stem cell factor, codeine, or C5a), leading to degranulation.

Allergic Urticaria

The classic example of immunological MC activation via FcεRI is IgE-mediated urticaria (often termed *allergic urticaria*). Cross-linking of receptor-bound IgE leads to the release of preformed mediators and newly synthesized lipid mediators and cytokines, resulting in the early- and late-phase IgE-mediated allergic inflammatory responses.

IgE-mediated MC activation can present as acute urticaria in those individuals previously sensitized to exogenous allergens such as foods, drugs, and latex. Allergic urticaria to inhaled allergens (e.g., latex, animal epithelia) is often accompanied by respiratory symptoms. Generalized allergic urticaria may progress to anaphylaxis. Allergic urticaria resolves rapidly on withdrawal of allergen exposure and recurs with each re-exposure to the allergen or cross-reactive agents.

Autoimmune Urticaria

Two types of autoimmunity (type I and type IIb) are proposed in CSU.[13] IgE-mediated type I autoimmunity is referred to as autoallergy.[13] Autoallergens are thought to activate MCs by cross-linking of receptor-bound IgE autoantibodies. In CSU patients, IgE autoantibodies have been demonstrated to thyroperoxidase and thyroglobulin, double-stranded DNA, interleukin-24 (IL-24) and tissue factor.[12,13] There is currently no direct evidence for this theory, which remains controversial, but type I autoimmunity may play a role in CSU based on (1) IgE sensitization to a wide range of autoantigens,[12] (2) a correlation of total IgE with CSU severity, and (3) the therapeutic efficacy of anti-IgE monoclonal antibody omalizumab in CSU.

Type IIb autoimmunity in CSU is mediated by functional autoantibodies directed against the extracellular α-chain of FcεRI on dermal MCs and basophils or, less frequently, against receptor-bound IgE, which can lead to degranulation in vitro. As determined by Western blotting or immunoenzymometric assays, the rates of IgG-anti-FcεRI in CSU ranged from 4% to 64% and that of IgG-anti-IgE, from 0% to 69%.[13] It is currently accepted that only functional autoantibodies (e.g., with histamine-releasing activity) are clinically relevant in CSU.

Although direct evidence for type II autoimmunity in animal models of CSU is lacking, the indirect evidence is compelling: (1) the detection of histamine-releasing IgG1/IgG3 anti-FcεRIα autoantibodies in CSU but not in other cutaneous diseases such as pemphigus vulgaris, dermatomyositis, systemic lupus erythematosus, bullous pemphigoid; (2) the functional relevance of anti-FcεRIα/anti-IgE autoantibodies demonstrated by in vitro activation of basophils and cutaneous MCs by IgG purified from CSU sera and by neutralization of serum-induced basophil HR by soluble recombinant α-chains of the high-affinity IgE receptors in some patients; (3) passive transfer of the autologous skin test response by serum or IgG serum fraction from CSU patients to healthy recipients;[14] (4) correlation with CSU severity; and (5) a decline of serum HR activity in parallel with CSU clinical improvement following plasmapheresis or cyclosporine.[15]

Immune Complex–Mediated Urticarial Rash

MC activation can result from binding of circulating immune complexes to FcγRIII, expressed on MCs. In addition, circulating immune complexes can activate complement, leading to C3a and C5a anaphylatoxin formation. Urticarial rash caused by immune complexes can occur acutely in serum sickness-like reactions, transfusion reactions, some drug-induced urticarias, and urticaria associated with infections or autoimmune diseases. Immune complex–mediated urticarial rashes usually develop 1 to 3 weeks after initial exposure to the antigen and disappear several weeks after antigen discontinuation.

Chronic whealing mediated by immune-complex damage and associated with histological evidence of leukocytoclastic vasculitis is known as *urticarial vasculitis* (see below). In this condition, urticaria can be associated with systemic symptoms, such as fever, arthritis, or nephritis, mainly with the uncommon hypocomplementemic variant (hypocomplementemic urticarial vasculitis syndrome [HUVS]). Damage to postcapillary venules results from the deposition of immune complexes or complement in the vessel wall. Immune complexes are formed on exposure to external (drug or infections) or internal (collagen-like region of C1q) antigens. Complement activation via the classical pathway leads to neutrophil chemotaxis through cytokine expression and adhesion molecule activation (Fig. 46.4). Proteolytic enzymes released from neutrophils damage vessel walls, leading to wheal formation and red blood cell (RBC) extravasation.

Mast-Cell Activation via MRGPRX2 Receptors

In humans, a novel G protein-coupled receptor, Mas-related GPRX2 was identified in 2015.[16] Numerous agents, including neuropeptides (substance P, neuropeptide Y, vasoactive intestinal peptide, or somatostatin), major basic protein, eosinophil peroxidase, basic secretagogues (e.g., synthetic compound 48/80), antimicrobial peptides, and many drugs (e.g., cationic peptidergic drugs), can activate cells via MRGPRX2.[16] The MRGPRX2 expression in cutaneous MCs was reported to be increased in severe CSU patients compared with healthy controls.[17]

Mast Cell and Basophil Releasability in Urticaria

In patients with CSU, dermal MCs show a decreased activation threshold to anti-IgE. Although CSU basophils are often

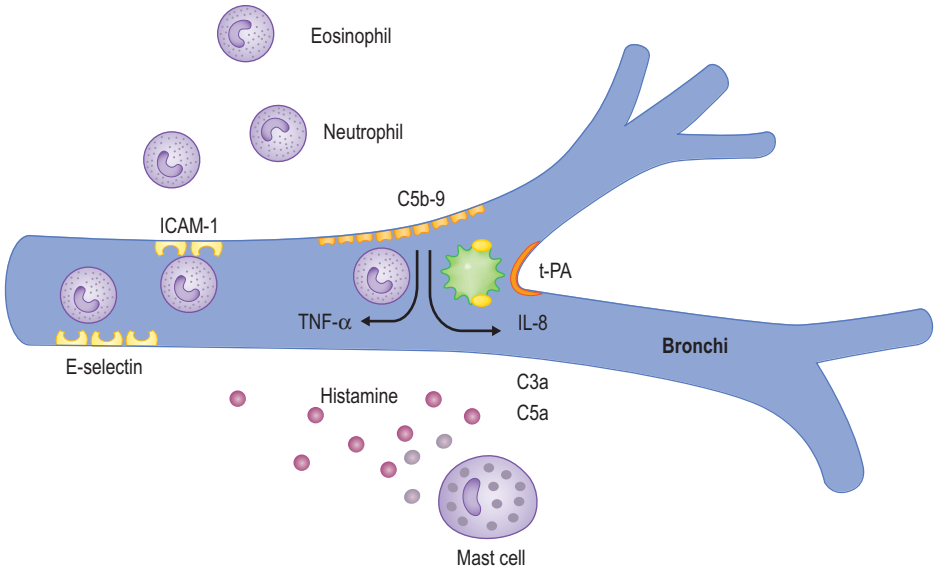

FIG. 46.4 Immune Complex–Mediated Urticaria Initiated by Lodging of Antigenic Complexes in Small Blood Vessels Followed by C3a and C5a Generation. This results in mast-cell degranulation and cytokine upregulation of adhesion molecules (intercellular adhesion molecule-1 (*ICAM-1*), E-selectin) by tumor necrosis factor-α (*TNF-α*) and interleukin-8 (*IL-8*), which leads to tissue recruitment of neutrophils and eosinophils and activation of tissue plasminogen activator (*t-PA*).

hyporesponsive to anti-IgE, they are paradoxically hyperresponsive to an as-yet unidentified factor in normal human serum.

Skin Response to Mast Cell Activation in Chronic Urticaria

Despite the existence of different pathways for MC activation, the end result is degranulation with release or secretion of mediators. Histamine is crucial for the development of cutaneous manifestations of urticaria and is found in high concentrations in tissue fluid of wheals. It causes localized redness resulting from vasodilatation, wheal formation from increased vascular permeability leading to plasma leakage, and a surrounding axon reflex-neuropeptide mediated flare-up. Histamine is also the main mediator of itch in urticaria. However, histamine-induced wheals are short-lived in contrast to urticarial lesions that may persist up to 24 hours, implying that other proinflammatory mediators and/or cellular infiltrates contribute to CSU pathogenesis, especially the delayed phase.

Mast Cell–Independent Mechanisms of Urticaria

Pseudoallergy, or nonallergic hypersensitivity, mimics immediate-type allergic reactions clinically without evidence of underlying immunological mechanisms. The most common triggers of pseudoallergic reactions are aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), as well as some food ingredients and additives, such as salicylates, benzoates, and tartrazine. These reactions do not involve IgE sensitization and can, therefore, occur on first exposure. Pseudoallergic reactions are dose-dependent and usually occur with chemically unrelated substances. Diagnosis of nonallergic hypersensitivity is based on a distinctive clinical pattern, time course, clinical signs, and response to elimination of the cause. In the appropriate clinical context, pseudoallergy can be confirmed with oral challenge tests.

Nonsteroidal Anti-Inflammatory Drugs

Aspirin and other NSAIDs inhibit constitutive cyclooxygenase (COX-1) and inducible cyclooxygenase (COX-2), thereby diverting arachidonic acid metabolism toward the 5-lipoxygenase pathway in some cell types, notably eosinophils. This modulation of arachidonic acid metabolism results in overproduction of cysteinyl-leukotrienes LTC_4, $-D_4$, and $-E_4$, leading to vasodilatation and edema. Furthermore, reduction of PGE_2 formation by COX inhibition has two further effects that promote urticaria: first, by reducing inhibition of cysteinyl leukotriene production and second, by reducing an inhibitory effect on immunologically mediated mast-cell degranulation (Fig. 46.5). Cross-sensitivity occurs with other nonselective NSAIDs in susceptible individuals, depending on their pharmacological potency for COX inhibition but not their chemical structure.

Aspirin and NSAIDs can trigger acute urticaria as well as causing flare-ups of pre-existing chronic spontaneous (but not physical) urticaria. Aspirin-induced exacerbations have been reported in up to 30% of patients with CSU although the frequency of NSAID intolerance may fluctuate depending on the activity of the underlying CSU. NSAID intolerance may even resolve in the remission of CSU in up to one-third of patients. In some cases, aspirin can act as a cofactor in food- or exercise-induced anaphylaxis.

Urticaria can develop from a few minutes to 24 hours after aspirin ingestion but usually within 1 to 2 hours. Angioedema of the lips and tongue, impaired swallowing, and laryngeal edema develop occasionally. Aspirin-induced skin symptoms usually subside 24 to 48 hours after discontinuing the drug. However, severe exacerbations of CSU caused by NSAIDs can last from several days to several weeks.

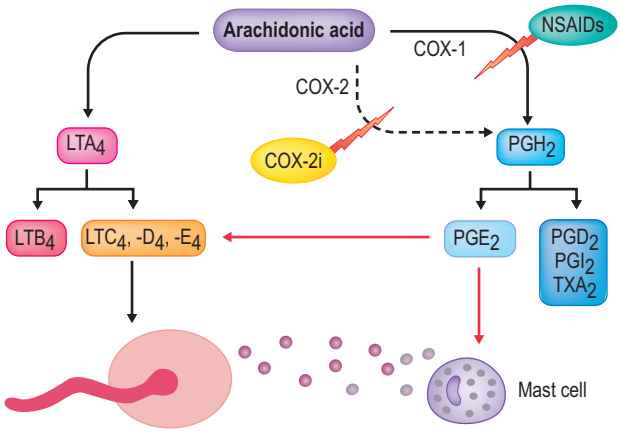

FIG. 46.5 Arachidonic Acid Pathways. Potential Diversion from Prostaglandin Synthesis to Cysteinyl leukotrienes (***LTC$_4$, -D$_4$, -E$_4$***) by Blocking Cyclooxygenase (***COX***), Leading to Increased Vasopermeability. Reduction of prostaglandin E_2 (PGE_2) also reduces its direct inhibitory effect on leukotriene production and on immunological mast-cell degranulation.

The diagnosis can be established by challenge tests. Patients should avoid aspirin and other NSAIDs, but COX-2 inhibitors (coxibs) are usually well tolerated and can probably be used safely. Long-term low-dose aspirin for thromboprophylaxis is often well tolerated and should not be discontinued routinely.

Food-Induced Pseudoallergic Reactions in Chronic Spontaneous Urticaria

Pseudoallergic food reactions appear to be important in some patients with CSU. Pseudoallergic food triggers include natural salicylates in fruit and vegetables and artificial food additives in processed foods, such as benzoates and tartrazine. Low-molecular-weight aromatic compounds in tomatoes, white wine, and herbs have also been implicated. Clinically, exacerbations of CSU resulting from dietary pseudoallergens gradually subside within 10 to 14 days on an exclusion diet in contrast to 1 to 3 days in acute allergic urticaria. Responders to a low pseudoallergen diet demonstrated normalization of gut mucosal permeability and skin symptoms. Although the underlying mechanisms for pseudoallergic reactions in CU remain unproven, an impaired gastroduodenal barrier function may be a contributory factor.

Bradykinin-Mediated Angioedema

The principal mediator of angioedema resulting from hereditary and acquired C1 esterase inhibitor (C1-INH) deficiency is bradykinin. Hereditary angioedema (HAE) attacks are characterized by overproduction of bradykinin. Angiotensin-converting enzyme inhibitor (ACEI)-induced angioedema results from reduced catabolism with accumulation of bradykinin. Idiopathic angioedema not responding to antihistamines may be mediated by bradykinin in some patients. Increased levels of bradykinin lead to activation of bradykinin β2 receptors, thereby increasing vascular permeability and causing vasodilatation and edema.[18]

CLINICAL CLASSIFICATION

CU may be spontaneous, inducible, or both.

Spontaneous Urticaria

Spontaneous urticaria is the most common presentation. The term "spontaneous" makes no assumption about etiology, which may include autoimmunity, allergy, pseudoallergy, or infection. Spontaneous urticaria can be further classified by duration of attacks into acute and CU.[2]

Acute Spontaneous Urticaria

Acute urticaria is defined as continuous disease lasting less than 6 weeks. Individuals with an atopic predisposition are at higher risk of acute urticaria; atopic diseases are found in about half the patients with acute urticaria. Most acute urticaria resolves spontaneously within 6 weeks, but in 10% of patients, it may progress to CSU.

Viral infections, foods, or drugs are common identifiable causes of acute urticaria. For example, urticaria was reported during or after the COVID-19 infection.[19] A specific cause of acute urticaria will not be found in about 50% of patients. Foods may cause acute urticaria in young children but are rarely responsible for acute urticaria in adults. In infancy, cow's milk allergy may cause acute allergic urticaria. Acute urticaria is the most common presentation of drug hypersensitivity, accounting for a quarter of all adverse drug reactions, with penicillin and NSAIDs being the most common causes of allergic and nonallergic drug-induced urticaria, respectively. Drug-induced urticaria is more likely in older adults, perhaps reflecting polypharmacy and age-related pharmacokinetic changes, and in patients with human immunodeficiency virus (HIV) infection and those with renal or liver diseases.

Chronic Spontaneous Urticaria

CSU is characterized by daily or almost daily itchy wheals on skin, with or without angioedema, for more than 6 weeks. CSU can be mediated by type I and type IIb autoimmunity (see Autoimmune Urticaria). However, in 50% of patients, the etiopathogenesis of the disease remains unknown (idiopathic) and seems to be endogenous. Whatever the primary cause, CSU appears to be aggravated by a variety of exogenous exposures, including acute infections (most commonly viral upper respiratory tract infections), NSAIDs, dietary pseudoallergens, menses in women, tiredness, and stress. The contribution of these factors probably explains why the clinical course is often erratic and unpredictable.

CSU affects women twice as often as men. There is a common link between CSU and thyroid autoimmunity as well as other autoimmune diseases, including Graves disease, vitiligo, systemic lupus erythematosus, pernicious anemia, and insulin-dependent diabetes.[20] Adult female patients with a family history and a genetic predisposition for autoimmune diseases are at an increased risk of autoimmune comorbidity.[20] CSU may be associated with inducible urticaria (e.g., dermographism or delayed-pressure urticaria [DPU]). Around 50% of patients present with both wheals and angioedema. CU can have a continuous or a relapsing course. CU of all types—including CSU—can cause serious disability in patients, including loss of sleep and energy, social isolation, altered emotional reactions, and difficulties in aspects of daily living similar in degree to patients with severe ischemic heart disease.

Chronic Inducible Urticarias

Chronic inducible urticarias (CIndUs) are common, accounting for around 25% of all cases of CU. These include physical urticarias, such as symptomatic dermographism, cold and heat urticarias, DPU, solar urticaria, and vibratory angioedema, in which symptoms are triggered reproducibly by an external mechanical or thermal/ultraviolet stimulus. CIndUs now also include cholinergic, adrenergic, aquagenic, and contact urticarias, in which the eliciting stimuli for MC degranulation are defined by a nonphysical exposure. CIndUs can coexist with CSU and more than one CIndU can occur in the same patient (e.g., dermographic and cholinergic urticarias), which may lead to difficulty in diagnosis. With the exception of DPU, CIndU develop rapidly after exposure to the relevant trigger and fade within an hour.[2]

The pathogenesis of CIndUs is unclear except in the case of allergic contact urticaria, which is caused by mucocutaneous exposure to an allergen in IgE-sensitized individuals, analogous to acute urticaria. A diagnosis of CIndUs is confirmed if the symptoms can be reproduced by challenge testing with the suspected stimulus.[21] Challenge testing can be used for monitoring threshold changes during treatment. In general, treatment of CIndUs involves avoidance of known triggers and taking antihistamines. Off-label treatment with omalizumab can be beneficial in patients with various CIndUs, with the strongest evidence for symptomatic dermographism, cold and solar urticarias.[22] Sometimes tolerance can be induced for cold and solar urticarias but these historical approaches to treatment are now rarely used.

Mechanical Urticaria

Symptomatic Dermographism

Dermographism is the most common CIndU, mainly affecting young people. Typical red, itchy, linear wheals are evoked within minutes of stroking, friction, rubbing, or scratching the skin (Fig. 46.6).

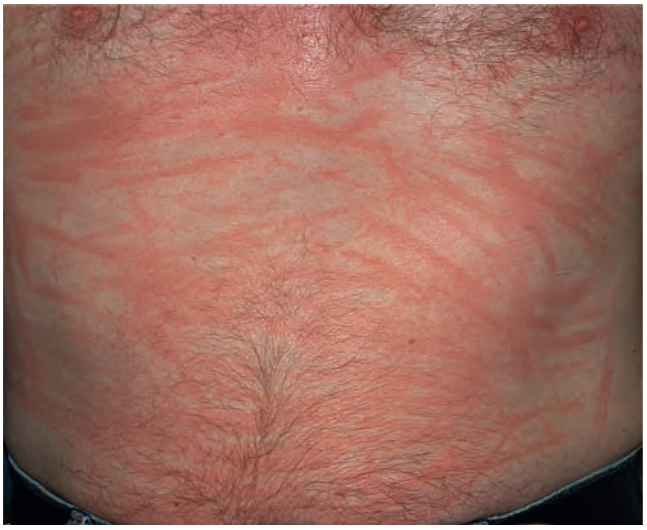

FIG. 46.6 Extensive Induced Dermographic Whealing on the Chest of a Patient as a Result of Scratching.

Delayed-Pressure Urticaria

Isolated DPU occurs in less than 2% of all patients with urticaria. DPU has been reported to coexist with CSU in up to 40% of patients but needs to be distinguished from pressure-aggravated CSU by provocation testing (below). DPU is the most debilitating of CIndUs and is triggered by sustained local pressure (e.g., wearing tight shoes, carrying heavy bags, long walks, sitting or leaning against firm objects, climbing ladders, jogging, driving, or clapping hands). Deep and painful swellings, clinically resembling angioedema, develop 30 minutes to 12 hours after pressure, and may be associated with 'flu-like symptoms, fever, arthralgia, and fatigue. The most frequently affected sites are hands, soles, buttocks, shoulders, and areas under straps and belts. DPU lesions last 12 to 48 hours and are usually painful rather than itchy, especially on the hands and feet. Laboratory investigation reveals transitory leukocytosis and elevated erythrocyte sedimentation rate (ESR). Hanging a heavy weight suspended on a narrow band over the forearm or thigh for 15 minutes may be used as a challenge test, but more reliable results can be obtained with special instruments. DPU is difficult to treat because it responds poorly to antihistamines.

Vibratory Angioedema

Vibratory angioedema is rare and has been linked to mutations in the *ADGRE2* gene.[23] Local swellings, or rarely wheals, develop several minutes to 6 hours after using vibrating machinery, lawn mowing, applauding, and jogging, for instance. Systemic symptoms may occur (headache, chest tightness, diffuse flare, facial flushing). Placing the elbow or hand on a laboratory vortex for 5 to 15 minutes is a useful challenge test.[21] Avoidance of the trigger is the only helpful treatment strategy. In rare cases, antihistamines can relieve the symptoms of vibratory angioedema.

Thermal or Ultraviolet-Induced Urticaria

Cold Urticaria

The incidence of cold urticaria (ColdU) is estimated at 0.05%. It occurs in both children and adults and is more common in cold climates, in women, and in atopic patients. The majority of cases are primary with no identifiable cause, but some cases are secondary to internal disease. Clinical manifestations can be local or generalized. Mucosal involvement may develop after drinking cold beverages. Systemic symptoms may be respiratory (laryngeal angioedema, tongue or pharyngeal swelling, wheezing), vascular (hypotension, tachycardia), GI (hyperacidity, nausea, diarrhea), or neurological (disorientation, headache). ColdU can be evoked by low ambient temperature, contact with cold objects, food or beverages, or immersion in cold water. Wheals develop during the cold exposure or, more commonly, on rewarming. The severity of ColdU depends on the intensity and duration of the cold stimulus. ColdU is potentially life threatening, with a risk of anaphylaxis and death on exposure of large skin areas to cold: for example, jumping into cold water and hypothermia in neurosurgical and cardiothoracic operations.[24]

In most studies, cryoproteins (mainly cryoglobulins) can be detected in less than 1% of patients (secondary ColdU). ColdU can be associated with infections (hepatitis C, infectious mononucleosis, syphilis, *Mycoplasma* infection), autoimmune diseases, and lymphoreticular malignancy (Waldenström macroglobulinemia, myeloma), although the evidence for causal relationships is weak. ColdU can precede these diseases by several years. Secondary ColdU can also be drug-related (penicillin, oral contraceptives).

The diagnosis of ColdU is confirmed by a 5-minute ice cube challenge or TempTest.[21] In patients with negative provocation tests for ColdU, atypical forms or familial cold autoinflammatory syndrome (FCAS) should be considered.

The clinical work-up in ColdU includes differential blood count, ESR, or C-reactive protein (CRP).[2,21] Additional work-up includes a search for underlying infections, if indicated by patient's history or required for the differential diagnosis. Cryoproteins can be measured, although there is no guidance on clinical relevance in ColdU. Patients should be cautious about bathing or swimming in cold water and consuming cold food or drinks. Antihistamine treatment is often helpful but does not prevent anaphylaxis caused by swimming in cold water. Omalizumab can be effective for patients with ColdU. In severe ColdU, tolerance induction by repeated cold exposure may be attempted but is very difficult to maintain.

Heat Urticaria

Heat-induced urticaria is very rare. It is induced by local heating of the skin at 38°C to 44°C. Antihistamines are only of limited therapeutic value, but omalizumab may be effective.

Solar Urticaria

Solar urticaria affects about 1% of all patients with urticaria and has a slight female predominance. It can be associated with erythropoietic porphyria. Wheals are caused by electromagnetic wavelengths ranging from 290 to 760 nm (ultraviolet B [UVB], UVA, and visible spectrum). In patients with solar urticaria, the action spectrum lies predominantly within longer UVA wavelengths and shorter visible light wavelength.[25] It develops within minutes or hours after sun exposure and fades within 24 hours. Lesions are usually confined to sun-exposed skin, although they can also develop under clothing. The severity of solar urticaria depends on the wavelength, intensity, and duration of irradiation. Short exposures induce flare and pruritus, whereas longer exposures cause whealing. In patients sensitive to the visible spectrum and UVA, reactions may occur through window glass.

Solar urticaria is diagnosed by phototesting with broadband UVR and monochromator sources. Patients are advised to use creams with a high sun protection factor (SPF), protective clothing, and protective window shields and to limit the time spent outdoors. Omalizumab may be effective. Phototherapy (PUVA and narrow band UV 311 nm) can also be used.

Other Patterns of Inducible Urticaria

Cholinergic Urticaria

Cholinergic urticaria (CholU) is the second most common CIndU and occurs mainly in adolescents, young adults who are usually atopic. CholU usually follows a rise in core temperature resulting from physical exercise, fever, or external passive heat (hot bath, shower, sauna), but may also be provoked by emotional stress and spicy food. The characteristic lesions are highly pruritic pinpoint pale wheals of 1 to 3 mm surrounded by a red flare. The wheals may occur anywhere except the soles and palms. Lesions usually begin on the trunk and the neck, extending outward to the face and limbs. As lesions progress, confluent areas of whealing and redness may develop. Severely affected patients may develop angioedema and even anaphylaxis. The

rash is triggered by activation of cholinergic sympathetic innervation of sweat glands, but the mechanism of activation remains unclear. Some patients with CholU have acquired generalized hypohidrosis/anhidrosis.[26] Decreased blood protease inhibitor levels have been reported, and this is the rationale for using anabolic steroids to treat severe, unresponsive disease. The prognosis is reasonably favorable, with spontaneous resolution within 8 years in most patients. However, 30% of patients are affected for over 10 years.

CholU can be confirmed by reproducing the rash with exercise to the point of sweating or passive heating in a hot bath or shower at up to 42°C. The condition may be refractory for up to 24 hours after provocation, and this may enable patients to prevent attacks by taking daily exercise. Treatment is primarily with antihistamines, but beta-blockers, danazol, ketotifen, and montelukast have also been used. Some patients with CholU may respond to omalizumab treatment although the evidence for its clinical efficacy is limited.[22]

Aquagenic Urticaria

Aquagenic urticaria is rare. It occurs in women more often than in men and is triggered by water contact but not after drinking water. Scattered small papular wheals, similar to CholU but with a larger flare, appear within 10 to 20 minutes of water contact and resolve in 30 to 60 minutes. Diagnosis is made by water immersion or applying a wet compress at body temperature for up to 10 minutes on whichever part of the body is usually affected. Associations with HIV and hepatitis B infection have been described.

Contact Urticaria

Contact urticaria occurs locally after skin or mucosal contact with the eliciting agent.[2] Reactions usually develop within a few minutes and resolve over 2 hours, although delayed-contact urticaria can occur with a latent period up to 48 hours. Contact urticaria can be caused by many organic and inorganic stimuli, such as latex, animal danders and secretions, foods, plants, topical drugs, and cosmetics.

Allergic contact urticaria occurs mainly in atopic subjects. Foods are the most common cause. Very rarely, contact with the allergen may induce anaphylaxis, especially in the context of latex allergy. The severity of contact reactions depends on many factors (area of exposure, duration of contact, amount and concentration of substance, patient reactivity, comorbidity, and concomitant treatment).

Nonallergic contact urticaria is common and is usually caused by low-molecular-weight chemicals. Nonallergic contact urticaria may occur on first exposure and may depend on dose and concentration of the chemical.

DIFFERENTIAL DIAGNOSIS OF URTICARIA

Urticarial Vasculitis

Urticarial vasculitis (UV) is characterized clinically by urticarial rash with or without angioedema and histologically by leukocytoclastic vasculitis on lesional skin biopsy. UV is idiopathic in most cases but has been reported in association with drugs, malignancy, autoimmunity, and infections. It is important to differentiate UV from CSU in terms of prognosis, approach to diagnostic evaluation, and therapy.

Angioedema Without Wheals

Angioedema occurs in nearly half the patients with CSU; in these patients, the disease tends to be more severe and more difficult to treat. Angioedema without wheals occurs in about 10% of patients with CSU but needs investigation to distinguish angioedema due to C1 inhibitor deficiency or drugs, such as ACEI, although many cases of angioedema without wheals remain unexplained (Fig. 46.7).

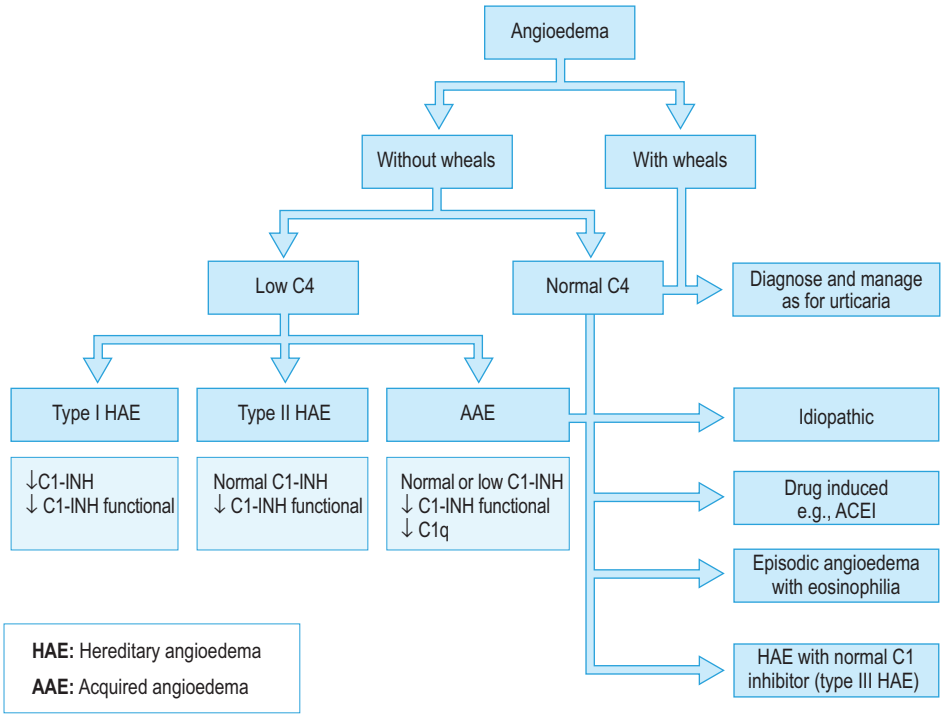

FIG. 46.7 Diagnostic Pathway for the Differential Diagnosis of Angioedema.

Angioedema Caused by C1 Inhibitor Deficiency

The diagnosis and clinical presentation of hereditary and acquired C1-INH deficiency are covered in Chapter 40.

Angioedema With Normal C1 Inhibitor

Histamine-Mediated Angioedema (without wheals). Histamine-mediated angioedema differs from bradykinin-mediated angioedema by the speed of onset, kinetics of resolution, prognosis, and response to treatment. Histamine-mediated angioedema develops rapidly, usually subsides within 48 hours, and responds well to antihistamines, corticosteroids, and epinephrine.

Idiopathic. Idiopathic angioedema is diagnosed when no cause can be established and can be histaminergic and non-histaminergic. It is generally self-limiting, but may follow a prolonged course. Treatment of idiopathic histaminergic angioedema should follow the same pathway as CSU. Antihistamines are the mainstay of therapy; corticosteroids (prednisolone 30 to 40 mg/day in adults) are useful for up to 3 days as rescue treatment to cover more severe episodes of the oropharynx, and epinephrine may be lifesaving in laryngeal angioedema.

Drug-induced. Histaminergic angioedema without wheals occasionally occurs with NSAIDs, usually within several hours of intake.

Bradykinin-Mediated Angioedema. Bradykininergic angioedema is usually characterized by a slower onset, a longer duration, and a little or no response to antihistamines, corticosteroids, and epinephrine. Bradykininergic angioedema can be idiopathic, due to hereditary or acquired C1 deficiency or ACEI therapy. Although the mortality due to angioedema is rare (0.34 deaths per 1,000,000 inhabitants), bradykininergic angioedema carries a 45 times higher mortality risk of mortality than angioedema due to MC-derived mediators.[27]

Hereditary. The prevalence of bradykininergic angioedema due to hereditary deficiency in C1 inhibitor is between 1.1 and 1.6 per 100,000.[28] HAE due to C1 inhibitor deficiency is characterized either by low antigenic and functional levels of C1 inhibitor (type1) or by normal (or elevated) antigenic but low functional C1 inhibitor levels (type 2). More than 500 mutations in the *SERPING1* gene have been reported. Some kindreds have been described with a dominant pattern of angioedema inheritance and normal C1 inhibitor, mainly in women, in whom a gain-of-function (GOF) mutation of the contact pathway of coagulation in *F12* has been found in about 20% of affected families. This used to be called type III HAE, but the term *hereditary angioedema with normal C1 inhibitor* is now preferred. HAE with normal C1 inhibitor can also be associated with mutations in plasminogen, kininogen 1, angiopoietin-1 or heparan sulphate 3-O-sulfotransferase 6 genes.

Drug-induced. The prevalence of bradykininergic angioedema due to ACEIs is between seven and 26 in 100,000.[28] It is thought to result from inhibition of kininase II, which breaks down bradykinin, as well as converting angiotensin I to angiotensin II in the renin–aldosterone pathway. It usually presents with episodic and unpredictable swellings of the head and neck, especially of the tongue and oropharynx. Although angioedema develops within the first week of treatment with ACEIs in most cases, symptom onset may occur after many years on treatment. Management involves discontinuation of ACEI therapy. Angioedema often recurs on re-exposure to ACEIs. ACEIs may also precipitate angioedema in patients with angioedema from other causes, including C1-INH deficiency. Rare instances of angioedema have also been reported with angiotensin II receptor antagonists. Additionally, dipeptidyl peptidase IV inhibitors (gliptins) used for the treatment of diabetes can affect bradykinin degradation and can cause angioedema. Current guidelines recommend close monitoring, airway intervention if needed, and lifetime avoidance of all ACEIs.

Acquired. Acquired deficiency in C1 inhibitor rarely occurs in association with lymphoproliferative or autoimmune disorders and is observed in patients over 40 years old and affects 0.15 per 100,000.[29] Acquired angioedema is often characterized by C1 inhibitor autoantibody or paraprotein and low C1q.

Idiopathic. Idiopathic non-histaminergic angioedema is bradykinin-mediated in approximately 10% of patients. A role for bradykinin has been suggested although the mechanisms remain unknown. Off-label therapeutic options in acute attacks of idiopathic angioedema include omalizumab, icatibant, C1 inhibitor, and ecallantide. Tranexamic acid is effective in more than 50% of patients with idiopathic angioedema without wheals. For prophylaxis, tranexamic acid, omalizumab, C1 inhibitor, and progestin were reported to be effective.

Autoinflammatory Syndromes Presenting With Urticarial Rash

Acquired

Schnitzler Syndrome. Schnitzler syndrome is a periodic fever syndrome with urticarial rash resembling CSU, bone pain, high ESR, and monoclonal IgM, or—very rarely—IgG gammopathy. Clinically, patients present with nonpruritic or mildly pruritic wheals, mainly affecting the trunk and limbs. The wheals are resistant to antihistamines, and angioedema is rare. Fever bouts may exceed 38°C, sometimes with chills and nocturnal sweating. Patients often suffer from bone pain, mainly in the pelvis or tibias, arthralgia, and sometimes full-blown arthritis. Lymphadenopathy, hepatomegaly, and splenomegaly may be present.

Monoclonal IgMκ and, less commonly, IgMλ or IgG paraproteins are found on serum electrophoresis. The ESR is persistently elevated at 60 to 100 mm/h, CRP (greater than 30 mg/L), with leukocytosis (greater than 10,000/mm^3), elevated platelet count, and anemia. Skin histology shows dermal neutrophils with a tendency to localize around appendages in most cases; monoclonal IgM is deposited in the epidermis around the keratinocytes and along basement membranes on direct immunofluorescence. Bone examination may demonstrate hyperostosis on radiography and hyperfixation on bone technetium scanning. Bone marrow examination shows normal results in most patients, but nonspecific lymphocytic, plasmocytic, or polyclonal infiltration is present in about 20%.

The pathophysiology of Schnitzler syndrome is still unclear, and the severity of urticarial rash does not depend on the paraprotein level. Evidence of activation of interleukin-1 (IL-1), increased IL-6, IL-18, granulocyte macrophage–colony-stimulating factor (GM-CSF), and confirming the efficacy of the IL-1 receptor antagonist anakinra, anti-IL1-β monoclonal antibody canakinumab, or fusion protein IL-1 antagonist rilonacept suggest that cytokines play a leading role in its pathogenesis. The outlook for maintaining symptom control is good, but long-term follow-up is recommended because patients may develop B-cell lymphomas 10 to 20 years after its onset. AA amyloidosis may also occur without effective treatment.

Hereditary (Cryopyrin-Associated) Periodic Syndromes

Several hereditary autoinflammatory urticarial syndromes show mutations of the *NLRP-3* gene on chromosome 1q44. *NLRP-3* encodes a protein called cryopyrin, which is involved in apoptosis and inflammation. These rare autosomal dominant disorders include FCAS, Muckle-Wells syndrome (MWS), and chronic infantile neurological, cutaneous, and articular (CINCA) syndrome, and newly described (FACAS)[9] and are grouped under the inclusive term *cryopyrin-associated autoinflammatory syndrome* (CAPS).[8] The diagnostic criteria for CAPS include raised inflammatory markers (CRP/serum amyloid A) in combination with at least two of six CAPS-typical symptoms: urticaria-like lesions, cold-triggered episodes, sensorineural hearing loss, musculoskeletal symptoms, chronic aseptic meningitis, and skeletal abnormalities.[8]

WORK-UP IN PATIENTS WITH URTICARIA

Evaluation of patients with urticaria requires a detailed history and physical examination.[2] The history is particularly important in patients with urticaria and should include a thorough inquiry for all potential comorbidities (e.g., autoimmune diseases), possible precipitating and aggravating factors, the timing of onset and duration of individual wheals, associated symptoms, as well as travel history, recent infection, occupational exposure, and food and drug intake. The duration of individual lesions can be very helpful in distinguishing the different clinical patterns of urticaria. Patients should be asked to complete Patient Related Outcome Measures and weekly urticarial activity scores for CSU.[2]

CLINICAL PEARLS

Diagnosis of Clinical Patterns of Urticaria

- The duration of individual wheals can help define the pattern of urticaria.
- Wheals lasting no more than 1 h are usually induced rather than spontaneous except delayed-pressure urticaria, which lasts longer.
- Localized wheals lasting up to 2 h may be caused by skin or mucosal contact with an allergen or other contactant.
- Wheals that take 1 to 24 h to fade are usually a presentation of chronic spontaneous urticaria.
- Wheals lasting more than 24 h may be caused by delayed-pressure urticaria or urticarial vasculitis.
- Urticarial rash in a neonate may be a symptom of cryopyrin-associated periodic syndromes.

Work-Up of Acute Urticaria

No routine testing is recommended for the patients with acute urticaria.[2] When allergens are suspected as the cause, there should be a close temporal relationship to the time of exposure—usually starting within minutes—a history of previous exposure causing sensitization, and prompt resolution on allergy withdrawal. Allergy testing can be performed if indicated.

Work-Up in Chronic Inducible Urticarias

When CIndU is suspected, appropriate challenge testing should be performed to confirm the diagnosis.[21] Generally, there is no need for further investigation, except for cold or solar urticaria.[21] In ColdU, a differential blood count, ESR or CRP, and cryoproteins are recommended and other photodermatoses should be considered in the diagnosis of solar urticaria.

Work-Up in Chronic Spontaneous Urticarias

A complete blood count with differential and ESR or CRP is routinely recommended for patients with CSU that is easily controlled by antihistamines, unless the history points to an underlying disease.[2] Studies have shown that random laboratory testing very rarely yields evidence of unsuspected internal diseases as a cause of CSU.

Extended laboratory evaluation can be considered in patients with CSU if indicated by the patient's history and/or physical examination.[2] Thyroid-stimulating hormone (TSH), thyroid antibodies, liver function tests, tryptase, and routine urinalysis will exclude most diseases associated with urticaria. Additional testing for infections, including *Helicobacter pylori*, can be performed if suggested by patient's history. Lesional skin biopsy can be considered if UV is suspected. Allergy testing should not be undertaken in chronic continuous urticaria unless the history indicates that allergy is likely.

The Diagnosis of Autoimmune Chronic Spontaneous Urticaria

The diagnosis of autoimmune CSU (type IIb autoimmunity) is not straightforward and involves in vivo and in vitro approaches. Autologous serum skin testing (ASST) is a simple and useful screening method for autoreactivity in patients with CU. The test is 80% specific and 70% sensitive as compared to a positive basophil histamine release assay (BHRA) and is, therefore, regarded as a useful test for autoimmune urticaria.

The diagnostic criteria for autoimmune CSU may include (1) positive in vivo autoreactivity (a positive ASST) as evidence of serum factors capable of inducing an inflammatory wheal response; (2) positive in vitro basophil reactivity as evidenced by BHRA or basophil activation test (BAT) using the patient's serum on healthy donor basophils or MCs; and (3) a positive immunoassay for specific identification of IgG autoantibodies against FcεRI and/or anti-IgE (Western blot or enzyme-linked immunosorbent assay [ELISA]. Being technically difficult, these assays are mainly confined to research centers. Low total IgE with positive thyroid antibodies may offer a useful surrogate for the BHRA. Results of nonfunctional immunoassays (Western blot, ELISA) based on binding of autoantibodies to relevant antigens (FcεRIα or IgE) do not correlate well with the results of functional assays.

MANAGEMENT OF URTICARIA

Finding effective treatment for urticaria can be challenging. Treatment should be tailored to the clinical pattern, duration, and severity of the urticaria. Management should include nonpharmacological measures and drug therapy with a stepwise approach.[2]

General Measures

Causes, triggers, and aggravating factors should be avoided or minimized, whenever possible. Patients with CSU should minimize exposure to nonspecific aggravating factors, such as overheating, wearing tight clothes and shoes, stress, alcohol, dietary pseudoallergens, and some drugs. NSAIDs aggravate up to 30% of patients with CSU and are best avoided. This does not apply to the physical urticarias, in particular DPU, where NSAIDs may be used as treatment. ACEIs are contraindicated in angioedema without wheals that may be mediated by kinins, but not

THERAPEUTIC PRINCIPLES

Management of Urticaria

- Eliminate infectious, drug, or food causes.
- Minimize nonspecific aggravators, including heat, stress, alcohol, nonsteroidal anti-inflammatory drugs, and pressure.
- Regular oral second-generation H_1 antihistamines are the first line of therapy for all spontaneous and inducible urticarias.
- Updosing of second-generation antihistamines is the second line of treatment for all spontaneous and inducible urticarias.
- Short courses of oral corticosteroids may be necessary as rescue medication for chronic spontaneous urticaria flare-ups, especially with oropharyngeal angioedema.
- Omalizumab (monoclonal anti-IgE) is often effective in chronic spontaneous urticaria refractory to H_1 antihistamines
- Immunosuppressive therapies should be reserved for patients with severe urticaria not responding to omalizumab. Careful monitoring for renal toxicity or hypertension is required with cyclosporine.

in other patterns of urticaria. Cooling lotions and creams, such as 1% menthol in aqueous cream, may help relieve pruritus. Some patients with spontaneous, but not inducible CU appear to respond to a low pseudoallergen diet. However, controlled clinical trials are lacking.

First-Line Therapy

Antihistamines are the cornerstone of treatment for acute and CSU. Second-generation antihistamines offer several advantages over classic H_1 antihistamines, including lack of sedation and impairment of performance, longer duration of action, and absence of anticholinergic side effects. Meta-analysis suggests that 63.2% of CSU patients respond to updosing of second-generation antihistamines although this approach is more effective against itching than whealing.[30] Second-generation antihistamines are inverse agonists of H_1 receptors, and stabilize H_1 receptors in the inactive conformation. Second-generation antihistamines are most effective in CSU when taken regularly for prophylaxis. The timing of antihistamine intake should be adjusted to suit the diurnal pattern of urticaria for each individual.

Second-Line Therapy

It has become common practice to increase second-generation antihistamines above their licensed doses up to fourfold when CU does not respond because clinical experience and updosing studies show that this achieves better control in some patients.

When urticaria does not respond to second-generation antihistamines, systemic corticosteroids may be used as short-term rescue therapy for acute urticaria or severe exacerbations of CSU. Long-term treatment with oral corticosteroids is not recommended because of safety concerns.

Third-Line Therapy

Omalizumab (anti-IgE) is licensed as add-on therapy for CSU not responding to antihistamines. The recommended dose is 300 mg by monthly subcutaneous injection, although clinical experience indicates that effective monthly doses may vary from 150 to 600 mg in different patients and the interval between treatments can be extended in good responders. Clinical experience and meta-analysis suggest that when used off-label, it may also be effective for many patients with CIndUs, with the strongest evidence for symptomatic dermographism, cold and solar urticarias.[22] Omalizumab was reported to rapidly reduce circulating free IgE, to downregulate high-affinity IgE receptors on MCs and basophils, resulting in a stabilizing effect. The mechanisms of omalizumab action in CSU remain certain but are likely to include reducing MC releasability, reversing basopenia, reducing activity of IgG autoantibodies against FcεRI and IgE, reducing activity of IgE autoantibodies against an as-yet undefined antigen or autoantigens, reducing the activity of intrinsically "abnormal" IgE and decreasing in vitro coagulation abnormalities.[31] Although experience to date suggests that omalizumab is often highly effective for control of urticaria symptoms, patients with serum autoreactivity as demonstrated by serum-induced BHRA and/ASST have a slower response.

Fourth-Line Therapy

The best-studied immunosuppressive therapy is cyclosporine, shown to be effective at low to moderate doses ranging from 1 to 4 mg/kg daily in patients with CSU. Patients must be monitored carefully for renal impairment and hypertension; treatment should normally be limited to 4 months. Cyclosporine is contraindicated in patients with previous malignant disease except nonmelanoma skin cancer.

MANAGEMENT OF HEREDITARY ANGIOEDEMA

The swellings of HAE are mediated by bradykinin rather than histamine, so the management of HAE is completely different from MC-dependent angioedema. The primary aim of therapy is to replace the missing functional C1 esterase inhibitor or stabilize the coagulation, fibrinolysis, complement, and kallikrein–kinin pathways. ACEIs should be avoided because ACE is a key enzyme involved in the breakdown of bradykinin. Exogenous estrogens (oral contraceptives and hormone replacement therapies) should be avoided in women as they activate kallikrein through activated factor XII. Lifestyle events that exacerbate HAE vary in their importance among individuals, but may include local trauma (e.g., dental extraction, sport activities), stress, tiredness, and intercurrent infections.

Attacks involving the extremities or abdomen are the most common. Up to 50% of patients will experience oropharyngeal swelling, with risk of asphyxiation at some point in their lives, so treatment for both emergencies and prophylaxis are essential. The intention of treatment is to reduce or curtail the severity of a swelling and to reduce the period of disability or disfigurement during or following the attacks.

Treatment of the Acute Attack

International guidelines strongly recommend early administration of C1 inhibitor concentrate, icatibant, or ecallantide for the treatment of the acute attacks.[32] Plasma-derived (pd-C1-INH) or recombinant C1 esterase inhibitor concentrate given by intravenous infusion is effective for oropharyngeal or GI attacks. Initial improvement in the swelling may be seen within 30 to 60 minutes, and time to clearance is usually in the order of 24 hours after pd-C1-INH. Self-administration can reduce the severity of attacks by allowing earliest treatment and should be encouraged.

If a C1 inhibitor concentrate, ecallantide, or icatibant is not available, solvent detergent-treated plasma should be used. If not available, up to three units of fresh frozen plasma (containing C1 inhibitor and its substrate, complement) may be given as an alternative in an emergency when C1-INH concentrate is not available.

Icatibant (a bradykinin 2 receptor antagonist) and ecallantide (a kallikrein inhibitor) are also highly effective for acute

episodes of HAE. Both are given by subcutaneous injection, which provides an easier route for administration than intravenous infusion. Ecallantide should be given under medical supervision, since there is a risk of allergic reactions. Icatibant is licensed for self-administration, which provides a potential advantage. Treatments developed for HAE with C1 inhibitor deficiency such as C1 inhibitor concentrate and icatibant are also effective in HAE with normal C1 inhibitor.

Laryngeal angioedema is a medical emergency and intubation or surgical airway intervention should be considered in the context of progressive respiratory compromise due to upper airway angioedema.

Antifibrinolytics (e.g., tranexamic acid) or androgens should not be used for acute treatment of HAE attacks.

Short-Term Prophylaxis

It has become common practice to give prophylactic treatment with pd-C1-INH before procedures involving local trauma to the oropharynx, including dental extraction, intubation for general anesthesia for invasive interventions. Common practice is to give 1000 units or a dose of 20 units/kg of pd-C1-INH as close as possible to the start of the procedure. Fresh frozen plasma can be used as a second-line agent for short-term prophylaxis. Another strategy is the prophylactic treatment with anabolic steroids for 5 days before and 2 to 3 days after the procedure. However, frequent short courses may lead to side effects. Specific guidance on dosing for adults and children can be found elsewhere. Tranexamic acid is no longer recommended for short-term prophylaxis.[32]

Long-Term Prophylaxis

Long-term prophylaxis is required in patients with frequent attacks. pd-C1-INH is the preferred first-line long-term prophylaxis for HAE attacks, usually given subcutaneously at doses of 40 to 60 units/kg bodyweight twice a week.[6]

Attenuated androgens are commonly used as second-line long-term prophylaxis as they increase intrinsic C1 inhibitor production by the liver in heterozygotes with a functioning allele and promote bradykinin degradation through an increase in aminopeptidase P. The dose should be titrated against the clinical response but not against blood levels of C1-INH to the lowest level that prevents or ameliorates the condition. Virilizing side effects may be a problem for women, and anabolic steroids are avoided in children due to growth retardation. Monitoring of liver function and lipid profiles should be undertaken periodically. Performing a liver ultrasound examination once every 2 years to screen for development of hepatoma is recommended in patients on long-term prophylaxis. Currently, tranexamic acid is not recommended for long-term prophylaxis given the lack of efficacy data and the availability of effective alternatives such as C1 inhibitors. However, tranexamic acid is preferred in children when C1 inhibitor concentrate is not available. Therapeutic advances include subcutaneous lanadelumab, a recombinant fully human monoclonal antibody against plasma kallikrein, which is currently licensed for HAE prophylaxis and berotralstat, a new oral kallikrein inhibitor.

Gene Therapy

Gene therapy using gene editing techniques or viral vector gene transfer is considered a potential treatment option for HAE patients in the future. The first report by Haslund and colleagues demonstrated an enhanced C1 inhibitor secretion in patient-derived fibroblasts transfected with wild-type *SERPING1* gene variant, pointing towards the potential of gene therapy in HAE.[33]

Anaphylaxis

Anaphylaxis is an acute, potentially life-threatening, systemic allergic reaction with variable clinical presentations. Its clinical features and management have been summarized in international guidelines.[34] A diagnosis of anaphylaxis is fulfilled if any one of the following are fulfilled: (1) acute onset (minutes to hours) with involvement of skin, mucosal tissue, or both with either respiratory involvement or reduced blood pressure (BP) and/or associated symptoms of end-organ dysfunction; (2) two or more of the following (skin-mucosal symptoms, respiratory involvement, reduced BP, GI symptoms) occurring rapidly on exposure to a culprit allergen; (3) reduced BP in response to exposure to a known allergen.[34]

Epidemiology of Anaphylaxis

The incidence of anaphylaxis in the general population in Europe varies from 1.5 to 7.9 cases per 100,000 per annum.[35] Lifetime prevalence of anaphylaxis is estimated at 0.3% in Europe[35,36] and varies between 1.6% and 5.1% in the United States. The mortality rate in anaphylaxis is estimated to be between 0.47 and 0.69 per million persons (1% of hospitalizations and 0.1% of emergency department visits).[37] There is a trend for increasing rates of anaphylaxis admissions in the UK, United States, Canada, and Australia.[37] The incidence of anaphylaxis in children ranges from 10.5 to 70 episodes per 100,000 persons-years.

Pathophysiology of Anaphylaxis

Although anaphylaxis can be mediated by immunological and nonimmunological mechanisms, the clinical presentation is similar in both, and most authorities no longer make a distinction. Immunological anaphylaxis is further classified as IgE-dependent and IgE-independent anaphylaxis. In IgE-mediated anaphylaxis, allergen cross-links allergen-specific IgE on the surface of MCs and basophils, leading to their degranulation. Release of mediators causes bronchoconstriction, mucus secretion, diminished cardiac contractility, increased vascular permeability, vasoconstriction of coronary and peripheral arteries, and vasodilation of venules, thereby producing clinical symptoms of anaphylaxis. IgE-mediated reactions occur in presensitized patients (e.g., those experiencing penicillin-, insulin-, latex-, or peanut-induced anaphylaxis). IgG- or IgM-related transfusion reactions should be classified as immunological, IgE-independent anaphylaxis. In contrast, opioids, radiocontrast media, vancomycin, and some muscle relaxants are capable of directly inducing HR from basophils and MCs without involvement of IgE. Although reactions to NSAIDs are considered pharmacological rather than immunological (because of the downstream effects of COX inhibition), an IgE-mediated mechanism has been suspected in some patients. In murine models IgG-mediated FcγRIII-dependent anaphylaxis elicited by a high dose of allergen has been described, however, there is not yet definitive evidence of IgG-mediated anaphylaxis in humans. Monocytes and macrophages are likely to play a role in in this type of anaphylaxis; however, the extent of their contribution is yet to be established. Cytokine storm–like reactions were reported in patients with chemotherapy-induced anaphylaxis.

Etiology of Anaphylaxis

Anaphylaxis is most commonly caused by foods, drugs, general anesthetic agents, insect stings, and, rarely, latex. Exercise can occasionally cause anaphylaxis either on its own (exercise-induced anaphylaxis) or after ingestion of a food in presensitized individuals (food- and exercise-induced anaphylaxis). The incidence and severity of anaphylaxis in patients with mastocytosis is four to six times higher than that in the general population. Up to 50% of patients with mastocytosis present with anaphylaxis during their lifetime.[38] Anaphylaxis occurs in the perioperative setting. Idiopathic anaphylaxis is diagnosed when no cause can be found.

Some anaphylactic cases are multifactorial. Cofactors are thought to lower the threshold for the induction of anaphylaxis and are implicated in about 30% of anaphylaxis cases in adults. The risk of severe anaphylaxis is increased in patients taking beta-blockers, ACEIs, or both. Rare causes include vaccines, semen, and aeroallergen inhalation.

The most common routes of allergen exposure are oral and parenteral, although inhalation of allergens (e.g., fish or legume allergens after cooking, latex particles in healthcare settings) or percutaneous penetration after skin contact can induce anaphylaxis in highly sensitized patients.

Food-Induced Anaphylaxis

According to a meta-analysis of 34 studies, food-induced anaphylaxis was reported to occur with an incidence of 0.14 cases per 100,000 person-years at all ages and up to seven per 100 person-years in children aged 0 to 4 years.[39] Fatal food-induced anaphylaxis causes from 0.03 to 0.3 deaths per million inhabitants per year.[40] According to the European Anaphylaxis Registry, foods are a predominant cause of anaphylaxis in children and young adults.[40] Young adults with a history of asthma, previously known food allergy, particularly to peanuts/tree nuts, are at higher risk of fatal food-induced anaphylaxis.

Peanuts, tree nuts, fish, and shellfish are the most frequent culprits in food-induced anaphylaxis, but almost any food can be implicated. Many cases of severe anaphylaxis are caused by unintended exposure to hidden food allergens. In addition, cofactors, such as alcohol, NSAIDs, exercise, and stress may increase the severity of a food-induced allergic reaction.[41]

Drug-Induced Anaphylaxis

Drug-induced anaphylaxis is more common in hospitalized patients than in the community. The incidence of drug-induced anaphylaxis is estimated at 0.04% to 3.1%[42] with the mortality rate of 0.65%. NSAIDs and antibiotics are the most common causes for drug-induced anaphylaxis. Anaphylaxis has been reported after treatment with monoclonal antibodies (basiliximab, rituximab, infliximab, omalizumab, etc.). IgE antibodies to the oligosaccharide galactose-α-1,3-galactose (α-gal) in mammalian meat and certain monoclonal antibodies (cetuximab, epidermal growth factor receptor inhibitor used for some cancers) may cause anaphylaxis with a delay of several hours on first exposure to cetuximab.

All routes of administration can potentially be fatal, including oral, intravenous, subcutaneous, intraarticular, intrauterine, inhalational, rectal, or topical, but the risk is greatest after parenteral administration. Patients older than 50 years with preexisting cardiovascular diseases are at higher risk of fatal drug-induced anaphylaxis.

Perioperative Anaphylaxis

The estimated incidence of perioperative anaphylaxis is 1:11,752.[43] Neuromuscular-blocking agents and antibiotics are the most common causes for perioperative anaphylaxis. Other causes may include blood and blood products, dyes, chlorhexidine, colloids or, rarely, natural rubber latex. Reactions to neuromuscular-blocking agents mostly occur on first exposure and have been associated with a 70% rate of cross-reactivity in this group; risk factors for fatal anaphylaxis include male gender, history of cardiovascular disease, emergency setting, and use of beta-blockers. The antiseptic chlorhexidine is increasingly recognized as a cause of IgE-mediated perioperative anaphylaxis.

Insect Sting–Induced Anaphylaxis

Insect sting–induced anaphylaxis is reported in 3% of adults and less than 1% of children.[44] Insect stings account for 10% to 20% of anaphylaxis but up to 50% of severe anaphylaxis.[45] Occupational anaphylaxis caused by venom allergy can occur in beekeepers, gardeners, forestry or greenhouse workers, farmers, truck drivers, and masons. The severity of reaction depends on the type of insect, amount of venom, location of sting, the patient's sensitivity, older age, preexisting diseases, previous less-severe systemic reactions, concomitant treatment, MC disorder, and elevated baseline tryptase. Allergen-specific immunotherapy with venom extracts has been shown to be safe and effective in patients with *Hymenoptera* venom allergy, providing some clinical protection within the first 8 weeks of treatment and a long-lasting effect after 3 to 5 years of maintenance treatment (see Chapter 47). Noteworthy, patients with systemic mastocytosis are at risk of potentially fatal anaphylaxis to insect stings even if they are not presensitized to venom: this may be attributed to venom components, such as phospholipase A_2, acting as MC liberators.

Other Rare Causes of Anaphylaxis

Anaphylaxis occurs during 1 in 20,000 to 47,000 transfusions of blood or blood products, especially in patients with IgA deficiency. IgA deficiency affects 1 in 500 to 700 Caucasians. One-third of these patients have circulating anti-IgA antibodies, which are associated with serious life-threatening anaphylactic reactions to blood products containing IgA. Seminal fluid allergy is extremely rare, mostly affecting young women with atopy, with 20% of cases developing life-threatening anaphylaxis. These reactions can be prevented with condom use or intravaginal desensitization with seminal fluid. Latex-induced anaphylaxis is now rarely reported but can be fatal. More than half the patients with latex allergy report allergic reactions to fruits, such as banana, avocado, kiwi fruit, chestnut, pear, pineapple, grape, and papaya. Bites by wild or laboratory animals can rarely cause anaphylaxis in sensitized individuals.

Anaphylaxis in Clonal Mast-Cell Disorders

There is a link between unexplained anaphylaxis and clonal mast-cell disease (systemic mastocytosis or monoclonal MC activation syndrome). In systemic mastocytosis, anaphylaxis may occur to *Hymenoptera* stings and drugs (NSAIDs, opioids, and drugs used in the perioperative setting, biologics, radiocontrast media, rarely vaccines). Patients with unexplained anaphylaxis should be evaluated for mast-cell clonality to exclude systemic mastocytosis or mast-cell activation syndrome.

Clinical Diversity of Anaphylaxis

Anaphylaxis can be preceded by prodromal symptoms, such as tingling and redness of the palms and soles, anxiety, sense of impending doom, and disorientation. Anaphylaxis most commonly begins in skin and mucous membranes, is followed by involvement of the respiratory and GI tracts and the cardiovascular system, and may finally proceed to cardiac and/or respiratory arrest. Generalized wheals with angioedema is the most common manifestation of anaphylaxis, observed in over 90% of cases, but may be absent. Respiratory symptoms may vary from rhinitis to potentially life-threatening laryngeal edema and airway obstruction. Cardiovascular manifestations in anaphylaxis include hypotension and/or cardiac arrhythmias. In adults, reduced BP is regarded as systolic BP of less than 90 mm/Hg or more than 30% decrease from that person's baseline values.[46] Some patients present with only cardiovascular collapse in the absence of other signs of anaphylaxis, especially during general anesthesia. Anaphylaxis is usually associated with tachycardia caused by increased cardiac sympathetic drive in response to a decreased effective vascular volume, but bradycardia may also occur. Anaphylaxis may result in up to 35% of intravascular fluid leaking into the extracellular space. A two-phase reaction to the hypovolemia may present with tachycardia as the first phase, followed by bradycardia when effective blood volume falls by 20% to 30%.

CLINICAL PEARLS

Diagnosis of Anaphylaxis

- Anaphylaxis—an acute, potentially life-threatening systemic allergic reaction with a wide range of clinical manifestations (see diagnostic criteria in Anaphylaxis section).
- It is nearly always accompanied by tachycardia, usually by flushing, urticaria, and panic, and sometimes by vomiting and diarrhea.
- Panic attacks do not cause airways obstruction, hypotension, or urticaria but may be accompanied by faintness or tetany of the hands as a result of hyperventilation.
- Vasovagal attacks present with fainting, nausea, slow pulse, and pallor without respiratory difficulty, diarrhea, or urticaria.

Diagnosis of Anaphylaxis

Measurement of blood tryptase is now widely used as a marker of MC degranulation for in vitro confirmation of anaphylaxis. Beta-tryptase is released from MCs, but not from basophils, and diffuses more slowly compared with histamine. The concentration of tryptase peaks 1 to 2 hours after the onset of reaction, with a half-life of approximately 2 hours. Samples for tryptase testing should be collected as soon as possible after emergency treatment of the patients and within 1 to 2 hours (but not later than 4 hours) of anaphylaxis onset, and again after 24 hours (baseline sample) to check that the value has returned to normal.

Normally, mature tryptase is below detection limits in the serum of healthy subjects, whereas it is elevated in most cases of anaphylaxis with vascular compromise, especially if it is parenterally induced. However, a normal tryptase result does not exclude anaphylaxis. Tryptase within the normal range during anaphylaxis is often observed in food-induced anaphylaxis and can occur in indolent mastocytosis. In infants, tryptase may not be elevated after anaphylaxis, although the baseline levels may be increased. The diagnostic value of the measurements of histamine, platelet-activating factor, chymase, carboxypeptidase A3, dipeptidyl peptidase I, basogranulin, and CCL-2 in anaphylaxis is under investigation.

In anaphylaxis, component-resolved diagnosis can be useful to stratify risk in certain clinical scenarios. For example, patients with wheat-dependent, exercise-induced anaphylaxis should be tested for omega-5-gliadin sensitization, whereas patients with anaphylaxis to vegetables, fruits, nuts, and cereals may have IgE to nonspecific lipid transfer proteins (mostly Pru p 3 and Tri a 14). In delayed anaphylaxis to mammalian meat or anaphylaxis to cetuximab, tests for IgE against galactose-α-1,3-galactose (α-gal) should be considered.

Differential diagnosis in anaphylaxis includes capillary leak syndrome, postural orthostatic tachycardia syndrome, carcinoid syndrome, neuroendocrine tumors, vasovagal reactions, seizures, and intoxications.

Management of Anaphylaxis

Early recognition of anaphylaxis facilitates removal of the cause and prompt institution of treatment. The patient with anaphylaxis should lie down with the lower limbs elevated to increase venous blood return and maintain cardiac output. Changes in posture may trigger decompensation and fatal outcome. In drug-induced or insect-induced anaphylaxis a tourniquet may be placed proximal to the site of the injection or insect sting to slow absorption of injected antigens. The tourniquet should be released for 3 minutes at 5-minute intervals, with the total duration of application not exceeding 30 minutes.

Epinephrine should be administered as first-line treatment by an intramuscular injection in the mid-outer thigh at the first sign of respiratory failure or cardiovascular collapse and repeated after 5 to 15 minutes if the response to the first injection is suboptimal. Epinephrine autoinjectors for self-administration are available, but a single epinephrine autoinjector may be insufficient to reverse severe reactions. Use of these epinephrine autoinjectors in anaphylaxis outside hospital can be lifesaving. Overall, prompt diagnosis of anaphylaxis, early administration of epinephrine, and fast transport to emergency rooms are crucial factors for successful management.

Epinephrine is both an α- and β-adrenergic agonist with cyclic adenosine monophosphate (cAMP)–mediated pharmacological effects on target organs. In patients with anaphylaxis, stimulation of α_1-adrenergic receptors increases peripheral vascular resistance, thereby improving BP and coronary perfusion, reversing peripheral vasodilation, and decreasing angioedema. Activation of β_1-adrenergic receptors increases myocardial contractility (inotropy, chronotropy) while stimulation of β_2-adrenoreceptors causes bronchodilation and decreases the release of inflammatory mediators from MCs and basophils.

Current guidelines recommend the intramuscular route for epinephrine administration because of faster absorption and higher plasma level of epinephrine after intramuscular injection compared with subcutaneous injection.[46] The appropriate dosage of epinephrine is 0.01 mg/kg of a 1:1000 (1 mg/mL) solution, to a maximum of 0.5 mg in adults and 0.3 mg in children (0.15 mg between 6 months and 5 years). Epinephrine has a rapid but short action, so the dose may need to be repeated every 5 to 15 minutes until symptoms improve. Intravenous administration of epinephrine should be reserved for severe anaphylaxis with profound life-threatening hypotension that is refractory to other treatment because of a risk of potentially fatal cardiac arrhythmias and myocardial infarction.

Common pharmacological adverse effects of epinephrine include anxiety, fear, headache, pallor, tremor, dizziness, and palpitation. In the event of an overdose, unwanted effects may include increased Q–T interval on electrocardiography, ventricular arrhythmias, angina, myocardial infarction, increased BP, pulmonary edema, and intracranial hemorrhage. Patients with cardiovascular diseases or thyrotoxicosis and cocaine users are particularly susceptible to the adverse effects of epinephrine.

The efficacy of epinephrine can be decreased by concomitant therapy with beta-blockers, which is associated with unopposed stimulation of α-adrenoreceptors and reflex vagotonic effects, leading to bradycardia, hypertension, coronary artery constriction, bronchoconstriction, and augmented mediator release. Anaphylaxis in patients on beta-blockers can be severe, protracted, and unresponsive to treatment. Patients treated with beta-blockers may require fluid replacement and treatment with glucagon, which increases intracellular cAMP independently of β-adrenergic receptors. Glucagon may improve hypotension in 1 to 5 minutes with maximal effect at 5 to 15 minutes. Side effects of glucagon include nausea and vomiting.

Corticosteroids are often administered in anaphylaxis to minimize the risk of recurrent anaphylaxis, although convincing evidence is lacking and it is still unclear how they may work for prevention of biphasic anaphylaxis.

If there is no response to epinephrine, life support measures should be instituted. The treatment choice depends on the clinical presentation. In hypotension, large volumes of fluids should be given rapidly using 0.9% normal saline to compensate for peripheral vasodilatation and for fluid loss into the extravascular space. Crystalloid normal saline should be preferred to colloids for intravenous fluid resuscitation. Other vasopressors (dopamine, glucagon) may be needed to reverse severe hypotension. Oxygen should also be administered in circulatory or respiratory failure. Bronchospasm should be treated with nebulized or inhaled β_2-agonists. If there is severe laryngeal edema, endotracheal intubation and even emergency tracheostomy may be needed to maintain the airway. Methylene blue, a selective nitric oxide cyclic guanosine monophosphate (cGMP) inhibitor, can prevent vasodilatation and has been reported to be effective in refractory anaphylaxis. Extracorporeal life support (extracorporeal membrane oxygenation) can be used in patients with refractory anaphylaxis.

Patients presenting with severe anaphylaxis or those who require more than one dose of epinephrine should be considered for longer observation time. Patients with a higher risk of biphasic anaphylaxis or risk factors for anaphylaxis fatality should be observed for up to 6 hours or longer.

Prevention of Anaphylaxis

The first step in prevention is to identify those at risk of anaphylaxis using predictors from epidemiological and clinical studies. Machine-learning approaches have been attempted for prediction of anaphylaxis.[47] Therefore, all patients with a history of anaphylaxis should be referred for assessment and undergo allergy evaluation. Patients should be instructed how to avoid culprit allergens and cross-reactive agents and should be advised on safe alternatives. The education of patients, their families, and, in the case of children, caregivers and school staff, about anaphylaxis and availability of first-aid measures is of primary importance. Written personalized emergency action plans should be provided to patients at special risk, such as school children. Emergency medications, such as epinephrine autoinjectors, should be dispensed, and patients should receive training on their correct use. Patients should be advised to carry an epinephrine autoinjector with them at all times. Immunotherapy is very effective for prophylaxis of bee- and wasp venom–induced anaphylaxis in sensitized patients and can be lifesaving. Drug-induced anaphylaxis can be prevented by avoidance of culprit drugs and cross-reacting agents. Current guidelines support the use of premedication with glucocorticosteroids and/or antihistamines to prevent anaphylaxis or infusion-related reactions for specific agents in chemotherapy protocols although premedication prior to radiocontrast media use is not supported. In rare cases, drug desensitization can be used for antibiotics, chemotherapeutic agents, insulin, vaccines, and biological agents. For food-induced anaphylaxis, avoidance of the culprit food is essential; oral immunotherapy is available in some allergy centers. In idiopathic anaphylaxis, patients with frequent episodes (more than six episodes per year or two or more episodes within 2 months) can be treated with steroids to prevent further episodes.

Omalizumab have been reported to be effective in preventing anaphylaxis in patients with systemic mastocytosis, exercise-induced anaphylaxis, intraoperative anaphylaxis, anaphylaxis during allergen-specific immunotherapy, and idiopathic anaphylaxis. IgE immunoadsorption has been reported to decrease the reactivity thresholds to foods in food-induced anaphylaxis.[48]

TRANSLATIONAL RESEARCH OPPORTUNITIES

ON THE HORIZON

- Novel insights into the autoimmune mechanisms and understanding the mast-cell activation signals in chronic spontaneous urticaria should improve clinical assessment and management of patient subgroups.
- Development of new bradykinin and kallikrein inhibitors for patients with hereditary angioedema should further improve the acute management of this rare but very important condition. Gene therapy for hereditary angioedema may be an attractive treatment option in the future.
- Understanding the full clinical spectrum of patients with cryopyrin-associated periodic syndrome with *NLRP-3* mutations should allow earlier identification and treatment of these individuals with interleukin-1 blockers to improve quality of life and prevent later complications.
- Novel prevention strategies may include off-label use of omalizumab for different types of anaphylaxes. Machine-learning approaches may improve the prediction of anaphylaxis in the future.

Allergic Reactions to Stinging and Biting Insects

Anna Gschwend and Arthur Helbling

ENTOMOLOGICAL ASPECTS[1,2]

Stinging hymenoptera belong to the suborder Aculeata, with the families Apideae, Vespidae, Formicidae (Table 47.1).

Apidae[1]

In this family, the honeybee (*Apis mellifera*) (Fig. 47.1A) is clinically the most important cause of allergies. Bumblebees (see Fig. 47.1B) may occasionally cause allergic sting reactions (see Table 47.1).

Vespidae[3]

The vespids are divided into the subfamilies Vespinae and Polistinae, which differ morphologically in the junction between thorax and abdomen (see Fig. 47.1C and D). The subfamily Vespinae contains the three genera *Vespula, Dolichovespula*, and *Vespa* (see Table 47.1). *Vespula* are called *wasps* in Europe and *yellow jackets* in the United States. Most species of *Dolichovespula* look very similar to *Vespula*, with black and yellow stripes on the abdomen and only a slightly larger size. They can be distinguished from *Vespula* by the larger distance between the eyes and the mandibles. The genus *Vespa* (European hornet) is easy to distinguish from other vespids due to its much larger size. The Asian hornet (*V. velutina*) is naturally distributed in Asia from Afghanistan to eastern China, Indochina, and Indonesia. *Vespa velutina* is one of the most aggressive Hymenoptera species in China, where it is known as killer-wasp. *Vespa velutina nigrithorax* (VVN) has spread rapidly across France and the Basque Country in the North of Spain, Portugal, Italy, and the UK. Anaphylactic Reactions due to VVN are an emerging problem in Spain.[4] The species *Polistes dominula* and *Polistes gallicus* are European paper wasps and of particular relevance in Mediterranean areas of Europe; *P. dominula* has also spread to the northeastern United States and been reported in Australia. Polybia wasps, particularly *P. paulista*, are present in South America.[3]

Ants (Formicidae)[2]

In South and Central America and in the southern states of the United States, fire ants (Fig. 47.2) are responsible for many systemic allergic sting reactions. Occasional allergic sting reactions to *Pogonomyrmex*, the North American harvester ant, have been described, and extremely rarely to the European red ant, *Formica rufa*. The species of Myrmicinae are an important cause of allergic sting reactions in southern Australia. Another group of aggressive ants is the *Pachycondyla*, in the Far East and Middle East (see Table 47.1).

ALLERGENS IN HYMENOPTERA VENOMS

The best-characterized venom is that of the honeybee, *Apis mellifera*, with more than 100 identified proteins. Among them, Api m1, Api m2, Api m3, Api m5 and Api m 10 can be defined as major allergens for which more than 50% of patients show IgE reactivity.[5] Prominent yellow jacket venom (YJV) allergens include phospholipase A1 (Ves v 1) and antigen 5 (Ves v 5). A detailed proteomic analysis of pure *P. dominula* venom (PDV) led to the identification of 47 proteins (unpublished data). These and other allergens of Hymenoptera Venoms are listed in Table 47.2.[5] The amount of venom injected during a sting varies between and within species, especially in vespids. Bees release 50 to 140µg venom per sting, and vespids between 2 and 17µg.

CLINICAL RELEVANCE

- Not every swelling after an insect sting is an allergy.
- Systemic allergic reaction to hymenoptera venom are usually caused by immunoglobulin E ((IgE)-mediated immunological mechanisms).
- Although hymenoptera venom allergy is not as prevalent as respiratory allergies, severe systemic reactions—even fatal—occur regularly worldwide.
- It is crucial to recognize specific risk factors for hymenoptera venom allergy and identify persons at risk for severe reactions or treatment failure.
- Every patient who has experienced a systemic allergic sting reaction should be investigated in consideration of venom specific immunotherapy.
- All patients with history of systemic reaction upon stinging should be provided with adrenaline auto-injectors (AAIs).

CLINICAL PICTURE

The clinical presentations following insect stings are classified into normal, large local, systemic allergic, systemic toxic, and unusual reactions (Table 47.3).

Normal Local Reactions

The normal local reaction of a nonallergic subject to a hymenoptera sting consists of a painful, sometimes itchy, local wheal flare reaction with swelling up to 5 to 10 cm in diameter, which unusually resolves within a few hours. The fire ant (*S. invicta*) attaches to the skin by means of its powerful mandibles and stings, releasing venom that produces a characteristic fire-like pain. After the ant stings, a vesicle is left behind, which later develops into a pustule that only heals after 1 to 2 weeks.[2]

TABLE 47.1 Taxonomy and characteristics of Hymenoptera

Families/Subfamilies	Genera	Species	Characteristic
Apidae Apinae	Apis Bombus	*A. mellifera* *B. terrestris*	• Apis stings occur in the vicinity of beehives or when the insect feels threatened • Apis stings can occur in spring, summer, and occasionally on warm winter days • Apis usually lose their barbed sting when stinging
Vespidae Vespinae Polistes	Dolichovespula Vespula Vespa	*D. maculata*, *D. arenaria*, *D. media* *V. germanica* *V. vulgaris*, *V. maculifrons* *V. carbo*, *V. orientalis* *P. dominula* *P. gallicus* *P. exclamans*, *P. annularis*, *P. fuscatus* Polybia	• Dolichovespula build their nests in tree branches or under the roofs of houses • Dolichovespula sting almost exclusively in the vicinity of their nests • Vespula stings occur near the nests and while victims are eating outdoors • Vespids do not usually lose their stinger • Vespula stings occur in summer and fall • Hornet stings are rare and occur almost exclusively in the vicinity of nests • Polistes commonly build nests on human habitation • Polistes although generally not aggressive, they can be provoked into defending their nests • Some Polybia species produce enough honey to be collected and eaten by local people
Formicidae Myrmicinae	Solenopsis Myrmicinae Pachycondyla	*S. invicta* *S. richteri* *M. pilosula* *P. chinesis* *P. senna* *P. arensis*	• Fire ants build their mounds in yards/playgrounds/fields and are responsible for many systemic allergic sting reactions • Jack-jumper ants are an important cause of allergic sting reactions in southern Australia

Large Local Reactions

Large local reactions (LLRs) are defined as swellings around the sting site exceeding 10 cm in diameter and lasting more than 24 hours. LLRs may cause significant discomfort, especially when they last for days or even weeks and involve a whole limb, eyelids, or lips. The development of local infection, abscesses, or a phlegmon at the sting site is usually inhibited by the bacteriostatic effect of hymenoptera venoms.

Systemic Reactions

Systemic reactions (SRs) are usually caused by immunoglobulin E ((IgE)-mediated immunological mechanisms). Affected organs include skin, the gastrointestinal tract, the respiratory tract, and the cardiovascular system (see Table 47.3). Cutaneous involvement is very frequently observed in both adults and children, accounting for 80% and more than 90% of SR reactions, accordingly. Respiratory involvement is observed in around half of SRs.[6] The hypotension and cardiovascular collapse might occur independently of other symptoms, especially in case of systemic indolent mastocytosis. Recurrence of symptoms after 4 to 12 hours from the resolution of the first anaphylactic episode, without reexposure to stings (biphasic anaphylaxis), is reported in 0.4% to 14.7% of cases. Known risk factors for biphasic reactions are history of previous anaphylactic episodes and delayed treatment with adrenaline.[7]

Several classifications were proposed to assess the degree of severity of anaphylaxis; the most used in clinical practice are Mueller's and Ring's.[6]

Systemic Toxic Reactions

Toxic reactions are dose-dependent. Toxic reactions and allergic reactions are etiologically different conditions. Clinically significant toxic effects appear after multiple stings—usually 50 to several hundred—and develop within hours to days (see Table 47.3). The number of stings needed to cause a fatal reaction in adults varies between 200 and 1000. In small children, however, fewer than 50 stings may be lethal. In most cases, death is not immediate but occurs after several days.

Unusual Reactions

Unusual sting reactions are rare and appear after hours to days, and more than half of them follow local or SRs.[8] Non–IgE-mediated immunological mechanisms are likely involved. The causal relation to the sting event often remains uncertain (see Table 47.3).

EPIDEMIOLOGICAL ASPECTS

Prevalence of Allergy to Hymenoptera

Cumulative lifetime sting rates of 61% to 95% have been reported in people aged 16 to 65 years. Of course, this can vary considerably in different regions of the world. Asymptomatic sensitization with the development of specific IgE to bee and wasp venoms is a frequent finding and has been reported in up to 40% of individuals.[9] Hymenoptera venom allergy (HVA) can occur at any age. In general, because of their higher level of outdoor activities, men are more frequently stung than women, and children are more frequently stung than adults. The reported cumulative lifetime prevalence of LLRs ranges from 2% to 26%, and that of SRs up to 8.9% in the adult European population. Among beekeepers, it varies between 14% and 32%. SRs are more frequently caused by vespids than by honeybees.[9] In the southern states of the United States and in Australia, ants are important causes of SR.[2]

Risk Factors for Developing Hymenoptera Allergy

The risk of developing a sting allergy increases with the number of stings, especially if two stings occur within a short period (up to 2 months). However, beekeepers stung less than 10 times a year have a much higher risk for SRs compared with those stung

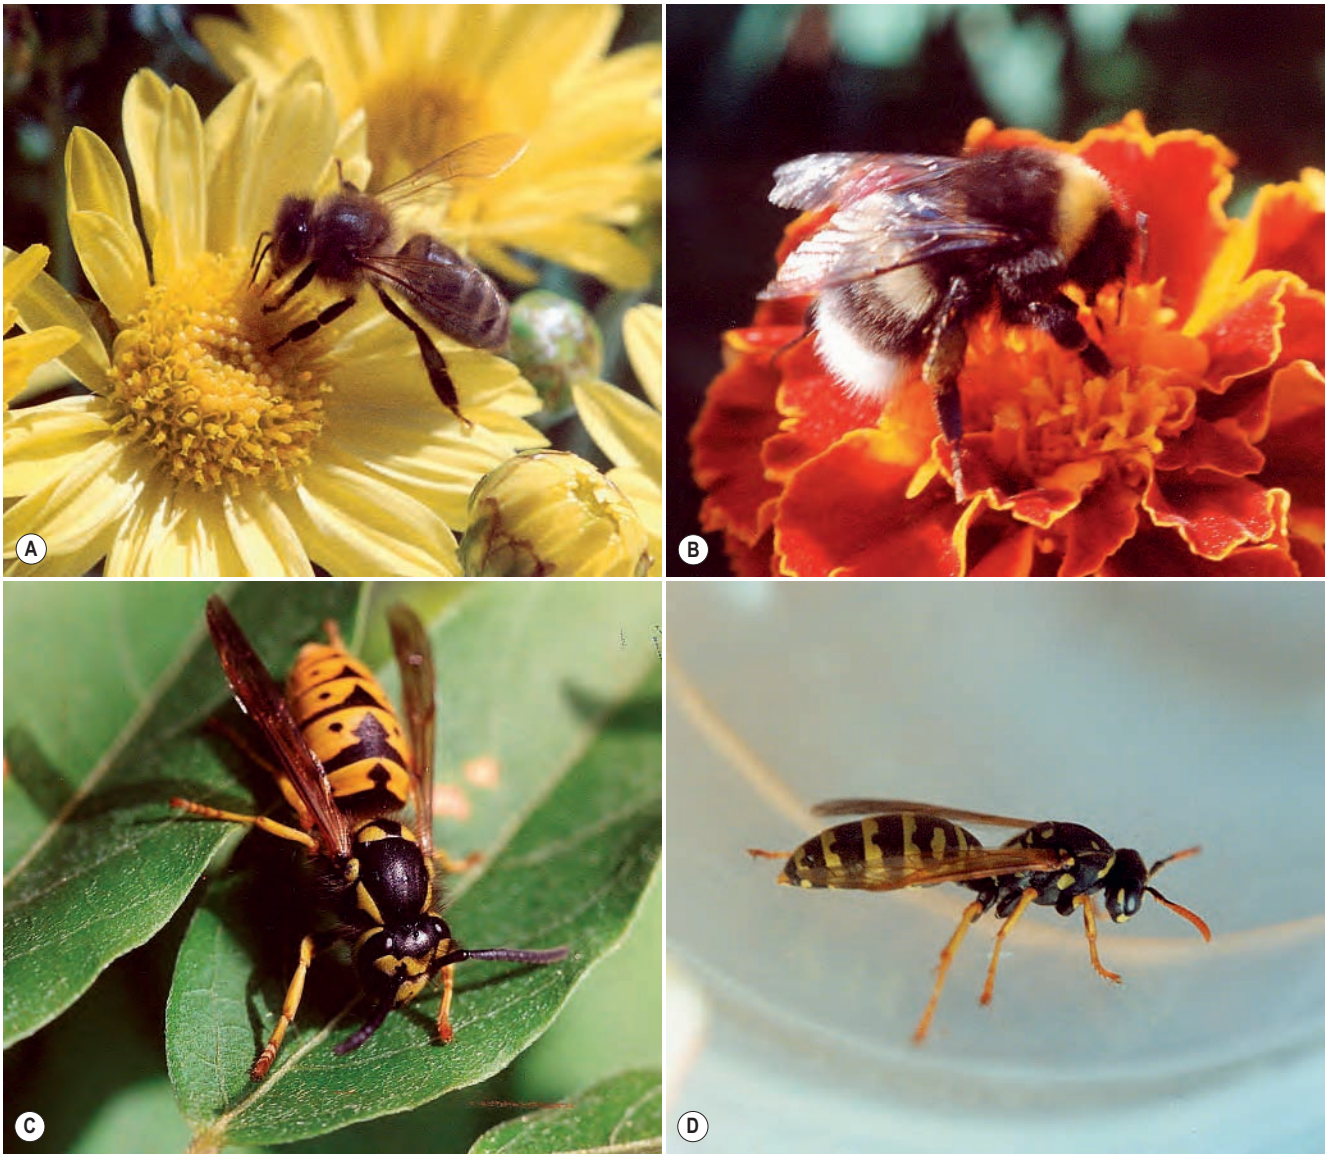

FIG. 47.1 Common hymenoptera. (A) Honeybee (*Apis mellifera*), (B) bumblebee (*Bombus terrestris*), (C) wasp/yellow jacket (*Vespula* spp.), (D) field wasp (*Polistes gallicus*). (Courtesy US Department of Agriculture.)

FIG. 47.2 Biting insect that may cause allergic reactions (fire ant—*Solenopsis invicta*).

more than 200 times a year.[10] Atopy is not more frequent in patients with hymenoptera sting allergy than in the general population. Systemic mastocytosis (indicated by elevated baseline serum tryptase) is a risk factor for developing a Hymenoptera venom allergy.[11]

Natural History of Hymenoptera Allergy and Risk Factors For Severe Reactions[9,12]

There is currently no reliable test that predicts the risk of future SRs to hymenoptera venom. The severity of an index sting reaction is an important factor determining the risk at re-exposure. Children are at lower risk of re-sting SR compared with adults. After a mild SR, the risk is between 15% and 30%, and after a severe SR, the risk is between 50% and 75%. The re-sting SR risk is definitely lower in patients with Vespula allergy than in those with bee venom allergy, probably because of the smaller and more variable amount of venom injected.

TABLE 47.2 Allergens of Hymenoptera Venoms

Recombinant Allergens

Apinae	Vespinae	Polistes	Ants
Bee	Vespen	Polistes	Solenopsis
Api m1 (PhospholipaseA2)	Ves v1 (Phospholipase A1)	Pol d1 (Phospholipase A1)	Sol i1
Api m2 (Hyaluronidase)	Ves v2 (Hyaluronidase)	Pol d2 (Hyaluronidase)	Sol i2
Api m3 (Acid phosphatase)	Ves v3 (Dipeptidylpeptidase)	Pol d3 (Dipeptidylpeptidase)	Sol i3
Api m4 (Melittin)	Ves v5 (Antigen 5)	Pol d4 (Serine protease)	Sol i4
Api m5 (Dipeptidylpeptidase)	Ves v6 (Vitellogenin)	Pol d5 (Antigen 5)	Myrmecia
Api m6 (Trypsin inhibitor)	Vespa	Pol a1 (Phospholipase A1)	Myr p1
Api m7 (CUBserine protease)	Vesp c1 (Phospholipase A1)	Pol a2 (Hyaluronidase)	Myr p2
Api m8 (Carboxylesterase)	Vesp ma2 (Hyaluronidase)	Pol a4 (Serine protease)	Myr p3

Api m12 (Vitellogenin)	Dol m5 (Antigen 5)	Poly p5 (Antigen 5)	

MRJP, Major royal jelly protein.

TABLE 47.3 Clinical Manifestations Following Insect Stings

Type of reaction	Clinical Symptoms	Pathogenesis	Venom Immunotherapy
Normal local reactions	Local wheal and flare reaction, followed by a swelling of up to 5–10 cm in diameter	Non-allergic	Not indicated
Large local reactions	Swellings around the sting site exceeding 10 cm in diameter, lasting more than 24 h. In some cases, lymphadenopathy or lymphangitis	Mostly non-allergic	Not indicated
Systemic Toxic reactions	Rhabdomyolysis, intravascular hemolysis leading to acute renal failure, myocardial damage, hepatic dysfunction, coagulation disorders, brain edema, and/or necrosis	Cytotoxic/toxic effect	Not indicated. Allergologic workup may be considered
Systemic reactions	*Skin:* pruritus, urticaria, flush, angioedema *Gastrointestinal:* cramps, vomiting or diarrhea, dysphagia *Respiratory tract:* laryngeal edema, bronchial obstruction, pulmonary edema *Cardiovascular system:* arterial hypotension, shock, arrhythmias	IgE-mediated immunological mechanisms	Allergologic workup in view to treatment with VIT
Unusual Reactions	Serum sickness–like syndromes with fever, arthralgias, exanthema, lymphadenopathy, peripheral neuropathy, polyradiculomyelitis, extrapyramidal syndromes, acute disseminated encephalomyelitis, glomerulonephritis, interstitial nephritis, hemolytic anemia, thrombocytopenia, Henoch-Schönlein syndrome, and other forms of vasculitis	Non–IgE-mediated immunological mechanisms	Not indicated. Allergologic workup may be considered

IgE, Immunoglobulin E; *VIT*, venom immunotherapy.

The degree of sensitization does not correlate with the severity of the sting reaction. Neither the amount of specific IgE antibodies to whole venom extracts nor to major allergens were significantly associated with the severity of the sting reaction.[12] Generally, patients with repeated LLRs are reported as having minimal risk of progressing to SR. Nevertheless, a recent prospective study indicates a risk of 24% SR in adults and children after an initial LLR.[13] In this study, the risk of SR was reported to be higher in cases of skin test reactivity to *Apis mellifera* or Vespula species (OR 2.1 and 3.8, respectively), if positive at 0.001 µg/mL concentration (OR 13.4 and 16.5, respectively). There is overwhelming evidence of a strong association of mast cell clonality with both a higher incidence and an increased severity of sting-induced anaphylactic reactions.[11] Moreover, older age and cardiovascular diseases are very potent risk factors for severe anaphylactic reactions in general.[12] There is some evidence that the intake of antihypertensive medication does not have an impact on the outcome of field sting-induced anaphylaxis. However, data from the European Anaphylaxis Registry suggest an increased frequency of severe reactions during concurrent intake of ACE inhibitors or beta-blockers and an even higher risk if both drugs are combined (Fig. 47.3).

Mortality Caused by Hymenoptera Stings

The estimated incidence of fatal hymenoptera sting reactions in Europe is around 200 deaths per year.[10] Up to 60% of fatal sting reactions occur in individuals who did not have a notion of being allergic to hymenoptera venom. Delayed administration of adrenaline is considered to dictate an unfavorable outcome of anaphylactic reactions regardless of the elicitor.

Epidemiological Aspects of Allergic Reactions to Ant Stings

Nearly 50% of inhabitants are stung each year in areas of the United States that are fire ant endemic.[2] Many report LLRs, but up to 1% of patients who are stung by imported fire ants develop anaphylaxis, and some deaths have been reported.

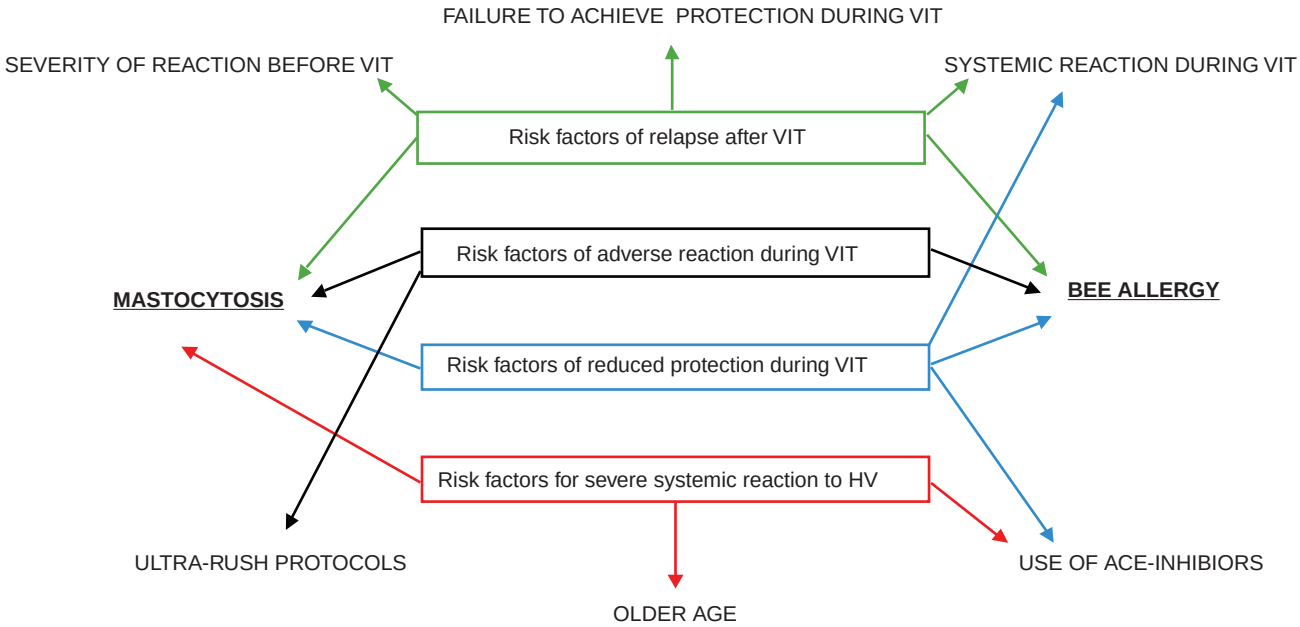

FIG. 47.3 Risk factors for severe systemic reactions to hymenoptera venom, adverse reactions, reduced protection, relapse during and after venom immunotherapy *(VIT)*.

DIAGNOSIS

Clinical History

As in all forms of allergy, the clinical history is key to diagnosing hymenoptera sting allergy. This includes the date, number, and circumstances of stings (*e.g.*, environment, activities); kind and severity of symptom; sting site; retained or removed stinger; interval to onset of symptoms; emergency treatment; risk factors for a particularly severe reaction (*e.g.*, comorbidity, drugs, elevated baseline serum tryptase/mastocytosis); tolerated stings after the first SR; reduction of the quality of life; and other allergies. For all patients with SRs, the following diagnostic tests are recommended: skin tests, venom-specific serum IgE antibodies, and baseline serum tryptase.[14]

Skin Tests[14]

Both skin tests and serologic tests should be performed in patients with a positive history of systemic reactions. If possible, skin tests should not be performed until at least 3 weeks after an SR, as false-negative results can occur (the refractory period). They are performed by intradermal or skin prick endpoint titration. Injection of 0.02 mL of venom solution is given intradermally in increasing concentrations—0.00001 to 1 µg/mL—into the volar surface of the forearm. For skin prick tests, concentrations of 0.01 to 300 µg/mL are used. However, even at 300 µg/mL, the sensitivity of skin prick is clearly lower than that of the intradermal test.

Venom-Specific Serum Immunoglobulin E Antibodies

Several different *in vitro* immunoassays for the detection of venom-specific serum IgE antibodies (sIgE) are commercially available. If no sIgE is found in a patient with a clear history of venom allergy, the test should be repeated after 2 to 4 weeks.[14]

Elevated sIgE levels after hymenoptera stings that cause a normal sting reaction are not predictive for future development of an SR. Specific IgE can be determined against the whole venom or components of the venoms. One of the most important disadvantages of whole venom extract is the under- representation of allergens that are present in low abundance. Increasing knowledge about the venom composition and availability of component-resolved diagnostics (CRD) have vastly augmented our ability to solve many diagnostic issues. Measuring sIgE to recombinant venom allergens has improved the precision of allergic diagnostic tests.[5]

Sensitivity and Specificity of Skin Tests and sIgE

The specific sensitization profiles obtained due to availability of CRD can clearly increase the specificity of HVA diagnosis. For instance, positive detection of 6 of the major allergens of bee venom (Api m 1 to 5 and Api m 10) increases the specificity of bee allergy diagnosis to 94.4%, compared to 84.4% if only two allergens are detected.[5] Similarly, concomitant Ves v 1 and Ves v 5 sensitization identifies 92% to 98% of Vespula spp. allergic patients. A major diagnostic problem is that currently available tests are not able to distinguish between asymptomatic sensitization and clinically relevant allergy; up to 40% of an unselected population have positive test results, whereas only 0.3% to 8.9% have a history of allergic sting reactions. Negative sIgE and negative skin tests have been reported in up to 15% of patients with systemic mastocytosis and history of a systemic reaction to insect stings.[6] For skin testing by ant-allergic patients, whole-body extracts are currently available.[2]

Cross-Reactivity

There is strong cross-reactivity between venom allergens within a family, such as among *Vespula, Dolichovespula*, and *Vespa*.[5] Immunotherapy with *Vespula* spp. in patients with anaphylaxis to *Vespa orientalis* und *Vespa carbo* has proven to be efficacious.[4] Conversely, the discrimination between *Vespula* spp. and *Polistes* spp. sensitization is more challenging. Some studies suggest that in clinical practice, assessing serum levels of Ves v 5 and Pol d 5 may be helpful to discriminate between sensitizations.[6] New recombinant antigens (*e.g.*, rPol d 3) for *Vespula-Polistes* could increase the diagnostic accuracy.[5]

Skin and/or serologic tests can frequently show positivity to multiple venoms (*i.e.*, *Vespula* spp. and *Apis mellifera* in 25% to 40% of the cases, *Vespula* spp. and *Polistes* spp. in over 50% of cases). For an accurate HVA diagnosis and treatment, it is important to discriminate between cross-reactivity and true sensitization.[5] Cross-reactivity between different venoms can occur due to high homology in the structural composition of allergenic molecules or cross-reactive carbohydrates. Most of the cross-reactive recombinant pairs (rApi m 2 / rVes v 2, rApi m 5 / rVes v 3, and rApi m 12 / rVes v 6) are commercially unavailable, thus preventing misleading diagnostic steps. Assessing IgE antibodies to species-specific nonglycosylated, recombinant major allergens (e.g., Api m 1, m 10 and Ves v 1, v 5) reduces the rate of double-positivity and is helpful in choosing venoms for immunotherapy. The cross-reactive carbohydrates can be detected in most major Hymenoptera venom allergens, and in many plant proteins (e.g., rapeseed pollen or bromelain). They are probably responsible for positive test results in individuals with no history of SRs.

Cellular Tests[15]

The basophil activation test (BAT) is based on flow-cytometric demonstration of an altered membrane phenotype of basophils stimulated by IL-3 and allergen exposure. At present, the most commonly used expression marker is CD63. The BAT is expensive and time consuming, but it may be used as an additional test to confirm the diagnosis in case of negative or inconclusive results of conventional diagnostic tests. The BAT should be exclusively performed by an experienced laboratory using a validated assay.[15]

Baseline Serum Tryptase

Tryptase is a serine protease produced and released by mast cells after IgE-mediated or non-IgE-mediated stimuli. Because elevated baseline serum tryptase levels (>11.4 μg/L) are associated with severe, systemic sting reactions, this enzyme should be determined in all patients with a history of venom allergy.[16] The basal tryptase value varies very little over time within the same individual and is determined by the genetic background, not by environmental factors. This information is useful, as even minimal variations in tryptase concentration in a single individual can be indicative of the presence of an anaphylactic event, even if values fall within the normal range. Serum levels of baseline tryptase (above 25 μg/mL) suggest clonal mast cell disorders (*e.g.*, systemic mastocytosis). In these patients, further diagnostic tests should be considered (*e.g.*, skin inspections/biopsy, testing for c-kit mutations). Of note, patients with severe anaphylaxis and absence of urticaria or angioedema due to sting should be investigated for mastocytosis, even in the presence of normal baseline tryptase level. The characteristic skin lesions, called urticaria pigmentosa, may be noticeable during skin inspections.[6]

Sting Challenge Tests

Sting challenge with a live insect is not recommended as a diagnostic tool in untreated patients. However, a sting challenge under well-supervised clinical conditions may be helpful in evaluating the efficacy of venom immunotherapy and improvement in health-related quality of life. A tolerated sting challenge does not definitively exclude a reaction to future stings after immunotherapy, especially if these are repeated.[16]

PREVENTION

All patients with a history of SRs should receive detailed instructions on the avoidance of future stings. Bee stings occur most often when walking barefoot on grass, and wasp stings occur when eating outdoors, in orchards with fallen fruits, and near open waste bins. While gardening, wearing long trousers, shirts with long sleeves, and gloves are recommended. Strongly scented perfumes, sun creams, or shampoos, as well as brightly colored garments, should be avoided.

Treatment of Large Local Reactions

Oral antihistamines and cooling of the sting site (*e.g.*, with ice cubes) reduces local swelling, pain, and itching. Anti-inflammatory ointments or topical corticosteroids may diminish the local inflammatory process. In cases of severe swellings, oral corticosteroids together with antihistamines over several days can be considered. Prescription of adrenaline auto-injectors (AAI) in LLR is usually not recommended.[16]

Treatment of Systemic Allergic Reactions

All patients experiencing SRs should seek medical advice and be medically observed until the symptoms resolve and blood pressure is stable. Mild reactions confined to the skin may be treated with rapid-acting oral antihistamines alone. If severe respiratory or cardiovascular symptoms occur, epinephrine (intramuscular injection in the vastus lateralis muscle of the thigh) must be given immediately (0.1 mg epinephrine/10 kg body weight), intravenous (IV) access should be established, and fluids, antihistamines, and corticosteroids given intravenously.[16]

All patients with a history of systemic reaction upon stinging should be provided with AAIs (dosage 0.3 mg adrenaline in adults, 0.15 mg in children with body weight <25 kg) and double-dose oral anti-histamines with two tablets of prednisolone of 50 mg or equivalent.[17] Double AAIs can be prescribed for patients with history of severe reactions, patients living, working or performing outdoor activities in out-of-reach locations or distant from emergency rooms, and patients with clonal mast cell disorders and/or elevated levels of baseline serum tryptase. These patients must be advised to bring AAIs and other rescue medications (*i.e.*, antihistamines and corticosteroids) along with them at all times, especially in situations at high risk of stinging (*i.e.*, outdoor activities) or in out-of-reach locations.[17]

Venom Immunotherapy[18]

Indications

Hymenoptera venom immunotherapy (VIT) is the only effective treatment able to prevent the onset (or to reduce the degree of severity) of systemic reaction at re-sting in subjects with HVA. VIT is indicated in children and adults with a history of severe SRs (grade III/IV), provided sensitization to the relevant venom has been demonstrated by skin and/or blood test. VIT is also recommended for patients who experience repeated mild, non–life-threatening reactions and are at high risk for re-exposure, such as beekeepers and their family members. VIT can be considered in adult patients if the quality of life is impaired. Concomitant cardiovascular disease and mastocytosis are relative indications for VIT in patients with non–life-threatening sting reactions.[18] VIT should not be considered in the context of

unusual reactions that are not attributed to type I hypersensitivity reactions (see Table 47.3).

Contraindications for VIT are the same as for immunotherapy with other allergens.[19] Beta-blockers had been considered to increase the risk of a systemic reaction during VIT, particularly in patients with cardiovascular diseases. However, a position paper published by the European Academy of Allergology and Immunology (EAACI) suggests that beta-blockers are no longer to be considered as contraindicated in VIT. Although angiotensin conversion enzyme inhibitors (ACEI) were previously associated with systemic reactions during VIT, the EAACI has now recommended that ACEI therapy can be continued during VIT as long as the patient is informed about possible risks.[19] Any use of anti-hypertensive drugs has been suggested as a significant risk factor of systemic reactions to VIT. However, in a retrospective study that focused on patients with cardiovascular diseases, cardiovascular medication did not impair the safety and/or the efficacy of VIT. Patients taking anti-hypertensive drugs should be evaluated carefully before starting VIT, based on an individual risk/benefit assessment.[18]

Dosage and Treatment Regimens

Venom extracts are commercialized either as aqueous or "retard" (adsorbed to alum hydroxide or other substances) preparations. The use of adsorbed (depot or retard) formulations overall showed less occurrence of reactions when compared to aqueous extracts. During VIT, the venom extract is administered subcutaneously following standardized protocols. These protocols always include two phases: an up-dosing phase that incrementally reaches the final dose, and a maintenance phase. This final dose may be reached within a few weeks to months (in outpatient clinics), days, or hours (ultra-rush or cluster protocols including several injections a day) depending on the protocol.[18]

The recommended maintenance dose for both children and adults is 100 µg of the venom. This maintenance dose is equivalent to approximately two bee stings or several vespid stings. A higher dose (*e.g.*, 200 µg) is recommended when SRs occur after re-exposure to a field sting or a sting challenge and in highly exposed subjects, such as beekeepers or professional gardeners. During the first year, maintenance VIT is given every four weeks. Subsequently, the intervals may be extended to six weeks during the second year and eight weeks between years three and five if VIT is well tolerated. In the case of lifelong therapy, 12-week intervals may still be safe and effective.[18]

Adverse Reactions to Venom Immunotherapy

The overall incidence of systemic adverse reactions to VIT varies between 5% and 40%.[20] VIT with bee venom causes side effects more often than with *Vespula* venom. Ultra-rush protocols are associated with a higher rate of side effects compared with conventional protocols (see Fig. 47.3). Most systemic side effects are mild, but life-threatening anaphylaxis and fatal anaphylaxis have been described. Uncontrolled asthma, a prior history of SRs, administration of subcutaneous immunotherapy (SCIT) injections during peak pollen season, and delay in administration of epinephrine are recognized factors of fatal reaction to VIT.[20] Some units routinely give antihistamines two hours before up-dosing injections until the maintenance dose has been repeatedly well tolerated. Levocetirizine decreased the rate of SSR and fexofenadine decreased the rate of LLR and cutaneous SSR. Importantly, premedication with antihistamines do not negatively influence the effect of the therapy. In patients with recurrent SRs during up-dosing, off-label use of anti-IgE (omalizumab) has made it possible to complete up-dosing and to continue maintenance VIT.[21]

Efficacy of Venom Immunotherapy

In addition to three prospective controlled trials, the efficacy of VIT has been confirmed by well-tolerated sting challenges during VIT in several uncontrolled prospective studies. Full protection is achieved in 80% to 85% of patients receiving bee venom and in 95% to 100% of patients receiving *Vespula* venom.[18] The higher risk of treatment failure in bee venom allergy may relate to differences in venom compositions. Important allergens, such as Api m10 or Api m 3, may be missing or present in low concentrations in some VIT products. It has therefore been suggested that patients with a predominant sensitization to these allergens may not be properly protected by VIT. Moreover, mastocytosis is a significant determinant of VIT failure (see Fig. 47.3).

Duration of Venom Immunotherapy

Lifelong treatment may be the safest recommendation, but in most allergy centers, VIT is given for up to a maximum of 5 years. If VIT is given for at least 3 years, greater than 80% of both adults and children are still protected when reassessed 1 to 7 years after discontinuation. Longer courses of treatment should be considered in high-risk patients, such as those with very severe systemic sting reactions, coexisting cardiovascular or pulmonary disease, systemic allergic reactions to VIT or stings during VIT, and in subjects with elevated basal serum tryptase levels. Lifelong VIT is advised for patients with cutaneous or systemic mastocytosis.[18]

ON THE HORIZON

- Addition of recombinant species-specific nonglycosylated major allergens from honeybee allergens to therapy solutions can increase the efficacy of venom immunotherapy (VIT) with bee venom, as these are lacking or insufficiently represented in currently available preparation.
- Further development of component resolved diagnostics and improvement in understanding of differences among venom allergens of different species (*A. melifera*/Bumblebee, Vespula/Vespa/Dolichovespa/Polistes).
- There is a need to improve the monitoring of VIT efficacy (*in vitro* test/s or biomarker/s to confirm tolerance and to identify treatment failure after stopping the VIT).
- Further research on immunological differences between insect venom-allergic patients with and without immunotherapy and asymptomatically sensitized subjects are needed.
- There is need for studies on biomarkers able to distinguish between asymptomatic and symptomatic sensitization.
- New VIT formulations and routes of administration would be helpful to make the therapy less invasive, potentially increasing the adherence and quality of life of patients.
- Allergic side effects of VIT might be reduced by using modified major allergens with reduced immunoglobulin E (IgE) binding but retained specific T-cell interactions.

Risk Factors for Recurrence of Systemic Reactions after Stopping Venom Immunotherapy

A number of risk factors have been identified for relapse of Hymenoptera venom allergy after discontinuation of VIT. In general, adults, especially older people, have a less favorable prognosis compared with children because of concomitant diseases. Patients with bee venom allergy have a higher risk of relapse compared with those allergic to *Vespula* venom. Patients with more severe pretreatment reactions and those with more SRs during VIT (to injections or field stings) have a higher risk for recurrent SRs to hymenoptera stings (see Fig. 47.3). The risk of relapse is lower after 5 years of VIT, compared with only three years of VIT.[18]

Atopic and Contact Dermatitis

Mark Boguniewicz, Luz Fonacier, and Donald Y.M. Leung

Atopic dermatitis (AD) and contact dermatitis (CD) are common inflammatory skin diseases.[1,2] The complex pathophysiology of AD involves both underlying skin barrier abnormalities and immune dysregulation. Its course is augmented by environmental influences, including stress, allergen exposure, and microbial infection. The systemic nature of AD has been increasingly recognized with type 2 immunity central across clinical phenotypes and endotypes and provides a rationale for treating patients with moderate-severe AD who do not respond to topical therapy with biologics targeting the key immune abnormalities.

CD is a skin disorder caused by contact with an exogenous substance that elicits an allergic and/or irritant response. Allergic contact dermatitis (ACD) accounts for 20%, whereas irritant contact dermatitis (ICD) accounts for 80% of all cases of CD. ACD is a delayed-type, T cell–mediated immune response consisting of an afferent limb and an efferent limb. Irritants cause direct activation of the innate immune system through hyperproduction of cytokines and chemokines. The management of ACD includes identification of the allergen, avoidance, pharmacological intervention, and prevention. This chapter reviews the clinical and mechanistic aspects of both AD and CD.

CLINICAL ASPECTS OF ATOPIC DERMATITIS

Epidemiology

Prevalence of AD has been documented in up to 24% of children, with no apparent difference seen between urban and rural districts or between the two sexes. Children from families with atopy have a significantly higher risk of developing AD. Data from an international study showed that the prevalence of current eczema in children varies widely among countries, ranging from 0.9% to 22.5%.[3] Prevalence in adults responding in the Atopic Dermatitis in America survey was found to be 7%.[4] These data point to AD as a global health problem in both developed and developing countries and suggest that the ultimate presentation of an atopic disease may depend on a complex interaction between environmental exposures and end-organ response in genetically predisposed individuals.

Natural History

AD typically manifests in early childhood, with onset in the first year occurring in more than 50% of patients and before 5 years of age in approximately 90% of patients. Although AD can present at any age, other diseases need to be considered especially in adults with new-onset dermatitis, without a history of childhood eczema, asthma, or allergic rhinitis (Table 48.1). Severity and atopic sensitization are major determinants of long-term prognosis. A registry of patients with mild-moderate AD showed that it was not until age 20 years that 50% had experienced at least one 6-month period free of symptoms and treatments.[5]

Clinical Features

AD has no pathognomonic skin lesions or unique laboratory parameters; the diagnosis is, therefore, based on the presence of major and associated clinical features (Table 48.2). The principal features include pruritus, a chronically relapsing course, typical morphology and distribution of skin lesions, and a history of atopic disease. Patients usually have dry (xerotic) skin, and those with mutations of the gene encoding the epidermal barrier protein filaggrin (*FLG*) typically have prominent scaling and hyperlinear palms. Acute AD is characterized by pruritic, erythematous papules associated with excoriations, vesiculations, and serous exudation. Subacute AD is characterized by erythematous, excoriated, scaling papules, whereas chronic AD is characterized by lichenification and fibrotic papules. During infancy, AD involves primarily the face, scalp, and the extensor aspects of the extremities; the diaper region is typically spared, although infants can have flexural involvement typical of older patients (Fig. 48.1).

Complicating Features

Ocular Problems

Atopic keratoconjunctivitis is bilateral, with intense pruritus, burning, tearing, and copious mucoid discharge. It is frequently associated with eyelid dermatitis and chronic blepharitis and may result in visual impairment from corneal scarring. Patients may also develop keratoconus from persistent rubbing of the eyes or anterior subcapsular cataracts.

Hand Dermatitis

Patients with AD may have a nonspecific irritant hand dermatitis aggravated by repeated wetting, especially in an occupational setting.

Infections

Patients with AD have an increased susceptibility to infection or colonization with a variety of organisms.[2] *Staphylococcus* (*S.*) *aureus* can be cultured from the skin of the majority of patients with AD. Preferential adherence of this organism in AD may

TABLE 48.1 Differential Diagnosis of Atopic Dermatitis

Congenital Disorders
- Netherton syndrome
- Familial keratosis pilaris

Chronic Dermatoses
- Seborrheic dermatitis
- Contact dermatitis (allergic or irritant)
- Nummular eczema
- Psoriasis
- Ichthyoses

Infections and Infestations
- Scabies
- Human immunodeficiency virus (HIV)–associated dermatitis
- Dermatophytosis

Malignancies
- Cutaneous T-cell lymphoma (mycosis fungoides/Sézary syndrome)
- Letterer-Siwe disease

Autoimmune Disorders
- Dermatitis herpetiformis
- Pemphigus foliaceus
- Graft-versus-host disease (GvHD)
- Dermatomyositis

Immunodeficiencies
- Wiskott-Aldrich syndrome (WAS)
- Severe combined immunodeficiency syndrome (SCID)
- Hyperimmunoglobulin E (IgE) syndrome (HIES)
- Dedicator of cytokinesis 8 (DOCK8)–associated immunodeficiency
- Tyrosine kinase 2 (TYK2) deficiency
- Immune dysregulation, polyendocrinopathy, enteropathy X-linked (IPEX) syndrome

Metabolic Disorders
- Zinc deficiency
- Pyridoxine (vitamin B6) and niacin deficiency
- Multiple carboxylase deficiency
- Phenylketonuria

TABLE 48.2 Clinical Features of Atopic Dermatitis

Major Features
- Pruritus
- Facial and extensor involvement in infants and children
- Flexural involvement at any age
- Chronic or relapsing dermatitis
- Personal or family history of atopic disease

Minor Features
- Xerosis
- Cutaneous infections
- Nonspecific dermatitis of the hands or feet
- Ichthyosis, palmar hyperlinearity, keratosis pilaris
- Pityriasis alba
- Nipple eczema
- White dermatographism and delayed blanch response
- Anterior subcapsular cataracts
- Elevated serum immunoglobulin E (IgE) levels
- Positive immediate-type allergy skin tests

Modified from Hannifin JM, Rajka G. Diagnostic features of atopic dermatitis. *Acta Derm Venereol (Stockh).* 1980;92:44–47.

be related to expression of adhesins, such as fibronectin and fibrinogen, in inflamed skin. Recurrent pustulosis has become a significant problem for a number of patients, especially with the emergence of methicillin-resistant *S. aureus* (MRSA) as an important pathogen in AD.

Viral infections in AD include herpes simplex, molluscum contagiosum, and human papillomavirus infections. Patients with eczema herpeticum (ADEH) have more severe disease, increased body surface area affected, and an increase in biomarkers, including circulating eosinophil counts, serum immunoglobulin E (IgE), thymus and activation-regulated chemokine, and cutaneous T cell–attracting chemokine, compared with patients with AD who do not have a history of EH. Patients with ADEH also have more cutaneous infections caused by S. aureus or molluscum contagiosum virus and are more likely to have a history of asthma, as well as food and inhalant allergies. Patients with ADEH have reduced interferon-γ (IFN-γ) production. IFNγ and IFNγR1 SNPs are significantly associated with ADEH and may contribute to an impaired immune response to herpes simplex virus. In addition, genetic variants in IFN-γ regulatory factor 2 (IFN-γR2) have been shown to be associated with ADEH and may contribute to abnormal immune responses to herpes simplex virus.

Superimposed dermatophytosis may contribute to cutaneous inflammation in AD. The opportunistic yeast *Malassezia sympodialis* (previously *Pityrosporum ovale*) has been associated with a predominantly head and neck distribution of AD.

Systemic Complications

A significant number of patients with AD do not outgrow their disease and can have systemic inflammation with increased risk for systemic diseases, although association with, for example, cardiovascular diseases, needs to be evaluated in prospective studies.

Psychosocial Implications

Patients with AD frequently respond to stress or frustration with itching and scratching. Stimulation of the central nervous system (CNS) may intensify cutaneous vasomotor and sweat responses and contribute to the itch–scratch cycle. Scratching can be associated with significant secondary gain or with a strong habitual component. Severe disease can lead to problems with self-esteem and social interactions. Sleep abnormalities are common and can contribute to impaired quality of life of patients and family members, even when the skin disease appears to be in remission.

Differential Diagnosis

A number of diseases can be confused with AD (see Table 48.1). Immunodeficiency with eczematous rash includes immune dysregulation, polyendocrinopathy, and enteropathy X-linked (IPEX) syndrome. IPEX results from mutations of *FOXP3*, a gene located on the X chromosome that encodes a DNA-binding protein required for development of regulatory T cells (Tregs). Patients may present with enteropathy, type 1 diabetes, thyroiditis, hemolytic anemia, and/or thrombocytopenia. Wiskott-Aldrich syndrome (WAS) is an X-linked recessive disorder characterized by an eczematous rash, associated with thrombocytopenia along with variable abnormalities in humoral and cellular immunity and severe bacterial infections. Hyper-IgE syndrome (HIES) with mutations in the signal transducer and activator of transcription 3 gene (*STAT3*) is an autosomal dominant multisystem

FIG. 48.1 (A) In patients with irritant contact dermatitis (ICD), exposure to an irritant exerts toxic effects on keratinocytes (KCs), activating innate immunity with release of interleukin (IL)-1α, IL-1β, TNF, granulocyte macrophage–colony-stimulating factor (GM-CSF), and IL-8 from epidermal keratinocytes. In turn, these cytokines activate Langerhans cells (LCs), dermal dendritic cells (DCs), and endothelial cells, all of which contribute to cellular recruitment to the site of keratinocyte damage. Infiltrating cells include neutrophils, lymphocytes, macrophages, and mast cells, which further promote an inflammatory cascade. (B) In the sensitization phase of allergic contact dermatitis (ACD), similar to ICD, allergens activate innate immunity through keratinocyte release of IL-1α, IL-1β, TNF, GM-CSF, IL-8, and IL-18, inducing vasodilation, cellular recruitment, and infiltration. LCs and dermal DCs encounter the allergen and migrate to the draining lymph nodes, where they activate hapten-specific T cells, which include T-helper cell-1 (Th1), Th2, Th17, and regulatory T cells (Tregs). These T cells proliferate and enter the circulation and site of initial exposure, along with mast cells and eosinophils (EOS). On re-encountering the allergen, the elicitation phase occurs, in which the hapten-specific T cells, along with other inflammatory cells, enter the site of exposure and, through release of cytokines and consequent stimulation of keratinocytes, induce an inflammatory cascade. (C) In patients with atopic dermatitis (AD), a disturbed epidermal barrier leads to increased permeation of antigens, which encounter LCs, inflammatory dendritic epidermal cells (IDECs), and dermal DCs, activating Th2 T cells to produce IL-4 and IL-13. DCs then travel to lymph nodes, where they activate effector T cells and induce immunoglobulin E (IgE) class-switching. IL-4 and IL-13 stimulate keratinocytes to produce thymic stromal lymphopoietin (TSLP). TSLP activates OX40 ligand–expressing dermal DCs to induce inflammatory Th2 T cells. Cytokines and chemokines, such as IL-4, IL-5, IL-13, eotaxin, CCL17, CCL18, and CCL22, produced by Th2 T cells and DCs stimulate skin infiltration by DCs, mast cells, and eosinophils. Th2 and Th22 T cells predominate in patients with AD, but Th1 and Th17 T cells also contribute to its pathogenesis. The Th2 and Th22 cytokines (IL-4/IL-13 and IL-22, respectively) have been shown to inhibit terminal differentiation and contribute to the barrier defect in patients with AD. Thus both the barrier defects and immune activation alter the threshold for ICD, ACD, and self-reactivity in patients with AD. MBP, Major basic protein. (Figure adapted from Gittler JK, Krueger JG, Guttman-Yassky E. Atopic dermatitis results in intrinsic and immune abnormalities: implications for contact dermatitis. *J Allergy Clin Immunol*. 2013;131:300–313.)

disorder characterized by recurrent deep-seated bacterial infections, including cutaneous cold abscesses and pneumonias caused by *S. aureus*. Patients with mutations in the gene encoding dedicator of cytokinesis 8 protein (*DOCK8*) have an immunodeficiency with eczema, recurrent viral infections, including some with CNS involvement, and many have associated food allergies. Patients with tyrosine kinase 2 (TYK2) deficiency can also present with an eczematous rash with high serum IgE and recurrent cutaneous staphylococcal infections. Other diseases to consider in the differential diagnosis of AD include cutaneous T-cell lymphoma, especially in adults with no history of childhood eczema and without other atopic features, human immunodeficiency virus (HIV) infection, and CD (see section on ACD). Contact allergy can also complicate AD, especially in patients whose AD does not respond to or worsens with therapy.

PATHOGENESIS OF ATOPIC DERMATITIS

Genetics

The genetics of AD are complex, with key roles played by skin barrier or epidermal differentiation genes and immune response or host defense genes.

KEY CONCEPTS

Pathogenesis of Atopic Dermatitis

- Patients with AD have abnormalities of skin barrier and immune dysregulation.
- Patients with AD can have decreased filaggrin in the skin based on mutations in the gene encoding filaggrin (*FLG*), copy number variation of *FLG*, or secondary to type 2–mediated cytokine (e.g., IL-4, IL-13) suppression of *FLG*.
- *FLG* mutations are associated with early-onset, severe, persistent AD with increased risk for asthma and allergic sensitization.
- Normal-appearing skin in patients with AD is associated with immune activation and epidermal terminal differentiation abnormalities.
- Patients with AD are predisposed to *Staphylococcus aureus* colonization or infection, and a subset are prone to eczema herpeticum.

Loss-of-function mutations of *FLG* are a major predisposing factor for AD. Patients with *FLG* gene mutations have early-onset, severe, and persistent AD and are at increased risk for developing asthma, as well as food and inhalant allergies.[6] Other skin barrier proteins implicated in AD include loricrin and involucrin, which are both significantly decreased in lesional and nonlesional skin of patients with AD. Candidate gene approaches have also implicated variants in the *SPINK5* gene, and haplotype tagging of SNPs for the claudin-1 gene (*CLDN1*) has revealed associations with AD. These observations have established a key role for impaired skin barrier function in the pathogenesis of AD that allows increased transepidermal water loss and penetration of allergens, antigens, and chemicals from the environment, resulting in cutaneous inflammation. Additional genome-wide significant susceptibility loci identified through the genome-wide association study (GWAS) and immunochip analysis continue to be reported and suggest a role for epidermal barrier function, innate-adaptive immunity, interleukin-1 (IL-1) family signaling, Tregs, the vitamin D pathway, and the nerve growth factor pathway in the pathogenesis of AD. Thus, a combination of varied genetic factors may influence a wide range of phenotypes of AD among individuals.

Immune Abnormalities in Atopic Dermatitis

Immunohistology

On the basis of clinical appearance and duration of illness, AD skin can be characterized as nonlesional AD, acute AD lesions (3 days or fewer after onset), and chronic skin lesions. Nonlesional AD skin is not normal and is characterized by a sparse perivascular T-cell infiltrate, suggesting the presence of minimal inflammation at baseline. Langerhans cells (LCs) also exhibit surface-bound IgE molecules, which have enhanced capacity to present allergen to T cells. In acute lesions, there is epidermal spongiosis with an increased infiltration of activated memory T cells bearing the skin-homing cutaneous lymphocyte-associated antigen (CLA^+). Eosinophils, basophils, and neutrophils are rare. Mast cells are seen in various stages of degranulation.

Chronic lichenified AD lesions are characterized by epidermal hyperplasia, prominent hyperkeratosis, and an increased number of dendritic cells (DCs) bearing surface IgE. Macrophages dominate the dermal mononuclear cell infiltrate, but lymphocytes remain prominent. Although intact eosinophils are rarely seen, eosinophil product deposition can be readily identified, suggesting they contribute to allergic skin inflammation.

Immune Pathways in Atopic Dermatitis

AD is associated with a combination of defective innate responses to microbes and altered adaptive responses to environmental allergens (reviewed in references).[1,2,7] A key difference between epidermal keratinocytes found in AD skin, compared with normal skin, is the presence of thymic stromal lymphopoietin (TSLP) and IL-33 in the AD epidermis. TSLP and IL-33 are key cytokines secreted by epithelial cells that induce DCs to drive T-helper 0 (Th0) cells into the Th2-cell differentiation pathway. Nonlesional AD and acute AD skin lesions are predominantly associated with expression of IL-4, IL-5, IL-13, IL-25, and IL-33. These type 2 cytokines are present in all stages of AD and can be secreted by multiple cell types, including innate lymphoid type 2 cells (ILCs), mast cells, and basophils, which are present in AD skin lesions and contribute to substantial redundancy in allergic inflammation. As such, cytokine targeting, as opposed to cell targeting, is considered a more effective approach in the treatment of AD. It is noteworthy that experimental studies demonstrate pretreatment with IL-4, and IL-13 dampens responses to IFNs and IL-17, suggesting that once the early AD lesion is exposed to IL-4 and IL-13, there is a long-lasting persistent effect.

Besides Th2, other cytokine pathways are also activated during the evolution of AD. The IL-22–IL-17 pathway is of particular interest, since it, along with IL-4 and IL-13, can inhibit terminal keratinocyte differentiation, including filaggrin expression. Since DC-derived IL-23 enhances IL-22/IL-17 cell differentiation, all of these cytokines are being closely examined for their potential role in AD. It is interesting that IL-4 and Il-13 can enhance IL-23 production by DCs. Furthermore, blockade of the IL-4 and IL-13 pathway, leading to improvement in AD, is also associated with reduced IL-23 and IL-17 expression in AD skin. When acute AD skin lesions become chronic, there is an increase in Th1 cytokines, such as IFN-γ, which potentiates AD skin inflammation. TSLP can be detected in at-risk infants before onset of AD, suggesting that the TSLP–Th2–ILC2 pathway plays a critical role in initiation of AD.

Epidermal Barrier Dysfunction

The clinically dry skin and increased transepidermal water loss (TEWL) in AD reflect underlying skin barrier dysfunction and loss of natural moisturizing factors that play an important role in the pathogenesis of AD. However, only a minority of patients have *FLG* null mutations. Other genetic variants in the epidermal differentiation complex (EDC) and tight junctions are even rarer. The majority of patients with AD likely have immune-mediated reduction in epidermal terminal differentiation, which leads to reduced generation of various epidermal structural proteins, filaggrin breakdown products, lipids, and antimicrobial peptides. TSLP, IL-4, and IL-13 are the most potent cytokines downregulating filaggrin expression by keratinocytes.[6] IL-17, IL-22, IL-25, and IL-33 can act synergistically with IL-4 and IL-13 to further downregulate expression of epidermal proteins and lipids. This combination of events, along with activation of proteases and lipases, creates defective epidermal barrier function, alters epidermal acidification, and leads to loss of moisturization in AD, thereby contributing to enhanced allergen and microbial penetration met by the host immune response and the clinical appearance of AD.

MANAGEMENT OF ATOPIC DERMATITIS

Management of AD is addressed in both an AD practice parameter update[8] and AD guidelines[9] with a more recent AD yardstick including newer therapeutic options.[10] Recognition of skin barrier and immune abnormalities suggests the need for barrier repair and maintenance along with antiinflammatory measures.

THERAPEUTIC PRINCIPLES

Atopic Dermatitis

- Fundamentals of skin care in AD include avoidance of irritants and proven allergens, along with proper skin hydration and use of moisturizers.
- Patients and caregivers have concerns about topical steroids and calcineurin inhibitors and tend to underuse prescribed medications.
- If eczema cannot be cleared and the patients keep relapsing, they may benefit from proactive intermittent antiinflammatory therapy.
- The diagnosis of AD should be reconsidered in patients not responding to conventional therapy, as the differential diagnosis includes a number of immunodeficiencies with eczematous rash.
- Systemic therapies should be reserved for patients with moderate-to-severe AD that does not respond to conventional therapy.

Identification and Elimination of Exacerbating Factors

Irritants

Patients with AD have a lowered threshold of irritant responsiveness. Recognition and avoidance of irritants is integral for successful management of this disease.

Allergens

Identification of clinically relevant allergens involves taking a careful history and doing selective testing, when appropriate. Negative skin tests with proper controls have a high predictive value for ruling out a suspected allergen. Positive skin tests have a lower correlation with clinical symptoms and may reflect sensitization.[8] Patients with severe AD who are avoiding foods based on *in vitro* testing results can tolerate many of the foods previously avoided when they are introduced under supervision. Environmental control measures aimed at reducing dust mite allergen can also improve AD in sensitized patients.

Psychosocial Factors

Recognizing and addressing sleep disturbance in patients is critical in managing a chronic, relapsing disease such as AD. Counseling together with relaxation, behavioral modification, and biofeedback may all be of benefit, especially for patients with habitual scratching.

Patient Education

Patients and caregivers need to be educated regarding the chronic relapsing nature of AD, its natural history, exacerbating

factors, and treatment options. Recognizing that normal-appearing skin in patients with AD is, in fact, *not* normal is a difficult concept to understand but has important therapeutic implications. Patients should be counseled about prognosis and receive appropriate vocational counseling.

Hydration

The skin of patients with AD shows enhanced TEWL and lipid abnormalities that result in reduced water-binding capacity, higher TEWL, and decreased water content.[7] Skin hydration by soaking the affected area or bathing and applying an occlusive agent to retain absorbed water can help restore barrier function.[8] Bathing can also remove allergens, reduce *S. aureus* colonization, and act as relaxation therapy.

Moisturizers and Occlusives

Use of moisturizer or occlusive, especially when combined with hydration therapy, helps restore and preserve the skin barrier and can result in decreased need for topical corticosteroids. Twice-daily emollient application can improve barrier function and protect the skin from *S. aureus* proliferation while preserving microflora biodiversity. Patients with AD have been shown to have a ceramide deficiency of the stratum corneum; barrier repair may be accelerated by increasing the ratio of ceramides, cholesterol, and either the essential fatty acid linoleic acid or the nonessential palmitic or stearic fatty acids.

Corticosteroids

Corticosteroids reduce inflammation and pruritus in acute and chronic AD, acting on multiple resident and infiltrating cells, primarily through suppression of inflammatory genes. Topical corticosteroids have been the mainstay of conventional therapy: when they are appropriately used, side effects are infrequent. Thinning of skin, telangiectasia, bruising, hypopigmentation, acne, striae, and secondary infections may occur. The face, particularly the eyelids, and the intertriginous areas are especially sensitive to these adverse effects. If topical corticosteroids are used on the face, this can lead to perioral dermatitis, characterized by erythema, scaling, and follicular papules and pustules around the mouth, in the alar creases, and sometimes on the upper lateral eyelids.

An important concept with translational applications is the recognition that nonlesional skin in AD shows evidence of both immunological dysregulation and skin barrier abnormalities.[11] This observation provides a rationale for the use of topical corticosteroids in a proactive manner.[8] If the eczema can be cleared or almost cleared but has a relapsing course, long-term control can be maintained with twice-weekly applications of topical corticosteroid to areas that had previously been involved but now appear normal, with fewer relapses and less need for topical corticosteroids compared with treating eczema in a reactive manner.

In addition to their anti-inflammatory properties, topical corticosteroids can decrease *S. aureus* colonization in patients with AD. Failure to show clinical improvement with topical corticosteroids may be due to inadequate potency or amount of medication used, superinfection, steroid allergy, steroid resistance, or, more commonly, nonadherence with the treatment regimen, emphasizing the need for both education and alternative therapies.

Systemic corticosteroids, including oral prednisone, should be avoided in the management of a chronic disorder such as AD.[8,12] Improvement observed with systemic corticosteroids may be associated with flaring of AD after discontinuation. If a short course of oral corticosteroids is given, topical skin care should be intensified during the taper to suppress rebound flaring of AD.

Topical corticosteroid treatment in patients with AD can result in improvements of the AD genomic signature. Cytokine levels (IL-12p40, IL-13, IL-22, CCL17, CCL18, peptidase inhibitor 3 [PI3]/elafin, and S100As) were consistently reduced, with corresponding improvements in epidermal disease markers (keratin 16 and loricrin) in lesional skin from responders. Even low-potency corticosteroids can affect a broad array of immune and barrier responses in patients with AD.

Topical Calcineurin Inhibitors

Tacrolimus ointment (0.03% and 0.1%) and pimecrolimus cream (1%) are nonsteroidal topical calcineurin inhibitors (TCIs) approved for the treatment of AD.[8–10] Both drugs have proven effective, with a good safety profile even when used over extended periods, including in infants treated with pimecrolimus. Treatment with TCIs is not associated with skin atrophy and may also be useful in treating patients with steroid insensitivity. A common side effect with TCIs is burning or stinging sensation of skin. Ongoing surveillance and recent reports have not shown a trend of increased frequency of viral infections or problems with response to childhood vaccinations. Although there is no evidence of a causal link to cancer and the use of TCIs, the US Food and Drug Administration (FDA) issued a "box warning" because of lack of long-term safety data. The labeling states that these drugs are recommended as second-line treatments and that their use in children under the age of 2 years is currently not recommended. However, a review of epidemiological and clinical data concluded that the published data did not demonstrate any causal relationship between TCI use and malignancy or lymphoma risk. Proactive treatment with tacrolimus ointment may benefit patients with a relapsing course.[8,10]

Phosphodiesterase-4 Inhibitor

Crisaborole is a phosphodiesterase 4 (PDE4) inhibitor approved as a 2% topical ointment for adults and children 3 months and older with mild to moderate AD.[10] The unique configuration of boron within the crisaborole molecule enables selective targeting and inhibition of PDE4, increasing cAMP levels and reducing inflammation. In addition, the boron molecule allowed for synthesis of a low-molecular-weight compound (251 daltons), thereby facilitating penetration of crisaborole through human skin.[13] *In vitro* crisaborole inhibits cytokine production by peripheral blood mononuclear cells similar to other PDE4 inhibitors and distinct from corticosteroids.

Antiinfective Therapy

Systemic antibiotic therapy may be necessary when a secondary infection with *S. aureus* is present.[2] Recolonization after a course of anti-staphylococcal therapy occurs rapidly. Maintenance antibiotic therapy should be avoided because it can result in colonization by MRSA. Bleach baths with dilute sodium hypochlorite may reduce skin infections, although data showing clinical benefit versus plain water baths for eczema have been questioned.[14]

Patients with disseminated EH require treatment with a systemic antiviral, such as acyclovir.[2] Recurrent cutaneous herpetic

infections can be treated with prophylactic oral acyclovir. Superficial dermatophytosis can be treated with topical or, rarely, with systemic antifungals.

Antipruritic Agents

Pruritus is the most common and least tolerated symptom in AD. Mediators other than histamine, including neuropeptides and cytokines, especially IL-31, can contribute to pruritus, and centrally acting agents, such as opioid receptor antagonists, have been shown to be effective against the itch of AD. Treatment with cyclosporine, which results in decreased transcription of a number of proinflammatory cytokines, leads to rapid improvement in pruritus in many AD patients. Monoclonal antibodies (mAbs) against IL-31 receptor are currently in phase 3 clinical trials in patients with AD, and trials with dupilumab (discussed below) showed significant reduction in pruritus.[15] Systemic antihistamines and anxiolytics may be most useful through sedative effects and should be used primarily at bedtime to avoid daytime somnolence. Short-term use of a sedative to allow adequate rest may be appropriate. Treatment with topical antihistamines and topical anesthetics should be avoided because of the potential for allergic sensitization.

Biologic therapy

Dupilumab is a fully human mAb directed against the IL-4 receptor α subunit that blocks signaling of both IL-4 and IL-13. Results from randomized, double-blind, placebo-controlled trials involving adults with moderate-to-severe AD showed that treatment with dupilumab resulted in rapid and dose-dependent improvements in clinical indexes, biomarker levels, and disease transcriptome.[15] Of the patients in the dupilumab group, 85% had a 50% reduction in the Eczema Area and Severity Index (EASI) score compared with 35% in the placebo group; 40% of patients in the dupilumab group had an investigator's global assessment score of 0 to 1 (clear or almost clear) compared with 7% in the placebo group; and pruritus scores decreased by 55.7% in the dupilumab group versus 15.1% in the placebo group. In a 52 week study of dupilumab with concomitant topical steroids, 100% of the patients in the dupilumab group had a 50% improvement in EASI, compared with 50% of those in the placebo group, even though the patients who received dupilumab used less than half the amount of topical steroids compared with those in the placebo group.[15] Adverse events, such as skin infection, occurred more frequently with placebo; nasopharyngitis and headache were the most frequent adverse events with dupilumab. In addition, conjunctivitis was reported in approximately 10% of patients in the phase 3 trials, although this adverse event did not require discontinuation in the majority of patients. Of note, treatment with dupilumab can correct both cutaneous and systemic abnormalities.[16] Dupilumab was well tolerated with no dose-limiting toxicity. Studies in adolescents confirmed both safety and efficacy.[17] Dupilumab is indicated for the treatment of patients 6 years or older with moderate-to-severe AD whose disease is not adequately controlled with topical prescription therapies or when those therapies are not advisable. Dupilumab can be used with or without topical corticosteroids. Dosing in adults is 600 mg loading dose subcutaneously followed by 300 mg every other week. Dosing for patients 6-17 years is weight dependent with patients 60kg or more receiving adult dosing, patients 30kg to less than 60kg receiving 400mg loading dose followed by 200mg every other week, and patients 15kg to less than 30kg receiving 600mg loading dose followed by 300mg every 4 weeks. Currently, no laboratory monitoring is required.

RECALCITRANT DISEASE

Patients failing conventional therapy should be evaluated to confirm the diagnosis of AD and review treatment regimen as well as triggers and confounding problems. An approach to such patients with an annotated figure was the subject of a recent review.[18]

Hospitalization

Patients who experience erythroderma, appear toxic, or fail conventional therapies may require hospitalization. Removing the patient from environmental allergens or stressors, intense education, and assurance of adherence with therapy usually result in marked clinical improvement. The patient can also undergo appropriately controlled provocative challenges to identify potential triggering factors.

Wet Wrap Therapy

Wet wrap therapy (WWT), in which a layer of wet clothing or bandages is placed over topical corticosteroid with a dry layer on top, can reduce inflammation and pruritus and acts as a barrier to trauma associated with scratching.[18] WWT can aid epidermal barrier recovery that persists even after this therapy is discontinued, and clinical benefit can be demonstrated after discontinuation. Overuse can result in chilling, maceration of skin, or secondary infection. WWT should be employed for acute exacerbations of AD or for selective use in areas of resistant eczema, rather than as a maintenance treatment. The package inserts for topical calcineurin inhibitors recommend that they should not be used under occlusive dressings.

Systemic Immunosuppressive Agents

Oral cyclosporine has been shown to be effective in placebo-controlled studies in severe AD, although it is not approved for treatment of AD in most countries. A systematic review of randomized controlled trials evaluating systemic immunomodulating treatments for moderate-to-severe AD found that, of 12 different interventions studied in 34 randomized controlled trials, strong recommendations were only possible for the short-term use of cyclosporine.[19] Patients need to be appropriately monitored while on this medication.[12] Other systemic immunosuppressive drugs that have been used off-label to treat severe AD include methotrexate (a folic acid antagonist that interferes with purine and pyrimidine synthesis), and less commonly mycophenolate mofetil (a purine biosynthesis inhibitor) and azathioprine (a systemic immunosuppressive agent affecting purine nucleotide synthesis and metabolism).[12,18] All of these drugs require careful monitoring of patients for potential serious adverse effects.

Phototherapy and Photochemotherapy

Ultraviolet (UV) light therapy can be a useful treatment for chronic, recalcitrant AD.[10,12] In patients with moderate-to-severe chronic AD treated with narrow-band UVB phototherapy, gene expression, and immunohistochemistry studies of both lesional and nonlesional skin showed that Th2, Th22, and Th1 pathways were suppressed and that measures of epidermal hyperplasia and differentiation were normalized. Clinical improvement was associated with decrease in Th2/Th22–associated cytokines and chemokines and, importantly, normalized expression of epidermal

barrier proteins. UVB phototherapy has also been shown to significantly decrease levels of toxin-producing *S. aureus* on the skin of pediatric patients with AD. Potential long-term adverse effects include premature skin aging and cutaneous malignancies.

Allergen-Specific Immunotherapy

Allergen-specific immunotherapy (AIT; see Chapter 88) may be effective for a subset of patients with AD and aeroallergen sensitivity.[8] However, a Cochrane review of randomized controlled trials of AIT in AD found results confounded by high loss to follow-up and lack of blinding.[20] Subgroup analyses did not identify if a particular allergen, age, or level of disease severity predicted treatment success.

Investigational Therapies

Intravenous Gammaglobulin

Because chronic inflammation and T-cell activation appear to play a critical role in the pathogenesis of AD, high-dose intravenous immunoglobulin (IVIG; see Chapter 82) could have immunomodulatory effects in this disease. IVIG could also interact directly with infectious organisms or toxins involved in the pathogenesis of AD. IVIG has been shown to contain high concentrations of staphylococcal toxin–specific antibodies that inhibit the *in vitro* activation of T cells by staphylococcal toxins. Treatment of severe refractory AD with IVIG has yielded conflicting results. Studies have not been controlled and have involved small numbers of patients. A systematic review of systemic therapies found that IVIG was not efficacious in the treatment of moderate-to-severe AD.[19]

Omalizumab

Treatment of patients with AD with omalizumab off label has mainly been reported in case reports and case series, showing both clinical improvement and lack of benefit.[10] No specific markers have been identified that define responders, although one study suggested that adult patients with AD that respond to treatment have wild-type *FLG* mutations. In addition, patients receiving omalizumab have been shown to have decreased levels of TSLP, OX40L, thymus and activation-regulated chemokine (TARC), and IL-9 and marked increase in IL-10 compared with placebo. A systematic review and meta-analysis of omalizumab in AD found that fewer than 50% of the patients treated with this biologic achieved a significant clinical improvement.[21] In the two randomized controlled trials in that review, patients failed to show any significant clinical improvement with omalizumab, or their clinical response was comparable to that of the control group. However, the authors noted that 43% of patients treated with omalizumab had a good response, suggesting that a subset of patients with AD, possibly those with an urticarial component to their disease might still benefit from this therapy. Furthermore, a recent randomized clinical trial in children with severe AD found that omalizumab significantly reduced disease severity and topical steroid use.[22]

Recombinant Human Interferon-γ

Interferon-γ suppresses IgE synthesis and inhibits Th2 cell function. In patients with AD, treatment with subcutaneous recombinant human interferon-γ (rhIFN-γ) resulted in reduced clinical severity and decreased total circulating eosinophil counts.[8,18] rhIFN-γ may act primarily on the allergic inflammatory response as opposed to IgE synthesis, and a subset of patients treated with rhIFN-γ could respond to individualized titration of their treatment dose. In pediatric patients with ADEH, IFN-γ and IVIG were thought to be less likely to enhance the cutaneous viral susceptibility of these patients compared with systemic immunosuppressive therapies.

Probiotics

Clinical trials of probiotics in patients with AD show varying results. Probiotic supplementation during the prenatal and the postnatal period may reduce the incidence of AD in infants and children. In contrast, the most recent Cochrane review found no benefit for probiotics as a treatment for eczema.[23]

Other Biologics and Small Molecules in Clinical Trials

A number of biologics are currently in trials for moderate-to-severe AD (reviewed in reference 24). These include anti–IL-13 (lebrikizumab, tralokinumab), anti–IL-31-receptor (nemolizumab), and anti-OX40 (GBR 830). In addition, several Janus kinase inhibitors in both topical (ruxolitinib, delgocitinib) and oral (abrocitinib, baricitinib, upadacitinib) formulations are being studied in AD.[24] Ruxolitinib cream is approved by the FDA for patients 12 years and older with mild-moderate AD. New insights into AD phenotypes and endotypes will likely lead to improved selection of appropriate patients for more targeted therapies.

PREVENTION

Because infants at risk for AD could be identified as early as day 2 of life by TEWL measurement, independent of parental atopy or *FLG* mutation status, early treatment with emollients has been suggested as a strategy to reduce incidence of AD. While preliminary studies suggested that emollient therapy started in early infancy in at-risk neonates reduced the incidence of AD, recent large trials failed to reproduce these results.[25,26]

CONTACT DERMATITIS

CD is a skin disorder caused by contact with an exogenous substance that elicits an allergic and/or irritant response. The vast majority of cases of contact-induced skin reactions are attributable to CD. However, there are other less-well-defined contact reactions, including contact urticaria, contact urticaria syndrome, and protein contact dermatitis. ACD affects approximately 7% of the general population, 13.3% to 24.5% of pediatric patients,[27] and up to 65% among children with suspected ACD. Numerous studies have reported an increased frequency of ACD in patients with AD, likely as a result of the increased exposure to products and chemicals used to treat AD, the barrier defect, and immunological changes in AD, which predispose a patient to both ICD and ACD.[28]

PATHOGENESIS OF ALLERGIC CONTACT DERMATITIS

The Genes

ACD is a multifactorial condition in which genetic background plays an important part, as shown by twin and family studies.

An association has been demonstrated between loss of function mutations R501x and 2282del4 in the filaggrin (*FLG*) gene and contact sensitization against nickel II-sulfate, combined with an intolerance to fashion jewelry but not with other contact allergens. *FLG* mutations have further been shown to lower the age of onset of nickel sensitization.[29] Thus FLG defects may be a risk factor for contact sensitization to allergens.

The Allergens

Most contact allergens are *haptens*, that is, simple chemicals that bind to carrier proteins present in skin to form a complete antigen (see Chapter 6). To be allergenic, the chemical must be able to penetrate the principal barrier in skin (stratum corneum) and reach the living cells of the epidermis. Only molecules with molecular mass of less than 500 daltons (Da) are capable of penetrating the stratum corneum. Lipid solubility promotes transit through the stratum corneum. Thus, most contact allergens are small, lipophilic molecules. Once in the epidermis, the nature of the protein carrier for the hapten is very important because if the contact sensitizer is complexed to nonimmunogenic carriers, this may induce tolerance rather than sensitization.

The Immune Response

KEY CONCEPTS

Pathogenesis of Contact Dermatitis

- Allergic contact dermatitis (ACD) is a delayed-type, T cell–mediated response with an afferent limb or sensitization phase and an efferent or elicitation phase.
- Irritant contact dermatitis (ICD) is caused by irritants exerting toxic effects on keratinocytes, causing a direct activation of the innate immune system through hyperproduction of cytokines and chemokines and inducing an inflammatory skin reaction.
- Patients with ICD are more susceptible to the development of ACD, indicating that the activation of innate immunity by irritants likely reduces the threshold for development of ACD.
- There is an increased frequency of ACD in patients with AD likely because of the disturbed skin barrier allowing increased allergen penetration on an already amplified adaptive response in AD.
- Although ACD, ICD, and AD are independently defined diseases, they frequently interact and coexist.

The immune response of ACD requires completion of both an afferent (sensitization) and an efferent (elicitation) phase. In the afferent limb, the hapten enters the epidermis and activates keratinocytes to release inflammatory cytokines and chemokines, including tumor necrosis factor (TNF), granulocyte macrophage–colony-stimulating factor (GM-CSF), IL-1α, IL-1β, IL-8, IL-10, IL18, and macrophage inflammatory protein-2 (MIP-2). The activation of LCs, other DCs, and endothelial cells can lead to recruitment of even more DCs at the site of antigen contact. The release of IL-1β by epidermal LCs promotes their egress from the epidermis. LCs process the antigen while migrating to regional lymph nodes, where they present it to naïve T cells. This phase is influenced by multiple factors. Defects in the integrity of the stratum corneum allow greater penetration of allergen and increase the chances of activating antigen-presenting cells (APCs) in skin. The availability and viability of APCs in skin, as well as the presence or absence of cytokines produced by keratinocytes, can promote or hinder APC–T-cell engagement.

In the draining lymph nodes, LCs present the peptides to T cells and activate CD4 and CD8 antigen-specific T cells. An important property of LCs and DCs is their ability to present exogenous antigens on both major histocompatibility complex (MHC) class I and class II molecules. This cross-priming leads to the activation of both CD4 and CD8 hapten-specific T cells. Although classic delayed-type hypersensitivity reactions are mediated primarily by CD4 cells, contact dermatitis to haptens is mediated primarily by CD8 cells with a Th1-type cytokine profile. LCs activate hapten-specific T cells, which include Th1, Th2, Th17, and Treg subsets.[30] This preexisting mix of T-cell subtypes specific for the antigen influence the outcome of this process. The higher the frequency of cells of an effector subtype, the higher the likelihood that dermatitis will result, whereas a higher frequency of cells of a regulatory subtype may limit or prevent the development of dermatitis.

The efferent phase of ACD occurs on subsequent contact of skin with the hapten. Antigen-specific memory T cells and other inflammatory cells leave vessels and enter skin through sequential activation of a number of adhesion molecules by cytokines. Memory T cells constitutively express CLA. E-selectin, the ligand for CLA, is induced on vascular endothelium by inflammatory mediators, such as IL-1 and TNF. This interaction causes memory T cells to slow down and roll along the endothelial surface as a prelude to migration to sites of inflammation. Firm adhesion and migration of leukocytes to the endothelium are mediated by T-cell very late antigen-4 (VLA-4)/leukocyte function–associated antigen-1 (LFA-1) and endothelial cell vascular cell adhesion molecule-1 (VCAM-1)/intercellular adhesion molecule 1 (ICAM-1), respectively (see Chapter 16). Subsequently, LFA-1^+ T cells migrate toward ICAM-1^+ epidermal cells.

Mast cells can also participate in the elicitation phase. Mast cells contain preformed TNF, which may regulate the adhesion molecules involved in the early recruitment of Th cells. The net result is an influx of sensitized T cells homing to the hapten-provoked skin site, releasing their inflammatory mediators, IL-2 and IFN-γ, and this results in an enhanced immune response through activation and recruitment of more inflammatory cells, producing spongiosis and the inflammatory dermal infiltrate characteristic of ACD.

Although Th1 cells have been classically considered the primary effector cells of ACD (responses to haptens, such as nickel, were dominated by IFN-γ–producing cells), recent studies have indicated that Th2 cells also participate in the development of contact hypersensitivity.[31]

Recently, both murine models and human studies have suggested the potential role of Th17 cells in the immunopathogenesis of ACD. In patients with ACD, Th17-associated mediators, such as IL-17A, IL-17F, IL-22, IL-23, chemokine receptor 6 (CCR6), IL-22 receptor, and the Th17 transcription factor retinoic acid–related orphan receptor γ (ROR-γ) were shown to be produced by nickel-specific T cells and were upregulated in ACD lesional skin and positive patch test biopsy specimens.[32] Nickel exposure was reported to induce production of IL-23 by keratinocytes, promoting a Th17-mediated response, as detected by the presence of IL-17–producing T cells in peripheral blood from patients with nickel allergy.[33] The role of IL-17 in ACD lesions includes induction of keratinocyte release of cytokines and chemokines (i.e., IL-8 and IL-6) and promotion of T cell–induced apoptosis of keratinocytes.

The immunological mechanism of ACD appears to be hapten-specific with allergens like nickel inducing Th1/Th17 polarization, while fragrance induces Th2/Th22 polarization.[34]

The concept that ACD may differ mechanistically according to allergen is likely to have significant therapeutic relevance as a consideration in the choice of future targeted therapy.

The skin of patients with AD is at increased risk for the development of ACD, and this may be attributed to multiple factors. First, AD skin is exposed to a large number of different chemicals used to treat AD, including moisturizers, topical corticosteroids, and TCIs. Second, the disturbed barrier system allows increased permeation of allergens leading to greater access of surface antigens to LCs. Third, AD skin has a heightened immunological status with existing activation of innate immunity and selective upregulation of the Th2 adaptive immune response. In patients with AD, cutaneous contact with irritants and allergens leads to amplification of innate immunity and enhanced adaptive immune responses, including Th2 and Th17 in patients with acute AD and Th22 and Th1 in patients with chronic disease. Just as innate immune activation stimulated by an irritant permits a lower threshold of ACD elicitation, the amplified adaptive responses in lesional and nonlesional skin promote increased expression of ACD and ICD in patients with AD.

PATHOGENESIS OF IRRITANT CONTACT DERMATITIS

ICD accounts for 80% of cases of CD. The clinical presentation of ICD is usually restricted to skin that is directly in contact with the offending agent, with little or no extension beyond the site of contact. The inflammatory response is dose- and time-dependent. Any impairment to the epidermal barrier layer (e.g., fissuring, overhydration) renders skin more susceptible to an irritant effect. Contact with agents such as detergents, solvents, alcohol, creams, lotions, ointments and powders, and environmental factors such as wetting, drying, perspiration, and temperature extremes, can abrade or irritate skin. After exposure to skin irritants, perturbation of the skin barrier and disorganization of the lipid bilayers with lamellar body lipid extrusion in the epidermis is seen with an associated increase in TEWL.[35]

Irritants cause direct activation of the innate immune system through hyperproduction of cytokines and chemokines, such as IL-1α, IL-1β, IL-6, IL-8, and TNF, which further induce a cytokine cascade and inflammatory reaction with infiltration of inflammatory cells. Epidermal keratinocytes have been identified as key effector cells in the initiation and propagation of contact irritancy. Keratinocytes can release both preformed and newly synthesized cytokines and can upregulate MHC class II molecules and induce adhesion molecules in response to irritants.[30] These mediators can cause direct tissue damage, activating LCs, dermal DCs, and endothelial cells, which contribute to further cellular recruitment, including neutrophils, lymphocytes, macrophages, and mast cells, which also contribute to the inflammatory cascade. The "final" cellular damage results from inflammatory mediators released by activated nonsensitized T cells.

Sodium lauryl sulfate (SLS), a common ingredient of cleaning products, is directly toxic to keratinocytes (an experimental model of ICD) and has been demonstrated to induce LC mobilization and consequent migration to the draining lymph nodes. Other irritants have been shown to cause direct activation of the innate immune system through a set of membranous and intercellular receptors called Toll-like receptor 7 (TLR-7) and nucleotide-binding oligomerization domain (NOD)–like receptors (NLRs) that activate the inflammasome and nuclear factor-κB (NF-κB) pathways, inducing release of many cytokines and chemokines.

Although few immunohistopathological differences have been noted between ICD and ACD, both ICD and ACD begin with activation of the innate immune system.

ICD does not require prior sensitization, and immunological memory is not involved. The cellular infiltrate includes CD4 T cells with a Th1-type profile. Irritant reactions predispose to allergic reactions, making patients with ICD more susceptible to the development of ACD. In human studies, when patch test sites were pretreated with SLS, the threshold elicitation concentrations of contact allergens, such as cobalt, nickel, and colophony, were significantly decreased, indicating that the activation of innate immunity by irritants likely reduces the threshold for the development of ACD.

In summary, although ACD, ICD, and AD are independently defined diseases, they interact and frequently occur in combination. In patients with AD, if the activation of an innate immune response is preceded by exposure to irritants and allergens, there is altered permeation of contact allergens, which are introduced into an already activated innate immune system, resulting in amplification of innate immunity and enhanced adaptive immune responses. The amplified adaptive responses in AD promote increased ACD and ICD. Conversely, the innate immune activation stimulated by an irritant permits a lower threshold of ACD elicitation (see Fig. 48.1).

CLINICAL MANIFESTATIONS OF CONTACT DERMATITIS

The clinical and histological findings of ACD are characteristic, but not diagnostic. ACD should be suspected in patients with acute and chronic eczematous or noneczematous dermatitis and is diagnosed on the basis of the clinical appearance of the lesions, the distribution of the dermatitis, the presence of pruritus, and the absence of other etiologies. Acute CD is characterized by erythematous papules, vesicles, oozing, and crusted lesions (Fig. 48.2). Recurrence and persistence of the dermatitis may lead to subacute and chronic lesions. Subacute CD manifests as erythema, scaling, fissuring, or a parched, scalded appearance, and chronic inflammation may have more skin thickening, hardening, scaling, fissuring, and lichenification.

Although the location of the dermatitis serves as an important clue to the source of the offending chemical, multiple factors contribute to the distribution of ACD. Spread from the principal site of exposure can involve distant sites, either by inadvertent contact or by autosensitization. Areas of the scalp, palms, and soles have thicker skin, whereas the eyelid, face, and genital areas have thinner skin that is more sensitive to contact allergens (Figs. 48.3 and 48.4). A geographical approach can be very helpful in identifying the causal allergen.

The hand is a common body site involved in contact dermatitis.[36] Hand dermatitis may be due to ICD, ACD, AD, dyshidrosis, or psoriasis. Because the skin on the palm is much thicker than that on the dorsum of the hands, ACD is often associated with vesicles, occurring most often on the thinner skin on the dorsum of the hands, the fingertips, nail folds, and less commonly involves the palms (Fig. 48.5). Patch tests in patients with hand eczema showed that relevant allergens included nickel sulfate, potassium dichromate, rubber accelerators, and cobalt

FIG. 48.5 Allergic Contact Dermatitis of the Hand Caused by Rubber Accelerators.

chloride.[37] The prevalence of hand eczema in patients with AD is 2- to 10-fold higher than in nonatopics.

Facial presentation of dermatitis ranks third by location in the results from the NACDG from 2015 to 2016.[36] Symmetrical, central, or patchy distribution tends to be seen with cosmetics and personal products (moisturizers, sunscreens, foundations, and powders) whereas peripheral face (pre-auricular, submental and jawline areas) involvement can be due to shampoos, conditioners, and facial cleansers. Involvement of the lateral neck could be due to perfumes/colognes, ectopic transfer of nail cosmetics, or as a "run-off" pattern from cosmetics applied to face, scalp, or hair. Although the regional distribution may be helpful in some cases, dermatitis with scattered generalized distribution, which lacks the characteristic distribution that gives a clue as to the possible etiology of ACD, is actually the second most common pattern of dermatitis in both children and adults, as reported by the North American Contact Dermatitis Group in 2018.[36] Systemic contact dermatitis (SCD), specifically the "baboon syndrome," is a diffuse eruption involving flexural and intertriginous areas following oral, intravenous, or transcutaneous exposure to the allergen in a contact-sensitized individual. Aside from the baboon syndrome, SCD could also manifest as a recall reaction (reactivation of a previous site of dermatitis or a previous positive patch test), dyshidrotic hand eczema, flexural dermatitis, exanthematous rash, erythroderma, and even vasculitis-like lesions. The most common causes of SCD are (1) metals, such as mercury, nickel, and gold; (2)medications, including aminoglycoside antibacterial, topical corticosteroids, and aminophylline; and (3) plants and herbal products, including Compositae and Anacardiaceae families and Balsam of Peru (also known as *Myroxylon pereirae* resin).

Histologically, CD demonstrates intercellular edema of the epidermis (spongiosis) with varying degrees of acanthosis (thickening of the epidermal stratum basale and stratum spinosum) and superficial perivascular, lymphohistiocytic infiltrates. It is often difficult to distinguish ACD (see Fig. 48.5) from ICD (Fig. 48.6) on the basis of physical examination or histological findings.

MANAGEMENT OF ALLERGIC CONTACT DERMATITIS

The management of ACD includes identification of the allergen, avoidance, pharmacological intervention, and prevention.

FIG. 48.6 Irritant Contact Dermatitis.

THERAPEUTIC PRINCIPLES

Contact Dermatitis

- Patch testing is the procedure of choice to confirm the diagnosis of allergic contact dermatitis (ACD) and to identify offending contact allergens.
- The interpretation of patch tests requires both experience and judgment on its relevance.
- Once identified, the key to management of ACD is prevention by avoiding substances containing the allergens or irritants that have been identified and providing patients with alternatives and substitutes of products that do not contain their allergen.
- Medical treatments such as topical and/or systemic corticosteroids can be used to relieve ongoing dermatitis.

Identification of the Allergen

The most widely acceptable and available method for confirming the diagnosis of ACD is patch testing. Nickel remains the most common contact sensitizer and is more common in women than in men, likely because of greater exposure to nickel in jewelry and body piercing practices. In cosmetic and personal products, fragrances, preservatives, and emulsifiers are the most common causative allergens. In addition, paraphenylenediamine (in hair dye), cocamidopropyl betaine (in shampoos and soaps), and medications (e.g., neomycin, benzocaine, corticosteroids) are commonly reported allergens in personal hygiene and medical products. Methylisothiazolinone is a preservative widely used in cosmetics, toiletries, and household products including shampoos, conditioners, baby soaps, detergents, dishwashing liquid, stain removers, and fabric softeners. It is the second most common positive patch test (second only to nickel) in the 2018 NACDG patch test results.[36] The results of patch tests must be interpreted in the context of the patient's experience; exposure and relevance should be established.[38]

Allergen Avoidance and Treatment

Once the allergen is identified, avoidance of contact to the allergen and education of patients and/or families is the mainstay of treatment for ACD. All other measures are palliative and temporary. Patients and/or caregivers must be educated regarding the nature of the dermatitis, triggering agents and irritant factors, and avoidance of further contact with the offending agent. A list of the offending agents, potential exposure alternatives, and substitutes should be offered to the patient. The names of the allergens are long, complex, and confusing. There are also numerous synonyms and cross reactions, thus a list of "safe products" to use can increase compliance.

The dimethylglyoxime test (nickel spot test) and the cobalt spot test (based on disodium-1-nitroso-2-naphthol-3, 6-disulfonate) can be used to detect nickel or cobalt released from metal objects and dermal exposure, thus aiding in avoidance of contact in sensitized patients.

Cool compresses with aluminum subacetate (Burrow's solution), calamine, or colloidal oatmeal may help acute, oozing lesions. Excessive handwashing should be discouraged in patients with hand dermatitis, and nonirritating or sensitizing moisturizers must be used after washing. Soaps and nonalkaline cleansers should be avoided.

In addition to avoidance of exposure, appropriate adjunct medical treatment can be prescribed. First-line therapy is with topical corticosteroids, and second-line treatment includes phototherapy, oral retinoids, and immunosuppressant agents. Topical corticosteroids may be sufficient for localized lesions. Patients with dermatitis that is acute, extensive (particularly if involving greater than 10% of total body surface), or severe (such as poison ivy) may benefit from systemic therapy. Due to its high side effect profile, their use for chronic allergic contact dermatitis is not recommended.

Contact sensitization to the corticosteroid itself, the vehicle, or other ingredients in the topical corticosteroid should be suspected if symptoms worsen, initially improve but then worsen with continued treatment, or do not respond to treatment at all. Several topical T-cell selective inhibitors (tacrolimus and pimecrolimus) have been used successfully in the treatment of AD, but their efficacy in ACD or ICD has not been established.

Antihistamines may offer some benefit in contact urticaria and some relief from pruritus.

Phototherapy (UVB) may be effective in the treatment of ACD, especially in chronic ACD of the hands. Other immunomodulating agents such as cyclosporin, methotrexate, azathioprine, and mycophenolate mofetil have been used, especially in patients who could not avoid their allergens.

There are conflicting reports on whether dupilumab is effective or exacerbates some cases.

New evidence is emerging to support that dupilumab (IL-4RI) may be a treatment option in some patients with recalcitrant ACD.[39]

Mechanical barriers such as protective gloves and clothing and barrier creams may help with avoidance of exposure, especially in the occupational setting.[40] For nickel-allergic patients, barriers such as gloves, covers for metal buttons, and identification of nickel by the dimethylglyoxime test can be prescribed, but results can be disappointing.

Patient education regarding the nature of the dermatitis, triggering agents and irritant factors, plus instruction for avoidance and appropriate substitutes will not only aid in clearing the dermatitis but also prevent or minimize recurrences. At present, hyposensitization of patients with ACD is not a viable therapy.

PERSPECTIVES IN ATOPIC DERMATITIS AND ALLERGIC CONTACT DERMATITIS

Looking into the future, as we define the immune pathways that cause AD, novel biologics and molecules currently in clinical trials may provide more targeted therapy in AD.

ON THE HORIZON

- Novel biologicals and small molecules currently in clinical trials may provide more targeted therapy in atopic dermatitis (AD).
- Characterization of unique clinical phenotypes of AD may lead to a better understanding of AD pathophysiology and a precision-medicine approach to treatment.
- Identification of "at risk" patients will facilitate preventative strategies.
- A large number of chemicals are in everyday usage: new, rare, and emerging allergens should be considered in the assessment of suspected ACD. Patch testing to these allergens has yet to be standardized and irritant and elicitation concentration to patch testing determined.
- Data about contact allergen sensitization in children with AD are limited and are continually expanding. Frequency and patterns of CD in children with AD and results of patch testing have yet to be determined.

Identification of the endotypes involved in the pathogenesis of unique clinical phenotypes of AD will be required for a precision-medicine approach to treatment. In the absence of a low-cost cure for AD, biomarkers to identify "at-risk" patients could facilitate preventative strategies.

In the area of ACD, a large number of chemicals are being evaluated for their role, and new, rare, and emerging allergens should be considered in the assessment of suspected ACD. Patch testing to these allergens has yet to be standardized; irritant and elicitation concentrations to patch testing need to be determined. Data about contact allergen sensitization in children with AD are limited but are continually expanding. Frequency and patterns of CD in children with AD and the results of patch testing have yet to be determined.

Food Allergy

J. Andrew Bird and A.Wesley Burks

Adverse reactions to foods may be mediated by immunological mechanisms (food allergy) and nonimmunological mechanisms (food intolerance). Immune-mediated reactions to foods most commonly involve immunoglobulin E (IgE), an antibody that binds to mast cells and basophils. Upon exposure to an allergen, they release inflammatory mediators, such as histamine, prostaglandins, and leukotrienes, producing symptoms ranging from localized oral itching to anaphylaxis, the latter being a potentially fatal systemic reaction. Non–IgE-mediated immune reactions to foods include such diseases as celiac disease and food protein–induced enterocolitis syndrome (FPIES), while other diseases, such as eosinophilic esophagitis (EoE) and eosinophilic gastroenteritis (EGE), involve both IgE-mediated and non–IgE-mediated mechanisms. Food allergies have a significant negative effect on quality of life, and the burden on the health system amounts to approximately $25 billion annually.[1] Current management of food allergy relies on avoidance, but ongoing research into treatment for food allergy may offer interventional approaches to provide additional protection for allergic patients. This chapter reviews the basics of food allergy diagnosis, management, and natural history, with a specific focus on IgE-mediated food allergies.

KEY CONCEPTS

Common Characteristics of Most Frequently Encountered Food Allergens

- A relatively small molecular weight (<70 kDa)
- Abundant source of the relevant allergen
- Glycosylation residues
- Water solubility
- Most are resistant to heat and digestion

PREVALENCE

The true prevalence of food allergy is difficult to establish. This is most likely because (1) studies have focused on only the most common food allergens; (2) the incidence and prevalence of food allergy may be increasing and changing with time, with studies showing an increasing prevalence over the past 10 to 20 years; and (3) studies of prevalence are difficult to compare because of inconsistencies and deficiencies in study design.[2] Population-based surveys indicate that about 10% of the US population (1 in 10 adults and 1 in 12 children) suffer from at least one IgE-mediated food allergy.[3] More than 170 foods have been reported to trigger allergic reactions, though the most common foods that trigger reactions in US children are peanuts (2.2%), milk (1.9%), shellfish (1.3%), tree nuts (1.2%), egg (0.9%), finned fish (0.6%), wheat (0.5%), soy (0.5%), and sesame seed (0.2%).[3] Prevalent allergens vary in different cultural groups, with milk, egg, peanut, and tree nut allergens topping the lists in the Americas, Australia, and Western Europe, whereas fish and shellfish allergies are more common in Asia.[4] Food allergies commonly co-occur with other atopic diseases, such as atopic dermatitis (AD), asthma, and allergic rhinitis.[5] The most common food and plant allergens are listed in Table 49.1.

SPECTRUM OF DISEASE

Immunoglobulin E–Mediated Food Allergies

Immediate reactions to foods compose the largest proportion of food-induced allergic diseases. IgE-mediated food allergy occurs when allergenic proteins cross-link allergen-specific IgE bound to mast cells or basophils, leading to release of histamine and other inflammatory mediators. Symptoms of IgE-mediated food allergies usually occur within minutes of ingestion of the provoking food allergen, and do not present more than 2 hours later, except in rare circumstances (*e.g.*, delayed anaphylaxis related to red meat ingestion).

Symptoms may be severe (*e.g.*, anaphylaxis) or localized (*e.g.*, pollen-food allergy syndrome). Characteristic signs of an immediate allergic reaction manifest through skin and subcutaneous tissues (*e.g.*, urticaria and/or angioedema), the respiratory system (*e.g.*, bronchospasm), the gastrointestinal system (*e.g.*, vomiting and/or diarrhea), and/or the cardiovascular system (*e.g.*, increased vascular permeability leading to hypotension). Anaphylaxis is the most severe symptom of food allergy and may result in death (Chapter 46).

Pollen-food allergy syndrome (PFAS, or oral allergy syndrome) symptoms are restricted to the lips, throat, and mouth and are most commonly elicited due to fruit and vegetable proteins cross-reacting with antibodies against pollen proteins in individuals with pollen allergy. Affected individuals will typically complain of pruritus and/or tingling of the lips, tongue, roof of the mouth, and throat with or without swelling. PFAS reactions are unlikely to progress to a systemic reaction.

Because of protein similarities between allergens, cross-reactivity occurs. Patients allergic to certain foods should be counseled to avoid cross-reactive food proteins. It is common to find cross-reactivity among tree nuts; in particular, cashews and pistachios share common allergen binding sites, as do walnuts and pecans. Between 25% and 50% of patients with a peanut allergy are also allergic to tree nuts, with particular

TABLE 49.1 Food Allergens by Family

Food Allergen Family	Foods Containing Allergen	Description
Tropomyosins	Crustacean shellfish (*e.g.*, shrimp, lobster, crab), mollusks (*e.g.*, oyster, scallop, squid)	Invertebrate tropomyosins are a family of muscle proteins that share homology across invertebrate species and therefore may act as panallergens. They do not share homology with vertebrate tropomyosins. They are generally heat stable and highly cross-reactive.
Parvalbumins/EF-hand proteins	Vertebrate fish and frogs	Muscle proteins that possess a calcium-binding domain referred to as an EF-hand motif. This is the second-largest family of allergens, and these allergens are considered highly cross-reactive panallergens.
Casein	Mammalian milk	Function to bind calcium and stabilize it in micellar form. There is high sequence homology between cow's milk and other mammalian milks, such as goat's milk and sheep's milk. Other animal milks such as human milk, horse's milk, donkey's milk, and camel's milk have caseins with approximately 60% homology, which may account for less allergenicity than seen with cow's milk.
Prolamin superfamily	Seeds, tree nuts, legumes (including peanut), fruits, vegetables, wheat, corn, rice	This family contains the highest number of plant food allergens and is characterized by rich disulfide bonds and a core of eight conserved cysteine residues, providing stability and resistance to digestion. Families within this superfamily include 2S albumin seed storage proteins, nonspecific lipid transfer proteins, and α-amylase/trypsin inhibitors.
Cupin superfamily	Legumes, nuts, seeds	A large and functionally diverse superfamily of proteins termed seed storage globulins that share a β-barrel structural core domain. Seed storage globulins may be grouped into two families: vicilins and legumins.
Bet v 1 superfamily	Apple, pear, stone fruits, celery, carrot, soybean, peanut	Bet v 1 is the major birch pollen allergen and is a member of the pathogenesis-related protein 10 family within this superfamily. Symptoms of Bet v 1 hypersensitivity typically present with pollen food allergy syndrome (also known as oral allergy syndrome), which is caused by IgE cross-reactivity between Bet v 1 and homologous allergens from plant foods.

From Sampson HA, Aceves S, Bock SA, et al. Food allergy: a practice parameter update—2014. *J Allergy Clin Immunol.* 2014;134:1016–1025.e1043.

cross-reactivity noted between peanut allergens and tree nut allergens in almonds, walnuts, pecans, hazelnuts, and Brazil nuts. Tropomyosins found in crustacean shellfish are a panallergen,[5] and approximately 75% of individuals who are allergic to one crustacean (*e.g.*, shrimp) are also likely to react to another crustacean (*e.g.*, lobster).[8] Parvalbumins found in vertebrate fish are commonly cross-reactive on testing, but clinical relevance of cross-reactivity varies. Studies have shown that an individual who is allergic to one fish species has approximately a 50% likelihood of reacting to another species of fish.

Although most reactions occur immediately after ingestion, some individuals may experience delayed anaphylaxis following ingestion of mammalian meat.[5] Delayed allergy to mammalian meats has been linked to the production of IgE to α-gal in susceptible subjects. α-Gal is an immunogenic oligosaccharide, and sensitization is believed to occur via a tick bite. Symptoms of urticaria, angioedema, and anaphylaxis can occur 3 to 6 hours after eating beef, pork, lamb, and venison. The mechanism(s) underlying the delayed reaction is poorly understood.

Mixed Immunoglobulin E/Non–Immunoglobulin E– and Non–Immunoglobulin E–Mediated Food Allergies

Delayed gastrointestinal (GI) reactions to foods include such diseases as EoE, EGE, FPIES, and eosinophilic proctocolitis. The most common food proteins involved in these diseases include milk, egg, wheat, and soy. Celiac disease is a non–IgE-mediated food allergy triggered by ingestion of gluten-containing grains (*e.g.*, wheat, barley, and rye). Human leukocyte antigen (HLA) DQ2- or DQ8-restricted CD4 T cells, which recognize gluten selectively in affected persons, are critical to the pathogenesis of celiac disease.

EoE is a clinicopathological diagnosis, based on symptoms of esophageal dysfunction (including dysphagia, vomiting, feeding disorders, and abdominal pain) together with pathological findings of at least 15 eosinophils per high-power field on light microscopy.[9] The precise role of food allergy in EoE is not well defined; IgE-mediated and non–IgE-mediated mechanisms may be involved in the pathogenesis. The most common food allergens implicated in the pathogenesis include milk, egg, wheat, and soy. Numerous other foods have been implicated in the pathogenesis of EoE, and a common approach to treatment is initial elimination of milk, egg, wheat, soy, peanut, tree nuts, fish and shellfish. If dietary elimination is not successful or not feasible for the patient, then topical (swallowed aerosol) inhaled steroids (*e.g.*, fluticasone or budesonide) may be swallowed rather than inhaled to treat the inflammation.

EGE is less common than EoE and, like EoE, it is believed that its pathogenesis involves both IgE-mediated and non-IgE-mediated mechanisms. Common symptoms of EGE include vomiting, abdominal pain, diarrhea, and failure to thrive/weight loss. Multiple food allergens are often implicated, although response to dietary elimination of the most common food allergens (milk, egg, wheat, soy, peanut, tree nuts, fish, and shellfish) is typically less successful than dietary elimination reported in patients with EoE. Topical (swallowed aerosol) inhaled steroids (*e.g.*, fluticasone and budesonide) may provide some benefit; however, systemic steroids are often necessary for disease control.

FPIES is a non–IgE-mediated disease usually occurring in infants.[10] Characteristic symptoms of FPIES manifest as repetitive emesis with or without diarrhea accompanied by lethargy occurring 2 to 4 hours after ingestion of the offending food protein. The risk of abrupt volume loss, hypotension, and potential for bowel perforation makes this a medical emergency. Treatment is reliant on rehydration. Ondansetron may be helpful in managing acute FPIES reactions. Milk and soy are most commonly implicated, along with less common food allergens such as rice, oats, fruits, or vegetables. FPIES is outgrown in the majority of affected children by 3 years of age but may be protracted for many years in a smaller subset of patients.

Celiac disease is an immune-based reaction to gluten, a storage protein for wheat, barley, and rye. The small intestine is typically affected in genetically predisposed individuals, and symptoms resolve with gluten avoidance. Symptoms of celiac disease are variable and may include diarrhea, steatorrhea, weight loss, bloating, flatulence, abdominal pain, and also non-GI symptoms, such as abnormal results on liver function tests, iron deficiency anemia, bone disease, and skin disorders. Celiac disease is detected with serological testing of celiac-specific antibodies and confirmed by duodenal mucosal biopsy, both of which should be performed while the patient is on a gluten-containing diet.[11]

PATHOPHYSIOLOGY

Food allergy results from a breakdown of oral tolerance (or failure to develop it); foods that are ordinarily harmless may then trigger an immune response that results in harmful adverse symptoms upon exposure. Maintaining tolerance requires a delicate balanced effort from multiple arms of the immune system. Deviation from the protective response may result in the development of an allergic response.

PROPERTIES OF FOOD ALLERGENS

An intact GI mucosal barrier is required to maintain tolerance. The first line of defense against the mucosal immune system is a hydrophobic layer of mucin oligosaccharides, which serve to trap antigen.[12] Secretory IgA is also a part of the outer layer of the intestinal defense against dietary antigens. Dietary antigens must then penetrate the intestinal epithelium, which is maintained by epithelial junction complexes (adherens junctions) and tight junctions. Intestinal epithelial barrier dysfunction may play a role in food allergen sensitization. Alterations in the integrity of junctional complexes may be induced by calcineurin inhibitors, and this can result in food allergen sensitization. Genetic defects, such as those in individuals with filaggrin mutations, a protein that binds to keratin and is important for epithelial cell integrity, may predispose individuals to increased risk of EoE. Other factors that have been shown to affect intestinal permeability include viruses, alcohol, and nonsteroidal anti-inflammatory drugs (NSAIDs). These environmental exposures may alter intestinal epithelial integrity, thus allowing antigen to interact with the next layer of defense, mucosa associated lymphoid tissue (MALT; Chapter 24).

KEY CONCEPTS

Risk Factors for Fatal Food-Induced Allergic Reactions

- Peanut and/or tree nut allergy
- Delay in administration of auto-injectable epinephrine
- Preexisting and/or poorly controlled asthma
- Concomitant use of beta-blocker medications
- Teen and young adult age groups

MALT is composed of lymphocytes, antigen-presenting cells (APCs), stromal cells, and other immune cells in the lamina propria. It is within MALT that dendritic cells (DCs) interact with dietary antigens.

There are several common characteristics among the most commonly allergenic foods: (1) relatively small molecular weight, generally less than 70 kilodaltons (kDa); (2) an abundant source of the relevant allergen; (3) glycosylation residues; (4) water solubility; and (5) resistance to heat and digestion. These characteristics allow the proteins to stay intact until reaching the small intestine, wherein they initiate a T-helper-cell type 2 (Th2) response that results in production of specific IgE and eventual allergic disease. *Glycosylation* refers to the reaction by which carbohydrates are attached to molecules; in food allergens, the carbohydrate is most often attached to a protein. Carbohydrate residues surrounding proteins may be important in initiating the immune response. For example, interaction with DC-specific intercellular adhesion molecule–grabbing nonintegrin (DC-SIGN), a c-type lectin expressed on APCs that identifies conserved carbohydrate residues, has been shown to mediate recognition of the major peanut protein, Ara h 1. This interaction allows DC activation and Th2 skewing of naïve human T cells.

Once the Th2 response is initiated, it is strengthened through the induction of interleukin-4 (IL-4) signaling. IL-4 signals B cells to undergo class-switch recombination and begin producing IgE. Basophils have been implicated as a likely contributor of early IL-4 production and may play an important role in priming the T-cell response to allergens.

The Allergic Response

Allergenic food proteins that survive the initial stages of digestion are taken up by the APCs in MALT. Mucosal DCs may encounter antigen through (1) extending dendrites through the paracellular space between epithelial cells to sample luminal contents; (2) directly interacting with the epithelial cells; and (3) taking up antigen in the Peyer patch. Once contact with the antigen is established, the antigen is processed and loaded onto major histocompatibility complex (MHC) class II molecules on the cell surface, costimulatory molecules necessary for T-cell activation are upregulated, and chemotaxis to the draining lymph node occurs. Once a DC encounters a T-cell receptor with the same specificity as the peptide antigen, an immune response ensues. In the presence of cytokines, such as IL-4, IL-5, and IL-13, the responding T cell is programmed to be a Th2 cell. The Th2 cell will then signal B cells to generate IgE antibodies.

Soluble IgE that is produced by B cells circulates and binds to the surface of mast cells and basophils. Mast cells are found in skin, the gut, and the respiratory tract and are located adjacent to nerves and blood vessels. When an allergen is encountered and recognized by cell-bound IgE, calcium influx ensues, activating the mast cell. Once activated, the mast cell degranulates and releases vasoactive compounds and proteases, including histamine, platelet-activating factor, tryptase, chymase, carboxypeptidase, and heparin, resulting in the characteristic symptoms of an allergic reaction: urticaria, angioedema, flushing, nausea, vomiting, abdominal pain, diarrhea, wheezing, coughing/bronchospasm, rhinorrhea, and hypotension/syncope. Symptoms may occur alone or in combination and typically appear within minutes of ingestion.

Natural History

The majority of food allergies are outgrown. Allergies to peanuts, tree nuts, fish, and shellfish are more likely to persist.[13] Clinical characteristics and laboratory measures may help predict which food allergies will be outgrown and which are more likely to be lifelong.

CLINICAL PEARLS

Important Diagnostic Considerations

- The patient's history should support a diagnosis of immunoglobulin E (IgE)–mediated food allergy before performing either serum-specific IgE testing or the skin prick test.
- 95% predictive probability cutoffs have been established for only a few foods, including cow's milk, hen's egg, and peanut.
- Even with negative specific IgE serum testing or skin testing, the patient could be allergic if he or she has a convincing history. In this case a physician-supervised oral food challenge (OFC) may be required to confirm the presence or absence of an IgE-mediated food allergy.
- Testing for food allergies should be limited to the food(s) in question, since positive IgE tests are not always clinically relevant. Unnecessary avoidance of foods may lead to nutritional deficiencies.

Cow's milk is typically one of the first foods introduced to infants in the form of infant formula; it is present in diets across cultural groups and is one of the most common allergens globally. Fortunately, cow's milk allergy is typically outgrown without intervention. Studies of natural resolution vary but about 50% of children with a milk allergy develop tolerance between 5 and 10 years of age.[13] High levels of milk-specific IgE generally indicate a higher likelihood of persistent disease, but as many as 60% of children whose milk-specific IgE level peaks at over 50 kU/L will achieve natural tolerance by age 18 years. Up to 75% of children with reactions to uncooked milk can tolerate baked milk products. Consumption of heated milk products has been associated with accelerated acquisition of tolerance.[14]

Hen's egg allergy is another common food allergen across cultural groups. Most of the allergenic proteins in hen's eggs are in the egg white. Allergy typically develops in the first year of life, while in some children, especially those with atopic dermatitis, it may develop before 4 months of age.[13] Similar to cow's milk allergy, egg allergy usually resolves during childhood without intervention. Roughly 50% of individuals with egg allergy in infancy develop natural tolerance between 6 and 9 years of age. Baked egg is tolerated by approximately 70% of children with egg allergy.[15] Individuals who can tolerate baked egg are likely to develop tolerance to lightly cooked egg sooner compared with individuals who are unable to tolerate baked egg.[16]

Although the majority of individuals who are allergic to peanuts will remain reactive throughout life, approximately 20% of individuals with peanut allergy may develop natural tolerance. Favorable prognostic factors include low levels of peanut-specific IgE antibodies in the first 2 years of life and decreasing levels of IgE sensitization by 3 years. Those with peanut-specific IgE $\geq$ 3 kU/L and skin prick test (SPT) wheal diameter >6 mm before 2 years of age are more likely to have persistent a peanut allergy.[17]

Allergy persistence, regardless of the food allergen, has been associated with the following factors: (1) earlier age at diagnosis; (2) concomitant presence of other allergic diseases (e.g., allergic rhinitis, asthma, and eczema); (3) severity of those allergic diseases; (4) symptom severity after ingestion; and (5) lower threshold dose required to elicit a reaction. The higher the food-specific IgE level, the more likely it is that the allergy will persist. In clinical practice, food-specific IgE levels are typically checked yearly except in patients whose specific IgE levels remain high and unchanged over several years.

DIAGNOSIS

The diagnosis of food allergy begins with obtaining a detailed medical history.[6] Food-induced allergic reactions result in reproducible characteristic symptoms, as described above. Validated testing modalities are only available for IgE-mediated food allergies and celiac disease. If the clinical history does not support either diagnosis, then food allergy serum or skin testing should not be done, since there is a risk of finding sensitization to allergens that are not clinically relevant and multiple studies have shown the dangers of unnecessary dietary avoidance. When the clinical history does support a diagnosis of food allergy, this can be confirmed by SPTs and detection of specific IgE in serum.

SPTs to food allergens can be performed in the office setting and are both safe and effective, with results being available within minutes. A positive result of the SPT reflects the presence of specific IgE bound to the surface of cutaneous mast cells, but as with serum IgE testing, a positive test result does not always indicate clinical reactivity. A positive test result is generally interpreted as 3 mm larger than the negative SPT control, and the larger the SPT mean wheal diameter, the more likely it is indicative of a clinically relevant response. Negative SPT results have been associated with a high negative predictive value and may lead the physician either to offer an observed OFC or to counsel the patient on dietary reintroduction, depending on the clinical history and circumstances.

Serum-specific IgE testing is useful in providing an objective measure of food-specific IgE antibody, especially if the patient cannot stop antihistamine therapy or has extensive skin disease making it impossible to perform the SPT, and serum IgE testing may be helpful in counseling patients on the natural history of their food allergy. Predictive values have been established for a limited number of foods. Higher specific IgE levels are more likely to be associated with clinical reactivity, but the predictive value of specific IgE levels varies across patient populations and is affected by such factors as the patient's age, ethnicity, and time since last ingestion of allergen. Specific IgE levels may also help physicians decide when an OFC is or is not appropriate.

The component-resolved diagnostic (CRD) test uses allergenic proteins derived from recombinant DNA technology or purification from natural sources to identify the patient's specific IgE reactivity to individual allergenic proteins rather than to the whole allergen. Diagnostic accuracy can be enhanced in specific circumstances (*e.g.*, for peanuts and hazelnuts).[18] However, CRD is not routinely used for diagnosis and has not been shown to provide significant additional clinical information for most allergens. CRD for peanuts and hazelnuts provides additional diagnostic information that is helpful to the clinician, but standardized decision-making cutoffs have not yet been established.

The basophil activation test (BAT) uses flow cytometry to detect upregulation of cell-surface molecules, such as CD63 and CD203c, after stimulation with allergen.[19] BAT has been reported to be superior to the SPT, the CRD test, and the whole-allergen-specific IgE test for diagnosis of peanut allergy; however, testing has not been standardized. Further research is needed to standardize the BAT and validate results with various food allergens.

The OFC remains the gold standard for the diagnosis of food allergy.[20] OFCs can be conducted in an open manner; with a placebo control, where the patient is blinded to the product

being given; or in a double-blinded manner, with both the physician and patient blinded to the food being given to the patient. An open OFC is most commonly performed in clinical practice, while the double-blind, placebo-controlled food challenge (DBPCFC) is considered the diagnostic standard typically reserved for research studies. During the OFC, a standard serving size of the allergen is divided into 4 to 7 servings and administered over 60 to 90 minutes, with each dose being given 15 to 20 minutes apart. The initial amount fed to the patient is typically a very small proportion of the total serving, and each successive dose administers a larger amount of protein. At the first sign of an objective reaction, the OFC is stopped and appropriate treatment administered. In cases where anxiety or subjective symptoms may affect the interpretability of the OFC, a single-blind or DBPCFC may be preferred.

MANAGEMENT

The patient with a food allergy must maintain strict avoidance of the food allergen to prevent an allergic reaction. Accidental ingestion is common, with reports showing that as many as 50% of children with a peanut allergy may experience an adverse reaction in a 2-year period, while up to 75% have this experience over 10 years.[6] Individuals with food allergies and their caregivers must read ingredient labels carefully, prevent cross-contact, communicate with restaurant staff when eating outside of the home, and be prepared to treat a reaction, when necessary.

Food allergy labeling laws in the United States require that the presence of the most common allergens (milk, egg, peanut, tree nuts, wheat, soy, fish, and crustacean shellfish) must be declared in simple English on the ingredient labels of all packaged foods. Individuals allergic to foods other than the eight most common allergens may have more difficulty with interpretation of ingredient labels. Ingredient labels may report "spices" or "natural flavors," which could include a multitude of foods or food products not covered by food allergy labeling laws. Statements such as "may contain [allergen]" and "manufactured on shared equipment with [allergen]" are voluntary and not regulated. Allergen content in such products is unknown, and it is typically recommended that individuals with allergies avoid products with "may contain" labeling.

Children with milk allergy or with two or more food allergies have been shown to be at particular risk of growth deficiency. Nutritional counseling with a registered dietitian is encouraged for these patients. A registered dietitian will help educate the patient and his or her family on avoidance of food allergens, in addition to providing guidance on nutrient supplementation to avoid potential dietary deficiencies.

TREATMENT OF A REACTION

An acute reaction must be recognized and treated expeditiously. Food-induced fatalities are most commonly reported from ingestion of peanuts and tree nuts, but any food allergen can induce a severe reaction. Fatalities have been associated with delay in administration of auto-injectable epinephrine, preexisting and/or poorly controlled asthma, and concomitant use of beta-blocker medications; there is increased mortality in teen and young adult age groups. Intramuscular auto-injectable epinephrine must be readily available to patients with IgE-mediated food allergies and is the first-line treatment for a food-induced allergic reaction. Patients with food allergies are encouraged to have a written emergency action plan that lists the signs and symptoms of an allergic reaction and details treatment of those symptoms.

PREVENTION OF FOOD ALLERGY

Exposure to antigen early in life is likely important for shaping the appropriate immune response to foods. Primary exposure through the oral route is believed to predispose patients to the development of a tolerogenic response, whereas primary exposure through skin may result in sensitization.[21] Support for the theory of prevention through primary oral exposure has been strongly supported through epidemiological studies showing that some cultural groups that introduce peanuts to their children in the first year of life have a lower incidence of peanut allergy.[22] This theory has been strengthened by evidence demonstrating that children identified as being at high risk of developing peanut allergy (severe atopic dermatitis and/or egg allergy) are substantially protected against the development of peanut allergy if they regularly ingest peanuts from between 4 and 11 months of age through 60 months of age, compared with matched controls who avoid peanuts.[23] Based on the results of this study, it is globally recommended to introduce peanut in an infant-safe form into the diet of high-risk infants (as defined above) between 4 and 11 months of age, and both Australian and British allergy societies also recommend early introduction of egg into the diet of high-risk infants to prevent the development of egg allergy.[23] Data to support introduction of other allergens into the diet to prevent development of those food allergies is lacking; however, there is no evidence that suggests delayed introduction of allergenic solids is beneficial. Ongoing studies may reveal whether reduction in the risk of AD development may prevent food allergy development.

The role of the microbiome's contribution to food allergy development is an intense area of study. Microbial products in the gut flora interact with innate immune receptors, such as Toll-like receptors (TLRs) and relay signals implicated in the activation of regulatory T cells (Tregs), which are important in the promotion of tolerance. Activation of a specific TLR using nonpathogenic bacteria (probiotics) could conceivably prevent allergic disease. Unfortunately, data on probiotic supplementation for food allergy is insufficient at this time to offer any specific recommendations.[24]

EXPERIMENTAL INTERVENTIONAL THERAPIES

The standard of care for IgE-mediated food allergy is avoidance of the potentially triggering allergen, treatment of a reaction with autoinjectable epinephrine, and dietary supplementation of potentially deficient nutrients in the diet of the patient with a food allergy. Allergen-specific immunotherapies are currently under investigation utilizing the oral, sublingual, and epicutaneous routes for the application of the allergen. The US Food and Drug Administration (FDA) has approved a regulated oral immunotherapy product for peanut allergy at the time of this writing, and it is anticipated that more FDA-approved products will soon follow.

Oral Immunotherapy

Oral immunotherapy (OIT) is accomplished by mixing the allergenic food into a vehicle food, initially giving doses below the level that would trigger reactions in an allergic individual and

gradually increasing the amount of protein ingested over time. The buildup phase of therapy typically lasts several months; once a maintenance dose of allergen is achieved, the patient must ingest the allergen for a certain period (typically ≥1 year, possibly indefinitely) to maintain a protected, desensitized state. Most studies have focused on achievement of desensitization, which refers to a temporary increase in the threshold of allergen required to elicit a reaction and is dependent on regular exposure to the allergen.

OIT will induce significant desensitization in most patients who are able to tolerate therapy. The largest OIT trial to date showed that 67.2% of participants by intention-to-treat were desensitized (defined by ability to ingest 600 mg of peanut protein without dose-limiting symptoms) after 6 months of daily ingestion of 300 mg of peanut protein, compared to 4% of placebo-treated subjects.[25] Most individuals undergoing OIT will experience adverse reactions at a greater frequency than patients practicing avoidance, though adverse reactions are typically mild and tolerable. Transient abdominal pain and oral pruritus are the most common problems reported across OIT studies; reactions do not typically require any treatment. Severe reactions, such as anaphylaxis, may develop during therapy; predisposing factors include infection, exercise, and allergen co-exposure. GI symptoms and anaphylaxis are the most common reason for participants withdrawing from OIT trials, and EoE has occasionally been documented. Sustained protection against an allergic reaction, independent of ongoing allergen exposure (sustained unresponsiveness [SU]), has not been adequately measured; only a minority of individuals achieved SU in the few studies measuring this outcome.[25] Further work is needed to determine which patients are most likely to develop SU, who will tolerate OIT with few dose-limiting adverse events, and the mechanisms underlying the development of desensitization and SU.

The initial immune response detected in desensitization includes an increase in food-specific IgG4, decreased basophil and mast cell responsiveness, and an initial increase in allergen-specific IgE. Allergen-specific IgE then decreases gradually over time. After 6 to 12 months of therapy there appears to be a shift away from Th2 cytokine production in response to allergen toward a Th1 profile. Treg upregulation occurs later in the course of OIT, with studies showing increased function of antigen-specific $CD4^+CD25^+$ $FOXP3^+$ Tregs. Epitope mapping typically changes over time indicating different antigen-specific responsiveness. Unfortunately, there are no biomarkers that consistently predict successful desensitization or SU.

Sublingual Immunotherapy

Sublingual immunotherapy (SLIT) utilizes a food protein dissolved in a liquid medium and delivered beneath the tongue. The oral mucosa contains tolerogenic APCs: SLIT is thought to rely on these cells to induce a desensitized state. SLIT dosing utilizes microgram to milligram quantities of protein, whereas OIT protocols utilize gram quantities of protein. Increasing the amount of allergen given is limited by the concentration of available extracts and the volume of liquid that can be held sublingually.

Peanut allergy with SLIT has been more closely studied than SLIT for other food allergies. Peanut SLIT treatment in both children and adults has shown an ability to raise the dose-triggering threshold while on therapy for the majority of participants.[25] The most commonly reported complaint is transient oropharyngeal itching and systemic reactions are rare.

Few studies have compared SLIT with OIT; current evidence indicates that SLIT has fewer side effects compared with OIT but SLIT does not appear to induce a similar level of desensitization or achieve SU as often as OIT; however, SLIT has not been as closely studied as OIT with many fewer participants receiving SLIT in randomized, controlled trials. Additional studies are needed to reveal whether adjuvant therapy with SLIT increases efficacy and to understand whether SLIT could be combined with OIT to improve its safety.

THERAPEUTIC PRINCIPLES

Avoidance

- Read ingredient labels closely. The eight most common food allergens are required to be disclosed on ingredient labels of foods manufactured and sold in the United States.
- Minimize cross-contact with food allergens during meal preparation.
  - Use utensils, cutting boards, and pans that have been thoroughly washed with soap and water.
  - If you are preparing several foods, make the allergy-safe food first.
  - Wash hands with soap and water before touching anything else if you have handled a food allergen.
  - Wash counters and table with soap and water after making meals.
- When eating at a restaurant, inform the waiter and cooking staff about food allergens.
- Avoid buffets.

Treatment

- Advise patients at risk of anaphylaxis to carry two auto-injectable epinephrine devices at all times.
- Recommend a medical identification bracelet.
- Provide an anaphylaxis emergency plan, and review indications for administration of auto-injectable epinephrine.
- Demonstrate the appropriate use of auto-injectable epinephrine with a trainer device at the physician's clinic visits.
- FDA-approval of a regulated peanut oral immunotherapy product may provide a therapeutic option for some patients.
- Actively engage patients and their families when discussing the pros and cons of interventional therapy versus continued avoidance.

Epicutaneous Immunotherapy

Epicutaneous immunotherapy (EPIT) delivers allergen to the skin through daily application of an allergen-containing patch. Langerhans cells in the skin are activated and effector cell responses are downregulated. A phase 3 trial for peanut EPIT reported 35.3% of peanut EPIT subjects responded to 12 months of treatment compared to 13.6% of subjects receiving placebo.[25] Despite the statistically significant difference in groups, the difference in responder rates did not meet a prespecified confidence interval boundary for the study to be considered positive. The most common side effect of EPIT a is an eczematous response at the site of patch application. Eight subjects in the phase 3 trial reported anaphylaxis from the peanut patch. SU has not been closely studied with EPIT use. Surrogate biomarkers do not predict response to therapy and at the present time an OFC is necessary to gauge treatment response.

Diagnosis of food allergy is reliant on an understanding of its pathogenesis and proper application of available diagnostic tools. Management of food allergy requires education about avoidance of the allergenic food(s), dietary supplementation of missing nutrients, and recognition and early treatment of any allergic reactions. Although food allergy has increased in prevalence over the past two decades, preventive strategies, including

ON THE HORIZON

- Oral immunotherapy (OIT) exposes the allergic patient to progressively larger doses of ingested allergen in an effort to induce a desensitized state. Gram quantities of allergen are typically administered. Side-effects, though typically mild, are common and significant treatment burden may prevent wide-spread adaptation.
- Epicutaneous immunotherapy (EPIT) applies microgram amounts of allergen directly to the allergic patient's skin, resulting in an effort to increase the threshold of reactivity. EPIT patch is typically kept on skin for up to 24 h at a time, and a new patch is applied daily. Therapeutic benefit is not as consistent as the benefit reported with OIT; however, the therapy is safe with few severe adverse effects reported.
- Sublingual immunotherapy (SLIT) involves sublingual administration of milligram quantities of allergen solubilized in a liquid formulation. Systemic reactions are rare. However, few studies have rigorously investigated SLIT for treatment of food allergy.

early introduction of allergenic solids, may help curb this as yet unexplained epidemic. As our knowledge of food allergy grows, we can expect significant changes in our approach to the treatment of those affected in the years to come.

Drug Hypersensitivity

Shyam R. Joshi, Whitney Salinas and David A. Khan

Drug therapy requires an understanding of the fine line between the beneficial and harmful effects of the drug. While the majority of adverse drug reactions (ADRs) are predictable (type A reactions or "on target"), drug allergies are difficult to foresee, hence their designation as type B (*bizarre* or "off target") ADRs. Any drug is assumed to be capable of eliciting these types of reactions; however, the frequency differs widely, with antibiotics being the most common offender. Multiple factors play a role in the risk and severity of reactions, including the class of drug, dose, administration route, frequency, and duration of exposure, and the genetic predisposition of the subject, particularly with human leukocyte antigen B (HLA-B) alleles.

Drug hypersensitivity reactions can be a significant source of morbidity and mortality in clinical practice. Beyond a thorough clinical history, the tools available for identifying and diagnosing hypersensitivities are currently limited; however, accurate diagnoses are still possible and important to help protect patients from re-exposure to the culprit medication. Drug allergy labels can also often prohibit patients from receiving first-line therapies, and, therefore, previously diagnosed drug allergies should always be questioned.

EPIDEMIOLOGY

ADRs are common and occur in approximately 15% to 25% of patients.[1] This includes predictable pharmacologic side effects and account for 3% to 6% of all hospital admissions.[2] Hypersensitivity reactions, however, are considerably less common and account for only 5% to 10% of all ADRs. The true overall incidence of drug allergy remains unknown, as the available epidemiologic studies typically focus on select populations or specific subtypes of drug allergies. In addition, the heavy reliance on historical information and lack of standardized clinical questionnaires or confirmatory diagnostic testing complicates the interpretation of these studies.

ADRs occur more frequently in females with a 2:1 predominance, although there has been a higher prevalence of acute interstitial nephritis and fixed drug eruptions in males.[3] Overall, ADRs are most common in white races, although there have been select racial associations to certain ADRs: Black people have a higher prevalence of angiotensin converting-enzyme inhibitors (ACE-I) induced angioedema, while Asians have a higher prevalence of fixed drug reactions and severe cutaneous drug reactions (SCARs).[3] In regard to age groups, the incidence is less understood but seems to increase with age, likely due to increased drug exposure; however, elderly hospitalized patients appear to have a lower incidence of anaphylaxis and SCARs.[4]

Approximately half of reactions occur immediately (within 6 hours of last exposure) with the most common reported symptom being urticaria followed by itching and angioedema. Rashes are also the most frequently encountered delayed (>6 hours after exposure) hypersensitivity symptom. Of the delayed reactions, SCARs are very rare, affecting approximately 0.4% of the population, but do account for a significant portion of mortality associated with drug allergies.[3]

While any drug can elicit hypersensitivity reactions, the most frequently implicated are antibiotics, nonsteroidal anti-inflammatory drugs (NSAIDs), antiepileptics, chemotherapeutics, and radiocontrast media (RCM). Penicillin is the most commonly reported of all drug allergies at approximately 10% of the general population.[5]

IMMUNE SYSTEM RECOGNITION OF DRUGS

Drug allergies can present in a multitude of ways, which will be discussed later in this chapter. The initial recognition of a drug as a foreign antigen by the immune system remains an important step in this process. This is dependent on the structure, shape, and multimeric/multivalent presentation of the drug. Four hypotheses have been proposed to explain how drugs interact with HLA and T-cell receptors (TCRs) in the development of hypersensitivity reactions. These include (1) the hapten theory, (2) the direct pharmacologic interaction with immune receptor (p-I) concept, (3) the altered peptide repertoire model, and (4) the altered TCR repertoire model (Fig. 50.1).[6] It should be noted that these models are not mutually exclusive and can occur simultaneously during a drug reaction.

RISK FACTORS FOR DRUG ALLERGY

Drug-Related Factors

The immunogenicity of a drug is based on several factors, with its ability to be recognized by the immune system likely being the most important. The manufacturing process of the drug and the metabolic processes that occur within the body after administration can lead to undesired byproducts that can be highly immunogenic. Drug-specific risk factors for hypersensitivity reactions include higher doses, parenteral administration, intermittent and repeated doses compared to uninterrupted treatment, and concurrent illness.

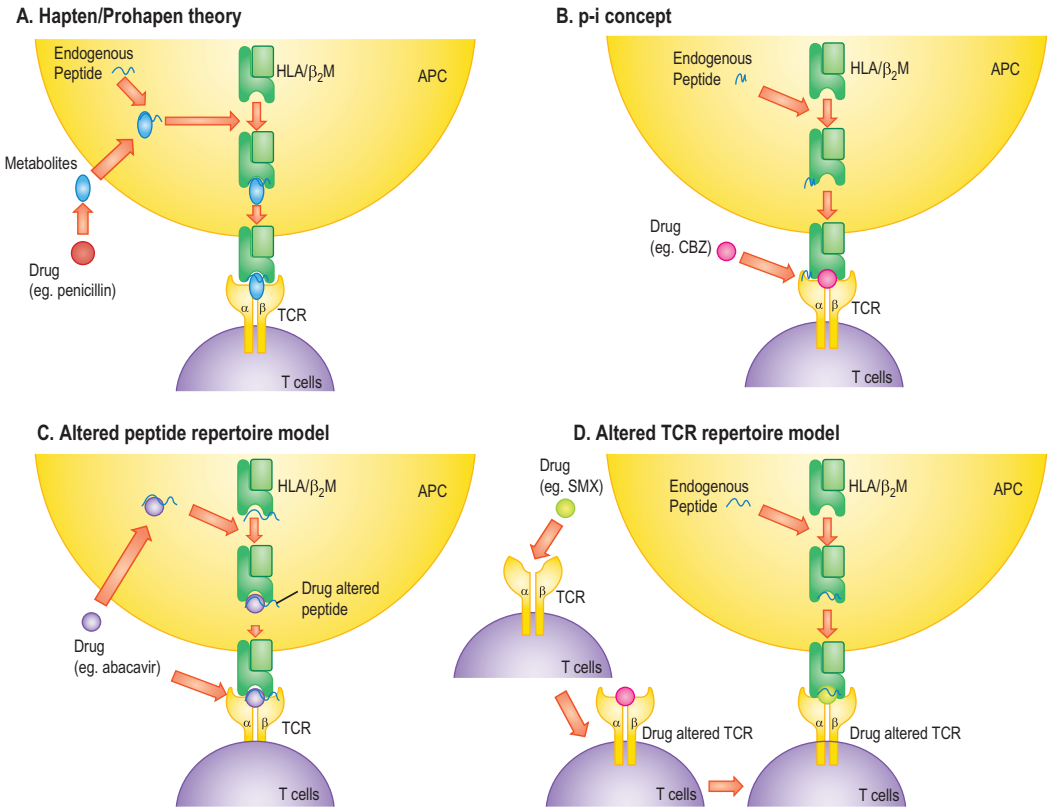

FIG. 50.1 Four proposed hypotheses on how drugs interact with human leukocyte antigen *(HLA)* and T-cell receptor *(TCR)* in the development of hypersensitivity reactions. (A) The hapten theory: drugs or their metabolites bind to endogenous proteins as haptens. This forms the HLA-peptide-drug complex in the antigen-presenting cell (APC) which is presented to and recognized by TCR leading to drug-specific T-cell activation. (B) The p-I concept: drugs directly bind to the HLA-peptide complex or TCR without intracellular processing in the APC. (C) The altered peptide repertoire model: small molecules directly bind to the MHC peptide-binding groove, altering the specificity of the binding cleft and allowing a novel presentation of the peptide. (D) Altered TCR repertoire model: drugs can bind directly to the TCR, allowing it to recognize HLA-self peptide complexes. (Adapted from Chung W, Wang C, Dao R. Severe cutaneous adverse drug reactions. *J Dermatol.* 2016;43:758–766.)

Host Related Factors

Women have consistently been shown to report drug allergies more frequently than men, but this propensity has not been thoroughly investigated.[3] The risk of drug allergy is lower in children, but this may be due to their infrequent exposure to drugs. Conversely, children with chronic medical conditions, such as cystic fibrosis, have a significantly higher rate of reported drug allergies to antibiotics, which has been suggested to be caused by their repeated exposure to these medications.[7–12]

Underlying disease states may increase the risk of drug hypersensitivity reactions with human immunodeficiency virus (HIV) being a prominent example. These patients are at particularly high risk for reactions to sulfonamide antibiotics, abacavir, and nevirapine, which appears to be related to the degree of immunodeficiency.[2, 13]

About 25% of women who are treated with carboplatin for gynecological cancers become sensitized after multiple exposures and then develop type I immunoglobulin E (IgE)–mediated reactions, most of which are anaphylactic. Since women with BRCA1 and BRCA2 mutations seem more prone to carboplatin reactions after fewer exposures, it is possible that these genetic mutations facilitate T-cell presentation.[14]

Heterologous responses to viral infections, in the context of specific HLA alleles, have been implicated in severe skin reactions. The induction of this type of drug hypersensitivity requires an HLA risk allele, a primary infection with human (HHV) or other viruses in the context of that HLA risk allele, polyclonal expansion of CD8 T cells, and the induction of memory T cells. Upon exposure to the drug, the interaction with HLA induces neoantigens, and the peptide–MHC complex is recognized by the TCR, triggering activation of T cells (Fig. 50.2).

Atopy does not appear to be a major risk factor for most drug allergies. The presence of autoimmunity as a risk factor remains unclear and additional studies are needed to further explore this association.

Genetics of Drug Allergy

Genetic studies have mainly focused on the area of HLA genotypes and their association with severe drug hypersensitivity. HLA molecules function as antigen presenters to the TCR and are categorized as HLA Class I (HLA A, HLA B, HLA C) or HLA Class II (HLA DP, HLA DQ, HLA DR). Specific HLA types have been associated with SCARs, which are outlined in Table 50.1.

The best examples include abacavir hypersensitivity syndrome and its association with HLA-B*57:01, carbamazepine-induced SJS/TEN associated with HLA-B*15:02, and allopurinol-induced DRESS/HSS/SJS/TEN associated with HLA-B*58:01. Routine HLA B*57:01 screening is now performed prior to initiation of abacavir therapy.[15] Recently, HLA-A*32:01 has been identified as a risk allele for vancomycin-induced DRESS.[16] HLA screening

Diclofenac	DILI	HLA-B11, C-24T, UGT2B7*2, IL-4 C-590-A			European
Flucloxacilin	DILI	B*57:01, DRB1*01:07-DQB1*01:03	0.12%	99.99%	European
Lapatinib	DILI	DRB1*07:01-DQA2*02:01-DQA1*02:01			International, multicenter

DILI, Drug-induced liver injury; *DRESS*, drug-induced reactions with eosinophilia and systemic symptoms; *HSS*, hypersensitivity syndrome; *MPE*, maculopapular eruption; *SJS*, Stevens-Johnson syndrome; *SNP*, single nucleotide polymorphism; *TEN*, toxic epidermal necrolysis.
From White KD, Chung W-H, Hung S-I, *et al.* Evolving models of the immunopathogenesis of T cell-mediated drug allergy: the role of host, pathogens, and drug response. *J Allergy Clin Immunol.* 2015; 136: 219–234.

will likely become more common for the prevention of hypersensitivity reactions in at-risk populations.

There are also non-HLA-related genetic associations that have been studied including single-nucleotide polymorphisms (SNPs) in IL-13 and the α chain of IL-4 that has been linked to immediate-type hypersensitivity reaction to β-lactams.[17] Other drugs associated with pharmacogenetic associations for immediate reactions include aspirin, NSAIDs, asparaginase, and infliximab.

HYPERSENSITIVITY REACTIONS

Historically, drug reactions were classified based on their immunologic mechanism, as defined by Gell and Coombs in 1968, into types I-IV, the last of which has been further subdivided into type IV a–d (Table 50.2). This classification system is useful; but unfortunately, not all drug reactions can be neatly categorized into a specific type. Examples of well-categorized hypersensitivities are demonstrated in Fig. 50.3.

Type I IgE-Mediated Hypersensitivity

Type I hypersensitivity reactions are classically referred to as IgE-mediated reactions; however, non-IgE-mediated mechanisms have also been described such as IgG-related activation of mast cells and basophils as well as direct mast cell activation, the latter of which is discussed later in this chapter.

TABLE 50.2 Immunologic mechanisms for drug hypersensitivity reactions type I-IV

Classification	Type I	Type II	Type III	Type IVa	Type IVb	Type IVc	Type IVd
Common name	IgE mediated	Antibody dependent	Immune-Complex	Delayed-type hypersensitivity, cell-mediated, antibody-independent			
Onset time	Minutes	Hours to days	Hours to days	Days to weeks			
Immune reactant	IgE	IgG	IgG	CD4 Th1	CD4 Th2	CTL	CD4 Th17
Effector	Mast cell/basophil activation	Phagocytes and NK cells	FcR^+ cells complement	Macrophage activation	Eosinophils	T cells	Neutrophils
Picture							
Example	Anaphylaxis, urticaria	Hemolytic anemia, thrombocytopenia	Serum sickness, arthus reaction, Drug fever, vasculitis	Tuberculin reaction, sarcoidosis	DRESS, maculopapular exanthema	SJS/TEN	AGEP

AGEP, Acute generalized exanthematous pustulosis; *IgE*, Immunoglobulin E; *NK*, natural killer; *SJS*, Stevens-Johnson syndrome; *TEN*, toxic epidermal necrolysis.

FIG. 50.3 Examples of hypersensitivity reactions: (A) Urticaria seen with type I hypersensitivity. (B) Epidermal detachment in toxic epidermal necrolysis (TEN) seen with type IVc hypersensitivity. (C) Mucousal involvement in Stevens-Johnson syndrome/TEN seen with type IVc hypersensitivity. (D) Acute generalized exanthematous pustulosis seen in type IVd hypersensitivity.

For IgE-mediated reactions, the sensitization phase is thought to occur mainly through the hapten mechanism, resulting proliferation and differentiation of drug-specific B cells into plasma cells, and ultimately drug-specific IgE production. The sensitization process takes several days, which is why patients typically do not react to drugs on initial exposure. Upon re-exposure to the offending drug, polyvalent haptenated allergens crosslink the high affinity IgE receptor, FcεRIα, on mucosal and connective tissue mast cells and blood basophils that have drug-specific IgE bound on their surface. This results in cell activation and degranulation with the release of preformed mediators such as histamine, tumor necrosis factor-α (TNF-α), and tryptase. Within minutes, membrane arachidonic acid releases leukotrienes (LTs) and prostaglandins (PGs), and within hours, newly generated cytokines such as IL-4 and IL-13 are also released to augment the Th2 response.

Symptoms of type I mediated reactions, such as urticaria, cardiovascular collapse, and bronchospasm, are directly correlated to the release of these vasoactive mediators. Reactions can be limited to one system, such as the skin, or can involve multiple systems. Despite a lack of consensus for the diagnostic criteria for anaphylaxis, the most commonly used definition is involvement of two or more organ systems. The World Allergy Organization's grading system for systemic adverse reactions highlights common symptoms seen in type I hypersensitivity reactions. The presence of urticaria is useful in detecting IgE-mediated hypersensitivity, as the wheal and flare are a direct result of mast cell degranulation; although, the lack of urticaria does not rule out an IgE-mediated allergy.

KEY CONCEPT

World Allergy Organization Systemic Allergy Reaction Grading System for Anaphylactic Reactions.

Grade	Description
1	Symptoms of 1 organ system involved: • Cutaneous: pruritus, urticaria, tingling/itching of lips, angioedema (not laryngeal) OR • Upper respiratory: nasal symptoms, throat clearing, cough (not bronchospasm)
2	Symptoms from ≥2 organ systems listed in grade 1
3	Symptoms involving ≥2 organ systems including: • Lower airway: mild bronchospasm (cough, wheeze, or shortness of breath that responds to treatment) OR • Gastrointestinal/Genitourinary: abdominal/uterine cramps, vomiting, or diarrhea • Any symptoms from grade 1
4	Symptoms involving ≥2 organ systems including: • Lower airway: Severe bronchospasm (not responsive to treatment) • Upper airway: laryngeal edema with stridor • Any symptoms from grade 1 or 3
5	Symptoms involving ≥2 organ systems including: • Lower or upper airway: respiratory failure • Cardiovascular: hypotension, loss of consciousness (vasovagal excluded) • Any symptoms from grades 1, 3, or 4

From Cox LS, Sanchez-Borges M, Lockey RF. World Allergy organization systemic allergic reaction grading system: is a modification needed?. *J Allergy Clin Immunol Pract.* 2017;5(1):58–62.

Type I hypersensitivity is generally considered an immediate-type reaction with symptoms often occurring within seconds of parenteral exposure or within minutes of oral administration. Symptoms generally occur upon the first dose after sensitization, and not days into the course, unless there are breaks in the treatment course. Symptoms occurring ≥6 hours after drug exposure are likely not IgE-mediated, although very rarely IgE-mediated reactions can occur up to 24 hours after exposure.[18] Elevation of serum inflammatory markers and fever are not commonly seen in IgE-mediated reactions and alternative causes should be considered.[19] Common implicated drugs include β-lactam antibiotics, neuromuscular blocking agents (NMBAs), platinum based chemotherapeutics, and chimeric and non-chimeric monoclonal antibodies (mAbs). The diagnosis and management of type I reactions are discussed later in this chapter.

Type II Antibody-Dependent Hypersensitivity

Type II responses require the development of specific IgG (specifically IgG1 and IgG3 subclasses) or IgM in response to a drug hapten-carrier complex. These antibodies bind directly to Fcγ receptors on macrophages, natural killer (NK) cells, platelets, or granulocytes. The antibody specificity is directed against antigens on the cell membranes of erythrocytes, leukocytes, platelets, or other cell membranes or tissues that are either destroyed or sequestered within the liver and spleen via complement fixation. Typically type II, in addition to type III, reactions are in the setting of high-dose and prolonged drug administration (Table 50.3).

Heparin-induced thrombocytopenia (HIT) is a prime example of a type II reaction and occurs when IgG and IgM immune complexes form with heparin and platelet factor 4 (PF4), leading to platelet activation through the FcγRIIa receptor. Activated platelets then release PF4 that causes platelet destruction and thrombocytopenia. This typically occurs 5-14 days into the treatment course and is more frequently encountered with unfractionated heparin compared to low molecular weight heparin.

Type III Immune-Complex Hypersensitivity

Immune complexes are created in the presence of drugs that form hapten-carrier complexes, which then bind to endothelial cells, leading to complement activation in small blood vessels, joints, or renal glomeruli. Typically, these complexes appear 4 to 10 days after initial exposure and interact with drug antigens,

TABLE 50.3 Type II Hypersensitivity Reaction Presentation and Common Culprits

Condition	Presentation	Common Drug Culprits
Drug-induced hemolytic anemia	Pallor, fatigue, dyspnea, dark urine, splenomegaly, signs of hyperdynamic state	Penicillins, cephalosporins, NSAIDs, quinine-quinidine
Drug-induced thrombocytopenia	Petechial rash, epistaxis, bleeding gums, hepatosplenomegaly	Heparin, abciximab, quinine-quinidine, sulfonamides, vancomycin, gold compounds, penicillins, cephalosporins, carbamazepinee, NSAIDs
Drug-induced neutropenia	Symptoms of infection including fever, sepsis, pneumonia, pharyngitis, stomatitis	Propylthiouracil, flecainide

NSAIDs, Nonsteroidal anti-inflammatory drugs.

TABLE 50.4 Type III Hypersensitivity Reaction Presentation and Common Culprits

Condition	Presentation	Common Culprits
Serum sickness	Fever, urticarial or pruritic rash, arthralgias, lymphadenopathy, and/or acute glomerulonephritis.	Penicillins, cefaclor, trimethoprim-sulfamethoxazole
Vasculitis	Fever, petechiae/palpable purpura, myalgias, arthralgias, lymphadenopathy. GI tract and kidneys can be involved.	Penicillins, cephalosporins, sulfonamides including diuretics, phenytoin, allopurinol
Drug-induced lupus erythematosus	Fever, myalgias, arthralgias, rash, serositis. Liver and kidney can be involved.	Procainamide, hydralazine, minocyline
Arthus reaction	Painful local swelling and erythema to site of injection	Tetanus, diptheria, hepatitis B vaccines

forming circulating immune complexes. Symptoms typically develop one to two weeks after drug introduction. The clinical consequences of immune complex hypersensitivity can affect the GI tract, kidneys, joints, and skin.

Serum sickness (SS) was first described in the early 1900s when heterologous serum was used in the treatment of diphtheria and scarlet fever as an anti-toxin (Table 50.4).

Antigen-antibody complexes form and, if not cleared efficiently, deposit most commonly in parenchymal tissues and synovial joint fluid. This process activates the classical complement pathway, triggering histamine release and an increase in vascular permeability. Inflammatory cells infiltrate the tissue causing various types of rashes (sparing the mucous membranes), arthralgias, arthritis, lymphadenopathy, fevers, and nephropathy. Presently, SS is most often seen in transplant patients receiving anti-thymocyte globulin or in individuals receiving mAb therapy such as rituximab.

Serum sickness-like reactions (SSLR) are much more common than SS. Antibiotics are a leading cause of SSLR, but many other drugs can cause these reactions, including several biologics. While often characterized as type III reactions due to the clinical similarities with SS, immune complexes have not been identified in SSLR. The triad of fever, rash, and arthralgias is common in SSLR as it is in SS; however, renal involvement and hypocomplementemia are typically absent.

Type IV Delayed-Type Hypersensitivity

Unlike type I-III reactions that are antibody-mediated, type IV reactions are dependent on the activation and expansion of T cells. These reactions are subdivided into subtypes a-d based on the cytokines produced and effector cells involved. Given that these reactions are cell-mediated, the timing of symptom onset can be days to weeks after drug exposure. If a patient is re-exposed after an initial reaction, symptoms may appear quickly, possibly within 24 hours. The skin houses a large number of T cells that are primed memory-effector cells. These cells respond rapidly to immunogenic agents, resulting in skin rashes, which is the most commonly encountered manifestation for this type of hypersensitivity reaction.[3]

Type IVa Reactions

Type IVa reactions are characterized by T helper 1 (Th1) cells stimulating macrophages through the release of interferon-γ and TNF-α. Activated macrophages can cause local cutaneous-only or systemic inflammatory responses. Examples of type IVa reactions include tuberculin reaction, allergic contact dermatitis, and sarcoidosis.

Type IVb Reactions

Type IVb reactions, on the other hand, are associated with type 2 inflammation. Eosinophils, mast cells, and IgE- and IgG4-producing B cells are promoted through Th2 release of IL-4, IL-5, IL-13, and eotaxin.

Maculopapular exanthema is the most common delayed-type hypersensitivity reaction causing a benign moribilliform rash occurring 4 to 9 days after drug exposure.

Another example of a type IVb reaction is DRESS, which is a rare, life-threatening drug reaction typically involving a rash, hematologic abnormalities such as leukocytosis with eosinophilia and/or thrombocytopenia, internal organ involvement (most often liver), and lymphadenopathy. Frequently implicated drugs include allopurinol, carbamazepine, lamotrigine, phenytoin, sulfasalazine, vancomycin, minocycline, dapsone, and sulfamethoxazole with a latency period of 2 to 8 weeks. DRESS remains a clinical diagnosis which is supported by laboratory data and histologic findings. The European Registry of Severe Cutaneous Adverse Reactions (RegiSCAR) has developed a scoring system to help assist with the probability of diagnosis based on clinical criteria.

KEY CONCEPT

RegiSCAR criteria for diagnosis of DRESS

Primary Criteria

Must have 3 of the following:

- Fever >38°C
- Enlarged lymph nodes at a minimum of 2 sites
- Involvement of at least 1 internal organ
- Blood count abnormalities

Secondary Criteria

- Hospitalization
- Reaction is suspected to be drug related
- Rash
- Lymphocytes above or below normal range
- Peripheral eosinophilia
- Thrombocytopenia

Type IVc Reactions

Type IVc reactions occur due to the migration of activated drug-specific $CD8^{St}$ cytotoxic T cells to various tissues, leading to cellular apoptosis or death secondary to the release of granzyme and perforin or through the Fas-ligand dependent pathway. This results in the recruitment of additional inflammatory cells such as neutrophils, eosinophils, and monocytes. Examples of type IVc hypersensitivity reactions include Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN).

SJS and TEN are on a spectrum of bullous diseases and are distinguished from one another by disease severity and body surface involvement (Table 50.5). SJS/TEN is characterized by skin necrosis and detachment of the epidermis, usually involving ocular, oral, or genital mucous membranes. Commonly implicated drugs include allopurinol, aromatic antiepileptics, lamotrigine, antibiotics (sulfonamides, β-lactams, and fluoroquinolones), nevirapine, and NSAIDs with a latency

TABLE 50.5 Spectrum of Stevens Johnson Syndrome/Toxic Epidermal Necrolysis

Characteristic	SJS	SJS/TEN Overlap	TEN
% BSA	<10	10–30	>30
Mucosal involvement	Yes	Yes	Yes
Primary lesions	Dusky red lesions Flat atypical targets	Dusky red lesions Flat atypical targets	Poorly delineated erythematous plaques Epidermal detachment Flat atypical targets
Distribution	Face and trunk	Confluent on face and trunk	Confluent throughout the body
Systemic involvement	Usually	Always	Always
Mortality	10%	30%	50%

BSA, body surface area; *SJS*, Stevens Johnson syndrome; *TEN*, toxic epidermal necrolysis.

period of 4 days to 4 weeks. Complications seen with SJS/TEN are secondary to the loss of the protective skin barrier, which leads to massive fluid losses, infections, electrolyte imbalance, hypovolemic shock, and multiple organ dysfunction. There are many potential long-term sequelae of SJS/TEN, including ocular complications that can be sight-threatening, and oral, gastrointestinal, genitourinary, pulmonary, autoimmune, and psychiatric complications.

Type IVd Reactions

Type IVd reactions are characterized by drug-specific T cells producing IL-8 and granulocyte macrophage-colony-stimulating factor (GM-CSF), which induces neutrophil chemotaxis and inhibits cellular apoptosis, ultimately creating sterile neutrophilic inflammation. Acute generalized exanthematous pustulosis (AGEP) is an illustrative example, which is diagnosed clinically through the appearance of numerous sterile, pin-sized, non-follicular pustules with surrounding edematous erythema. It is often associated with fever and neutrophilic leukocytosis, and the onset of symptoms typically occurs between 24 hours and 10 days after drug exposure. Commonly implicated drugs include antibiotics, antimycotics, protease inhibitors and other antimicrobials such as hydroxychloroquine, nifuroxazide, and pyrimethamine.

Direct Mast Cell Activation

Another type of hypersensitivity reaction occurs via innate immune activation of mast cells and are referred to as pseudoallergic reactions. These are important to recognize as diagnosis and management may be drastically different.

Mas-Related G Protein-Coupled Receptor-X2 (MRGPRX2)

First recognized in 2015 by McNeil *et al.*, Mas-Related G Protein-Coupled Receptor-X2 (MRGPRX2) was found to be one of many mast cell receptors capable of recognizing endogenous and exogenous stimuli provoking degranulation.[20] MRGPRX2 is expressed in sensory neurons, mast cells (particularly MC_{TC} found in the skin), and keratinocytes. MRGPRX2-mediated responses seem to be more rapid but transient in comparison to IgE-triggered events. Several medications have been identified that activate mast cells through MRGPRX2 including NMBAs (except for succinylcholine), fluoroquinolones, vancomycin (Red Man syndrome), icatibant, leuprolide, and morphine. Single nucleotide polymorphisms may be linked with MRGPRX2 variants that could predispose individuals to hyperactivation of this receptor by changing its structure, although additional studies are needed to determine their exact significance in clinical practice.[21] Fig. 50.4 demonstrates the main receptor systems and examples of ligands involved in mast cell activation.

Cytokine Release Syndrome

Cytokine release syndrome (CRS) is most commonly associated with biologic and cancer therapies. Patients can develop acute symptoms that may be mistaken in some cases for anaphylaxis. The clinical presentation can range from mild symptoms, such as fever, nausea, vomiting, back pain, and/or erythema, to more severe manifestations including hypoxia, hypotension, organ failure, and even death. Proinflammatory cytokines such as IL-6, IL-10 and IFN-γ are often elevated and targeted therapies against IL-6 or its receptor have been shown to be effective, especially in association with CAR T-cell therapy.

DIAGNOSIS

A detailed history is the most important element in the diagnosis of all drug reactions. It is necessary to determine the type of reaction, the test(s) required to confirm or refute the diagnosis, and to establish a management plan. Diagnostic tools including skin prick testing, intradermal skin testing, patch testing, and *in vitro* testing have been utilized, although most are not standardized or validated, making their interpretation challenging. The gold standard remains an observed drug challenge, which should be considered only if there is uncertainty in the diagnosis after obtaining a detailed history and completing appropriate testing.

Tryptase

Activation of mast cells leads to degranulation and the release of histamine, tryptase, and several other important mediators. This process can be triggered by IgE-dependent or independent pathways and results in symptoms typical of a type I hypersensitivity reaction. After secretion from tissue mast cells, tryptase requires 30 minutes to reach peripheral blood. Its level peaks 1.5–4 hours after symptom onset, but in some patients with anaphylaxis, the level may remain elevated for >24 hours. If the tryptase level is found to be elevated during an event, a baseline tryptase level at least 2 weeks after the episode should be drawn when the patient has returned to a normal state of health. This is helpful in evaluating patients for underlying mast cell disorders in which patients have chronically elevated tryptase levels.

Drug Challenges

Drug challenges (also known as provocation testing or *test dosing*) remains the gold standard for the evaluation of drug allergies. The objective of a challenge is to cautiously introduce a drug in patients who are unlikely to be allergic to it. Drug challenges can be performed as part of the initial diagnostic evaluation if the risk of a reaction is low or after negative skin and/or *in vitro* testing. Challenges can trigger mild to severe, acute and/or delayed reactions, but are considered

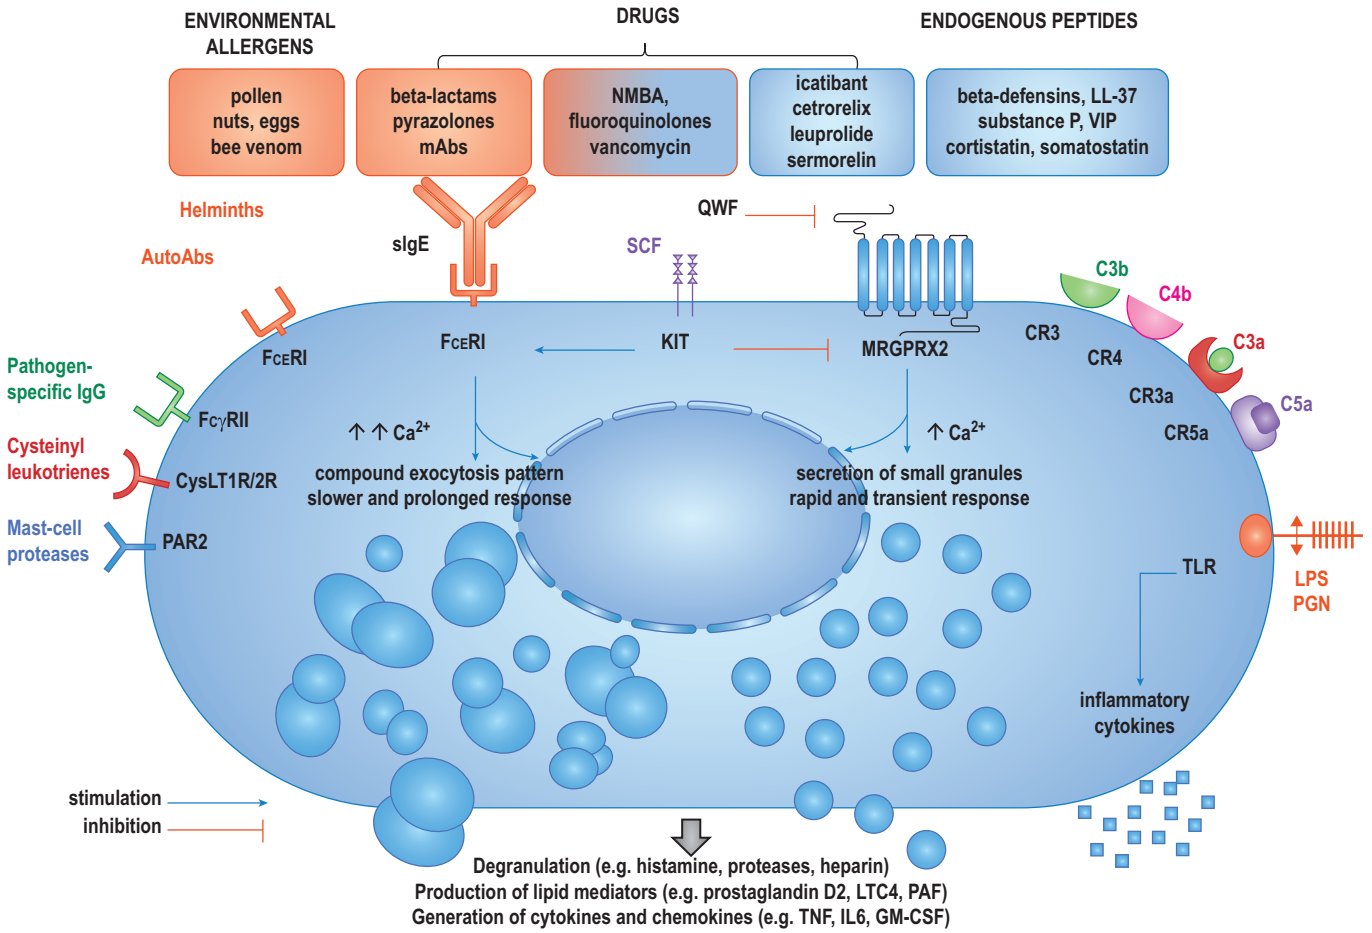

FIG. 50.4 Main receptor systems and examples of ligands involved in mast cell activation. Drugs can activate mast cells through both sIgE-dependent mechanism and the MRGPRX2 receptor. These activation routes are independent and inversely regulated by SCF (51). QWF inhibits activation of human MRGPRX2 by a number of basic secretagogues and medications. Granule processing and response program after the MRGPRX2 engagement differ from FcεRI-mediated response. Several other representative MC receptor systems and ligands are shown. *CR*, Complement receptor for corresponding complement components; *CysLT1R/2R* receptors, cysteinyl leukotrienes; *FcγRII*, a low-affinity receptor for IgG; *FcεRI*, the high affinity IgE receptor; *GM-CSF*, granulocyte/macrophage colony-stimulating factor; *IL*, interleukin; *KIT*, mast/stem cell growth factor receptor (CD117); *LPS*, lipopolysaccharide; *LTC4*, leukotriene C4; *Abs*, antibodies; *MRGPRX2*, Mas-Related G Protein-Coupled Receptor-X2; *NMBA*, neuromuscular blocking agents; *PAR2*, protease-activated receptor 2; *PGN*, peptidoglycan; *SCF*, stem cell factor; *sIgE*, specific IgE; *TLR*, Toll-like receptor; *TNF*, tumor-necrosis factor; *QWF*-tripeptide (the glutaminyl-D-tryptophylphenylalanine); *VIP*, vasoactive intestinal peptide. The schematic drawings were generated by modifying images obtained from Motifolio (Motifolio Inc., Elliocott City, MD).

extremely safe if performed appropriately. Important considerations to determine if a challenge is indicated include the risk of a severe reaction, patient comorbidities, comfort level of the provider in managing reactions, rescue protocol/medication availability, and the patient's needs for the specific drug in question. This procedure should almost never be performed if the reaction history is consistent with a severe non-IgE-mediated reaction, such as SJS/TEN, DRESS, or non-cutaneous organ-specific reaction (*e.g.*, hemolytic anemia).

Challenges can be a single, full-dose administration, or graded, with a small test dose followed by incrementally larger doses. Graded challenges are useful in higher-risk patients, as the initial smaller dose could potentially trigger a less severe reaction compared to a full-dose, single-step challenge.

If there is a concern for patient anxiety interfering with a challenge or actually causing the reaction symptoms, a placebo challenge should be incorporated. This could entail multiple doses of placebo given interspersed with actual drug, blinding the patient so symptoms reported can be objectively assessed without bias.

Skin Prick and Intradermal Testing

Skin prick and intradermal testing can be a valuable tool for evaluating IgE-mediated hypersensitivity reactions. The negative predictive value for penicillin skin testing is >97%. However, the sensitivity and specificity of skin prick testing for most drugs is unknown, which limits their utility in many circumstances. At higher concentrations, drugs can be very irritating to the skin, leading to false positive results. Examples of non-irritating concentrations for common antibiotics are listed in Table 50.6. Delayed intradermal readings (24 to 96 hours after injection) have been suggested as a possible tool for the diagnosis of type IV hypersensitivity reactions, but additional studies are needed to standardize this approach.

Patch Testing

Drug patch testing can be used for the evaluation of T-cell-mediated hypersensitivity reactions including maculopapular exanthem, fixed drug eruptions (FDE), SJS/TEN, DRESS, and AGEP. Current literature supports patch testing for select drugs, including antiepileptics and certain antibiotics; however, it cannot be used reliably for many medications (Table 50.7). Guidelines recommend that testing should occur between 6 weeks and 6 months after resolution of the initial reaction and at least 1 month after discontinuation of systemic steroids or immunosuppressants. Patch testing is typically placed on the upper back, except for FDEs, for which it needs to be performed on previously affected skin. If confirmatory testing is indicated for a T-cell-mediated hypersensitivity reaction and is not apparent based on history alone, delayed intradermal testing or patch testing should be considered.

TABLE 50.6 Nonirritating Concentrations for 15 Commonly Used Antibiotics

Antimicrobial Drug	Full-Strength Concentration (mg/mL)	NIC (as Dilution From Full-Strength Concentration)	No. of Patients Tested
Cefotaxime	100	10^{-1}	25
Cefuroxime	100	10^{-1}	25
Cefazolin	330	10^{-1}	25
Ceftazidime	100	10^{-1}	25
Ceftriaxone	100	10^{-1}	30
Tobramycin	40	10^{-1}	25
Ticarcillin	200	10^{-1}	25
Clindamycin	150	10^{-1}	25
Gentamicin	40	10^{-1}	30
Cotrimoxazole	80	10^{-2}	25
Levofloxacin	25	10^{-3}	25
Erythromycin	50	10^{-3}	25
Azithromycin	100	10^{-4}	30
Nafcillin	250	10^{-4}	25

In Vitro Testing: Specific IgE and Basophil Activation Test

In vitro specific IgE testing to drugs has limited utility at this time due to its lower sensitivity than skin testing. Basophil activation testing (BAT), an *in vitro* method to evaluate for immediate-type reactions, has shown some promising results in the evaluation of NMBAs as a cause of perioperative anaphylaxis when skin testing has been unrevealing.[22] BAT may also be helpful in the evaluation of IgE-mediated reactions to chlorhexidine and latex, but additional studies are needed. There are significant limitations to BAT, including up to 17% of patients being basophil non-responders and the need for fresh blood (<24 hours since blood collection).[23] Commercially available BAT tests generally have not been validated.

MANAGEMENT

Acute Treatment

Initial management is cessation of the suspected culprit drug. After discontinuation of the medication, the symptoms may resolve rapidly, such as in type I hypersensitivity reactions, or could persist for weeks, which can occur with FDEs or DRESS. Additional treatment is imperative for certain types of reactions;

TABLE 50.7 Patch Testing by Type of Drug Reaction

Drug Reaction	Grade of Recommendation[a]	Quality of Evidence[b]	Summary of Published Studies[c]
MPE	2A	B	Overall, 10.8%–38.4% of patients with MPE test positively to the implicated medication on patch testing. Radio contrast media, antiepileptics, penicillins, clindamycin, pristinamycin, and metamizole are more likely to have positive results compared with macrolides and sulfonamides, which are usually negative on patch testing for MPE.
FDE	2A	B	Patch testing is most likely to confirm culprit medication when NSAIDs and sulfa-based antimicrobials are tested. Note: patch testing must be performed on previously affected skin in FDE, with appropriate vehicle (*i.e.*, patch testing of cotrimoxazole is usually negative in petrolatum vehicle and more likely positive in DMSO).
AGEP	2A	B	Limited data suggest patch testing is often positive in AGEP (approximately 58% of cases). Most common medications that illicit positive patch tests include pristinamycin, β-lactams, antiepileptics, and diltiazem.
SCD	2B	B	Limited data suggest patch testing is diagnostic in 100% of cases of SCD with known prior sensitization, and 50% of cases without known prior sensitization.
DRESS	2A	B	Patch testing can confirm the culprit medication in 32%–64% of cases of DRESS. Patch testing is most helpful for DRESS caused by antibiotics (β-lactams and vancomycin), proton-pump inhibitors, and antiepileptics.
EM and SJS/TEN	2B	B	Data on patch testing for EM are limited. Data on SJS/TEN are limited and suggests no utility of patch testing, except possibly for carbamazepine induced SJS/TEN.

[a]According to criteria by Robinson et al.[1] 1 indicates a strong recommendation with high-quality, patient-oriented evidence; 2A indicates a weak recommendation with limited quality, patient-oriented evidence; and 2B indicates a weak recommendation with low-quality evidence.
[b]B indicates a systemic review or meta-analysis of low-quality clinical trials or studies with limitations and inconsistent findings, low-quality clinical trials, cohort studies, and case-control studies.

for instance, the early use of epinephrine with anaphylactic reactions can be life-saving. In severe drug-induced immunopathology, such as SJS/TEN and DRESS, there are no specific therapies outside of removal of the offending drug. However, corticosteroids and/or high-dose immunoglobulin therapy are frequently used to assist in decreasing inflammation and accelerating recovery.

In certain clinical scenarios, removal of the culprit drug is not feasible. Depending on the reaction to the treatment medication, continuation of the drug ("treating through") can be considered if the reaction is mild, such as itching or a maculopapular rash. These symptoms may respond favorably to medications such as antihistamines or topical steroids. This approach should be taken with caution with frequent monitoring for progression to more a serious reaction such as DRESS.

Alternative Medications

After an ADR, there are three options for alternative treatment: administering a different medication class, giving a drug within the same or similar class with potential cross-reactivity, or re-administering the same medication. The safest and most common approach is choosing a medication outside of the drug class that caused the reaction. This approach should be taken with caution as second-line therapies may not be as effective in treating the underlying infection and could actually increase risk for multi-drug resistant infections, increased length of hospitalizations, and greater overall healthcare cost, as seen with use of broad-spectrum antibiotic alternatives in patients with reported penicillin allergy.[5]

The second option is choosing a drug that can be potentially cross-reactive, either within the same drug class or if the drug has a similar chemical structure. Commonly implicated drugs with cross-reactivity are penicillins with cephalosporins and carbapenems; sulfonamide-containing drugs; and aromatic anticonvulsants, which will be discussed in more detail later in this chapter.

The third option is re-administration of the same drug. Depending on the type of reaction and duration from the reaction, consideration can be taken to perform a challenge versus desensitization. This is discussed in more detail in the following sections.

Desensitization

For patients who have experienced a type I (either IgE- or non-IgE-mediated) reaction but still require the culprit drug for first-line therapy, desensitization is an option and has been successful with numerous types of drugs, including antibiotics, mAbs, insulin, and chemotherapy. Desensitization is a procedure of incremental administration of increasing sub-optimal doses of the drug to reach a target dose with the goal of remaining beneath the threshold for a hypersensitivity reaction. The underlying mechanism is not completely understood. When drugs are administered at typical doses, antigen-induced membrane changes occur with internalization of the antigen, IgE, and FcεRI leading to activation of mast cells or basophils. Decreasing the amount of drug administered to sub-optimal doses allows the antigen to bind to the membrane but cross-linking of IgE does not occur. Therefore, internalization of the surface molecules does not occur, ultimately preventing actin rearrangement, calcium entry, and the release of inflammatory mediators.

Desensitization protocols can be performed with oral or intravenous medications, with safety in favor of oral administration. There have been numerous effective protocols published with most protocols beginning in the range of 1:100, 000. Typically, the dose is incrementally doubled every 15 to 20 minutes until the target cumulative dose is reached. For parenteral administration of medications, a multi-bag approach was previously the standard of care, but recent single-bag protocols have been developed which demonstrate equivalent safety and efficacy.[24] An example of a parenteral paclitaxel protocol is shown in Table 50.8.

Desensitization lasts as long as the drug is present. If there are lapses, missed doses, or delayed doses, the procedure will need to be repeated. Depending on the half-life of the medication, the desensitized state will dissipate in days to weeks.

Drug Challenges

A drug challenge to a medication that had previously caused an ADR is a common approach taken to assess an allergy. Examples of situations when this practice is utilized includes: if the offending agent was not thought to be the cause of the reported symptoms, if the reaction was reported many years after occurrence, or if the medication is required and symptoms reported were mild. Details of drug challenges are described earlier in the Diagnosis section.

Premedication Protocols

Premedications can be useful in pseudoallergic reactions such as with vancomycin-induced Red Man Syndrome or prior to desensitization protocols for nonallergic reactions such as with taxanes. Premedications given prior to administration of the drug include antihistamines, topical or systemic steroids, leukotriene receptor antagonists, or NSAIDs. Premedicating is not recommended for drug challenges if there is concern for an IgE-mediated reaction, as premedications may mask symptoms and lead to false negative results. In this situation, subsequent administration of the drug could lead to a severe reaction even if the same pretreatment regimen is used.

Delabeling Allergy After Negative Testing

If the drug allergy in question has been confirmed negative, it is important to delabel (remove the label) from the medical record(s) of the patient. It is important to review this with the patient to assure optimal treatment in the future is utilized. Commonly, patients are provided with wallet cards that highlight all of their current allergies, in addition to negative testing of previously reported drug allergies; such cards can be helpful if the patient is seen by different providers in various care settings.

SPECIFIC DRUG HYPERSENSITIVITY

Antibiotics

Penicillins

It has been reported that all hypersensitivity reactions can be caused by penicillins (types I–IV), with the highest rate of type I-IgE mediated hypersensitivity reactions. Type I, II, and III hypersensitivity reactions occur through the development of hapten-carrier complexes which is discussed previously in this chapter and demonstrated in Fig. 50.5. While penicillin allergy is the most commonly reported drug allergy, comprising approximately 10% of the U.S. population, over 90% of patients can actually tolerate re-exposure.[5] This is in part due to the loss of sensitization overtime, as approximately 80% to 90% of allergic patients will lose their sensitivity with 10 years of avoidance.

Drug allergy evaluation should be considered for nearly all patients with a history of penicillin allergy as recent studies have shown carrying a penicillin allergy label can have significant clinical consequences. These include the more frequent use of second-line antibiotics, increased treatment failure rates, longer hospital stays, increased risk for the development of resistant organisms, *Clostridium difficile* infections, and higher rates of surgical site infections perioperatively.[5]

For assessment of a type I IgE-mediated allergy, skin testing and/or direct challenges have been used effectively. Multiple protocols have been published to assist in risk-stratifying patients to determine if skin testing is necessary or if the patient can go directly to an observed challenge. For skin testing, typically both major and at least one minor determinant (usually benzylpenicillin) are tested, though there is lack of uniformity of which minor determinants should be used. There is significant cross-reactivity between penicillins, although in Europe, there are higher reports of isolated allergy to amoxicillin, which is not observed in the United States, possibly making more extensive skin testing to include amoxicillin a minor determinant useful for select high-risk patients. Currently, there are no commercially available skin test reagents for amoxicillin and all of the minor determinants, so skin testing with benzylpenicilloyl polylysine and benzylpenicillin followed by amoxicillin oral challenge is the most commonly utilized method for penicillin skin testing in the United States.

Assessment of type IV hypersensitivity reactions is less standardized. Delayed skin testing and patch testing have been attempted but results have been inconsistent. It is not currently recommended for clinical practice, therefore, oral challenges are the suggested method of assessment. Careful history taking remains paramount as challenges are relatively contraindicated for reactions consistent with drug-induced cytopenias, vasculitis, and SCARs. If there is a concern for a benign, delayed-type reaction, administration of a single-dose amoxicillin 250 mg challenge with at home assessment over 1 week for a potential delayed exanthem is a reasonable option.

In penicillin allergy, the degree of similarity of the R-group side chains determines the amount of cross-reactivity. In a recent meta-analysis of patients with proven penicillin allergy (mostly aminopenicillins), identical R-groups had a 16.45% risk of cross-reactivity with only 2.11% in dissimilar R-groups. Carbapenem cross-reactivity to penicillins was even lower at 0.87%.[25] The rates of cross-reactivity are likely much lower in patients with self-reported penicillin allergy since >95% of such patients when tested are not truly allergic.

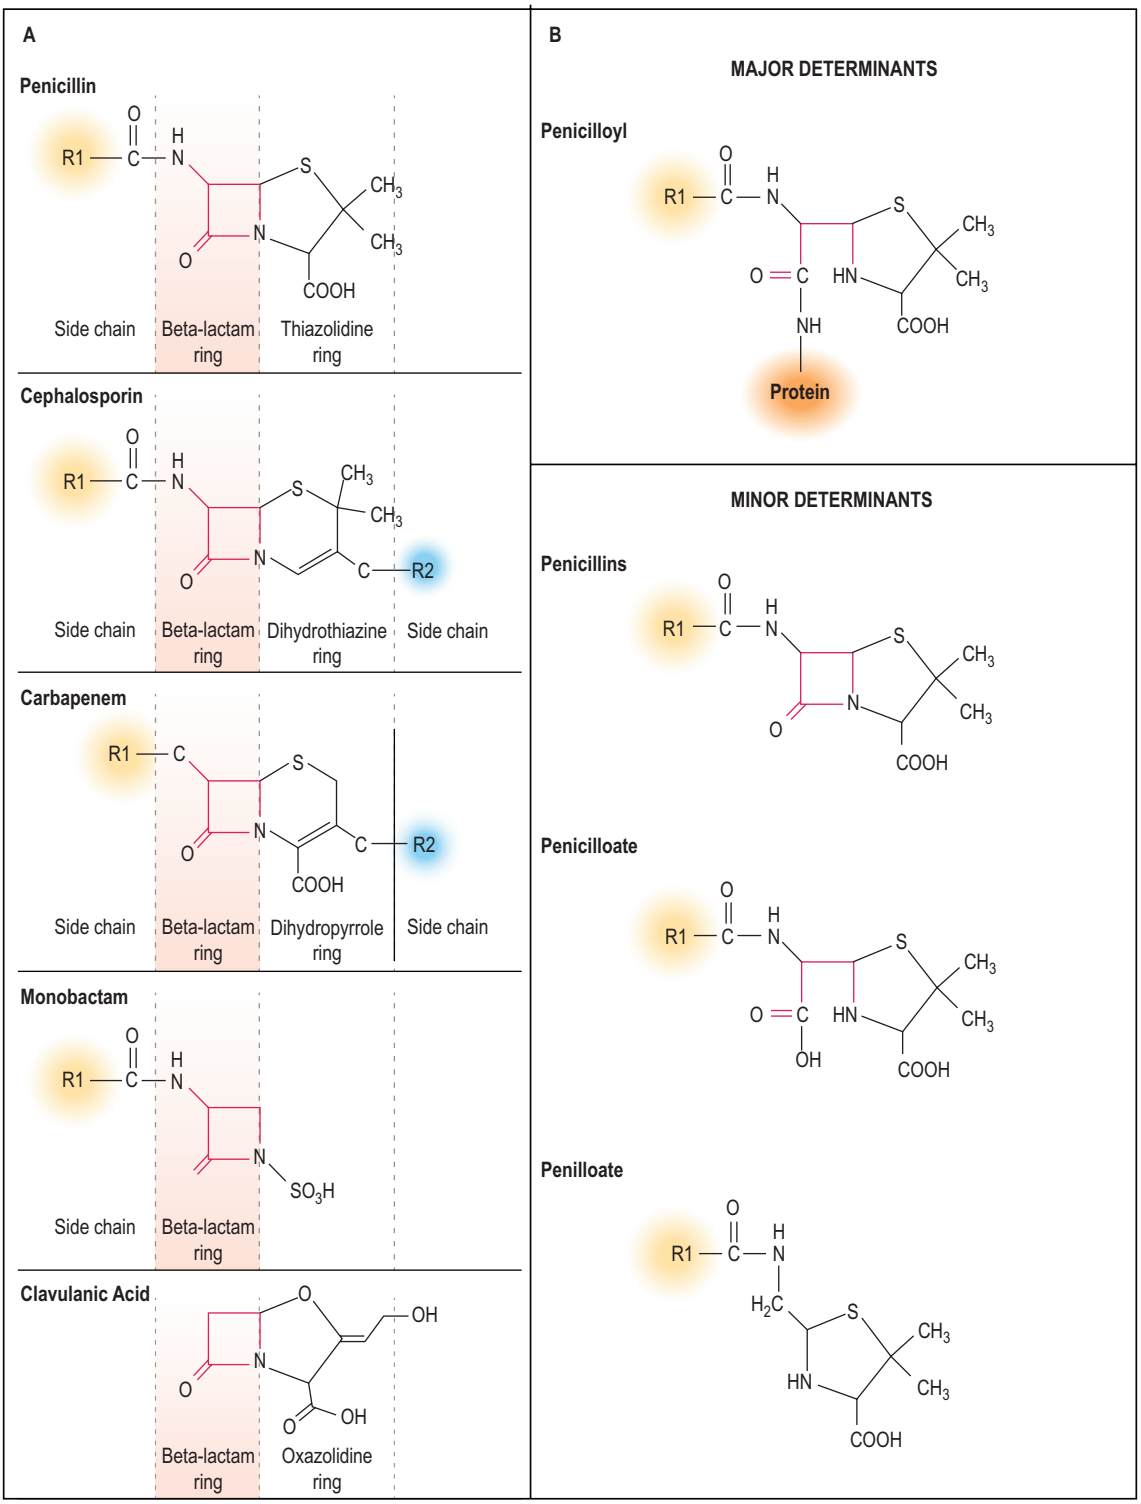

FIG. 50.5 Penicillin and beta-lactam structure and major and minor penicillin determinants. (From Castells M, Khan DA, Philips EJ. Penicillin allergy. *N Engl J Med.* 2019;381[24]:2338–2351.)

Cephalosporins

Like penicillins, cephalosporins have been associated with all types of hypersensitivity reactions. Skin testing to penicillins is not an appropriate method of evaluating cephalosporin allergy. In patients reporting an allergy to specific cephalosporins, skin testing can be considered, although the exact sensitivity and specificity for each cephalosporin is not currently known. They should, however, be able to tolerate other cephalosporins that do not share a common side chain, as demonstrated in Fig. 50.6. For patients with anaphylactic reactions to cephalosporins, skin testing to an alternative cephalosporin with a disparate R1 side chain is recommended prior to administration.

Cephalosporin	R_1 Structure	Penicillin Identical R_1	Penicillin Similar R_1
Cephalexin Cephaloglycin Cefaclor Loracarbef		Ampicillin Pivampicillin*+ Bacampicillin*+ Talampicillin*+	Mezlocillin+ Piperacillin Azlocillin+
Cefadroxil Cefatrizine Cefprozil		Amoxicillin	Mezlocillin Piperacillin Azlocillin
Cefamandole Cefonicid			Ampicillin Amoxicillin Pivampicillin Bacampicillin Talampicillin
Cefoxitin Cephaloridine Cephalothin			Ticarcillin+ Temocillin+
Cefbuperazone			Piperacillin
Cefbuperazone			Piperacillin

FIG. 50.6 Cephalosporin drugs with similar R1 side-chain structures. (From Zagursky RJ and Pichichero ME. Cross-reactivity in β-lactam allergy. *J Allergy Clin Immunol Pract*. 2018;6:72–81.)

Sulfonamide Antibiotics

Sulfonamide antibiotics are characterized by a five or six membered ring with sulfonamide (SO2-NH2) directly attached to the ring and an unsubstituted amine (-NH2) at position N4. There are non-antibiotic sulfonamide drugs that do not share these same structures, therefore, they are tolerated safely by patients with sulfonamide antibiotic allergy. This group of antibiotics is most commonly associated with delayed hypersensitivities, which includes FDEs, maculopapular rash, and SCARs, although all types of reactions have been observed. In comparison to other antibiotics, sulfonamide antibiotics have a higher risk of SJS/TEN. Patients with untreated HIV or with low $CD4^+$ T-cell counts have been found to have a higher risk for sulfonamide antibiotic allergy.[2] Most patients with histories of benign reactions to sulfonamide antibiotics will tolerate challenges to trimethoprim-sulfamethoxazole.[26]

Other Antibiotics

Intolerance prevalence and immunogenicity of common antibiotics are highlighted in Table 50.9.

Aspirin and Nonsteroidal Anti-Inflammatory Drugs

After antibiotics, nonsteroidal anti-inflammatory drugs (NSAIDs) are the most commonly reported drug allergy by patients with a variety of different mechanisms, including immunologic and non-immunologic processes. NSAID reactions can be classified into one of five subtypes, which are highlighted in Table 50.10. The diagnosis can often be made on clinical history alone, while some patients require a drug challenge. Skin and *in vitro* testing have not been shown to be reliable for NSAID allergies.

NSAID-Exacerbated Respiratory Disease

NSAID-exacerbated respiratory disease (N-ERD), also known as aspirin-exacerbated respiratory disease (AERD) in the United States, is a chronic inflammatory disorder of the upper and lower respiratory tract. This eosinophilic-predominant condition was previously referred to as Samter's triad and involves asthma and/or chronic rhinosinusitis with nasal polyps along with NSAID sensitivity, including aspirin. NSAID-related reactions typically occur within 30 to 180 minutes after exposure and can include nasal congestion, rhinorrhea, wheezing, coughing, and shortness of breath. A subset of patients may have cutaneous or gastrointestinal symptoms as well. The provocation dose is typically between 30 and 300 mg of aspirin with most reacting to doses of 60 mg or less.

The underlying pathophysiology of N-ERD has been hypothesized to be related to blocking cyclooxygenase-1 (COX-1), and not COX-2, causing inhibition of prostaglandin E_2 (PGE_2). This decrease in PGE_2 biosynthesis can trigger innate activation of inflammatory cells, specifically mast cells, basophils, eosinophils and possibly platelets. The eventual release of cysteinyl leukotrienes, PGD_2, histamine, tryptase, and other mediators could explain the clinical phenotype. Desensitization protocols

TABLE 50.9 Intolerance Prevalence and Immunogenicity of Common Antibiotics

Antibiotic or Antibiotic Family	Intolerance Prevalence (%)	IgE-Medicated Allergy	T-cell-Mediated Delayed Hypersensitivity	Intrafamily Immunologic Cross-Reactivity

have been successful in N-ERD patients to decrease nasal polyp burden, improve asthma control, and improve hyposmia/anosmia.

Radiocontrast Media

Severe reactions to iodinated and noniodinated contrast media are relatively rare (0.02% to 0.03%), and their mechanisms are not completely understood. In the past, high-osmolar iodinated contrast media (ICM) were thought to cause reactions through IgE-independent pseudoallergic mechanisms, and premedication regimens were considered effective. Use of low or iso-osmolar ICM has further reduced the rate of severe hypersensitivity reactions. There is accumulating evidence that reactions to low or iso-osmolar ICM may be IgE-mediated. A recent consensus document suggested that skin testing may help identify safe alternatives, but prospective studies are needed to determine the optimal testing strategy.[27] Skin testing therefore remains controversial as a means of predicting subsequent reactions, and the decision to perform testing remains with the clinician.[28, 29] The most recent update to the anaphylaxis parameters, based on a systematic review, recommended against routinely administering glucocorticoids and/or antihistamines to prevent anaphylaxis in patients with prior radiocontrast hypersensitivity reactions when re-administration of a low- or iso-osmolar, nonionic ICM agent is required.[30] The parameter notes that premedication may be considered in clinical circumstances associated with greater anaphylaxis fatality risk (*e.g.*, underlying cardiovascular disease, prior severe anaphylaxis). Numerous pretreatment regimens have been proposed with the most widely used protocols involving systemic steroids and antihistamines at various intervals prior to contrast exposure.

Gadolinium-based contrast agents (GBCA) do not cross-react with ICM and risk of hypersensitivity reactions is even lower. Rates of immediate reactions to different GBCAs vary with higher hypersensitivity reactions associated with protein binding, macrocyclic structure, and ionicity.[31] Reactions to GBCA may also be IgE-mediated, and skin testing has been utilized to identify alternative GBCAs.[32]

Angiotensin-Converting Enzyme Inhibitors

ACE-I competitively inhibit angiotensin-converting enzyme, blocking the synthesis of angiotensin-II. In addition to the desired effect of decreasing cardiac preload and afterload, ACE-I can reduce the breakdown of bradykinin and substance P, resulting in bradykinin-mediated angioedema. A higher risk of ACE-I induced angioedema has been seen in Black people, women, smokers, and those with underlying hereditary angioedema. After the first episode of angioedema, ACE-I should be permanently discontinued, but many patients can continue to have episodes of angioedema for several months after ACE-I

cessation.[33] Angiotensin receptor blockers (ARBs) can safely be used in these patients.

Perioperative Anaphylaxis

The incidence of perioperative anaphylaxis is reported to be between 1:1, 250 and 1:20, 000 with a 3% to 9% mortality rate.[34] Evaluation of these events can often be complex due to multiple drugs used in a short period of time; furthermore, early signs of a hypersensitivity reaction are often missed due to the setting, as patients are intubated, sedated, and draped. While nearly all medications and substances used in the perioperative period have been implicated as causes of anaphylaxis, the most common include neuromuscular blocking agents (NMBAs), antibiotics (particularly cefazolin), disinfectants, and latex. While skin and *in vitro* specific IgE testing can be helpful, the causative agent in 30% to 50% of cases remains unknown. Common skin testing concentrations can be found in a review by Volcheck and Hepner.[34] Other diagnostic modalities that are less frequently utilized include direct provocation challenges and BAT.

Local Anesthetics

Systemic hypersensitivity reactions to local anesthetics are exceedingly rare, and most are not IgE-mediated. While reactions are often reported by patients, the largest cohort study to date showed that >85% of episodes were due to psychosomatic or vasovagal reactions.[35] Only 0.5% of the reported cases were attributed to the local anesthetic. The categorization of local anesthetics into benzoic ester and amide drugs is not particularly meaningful in the evaluation of systemic reactions. The original publications used this classification only for allergic contact dermatitis reactions, and its relevance for other types of hypersensitivity reactions is unknown.

Chemotherapy

Anti-cancer drug therapies are defined based on their target and include chemotherapy, hormonal therapy, and immunotherapy. Chemotherapeutics are then sub-grouped based on their structure and mechanism of action. Chemotherapeutics commonly associated with adverse reactions include platinum salts and taxanes.

Platinum salts have been implicated in both IgE- and non-IgE-mediated reactions with an incidence of 12% to 17% respectively.[36] The most common implicated platinum salt causing reactions is carboplatin followed by oxaliplatin and cisplatin.[36] Cross-reactivity is much higher between carboplatin and oxaliplatin and is less common with carboplatin.[37] Risk factors for platinum salt reactions are female gender, platinum-free interval greater than 1 year, and BRCA-positive genetic mutations. Hypersensitivity reactions generally occur between the 4th and 10th dose, while non-IgE-mediated reactions will occur on the 1st or 2nd dose. Skin testing to platinum salts has been demonstrated to be useful given most reactions are IgE mediated, and it is often used to predict the need to desensitize, although this process is not currently standardized.[38]

Taxane reactions are most often caused by non-IgE mediated hypersensitivity, with reactions typically occurring on the 1st or 2nd exposure. The reactions are thought to be secondary to formulation vehicles, such as polyethoxylated castor oil and polysorbate 80, which are used to solubilize taxanes and are capable of causing mast cell activation. Typically, these reactions respond favorably to premedication regimens. Taxanes have also been implicated in IgE-mediated hypersensitivity, although less commonly than platinum salts. The use of skin testing is less established.

Biologics and Monoclonal Antibodies

Biologic agents (BA) are becoming increasingly prevalent in the medical management of cancer and chronic inflammatory conditions. As BAs have been developed to mimic and alter the immune system, it is not surprising that new types of AEs have been noted. These are often due to overstimulation or suppression of the immune system leading to conditions such as CRS, infusion reactions, secondary immunodeficiency, and autoimmunity. mAbs, one type of BA, were originally created as murine analogs but have been generally replaced by chimeric, humanized, and fully human antibodies to improve efficacy and decrease allergenicity.

Reactions to mAbs can occur during the first exposure, as has been reported with cetuximab and trastuzumab or after multiple exposures, such as with rituximab. Infusion-related reactions to mAbs present as cytokine storm-like reactions with symptoms of nausea, chills, fever, and malaise. These are thought to be caused by release of proinflammatory cytokines

TABLE 50.11 Biologic Agents: Actions, Incidence, and Hypersensitivity Drug Reactions

Drug	Target	Overall Reactions	HSR
Rituximab (Rituxan) IV	CD20	77% (first infusion)	5%–10%
Ofatumumab (Arzerra) IV	CD20	44% (first infusion) 67% (combination therapy)	2%
Obinutuzumab (Gazyva) IV	CD20	66%	[a]
Trastuzumab (Herceptin) IV	HER-2	40% (mild; first infusion)	0.6%–5%[a]
Cetuximab (Erbitux) IV	EGFR	15%–21%	1.1%–5% 14%–27% (southern USA)[a]
Tocilizumab (Actemra) IV	IL-6 receptor	7%–8%	0.1%–0.7%[a]
Infliximab (Remicade) IV	TNF-α	5%–18%	1%[a]
Etanercept (Enbrel) SC	TNF-α	15%–37%	<2%[a]
Adalimumab (Humira) SC	TNF-α	20%	1%[a]
Golimumab (Simponi) SC	TNF-α	4%–20%	Not reported
Certolizumab (Cimzia) SC	TNF-α	0.8%–4.5%	Not reported
Brentuximab (Adcetris) IV	CD30	12%	[a]
Bevacizumab (Avastin) IV	VEGF-A	<3%	[a]
Omalizumab (Xolair) SC	IgE	45%	0.09%–0.2%[a]

[a]Case reports of anaphylaxis.
HSR, Hypersensitivity reactions; *IL*, interleukin; *TNF*, tumor necrosis factor.
Modified from Galvao VR, Castells MC. Hypersensitivity to biologic agents-updated diagnosis, management, and treatment. *J Allergy Clin Immunol Pract.* 2015;3(2):175–185; quiz 186.

(*e.g.*, IL-1, IL-6, and TNF-α) and respond to NSAIDs and systemic steroids.

Hypersensitivity reactions to cetuximab and several other biologics on first exposure have been attributed to sensitization to the galactose-α-1, 3-galactose (alpha-gal) epitope caused by a bite from the lone star tick (*Amblyomma americanum*), which has a high prevalence in Southeastern United States.[39] The carbohydrate alpha-gal is expressed in the major blood group of non-primate mammalian proteins and also on cetuximab, abciximab, basiliximab, canakinumab, infliximab, golimumab, and ustekinumab.

mAbs given subcutaneously can elicit injection-site reactions, with symptoms including local redness, warmth, burning, stinging, itching, urticaria, pain, and induration. Such reactions can start within one hour of the injection and usually resolve over a few days, but large and persistent reactions can lead to discontinuation of the mAb; desensitization protocols have been developed for patients who have no alternative medication options (Table 50.11).

CONCLUSION

The understanding of immunologic and non-immunologic ADRs remains incomplete and is further compounded by the limited number of reliable diagnostic tests. A detailed history remains the key to distinguishing a true drug allergy from a non-immunologic or anxiety reaction, which can further delineate the underlying mechanism and diagnostic approach that should be taken. Given the high morbidity and mortality associated with drug hypersensitivity reactions as well as the increased failure rate with second- or third-line therapies, appropriate evaluation by Allergy & Immunology specialists is imperative.

KEY CONCEPT

General Evaluation of Drug Allergy

General Evaluation of Drug Allergy

- History: Indication for drug use, association with viral/bacterial infection
- Physical examination
- Blood count/differential, Liver function tests
- Serum tryptase
- Skin testing
- Patch testing/delayed reading of skin test
- Specific IgE, basophil activation test
- Genotyping

Specific Evaluation of Drug Allergy

- Name of the drug, ingredients, preservatives
- First exposure
- How long ago did the reaction occur?
- Re-exposure: Has the patient been exposed to the drug or a related drug?
- Other drugs administered at the same time
- Associated narcotics
- Symptoms and signs of the reaction
- Timing of symptoms relative to the drug exposure

Underlying Condition for which the Drug was Prescribed

- Similar symptoms unrelated to the drug exposure (urticaria)
- Treatment and response to treatment (epinephrine)
- Timing of resolution

Mechanisms of Autoimmunity

Tory P. Johnson, Brendan Antiochos, and Antony Rosen

Human autoimmune diseases affect >5% of the population worldwide and impose a significant burden of morbidity and mortality. Autoimmune diseases are defined as diseases in which immune responses to specific self-antigens contribute to ongoing tissue damage. Both the specificity of the immune response and its role in tissue damage are central componnts of the definition. Autoimmune diseases can be either tissue-specific (e.g., thyroid), where unique tissue-specific antigens are targeted, or they can be systemic, in which multiple tissues are affected and a variety of ubiquitously expressed autoantigens are targeted.[1] Although the definition appears simple in concept, the enormous complexity of this spectrum of disorders has challenged clarification of simple shared mechanisms. This complexity affects almost every domain, including genetics, phenotypic expression, and kinetics. For example, there is frequently a prolonged period between initial onset of symptoms and development of the diagnostic phenotype, and the expression of disease may vary within the same individual over time. However, despite this enormous complexity, there is a striking association of the clinical phenotype with the targets of the autoimmune response. Indeed, this association is so strong that autoantibodies have been used for diagnosis and prognosis in human autoimmune diseases.[1] For example, autoantibodies recognizing thyroid peroxidase are found in patients with autoimmune thyroiditis, and autoantibodies to the Sm splicing ribonucleoprotein (RNP) complex are diagnostic of systemic lupus erythematosus (SLE). The immune response in autoimmune diseases has features of an adaptive immune response—usually directed against exogenous antigens—but its targets are autoantigens. Since the adaptive immune response is initiated when suprathreshold concentrations of molecules with structures not previously tolerized by the host are encountered in a proimmune context, the association of specific autoantibodies with distinct clinical phenotypes provides critical clues to understanding the initiation and propagation of autoimmune diseases.

KEY CONCEPTS

Autoantibodies in Autoimmune Diseases

- Autoantibodies may precede the development of any symptoms by years (e.g., antinuclear antibodies and antiphospholipid antibodies in systemic lupus erythematosus [SLE], anti-cyclic citrullinated peptide [CCP] in rheumatoid arthritis [RA])
- Some autoantibodies only occur at the onset of disease manifestations (e.g., anti-Sm and anti-ribonucleic protein [RNP] in SLE).
- There is a striking association of specific autoantibodies with distinct clinical phenotypes (e.g., antitopoisomerase-1 with diffuse scleroderma and interstitial lung disease).

This chapter highlights some of the mechanistic principles that underlie autoimmune diseases. The extraordinary breadth and complexity of this disease spectrum precludes encompassing everything relevant.

THE DISTINCT PHASES IN THE DEVELOPMENT OF AUTOIMMUNITY

A major barrier to understanding mechanisms of autoimmunity comes from difficulty in defining early events in these diseases. Since diseases are only recognizable after development of the diagnostic phenotype, there has been a tendency to interpret findings at the time of diagnosis with disease initiation. However, significant recent data from longitudinal studies have demonstrated that the onset of autoimmune responses and the development of clinical symptoms are separated in time.[1,2] For example, development of islet cell autoantibodies frequently precedes diabetes and autoantibodies recognizing citrullinated proteins (rheumatoid arthritis [RA]–specific autoantibodies) precedes the development of RA.[2] These findings indicate that either a threshold needs to be exceeded in terms of tissue damage before symptoms manifest, or that there are two distinct phases in disease development—one marked by production of a group of autoantibodies and the second by autoamplifying tissue damage. In a landmark study in SLE, Arbuckle et al. have provided important insights into this issue.[3] They analyzed sera collected from patients from the US military, who subsequently developed SLE. Interestingly, autoantibodies in SLE could be divided into two groups: *(i)* those that precede the diagnosis of SLE by several years—these included antinuclear and antiphospholipid antibodies; and *(ii)* those that occurred around the time of onset of symptoms—these included anti-Sm, anti-RNP, and to a lesser extent anti-DNA. The observation that one group of autoantibodies precedes symptoms in SLE and that another group appears coincident with the phenotype strongly suggests that the groups mark distinct events in the development of autoimmune disease. Members of the first group are likely markers of disease initiation; members of the second group are likely markers of disease propagation. The antigens targeted by the immune system in this latter phase (i.e., associated with clinical disease) are more likely to have some function in disease propagation, possibly through their possession of proinflammatory or adjuvant functions (see below).[1]

KEY CONCEPTS

Barriers to Defining Mechanisms of Human Autoimmune Disease

- Genetic and phenotypic complexity.
- Interval between initiating events and development of diagnostic phenotype.
- Challenges in quantifying human immune responses.

Development of autoimmune diseases can therefore be examined in four phases (Fig. 51.1):

1. *Susceptibility phase*—before disease, but where one or several preconditions for later initiation are satisfied. This would include impaired tolerance induction or altered immune signaling thresholds. The susceptibility phase could either be inherited or acquired and permanent or transient.
2. *Initiation phase*—before onset of clinical disease but marked by the presence of an autoimmune response (e.g., in the case of SLE—antiphospholipid antibodies).
3. *Propagation phase*—this corresponds with the onset of clinical disease, marked by propagation-specific immune responses (e.g., in the case of SLE—anti-Sm antibodies).
4. *Regulation/resolution phase*—it should also be noted that in many cases during disease propagation, immunoregulatory pathways are also activated, which may result in natural inhibition of clinical disease over time. In rare cases, these inhibitory pathways can lead to permanent resolution. This resolution phase will not be discussed further here, but its existence provides important evidence that homeostasis can be reestablished even after the amplified phenotype develops.

PHASE 1: SUSCEPTIBILITY

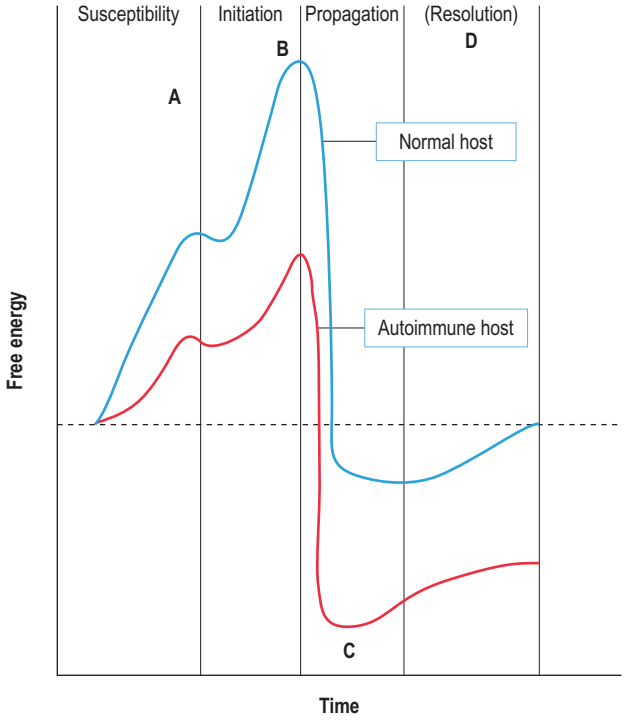
Although autoimmune diseases in humans are genetically complex, decreasing costs and expanding capacity of sequencing studies have led to the generation of large datasets from patients with a wide repertoire of autoimmune diseases. The strength of these sequencing studies has allowed for unbiased genome-wide association studies (GWAS) that have revealed several genetic risk factors for autoimmune diseases, many of which are associated with multiple diseases[4] GWAS studies have also allowed for the development of disease prediction models based on genetic susceptibility.[5]

Important advances in the genetics of autoimmunity also come from the study of autoimmunity with mendelian patterns of inheritance (e.g., autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia [APECED], immune dysfunction/polyendocrinopathy/enteropathy/X-linked [IPEX] syndrome, C1q deficiency) and from several mouse models. Collectively, these studies highlight a critical role for pathways of tolerance induction, immunoregulation, and setpoints/thresholds for immune signaling in avoiding emergence of autoimmunity.

KEY CONCEPTS

Mechanisms Underlying Susceptibility to Autoimmunity

- Incomplete induction of tolerance in the thymus to peripherally expressed autoantigens (autoimmune regulator [AIRE] deficiency causing autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia [APECED]).
- Impaired clearance and tolerance induction by apoptotic cells (e.g., deficiency of C1q, C4, milk fat globule–epidermal growth factor [EGF] 8 [MFG-E8], Mer).
- Defective production of regulatory T cells (FOXP3 deficiency causing immune dysfunction/polyendocrinopathy/enteropathy/X-linked [IPEX] syndrome).
- Altered immune signaling thresholds (e.g., cytotoxic T lymphocyte antigen-4 [CTLA-4] polymorphisms, protein tyrosine phosphatase, non–receptor type 22 [PTPN22] polymorphisms).
- Infection and dysbiosis.



A	**Susceptibility**
• Impaired tolerance induction • Impaired production of regulatory T cells • Altered immune signaling thresholds	
B	**Initiation**
• Suprathreshold concentration of autoantigens • Non-tolerized structure • Pro-immune context — infection, malignancy, exposure to adjuvants	
C	**Propagation**
• Acquisition of adjuvant properties by disease-specific autoantigens • Increased autoantigen expression in the target tissue • Immune effector pathways generate/expose autoantigen, which further drives the immune response	

FIG. 51.1 Mechanisms of Autoimmunity. Autoimmune diseases result from a complex interplay of pathways and events that allow autoreactivity to manifest and cause self-sustaining tissue damage. Mechanistically, it is useful to divide the process into three phases: (A) susceptibility phase—this is present before disease and is the phase in which one or several preconditions for later initiation are satisfied; (B) initiation phase—this is marked by the presence of autoimmunity, but precedes the diagnostic clinical phenotype; (C) propagation phase—this is marked by autoimmunity and tissue damage, in which immune effector pathways cause damage and provide antigen to drive the ongoing immune response.

Incomplete Thymic Tolerance Induction Predisposes to Autoimmunity

Insights into basic mechanisms can derive from the study of rare human phenotypes. This has been true for autoimmunity, where several monogenic disorders have defined important pathogenic principles. Autoimmune polyendocrinopathy syndrome type 1 (APS-1; also called APECED) is a rare disease in which patients develop multiple autoimmune diseases, often beginning in childhood. Although candidiasis and ectodermal dystrophy (including involvement of enamel and nails, as well as keratopathy) are features of the disease, the syndrome is characterized by striking autoimmunity directed against multiple different target tissues. Autoimmune processes include autoimmune hypoparathyroidism, Addison disease, autoimmune gastritis with pernicious anemia, type I DM, thyroid disease, autoimmune hepatitis, celiac disease, and gonadal failure. Numerous autoantigens have been defined as targets of autoimmunity in APS-1, including enzymes specifically expressed in various endocrine tissues. The genetic basis of APS-1 was mapped to a gene on chromosome 21q22.3, subsequently termed *AIRE* (for autoimmune regulator). *AIRE* expression is highest in the thymus, where it is expressed in medullary thymic epithelial cells. Several predicted structural features of the AIRE protein and its localization in nuclear dots suggested that the protein might be a transcriptional regulator, and significant evidence for this proposal was obtained in vitro. Several *AIRE*-deficient mouse models were subsequently generated, which allowed for the definition of important pathogenic pathways in APS-1 that may be broadly relevant to the mechanisms of autoimmunity in general. Mice deficient in *AIRE* developed various autoimmune phenotypes, resembling those found in human APS-1. These included multiorgan lymphocytic infiltration and autoantibodies, as well as autoimmune eye disease. In an elegant series of experiments, Anderson et al. demonstrated that AIRE regulates expression in thymic epithelial cells of various peripheral autoantigens normally expressed exclusively in endocrine target tissues.[6] Thus, AIRE appears to regulate the ectopic expression in the thymus of tissue-restricted autoantigens and to provide an antigen source against which to establish central tolerance.[6] In a recent study, phage display immunoprecipitation and sequencing (PhIP-seq) was used to define novel autoantigens in patients with APS-1. Interestingly, the defined autoantigens had tissue-specific expression, and autoantibodies were associated with tissue-specific autoimmune phenotypes in APS1, providing novel diagnostic tools and evidence that the proposed mechanism is operative in the human syndrome.[7]

Impaired Clearance and Tolerance Induction: Susceptibility Defect in Systemic Autoimmunity

Although little is known in humans about the cell biology of thymic pathways of tolerance induction to ubiquitously expressed autoantigens, there is accumulating evidence to suggest that in the periphery, apoptotic cells play an important role in providing a source of autoantigens against which the organism becomes tolerant.[1] Apoptotic cells are generally very efficiently cleared by phagocytic cells; these events are normally associated with the production of anti-inflammatory cytokines and result in tolerance induction.[1] Interestingly, early components of the classical complement pathway (e.g., C1q and C4) and cross-reactive protein (CRP) are required for efficient apoptotic cell clearance. Therefore it is of particular note that homozygous C1q deficiency is associated with a striking susceptibility to SLE in humans, and this suggests that efficient, tolerance-inducing clearance of apoptotic cells may play a role in preventing subsequent emergence of autoimmunity to ubiquitously expressed autoantigens.[8] Additional support for this model comes from recent studies of milk fat globule–epidermal growth factor (EGF) 8 (MFG-E8), a glycoprotein secreted from macrophages that is required for the efficient attachment and clearance of apoptotic cells by macrophages and immature dendritic cells (DCs). MFG-E8 is expressed in tingible-body macrophages in the germinal centers of secondary lymphoid tissues. Interestingly, many unengulfed apoptotic cells are present in the germinal centers of the spleen in *MFG-E8*–deficient mice, which develop a striking lupus-like phenotype (reviewed in Rai and Wakeland[9]).

Netosis—the process of neutrophil extracellular traps (NET) release—is another form of cellular death that results in antigen presentation. In this process, neutrophils release extracellular fibers, composed of DNA and proteins, that trap and prevent the spread of extracellular pathogens (reviewed in Papayannopoulos[10]). In this manner, neutrophils prevent pathogen spread in a proinflammatory context, which recruits further immune responses to the site of infection. Thus, the formation of NETs, although only recently recognized, is an important component of the innate immune response. However, during netosis, self-antigens are also presented. Known targets of the immune response in SLE, RA, and vasculitis have all been identified in NETs from patients with these conditions. Additionally, elevated NETs or fragments of NETs have been observed in the serum of patients with rheumatic diseases. Therefore, factors that contribute to enhanced netosis may also impair peripheral tolerance by allowing for autoantigen presentation in a highly proinflammatory setting. Collectively, these data strongly suggest that efficient, anti-inflammatory clearance of NETs and apoptotic cells plays a central role in tolerance induction and prevention of autoimmunity.

Defective Production of Regulatory T Cells

Although there are pathways that (i) regulate autoantigen expression at sites of tolerance induction and (ii) guide autoantigens toward tolerance-inducing outcomes, these pathways alone are clearly insufficient to prevent the emergence of autoimmune disease. This fact is highlighted by the emergence of autoimmunity when regulatory T-cell (Treg) differentiation is abnormal in humans with IPEX syndrome, the human equivalent of the *scurfy* mouse. IPEX is a rare, X-linked recessive disorder characterized by type I DM, thyroiditis, atopic dermatitis, and inflammatory bowel disease (IBD) and is caused by mutations in the *FOXP3* gene.[11] FOXP3 is a member of the forkhead family of transcription factors and is essential for the development of $CD4^+$ Tregs, which have been shown to regulate the activation and differentiation of effector T cells.

Decreases in numbers and functionality of Tregs have been detected in some autoimmune conditions. These cells likely play important roles in regulating disease onset and amplitude, and therapeutic interventions focusing on Tregs are under investigation in numerous clinical trials (reviewed in Romano et al.[12]).

Signaling Thresholds and Susceptibility to Autoimmunity

Several modulators of T-cell signaling, including CTLA-4 and PD-1, have been defined as important susceptibility determinants in autoimmunity.[9] For example, cytotoxic T-lymphocyte antigen-4 (CTLA-4) polymorphisms are associated with increased risk of a variety of autoimmune diseases, including type I DM, Graves disease, and RA. Similarly, a functional polymorphism in protein tyrosine phosphatase—non–receptor type 22 (PTPN22)—has been identified as a major risk factor for several human autoimmune diseases, including SLE, RA, and type I DM. Although the exact mechanisms underlying susceptibility to autoimmunity remain unclear, these polymorphisms appear to regulate the balance of stimulatory and inhibitory signaling in effector and Tregs, favoring effector T-cell activation. These findings have recently been underscored by the introduction of checkpoint inhibitor therapies.

In 2013, "Cancer Immunotherapy" was named the Science Breakthrough of the Year. Since then, multiple checkpoint inhibitor therapies have been developed for treatment of cancer. By inhibiting the negative regulation of immune cells, checkpoint inhibitor therapy alters signaling thresholds, leading to the activation of effector cells and restricting the function of Tregs (Chapter 80). Thus, checkpoint inhibitor therapy has harnessed the power of the immune system to kill cancer cells that had previously evaded the immune system through tumor- and microenvironment-mediated tolerance. This major contribution to the field of medicine has also emphasized the importance of signaling thresholds in the development of autoimmunity. Indeed, one of the major complications of the use of checkpoint inhibitor therapies is the concurrent development of various autoimmune diseases collectively called immune-related adverse events (irAEs), which could inform on autoimmune diseases (recently reviewed in Ramos-Casals et al.[13]). For example, in patients treated with ipilimumab—a CTLA4 inhibitor—increasing numbers of effector T cells as compared to Tregs are observed as well as an increase in the number of interleukin-17 (IL-17)–expressing cells, potentially driving autoimmunity. Inhibition of the PD-1 pathway also skews the immune response to a more aggressive effector response, often directed at neoepitopes generated by somatic mutation, releasing a prominent anti-cancer effect and proinflammatory side effects.[14] Interestingly, pre-existing autoimmunity does not preclude successful treatment with checkpoint inhibitor therapy and some irAEs resolve after cessation of checkpoint inhibitor therapy. Systemic autoimmune disease in patients treated with checkpoint inhibitors indicates that immune recognition of autoantigens is the rule and not the exception and that antigen recognition is only one aspect of turning protective into pathogenic immune responses.

Recent genetic studies have also suggested a potential role for innate immune sensors in autoimmunity, focusing attention on the critical balance between activation of the immune response to mitigate infectious damage and limiting the magnitude of the response to avoid immunopathology. Gain-of-function (GOF) variants of *IFIH1* (encoding melanoma differentiation-associated protein 5 [MDA5]) are associated with susceptibility to SLE.[15] This RNA helicase is essential for the detection of cytoplasmic viral RNA and activation of type I interferon (IFN) secretion by infected cells. Increased susceptibility to SLE with increased activity of this antiviral pathway suggests that excessive IFN signaling may facilitate the development of autoimmunity. Key immune signaling pathways that protect the host from deleterious infectious and malignant challenges but also enhance tissue damage in the process may, therefore, be important susceptibility factors in autoimmune diseases.

Infections and the Microbiome

Association studies have suggested that both the microbiome and infections (reviewed in Christen[16]) can influence the development of autoimmune diseases. Some infections are associated with specific autoimmune diseases, e.g., herpes simplex virus and NMDAR-encephalitis, *Helicobacter pylori* (HP) and SLE, H1N1 influenza and narcolepsy, *Campylobacter jejuni* and Guillain-Barré syndrome (GBS), and periodontal infections and RA. Dysbiosis may also influence autoimmunity, through several proposed mechanisms, and remains an area of active investigation (reviewed in Christen[16]). Yet, many of the microbes associated with autoimmunity are typically harmless or have limited disease courses and infect a great number of people without giving rise to autoimmunity. For example, 46% of the adult population in the United States has periodontitis, with 8.9% having severe disease, yet only approximately 0.6% of the population develops RA.[17] Although data indicate that, in some people, infections may increase susceptibility to autoimmunity, it remains unclear as to whom or how. Until recently, few studies have highlighted the molecular mechanisms potentially driving these relationships.

Recent work identified a role for microbial translocation in the development of autoimmune disease. Here, the authors demonstrated that translocation of the intestinal bacteria, *Enterococcus gallinarum*, could induce autoimmune responses in a murine model of SLE.[18] Importantly, antibiotic treatment that targeted *E. gallinarum* or vaccination against these bacteria decreased mortality and suppressed the development of autoantibodies and autoreactive T cells. This study suggests that intestinal infection alone was insufficient to increase the risk of autoimmunity, but infection of internal organs after bacterial translocation was. These findings may help explain some of the disparity between infection rates and autoimmune disease occurrence.

Microbes may also directly influence the generation of autoantigens. Evidence for this comes from a study investigating microbial factors that contribute to the development of RA. Konig et al. showed that a pore-forming protein produced by *Aggregatibacter actinomycetemcomitans*— one strain of bacteria that was found in the examined periodontal infections—induced protein citrullination in neutrophils.[19] This is a critical observation, as hypercitrullination of autoantigens in the RA joint by a similar mechanism has been described.[1] Further, the authors demonstrated that infection by this microbe was associated with the presence of known autoantigens in RA.[19] Collectively, these studies provide mechanistic links between infection and autoimmune disease and implicate these bacteria not only in increasing susceptibility to autoimmunity but also in disease initiation, discussed in the following section.

PHASE 2: INITIATION

Initiation of an adaptive immune response requires presentation to T cells of suprathreshold concentrations of molecules with structures not previously tolerized by the host. The immunodominance of T-cell epitopes is one model proposed that explains the existence of potentially autoreactive T cells. This model provides major insights into the pathogenesis of autoimmunity.[9,20]

KEY CONCEPTS

Potential Mechanisms That Can Alter Antigen Processing to Reveal Potentially Cryptic Epitopes

- Modification of autoantigen processing through high-affinity binding to ligands or antibodies.
- Distinct proteolytic machinery in the thymus and periphery—or differential modification of proteolytic activity.
- Modification of autoantigen structure that modifies its processing by endogenous antigen-presenting cell (APC) machinery, generally through posttranslational modifications.
- Novel proteolytic events not present in the normal APC pathways (e.g., novel cleavage during cell death or damage or inflammation).
- Novel forms of autoantigens generated by mutation, truncation, or splicing.

Dominance and Cryptticity

Studies by Sercarz et al.[20] have stressed that, although antigens contain numerous potential determinants that could be presented on major histocompatibility complex (MHC) class II molecules during antigen processing, not all determinants are equally likely to be presented. Those determinants that are most efficiently presented are termed *dominant*; those that are not recognized to a significant degree are termed *cryptic*. For self-antigens, it is likely that a constant set of dominant determinants are generated during antigen processing under most circumstances, with similar outcomes in the thymus and periphery. Antigens processed by the "standard" pathway are, therefore, fully tolerized, with the T-cell repertoire purged of reactivity to the dominant self. However, the balance of dominant and cryptic epitopes presented during antigen processing is influenced significantly by changes of protein structure, which occur during various relevant physiological states.[21] Several potential mechanisms that may alter antigen processing to reveal potentially cryptic epitopes are summarized below.

High-Affinity Binding of Antigen to Ligands or Antibodies

Several studies have demonstrated that antigen processing can be dramatically altered when the antigen binds with high affinity to a ligand or antibody. The study by Simitsek and colleagues (reviewed in Lanzavecchia[21]) demonstrated that presentation of T-cell determinants in tetanus toxin can be either enhanced or suppressed as a direct consequence of antibody modulation of antigen processing in human B-lymphoblastoid cells. Remarkably, a single bound antibody can simultaneously enhance the presentation of one T-cell determinant by more than 10-fold while strongly suppressing the presentation of a different T-cell determinant. Biochemical analyses have shown that both the suppressed and boosted determinants fall within an extended domain of antigen stabilized by this antibody during proteolysis. Thus, ligand-induced changes in processing can destroy dominant determinants or reveal cryptic self determinants. Similar observations have also been made with numerous other antigen–antibody partners.[21]

Tissue-Specific Protease Expression

The study by Watts and associates (reviewed in Rosen and Casciola-Rosen[1]) showed that a principal human leukocyte antigen–D related type 2 (HLA-DR2)–restricted epitope in myelin basic protein amino acids 85–99 (MBP85–99) contains a processing site for asparagine endopeptidase (AEP), with cleavage by AEP abolishing the epitope. AEP, which is abundantly expressed in the thymus, is therefore a critical factor in presentation of this epitope.[1] In human antigen-presenting cells (APCs), presentation of MBP85–99 is inversely proportional to the amount of cellular AEP activity, and inhibition of AEP greatly enhances presentation of the MBP85–99 epitope. Thymus-specific serine protease (TSSP) is also expressed in the thymus and also limits the expression of self-antigens, thereby reducing negative selection. In murine models of MS, the elimination of TSSP resulted in a decrease in autoreactive T cells and disease severity.[22] Collectively, these data suggest that major epitopes in neurological autoimmunity may not be presented under normal circumstances in the thymus as a result of destruction by proteases, therefore raising the potential for later presentation in the periphery in the setting of decreased enzymatic activity.

Posttranslational Modification of Autoantigens

Autoantigens undergo a variety of posttranslational modifications, including phosphorylation, proteolytic cleavage, ubiquitination, transglutamination, citrullination, and isoaspartyl modification.[23] In several cases, autoantibodies recognize exclusively the modified form of the antigen (e.g., citrullinated vimentin), indicating that the modified forms of the molecules are important in driving the immune response. In addition, Doyle and Mamula[23] have demonstrated that posttranslational modification of autoantigen structure may be more broadly relevant than can be appreciated by studying autoantibody specificity alone. They showed that, although mouse immunization with a murine cytochrome c peptide (amino acids 90–104) resulted in no T- or B-cell response, immunization with the isoaspartyl form of this peptide resulted in strong T- and B-cell responses. The autoantibodies that were elicited recognized both the modified and the native forms of the antigen, but T cells only recognized the isoaspartyl form. Similar observations have also been made for several SLE autoantigens. The difficulty detecting and quantifying antigen-specific T cells in various autoimmune diseases may reflect their preferential recognition of subtly modified forms of autoantigen.

Novel Antigen Cleavage During Cell Damage, Cell Death, or Inflammation

Recent studies have provided evidence that single proteolytic events early in antigen processing can play critical roles in defining the epitopes generated. For example, Watts and colleagues (reviewed in Rosen and Casciola-Rosen[1]) have demonstrated that early cleavage by AEP determines subsequent proteolytic events. Antigen modifications that affect this early cleavage dramatically change the epitopes loaded onto MHC class II molecules.[1]

Inflammatory microenvironments can create significant potential to load distinct epitopes because unique proteolytic activities are present. Activated inflammatory cells constitute a major source of proteases, including various cytotoxic lymphocyte granule proteases (granzymes) as well as numerous neutrophil and monocyte granule proteases. It is of interest that numerous autoantigens targeted in systemic autoimmune diseases are substrates for these inflammatory proteases and that unique autoantigen fragments are generated through the activity of granzyme B and potentially other similar proteases.[1] This was recently demonstrated within the context of RA. In this study, Darrah and colleagues demonstrated that proteolysis of the autoantigen PAD4 by granzyme B induced conformational

changes in PAD4, which altered the peptides presented. Importantly, these peptides were recognized by PAD4-specific T cells in patients with RA.[24] Such autoantigen forms are not generated during other forms of cell damage or death, and similar activity is not observed against non-autoantigens. Thus, novel proteolytic cleavage of intracellular autoantigens during activity of cytotoxic immune effector pathways may provide a source of cryptic epitopes not generated during homeostatic "tolerance-inducing" tissue turnover.

Autoantigen Alteration Caused by Mutation, Truncation, or Splicing

Since the final epitopes generated and loaded onto MHC class II molecules can be profoundly influenced by single, early cleavage events during antigen processing, relatively minor but critically placed changes in the primary structure of autoantigens can have the capacity to influence peptide selection. A study of the melanoma and vitiligo-associated autoantigens, tyrosinase-related proteins (TRPs) 1 and 2 has demonstrated that this mechanism may play an important role in generating immune responses to self- and tumor antigens (reviewed in Rosen and Casciola-Rosen[1]). This study examined whether mutated self gene products are more likely to initiate immunity and used a systematic approach to define some of the principles that determine this. The investigators generated complementary DNA (cDNA) libraries encoding large numbers of random mutations in syngeneic TRPs. They then used an approach of DNA immunization of black mice to test the immunogenicity of the altered proteins encoded by the pools of mutated cDNA. Immunization with nonmutated proteins induced no detectable immune responses, consistent with establishment of tolerance to the full-length molecules. In contrast, the mutated cDNA pools elicited both autoimmune depigmentation and the ability to reject melanoma tumors. Additional analysis showed that autoimmunity resulted from mutations that altered autoantigen cell biology, particularly degradation rates and pathways. Mutations also created new T-helper (Th) cell epitopes and induced recognition of nonmutated but previously cryptic epitopes. Interestingly, mutations themselves did not form part of CD8 epitopes that drive anti-self and antitumor immune responses. Mutated molecules that were immunogenic were frequently truncated, leading the authors to propose that inappropriately truncated self proteins can provoke autoimmunity when present in a proinflammatory environment. This study has provided an important mechanistic underpinning for the proposal that accumulated mutations have a role in the initiation of autoimmunity and that "autoimmunity" might target the cancer mutanome. As further evidence for this hypothesis, investigations into the immunity induced by checkpoint blockade demonstrate a preferential targeting of the mutanome.[25,26]

Recent work in the autoimmune rheumatic diseases (scleroderma and dermatomyositis) highlights the relationship between cancer and the autoimmune process. In these diseases, patients demonstrate an increased risk of cancer and a temporal clustering of cancer diagnosis around the time of dermatomyositis or scleroderma onset (reviewed in Rosen and Casciola-Rosen[1]). Similarly, there is evidence for an association between SLE and cancer, particularly lymphoma, clustered within the first 2 years of SLE diagnosis. These associations—both with timing of diagnosis and preferentially with specific tumor types—are strongly indicative of a nonrandom clustering of autoimmune processes and cancer, which is likely of mechanistic significance.

A mechanistic link between scleroderma and cancer was confirmed in a study that tested the hypothesis that an anticancer immune response may target a mutated autoantigen in the patient's cancer, which spreads to the wild-type version of the antigen to trigger a self-sustaining autoimmune disease (reviewed in Rosen and Casciola-Rosen[1]). In this study of patients with scleroderma and cancer, genetic changes (either mutations or loss of heterozygosity) were identified in *POLR3A* (encoding RNA polymerase III large subunit) in the tumors of six of eight patients with anti-RNA polymerase III antibodies, whereas no such changes were identified in eight patients who lacked these antibodies. Anti-RNA polymerase III autoantibodies in patients with cancer demonstrated no specificity for the mutant form of the protein over the wild-type version, and analyses of peripheral blood lymphocytes identified T-cell reactivity against the mutant protein. These data suggest that somatic mutations arising in the context of cancer may prompt immune responses that mediate immunoediting as well as damage to nontumor host tissues.

Therefore, it is likely that somatic mutations acquired with age and their association with malignancy are important in the genesis of some forms of human autoimmunity. Additional studies to confirm this and elucidate the underlying mechanisms remain a high priority. However, the barriers to such studies in humans are very significant, as effective anticancer immunity may be phenotypically silent, and convenient technologies to quantify somatic mutation and specific immune responses in normal individuals will be needed to draw conclusions of causality.

Antigen Mimicry

Foreign antigens often differ structurally from their homologous self-antigens yet may bear significant similarity in focal regions. Initiation of an immune response to the foreign antigen may generate a cross-reactive antibody response that also recognizes the self protein. This process, known as antigen mimicry, has frequently been proposed as a potential initiator of autoimmune diseases.[27] When the antigen is a cell surface molecule, antibody-mediated effector pathways can lead to host tissue damage. Although the antibody response is cross-reactive with self molecules, the T cells that drive this response are generally directed at the foreign antigen. Diseases involving this sort of "antigen mimicry," therefore, tend to be self-limiting, although they can recur upon reexposure to the offending antigen. It is important to realize that antigen mimicry alone cannot explain self-sustaining autoimmune diseases, which are driven by self-antigens and autoreactive T cells. In these cases, there is a requirement for overcoming T-cell tolerance to the self protein. The central issues in this regard are *(i)* how T-cell tolerance to self-antigens might initially be broken, and *(ii)* once this has occurred, why these antigens continue to drive the immune response to self. Several studies have suggested that when a humoral response to a foreign protein is induced that cross-reacts with the self-antigen, a strong T-cell response specific for the self-antigen can occur. The simultaneous liberation of significant amounts of self-antigen in the setting of a cross-reactive antibody response may allow for effective presentation of cryptic epitopes in the self-antigen to autoreactive T cells by activated cross-reactive B cells. If continued release of self-antigen occurs, a specific, adaptive immune response to self will be sustained. Antigen release from tissues likely plays a critical role in driving this autoimmune process. Understanding the unique

pathways of cell injury and death that result in ongoing antigen release at sites of tissue damage in autoimmune disease is a high priority for future work.

The simultaneous confluence of susceptibility factors and initiation forces required to induce an autoimmune disease is a rare occurrence. In contrast, once activation of autoreactive T cells has occurred, the ability of the immune system to vigorously respond to low concentrations of antigen, to amplify responses to those antigens, and to spread the response to additional antigens in that tissue, greatly reduces the stringency that must be met to keep the process going.

PHASE 3: PROPAGATION

Principles of Amplification

One of the central features of human autoimmunity is the tendency of the process to amplify progressively with the accumulation of significant immune-mediated tissue damage. Furthermore, once such amplification begins, the process is very unlikely to resolve spontaneously. Autoantigens themselves can be very important in this phase, in terms of both acquisition of adjuvant properties and regulation of levels of expression. Amplification is a cyclical process in which antigen expression and adjuvant properties induce an immune response, which, in turn, induces increased antigen expression and tissue damage—and further drives the immune response. The importance of tissue-specific autoantigen expression in focusing such immune responses is only beginning to be recognized.

Acquisition of Adjuvant Properties by Disease-Specific Autoantigens

In spite of the fact that tens of thousands of molecules could be targeted by the immune system in autoimmunity, the number of molecules that is frequently targeted in the different phenotypes is markedly restricted—limited perhaps to 100 or so. This has led to the proposal that frequently targeted autoantigens may themselves have properties that make them proimmune. Work by Howard and associates (reviewed in Rosen and Casciola-Rosen[1]) provided important initial support for this proposal. They observed that the autoantigenic histidyl aminoacyl tRNA synthetase (HRS), which is targeted in autoimmune myositis (but not non–autoantigenic lysyl- and aspartyl-aminoacyl transfer RNA [tRNA] synthetases), is a chemoattractant to immature DCs and other leukocytes, which, in turn, may enhance its autoantigenicity. Additional support for this hypothesis comes from work demonstrating that antibodies against PAD2, an enzyme crucial in the formation of autoantigens in RA, are associated with a less severe phenotype.[28] These data suggest that a subset of the autoantigens targeted in autoimmune diseases may reflect an attempt by the immune system to absorb an excess of damaging, proinflammatory molecules.

Role of Innate Immune Receptors in Amplification

Innate immune receptors, including Toll-like receptors (TLRs), cyclic GMP-AMP synthase, and RIG-I, sense and transduce the signals from pathogen-associated molecular patterns (PAMPs). These receptors may also play roles in transducing the proinflammatory properties of autoantigens—the best understood are the TLRs.[1]

Ligands for TLRs are typically microbial. However, endogenous molecules, including complexes containing nucleic acids from stressed, injured, and dying cells (reviewed in Rosen and Casciola-Rosen[1]), are also able to activate TLRs with differences in adjuvant activity. For example, bacterial and viral DNA and oligonucleotides with CpG motifs have significant adjuvant activity, whereas mammalian genomic DNA, in which CpG is usually methylated, has very poor adjuvant activity. In contrast, human DNA within immune complexes in SLE serum effectively activate plasmacytoid dendritic cells (pDC) in a DNA-dependent way. Several potential explanations have been advanced to explain these observations. First, FcγR-mediated uptake effectively captures self DNA bound by anti-DNA antibodies and directs it to the correct endosomal compartment for TLR signaling. Second, co-ligation of TLR9 and either B-cell receptor or FcγR alters the signaling threshold of immune complexes. Last, the difference lies in the nucleic acid itself, with additional modifications of DNA and RNA structure occurring in cells under different physiological circumstances (e.g., cell death) and regulating nucleic acid binding to TLRs.[1]

The TLR–IFN interface has been recognized as critical in the propagation phase of systemic autoimmune diseases (reviewed in Hall and Rosen[29]). Type I IFNs have a broad set of functions that likely contribute to the propagation phase of systemic autoimmune diseases. For example, they (i) promote the differentiation of monocytes into mature DCs, which drive autoreactive T- and B-cell responses; (ii) increase target cell sensitivity to killing pathways; (iii) upregulate cytotoxic effector pathways; and (iv) upregulate expression of autoantigens.

This ability of autoantigens, particularly in the context of immune complexes, to stimulate secretion of IFN and other cytokines is likely an important principle in the initiation and propagation of autoimmunity. For example, Rönnblom and colleagues (reviewed in Hall and Rosen[29]) demonstrated that when added to material from apoptotic or necrotic cells, autoantibodies from patients with SLE and Sjögren syndrome (SS) with specificity for DNA or RNA autoantigens induce striking IFN secretion. Further, studies in mouse models have demonstrated that the TLR–IFN axis can alternately promote wound healing or chronic inflammation, depending on the predisposing genetic background. For example, nonspecific skin injury in wild-type mice (by tape stripping) leads to pDC recruitment, TLR7 and TLR9 recognition of nucleic acids, and transient expression of type I IFNs with subsequent wound healing. In contrast, the same skin damage in a lupus-prone mouse strain results in chronic inflammation mediated by sustained type I IFN expression, which can be ameliorated with pDC depletion or TLR7/9 inhibition (reviewed in Rosen and Casciola-Rosen[1]).

Enhanced Autoantigen Expression in the Target Tissue

The association of specific autoantibody responses with distinct phenotypes suggests that autoantigen expression or conformation in target tissues may play an important role in both focusing the immune response and generating tissue damage. For example, recent work demonstrated that within the labial salivary gland, the double-stranded DNA sensor IFN-inducible protein 16 (IFI16) was in an activated, filamentous form.[30] Importantly, antibodies from patients with SS preferentially recognized filamentous IFI16 as compared to inactivated IFI16. These results demonstrate that, within the target tissue, the autoantigen undertook a unique conformational form, which enhanced its immune recognition.

Likewise, enhanced autoantigen expression has been demonstrated in target tissues. For example, myositis-specific autoantigens are expressed at very low levels in control muscle

but at high levels in myositis tissue. Indeed, antigen expression is highest in regenerating muscle cells.[1] Further supporting this hypothesis, expression of 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR)—an autoantigen in patients with statin-associated autoimmune myopathy—was found to be induced by statins in vitro and enhanced in regenerating muscle fibers of anti–HMGCR-positive patients (reviewed in Rosen and Casciola-Rosen[1]). A recent case control study has also shown that the autoantigen topoisomerase-1 has enhanced expression in the lung tissues of patients with autoimmune inflammatory interstitial lung disease. Collectively, these data suggest that enhanced autoantigen expression in the target tissue and during tissue repair may provide an ongoing antigen source to sustain and amplify tissue damage.

ON THE HORIZON

- Precise clinical and molecular phenotyping of patients at various disease stages is critical for improving diagnosis, monitoring, and treatment of autoimmune diseases.
- Understanding mechanisms of disease amplification, propagation, and regulation will enable the development of effective targeted therapies.
- Understanding the mechanisms of human autoimmunity will likely provide important insights into the normal functioning of the immune system, particularly with regard to natural cancer immunity.

TRANSLATIONAL RESEARCH

Critical areas of future investigation include clarification of the roles of genetic, epigenetic, and environmental factors in disease susceptibility and initiation, understanding the role of the target tissue to ongoing disease amplification, and elucidating mechanisms of regulation of disease amplitude or disease resolution. Collectively, these investigations may provide important opportunities for interventions, including antigen-specific therapies. Further investigations into the molecular underpinnings of the distinct phases in the development of autoimmune disease will provide additional opportunities to identify patients at risk of developing tissue damage and to interdict the process before the amplification cycle is established. Precise biomarker identifications of all events in the development of autoimmunity requires exceptional clinical phenotyping of patients early in the disease course, longitudinal analyses that follow large numbers of patients, and effective coupling to basic laboratory enterprise.

Systemic Lupus Erythematosus

Cynthia Aranow, Betty Diamond, and Meggan Mackay

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease characterized by the production of autoantibodies and a broad spectrum of clinical manifestations. It most commonly presents in women during their childbearing years. Although the etiology of SLE is unknown, both genetic and environmental factors contribute to loss of self-tolerance. Current therapeutic modalities are antiinflammatory and immunosuppressive.

EPIDEMIOLOGY

Originally developed in 1982 and revised in 1997, the American College of Rheumatology (ACR) classification criteria for SLE (Table 52.1) have been used for diagnosis. In accordance with improved understanding of disease heterogeneity, additional classification criteria have been proposed to improve sensitivity and specificity for the diagnosis. The 2012 Systemic Lupus International Collaborating Clinics (SLICC) criteria improved sensitivity at the expense of specificity; added new mucocutaneous and neuropsychiatric manifestations, new antiphospholipid (APL) antibodies, and low complement components; and proposed that biopsy-proven lupus nephritis with either positive antinuclear antibodies (ANA) or antibodies to double-stranded DNA (dsDNA) was sufficient for diagnosis.[1] Recently, a third criteria set, the European League Against Rheumatism/American College of Rheumatology (EULAR/ACR) classification criteria has been developed and validated for use in clinical and translational SLE studies. It includes an obligatory positive ANA test followed by additive weighted clinical and immunologic criteria.[2] An important aim of refining classification criteria is to increase the sensitivity, especially for patients with early disease, to allow these patients access to early therapeutic interventions, including clinical trials.

During childbearing years, the ratio of women to men with lupus is approximately 9:1. This ratio is less in younger and older populations, supporting a role for hormonal factors in disease induction. The majority of SLE presents during adulthood; approximately 20% of cases are in the pediatric population. Recent studies suggest that age at diagnosis may be increasing in some populations; mean ages at diagnosis reported since 2002 range from 31 years in Martinique and Brazil to 51.7 years in Wisconsin (United States) and 47 years in Sweden.

Lupus occurs globally, and susceptibility is linked to race, ethnicity, and environmental exposures. Several recent population surveys[3] report prevalence in the Unites States ranging from 71 to 200 cases per 100,000. The highest prevalence was among Native American Indians, followed by African American, Hispanic, Asian, and White populations. Reported prevalence around the world is also variable; 37 to 65/100,000 in Estonia, Sweden, and Denmark, 85 to 124/100,000 in the United Arab Emirates, and the highest prevalence of 399 to 661/100,000 in Afro-Caribbeans in the United Kingdom. Although epidemiologic data are scant, it appears that the incidence of SLE in Africa is lower. Data from animal models suggest that this may be a consequence of a protective effect of malaria infection. Clinical manifestations, disease activity, damage accrual, mortality, and response to therapy are also modulated by ethnicity, and all studies support observations of increased disease activity, damage, and mortality in non-White populations (Table 52.2).[4]

Mortality and Organ Damage

Increased awareness leading to earlier diagnoses, availability, and use of immunosuppressive agents and to improved treatment for comorbid diseases has contributed to a dramatic decrease in mortality over the past 70 years, with a 5-year survival rate of 50% in the 1950s to 96% to 99% currently.[5] However, all-cause mortality for SLE patients is approximately twofold to threefold greater than for non-SLE patients and has not changed in the past 2 decades. Like disease susceptibility, mortality is also associated with sociodemographic, epidemiologic, clinical, and genetic factors. In general, higher mortality rates are associated with non-White race, Hispanic ethnicity, low socioeconomic status, childhood-onset disease, and male sex. Although mortality causes vary across regions, significant risk is associated with increased disease activity (lupus nephritis in particular), cardiovascular disease, and infection.[3,5] A bimodal distribution of death is well recognized; early deaths often result from infections or active disease, whereas deaths occurring later in the course of disease are frequently attributed to end-stage organ damage and cardiovascular disease. Hydroxychloroquine has been associated with increased survival. Other interventions that decrease mortality include vaccinations and life-style/therapeutic strategies that reduce risk for cardiovascular disease.

With improved survival, the impact of comorbid conditions and medication toxicities has become increasingly important. The ACR/SLICC Damage Index (SDI) is a validated instrument to measure damage related to disease activity, comorbid illness, and/or toxicities of medications that have accrued since SLE diagnosis. Damage scores are associated with poorer quality of life and increased morbidity and mortality. Renal, musculoskeletal, and cardiac domains are consistently the major contributors to damage.

TABLE 52.1 American College of Rheumatology Criteria for Systemic Lupus Erythematosus

Criteria	Description
Malar rash	Fixed malar erythema, flat or raised
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as an unusual reaction to sunlight, by patient history or physician observation
Oral ulcers	Oral and nasopharyngeal ulcers, usually painless, observed by physician
Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	Pleuritis (convincing history of pleuritic pain or rub heard by physician or evidence of pleural effusion) *or* Pericarditis (documented by electrocardiogram or rub or evidence of pericardial effusion)
Renal disorder	Persistent proteinuria >0.5 g per day or >3+ if quantification not performed *or* Cellular casts may be red cell, hemoglobin, granular, tubular, or mixed
Neurologic disorder	Seizures—in the absence of offending drugs or known metabolic derangements (*e.g.*, uremia, ketoacidosis, or electrolyte imbalance) *or* Psychosis—in the absence of offending drugs or known metabolic derangements (*e.g.*, uremia, ketoacidosis, or electrolyte imbalance)
Hematologic disorder	Hemolytic anemia—with reticulocytosis *or* Leukopenia (<4000/mm^3 total on two or more occasions) *or* Lymphopenia (<1500/mm^3 on two or more occasions) *or* Thrombocytopenia (<100,000/mm^3 in the absence of offending drugs)
Immunologic disorder	Anti–double-stranded DNA: antibody to native DNA in abnormal titer *or* Anti-Sm: presence of antibody to Sm nuclear antigen*or* Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of immunoglobulin G (IgG) or IgM anticardiolipin antibodies; (2) a positive test for lupus coagulant using a standard method; or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
Antinuclear antibodies	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome

IMMUNOPATHOGENESIS

The immune system is designed to protect the host against foreign pathogens and to remove cellular debris without damaging self. With their universal production of immunoglobulin G (IgG) autoantibodies and characteristic pathologic findings of inflammation, vasculopathy, and immune complex deposition, SLE patients display a failure to maintain immune tolerance and immune homeostasis. The heterogeneity of disease manifestations reflects the multiplicity of genetic, hormonal, and immune abnormalities and the diversity of environmental triggers or modifiers contributing to clinical disease (Table 52.3). Progression from initial autoreactivity to clinical disease occurs over time (Fig. 52.1); the first detectable immune abnormalities are either the presence of serum autoantibodies or the increased expression of interferon (IFN)-inducible genes in blood cells (the IFN signature).

It is now recognized that there are two dominant pathways involved in disease. The innate immune system is perturbed in ways that lead to the immunogenicity of cellular debris and the production of high levels of type I IFN. The adaptive immune system exhibits hyperactivation of B cells. These two pathways intersect. High IFN promotes enhanced B-cell activation. The failure to clear apoptotic debris leads to reactivity to cellular and especially nuclear antigens. Reciprocally, the increased production of IgG ANA leads to nucleic acid–containing immune complexes which transport nucleic acids to endosomal Toll-like receptors (TLRs) through an Fc receptor–mediated pathway. Thus active SLE exhibits perturbations in both innate and adaptive immune responses. SLE risk alleles contribute to these perturbations. Genes conferring risk for SLE are most abundantly expressed in myeloid cells and B cells. Many lead directly to the major immune abnormalities in SLE (*e.g.*, the failure in clearance of apoptotic debris, the increase in IFN production, or B-cell hyperactivity). These observations suggest that B cells and myeloid cells may be important drivers of disease. Alterations in B-cell tolerance, alterations in antigen presentation to T-effector and T regulatory cells (Tregs), and alterations in cytokine production are now recognized as central to disease pathogenesis.

Autoantibodies

ANAs are present in more than 98% of patients diagnosed with SLE. Their presence is not specific to SLE because they are observed in patients with other autoimmune diseases, malignancies, and viral (hepatitis) and parasitic (malaria) infections, as well as in response to environmental triggers such as therapeutic agents (see section on Drug-Induced Lupus, later). Furthermore, ANAs are found in low titer in 5% of the general population, with prevalence increasing with age. Common ANA specificities found in lupus patients include dsDNA, single-stranded DNA (ssDNA), extractable nuclear antigens (Sm, RNP, Ro, and La), histones, and chromatin. Specific antibody specificities are associated with disease subsets such as anti-Ro antibodies with subacute cutaneous and neonatal SLE, anti-dsDNA, and anti-C1q antibodies with renal disease.[6] Most autoantibody titers do not correlate with disease activity; anti-dsDNA antibodies

are a notable exception. Their fluctuation with disease activity suggests a pathogenic role for this autoantibody, and monitoring their titer helps to predict impending disease flare in some patients.

The Predisposed Host: Genetic Contributions

SLE is generally a multigenic disease. However, there are a few monogenic causes of SLE, such as C1q deficiency. Most disease-associated alleles are present in healthy individuals as well. Only when multiple alleles are present, along with an appropriate environmental trigger or other genes that are not identified as risk alleles, but function together with risk alleles to perturb the immune system, will a lupus-like phenotype arise. Familial disease clustering and a higher disease concordance in monozygotic than dizygotic twins suggest both an underlying genetic susceptibility and the importance of environmental or epigenetic factors.

Susceptibility genes affect lymphocyte activation, proliferation and apoptosis, cytokine production, antigen presentation, and clearance of apoptotic debris. Many of these genes are also implicated in susceptibility to other autoimmune diseases (*e.g., CTLA4* in Graves disease and type 1 diabetes, *PTPN22* polymorphisms in rheumatoid arthritis and type 1 diabetes).[7,8] Genome-wide association studies (GWASs) and genome-wide linkage analyses have utilized high-throughput techniques to study hundreds of thousands of single nucleotide polymorphisms (SNPs) in individual patients with SLE and have yielded approximately 100 SLE-associated susceptibility loci,[9] some of which are of relevance in particular ethnic and racial groups.

Antigen Presentation

Polymorphisms of major histocompatibility complex (MHC) genes determine the peptides of self and foreign antigens presented within MHC molecules that determine the naïve T-cell repertoire. Human leukocyte antigen (HLA)-DR2 haplotypes in African American, African, Taiwanese, and Korean populations and HLA-DR3 haplotypes in White populations have been associated with a twofold to threefold increased risk for developing SLE.[10] Associations between anti-Ro antibodies and HLA-DR3 and anti-La antibodies and HLA-DR25 are consistent with the concept of antigen-driven processes involving T-cell recognition. The association of HLA with SLE is not as dominant as with other autoimmune disease, suggesting that the T-cell response may dictate autospecificity (as earlier), but is less important in determining risk of disease.

Impaired Clearance of Apoptotic Debris

Patients with severe deficiencies of C2, C4, and C1q display disease risks of 10%, 75%, and 90%, respectively, for SLE.[11] Reduced uptake of apoptotic cells has been implicated in disease initiation in murine models of SLE and is seen histopathologically in lymph nodes of lupus patients.[12]

Polymorphisms of mannose-binding lectin (MBL) and C-reactive protein (CRP)—acute-phase reactants that facilitate opsonization and phagocytosis of immune complexes, apoptotic debris, and microbes—also associate with SLE susceptibility.

The Fcγ receptors—FcγR1 (CD 64), FcγRII (CD32), and FcγRIII (CD16)—have different binding affinities for IgG and immune complexes and different cell-specific expression and function. FcγRI, FcγRIIa, and FcγRIIIa and IIIb are all activating receptors. Cross-linking these receptors by immune complexes results in degranulation, phagocytosis, antibody-dependent cellular cytotoxicity, cytokine gene transcription, and release of inflammatory mediators by myeloid cells. Substitutions of one or more amino acids in the activating FcγR genes—arginine (R) for histidine (H) at position 131 in FcγRIIa and phenylalanine (F) for valine (V) at position 158 in FcγRIIIa—results in decreased affinity for IgG immune complexes. Because apoptotic debris is opsonized by antibody to promote clearance, such deficiencies may lead to immune activation by apoptotic debris. FcR polymorphisms may also predict a therapeutic response to immunobiologic agents such as rituximab.[13,14] In contrast to the activating Fc receptors, FcγRIIb is an inhibitory receptor. Engagement of FcγRIIb on macrophages and dendritic cells (DCs) delivers an inhibitory signal.

Lymphocyte Activation, Proliferation, and Function

Several SLE risk genes have been implicated in the regulation and activation of lymphocytes. *BLK*, *LYN*, and *BANK1* encode the tyrosine-kinase proteins Blk and Lyn and B-cell scaffold protein with ankarin repeats; all are associated with intracellular signaling pathways. *ETS1* and *IKZF1* encode transcription factors and are believed to play a role in B-cell differentiation and self-tolerance. Cytotoxic T lymphocyte antigen-4 (CTLA-4) is upregulated on T cells after activation and dampens inflammatory responses. It has a higher affinity than CD28 for B7.1 (CD80) and B7.2 (CD86), thereby competitively inhibiting engagement of CD28 and blocking the costimulatory signal

required for T-cell activation. CTLA-4 ligation of B7 also activates indoleamine dioxygenase (IDO) expression, an enzyme involved in tryptophan metabolism, and diminishes T-cell proliferation. Finally, CTLA-4 is critical for activation of regulatory T cells. In CTLA-4$^{-/-}$ mice, an uncontrolled, lethal inflammatory response occurs. CTLA-4 alleles with decreased production of soluble CTLA-4 are implicated in the pathogenesis of several autoimmune diseases, including Sjögren disease, ulcerative colitis, psoriasis, type 1 diabetes, and multiple sclerosis as well as SLE.[15]

The *PTPN22* gene encodes a tyrosine phosphatase that has been suggested to downregulate T-cell receptor (TCR) and B-cell receptor (BCR) activation, although the precise role of PTPN22 in disease pathogenesis remains unresolved. A *PTPN22* polymorphism resulting in diminished interaction with Csk has been reported in SLE and other autoimmune diseases, suggesting a common mechanism of immune dysregulation. Surprisingly, the PTPN22 risk allele has also been associated with reduced type I IFN production by myeloid cells after activation of TLR7.

Cross-linking of FcγRIIb and the BCR results in decreased intracellular calcium flux with decreased B-cell activation and proliferation. The FcγRIIb I232T allele leads to the inability of the receptor to enter lipid rafts and associate with the BCR, thereby diminishing its ability to perform an inhibitory function. Dysregulation of FcγRIIb expression on activated memory B cells has been reported in SLE patients.[14]

Cytokine and Chemokine Regulation

IFN regulatory factor 5 gene *(IRF5)* encodes a critical transcription factor in the type I IFN pathway; the *IRF5* locus has the strongest association with SLE outside of the MHC region. Four allelic variants have been identified in multiple ethnically diverse populations. These alleles seem to be most important for myeloid cell function, even though IRF5 is expressed in numerous cell lineages. Variants of the signal transducer and activator of transcription factor 4 protein *(STAT4)* gene have also been associated with SLE susceptibility. Interleukin (IL)-1 receptor-associated kinase 1 *(IRAK1)* and methyl-CPG-binding protein 2 *(MECP2)* genes are both found on the X chromosome. IRAK1 regulates multiple pathways in innate and adaptive immune responses, including the link between immune complexes, TLR signaling, and IFN production. Monocyte chemoattractant protein (MCP)-1 is a potent chemoattractant for monocytes, memory T cells, and natural killer T cells. MCP-1 expression is upregulated in renal tubular cells, and glomeruli and urine levels of MCP-1 are increased in patients with active lupus nephritis. An MCP-1 polymorphism resulting in increased MCP-1 production has been associated with nephritis.[16] Polymorphisms in the tyrosine kinase-2 *(TYK2)* gene are associated with increased expression of type I IFNs (IFN-α, IFN-β) in SLE. IFN-α–regulated genes are highly expressed in peripheral blood cells from SLE patients compared with healthy controls (the IFN signature).[17] IFN-α mediates maturation of DCs and monocytes, increasing the capacity for T-cell activation; promotes B-cell differentiation and immunoglobulin class switching; and skews to extrafollicular plasma cell differentiation. However, in two murine models of lupus, decreases in type I IFNs unexpectedly led to worsening disease, consistent with numerous studies showing that type I IFNs have both proinflammatory and antiinflammatory effects on innate and adaptive immune responses and suggesting that the effect of IFN-α on autoimmunity is complex.

TREX1 encodes a 3′ repair exonuclease that monitors DNA synthesis; TREX1 deficiency leads to accumulation of endogenous DNA and is associated with increased expression of IFN and autoimmunity.

Multiple polymorphisms in the *IL10* gene have been reported, with conflicting results with respect to SLE susceptibility. A meta-analysis of 15 studies concluded that some *IL10* polymorphisms do associate with SLE, but their importance is modulated by ethnic background.[18]

In the NZB/W murine model, a tumor necrosis factor (TNF) allele associated with low production is linked with disease, and treatment with TNF decreases autoantibody production. Consistent with this observation, TNF blockade for rheumatoid arthritis or inflammatory bowel disease can lead to autoantibody production and infrequently to frank lupus. Several polymorphisms for genes encoding TNF and lymphotoxin have been associated with SLE; these associations are also influenced by ethnicity.[19]

Cell Survival

Fas ligand (expressed on activated T cells) binding to Fas (CD95) stimulates a signaling pathway resulting in apoptotic death of the Fas-expressing cell. Fas-induced apoptosis of activated cells contributes to the elimination of autoreactive B and T lymphocytes. Lymphopenia in SLE has been associated with increased Fas expression on lymphocytes, and Fas and Fas ligand alleles have been linked to disease susceptibility.[20] Lack of Fas expression in mice leads to an SLE-like phenotype, whereas lack of Fas expression in humans is associated with a lymphoproliferative disease that does not share autoantigen specificities and target organs with SLE.

Bcl-2 family genes encode intracellular proteins that are either proapoptotic or antiapoptotic. Increased expression of Bcl-2, an antiapoptotic molecule, leads to a lupus-like serology and nephritis in mice with certain genetic backgrounds. Increased intracellular levels of Bcl-2 have been reported in SLE. The combination of a Bcl-2 susceptibility allele and IL-10 susceptibility allele confers a 40-fold increased risk of SLE, demonstrating that *infelicitous* combinations of risk alleles potentiate risk.[21]

Target Organ Damage

Only a few genes are known to regulate the vulnerability of target organs (*e.g.*, the kidney) to autoimmune attack. In mice, genes encoding kallikreins, which upregulate bradykinins, have SLE susceptibility alleles. In human studies a risk allele for ABIN1, which regulates nuclear factor (NF)-κB activation, can lead to greater kidney disease. Two risk alleles of APOL1 are particularly common in African Americans and are thought to contribute to the increased severity of renal disease in this population.

Epigenetic Contributions

Epigenetic regulation plays a determining role in gene activation. Major epigenetic influences in SLE involve DNA methylation at cytosine-guanine nucleotides (CpG methylation) and histone posttranslational modifications (lysine acetylation or methylation, phosphorylation of serine or threonine, arginine methylation).[22] SLE susceptibility and autoantibody production are associated with DNA hypomethylation.[23] Consistent with this observation is the fact that several drugs known to induce a lupus-like disease (procainamide, hydralazine) also cause decreased DNA methylation. A landmark study of high-throughput analysis of DNA methylation in discordant twins

demonstrated greater DNA hypomethylation in the affected siblings.[24] It is not surprising that genes encoding integrins, NGAL, CD40 ligand, IFN-γ receptor, and IL-6 are among the hypomethylated genes in SLE. Mechanisms for hypomethylation remain unclear; decreased efficacy of DNA methyltransferases (DNMTs) and overexpression of microRNAs (miRNA) that interfere with DNMT activity have been proposed.[25]

Vitamin D has been shown to contribute to the regulation of the epigenome. Vitamin D levels are low in many lupus patients, but the relationship of vitamin D levels to disease risk or disease severity remains controversial.[26]

Inflammation itself may alter the epigenome; some studies suggest that the metabolic modulator metformin can reverse some of the inflammation-induced alterations. Recent studies show that metformin can reduce murine lupus, although the mechanism for this therapeutic effect is not clear.

B Cells

The process of immunoglobulin variable region gene rearrangement produces large numbers of self-reactive B cells. Most B cells displaying self-reactive immunoglobulin are deleted centrally in the bone marrow and at subsequent checkpoints in the periphery (Fig. 52.2), so the frequency of autoreactive cells decreases from approximately 75% in immature B cells in the bone marrow to approximately 20% in the mature naïve B-cell population in healthy individuals. Many of the autoreactive B cells in the naïve population are normally suppressed by anergy induction. Several of these checkpoints may be deficient in SLE. The IgM autoantibodies made by these remaining autoreactive mature naïve B cells are thought to facilitate clearance of apoptotic cells in a non-immunogenic fashion. When IgM autoreactive antibodies are missing in mice, a lupus-like phenotype develops.

B cells differentiate to plasma cells through two distinct pathways, extrafollicularly or in the germinal center. Both these pathways have been implicated in SLE.

An important peripheral checkpoint for B cells maturing through a germinal center pathway is entry into the T-cell–dependent, long-lived memory compartment. B cells with the 9G4 idiotype express antibodies encoded by the *VH4-34* gene, reactive with *N*-acetyllactosamine (NAL) determinants of glycoproteins on blood group antigens targeted by cold agglutinins, gangliosides, gastrointestinal (GI) mucins, glycolipids, and CD45 on B lymphocytes.[27] 9G4 B cells are reported to be present in 5% to 10% of the naïve B-cell population in healthy donors as well as in the IgM memory compartment. However, 9G4 B cells are excluded from the T-cell–dependent IgG memory and plasma cell populations, suggesting that these autoreactive cells fail to cross a developmental checkpoint after activation in normal individuals. Evaluation of tonsillar biopsies and spleens from healthy donors shows that the frequency of germinal centers with 9G4-positive cells is less than 1%, implying that negative selection of autoreactive cells occurs at the transition of naïve to germinal center B cells. In contrast, tonsillar biopsies from SLE patients demonstrate that 15% to 20% of germinal centers are positive for autoreactive 9G4 B cells. This study and others suggest that checkpoints exist for entry into and egress from the germinal center response and that these may be altered in SLE.

It is clear that some pathogenic autoantibodies are not derived from natural autoantibodies. Back mutation of several anti-DNA antibodies to their germline-encoded precursors has identified non-autoreactive precursors. The failure of censoring mechanisms in germinal centers to prevent the maturation of autoreactive cells may reflect intrinsic B-cell abnormalities or abnormalities in costimulatory molecules, cytokines (*e.g.*, B cell–activating factor [BAFF]; see later), follicular DCs, or T-cell, B-cell interactions.

An alternative model recently put forth is that more B cells differentiate to IgG plasma cells in SLE patients, leading to greater antibody production rather than defects in specific tolerance checkpoints in SLE patients.[28]

B lymphocyte stimulator (BAFF; also known as BLyS) is a member of the TNF family and participates in B-cell maturation and survival. BAFF enhances survival of B cells through engagement of several receptors (BCMA, BAFF-R, and TACI). High levels of this cytokine allow survival of autoreactive B cells in mice, resulting in a lupus-like disease.[29] Evidence supporting a role for BAFF in autoreactive B-cell rescue and human SLE includes the elevated levels seen in lupus patients, associations of BAFF levels with autoantibody titers, and, in some reports, correlations with disease activity. Belimumab, a monoclonal antibody directed against soluble BAFF, has been shown to increase the percentage of anergic ANA-positive B cells in SLE patients.

Interactions between CD40 (B cell) and CD40 ligand (CD40L, T cell) are essential for B-cell proliferation, differentiation of memory cells into plasma cells, and germinal center formation. Immature autoreactive B cells can be rescued from antigen-induced apoptosis by engagement of CD40 or by IL-4. SLE T and B cells have upregulated CD40L, a critical molecule to mediate B-cell rescue. The combination of IL-17 and BAFF facilitates B-cell proliferation and maturation.[30] This combination can serve as an alternative stimulatory signal for B-cell activation and can replace CD40/CD40L interactions. Therefore in a permissible and proinflammatory cytokine milieu, B-cell

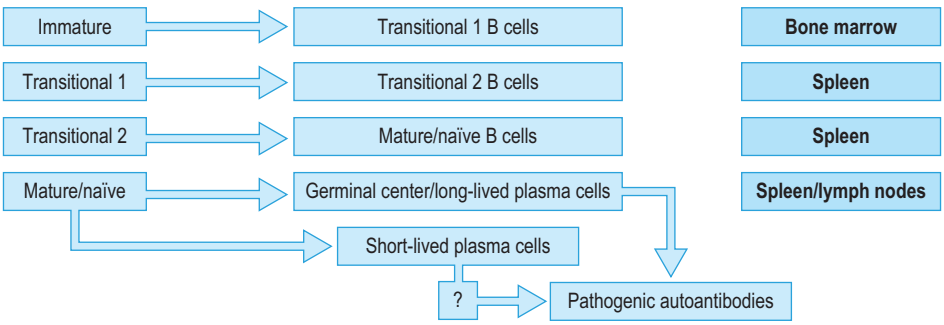

FIG. 52.2 Autoreactive B-Cell Checkpoints. There are tolerance checkpoints at every stage of B-cell activation and maturation. How many checkpoints need to be breached to achieve a pathogenic state and clinical disease is not known.

activation and autoantibody production may occur in the absence of cognate T-cell help.[31] These studies are consistent with the increased numbers of plasmablasts and class-switched CD27-negative B cells in blood of lupus patients.

B cells are efficient antigen-presenting cells; B cells with self-reactive specificity that have escaped tolerance are likely to present self-antigen to autoreactive T cells. This may explain, in part, the beneficial effects of treatment with rituximab, a B cell–depleting drug, in SLE even as autoantibody levels remain largely unaffected.

Hyperactive B-cell responses to immunologic stimulation are implicated in the production of pathogenic antibodies. SLE B cells have increased intracellular Ca^{2+} flux in response to BCR signaling,[31] partially due to FcγRIIb dysfunction (Ile 232 Thr).[32]

The intracellular protein tyrosine kinase Lyn has both positive and negative effects on BCR signaling. Decreased expression of Lyn results in increased intracellular Ca^{2+} flux and B-cell hyperactivity. Correspondingly, Lyn expression is decreased in resting and activated B cells in one-half to two-thirds of SLE patients.

A new B-cell subset has been identified, the so-called age or autoimmunity-associated B cells (ABCs). This subset is expanded in patients with SLE. It is dependent on TLR activation, and some studies suggest it is a major source of autoantibodies.[33]

Neutrophils

An important link exists between neutrophils and autoimmunity. Neutrophil extracellular traps (NETs) are chromatin filaments released from neutrophils to trap microbes. NETs also contain neutrophil peptides, including neutrophil-encoded antimicrobial peptide LL37 (cathelicidin). Anti-DNA antibodies bind to DNA in NETs and are potent TLR9 stimulants, resulting in production of IFN-α by plasmacytoid DC (pDC).[34] Moreover, anti-RNP antibodies induce "NETosis" in a process that is dependent on TLR7 and FcγRIIa signaling.[35] These studies confirm earlier work that described a "granulocyte signature" with significant upregulation of granulocyte-specific transcripts within peripheral blood mononuclear cells in pediatric SLE patients.[36]

Dendritic Cells

DCs recognize pathogens through membrane pattern recognition receptors (PRRs) and are a critical component of the immune system connecting innate and adaptive immune responses.[37] They can be tolerogenic or immunogenic due to their high expression of costimulatory molecules. DCs function normally as surveillance cells, phagocytizing cellular debris and determining whether there is cause for alarm. PRRs on DCs bind pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs) that are present in sterile inflammation. After internalization of the PAMPs or DAMPs, endosomal TLRs are activated by nucleic acids and other ligands. Enhanced IFN-α in SLE pathogenesis is now well described. The primary cells responsible for IFN-α production are pDCs. TLR7 or TLR9 activation with RNA and DNA, respectively, induces immature DCs to differentiate to immunocompetent, IFN-α–producing DC that have wide-reaching effects on T cells, B cells, neutrophils, and monocytes. Of note, type I IFN increases plasmablast differentiation favoring short-lived plasma cells over germinal center–matured long-lived plasma cells. pDCs have been demonstrated in skin and renal lesions, and upregulation of the "IFN signature" is observed in many, but not all, SLE patients and has been associated with disease activity. A number of susceptibility genes identified through GWASs are associated with IFN pathways in SLE.

T Cells

T cells are critical in the abrogation of self-tolerance by providing help to autoreactive B cells and facilitating the production of somatically mutated, high-affinity, pathogenic autoantibodies. Lupus patients can exhibit T cell phenotypes consisting of increased numbers of $CD3^+CD4^-CD8^-$ T cells, increased Th17 cells, T-follicular helper (Tfh) cells, and decreased numbers or function of Tregs.[38] In addition, lupus T cells display increased expression of activation markers and abnormal TCR signaling responses. A substitution of TCR ζ-chain by the γ-chain of the Fc receptor results in increased intracellular influx of Ca^{2+} after TCR stimulation and a concomitant decrease in IL-2 production, disfavoring the induction of Tregs.

Self-tolerance is maintained in part by the suppressive actions of Tregs. "Natural" Tregs arise *de novo* in the thymus, whereas "induced" Tregs evolve from naïve T cells exposed to IL-2 and transforming growth factor (TGF)-β in the periphery. These cells are characterized by high surface expression of the IL-2 receptor α-chain, CD25, and high levels of FOXP3 intracellularly. Tregs act together with tolerogenic DC to maintain a steady state of immature DCs. In contrast, effector T cells can secrete IFN-γ and IL-17 that promote immature DC differentiation to immunogenic DCs capable of secreting IL-1, IL-6, IL-12, and TNF and activating autoreactive T cells, thereby establishing a feedback loop with impaired Tregs and activation of autoreactive T cells.[39] Studies demonstrate alterations in Tregs in patients with SLE. Some have demonstrated reduced numbers and altered function of peripheral $CD4^+CD25^+FOXP3^+$ cells in patients with active disease, whereas others fail to identify a defect.[40] SLE and some other autoimmune diseases are characterized by an expanded population of $CD4^-CD8^-$ (double negative) T cells that produce IL-10; some believe these are autoreactive T cells.[41]

HORMONAL INFLUENCES

The most compelling evidence for the role of sex hormones in SLE is the observation that lupus preferentially affects women of childbearing age. The female-to-male ratio is 2:1 before menarche, 8 to 9:1 in the fourth decade, and 2:1 after menopause. Numerous case reports and studies of disease flares correlating with pregnancy, menstruation, and use of oral contraceptives containing high doses of estrogen suggest a role for estrogen in disease activity. A significant correlation between plasma levels of estradiol, increased α-hydroxylation of estrogen in SLE, yielding the more active metabolite 16α-hydroxyestrone, and clinical disease activity is also reported.[42] No significant differences in levels of sex hormones (including estrogen, testosterone, prolactin) are noted in male SLE patients, suggesting that the development of SLE in females may be more closely related to sex hormones than in men. Randomized controlled studies of estrogen in SLE suggest that the use of exogenous estrogen in patients with stable disease may be safe; however, a subset of patients appears to have an estrogen-sensitive disease. Mild to moderate flare rates were significantly increased in postmenopausal women treated with hormone replacement therapy.

Most of what we understand about hormonal modulation of B-cell development comes from mouse studies.[43] Estrogen

treatment of NZB/W and MRL/*lpr* mice or castration of male lupus-prone mice exacerbates disease, whereas oophorectomy of female mice ameliorates disease. Treatment of lupus-prone mice with the selective estrogen receptor modulator tamoxifen also ameliorates disease.

Estrogen and prolactin promote the loss of B cell tolerance in nonautoimmune mice. Estrogen results in diminished B-cell responsiveness to BCR cross-linking and in less stringent negative selection. In addition, estrogen has also been reported to inhibit activation-induced T-cell death by downregulation of Fas ligand expression, thereby permitting increased numbers of autoreactive T cells.[44] Emerging data suggest that estrogen receptor signaling promotes differentiation of DC into immune-competent DC through increased expression of the transcription factor IRF4.[45]

Elevated prolactin levels are reported in 20% of patients with SLE, and increased prolactin exposure in lupus-prone mice exacerbates disease activity. Treatment of patients with bromocriptine yielded equivocal results, whereas treatment of NZB/W lupus mice with bromocriptine results in improved survival. Transmembrane prolactin receptors are present on a variety of cells, including T and B cells. Upregulation of both Bcl-2 and CD40 on B cells and CD40L on T cells occurs in response to prolactin, suggesting pathways that may be involved in the prolactin-mediated rescue of autoreactive B cells.

Data on the microbiome demonstrate that sex hormones can modulate its composition. Studies in murine lupus suggest that androgens generate a microbiome that prevents the development of lupus, whereas estrogen maintains a disease-permissive microbiome. Studies of the microbiome in human disease are just beginning.[46]

CLINICAL MANIFESTATIONS

CLINICAL PEARLS

- Systemic lupus erythematosus (SLE) is a systemic disease with the potential to affect any organ system.
- Not all symptoms experienced by a patient with SLE are from SLE-disease activity. Attribution is critical to determine before initiation of treatment. The differential diagnosis of a lupus flare mandates consideration of infection, drug toxicities, or other etiologies.
- Corticosteroid exposure should be minimized.
- Use of aggressive treatment must be balanced against associated toxicities.
- SLE patients accumulate damage from both repeated episodes of inflammatory disease and medication toxicities. Prompt recognition and appropriate treatment of disease flares should result in reduced exposure to corticosteroids and immunosuppressive agents.
- SLE patients are at increased risk of developing atherosclerotic disease, osteoporosis, malignancy, diabetes mellitus, and hypertension. It is essential to screen for and reduce modifiable risk factors.

The prevalence of the diverse clinical and laboratory features of lupus varies in published reports (see Table 52.2). Both genetic and environmental factors are likely to account for much of the variability between cohorts. Characteristics of published cohorts, including inception versus long-standing lupus cohorts, community versus academic settings, socioeconomic factors, and ascertainment differences are also likely to contribute to observed differences in the prevalence of clinical manifestations. Over time, the course of lupus is characterized by disease flares and remissions.

KEY CONCEPTS

- Continued heightened awareness of systemic lupus erythematosus to shorten the time between onset of symptoms and diagnosis is needed to improve outcomes.
- Lupus is a disease characterized by recurrent flares.
- Attentive monitoring, even during periods of disease remission, leads to early recognition of impending flare, better control, and better prognosis.
- Lupus is a chronic disease; the importance of a therapeutic partnership between physicians and patients, emotional/social support, and patient education cannot be overemphasized.
- Advances in understanding mechanisms of disease pathogenesis correspond to advances in treatment strategies and development of therapies with improved efficacy and safety profiles.

The most common features of lupus are constitutional and include fatigue, malaise, low-grade fever, anorexia, and lymphadenopathy. These symptoms are believed to result from elevated serum levels of inflammatory cytokines and may accompany other organ system manifestations of active disease, or may occur in isolation. Although frequent, these symptoms are nonspecific and do not aid in making the diagnosis of SLE. Symptoms of fatigue and malaise may also represent fibromyalgia, which can co-occur with SLE or confound the diagnosis.[47]

Musculoskeletal Involvement

The musculoskeletal system is the most common organ system affected in SLE; joint pain is the presenting symptom in approximately 60% to 70% of patients, and 85% have joint involvement after 5 years.[48]

Arthritis and Arthralgia

The pattern of joint involvement is usually symmetric, affecting the small joints of the hands, wrists, and knees. Large joint or monoarticular involvement is less typical. In contrast to rheumatoid arthritis, morning stiffness is typically limited to several minutes. Frequently, the subjective complaints of pain are greater than the objective findings of warmth, swelling, and erythema and must be distinguished from concomitant fibromyalgia. Lupus arthritis is characteristically nonerosive on x-ray and nondeforming. Anticyclic citrullinated peptide antibodies occur frequently in the rare patients with erosive arthritis. Some lupus patients develop a nonerosive hand deformity with hypermobile joints secondary to tendon and ligamentous laxity (Jaccoud arthritis) (Fig. 52.3). Proliferative tenosynovitis, synovitis, small erosions not detectable on plain radiographs, capsular swelling, and bone marrow edema are features of joint and soft-tissue involvement that may be seen on MRI. Although sensitive techniques, the role of ultrasound and MRI in the evaluation and management of musculoskeletal symptoms is not established.

Joint effusions, when they occur, are usually small. The fluid is clear yellow with normal viscosity and forms a mucin clot. It is typically noninflammatory with a normal glucose level and a white blood cell (WBC) count of less than 2000 cells/mL that is predominantly lymphocytic. ANA performed on the synovial fluid may be positive, and lupus erythematosus (LE) cells may be present. Synovial fluid complement levels can be normal or depressed. Synovial histology in lupus is not specific and shows synovial hyperplasia with fibrin deposition and microvascular changes that include perivascular infiltrates in the majority of cases.

FIG. 52.3 Jaccoud Arthritis in Systemic Lupus Erythematosus.

Tendinitis

Tendinitis is not usually attributed to SLE unless associated with tendon rupture. When present, it is usually located in the Achilles tendon or the tendons around the knee. Tendon ruptures are more common in males and have been associated with trauma, steroid use, long disease duration, and Jaccoud arthropathy.[49] Biopsy shows a mononuclear infiltrate with tendon degeneration and neovascularization. The diagnosis can be easily made by ultrasound or magnetic resonance imaging (MRI).

Myositis/Myalgia

Generalized myalgia is extremely common in lupus. It frequently affects the deltoids and quadriceps and occurs during flares of active disease. Muscle disease secondary to treatment with corticosteroids, statins, and antimalarials or in association with hypothyroidism is also frequent and must be considered in the evaluation of a lupus patient with myalgia. Inflammatory muscle disease with weakness and an elevated creatine phosphokinase is less common, occurring in approximately 10% of lupus patients.[47] Electromyography can be normal or can be characteristic of the myositis observed in polymyositis or dermatomyositis. Muscle biopsy can also be normal or can show changes associated with dermatomyositis such as a perivascular or perifascicular infiltrate and immunoglobulin and complement deposition. Muscle atrophy, fiber necrosis, microtubular inclusions, and/or a mononuclear infiltrate have been documented. MRI findings are nonspecific.

Avascular Necrosis

Avascular necrosis (AVN) has been reported in up to 30% of lupus patients, is frequently asymptomatic, and is detected by MRI.[50] The most commonly affected site is the femoral head. Groin pain exacerbated with weight bearing is a common complaint. In addition to the hip, AVN can involve the knees, shoulders, and wrists. The majority of AVN is associated with previous administration of high doses of corticosteroids (>30 mg/day), vitamin D deficiency, minority ethnicity, hypertension, and renal disease. Disease activity, independent of corticosteroid exposure, is an additional risk factor in patients with early lupus.[51] Bone biopsy in lupus patients affected by AVN does not reveal unique findings.

Mucocutaneous Manifestations

Skin: Classification and Pathogenesis

Cutaneous lupus erythematosus (CLE) occurs commonly, up to 70% of the time, in the context of SLE. It consists of a wide variety of lesions from the characteristic malar erythema to severe bullous lupus and scarring discoid lesions. Although rarely life threatening, CLE can be disfiguring and contributes substantially to depressive symptoms and diminished life quality.[52,53] The 2012 SLICC classification criteria include 10 mucocutaneous lesions not included in the 1997 ACR criteria, making careful appraisal and attribution of these lesions critically important because they contribute substantially to SLE diagnosis. Skin lesions are generally categorized as acute cutaneous lupus erythematosus (ACLE), subacute cutaneous lupus erythematosus (SCLE), and chronic cutaneous lupus erythematosus (CCLE).[54] Genetic associations include HLA haplotypes and SNPs, most of which may contribute to CLE pathogenicity through dysregulated antigen presentation, IFN response, and apoptosis regulation.[55,56] Known triggers for CLE include ultraviolet (UV) light (UVA and UVB), infections, and drug reactions, the most common of which arise from angiotensin-converting enzyme inhibitors, calcium channel blockers, beta blockers, antifungal agents, and TNF inhibitors. UV light induces DNA strand breaks in keratinocytes, resulting in apoptotic cell death and providing a rich source of autoantigen (*e.g.*, Ro52 antigen). SLE patients have increased numbers of apoptotic keratinocytes after exposure to UV light, and these apoptotic cells have been identified in the basal layer of CCLE lesions. Particularly in a setting of impaired ability to clear apoptotic debris, the abundance of autoantigen, including endogenous RNA and DNA, provides stimuli for autoreactive T and B cells and recruitment of pDC with ensuing production of proinflammatory cytokines, chemokines, and TGF-β, which contributes to fibrosis and scarring.[55] Infiltrating pDCs have been identified in a majority of CLE lesions within perivascular inflammatory dermal nodules and at the dermal-epithelial junction in severely damaged skin in association with cytotoxic T cells.[57] Transcript analysis of lesional skin in CCLE demonstrates a paucity of Tregs with increased numbers of T helper 1 (Th1), IFN-γ–producing cells, and increased type I IFN signature.[58] Increased NETs extruded from dying neutrophils are also seen in CLE lesions. The DNA in NETs and UV-oxidized DNA is resistant to enzymatic degradation and may contribute to ongoing pDC activation and IFN-α production through TLR activation.

Recent molecular profiling of DLE and SCLE lesional biopsies has demonstrated significant similarity between both CLE subtypes in differentially expressed type I IFN pathway genes and in repression of epidermal growth factor receptor (EGFR) pathways, suggesting underlying pathobiologic similarities between phenotypically different clinical subtypes.[58]

Autoantibodies are frequently identified in the dermal-epidermal junction and may facilitate antibody-dependent cell-mediated cytotoxicity. However, their contribution to CLE pathogenesis is unclear except for the significant association between anti-Ro/SSA antibodies and SCLE.[59] The lupus band test (LBT) refers to the deposition of immunoglobulin (IgG, IgM, and/or IgA) and/or C3 along the dermoepidermal junction. Approximately 25% of normal individuals display weak IgM staining at the dermoepidermal junction, whereas 70% to 80% of SLE patients have a positive LBT in sun-exposed, nonlesional skin. Examination of non-lesional skin in SLE has also

FIG. 52.4 Malar Rash in a Systemic Lupus Erythematosus Patient.

FIG. 52.5 Discoid Lesion in Systemic Lupus Erythematosus.

demonstrated presence of a keratinocyte IFN signature and Langerhans cell depletion, suggesting an underlying propensity for inflammation.[55]

Acute Cutaneous Systemic Lupus Erythematosus

ACLE includes malar rash, bullous lupus, toxic epidermal necrolysis (TEN) variant, maculopapular lupus rash, and photosensitivity. Malar rash is the most common ACLE lesion, typically occurring across the cheeks and nose but sometimes including the forehead and chin, sparing the nasolabial folds (unlike seborrheic dermatitis) (Fig. 52.4). It usually begins as small discrete erythematous macules or papules that coalesce with or without facial swelling, is frequently associated with sun exposure, and heals without scarring. The differential diagnosis includes acne rosacea, seborrheic dermatitis, erysipelas, dermatomyositis, and contact dermatitis. Microscopic analysis reveals a sparse inflammatory lymphocytic dermatitis with occasional histiocytes engulfing nuclear debris resembling LE cells found close to the dermoepidermal junction. Immunofluorescent staining for complement components and immunoglobulin at the dermoepidermal junction is positive in 70% to 80% of patients.

Subacute Cutaneous Systemic Lupus Erythematosus

This distinctive rash is mostly diagnosed in White populations. It consists of erythematous papules and plaques, with or without adherent pityriasiform scaling, that erupt on the extremities and trunk, usually sparing the head and neck. These nonscarring lesions may assume an annular polycyclic form with central pallor and tiny vesicles at the active margins and can be mistaken for erythema multiforme. The differential diagnosis includes psoriasis, polymorphic light eruption, and tinea corporis. SCLE is exacerbated by UV light and a growing list of medications, including thiazides and calcium channel blockers. Biopsy reveals a lymphocytic dermatitis confined to the superficial and mid dermis, frequently with associated dermal edema, mucinosis, and degenerating keratinocytes. From 60% to 90% of SCLE patients have circulating anti-Ro antibodies; however, they are also deposited in non-lesional skin.

Chronic Cutaneous Systemic Lupus Erythematosus

CCLE includes discoid lupus erythematosus (DLE), verrucous lupus, panniculitis, tumidus, and chilblain lupus. DLE is the most common form of CCLE. Lesions and are usually localized to the head and neck in photo-exposed areas (Fig. 52.5) and are typically circular, vary in size, and scar with significant disfigurement. Early lesions appear as erythematous plaques with

FIG. 52.6 Cutaneous Vasculitis Affecting the Hands in a Patient With Active Systemic Lupus Erythematosus.

or without follicular hyperkeratosis, plugging, and scale and progress to scarring annular lesions with an erythematous, indurated border, adherent scale, and a central area with atrophy and telangiectasias. There are no autoantibody associations with DLE, and only 5% of patients with DLE develop systemic lupus. High-titer ANA, Raynaud phenomenon, and the presence of arthralgias may identify patients at risk for systemic evolution. Histopathology characteristically reveals a lymphocytic interface dermatitis with CD4 lymphocytes and pDCs involving follicles and epidermis. There is vacuolar degeneration of the basal layer of epidermal keratinocytes and prominent keratotic follicular plugging. Dermal mucin deposition is also present, and there is usually dense granular deposition of immunoglobulin (predominantly IgG) and C3 at the dermal-epidermal junction.

Lupus profundus typically presents as firm, tender, deep subcutaneous nodules that may atrophy over time. Overlaying epidermal changes include DLE, ulcerations, and dystrophic calcification. Biopsy reveals a lobular panniculitis with patchy lymphoplasmacytic infiltrate in subcutaneous fat lobules. Panniculitis (10% to 20% of patients) must be differentiated from a subcutaneous T-cell lymphoma, erythema nodosum, pancreatic panniculitis, and morphea.

Nonspecific skin lesions reported in SLE are typically seen during disease flares and are associated with greater disease severity. These lesions include, but are not limited to, cutaneous vasculitis (Fig. 52.6), urticaria, Raynaud phenomenon, livedo reticularis, alopecia, sclerodactyly, calcinosis cutis, atrophie blanche, bullous lesions, erythema multiforme, and leg ulcers.

Hair and Nail

Different patterns of hair loss occur in SLE.[60] Scarring alopecia with permanent hair loss is associated with DLE, and biopsy shows typical DLE infiltrates with interface dermatitis and immunofluorescence that differentiates it from other common forms of scarring alopecia. Patchy or diffuse non-scarring alopecia is frequently associated with disease activity and is SLE-specific according to the 2012 SLICC criteria for SLE. Although clinically it may appear similar to alopecia universalis, anagen, or telogen effluvium, SLE-related non-scarring alopecia is distinguished histologically by interface dermatitis, obscuring of the dermoepidermal junction with inflammatory cells. Non-scarring alopecia resolves with complete hair regrowth with control of disease activity.

A wide spectrum of nail abnormalities, including pitting, ridging, onycholysis, and dyschromia with blue or black hyperpigmentation, is reported in up to 30% of SLE patients, but none are lupus specific. Nail fold erythema with ragged cuticles and splinter hemorrhages resembling the changes of dermatomyositis are common.

Oral Lesions

The spectrum of oral lesions reported in SLE includes cheilitis, ulcerations, erythematous patches, lichen planus–type plaques on the buccal mucosa and palate, and DLE.[61] Most oral lesions are asymptomatic. Positive immunofluorescent staining on biopsy may be useful to differentiate DLE from lichen planus–like lesions and leukoplakia. Lupus mucosal ulcerations demonstrate an interface mucositis and not leukocytoclastic vasculitis.

Gastrointestinal Manifestations

GI symptoms occur commonly in SLE, with reported incidences of 15% to 75%; attribution is critical because at least half are attributable to side effects of medications and to infectious complications.[62–64]

Esophagus

The prevalence of esophageal involvement varies. Dysphagia and heartburn are reported in approximately 50% of patients, although many reviews citing high incidences of dysphagia and odynophagia predate the advent of proton pump inhibitors and H_2 blockers, and the relationship of medication use to symptoms is not clear. Esophageal dysmotility is observed in up to 70% and is attributed to an inflammatory process involving esophageal muscle or vasculitic damage to the Auerbach plexus. Ulceration is rarely seen outside the context of infections such as invasive candidiasis, herpes simplex, or cytomegalovirus. SLE patients with secondary Sjögren syndrome may have salivary gland dysfunction, resulting in decreased saliva contributing to dysphagia.

Abdominal Pain/Vasculitis

Acute abdominal pain is common in SLE with reported incidences as high as 40%. The differential diagnosis includes intestinal vasculitis (lupus enteritis, mesenteric vasculitis) (45.5%), pancreatitis (10.8%), hepatobiliary disease (18.8%), and intestinal pseudo-obstruction (IPO) (3.3%).[65] The most catastrophic and potentially fatal GI disturbances are related to ischemia of the small and large intestines resulting from medium- and small-vessel vasculitis or thrombotic complications of APL antibodies. Approximately half of SLE patients with acute abdominal pain will have intestinal ischemia; associated mortality is high, so early consideration and intervention are critical. Lupus enteritis and mesenteric vasculitis are frequently associated with active disease elsewhere, whereas SLE patients with inactive disease and acute abdominal pain will likely have intra-abdominal pathology unrelated to SLE. The clinical presentation may be acute, severe abdominal pain or an insidious, stuttering course with nausea, vomiting, bloating, diarrhea, postprandial fullness, anorexia, and weight loss. Mesenteric vasculitis preferentially affects the superior mesenteric artery, involving the small intestine more commonly than the large bowel. Vasculitis can also occur in the esophagus, stomach, peritoneum, rectum, gallbladder, pancreas, and liver. Computed tomography (CT) and/or magnetic resonance with or without angiography are the preferred imaging tests for evaluation of abdominal pathology; the radiographic signs of intestinal ischemia do not differ based on pathogenesis.

In cases with an insidious clinical course, endoscopy and colonoscopy may provide evidence of ischemia demonstrating ulcerating or heaped-up lesions with overt vasculitis on biopsy. The lesions are segmental and focal. Histologically, there is a small-vessel arteritis and venulitis with neutrophilic, lymphocytic, and macrophage infiltrates and fibrinoid necrosis of the vessel walls, associated thrombosis, and mononuclear infiltrate in the lamina propria. There may be immunoglobulin, C3, and fibrin deposition in the adventitia and media.

Intestinal Pseudo-obstruction

Although rare, SLE-associated IPO (SLE-IPO) may be the initial manifestation of SLE. Clinical symptoms (abdominal pain and distension with diminished or absent peristalsis) and radiographic findings of SLE-IPO mimic those of mechanical obstruction. Distinguishing features of SLE-IPO include concomitant active SLE in other organ systems and associations with hematologic cytopenias, hypocomplementemia, and serositis. Findings of coexisting ureterohydronephrosis and hepatobiliary dilatation in the absence of obstructing lesions suggest underlying smooth muscle dysmotility associated with vasculitis or autonomic nervous system dysfunction. Poor prognosis is associated with older age at SLE diagnosis, GI symptoms as the initial SLE manifestation, longer disease duration, and delayed diagnosis of IPO.[63]

Peritonitis

Symptomatic lupus peritonitis is seen in only 10% of patients, despite evidence of peritoneal inflammation in greater than 60% of autopsy studies. Acute peritonitis may be attributed to peritoneal vasculitis or ischemia and presents with abdominal pain (see earlier). The finding of ascitic fluid by CT scan or ultrasound mandates an evaluation of the fluid to exclude infection and malignancy. Rarely, ascites may be attributable to hepatic or portal vein thrombosis. Chronic peritonitis characterized by large amounts of painless ascites attributable to SLE and not to heart failure, constrictive pericarditis, or severe hypoalbuminemia due to nephrotic syndrome, liver disease, or a protein-losing enteropathy (PLE) is rare. In lupus peritonitis, the ascitic fluid is generally exudative with a predominance of lymphocytes; LE cells, autoantibodies, and low complement levels are frequent. On biopsy, the peritoneum is usually edematous; it is sometimes hemorrhagic with lymphocytic perivascular infiltrates.

Pancreatitis

Pancreatitis attributable to SLE is rare, occurring in 8% to 11% of patients with abdominal pain and having an annual reported

incidence of 1/1000 or less. Although both corticosteroids and azathioprine can trigger pancreatitis, 34% of reported cases are not on these medications at the onset of pancreatitis, and most patients respond to steroid therapy. The clinical presentation and diagnosis of pancreatitis are similar in patients with and without SLE. Specific findings in SLE include leukopenia, thrombocytopenia, and anemia. Inflammation and necrosis are common on biopsy; pathophysiology has been attributed to vasculitis, APL-related thrombosis of pancreatic vessels, and intimal thickening of pancreatic arterial walls with immune complex deposition.[62] Mortality rates are reported from 18% to 27%; poor outcome is associated with increased systemic SLE activity (particularly, low complement, and thrombocytopenia).

Liver

The term "lupoid hepatitis" was coined in the 1950s to describe cases of young women with chronic active hepatitis characterized by a lymphoplasmacytic infiltrate on biopsy, hypergammaglobulinemia, and a positive LE cell test in the blood. With the development of ANA testing, it became apparent that "lupoid" and "chronic active hepatitis" were indistinguishable in terms of clinical presentation, pathology, and response to treatment, and the term "autoimmune hepatitis" (AIH) was endorsed in 1993.[66] Importantly, only 10% of AIH patients meet criteria for SLE, and 2.4% to 4.7% of SLE patients have noninfectious "lupus hepatitis" (LH).[64] Mild/moderate transaminitis is reported in up to 55% of patients; however, medication-related effects, infection, venous congestion related to cardiopulmonary disease, hemolysis, myositis, and veno-occlusive disease must all be considered prior to SLE attribution. The distinction between subclinical LH and AIH is important because therapy and prognosis are different. LH is associated with mild enzyme abnormalities, whereas AIH is a progressive disease frequently leading to hepatic failure. Both conditions share a predilection for young women, and both demonstrate features of autoimmunity, including hypergammaglobulinemia, arthralgias, and serum autoantibodies. Histologically, LH biopsies reveal lobular and periportal lymphocytic infiltrates, in contrast to the periportal and piecemeal necrosis with dense lymphocytic infiltrates seen in AIH with progression to panlobular or multilobular necrosis and cirrhosis. Serologically, antibodies to ribosomal P (51%), dsDNA (70%), and Ro (60%) have been associated with LH, whereas AIH is associated with antibodies to liver and kidney microsomes. Anti–smooth muscle antibodies are observed in 60% to 80% of patients with AIH, compared with 30% of patients with LH. Although both have a favorable response to steroids, AIH usually requires additional immunosuppressive agents.[66]

Distinguishing LH from hepatitis C virus (HCV) can be difficult. Up to 30% of patients chronically infected with HCV have low titers of ANA and other autoantibodies (anti-DNA, anticardiolipin antibodies, and rheumatoid factor). They can also have cryoglobulins and associated cryoglobulinemic vasculitis. It is necessary to confirm a positive enzyme-linked immunosorbent assay (ELISA) for HCV with polymerase chain reaction (PCR) in patients presenting with arthritis, cutaneous vasculitis, and a positive ANA, because SLE patients may have false-positive serologic tests for HCV.

Protein-Losing Enteropathy

Profound hypoalbuminemia in the absence of severe nephrotic syndrome, liver disease, or constrictive pericarditis should trigger concern for PLE. The most common clinical presentations are related to hypoalbuminemia and include peripheral edema (94%), ascites (58%), pleural effusion (54%), and pericardial effusion (24%).[63] Clinically significant PLE is uncommon in SLE, with reported prevalence rates of 1% to 8%; it can present individually or in the context of severe disease activity with other organ involvement. The diagnosis is confirmed with an increased α_1-antitrypsin level in a 24-hour stool collection or with the presence of intravenously administered labeled human albumin in the stool. Imaging findings are nonspecific and include ascites and bowel wall thickening. Protein leakage occurs most commonly in the small intestine but may be multifocal, and intestinal histology reveals lymphangiectasis, edematous villi, inflammatory infiltrate, vasculitis, and mucosal atrophy. Biopsy results suggest a role of TNF, IFN-γ, and IL-6 in the increased vascular and enterocyte permeability in PLE.

Pulmonary Involvement

Lupus affects the lungs in diverse ways involving the pleura, lung parenchyma, and blood vessels. It is more common in late-onset lupus, in patients diagnosed at 50 years of age or older.[67] The most frequent and important complicating feature is infection.

Pleuritis

Pleuritis is the most common pulmonary manifestation of SLE, reported in 40% to 56% of patients.[68] Pleural involvement in up to 93% of lupus patients at autopsy suggests that much pleuritis may be asymptomatic. Clinically, patients note typical pleuritic pain. On physical examination, the most frequent abnormality is tachypnea; a pleural friction rub is present in some cases, and pleural effusions occur in more severe cases. Pleural fluid is usually exudative with normal glucose and pH, and elevated protein and lactate dehydrogenase levels. The leukocyte count can range from several hundred to 20 000 cells/μL; both a lymphocytic and neutrophilic predominance are reported. When performed, immunologic testing on pleural fluid may show reduced complement levels and the presence of ANA, anti-DNA antibodies, and LE cells. Although these tests are commonly obtained, these results are neither sensitive nor specific enough to diagnose lupus pleuritis.

Lupus Pneumonitis

Lupus pneumonitis occurs in up to 10% of patients. Patients present with dyspnea, cough, mild pleuritic chest pain, and fever. Pulmonary infiltrates are present on plain radiograph or CT. This presentation must be distinguished from an infectious etiology. Histologic examination of affected lung tissue shows alveolar edema and hemorrhage with hyaline membrane formation; immunofluorescent staining reveals immune complex deposition.

Pulmonary Hemorrhage

Pulmonary hemorrhage is a rare but potentially fatal complication of SLE which may be associated with APL antibodies. Symptoms include shortness of breath with or without hemoptysis, which may be stuttering in onset, accompanied by a fall in hemoglobin, usually occurring in the context of multiorgan involvement from SLE. Imaging may show patchy infiltrates. Pulmonary function testing is marked by an increased diffusion capacity (DL_{CO}) secondary to the presence of alveolar blood, whereas arterial O_2 saturation is decreased. Histopathology shows bland intra-alveolar hemorrhage and hemosiderin-laden macrophages. Microangiitis with an inflammatory infiltrate and necrosis of the alveolar septa can occur. As hemorrhage into the

lung may be secondary to thrombotic thrombocytopenia, infections, or pulmonary hypertension, demonstration of an inflammatory process in the pulmonary vessels or tissue is helpful to establish a diagnosis of primary pulmonary hemorrhage.

Chronic Diffuse Interstitial Lung Disease

Chronic diffuse interstitial lung disease is a relatively uncommon manifestation of SLE and is occasionally associated with anti-Ro antibodies. It usually has a progressive course with a chronic nonproductive cough, dyspnea, and pleuritic chest pains. Physical examination is frequently remarkable for basilar rales with diminished diaphragmatic movement. Pulmonary function tests demonstrate a restrictive pattern with decreased diffusion capacity; oxygen saturation is decreased. Imaging often shows interstitial fibrosis that is more prominent at the lung bases. High-resolution CT (HRCT) may also help to determine the extent of treatable disease (*i.e.*, fibrosis [honeycombing] versus inflammation [ground glass]). However, the most reliable method to assess the extent of pulmonary inflammation in comparison with fibrotic damage is histologic examination. Biopsies showing nonspecific interstitial pneumonia (NSIP) or lymphocytic interstitial pneumonia (LIP) are more frequent than usual interstitial pneumonia (UIP). Evaluation of bronchial alveolar lavage fluid helps to exclude infection.

Pulmonary Hypertension

Pulmonary hypertension unrelated to chronic pulmonary emboli or interstitial lung disease occurs in SLE and is associated with increased mortality. Severe cases are rare; the recent recognition of milder cases may be partially attributed to increased awareness and findings of elevated pulmonary artery pressures on echocardiograms obtained for evaluation of shortness of breath. Patients typically present with progressive dyspnea occurring in the absence of infiltrates on chest radiographs or significant hypoxemia. Chest pain and a chronic nonproductive cough are also frequently present. Autoantibodies to endothelin receptor type A may be present; brain natriuretic peptide is usually abnormal.[69] Pulmonary function testing reveals a reduced DL_{CO} with normal lung volumes. Elevated pulmonary artery pressure is confirmed with cardiac angiogram. Biopsy or autopsy specimens of the lung reveal "plexiform" lesions that resemble those seen in primary pulmonary hypertension.

Shrinking-Lung Syndrome

The shrinking-lung syndrome refers to the rare findings of shortness of breath occurring in the absence of pleuritis or interstitial lung disease plus a chest x-ray showing elevated hemidiaphragms. Pulmonary function testing shows a restrictive pattern with loss of lung volume. It was generally accepted that this syndrome results from diaphragmatic weakness (from a myopathic process) or chest wall restriction; however, more recent studies suggest that pleuritis and impaired ability to take deep inspirations, leads to parenchymal reorganization and reduced lung compliance may also play a causative role. There is no definitive therapy, although immunosuppressive therapy with cytotoxic agents usually results in an improvement of lung function and respiratory symptoms.

Cardiac Involvement

There are several ways in which lupus affects the cardiovascular system; targets include the myocardium, valves, pericardium, and blood vessels.

Myocardium

Myocardial dysfunction in SLE is likely to be secondary to factors other than lupus, such as hypertension, medications, or coronary artery disease (CAD). However, a cardiomyopathy resulting from immune-mediated myocardial inflammation does occur, either in isolation or concomitant with myositis or other manifestations of systemic disease. Inflammatory myocarditis is often associated with anti-RNP antibodies. Histopathology typically shows a mononuclear, inflammatory cell infiltrate. Perivascular or myocardial wall deposits of immune complexes and complement also occur. Cardiac MRI can facilitate a diagnosis of myocarditis; however, myocardial biopsy is the gold standard and provides additional information on the extent of active inflammatory disease and fibrosis. Symptoms and signs of myocarditis include unexplained tachycardia, an abnormal electrocardiogram (with ST- and T-wave abnormalities), cardiomegaly, and heart failure. Echocardiography may show systolic and diastolic ventricular dysfunction. Myocardial involvement without overt clinical signs occurs commonly and may be documented using Doppler echocardiography. A noninflammatory cardiomyopathy may be seen in association with high-dose cyclophosphamide and, although rarely, with hydroxychloroquine.

Valvular Heart Disease

Valvular abnormalities, with thickening, regurgitation, or verrucous vegetations, occur commonly in SLE (50% to 60%) and are best documented by transesophageal echocardiography.[70] They are observed more frequently in patients with high-titer APL antibodies. The characteristic Libman-Sacks lesion, nonbacterial verrucous vegetations, is noted at autopsy in 15% to 60% of patients. Mitral, aortic, and tricuspid valves are most frequently involved. Clinically, these lesions are usually asymptomatic, and hemodynamic compromise, rupture of the chordae tendineae, or infection are rare events. They are thought to result from valvulitis and subsequent healing with fibrosis and valvular thickening. On histologic examination, mononuclear cells, hematoxylin bodies, fibrin and platelet thrombi, and immune complexes are present.

Pericarditis

Pericardial inflammation in SLE is frequent. Although asymptomatic pericarditis occurs in more than 50% of patients, clinically apparent pericarditis occurs in only 25%, and cardiac tamponade and constrictive pericarditis are infrequent. Pericardial fluid and thickening are easily detected by echocardiography; cardiac silhouette enlargement on plain films is seen in the presence of large effusions. There are no unique signs and symptoms of pericarditis in lupus patients. The histologic findings of acute pericarditis in lupus are inflammation with a mononuclear cell infiltrate accompanied by immunoglobulin and complement deposition. Results of pericardial fluid analysis are neither sensitive nor specific; the fluid is usually an exudate with elevated protein concentrations, normal or low glucose levels, and an elevated WBC count that is primarily neutrophilic. Complement levels in the fluid are low, and autoantibodies (ANA, dsDNA) and LE cells have been reported.

Coronary Artery Disease

Accelerated atherosclerosis is well documented in SLE patients. Myocardial infarction, angina, and sudden death resulting from

CAD are described. Estimates of the prevalence of CAD vary widely depending on the methodology used for ascertainment. There is a 50-fold greater risk of myocardial infarction in young women with lupus compared with normal age-matched controls.[70] Cardiac events occur both late in the course of SLE and early and may even predate the SLE diagnosis. Coronary artery vasculitis is a potential cause of CAD but is exceedingly rare, and bland atherosclerotic plaque is typically described in surgical and postmortem specimens. Traditional risk factors such as hypertension, diabetes, and hyperlipidemia, are enriched in lupus patients, and an increased prevalence of the metabolic syndrome likely contributes additional risk. Lupus-related risk factors include duration of SLE, duration of corticosteroid use, renal disease, and absence of use of hydroxychloroquine. The potential contributing influence of antibodies to phospholipids or disease activity continue to be explored. Atherosclerosis is an inflammatory condition with the innate and adaptive immune system contributing to all stages of disease. Inflammation is now recognized to accelerate the formation and the rupture of atherosclerotic plaque. If endothelial dysfunction and vascular injury are the events triggering atherosclerosis, there are multiple potentially responsible processes in lupus; these include, but are not limited to, autoantibodies directed to endothelial cells, oxidized low-density lipoprotein (LDL) and/or APL antibodies, low-density granulocytes (LDGs), LDG NETs,[71] and immune complexes may contribute to accelerated atherosclerosis in SLE.

Renal Involvement

Lupus patients with kidney disease have increased morbidity and mortality compared with patients without this feature of disease. Lupus nephritis is a common with significant impact on morbidity and mortality. The prevalence of nephritis ranges from 50% to 75% overall, with increased prevalence of proliferative nephritis and more aggressive disease in African Americans, Asians, and Hispanics compared with Caucasians. Low socioeconomic status, independent of ethnicity, is predictive of poor prognosis, and pediatric lupus and male lupus are both associated with a greater incidence of, and more aggressive, nephritis. Onset of nephritis frequently occurs within 2 years after diagnosis but may occur at any time, so monitoring for potential renal activity is an ongoing obligation. Clinically, patients are asymptomatic unless they are nephrotic or have developed end-stage renal disease. Detection typically relies on examination of the urine, although a rising creatinine or hypertension may herald renal involvement. The presence of proteinuria on urinalysis, hematuria (>5 red blood cells [RBCs]/high-power field), or pyuria (>5 WBCs/high-power field) in the absence of other etiologies should prompt an evaluation for nephritis. A 24-hour urine collection remains the most accurate measurement of urinary protein loss; however, the protein/creatinine ratio in a spot urine is accepted and more commonly used for monitoring patients. Monitoring serum creatinine as a surrogate for the glomerular filtration rate is standard; however, creatinine is an insensitive marker of lupus renal disease and should be used in conjunction with other assays. Ultimately, a kidney biopsy should be performed to ascertain the type of kidney disease as well as the amount of fibrosis and degree of reversibility. Proliferative renal activity (see later) is usually preceded or accompanied by serological activity. Antibodies to dsDNA are almost always elevated or rising, whereas measurements of serum complement (C3, C4, or CH_{50}) are usually low or dropping.

Histologic findings of the kidney in lupus nephritis can be defined using the classification proposed by the International Society of Nephrology/Renal Pathology Society (ISN/RPS).[72] In general, membranous nephritis (class V) presents with a bland urinary sediment (*i.e.*, no RBCs, WBCs, or casts), nephrotic-range proteinuria, a normal to mildly elevated creatinine, a normal blood pressure, and normal serologies. Patients with mesangial disease (class II) present with a bland or minimally active sediment, low-grade proteinuria (less than 500 mg/24 hours), and a normal serologic profile. Class III (focal) and class IV (diffuse) proliferative nephritis are characterized by active urinary sediment, proteinuria (>500 mg/24 hours), active serologies, and, frequently, hypertension and elevated serum creatinine. Class III is defined as 50% or less glomerular involvement, and class IV is defined as greater than 50%. The extent of proteinuria, urinary sediment activity, serologic abnormalities, and creatinine elevation is often less in class III than in class IV renal disease. Most cases of class II nephritis do not require initiation of cytotoxic therapy, and progression to end-stage kidney disease is rare. The prognosis of class III disease is dependent on the degree of activity; patients with 40% to 50% of glomerular involvement have a prognosis similar to that of patients with class IV disease. In addition to the number of involved glomeruli, renal biopsy assessment includes measures of activity (proliferative response) and chronicity (sclerotic response). Therapeutic intervention in class III or IV disease requires cytotoxic therapy in addition to high-dose corticosteroids, provided the chronicity index is not too high, indicating irreversible damage. Even with potent immunosuppressant therapy such as cyclophosphamide or mycophenolate mofetil (MMF), a complete response is induced in only approximately 20%, with a partial response occurring in approximately 80% of patients. Moreover, repeat histopathologic studies of kidney biopsies in patients achieving a complete clinical response show ongoing renal inflammation in almost half. Relapses and flares of renal disease are not infrequent, particularly when tapering corticosteroids or discontinuing immunosuppressive treatment. Long-term prognosis is favorable in patients in whom proteinuria declines to 800 mg/day or less. Potential therapies that maintain podocyte integrity or prevent activation of renal endothelial cells as well as agents directed against inflammatory cytokines, B cells, or T cells may offer therapeutic advantage and improved renal outcome.[73]

Hematologic

Hemocytopenias occur frequently in SLE and are included in both the ACR and SLICC classification criteria; prevalence varies among lupus cohorts (Table 52.2). Most of the cytopenias are associated with increased antibody-mediated peripheral destruction; however, the bone marrow is also recognized as an immune target. Evaluation for medication effects or nutritional deficiencies is essential before attributing a cytopenia to an immune-mediated mechanism.

Anemia

Antibody-mediated peripheral destruction of RBCs, autoimmune hemolytic anemia (AHA), occurs in 5% to 14% of SLE patients. In the multiethnic Latin American Study Group for the Study of Lupus (GLADEL-(Grupo Latino Americano De Estudio del Lupus)) GLADEL cohort, AHA was an independent predictor of damage accrual and decreased survival and was associated with disease activity.[74] RBC antibodies are

usually opsonizing warm-type IgG antibodies that trigger removal in the spleen. Antigen specificities of the RBC antibodies in SLE remain elusive. The presence of AHA is readily diagnosed by an elevated reticulocyte count, positive Coombs test, elevated lactate dehydrogenase and total bilirubin, low serum haptoglobin, and the presence of spherocytes on the peripheral smear. AHA in SLE has also been associated with APL antibodies, which may reflect cross-reactivity with erythrocyte membrane antigens.[75]

Anemia of chronic disease (ACD) is the most common cause of anemia in SLE. It is characteristically normochromic and normocytic with normal or high serum ferritin and pathogenesis is related to abnormalities in iron homeostasis and/or erythropoietin response. The hepatic hormone hepcidin regulates serum iron by preventing gut absorption and iron release from hepatocytes and macrophages. Under inflammatory conditions, hepcidin production is increased, resulting in impaired erythropoiesis.[75] Low erythropoietin levels in SLE may be attributable to renal disease and antierythropoietin antibodies. Although hemophagocytosis of hematopoietic cells is frequently noted on bone marrow biopsies, the hemophagocytic syndrome characterized by spiking fevers, tender hepatosplenomegaly, anemia, leukopenia, and markedly elevated serum ferritin is rare.

Lupus is also associated with a thrombotic microangiopathic hemolytic anemia (TMHA) with schistocytes, helmet cells, and triangular fragments of RBCs on peripheral smear with a negative Coombs test. Clinical symptoms may include fever, renal insufficiency, neurologic symptoms, and thrombocytopenia, correlating with local or diffuse microvascular thrombosis. TMHA is associated with antiphospholipid syndrome (APLS), which in many cases precedes the diagnosis, prompting the observation that TMHA may be a manifestation of APLS.[76] The differential diagnosis includes catastrophic APLS, malignant hypertension, and thrombotic thrombocytopenic purpura (TTP). Coexistent TTP and SLE is a rare and frequently fatal phenomenon that has been associated with antibodies to ADAMTS 13 in 16% of SLE-associated TTP (ADAMTS 13 is *A D*isintegrin *A*nd *M*etalloprotease with *T*hrombo*S*pondin type 1 repeats; *13*th member).

Leukopenia

Leukopenia, either neutropenia or lymphopenia, occurs in 20% to 40% of patients, and attribution to SLE rather than medication effects is essential.[77] Lymphopenia has a reported prevalence of 15% to 80%, whereas severe lymphopenia (<500/mm^3) occurs in 4% to 10% of SLE patients. The prevalence of neutropenia, variably defined in the literature as less than 1800 to less than 2500/mm^3, is 20% to 40%, whereas severe neutropenia (<1000/mm^3) is rare (1% to 4% prevalence). Both neutropenia and lymphopenia can reflect disease activity; however, associations with infection remain controversial. Carli et al. found that associations between leukopenia and major infection lost significance in half of published studies after controlling for confounding factors.[77] Nonetheless, careful monitoring for infection is warranted, and prophylaxis against opportunistic infections should be considered in severe cases.

Autoantibodies are the pathogenic mechanism generally implicated in the leukopenias. Antineutrophil antibodies directed against membrane components of mature and progenitor cells, resulting in decreased phagocytosis and accelerated apoptosis, are implicated, as are antibodies against granulocyte–colony-stimulating factor (G-CSF) and hyposensitivity of myeloid cells to G-CSF. Binding of TNF-related apoptosis-inducing ligand (TRAIL) to TRAIL receptors on neutrophils also accelerates neutrophil apoptosis.[78] Lymphocytotoxic antibodies, particularly to CD4 T cells, increased apoptosis related to Fas and Fas ligand upregulation, and increased serum IL-10 levels have all been implicated in the pathogenesis of lymphopenia. B cells expressing the 9G4 idiotype found on V_H 4.34 heavy chains may be responsible for production of antilymphocyte antibodies.

Exclusion of drug effects, malignancy, or myelofibrosis is required before attribution to SLE. In the absence of recurrent infection, leukopenia in SLE rarely warrants treatment because increased steroids can also contribute to the risk of infection. Severe leukopenia has been treated with G-CSF; however, G-CSF has also been associated with disease flare in 30% of cases.

Thrombocytopenia

Low platelet counts (<100 × 10^9/mm^3) are seen in approximately 25% of patients, although severe thrombocytopenia is reported in fewer than 10%. Immune-mediated consumption is the most frequent cause, but in rare instances thrombocytopenia occurs as a manifestation of TMHA, TTP, or disseminated intravascular coagulation (DIC) or as part of the hemophagocytic syndrome, all of which are associated with high mortality and morbidity. A pathogenic role for antibodies against platelet membrane glycoproteins IIb/IIIa is well established, and glycoproteins Ia/IIa and IbIX have also been identified as antigens.[79] Other possible mechanisms include antibodies to the thrombopoietin receptor (TPOR), and APL and anti-CD40-ligand antibodies that bind to platelets, resulting in platelet sequestration.

Bone marrow involvement may present as pure red cell aplasia (PRCA), aplastic anemia, marrow fibrosis, agranulocytosis, and myelodysplastic syndrome.[75,80] PRCA attributed to SLE is associated with anti-erythropoietin antibodies and is characterized by a normocytic, normochromic anemia with low reticulocytes and normal leukocytes and platelets. Aplastic anemia, characterized by pancytopenia, is associated with antibodies to marrow progenitor cells.

Central and Peripheral Nervous System

Neurologic and psychiatric manifestations of SLE (NPSLE) are diverse. They can involve the peripheral nervous system (PNS) and/or the central nervous system (CNS) and frequently occur irrespective of systemic disease activity. All clinical manifestations of NPSLE can occur in non-autoimmune individuals; thus attribution to SLE is critically important as treatment decisions reflect attribution. Limited access to brain tissue and difficulties with assessment and attribution of individual symptoms have hindered progress in understanding SLE-related mechanisms for NPSLE and identification of reliable biomarkers for individual syndromes.

NPSLE Nomenclature and Epidemiology

In 1999, a consensus committee established by the ACR developed reporting standards, case definitions, and recommendations for laboratory and imaging studies for 19 neurologic, psychiatric, and cognitive syndromes involving the CNS and PNS. CNS syndromes are further categorized as focal or diffuse (Table 52.4). The clinical syndromes are well characterized with case definitions and attribution to SLE requires the exclusion

TABLE 52.4 Neuropsychiatric Lupus: Central and Peripheral Nervous System Syndromes

Central Nervous System		Peripheral Nervous System
Diffuse manifestations	Focal manifestations	
Cognitive dysfunction	Cerebrovascular disease	Cranial neuropathy
Mood disorder	Seizures	Autonomic neuropathy
Anxiety disorder	Aseptic meningitis	Mononeuropathy
Psychosis	Movement disorder	Polyneuropathy
Acute confusional state	Myelopathy	Myasthenia gravis
Headache	Demyelinating syndrome	Acute inflammatory demyelinating polyradiculopathy (Guillan Barré)
		Plexopathy

of comorbid illness, medication effects, or other conditions that may produce similar symptoms. Using this nomenclature, NPSLE is common overall, with a prevalence of 57% to 95%.[81] Reports of prevalence for NPSLE and individual syndromes vary widely and reflect differences in study methodology, racial and ethnic differences among cohorts, and criteria used to assess syndromes despite the ACR guidance. Nonetheless, cognitive impairment (7% to 95%) and mood (7% to 65%) and anxiety (6% to 40%) disorders occur most frequently, followed by headache (12% to 28%), seizures (7% to 20%), cerebrovascular disease (8% to 15%), and psychosis (1% to 11%). Others occur rarely (<7%), but all have significant impact on quality of life. Several attribution models have been developed that include the timing of NPSLE events relative to SLE diagnosis, presence of concurrent systemic disease activity, and selective criteria for inclusion. Autopsy studies have reported a range of neuropathologic findings including vasculopathy, micro and large ischemic infarcts, micro and large hemorrhage, microthrombi, vasculitis, myelopathy, small white matter lesions, and cortical atrophy.[82,83] Although pathologic lesions are more frequent in NPSLE, they are also found in SLE patients without diagnosed neuropsychiatric disease. Similarly, brain imaging studies using advanced imaging techniques have identified multiple gray and white matter abnormalities in SLE patients without NPSLE.[84] In aggregate, these findings support a continuum of subclinical brain involvement in SLE that is occurring even prior to SLE diagnosis. Therefore accurate assessment of true NPSLE prevalence awaits establishment of reliable and objective biomarkers for SLE-mediated mechanisms resulting in CNS or PNS pathology.

NPSLE Pathogenesis

Many of the focal CNS NPSLE syndromes occur as a result of vascular pathology: acute thrombotic events associated with APL antibodies (anticardiolipin, anti-β2 glycoprotein 1 antibodies, and lupus anticoagulant), and embolic events related to Libman-Sacks endocarditis or atherosclerotic disease, which is prevalent in SLE. More rarely, inflammation related to small-vessel vasculitis leads to intraluminal thrombosis. Proposed pathologic mechanisms for the diffuse CNS NPSLE syndromes include vasculitis, vasculopathy, immune complexes, brain-reactive autoantibodies, microglial cell activation, cytokine-induced, and/or cell-mediated inflammation and thrombosis,[81] leading to perfusion abnormalities, neuronal dysfunction, axonal damage, and microstructural damage. Given the fundamental importance of autoantibodies in SLE pathogenesis, it is not surprising that a growing list of autoantibodies have been associated with diffuse CNS disease, including anti–*N*-methyl D-aspartate receptor (NMDAR), anti–ribosomal-P (also termed anti–neuronal surface P antigen [NSPA]), anti–α tubulin, anti-Sm, and anti-RNP antibodies. These autoantibodies have been shown to either directly alter neuronal function or activate microglia (MG) cells to produce a proinflammatory state. APL antibodies have also been shown to impact neurologic function and structure through effects on vascular endothelium, separate from their prothrombotic effects. Evidence for these antibodies comes from clinical associations and murine models. Cytokines also contribute to CNS pathology. Type I IFN in particular has been associated with 50% to 90% of cases.[85] MG, resident macrophage-like cells in the brain that perform routine surveillance and debris clean-up under normal circumstances, can also promote damage. Activated MG are important pathologic mediators in other neurodegenerative diseases, and evidence from lupus mouse models and autopsy findings suggest they may play a role in NPSLE.

Presence of autoantibodies in CSF and brain tissue suggests an important role for a permeabilized blood-brain barrier (BBB) in NPSLE because antibodies are not made in the CNS and an intact BBB does not allow access to the brain. Indirect evidence for BBB disruption in SLE is supported by reports of an elevated albumin concentration gradient between cerebrospinal fluid (CSF) and plasma, an elevated IgG index, and elevated serum levels of proteins whose origins are exclusive to the brain parenchyma, such as S100B. Advanced neuroimaging studies of the BBB also suggest abnormal BBB permeability in SLE patients.[86,87] Proposed mechanisms for BBB disruption in SLE include brain endothelial cell disruption mediated by inflammatory cytokines, chemokines, complement C5a, antiendothelial cell antibodies, anti-NMDAR antibodies, and TWEAK (TNF-like weak inducer of apoptosis).[88–90] Anti–glucose-regulated protein-78 (anti-GRP78) antibodies have also been shown to alter BBB permeability through effects on brain endothelial cells.

This distinction between focal and diffuse CNS NPSLE and potential mechanisms is essential for the development of treatment strategies. Thrombotic events associated with APL antibodies are treated with anticoagulation, whereas high-dose corticosteroids and immunosuppression in combination with neuroleptic and antiseizure medications are generally required for treatment of diffuse CNS events. Because there is no intervening BBB, peripheral nerves are more accessible to circulating complement, autoantibodies, and inflammatory molecules, and vasculitis of epineural arteries is a common finding in PNS NPSLE.

NPSLE Assessment and Attribution

Currently, the diagnosis of NPSLE relies on clinical evaluation and an exhaustive search for other potential causes. CSF examination is useful for excluding infection or malignant cells. Although CSF in NPSLE can be characterized by a lymphocytosis and increased immunoglobulin with elevated total protein, IgG index, and oligoclonal bands, these abnormalities are not consistently present. Although numerous autoantibodies

and cytokines have been identified in the CSF of patients with SLE, none are specific for individual CNS NPSLE syndromes, and routine testing is not recommended. Although extremely sensitive for detection of structural and ischemic lesions associated with focal CNS NPSLE or non-SLE related pathology, MRI is frequently not helpful in diagnosing active diffuse CNS NPSLE because MRI studies are frequently normal in patients with psychiatric syndromes and global CNS dysfunction.[84]

In the CNS NPSLE syndromes, cognitive impairment tends to develop insidiously, irrespective of peripheral disease activity. CNS NPSLE syndromes may occur in isolation or in the context of globally increased disease activity. Although serologic evidence of disease activity (elevated anti-DNA antibodies and low complement) may help to diagnose CNS NPSLE, particularly if combined with other clinical signs of active disease, no serologic tests are specific for CNS NPSLE. Anti-NMDAR and anti-P antibodies have been identified in the serum, CSF, and brain of SLE patients and have been associated with cognitive and depressive syndromes and acute confusional state in some SLE patients. Advanced neuroimaging techniques, including structural and functional imaging studies, are currently evaluating associations between CNS microstructural integrity, cerebral perfusion, regional metabolism, BBB permeability, and clinical, serologic, and biologic parameters.[84]

PNS NPSLE events are recognized on the basis of clinical presentation with diagnostic studies such as electromyography and peripheral nerve biopsy.

APL antibody syndrome is described in detail in Chapter 61.

Drug-Induced Lupus

Until recently, drug-induced lupus referred to a clinical syndrome characterized by constitutional, musculoskeletal symptoms and serositis that resembles mild lupus and occurs after exposure to multiple drugs (most notably TNF inhibitors, IFN-α, procainamide, hydralazine, chlorpromazine, minocycline, and methyldopa). Drug-induced lupus has been associated with ANA and antihistone antibodies, whereas generation of more specific autoantibodies such as anti-dsDNA antibodies and hypocomplementemia are rare. Symptoms generally begin weeks to months after initiation of the inciting therapeutic agent and resolve within weeks after the drug is discontinued; autoantibodies can persist for up to 12 to 24 months. Host factors affecting drug metabolization (*e.g.*, slow acetylation of procainamide and hydralazine) and genetic predisposition contribute to the risk of developing drug-induced lupus. Multiple potential mechanisms resulting in the loss of self-tolerance have been suggested for this classic model. One of the most extensively explored is inhibition of DNA methylation with TLR activation, resulting in overexpression of costimulatory molecules such as leukocyte function–associated antigen-1 (LFA-1) on T cells and enhanced T-cell help.[91]

Since the introduction of anti-TNF agents, a different variant of drug-induced lupus has been recognized. Up to 30% of patients receiving TNF blockade develop autoantibodies, including a positive ANA and antibodies to dsDNA. However, clinical disease is uncommon, characteristically affecting the skin and joints while nephritis, and vasculitis are rare. The pathogenesis of this immunologic deregulation is not known.

Interestingly, although autoimmune inflammatory disease is well described following receipt of checkpoint inhibitors for treatment of malignancy, lupus-like syndromes occur less frequently.[92]

Treatment

THERAPEUTIC PRINCIPLES

Goals of Therapy in SLE

I. Suppression of inflammation
- Induction of remission/low lupus disease activity state (LLDAS)
- Maintenance of remission/LLDAS
- Preservation of organ function

II. Suppression of immune activation
- Modulation of the immune response

III. Prevention and management of drug-related toxicities

The goals of lupus treatment are to stop and reverse ongoing organ inflammation, to prevent or limit irreversible organ damage, and to suppress the immune response driving the inflammation and prevent flares. Therapeutic agents, and combinations thereof, are used for induction of remission, maintenance of remission, or prevention of flare. The efficacy of therapeutic agents must be balanced against their potential toxicity. Thus treatment must be tailored to the individual patient based on disease manifestations. In general, milder disease requires treatment with less potent or lower doses of antiinflammatory and immunosuppressive medications than more active, severe disease affecting major organs such as the kidney or brain. Individual patient responses to a given medication will vary, and patients must be monitored closely for response as well as toxicity. "Treat-to-target" recommendations in SLE from an international SLE task force include the following more specific guidelines: the treatment target should be remission of organ manifestations; factors such as pain that negatively influences health-related quality of life should be addressed; maintenance treatment should aim for the lowest glucocorticoid dose needed to control disease; and relevant therapies adjuvant to any immunomodulation should be considered to control comorbidity in SLE.[93] Low lupus disease activity state (LLDAS) is a less stringent target. Achieving LLDAS is associated with decreased accrual of damage, flare reduction, and improved quality of life.[94]

Some genetic factors predicting risk of toxicity or therapeutic benefit for individual agents have been identified. Polymorphisms of a key enzyme in the metabolism of azathioprine, thiopurine methyltransferase (TPMT), are common; 0.3% and 11% of Caucasians are homozygous and heterozygous, respectively, for mutations associated with altered expression of TPMT.[95] TPMT-deficient patients are especially susceptible to leukopenia and pancytopenia associated with azathioprine. Cyclophosphamide is metabolized to its active form by cytochrome P450. Individuals heterozygous or homozygous for a specific cytochrome P450 polymorphism *(CYP2C19*2)* have a lower probability of developing premature ovarian failure, but they also show a poorer response to therapy.[96]

Although corticosteroids are the foundation of treatment, exposure must be minimized to the greatest extent given their multiple and frequent side effects, including hypertension, diabetes mellitus, increased susceptibility to infection, bone loss, and weight gain (Chapter 83). Additional disease-modifying agents that are also steroid-sparing include antimalarials (hydroxychloroquine), antimetabolites such as azathioprine (1 to 2.5 mg/kg per day), methotrexate (7.5 to 25 mg/week), leflunomide (10 to 20 mg/day), MMF (2 to 3 g/day), and alkylating agents such as cyclophosphamide (monthly pulse

0.5 to 1.0 g/m^2) (Chapter 84). When more conventional therapies have failed, anecdotal reports, case series, and open-label studies suggest the use of intravenous immunoglobulin, thalidomide (50 to 100 mg/day), tacrolimus or cyclosporine. Medications such as dapsone, danazol, colchicine, and chlorambucil may be efficacious in cutaneous disease, hematologic disease, serositis, or arthritis and in severe refractory disease, respectively, but in general these medications are not commonly used due to their toxicity and the introduction and availability of better-tolerated, efficacious agents. Belimumab, a monoclonal antibody directed against BAFF (Chapter 84), was approved by the US Food and Drug Administration (FDA) for treatment of SLE in 2011 and represents a therapeutic option for patients with non-CNS active disease, including nephritis.[97]

Several newer agents are on the horizon for treatment of SLE. Some are currently available but approved for other indications, whereas others are still in the developmental stages. These therapies generally have more specific immunologic targets than standard treatments. Anifrolumab, a monoclonal antibody directed against the IFN-α receptor, was approved in 2021 for moderate to severe SLE; a study in lupus nephritis is ongoing. Voclosporin, a second-generation calcineurin inhibitor, was also approved for treatment of lupus nephritis in 2021.[97] Several new agents have been recently evaluated in phase III clinical trials and have been unable to demonstrate superiority over treatment with placebo or standard of care (SOC). Although imperfect trial design and imperfect outcome measures may account for some of these failures, the possibility remains that these agents are not effective treatments for SLE and do not confer a substantial improvement over current SOC therapies. Rituximab (anti-CD20 antibody), a B-cell–directed therapy approved for use in rheumatoid arthritis, targeting all B cells except plasma cells, failed to demonstrate improved performance over SOC in trials of patients with active SLE, or in patients with active lupus nephritis added to a background therapy of MMF and corticosteroids. Elevated BAFF levels are present after B-cell depletion that can facilitate maturation of autoreactive cells and exacerbate the impaired tolerance of SLE. This has led to ongoing evaluation of sequential therapy with belimumab following B-cell depletion.[98] Although conceptually attractive, the list of agents that have failed to show efficacy over standard of care or have been associated with increased toxicity are many and include abatacept (CTLA4-Ig), an approved (rheumatoid arthritis) monoclonal antibody which blocks T-cell activation; epratuzumab (anti-CD22 antibody), which targets all B cells by blocking both BAFF and APRIL; atacicept, a monoclonal antibody directed against BAFF and April (however, efficacy was demonstrated in a subset of patients with higher baseline disease activity); tabalumab and blisibumab, monoclonal antibodies directed against BAFF; ocrelizumab, an approved (multiple sclerosis) anti-CD20 monoclonal antibody; tocilizumab, an approved antibody to the IL-6 receptor, a cytokine involved in B-cell survival and activation as well as in differentiation of Th17 and Tfh cells; monoclonal antibodies to IFN-α; and ustikinumab, an approved monoclonal antibody targeting IL-12 and IL-23. Janus tyrosine kinase (JAK) inhibitors are approved for rheumatoid arthritis and are under study for discoid lupus (topical administration) and for systemic disease (given orally). Other agents in clinical development include CD40 and CD40 ligand antibodies, tyrosine kinase 2 (Tyk 2) inhibitors, Bruton tyrosine kinase inhibitors, SYK inhibitors, second-generation B-cell depleters (obinutuzumab), and immunoproteasome inhibitors.

Potential therapies aimed at DCs include vitamin D, which blocks DC maturation and T-cell activation, and inhibitory oligodeoxynucleotides, which block TLR9 signaling and DC maturation. However, a study of vitamin D supplementation designed to assess vitamin D inhibition of DC activation failed to demonstrate efficacy. Hydroxychloroquine, a standard agent for lupus, interferes with TLR7 and TLR9 signaling by preventing acidification of the endosomal compartment. A study of a novel RNase is under way and a phase 1 trial of anti-BDCA2 receptors on pDCs, inhibiting IFN-α production, demonstrated efficacy in CLE patients.[99]

Approved therapies or those in development for other autoimmune diseases may also prove useful in SLE. Eculizumab, currently approved for paroxysmal nocturnal hemoglobinuria, is an antibody directed against C5 that blocks cleavage of C5 and the subsequent triggering of the complement cascade. Alicaforsen, an antisense oligodeoxynucleotide that inhibits ICAM-1 expression, decreases inflammation in both rheumatoid arthritis and Crohn disease. Efalizumab, a monoclonal antibody against CD11a (an LFA-1 subunit that interacts with ICAM-1), benefits patients with psoriasis. Although no chemokine-targeted therapies are in clinical trial in lupus, a CCR1 antagonist slowed disease progression in a mouse model of lupus and has been tested in patients with rheumatoid arthritis. FTY720 (fingolimod), an agonist for the sphingosine 1 phosphate receptor that prevents egress of lymphocytes from secondary lymphoid organs and inflamed tissues, has beneficial effects in the MRL/*lpr* mouse model of lupus; it has been given to transplant recipients and to patients with multiple sclerosis and may provide benefit in CNS disease. The use of anti-TNF agents for SLE is complicated by its lupus-inducing effects in some patients. Paradoxically, TNF is involved in renal inflammation in SLE, and short-term treatment with monoclonal antibody to TNF appears to improve lupus nephritis, showing that agents can abort inflammation and yet exacerbate autoimmunity.

TRANSLATIONAL RESEARCH

ON THE HORIZON

- Increased understanding of the functional consequences of single nucleotide polymorphisms identified as susceptibility loci in systemic lupus erythematosus may provide insight into:
- Dysregulation of tolerance mechanisms and pathogenesis of disease in different ethnic populations
- Predictors of response to therapy
- New therapeutic targets
- Development of organ-specific biomarkers will allow for improved use of immunomodulating and immunosuppressive therapies and possibly for use of preventive therapies.

Laboratory research continues to inform us about dysregulated immunologic pathways in SLE. The current challenge of translational medicine is to shed light on the clinical relevance of these altered pathways. Increased understanding of the qualitative and quantitative differences of these molecular perturbations not only should result in improved diagnostic capabilities and biomarkers for disease but also will lead to the ability to subset patients for prognosis and response to therapy. Improved organ-specific biomarkers and methods for subsetting patients

on a molecular level are likely to result in improved use of immunologic therapies. In particular the brain, which has been relatively inaccessible to mechanistic and diagnostic probing, is likely to be an organ to be more fully explored. Ultimately, advances in translational studies should result in more effective and less toxic therapeutic interventions.

CONCLUSIONS

In the past several years, much has been learned about genetic susceptibility to SLE, and it is encouraging that many of the genes identified are associated with pathways that also have been implicated in disease pathogenesis. The role of B cells in disease pathogenesis has been confirmed, but recent studies have also highlighted the role of T cells, DCs, and neutrophils. Enhanced understanding of each of these contributing factors and the crosstalk between them has allowed identification of numerous potential therapeutic targets. The disappointing results from clinical trials of immunobiologic agents for lupus have highlighted the critical importance of study design and the complexity of disease in humans. The overall goal in therapy must be to eliminate autoreactivity while maintaining immunocompetence. Among the challenges now faced are the careful phenotyping of patients to identify etiopathologically distinct subpopulations and new clinical trial designs to allow the use of combinations of agents, each of which alone may have a minor effect on disease course.

Rheumatoid Arthritis

Andrew P. Cope

Rheumatoid arthritis (RA) is one of the most common chronic inflammatory diseases and in modern times has become a prototype disease entity for defining the molecular and pathological basis of chronic inflammatory syndromes. The term *rheumatoid arthritis* was coined by Garrod in 1859. However, this was probably an inappropriate use of the term because it encompassed polyarticular osteoarthritis as well as inflammatory polyarthritis. In spite of references to inflammatory afflictions of joints by the likes of Galen, Sydenham, and Heberden, the first convincing case reports of the disease, described in terms that would be recognizable today, were published in 1800 by Landré-Beauvais, who labeled the disease "la goutte asthénique primitive." This description was distinct because all patients were female, an observation that was significant when the most important differential diagnosis at that time was polyarticular gout, a disease predominantly of males.

Today we recognize RA as a chronic inflammatory disorder of joints of unknown etiology in which the major target tissue is the synovial lining of joints, bursae, and tendon sheaths. Although traditionally considered an autoimmune disease, RA differs from organ-specific autoimmune disease entities in several respects.[1] From the outset of clinically apparent disease, the systemic immuno-inflammatory process, driven by cytokines and other inflammatory mediators, promotes the activation and proliferation of stromal joint tissues, in particular the fibroblastic synovial lining layer. This appears to contrast with organ-specific autoimmune diseases, such as type 1 diabetes or autoimmune thyroiditis, characterized by an antigen-driven immune-inflammatory response *in situ* leading to targeted cellular destruction of autoantigen-expressing pancreatic β-islet or thyroid tissue cells. In RA, once the inflammatory process is established, the inflammatory synovium, or pannus, may invade and erode underlying cartilage and bone. Unlike autoimmune diseases that target single organs or tissues, RA is a systemic inflammatory disease that likely encompasses a heterogeneous syndrome with marked variation in clinical expression that most clinicians today would acknowledge is more than one disease entity. Indeed, it is now apparent that the disease is heterogeneous not only clinically but also pathologically, serologically, and genetically.

EPIDEMIOLOGY

The incidence of RA (the rate of new cases arising in a given period) is approximately 0.4 per 1000 when the 2010 American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) classification criteria are applied. Large cross-sectional population samples indicate that disease prevalence, which ideally should include all past and inactive cases, ranges from 0.5% to 2% for Caucasian European and North American populations over the age of 15, with a female to male excess of 2 to 4 times. Rates plateau between the ages of 45 and 75 years in some series, but can increase steadily with age until the seventh decade, declining thereafter. Despite similar prevalence estimates for these geographically diverse populations, greater diversity has been documented for rural African populations, where the prevalence has been reported to be as low as 0.1%, and for Native Americans (including the Pima, Yakima, and Chippewa tribes), where the prevalence may be as high as 5%. Such variance across geographical borders likely reflects distinct environmental factors and sociodemographic determinants, as well as a spectrum of genetic admixture. Lifetime risk has been estimated at 2% for males and 4% for females.

Complex polygenic autoimmune syndromes like RA are diseases of low penetrance, where thresholds of disease expression may be higher in males. Recent insights into familial clustering indicate that family history remains a strong independent risk factor for RA, but that this risk does not differ by gender.[2] This implies that nongenetic factors influence gender bias. Twin studies also provide compelling evidence for genetic effects, given the excess concordance rates for monozygotic (12% to 15%) compared with dizygotic twins (<5%, and probably nearer to 3.5%).[2] These concordance rates appear somewhat low, but compared with a background prevalence of 1% in outbred populations, genetic epidemiology studies report heritability estimates of 68% for those patients who carry antibodies to citrullinated protein antigens ($ACPAs^+$) and 66% for those who do not ($ACPAs^-$), indicating substantial genetic influence.[3] Human leukocyte antigen (HLA) is thought to contribute 35% to 40% of this value. This "missing heritability" leaves a substantial contribution to disease susceptibility from environmental factors, influenced by occupation, socioeconomic status, exposure to infectious pathogens, and lifestyle factors—a conglomeration of factors termed the "exposome."

Two of the more intriguing factors contributing to disease occurrence are age and gender. Age-associated changes in susceptibility to infection, neoplastic disease, and autoimmunity suggest that a common mechanism could be responsible. Immune senescence is one possibility, where age-related decline in host immunity is characterized at the cellular and molecular level by expansions of lymphocyte clones, corresponding contractions of the naïve T- and B-cell repertoires linked to depletion of lymphocyte precursors in thymus and bone marrow, and telomere erosion of leukocytes, features indicative of an extensive proliferative history. When combined with dysregulation of costimulatory receptors such as CD28, oxidative stress,

KEY CONCEPTS

Important Risk Factors for Developing Rheumatoid Arthritis

- Female gender; impact of X chromosome, micro-chimerism, lifestyle
- Age; associated with accelerated immune aging
- Inheritance of genetic variants, *e.g., HLADRB1* and *PTPN22*
- Autoantibodies to modified protein antigens (AMPAs), rheumatoid factor
- Family history; first-degree relatives have higher prevalence of genetic and serological risk factors
- Hormonal factors; nulliparity, the first 3 months postpartum, low androgen or high estrogen status (in males); longer-duration breastfeeding
- Smoking status; >25 cigarettes/day for >20 years confers a 15-fold risk in subjects who carry disease associated human leukocyte antigen (HLA)-*DRB1* alleles
- Low alcohol intake
- Environmental antigens (the "exposome"); dietary factors; exposure to infectious (and noninfectious/microbiota) pathogens at mucosal surfaces such as the lung, periodontium, and gut; non-inherited maternal antigens (NIMA)
- Urban dwelling, relating to airborne pollutants

and a range of biochemical derangements of pathways integral to antigen responsiveness and immune regulation, these factors may combine to (1) increase susceptibility to foreign pathogens, (2) augment reactivity to self-tissue antigens (which may be modified post-translationally by the aging process), and (3) generate a repertoire of lymphocytes defective in terms of tumor surveillance. Thus, physiological immune senescence could be considered a risk factor for RA in the elderly, while premature senescence may contribute to early onset RA.

The female sex preponderance implies that hormonal and reproductive factors strongly influence risk. On the one hand, nulliparity is a risk factor for RA. Women entering the first 3 months of the postpartum period are also at increased risk. By contrast, oral contraceptive use, pregnancy, and hormonal replacement therapy have all been associated with reduced risk or less severe disease, whereas extended periods of breastfeeding appear to increase risk. An influence of hormonal factors is further suggested in studies of men where disease is associated with lower androgenic testosterone and dehydroepiandrosterone (DHEA) levels, and increased estradiol, compared with healthy control male subjects.

ETIOLOGY AND PATHOGENESIS

Environmental and Nongenetic Factors

Most, but not all studies have reported an association between RA and smoking. One of the largest studies, comprising over 370,000 women from Women's Health Cohort Study, reported a relative risk of 1.4 for women who smoked more than 25 cigarettes per day for more than 20 years, compared with nonsmokers.[4] The association appears to be more closely related to duration than to the amount of tobacco exposure, with smoking status being a risk factor for older age of RA onset; smoking also may influence severity because smokers are more likely to have seropositive, erosive disease with extraarticular manifestations. Further evidence of gene-environment interactions with respect to smoking has been documented in a population-based case–control study of Swedish RA patients.[5] In this study the relative risk of developing rheumatoid factor (RF) positive (RF^+) RA was calculated according to smoking status and HLA-DRB1 genotype. The relative risk of developing RA increased from 2.5 in nonsmokers with disease-associated HLA-DRB1 genes to 7.5 and 15.7 in smokers who carried one or two copies of the susceptibility alleles, respectively. Follow-up gene-environment interaction studies demonstrate robust associations between heavy smoking, HLA-DRB1 alleles encoding specific amino acids at positions 11 and 13, and the presence of antibodies to citrullinated protein antigens (ACPA). Strongest associations were with antibodies to citrullinated α and β chains of fibrinogen (epitopes Fibα580–600 and Fibβ36–52) and α-enolase (CEP-1); IgA ACPAs were especially prevalent in smokers.

Being female, a smoker, and carrying specific disease-associated genetic variants may be necessary but not sufficient to initiate chronic inflammatory arthritis. Other environmental triggers may be involved. Not least among these is exposure to foreign pathogens. This association has gained credibility because of the presumed link not only between infection and autoimmunity but also between immunodeficiency and autoimmune disease. Nonetheless, no single pathogen or group of pathogens has been defined. This could imply that aberrant host responses (either exaggerated innate inflammatory responses or failure to terminate such responses) may arise after a wide range of infectious insults. Indeed, bacterial products including superantigens, mycoplasma species, viruses (including herpes family, parvovirus, and retroviruses), and fungi have all been implicated, but data are insufficient to prove causation. Epstein-Barr virus (EBV) infection is common, and antibodies to EBV nuclear antigens have been reported in patients with RA. EBV is a polyclonal activator of B lymphocytes and EBV-specific T cells reactive to EBV gp110 have been identified in RA synovial joints, in keeping with the detection of EBV RNA in synovium. There exists a tantalizing link between infection with *Porphyromonas gingivalis*, which expresses its own enzymatic machinery for generating bacterial or host-derived citrullinated proteins, severe periodontitis (which shares risk factors for RA), and RA.[6]

A comparison of the microbial genomes from the small intestine and colon of mice housed in conventional versus germ-free facilities suggests that a single gut-residing species, in this case segmented filamentous bacteria, can profoundly influence the clinical expression of inflammatory arthritis in mouse models of autoimmune arthritis. In the K/B × N serum transfer model of arthritis, segmented filamentous bacteria enhanced generation of interleukin (IL)-17-expressing T cells in lamina propria. Together with rapid advances in sequencing technologies, these data have prompted a systematic analysis of the symbiont microbial communities in patients with RA in comparison to those derived from healthy control populations. Microbiota are attractive environmental risk factors because they are acquired at around the time of birth and are modified by diet as well as the host genome. Studies from several groups have demonstrated irrefutable evidence of dysbiosis, with distinct patterns of microbiota depending on the stage of disease and the population studied. For example, the first US study reported enrichment of *Prevotella* spp. and *Bacteroides* spp., gram-negative anaerobes in the gut of patients with early but not established RA. Metagenomic sequencing of oral and fecal microbiota from a cohort of Chinese RA patients revealed enrichment of *Lactobacillus*, particularly in severe disease, and depletion of *Haemophilus* spp.[7] Recent studies indicate that enrichment of *Prevotella* spp. is associated with an RA polygenic risk score in unaffected twins, as well as subjects at risk of RA,[8] suggesting a link between host genetic factors and dysbiosis prior to disease onset.

Immunogenetics

RA is a clinically heterogeneous disease, and so comprehensive identification of disease susceptibility genes has been challenging, in spite of heritability estimates in excess of 60%. With the exception of the MHC, where extensive gene polymorphism contributes about one-third of genetic susceptibility, and *PTPN22* (odds ratio 1.8), individual genetic variants confer low to moderate risk and have low penetrance (odds ratios of 1.1 to 1.5). Numerous genome-wide linkage scans of multiplex families with RA have established and confirmed an important contribution of the MHC (Chapter 5). This lends support to a wealth of epidemiological and genetic data describing associations between RA and specific HLA-*DRB1* alleles, in particular HLA-DR4 subtypes. Although this association was first described by Stastny in the 1970s, it was shown more than a decade later that susceptibility to RA across different ethnic populations correlated closely with the expression of a specific consensus amino acid sequence (referred to as the "shared epitope," hereafter SE) within the HLA-DR β chain α-helix (Fig. 53.1).[9] This sequence was subsequently shown by several groups of investigators to be encoded by HLA-*DRB1* alleles, including *HLA-DR4 (*04:01, *04:04, *04:05*, and **04:08)*, but also *HLA-DR1 (*01:01), DR6 (*14:02)*, and *DR10 (*10:01)* alleles, among others. *HLA-DR9 (*09)* is also associated, but not in Caucasians. According to fine-mapping data, RA risk is linked not only to amino acids encoded by the RA SE sequence (71 and 74 positions of the alpha helix of the DRβ chain) but also to amino acid positions 11 and 13, located in the peptide binding groove of the HLA-DR heterodimer.[10] Single amino acid variants have also been defined in HLA-B (position 9) and HLA-DPβ (position 9). Differences in odds ratios associated with these five amino acid variants between ACPA-positive and ACPA-negative disease provide further evidence that seropositive and seronegative disease are genetically distinct.

Specific genotypes co-segregate with distinct clinical features. For example, in population-based studies, different HLA-*DRB1* alleles influence the severity of disease, including radiographic progression (confirmed in meta-analyses), with *DRB1*0401* being found in patients with severe, seropositive, erosive RA (often with extraarticular features such as vasculitis and Felty syndrome in *04:01 homozygous or *04:01/*04:04 compound homozygote individuals). Valine at position 11 of HLA-*DRB1* confers the strongest association with radiological damage and highest all-cause mortality. Statistical modeling points to HLA genetic polymorphism being associated with young-onset RA. *DRB1**01:01 and *10:01 are observed at a higher frequency in patients with less severe, seronegative, nonerosive disease. Inheriting two copies of alleles expressing the consensus sequence increases disease penetrance, time of onset, and severity. Thus, distinct genotypes can manifest as distinct clinical entities.

On the basis of early observations, two principal models were proposed to account for the association between RA and the consensus DR β-chain sequence. Both were based on the assumption

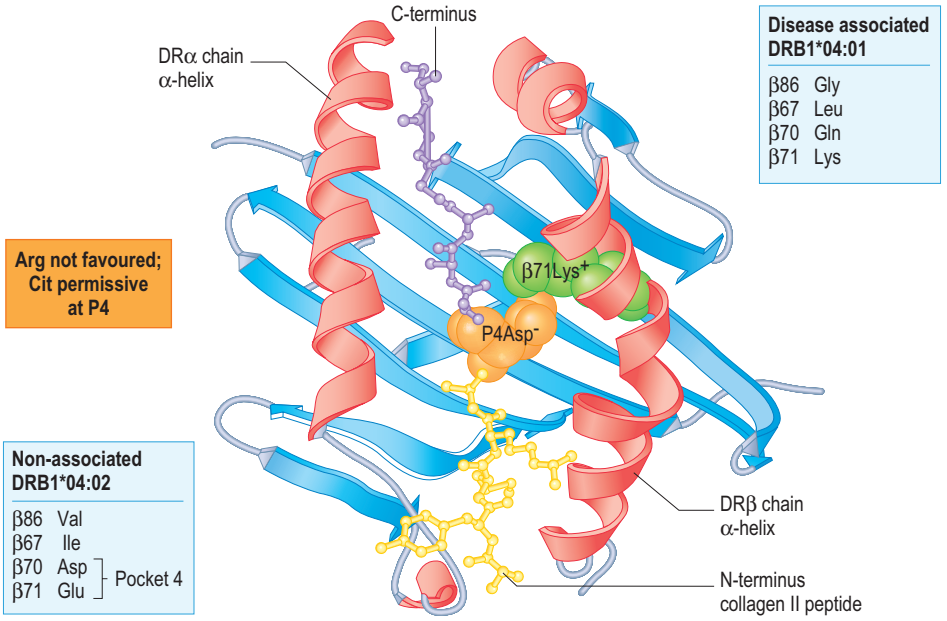

FIG. 53.1 Crystal Structure of a Collagen II Peptide/Human Leukocyte Antigen (HLA)-DR4 Complex. Ribbon model of an immunodominant collagen II peptide (1168 to 1180) complexed to HLA-DR4 (*DRA**01:01/*DRB1**04:01); a view of the major histocompatibility complex/peptide complex as seen from the T-cell surface. DRα and DRβ chain helices are shown in red, whereas the β-pleated sheet comprising the floor of the peptide-binding groove is shown in blue. Here, amino acids 11, 13, 71, and 74 form part of the fourth anchoring peptide-binding pocket, the same positions that confer highest risk of disease. Residues 67 to 74 of the DRβ chain, components of the third hypervariable region, derive the "shared epitope." The ball and stick model of the CII peptide is shown. Interacting residues of the peptide position 4 (Asp, orange) and DRβ chain residue (β71Lys, green), which make up part of pocket 4, are depicted as van der Waal's spheres. Differences in amino acid sequence between the closely related disease-associated DRB1*04:01 and non-associated *DRB1**04:02 gene products are illustrated. Note that although Arg would not be favored at position 4 in the peptide, modification of Arg → Cit by deimination would be permissive. These findings point to SE associating not with RA per se, but with an immunological phenotype, in this case autoantibodies to modified protein antigens (AMPA). Figure generated by R. Visse and A. Cope, based on crystal data derived by Wiley and colleagues (Courtesy Dessen A, Lawrence CM, Cupo S, Zaller DM, Wiley DC. X-ray crystal structure of HLA-DR4 (DRA*0101, DRB1*0401) complexed with a peptide from human collagen II. *Immunity*. 1997;7(4):473–481).

that the SE is the critical genetic element linked directly to disease. The first model proposed that the SE determines specific peptide binding and that "pathogenic" peptides bind preferentially to disease-associated HLA class II molecules (see Fig. 53.1). This model predicted that a gradient of affinities of disease-inducing peptide for MHC class II molecules might account for the differences in susceptibility and/or severity conferred by different HLA-DR molecules. Along the same lines, disease-associated alleles may preclude the binding of peptides required for the generation of naturally occurring Tregs specific for self-peptide antigens. The second model proposed that the SE influences T-cell receptor (TCR) recognition by binding and selecting autoreactive T cells during thymic maturation and expanding these populations in the peripheral compartment; again perturbations of a repertoire of Tregs could arise through opposing influences of the SE sequence. Based on crystal structures, both models hold up, with the shared epitope sequence conferring dual functionality by determining the repertoire of specific peptides for presentation and providing a determinant for TCR recognition.

Another important line of evidence pointing to specific functions of SE^+ alleles has arisen through analysis of autoantibodies in RA patients typed at the HLA-*DRB1* locus. These studies, replicated in European and US cohorts, demonstrated associations between SE frequencies and antibodies to cyclic citrullinated peptides (anti-CCPs), as distinct from rheumatoid factor (RF). When compared with healthy controls, the odds ratios for the association between one or two copies of the SE and anti-CCPs positivity was 4.4 and 11.8, respectively. The mechanism underlying this association is illustrated in Fig. 53.1, and discussed further below. The importance of citrulline as a molecular feature of human T-cell–specific autoantigenic determinants is further suggested through identification of autoreactive $CD4^+$ T lymphocytes by flow cytometry using HLA-citrullinated-peptide tetramer complexes.[11] These tools permit determination not only of the relative proportion of antigen-reactive effector T cells, but also regulatory T-cell subsets.

Meta-analyses and fine-mapping studies, including custom-designed single nucleotide polymorphism (SNP) arrays have identified more than 100 susceptibility loci with genome-wide significance, many of which have been validated in RA populations of diverse ancestry, and numerous small effect causal variants.[12] Among the strongest associations outside HLA is *PTPN22*, initially identified in candidate gene association studies. The *PTPN22* gene variant confers risk with odds ratios ranging from 1.5 to 1.9 in Caucasian and European populations, and it is unusual among most genetic variants in that it is a coding frame mutation (R620W). *PTPN22* encodes a hematopoietic cytoplasmic protein tyrosine phosphatase whose substrates include Src and Syk family kinases, CD3ε, TCRζ, and signaling intermediates such as Vav. These signaling intermediates operate downstream of antigen receptors, integrins, and pattern recognition receptors, and so the genetic variant that alters phosphatase function has become a highly plausible susceptibility allele from an immunobiological perspective. Indeed, studies in *Ptpn22* mutant mice have demonstrated that loss of PTPN22 function perturbs activation of dendritic cells and uptake of, and presentation to, T-cells of immune-complex-derived antigens. This, together with enhanced LFA-1 dependent cell adhesion at the immunological synapse,[13] and augmented antigen receptor signaling, places dysregulation of the initiation of adaptive immune responses firmly at the center of autoimmune susceptibility linked to *HLA* and *PTPN22* polymorphisms.

Scrutiny of other, non-MHC susceptibility loci point to genes whose products are involved in proximal signaling pathways that regulate T-cell activation, differentiation, and persistence. Besides *HLA* and *PADI4*, which influence the molecular determinants of T-cell "input signals," these include *CD28, CTLA-4*, and *CD2-CD58* (regulation of T-cell costimulation); *CD247, PTPN22, PRKCQ, TAGAP*, and *REL* (transducer modules of TCR signaling); *STAT4* and *TNFRSF14* (inducers of lineage-specific cytokine gene expression and persistence of memory T cells); and *REL, IL2-IL-21, IL2RA*, and *IL2RB* (regulators of IL-2 gene expression and IL-2R signaling). Notable overlap with these and other allelic variants has been reported in other autoimmune diseases, indicating that susceptibility to RA is linked to fundamental perturbations of immune tolerance. Variants mapping to cell surface receptors (*IL6R, CCR6, CD40, CD5, FCGR2A*) and intracellular signaling intermediates (*TNFAIP3, TYK2, TRAF1, TRAF6, RASGRP1, BLK*) are well represented, as are transcription factors linked to cell differentiation and effector function (*GATA3, IRF5, IRF8, IKZF3, RBPJ, RUNX1*). Perturbations in expression or function of these genes will influence the function of a broad range of immune cell subsets.

The identification of disease-associated genetic variants raises questions about precisely how they alter cellular function, and in which cell types. This is a challenge, not least because 90% of genome-wide association studies (GWAS) associations reside in non-coding sequences, and means that gene-targeting approaches to reveal functions in mammalian cells is not trivial. Nonetheless, identification of expressed quantitative trait loci (eQTL) has supported the view that a proportion of variants alter gene expression. For example, RA genetic studies have shown that SNPs are overrepresented in memory $CD4^+$ T-cell regulatory elements. Understanding cell-type-specific gene expression enrichment in GWAS risk loci remains a topic of considerable interest.

Synovial Pathology

RA targets diarthrodial joints, structures characterized by hyaline cartilage lining opposing articulating surfaces and a cavity of viscous synovial fluid lined by synovial membrane lacking a basement membrane but encased by a fibrous joint capsule. Normal synovial tissue comprises a lining layer, no more than a few cells in depth, of stromal fibroblast-like synoviocytes (FLSs—also known as type B synoviocytes) and sublining macrophages (type A synoviocytes). The normal synovium serves to line non-cartilaginous surfaces, and although blood vessels are sparse, it functions to provide essential nutrients to avascular structures including cartilage, tendons, and bursae.

Increased Vascularity and Cell Migration

The range of pathology observed in patients with RA perhaps most convincingly underscores the heterogeneity of the disease.[14] The earliest changes observed relate to increases in vascularity characterized by vascular congestion and thrombosis with obliteration of small vessels in association with perivascular inflammatory infiltrates. Hyperplasia of the synovial lining layer is another typical early finding. These changes are rather nonspecific and certainly not diagnostic.

A key checkpoint defining the switch from acute to chronic persistent inflammation is the sustained activation of microvascular endothelium, phenotypic changes in the high endothelial venules (reminiscent of tissue injury), and the concomitant upregulation of adhesion molecules such as intercellular

adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 (Chapter 16). According to current thinking, the expression of chemoattractants derived from synovial stromal cells heralds the rolling, adhesion, and transmigration of mononuclear cells through endothelial barriers into the synovial membrane. It also contributes to the progressive synovial hypertrophy and hyperplasia, sometimes with villous-like projections more typical of chronic, established inflammation. Intravital imaging of synovial joints of mice injected with arthritogenic antibodies derived from the serum of *K/B* × *N* mice indicates that enhanced vasopermeability at sites destined to become arthritic is a crucial early event, at least in antibody-induced disease. This process is dependent on mast cells and neutrophils and on the release of the vasoactive amines histamine and serotonin, which contribute to heightened vascular permeability. Neovascularization promotes further influx of inflammatory cells. To what extent this is driven by the hypoxic environment is not entirely clear, but expression of angiogenic growth factors such as vascular endothelial growth factor (VEGF), angiopoietin, Tie-2, and hypoxia inducible factor (HIF), as well as lymphangiogenic factors VEGF-C and VEGF-R3, are increased. The abundance of lymphatic vessels in inflamed synovium, suggested by expression of podoplanin and CD31 *in situ*, suggests that active lymphangiogenesis exists that may promote efflux of cells and fluid from the synovium.[14]

Organization of Lymphoid Tertiary Microstructures

Tissue microstructure both dictates and facilitates immune responses in secondary lymphoid organs and mucosa-associated lymphoreticular tissues (MALTs). These structures have evolved to coordinate responses to pathogens and to direct lymphocyte recirculation, and although their role in immune homeostasis is established, quite how they contribute to pathological states is less well understood. Thus, the inflamed, noncapsulated synovium appears to be uniquely suited to supporting distinct patterns of cellular infiltrates, including inducible lymphoid structures that promote pathways of cell activation, differentiation, and survival.[14] These include diffuse, rather disorganized lymphocytic infiltrates that comprise the most common form of synovitis, occurring in ~30% in prospective cohort studies; up to 70% has been described in late-stage disease (at arthroscopy, joint replacement surgery). In 40% to 50% of patients more organized follicular structures may exist (Fig. 53.2). Based on immunohistochemical analysis, approximately 25% of these follicular structures include organized germinal centers in which there are zones of proliferating B cells with affinity maturation, in addition to a distinct T-cell zone. In aggregates lacking germinal centers, follicular dendritic cells (DCs) are absent.

A fourth histological pattern, characterized by granulomatous reactions, has been described in a much smaller subset of patients. The cellular and molecular determinants of these structures include the homeostatic lymphoid chemokines CXCL13 and the CCR7 ligands CCL21 and CCL19, VCAM-1$^+$ICAM-1$^+$LTβR$^+$ mesenchymal-organizer cells, and hematopoietic-derived CD3$^-$CD4$^+$IL-7R$^+$RANK$^+$ lymphoid-inducer cells. Lymphoid-tissue-inducer cells produce LT-β, which is required for high endothelial venule differentiation, amplification of chemokine expression, and development of the stromal architecture. Documentation of class-switch recombination and somatic mutation of immunoglobulin genes *in situ* is further evidence of active adaptive immunity within synovial lymphoid follicles and suggests that supporting *in situ* production of pathogenic antibodies is of considerable pathobiological importance.

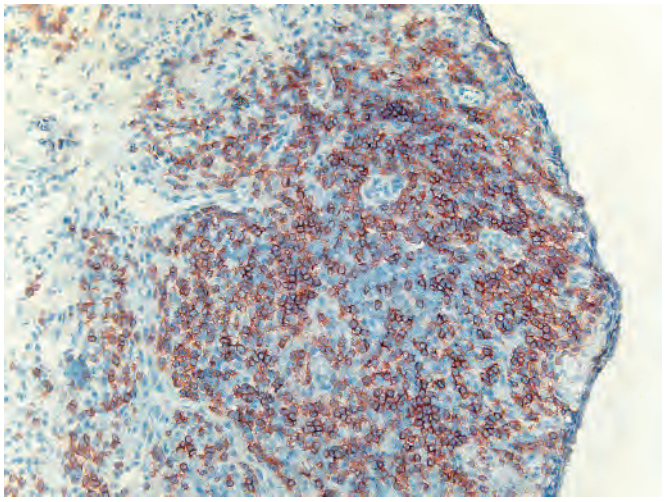

FIG. 53.2 Lymphoid Follicular Structures in Inflamed Rheumatoid Arthritis Synovial Tissue. A characteristic hematoxylin and eosin–stained tissue section from a patient with active RA showing a large follicular-like structure (original magnification ×100). This section is also stained with monoclonal antibodies to CD3ε, followed by a three-step immunoperoxidase staining protocol (CD3$^+$ T cells stained dark red). (Courtesy Tak PP, Taylor PC, Breedveld FC, Smeets TJ, Daha MR, Kluin PM, Meinders AE, Maini RN. Decrease in cellularity and expression of adhesion molecules by anti-tumor necrosis factor alpha monoclonal antibody treatment in patients with rheumatoid arthritis. *Arthritis Rheum.* 1996;39(7):1077–1081, with permission from J. Wiley and Sons, Inc.)

Functional correlates of these dynamic structures continue to emerge. Using conventional histology, immunohistochemistry, and RNA-seq on synovial tissue from early RA patients it has been possible to identify three broad groups (designated pathotypes) based on cell-specific gene modules. These bear similarities to those outlined above, and are described as fibroblastic pauci-immune pathotype, macrophage-rich diffuse-myeloid pathotype, and a lympho-myeloid pathotype characterized by infiltration of lymphocytes and myeloid cells.[15] Importantly, these phenotypes map to disease severity and clinical outcomes since pro-myeloid inflammatory synovial gene signatures correlate with clinical response to initial drug therapy, whereas plasma cell genes identified a poor prognosis subgroup associated with ultrasonographic synovial thickening and increased power Doppler scores, and progressive structural damage. In addition, a more inflammatory synovial phenotype at baseline correlated with a greater fall in DAS28-CRP after 6 months of disease-modifying anti-rheumatic drugs (DMARDs) treatment, while a robust type I interferon (IFN) response in peripheral blood was associated with synovial B-cell infiltration.

Immunobiology of Rheumatoid Arthritis

Initiation of the Immune Response

Synovial fibroblasts are exquisitely sensitive to inflammatory cytokines such as IL-1, TNF, and IL-6. Fibroblast-like synoviocytes (FLSs) also express a range of toll-like receptors (TLRs) that can respond to exogenous, pathogen-associated molecular

patterns (PAMPs) and a growing range of self-tissue proteins, some of which could be considered damage-associated molecular patterns (DAMPS). Endogenous ligands especially relevant to inflammatory arthritis include heat shock proteins, fibrinogen fragments, antibody-DNA complexes, high-mobility group box (HMGB)-1, and hyaluronan oligosaccharides. Stimulation of FLS through these pathways induces cytokines such as IL-6, matrix metalloproteinases, adhesion molecules, and an array of chemokines including granulocyte chemotactic protein (GCP)-2, RANTES, monocyte chemoattractant protein (MCP)-2, IL-8, growth-related oncogene-2, and, to a lesser extent, macrophage-inflammatory protein 1α, MCP-1, EXODUS, and CXCL-16. This creates an inflammatory niche for recruiting and sustaining leucocytes in the synovial joint.

Cell-surface phenotyping of synovial FLS by mass and flow cytometry has uncovered seven subsets based on expression of podoplanin, cadherin 11, and Thy-1, segregated on the basis of the hematopoietic marker CD34.[16] In-depth transcriptomic profiling identified three broader subsets, discrete from OA synovial FLS. While $CD34^+$ fibroblasts are observed in both superficial lining and deeper sublining areas, $CD34^-Thy1^+$ fibroblasts in RA form a discrete perivascular zone surrounding capillary structures in the deep sublining layer of the synovium, especially near accumulations of lymphocytes. $CD34^-Thy1^-$ fibroblasts were mostly observed in the lining area. Synovial tissue from active, clinically swollen joints had fewer $CD34^-Thy1^-$, more $CD34^-Thy1^+$, and more $CD34^+$ fibroblasts, and the proportion of $CD34^-Thy1^+$ fibroblasts positively correlated with the proportion of infiltrated leukocytes determined by flow cytometry. These expanded, putative pathogenic populations are more proliferative and express genes associated with a migratory response, and expression of inflammatory cytokine genes such as IL6, CXCL12, and CCL2 that support matrix invasion, immune cell recruitment, and osteoclastogenesis. Adoptive transfer experiments in mice have demonstrated that two anatomically discrete and functionally distinct populations of fibroblast-activation protein alpha (FAPα) expressing FLS segregate based on Thy1 expression; $Thy1^+$ FLS are effector cells largely confined to the sub-lining layer, while the lining layer $Thy1^-$ subset express *Ccl9* and *Tnfsf11*, both potent inducers of osteoclast activity, as well as *Mmp3*, *Mmp9*, and *Mmp13*, and promote cartilage destruction.[17]

Dendritic cells (DCs) are thought to be the most important antigen-presenting cells in RA. Indeed, the proinflammatory environment favors DC maturation in regional lymph nodes as well as inflamed tissue. Thus in peripheral blood, DC precursors express either an immature $CD33^{dim}CD14^{dim}CD16^-$ phenotype or a more mature MHC class II^{bright} $CD11c^+CD33^{bright}CD14^{dim}$ surface phenotype typical of conventional myeloid DC (mDC); neither population expresses costimulatory molecules. In contrast, synovial fluid and tissue DC subsets resemble mature peripheral blood cells; in addition, a subset expresses high levels of CD86 that can support allogeneic mixed leukocyte reactions. More recent data indicate that they may differentiate further *in situ* as suggested by nuclear translocation of RelB in DC localized within perivascular infiltrates, consistent with prior cytokine receptor or Toll-like receptor (TLR) engagement *in vivo*. Perivascular RA synovium also contains populations of MHC class $II^+CD11c^-CD123^+$ plasmacytoid DC (pDC); in contrast to the conventional myeloid DC subset, these are $RelB^-$ and comprise ~30% of all synovial DC. A subset of pDC express BDCA2, capable of producing IFN-α *in situ*. Unlike their peripheral blood counterparts, synovial pDC efficiently activate allogeneic T cells to proliferate as well as to produce IFN-γ, TNF, and IL-10.

Although the common myeloid precursor cell is the precursor for all myeloid cells, including DC and tissue macrophages, the precise role of monocytes—namely $CD14^+CD16^-$, $CD14^+CD16^+$, and the more recently described $CD14^{dim}CD16^+$ subset—in synovial inflammation is uncertain. They are good candidates as persistence factors through their capacity to activate and polarize T-cell subsets, to respond to the environment through TLR expression, and to produce a wide range of inflammatory mediators, including IL-1, TNF, IL-6, IL-8, CCL2, NO, and type I IFN.

It turns out that not all myeloid cells are inflammatory. A comprehensive spatiotemporal analysis of the composition, origin, and differentiation of subsets of macrophages within healthy and inflamed joints of mice using fate-mapping approaches, fluorescence microscopy, and single-cell RNA sequencing has identified a population of CX_3CR1^+ tissue-resident, lining synovial macrophages with barrier functions typical of epithelial cells.[18] This population was derived from a proliferative subset of CX_3CR1^- cells in the deeper layers of the synovium, which acquire transcription factors for terminal differentiation into the CX_3CR1^+ lining subset, and genes with immune regulatory functions for clearance of apoptotic debris, and genes encoding tight-junction proteins. Similar populations have been defined in human synovium expression genes associated with gate keeping functions. In the serum transfer model of arthritis, inflammation-associated barrier breakdown occurred after the deposition of autoantibody-containing immune complexes.

The initial wave of inflammation has two major consequences. First, inflammatory cytokines will promote the activation of vascular endothelium, changes that occur very early in disease (see above and Fig. 53.3).[19] Under the influence of locally generated cytokines and chemokines, synovial postcapillary venules undergo morphological changes to an extent that they resemble high endothelial venules similar to those observed in secondary lymphoid organs. The second major consequence is the migration of inflammatory leukocytes, including polymorphonuclear leukocytes and immature or undifferentiated monocytes, orchestrated by chemokines produced by resident stromal as well as infiltrating cells (see Fig. 53.3). CXC, CC, C, and CX_3C chemokines all play a role, exerting chemotactic activity toward neutrophils, lymphocytes, and monocytes but also influencing the topology of inflammatory infiltrates. Besides the homeostatic chemokines described above, the key players include IL-8/CXCL8, RANTES/CCL5, MIP-1α/CCL3, SDF-1/CXCL12, IP-10/CXCL10, and MCP-1/CCL2. Upregulation on endothelium of cell-surface adhesion molecules, including ICAM-1, VCAM-1, and E-selectin, permits the rolling and adhesion of leukocytes as they migrate. In synovial joints, resident stromal cells and infiltrating macrophages are a dominant source of such factors. Crucially, the expression of cognate chemokine receptors such as CCR4, CCR5, CCR6, CXCR3, and CX_3CR1 on inflammatory cell subsets contributes selectivity of cellular recruitment.

Autoantigens in Rheumatoid Arthritis

Although current models of adaptive immune responses would suggest that DC carry antigens derived from damaged or dying synovial tissue, the molecular nature of disease-associated antigens has, until recently, remained an enigma. Many RA-associated

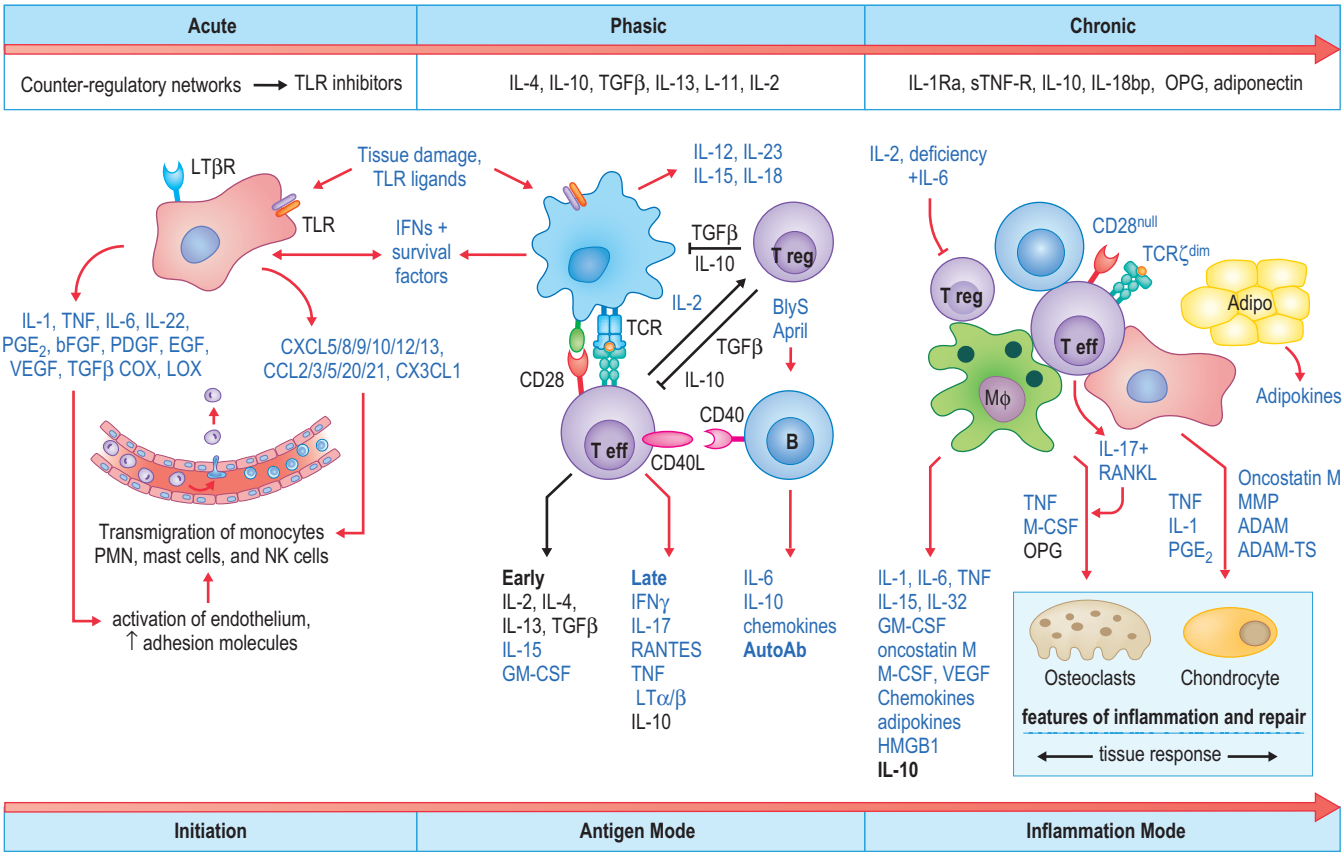

FIG. 53.3 Cytokine Networks in Rheumatoid Arthritis. The pathogenesis of rheumatoid arthritis can be thought of as a series of complex and closely related pathways temporally and spatially regulated. These include (1) an acute insult that may trigger the disease, characterized by stimulation of FLSs by inflammatory stimuli and the generation of cytokines and chemokines that promotes the migration and infiltration by cells of the innate immune system; (2) repeated episodes of antigen-specific adaptive immune responses (in lymph node, bone marrow, and *in situ*). Failure to resolve adaptive immunity is a key checkpoint that may lead to (3) a cytokine-driven chronic inflammatory phase when multiple cellular and molecular components sustain the response. Through multiple pathways acting on many cell types, this process leads to tissue injury. Proinflammatory pathways are shown in blue (text) and red (arrows), whereas anti-inflammatory, counterregulatory pathways are shown in black (text and arrows). *Adipo*, Adipocyte; *AutoAb*, autoantibodies; *B*, B cell; *DC*, dendritic cell; *FLSs*, fibroblast-like synoviocytes; *MΦ*, macrophage; *TCR*, T-cell antigen receptor; T_{eff}, effector T-helper cell; *Treg*, regulatory T cell.

autoantigens have been described (Table 53.1 for examples), and for some there exist clear correlates linked to *in vivo* arthritis models. The best described are collagen II, proteoglycans, HCgp-39, glucose-6-phosphate isomerase, α-enolase, vimentin, and citrullinated fibrinogen. However, when used as recombinant native antigen, few have been found to elicit reproducible and/or robust PB or SF T- or B-cell responses in a significant proportion of patients, when compared to healthy donors. There are several plausible explanations for this. Perhaps the most obvious is that the autoantigens used to test lymphocyte reactivity in vitro do not carry the posttranslational modifications (i.e., the neoepitopes) recognized by autoantibody or antigen receptor.

The Discovery of Citrulline as a Key Target for Autoimmunity in Rheumatoid Arthritis

In 1998, van Venrooij and colleagues first reported that patients with RA carried serum autoantibodies that recognized deiminated peptides of fillagrin.[20] Using new-generation anti-cyclic citrullinated peptide (anti-CCP) based assays, the presence of these antibodies, now collectively termed ACPAs, is now confirmed to be both sensitive (up to 80%) and highly specific (>95%) for the diagnosis of RA. Indeed, serum anti-CCPs levels are stable in established disease, can be detected many years before disease onset, and have been shown to be predictors of radiographic progression. Changes in isotype usage and spreading of antigenic specificities suggest that ACPA responses mature before disease onset. While citrullination is not specific for RA, it may be inflammation specific, having been documented in inflamed synovium from patients with reactive arthritis and psoriatic arthritis as well as RA, but not osteoarthritis (OA). What appears specific for RA is the immune response to citrulline (Fig. 53.4). Initially, linkage analysis across chromosome 6 documented a peak with logarithm of odds (LOD) scores in excess of 10 for $ACPA^+$ patients, but not for those who do not carry these antibodies. This relationship was independent of RF status because the SE allele frequencies in $ACPAs^+$ patients were twice those of $ACPAs^-$ patients, even for those patients who are RF^+.

An emerging model proposes that SE^+ DRB1 alleles are not involved in the initial breach of tolerance, but play a role in boosting the immune response to citrullinated proteins, hence

TABLE 53.1 Autoantigens in Rheumatoid Arthritis

Established	T or B Cell[a]	Molecular Specificity	Assay[b]
Immunoglobulin G	B	Human Fc IgG	Rheumatoid factor
Cyclic peptides	T and B	Citrullinated peptides	Anti-CCPs
Various peptides	B	Carbamylated peptides	Research[b]
Various peptides	B	Acetylated peptides	Research[b]
Fibrinogen peptides	T and B	Citrullinated α- and β-chain epitopes	Research[b]

the strong association between SE$^+$ DRB1 alleles and ACPA$^+$ arthritis. This concept is further reinforced by crystallographic studies suggesting that the conversion of positively charged arginine at key residues in antigenic peptides from candidate autoantigens such as fibrinogen to neutral citrulline is permissive for peptide binding and recognition by autoreactive T cells *in vivo*.[11]

Citrullination is widespread in multiple tissues in response to appropriate provocations. Although the molecular basis for these triggers is poorly understood, recent data point to a link between smoking—an environmental exposure known to be linked with RA—citrullination, and individuals carrying SE.[21] Thus, cells derived from bronchoalveolar lavage from smokers, but not from nonsmokers, express citrulline. The association between the development of RA and smoking has now been linked to ACPAs$^+$ patients, whose relative risk increases 20-fold if they smoke and carry two copies of the SE$^+$ DRB1 alleles; in comparison, the relationship in ACPAs$^-$ patients appears to be much weaker or nonexistent. A second example relates to the fact that *Porphyromonas gingivalis*, a pathogen associated with severe periodontitis, expresses its own deiminating enzyme and has the capacity to modify host proteins such as fibrinogen and α-enolase in inflamed gingival tissue. Molecular mimicry is suggested by the finding that anti-α-enolase autoantibodies from patients with RA cross-react with *P. gingivalis*–derived α-enolase. The links between autoantibodies to the immunodominant α-enolase epitope CEP1, smoking, SE$^+$DRB1, and disease-associated *PTPN22* alleles are some of the strongest defined to date, and show direct links between environmental exposure and disease-specific immune responses governed by immune-response genes.

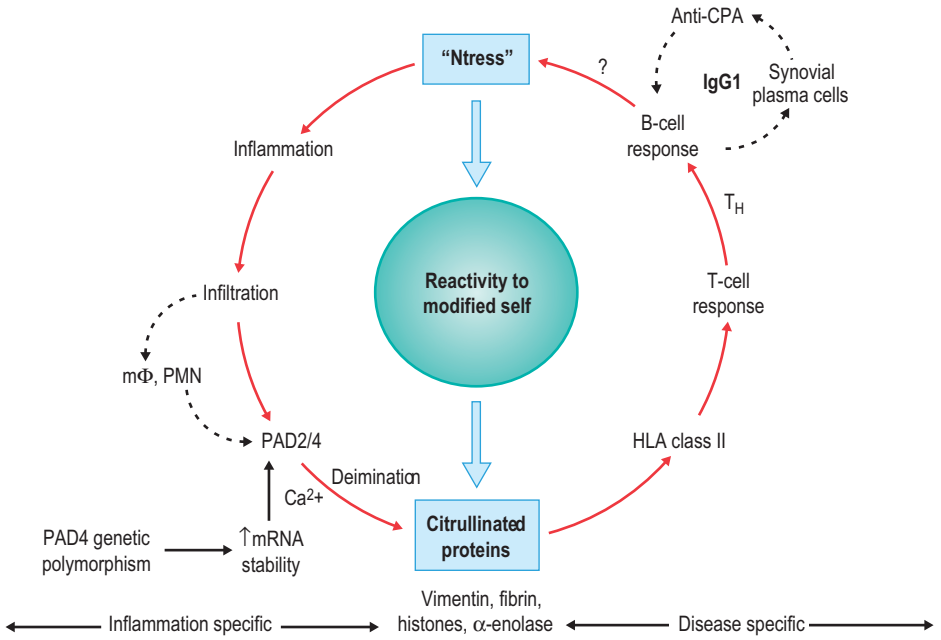

FIG. 53.4 The Generation of Autoantibodies to Citrullinated Protein Antigens. The stressed and inflamed synovium is characterized by an influx of inflammatory cells, including macrophages and neutrophils that express peptidyl-arginine deiminases (PAD). In the presence of sufficient Ca^{2+}, PADs deiminate target proteins including, among others, vimentin, fibrinogen, aggrecan, type II collagen, histones, and α-enolase. This reaction is inflammation, but not disease specific. The combination of environmental stimuli (including inflammation and exposure to tobacco smoke) and the inheritance of specific HLA-DRB1 alleles favor T- and B-cell immune responses to the host's derivatized neoepitope peptide antigens. Neoepitopes may also be generated by changes in peptide cleavage during antigen processing as a consequence of the Arg → Cit modification. *Anti-CPA*, Autoantibodies to citrullinated protein antigens; T_H, T-helper effector cell.

Our growing appreciation of the importance of post-translational modifications (PTMs) in general, and citrullination in particular, has driven a search for alternative PTMs that might contribute to the triggering or perpetuation of autoimmune responses to altered self.[22] For example, autoantibodies recognizing peptides carrying amino acids modified by carbamylation (to homocitrulline) or acetylation (to acetyllysine) are readily detectable, collectively termed anti-modified protein antibodies (AMPA). Mapping antibody reactivities against multiple peptide specificities indicates that citrulline-specific B cells are highly cross-reactive—a feature that likely underpins the basis of breech of immune tolerance prior to the onset of RA, and supported by findings from mouse immunization experiments revealing that different AMPA responses emerge from exposure to a single type of modified protein.

Lymphocyte Biology

Flow cytometric analysis of dissociated synovial mononuclear cell cultures indicates that infiltrating T lymphocytes make up approximately 10% to 35% of cells in inflamed tissue. Synovial T cells express phenotypic markers of antigen experienced, terminally differentiated T cells with enhanced migratory capacity. Thus, synovial T cells typically carry cell surface markers such as HLA-DR$^+$, LFA-1$^+$, VLA-1$^+$, CXCR3, CD69$^+$, CD45RO$^+$, CD45RA$^-$, CD45RB^{dim}, CD29^{bright}, CD27$^-$, and CD25$^-$, and low expression of TCRζ. While synovial fluid T cells are also FasL$^+$, Bcl2$^-$, Bax^{bright}, favoring a proapoptotic state, it is thought that environmental cues transduced through common γ chain receptor signaling cytokines such as IL-2, IL-7, and IL-15, as well as type I interferons, prevent apoptosis of T cells *in situ*. Synovial tissue–derived lymphocytes may be different. Consistent with their state of terminal differentiation, a subset of synovial T cells are CD28$^-$, while at the same time expressing a range of natural killer (NK) cell-surface receptors that are thought to contribute to effector function independently of cognate antigen.

Recent analysis of citrulline-reactive B cells from RA patients indicate that they display markers of class-switched memory B cells and plasmablasts (CD20$^+$CD27$^+$IgD$^-$). Analysis of the variable (V) regions of the immunoglobulin heavy and light chains confirm that antigen-specific activation and differentiation of B cells into plasma cells takes place in draining lymph nodes as well as in the chronically inflamed synovial tissue of patients with RA. Likewise, analysis of the T-cell repertoire indicates that the synovium provides a niche for supporting expansion of specific T cells, whose clonality is shared between different joints from the same patient, but not substantially with clones from paired blood samples.

For over a decade it has been known that one of the dominant cytokines expressed in synovial T cells from patients with established disease is IFN-γ. Somewhat surprisingly, a significant proportion of IFN-γ$^+$ cells also express IL-10. Recent data support a model in which there exists, during differentiation, a transition from IFN-γ$^+$ Th1 T cells through an IFN-γ$^+$IL-10$^+$ double-positive stage to a single-positive IL-10$^+$ stage. This last phase could represent part of the normal life cycle of an effector T cell, where IL-10 expression promotes the resolution of the adaptive immune response, attenuating the function of DCs. Interestingly data indicate that this Th1 life cycle involving a switch from IFN-γ to IL-10 production may be defective in individuals at risk of developing RA.

Recent, systematic approaches for studying synovial T cells at a single cell level has uncovered a markedly expanded population of PD-1^{hi}CXCR5$^-$CD4$^+$ T cells in synovium of patients with RA.[23] These are unusual in light of high expression of PD-1 and lack of CXCR5, and while they express activation markers such as MHC class II, they are not exhausted. Defined as peripheral helper T cells (T_{PH}), and distinct from T_{FH} cells, synovial PD-1^{hi}MHCII^{hi}CXCR5$^-$ cells support B-cell help via expression of IL-21, CXCL13, ICOS, MAF, and BLIMP1, and have been shown to induce plasma cell differentiation at least *in vitro*.

Finally, PTM of immunoglobulins, most notably glycosylation of the Fc domain, has been a recognized feature of the evolving immune response for decades, with distinct moieties being linked to specific IgG effector functions. Besides glycosylation at position 297 in the IgG Fc tail of APCAs, where animal studies suggest that disease-associated glycosylation patterns are regulated by IL-23 and Th17 cells, a recent addition to the repertoire of glycosylation of ACPAs has been the identification of highly sialylated N-linked glycans in the antigen variable domain of up to 90% IgG ACPA, arising as a consequence of T-cell dependent, variable region somatic hypermutation.[22] This is rather uncommon in other IgG molecules. Analysis of IgG ACPA in first-degree relatives of RA patients suggests that extensive glycosylation precedes the onset of disease, and thus represents a signature of high risk. While Fc tail agalactosyl "pro-inflammatory modifications" likely alters immunity through effects on FcR binding and effector responses, current thinking suggests that ACPA IgG variable domain N-glycans could influence antigen binding avidity, B-cell receptor signaling and tolerance, or binding to glycan receptors such as lectins.[22] Further work is needed to evaluate each of these possibilities.

Immune Regulation

Investigation of regulatory cell subsets and their anti-inflammatory properties has perhaps more firmly established the concept that failure of the host's intrinsic mechanisms of immune regulation can underpin autoimmune diseases. Experiments in gene-deficient mice (*e.g.*, Foxp3, IL-2, IL-2R, IL-2R signaling, STAT5, IL-10, TGF-β) lend support to this concept. In RA the data remain less clear. For example, there is *in vitro* evidence for a relative deficiency of constitutive IL-10 expression in synovial cell cultures, and yet clinical trials of IL-10 have been disappointing. These results may reflect the complex role of these cytokines in disease pathogenesis. The identification of defective numbers and/or function of CD4$^+$CD25^{bright} Tregs has been suggested by several investigators, but reports are conflicting.[24] Some studies have shown clear reductions in numbers of peripheral blood Tregs in patients with RA, whereas others have shown no difference. In synovial joints, the data are more consistent, with many reports showing substantial increases in Treg numbers in synovial tissue and fluid compared with paired PB. However, some studies have reported normal function at a cellular level, whereas others have shown depressed regulatory function. One possible mechanism is that synovial effector T cells are refractory to regulatory pathways.

The advent of immune checkpoint inhibition (CPI) for the treatment of a wide range of cancers has, serendipitously, provided incontrovertible *in vivo* evidence that immune checkpoints CTLA-4 and PD-1 contribute to immune homeostasis in individuals at risk of inflammatory arthritis.[25] Immune-related adverse events (irAEs) are now a well-recognized complication of CPI with anti-PD-1/PDL-1 and anti-CTLA4, targeting any organ or tissue in the body. These inflammatory syndromes, which phenocopy idiopathic autoimmune diseases, can arise within weeks or months of treatment initiation, and are thought to represent an abrupt breach of immune

tolerance. Both seronegative and seropositive subsets of inflammatory polyarthritis, indistinguishable from RA, have been reported by many groups; some cases are transient and self-remitting, while others persist, requiring disease-modifying therapy. What remains unclear is whether this RA-like syndrome arises only in susceptible individuals or whether the inflammatory process arises *de novo*, regardless of genetic or environmental factors.

Impact of the Inflammatory Response on Cartilage and Bone

For many years, it was considered that the terminal effector phase of chronic inflammation that led to cartilage destruction and bone resorption was driven almost exclusively by inflammatory cytokines and proteinases. IL-1, MMPs (MMP1, 3, 8, 13), and aggrecanases (ADAMTS 4 and 5) were, and remain, major drivers. Attempts to establish more directly a link between adaptive immunity and destruction of target tissue failed, not least because of the lack of a direct physical link between lymphocytes, chondrocytes, and bone. A breakthrough came in the late 1990s with the identification of the TNF/TNFR family member receptor for activation of nuclear factor (NF)-κB ligand (RANKL)/TRANCE/ODF and its counter-receptor RANK, and the dissection of the molecular and cellular components required for osteoclast differentiation from monocyte precursors.[26] According to contemporary paradigms, RANKL is necessary and sufficient for osteoclast differentiation. TNF, M-CSF, IL-1, and IL-17 contribute, and RANKL-independent pathways may also play a role. RANKL is expressed on synovial fibroblasts and osteoblasts but also on activated T cells, its counter-receptor being expressed on myeloid lineage cells including monocytes, osteoclast precursors, and DCs. Its expression is regulated by inflammatory mediators including TNF and PGE_2. RANKL is shed, probably through the action of several membrane-associated proteases including MT1-MMP (MMP14). Gene targeting of RANKL or RANK in mice leads to inhibition of osteoclastogenesis and a profound osteoporotic bone phenotype. Deletion of osteoprotegerin (OPG), the naturally occurring decoy soluble receptor for RANK, leads to unbridled osteoclast differentiation and bone resorption and substantially reduced bone mass. In RA, several studies have demonstrated perturbations of serum RANKL/OPG ratios, and recent clinical experience with denosumab, a fully humanized monoclonal antibody that binds to RANKL, demonstrates increased bone mineral density and reduced bone turnover in patients with RA.

Distinct from enhanced bone resorption, bone formation is impaired in RA, although until recently the pathways involved were rather obscure. The inflammatory process itself, along with its effects on osteoblast maturation and function, has been directly implicated because bone formation at surfaces adjacent to bone marrow, as opposed to inflamed synovium, are relatively well preserved. Recent data suggest that ACPAs can also directly promote osteoclastogenesis, providing a mechanistic link between autoantibodies and joint destruction that also depends on IgG glycosylation status. Evidence now points to the canonical Wingless (Wnt) signaling pathway as being an essential control point in osteoblast function, based on the observation that in animal models of RA antibodies to Dickkopf homologue 1 (DKK1), a secreted antagonist of Wnt blocking, signals at the level of its cognate receptor Frizzled, promote bone formation and inhibit bone resorption indirectly by increasing production of OPG. This indicates that Wnt signals negatively regulate osteoclastogenesis.

The interplay between bone formation and resorption is fundamental to bone homeostasis, especially in the context of chronic inflammatory disease. Recent evidence suggests that the molecular basis for this so-called coupling lies with the osteoprotective factor semaphorin 3 A. This factor regulates bone mass in both osteoblasts (through effects on the canonical Wnt/β-catenin signaling pathway) and osteoclasts (by inhibiting RANKL-dependent osteoclast differentiation). Together these data support the view that bone and joint integrity are regulated by a delicate balance of catabolic and anabolic immune and inflammatory mediators influencing the maturation and function of osteoblasts (Wnt:DKK1) and osteoclasts (RANKL:OPG).

CLINICAL FEATURES

Disease Onset

RA is a heterogeneous disease that does not conform to a single clinical entity. Whereas 10% of patients may have an acute severe onset and 20% a more subacute onset, the onset of signs and symptoms may be insidious in up to 70% of patients. A more episodic or palindromic onset has also been described. A common presentation, more likely during the winter months, will be that of a female in her fifth to sixth decade of life who complains of diffuse symmetrical joint pain, swelling, and stiffness of peripheral joints. Patients may complain that they can no longer make a fist, especially in the early morning. The targeting of afflicted synovial joints may be symmetrical in most, but not all, cases, typically affecting small joints of the hands and feet as well as wrists. Less frequent are those presenting with slow-onset monoarticular disease. Patients not fulfilling the diagnostic classification criteria for RA may be ascribed the more appropriate diagnostic label of undifferentiated arthritis, because in a proportion of cases signs and symptoms may resolve spontaneously. Systemic disease is much less common in current clinical practice, in part through application of earlier, more intensive treatment regimens (see below). Nonetheless, the systemic nature of the disease can be manifested through a wide array of systemic, extraarticular clinical features that may occur in patients with disease at the more severe end of the spectrum. A spectrum of disease severity may also be evident from hand radiographs; examples are shown in Fig. 53.5.

Diagnosis

Classification Criteria

The American College of Rheumatology criteria for the classification of RA are a set of clinical and laboratory parameters, established largely for epidemiological purposes, that serve as a guide for the diagnosis of RA. They are relatively straightforward and easy to apply, especially to patients with established disease. However, failure of a patient with early signs and symptoms of an inflammatory arthropathy to fulfill them does not mean that the individual does not have RA. The 1987 criteria were simplified further by removing the "probable," "definite," and "classic" subclassifications. These criteria returned a sensitivity for RA of 91% to 94% and a specificity of 89% in the clinical setting. New criteria, established by a steering group comprising members of the ACR and EULAR and published in 2010, are based on a weighted score around four domains, including distribution and type of joint involvement (tender as well as swollen joints are included, scoring 0 to 5 points), serology (0 to 3) that includes RF or ACPAs and is weighted according to antibody

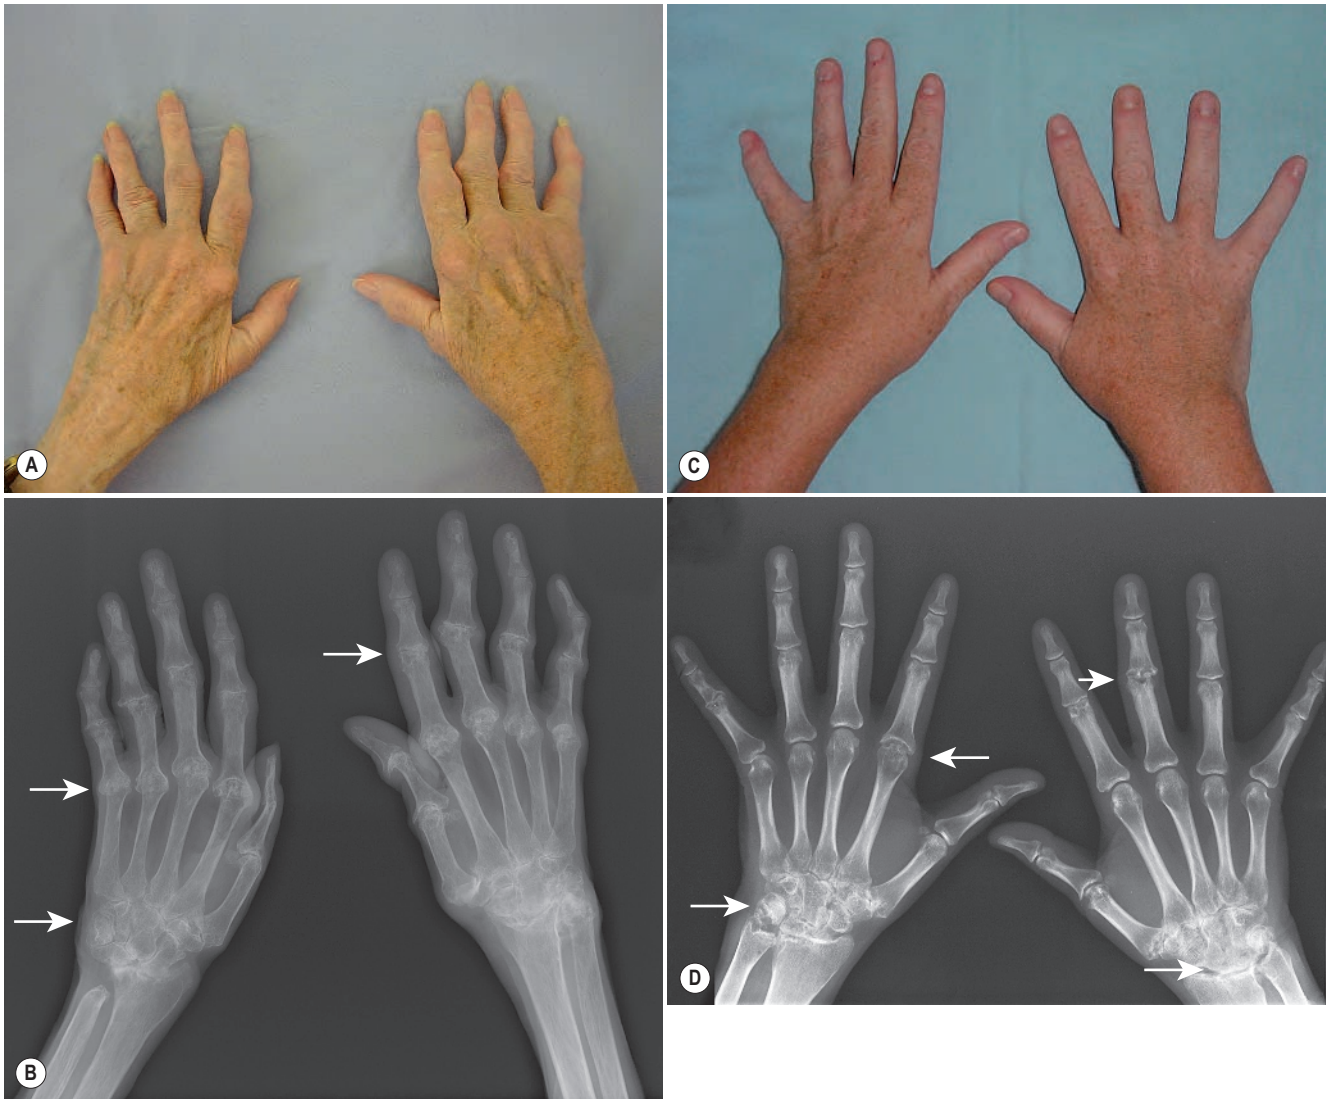

FIG. 53.5 Photomicrographs and Radiographs of the Rheumatoid Hand. Chronic, severe, and erosive RA, refractory to treatment and showing joint swelling and classical deformities (A and B), is compared with erosive disease whose progression has been attenuated by combination and biological therapy (C and D). White arrows indicate major areas of bone and cartilage destruction. (Reproduced with kind permission from the patients.)

levels, duration of synovitis (0 to 1), and acute-phase reactants erythrocyte sedimentation rate or C-reactive protein (0 to 1). A score of 6 or above is indicative of an early disease state requiring initiation of DMARDs such as methotrexate (Table 53.2), and so these criteria are thought to better reflect an intention to treat on the part of the supervising physician. Although the presence of synovitis in at least one joint is required (in the absence of an alternative diagnosis that better explains the synovitis), there remains debate as to whether subclinical synovitis of specific joints, defined by magnetic resonance imaging (MRI) or high-resolution ultrasonography (HRUS), should be included in the joint score.

Laboratory Findings

Until the late 1990s, IgM RFs, autoantibodies that recognize the Fc subunit of IgG, remained one of the few parameters of value in the clinical setting, forming the basis of the seropositive versus seronegative RA stratification and identifying those patients more likely to progress to erosive disease with or without extraarticular features. Nevertheless, RF can be detected in up to 5% of the healthy population and in 10% to 20% of the elderly population (>65 years of age); RF is found in a range of rheumatic conditions including Sjögren syndrome, SLE, and cryoglobulinemia, as well as in acute infectious and neoplastic disease entities, influencing its diagnostic utility. In general RF is not of value for monitoring responses to therapy.

The discovery of ACPAs, which can be detected very early in the disease process, has had a major impact on diagnostic practice as the assays have become more widely available.[20] They also have prognostic value in terms of radiographic progression, and titers may alter with therapy. The new-generation anti-CCPs kits have demonstrated diagnostic sensitivity of 80% and specificity of 98%. As the range of RA-associated autoantigens has expanded and the repertoire of citrullinated target autoantigens has become better defined, multiplex assays of serum autoantibodies are likely to play an increasingly important role in the diagnosis and prognosis of subsets of autoantibody-positive inflammatory arthritides.

TABLE 53.2 2010 ACR/EULAR Classification Criteria for Rheumatoid Arthritis

Domain	Weighted Score
Joint Involvement (0–5)	
1 medium to large joint	0
2–10 medium to large joints	1
1–3 small joints	2
4–10 small joints	3
>10 joints (with at least one small joint)	5
Serology (0–3)	
Neither RF- nor ACPAs-positive (≤ULN)	0
At least one test, low positive titer (>1 ≤3 × ULN)	2
At least one test, high positive titer (>3 × ULN)	3
Duration of Synovitis (0–1)	
<6 weeks	0
≥6 weeks	1
Acute-Phase Reactants (0–1)	
Neither ESR nor CRP abnormal	0
Abnormal ESR or CRP	1
TOTAL (≥6 indicates *definite* RA)	_____

ACPAs, Antibodies to citrullinated protein antigens; *ACR*, American College of Rheumatology; *CRP*, C-reactive protein; *ESR*, erythrocyte sedimentation rate; *EULAR*, European League Against Rheumatism; *RF*, rheumatoid factor; *ULN*, upper limit of normal.

CLINICAL PEARLS

Predictors of Poor Outcome in Rheumatoid Arthritis

- Chronic, unremitting disease onset, especially at advanced age
- High disease activity scores at baseline
- Female gender
- Poor functional status as determined by validated functional disability indices such as the Stanford Health Assessment Questionnaire (HAQ) and the Arthritis Impact Measurement Scale (AIMS)
- Low socioeconomic status
- Systemic and extraarticular features
- Depression and anxiety
- Comorbidity, for example, infection, cardiovascular disease, renal impairment
- Early erosive disease (in first 6–12 months; may be associated with ACPAs autoantibodies)
- Persistent acute-phase response (e.g., time-integrated CRP levels)
- Autoantibodies (RF and ACPAs) and HLA-DRB1 status (SE+)
- Significant delay in early use of DMARDs and corticosteroids

ACPAs, Antibodies to citrullinated protein antigens; *CRP*, C-reactive protein; *DMARDs*, disease-modifying antirheumatic drugs; *RF*, rheumatoid factor; SE, shared epitope.

The Preclinical Phase of Rheumatoid Arthritis

The identification of a preclinical phase of RA, that can be detected by virtue of serum autoantibodies up to 14 years before disease onset, has provided opportunities to characterize the RA prodrome in more detail. Work has centered around evaluation of acute-phase proteins and serum cytokines and chemokines, which appear to rise 1 to 2 years before onset of clinical disease; ACPAs isotype usage, N-glycan modifications, and epitope spreading; whole-blood gene expression analysis, which shows similarities to patients with established disease (including type I interferon-inducible gene signatures in a subset); imaging by MRI and ultrasonographic modalities; and, most recently, analysis of lymph node immune phenotypes, showing evidence of lymphocyte activation. The strongest predictors of progression in those at-risk subjects are joint pains without clinically detectable synovitis (arthralgia), combined with the presence of high-titer ACPAs and RF autoantibodies. Risk scores, which take into account other demographic factors, have been developed and are currently being validated. In 2016, a EULAR definition of the clinical characteristics of patients at risk of developing RA was published.[27]

Progression rates for ACPA+ arthralgia patients with subclinical synovitis detected by ultrasound examination are of the order of 20% over a median of 28 months,[28] while arthritis-free survival curves suggest that 40% to 50% of those at highest risk will develop clinically apparent synovitis in 2 to 3 joints within 24 months. Somewhat surprisingly, genetic markers, such as HLA-DRB1 SE, have not contributed dramatically to risk estimates, while emerging patterns of tenosynovitis by ultrasonography or MRI, or bone marrow oedema (or osteitis) by MRI define some of the earliest articular features of this at-risk state. Rates of progression are remarkably consistent across at-risk cohorts and are considered sufficient to justify secondary prevention intervention studies. Thus, in 2019 the effects of a single IV dose of rituximab were studied in ACPA+ arthralgia subjects. Compared to a control group (who also received IV hydrocortisone at baseline), rituximab delayed disease onset by about 12 months. As of spring 2020, there are three other clinical trials actively examining the impact of a fixed period of therapy with hydroxychloroquine, methotrexate, or abatacept versus placebo and followed up for a 2- to 3-year period. If delay or prevention is observed, even in a subset of individuals, this is likely to transform the way we approach the treatment of RA.

ON THE HORIZON

The Preclinical Phase of Rheumatoid Arthritis

- High-risk individuals include those with inflammatory joint pain (arthralgia) and serum RA–associated autoantibodies. From 40% to 50% of those with high-titer ACPAs (with or without rheumatoid factor) may develop clinical synovitis within 24 months.
- Targeting these high-risk individuals with preventative strategies provides the best chance of achieving cure. Trials of rituximab, abatacept, or hydroxychloroquine are ongoing.
- In-depth molecular and cellular studies for characterizing the preclinical phase of disease will be critical to the success of this endeavor.
- Models for progression to RA have identified the following phases:
  - I. Genetic risk
  - II. Genetic risk with autoimmunity (e.g., ACPAs, rheumatoid factor)
  - III. Genetic risk with autoimmunity and arthralgia (but absence of clinically apparent synovitis)
  - IV. Undifferentiated arthritis (clinically apparent synovitis, not fulfilling RA classification criteria)
  - V. Early RA (fulfilling disease criteria; need for DMARDs)
- Stratification of risk, including genetic, serological, and demographic factors, will permit the identification of subjects most suitable for intervention studies.
- Studying the impact of lifestyle modifications, for example, diet, stopping smoking, would be of great interest.
- Reestablishing immune homeostasis and/or induction of immune tolerance may provide the best chance of achieving cure in subjects during the preclinical phase of disease. Early-phase studies of peptide immunotherapy indicate that this approach is well tolerated.
- Establishing robust assays for signatures of immune tolerance (e.g., immune phenotyping by flow cytometry, extended autoantibody serotyping, multiplex assays for detection of inflammatory mediators in serum, whole-blood transcriptomic profiles) that reflect a healthy immune system will greatly facilitate these endeavors.

ACPAs, Antibodies to citrullinated protein antigens; *DMARDs*, disease-modifying antirheumatic drugs; *RA*, rheumatoid arthritis.

TREATMENT

Disease-Modifying Antirheumatic Drugs

THERAPEUTIC PRINCIPLES

Treatment Paradigms in Rheumatoid Arthritis

- Education and counseling through early involvement of a multidisciplinary team, including specialist nurse and other health-care professionals; appropriate balance of rest and exercise during disease flares
- Adequate nutrition (especially important with severe, active disease)
- Comprehensive assessment of disease activity, especially during early phase of disease to achieve rapid disease control
- Complete suppression of inflammation early in the disease, with tight control through regular and frequent reassessments focused around disease activity scores
- Yearly imaging assessments to monitor radiographic progression, for example, X-rays or high-resolution ultrasonography of hands and feet
- Early use of DMARD/SAARDs
- Early use of corticosteroids, including use of intraarticular joint injections to suppress inflammation, and use of step-up combination therapy in severe disease
- Appropriate use of biologicals, for example, early use of anticytokine, T- or B-cell–targeted therapies in severe disease
- Early relief of pain with judicious use of NSAID or COX2 inhibitors according to safety/risk profile
- Monitoring for drug toxicity
- Effective contraception, where appropriate
- Bone protection
- Monitoring for risk factors of key comorbidities, including cardiovascular disease
- Prevention of infection through vaccination (preferably before instituting immunosuppressive agents), for example, against influenza, pneumococcus, and herpes zoster

COX, Cyclooxygenase; *DMARD*, disease-modifying antirheumatic drugs; *NSAID*, nonsteroidal anti-inflammatory drugs; *SAARD*, slow-acting antirheumatic drugs.

Over the past two decades there has been a dramatic paradigm shift in the therapy of RA from control of symptoms to the control of the disease process and aggressive suppression of inflammation. This shift has come about through a growing appreciation of the relationship between joint inflammation and joint destruction, as well as the development of imaging technology for detecting the very earliest changes in joint structures. The impact of this paradigm shift in therapeutic terms is striking. Traditional "go-low, go-slow" regimens of the 1970s and 1980s included the initiation of nonsteroidal anti-inflammatory drugs (NSAIDs), followed by implementation of DMARDs only after destructive disease became evident. Depending on the clinical response, sequential monotherapy was the norm. Although this strategy may still be appropriate for patients with mild disease, current practice now dictates aggressive combination therapy (two or more conventional DMARDs) from the outset for patients with poor prognostic factors, with preference for the faster-acting DMARDs such as methotrexate, leflunomide, and sulfasalazine (onset 3 to 6 weeks) over slower-acting agents such as hydroxychloroquine, gold, and D-penicillamine (onset 3 to 6 months), but with the addition of oral or parenteral prednisolone. More recent data suggest that the specific choice of therapy may be less important than the strategy. For example, the pioneering TICORA and BeST studies both indicate that intensive treatment when combined with intensive control most convincingly influences outcome measures, including clinical response, retention, functional status, and radiographic progression. The benefits of tight control have been substantiated in many subsequent clinical trials, as well as in "real-life" clinical practice.[29]

Anti-Cytokine Therapy

The introduction of targeted therapy to the clinic using biological agents (e.g., chimeric or fully humanized antibodies to ligands or receptors, soluble receptor fusion proteins, or recombinant receptor antagonists) has transformed the treatment of RA. The prototype biologic, developed in the 1990s, was TNF blockade.[30] The rationale for inhibiting TNF bioactivity is based upon its pleiotropic effects on cell activation, cellular adhesion and migration, induction of cytokine and inflammatory gene mRNA and protein, neoangiogenesis, and the regulation of cartilage catabolic factors such as IL-1 and matrix metalloproteinases (see Fig. 53.3). TNF and other inflammatory cytokines such as IL-1, IL-6, IL-15, IL-17, and GM-CSF are expressed constitutively in inflamed synovial tissue at mRNA and protein level. In many cases the expression of their high-affinity cognate receptors is also upregulated and the functional activity of the corresponding naturally occurring inhibitors (e.g., soluble TNF-R or IL-1Ra) is reduced further, promoting persistence of the inflammatory response (although levels of protein may be increased, reflecting an attempt at restoring homeostasis).

Chimeric anti-TNF monoclonal antibodies (infliximab) were first used to treat RA in open-label clinical trials in 1992.[30] Humanized antibodies (adalimumab) and the soluble p75 TNF-R IgG fusion protein (etanercept) were tested soon after with comparable therapeutic effects; golimumab and a construct comprising a PEGylated anti-TNF antibody Fab fragment (certolizumab) are also licensed for use in patients with RA, as are a growing number of "biosimilar" TNF inhibitors. TNF-α blockade leads to dramatic and rapid reductions in symptoms (pain, stiffness, and fatigue) and signs (joint pain and swelling) of arthritis in a dose-dependent fashion, and in a significant proportion of patients (~60% to 70%) who have failed conventional DMARDs.[30] As a class, and when used in combination with methotrexate, the majority are superior to either drug alone.

The clinical benefit of TNF blockade has prompted extensive mechanism of action studies.[30] Anti-TNF reduces the acute-phase response, including IL-6 serum levels. Leukocyte trafficking is inhibited, as demonstrated through an early (within hours) and dramatic rise in lymphocyte counts through demargination, a more prolonged and sustained exclusion of leukocytes based on reductions in cellularity of synovial tissue biopsies after treatment and suppression of markers of angiogenesis, including VEGF; TNF blockade promotes lymphangiogenesis and may facilitate cell egress from inflamed synovium. TNF blockade has also been shown to downregulate markers of cartilage and bone destruction, including the collagenases MMP1 and 3, and to reduce the ratio of RANKL and OPG in serum, effects that might explain in part the joint-preserving effects of anti-TNF *in vivo*.

The IL-1 receptor antagonist (IL-1Ra) is the only IL-1 inhibitor currently licensed for use in RA. It has disease-suppressing effects in animal models of arthritis, with potent joint protection, but has proven less effective than anti-TNF in patients with RA. Nevertheless, it has been used effectively to treat patients who have failed TNF blockade, slowing radiographic progression, and may be efficacious in a subset of individuals with more systemic autoinflammatory

syndromes. Anti-IL-6R blockade (tocilizumab) is licensed for use in patients with established RA. Evidence suggests that in early disease, tocilizumab as monotherapy is as effective in suppressing signs and symptoms of RA as when it is combined with methotrexate. These effects are mediated through blocking IL-6 actions on the immune response, the acute-phase response, osteoclastogenesis, B-cell activation and immunoglobulin production, angiogenesis, and cell adhesion (reviewed in Kishimoto).[31] Clinical responses are comparable to those observed with TNF blockade, and a range of IL-6 inhibiting drugs are now licensed for use. Unlike in psoriasis, the effect of inhibiting IL-17 in RA (with humanized monoclonal antibodies ixekizumab or secukinumab that block IL-17A) has been more modest, although there may exist a subset of RA patients in whom IL-17-driven inflammatory responses dominate. A role for blocking GM-CSF is emerging.

Finally, the impact of using small molecule inhibitors of cytokine signals, transduced through receptors that utilize members of the Janus kinase (JAK) family of tyrosine kinases,[32] has been evaluated in some detail. These are interesting, immunologically important kinases, because gain-of-function mutants are associated with leukemia and lymphoma, whereas loss-of-function is associated with primary immunodeficiency. Jakinibs, including tofacitinib, baricitinib, and upadacitinib, have been studied in phase III clinical trials of RA patients. Tofacitinib has high affinity for JAK3, but is also able to partially inhibit JAK1 and, to a lesser extent, JAK2; baricitinib blocks JAK1 and JAK2 to a similar extent, with some Tyk2 targeting activity, while upadacitinib has more JAK1 selectivity. These agents are well tolerated, with acceptable safety profiles and now provide physicians with an orally available agent with efficacy comparable to biologic agents. This is likely due to the wide range of inflammatory pathways that are targeted, including common gamma chain cytokines IL-2, IL-7, IL-15, and IL-21, type I and type II interferons, and IL-6 family cytokines.

Anti-T-Cell Therapy

The contribution of costimulatory signals ("signal 2") transduced through CD28 to priming and activation of naïve T cells and amplification of cytokine gene expression and proliferative responses has provided a rationale for testing costimulatory blockade in patients. This has been achieved using a nondepleting humanized IgG1-CTLA-4 fusion protein that prevents CD80 and CD86 (expressed on antigen-presenting cells) from engaging CD28 (but also CTLA-4) expressed on T cells. Initial studies confirmed that the agent was safe and well tolerated.[33] As well as suppressing disease activity, CTLA-4-Ig (licensed as abatacept as intravenous and subcutaneous formulations) inhibits radiographic progression and structural damage and it is also effective in treating those patients who have had inadequate responses to TNF blockade as well as to methotrexate. Head-to-head studies indicate that the kinetics of response are remarkably similar to those of anti-TNF when compared as monotherapy, indicating that a significant number of costimulation-dependent T cells actively participate in the ongoing inflammatory response. Clinical improvement may continue beyond 12 months. Recent data suggest that inhibition of CD28 signals reduce the number of T_{FH}. Abatacept targets one of the earliest stages of adaptive immunity, and so offers a biologically plausible pathway to target in subjects at high risk of progressing to RA.

Anti-B-Cell Therapy

Rituximab is a humanized monoclonal antibody that recognizes human CD20, a 33- to 37-kDa membrane-associated phosphoprotein expressed on pre-B, immature, and mature B cells but not on plasma cells. It was initially developed, and then licensed, for the treatment of non-Hodgkin lymphoma. While CD20 ligation promotes B-cell activation, differentiation, and cell cycle progression, the function of CD20 is still poorly understood. The therapeutic effects of anti-CD20 are related to B-cell depletion, which can vary between patients due to antibody-dependent cell cytotoxicity, complement-mediated cell lysis, and/or triggering of intracellular pathways for apoptotic cell death.[34] The effects on serum immunoglobulin levels are modest with levels remaining in the normal range, unless patients undergo repeated cycles of B-cell depletion.

A pivotal placebo-controlled trial of rituximab therapy randomized 161 patients with RF-positive RA to compare the efficacy and safety of methotrexate alone (standard therapy) versus methotrexate plus rituximab (1000 mg on days 1 and 15), rituximab alone, or rituximab plus cyclophosphamide.[34] Up to 43% of patients receiving the combination of rituximab and methotrexate achieved 50% improvement in clinical and laboratory parameters after 24 weeks (ACR50), and this was at least as good as the rituximab/cyclophosphamide combination (41% achieving ACR50) and superior to methotrexate (13%) or rituximab alone (33%). Follow up studies indicate that B-cell repopulation occurs at a mean of 8 months after treatment, comprising immature $IgD^+CD38^+CD27^-CD5^+$ B cells, and is associated with increased serum B cell–activating factor (BAFF) levels. Early relapse is associated with reconstitution of the $CD27^+$ memory B-cell compartment.

Future Prospects for Therapy

There remain unmet needs in the treatment of RA. Principal among these are the fact that until relatively recently, treatment has been considered lifelong for the majority of patients, imposing greater risk of toxicity and, as the immune system senesces, increased risk of infection or lymphoproliferative disease. There is little doubt that early treatment with tight control offers the best outcomes, and evaluation of synthetic and biological DMARDs in at-risk subjects to establish whether they can delay or even prevent development of clinically apparent disease could be transformative. A better appreciation of the profile of RA-specific autoantigens has prompted early-phase studies to establish the safety and tolerability of peptide immunotherapy delivered by autologous DCs. From an immunological perspective, there remains a pressing need to develop immunological tools or immune biomarkers that can redefine disease subsets and measure effector and regulatory cell subsets; progress has been made with synovial pathotypes. While such tools may provide better insights into disease pathogenesis, they can also be adapted to monitor the impact of therapeutic intervention, whether this turns out to be cell-based therapy or the application of novel immune modulators. Similar approaches should be used to identify those $ACPA^+$ arthralgia patients who have a genetic predisposition to RA and are at highest risk of developing the disease.

Juvenile Idiopathic Arthritis

Randy Q. Cron, Peter Weiser, and Timothy Beukelman

Juvenile idiopathic arthritis (JIA) is a collection of chronic inflammatory arthropathies of childhood. By definition, JIA occurs prior to the 16th birthday, has no known causes, and has evident chronic, more than 6 weeks' duration of, joint inflammation.[1]

The currently utilized 2004 revision of the International League of Associations for Rheumatology (ILAR) nomenclature and subcategorization of JIA unifies the American (juvenile rheumatoid arthritis [JRA]) and European (juvenile chronic arthritis [JCA]) classification schemes.[1] It addresses arthritis features different from those in adults and removes the word "rheumatoid" to distinguish it from adult rheumatoid arthritis (RA) (Chapter 53). The ILAR classification of JIA also includes the human leukocyte antigen HLA-B27–associated spondyloarthropathies (Chapter 58), which occur frequently during childhood (Table 54.1). There are still ongoing efforts to further re-classify JIA subcategories based on genetic research suggestive of some of the subgroups being actually identical to adult forms of chronic arthritis rather than existing as a separate childhood entity (e.g., rheumatoid factor [RF] positive polyarticular JIA and RA).[2]

Because JIA is a diagnosis of exclusion, other entities with chronic arthritis need to be ruled out first. Sarcoidosis (Chapter 72), Sjögren syndrome (SS) (Chapter 55), systemic lupus erythematosus (SLE) (Chapter 52), mixed connective tissue disease (MCTD) (Chapter 56), Lyme disease (Chapter 27), dermatomyositis (Chapter 57), and a variety of vasculitides (Chapters 59 and 60) can present with joint inflammation. While JIA is idiopathic by definition, chronic arthritis as part of inflammatory bowel disease (IBD) (Chapter 75) or associated with psoriasis (Chapter 64) is included under the JIA umbrella. When considering the seven categories of JIA together, the estimated prevalence of JIA is roughly 1 in 1000 children, with rates varying in different regions of the world, likely because of genetic risk factors and/or environmental triggers. Moreover, the relative rates of JIA categories vary in different regions of the world (e.g., oligoarticular JIA is common in Scandinavia, and enthesitis-related JIA is more typical in Latin America with the caveat of some variability in classification).

ETIOLOGY AND PATHOGENESIS

Genetic Contribution

Because JIA is an eclectic group of unique categories based largely on empirical clinical phenotypes and is far less common than RA, understanding its genetic causes is extremely difficult. Clinical examination is neither sensitive nor specific for diagnosing joint inflammation, and certain joints like in the case of the temporomandibular joint (TMJ) require imaging to screen for involvement.[3] Thus, the arbitrary distinction of subgroups based on number of involved joints can lead to misclassification, which would subsequently influence data analysis. Distinctions based on the types and location of involved joints and data from biosamples may prove useful in identifying more homogeneous subtypes and lead to better genetic understanding of etiology.[4]

Polygenic Disorder

In general, JIA is a polygenic autoimmune condition with ≥20 potential genes involved. An exception is systemic JIA (sJIA), which resembles both an autoimmune and an autoinflammatory disorder.[5] Unlike autoimmunity, which is believed to be the result of an imperfect adaptive immune system, autoinflammatory conditions are thought to result from genetic perturbations in the innate immune response, for example, as in the autoinflammatory recurrent fever syndromes.[5] Whether sJIA is the result of a single or multiple gene defects in the same immune pathway is currently unknown. However, a relatively common complication of sJIA is the life-threatening condition of macrophage activation syndrome (MAS), which resembles familial hemophagocytic lymphohistiocytosis (fHLH) (Fig. 54.1). MAS may be present in ≈50% of children with sJIA in either an overt or occult/subclinical fashion.[6] Recently, genetic polymorphisms and heterozygous (single copy) mutations in genes associated with fHLH when present as homozygous defects have been identified in children with sJIA and overt MAS.[6] Protein products of these genes, including perforin 1 and MUNC 13-4, are critical in the pathway mediating cytolysis by CD8 T cells and natural killer (NK) cells (Chapter 12). This cytolysis is crucial to the ability to shut down an immune response following control of infection. Defects in this pathway can result in a hyperinflammatory state (cytokine storm), leading to pancytopenia, coagulopathy, and multisystem organ failure.[6] As sJIA is the most common condition resulting in MAS during childhood, it might indeed be genetically related to fHLH but possibly associated with heterozygous, rather than homozygous, mutations in genes critical for cytolysis.[6]

Human Leukocyte Antigen Associations

For all other JIA categories, polygenic influences—including the major histocompatibility complex (MHC)—contribute to disease pathology. The MHC is densely packed (greater than 200 genes) with immune-associated genes (Chapter 5). It is also the most polymorphic region of the human genome and gives rise to MHC class I and class II genes, complement proteins, tumor

TABLE 54.1 Clinical and Laboratory Features of the Juvenile Idiopathic Arthritis Categories

	JUVENILE IDIOPATHIC ARTHRITIS					
Classifications	**Former Juvenile Rheumatoid Arthritis**				**Spondyloarthropathy**	
Juvenile idiopathic arthritis categories/feature	Systemic	RF⁻ polyarticular	RF⁺ polyarticular	Oligoarticular (persistent and extended)	Psoriatic (early and late onset)	Enthesitis-related arthritis (ERA) (including ankylosing spondylitis (AS) and inflammatory bowel disease [IBD])
Human leukocyte antigen (HLA)	DRB1*11	DRB1*08	DRB1*04	A2	DRB1*01	B27
Gender	Equal	F ≫ M	F ≫ M	F ≫ M	F > M	M ≫ F
Age at onset	Peak 2 years	Dual peaks	Teenage	1–3 years	Dual peaks	Teenage
Antinuclear antibody (ANA)	Rare	Yes	Yes	Yes	Yes	Rare
Uveitis	Rare	Yes	Rare	Yes	Yes	Nonsilent
Temporomandibular joint (TMJ)	Yes	Yes	Yes	Yes	Yes	Yes
Enthesitis	No	No	No	No	Older age	Yes
Arthritis	Erosive	Symmetric	Erosive	Mixed	Dactylitis	Axial

necrosis factor (TNF), and others. The critical role of MHC proteins in preventing autoimmunity by shaping the T-cell repertoire (Chapter 9) likely explains why the MHC is the most consistently and strongly associated genetic locus for most JIA categories. Recently, MHC class II associations have been identified in children with sJIA, providing evidence for an autoimmune component in addition to the autoinflammatory one, as mentioned above.[7]

By comparison, enthesitis-related arthritis (ERA) and psoriatic JIA share one of the strongest known MHC associations, HLA-B27, for any described autoimmune disorder. HLA-B27 is present in 70% to 90% of Caucasian children with ERA, which follows an autosomal dominant pattern and is the only JIA category likely to have similarly afflicted first-degree relatives. The pathophysiological explanation for the HLA-B27 association remains unknown, but hypotheses vary from molecular mimicry of pathogens presented by HLA-B27 (Chapter 51) to the unfolded protein response.[8]

The remaining JIA categories have all been linked to various other MHC proteins to lesser degrees (see Table 54.1).

Nonhuman Leukocyte Antigen Associations

Genes outside of the MHC have also been linked to developing JIA. Genetic approaches have highlighted the importance of genetic differences in the development of JIA, but at most, 11% of the contribution can be linked to the MHC.[4] Recent developments in high-throughput genetic sequencing, combined with the identification of densely present restriction fragment length polymorphisms (RFLPs) throughout the human genome, have allowed for powerful new genetic approaches. These include genome-wide association studies (GWAS) designed to identify genes associated with a variety of disorders, including autoimmune diseases such as JIA.[9] To date, several genes have been reported to be associated with JIA.[4]

Strong evidence that genetic factors contribute to JIA susceptibility include twin and family studies. Data from a JIA national registry revealed that monozygotic twin pairs have a higher-than-expected proportion of twins with JIA. Moreover, siblings of children with JIA have as high as a 30-fold increased risk of JIA compared with the general population. Interestingly, siblings with JIA typically share the same JIA category, age of onset, and disease course.[4] Polymorphisms in MHC class II genes have been estimated to account for less than 20% of the recurrence risk of JIA in siblings and thus support the concept that JIA is a complex genetic trait. JIA likely shares general or common autoimmunity gene risk factors with many autoimmune disorders but may also be influenced by specific JIA risk-associated genes.[9]

Using linkage and association studies, researchers have identified a variety of potentially JIA-associated genes. However, outside of the human leukocyte antigen (HLA) genes, only a small percentage of these genes have been independently confirmed by other investigators. A few of these genes/gene products include *PTPN22* (a phosphatase involved in inhibition of T-cell activation), *WISP3* (a signaling protein), interleukin-1α (a proinflammatory cytokine), tumor necrosis factor (TNF; another proinflammatory cytokine), macrophage migratory inhibitory factor (MIF), and *SLC11A1* (a resistance factor to intracellular pathogens in macrophages).[4] Thus, gene products linked to both innate and adaptive immune responses likely contribute

to JIA disease susceptibility. Ongoing GWAS may help validate the importance of these genes and may identify other candidate gene risk factors for JIA in the future. Recently, epigenetic (modifications to DNA nucleotides rather than changes in the DNA sequence) risk factors that confer susceptibility to JIA are beginning to be explored.[10] Indeed, chromatin architecture itself is being analyzed to better understand the mechanisms of gene expression in JIA.[11]

ENVIRONMENTAL FACTORS

In addition to genetic factors, there are likely a variety of environmental triggers for developing JIA in genetically susceptible hosts. Numerous infectious agents (e.g., parvovirus, rubella virus) have been explored as risk factors for development of JIA; however, replication of these associations has been difficult. In addition, some scientists have suggested that heat shock proteins, resulting from cells undergoing environmental stress, may contribute to the development of JIA.[12] There is also a clear link between gut pathogens and potentially commensal organisms (gut microbiome) and the development of HLA-B27–associated spondyloarthropathies.[13] The role of the gut microbiome is also implicated in the pathogenesis of other subcategories of JIA.[14] Last, prior to the identification of *Borrelia* as a cause of childhood arthritis, Lyme disease–associated arthritis was difficult to distinguish from oligoarticular JIA.[15] Perhaps because of the variety of potential environmental triggers for JIA, combined with the number of different JIA categories, no single environmental trigger has been conclusively identified as contributing to the development of JIA.

IMMUNE ABNORMALITIES

Autoantibodies

As JIA is considered an autoimmune disease, except for aspects of sJIA as discussed earlier, there have been a variety of explorations into the role of various components of the immune system involved in JIA pathogenesis. The importance of the immune system in JIA pathology is highlighted by the increased incidence of childhood chronic arthritis among children with various immunodeficiencies. For example, children with immunoglobulin A (IgA) deficiency are at increased risk of developing chronic arthritis. In contrast, the presence of specific autoantibodies is associated with various forms of JIA. ANAs are present in up to 40% of patients with JIA, particularly those with oligoarticular JIA, and are associated with silent uveitis (Chapter 74).[16] Similarly, antibodies to the nuclear oncoprotein DEK have been associated with uveitis as well as joint inflammation in children with JIA. IgM RF is present in a smaller subset of children with polyarticular JIA and is associated with a more aggressive/erosive form of arthritis as in adults with rheumatoid factor–positive (RF^+) RA (Chapter 53).[1] More recently, identification of anti–cyclic citrullinated peptide (CCP) antibodies have been found in a partially overlapping subset of children with RF^+ poly-JIA.[17] Thus, a variety of autoantibodies are associated with JIA.

T-Helper Cells

T lymphocytes are also thought to play a major role in the development of JIA, as evidenced by their relative predominance among mononuclear cells in synovial fluid of chronically inflamed joints in children with JIA. CD4 T-helper (Th) cells have been categorized into a variety of cytokine-producing subsets (Chapter 11). CD4 Th1 cells, characterized by the production of interferon-γ (IFN-γ), have been identified in chronically inflamed joints in children with JIA, whereas IL-4–producing Th2 CD4 T cells are more commonly involved in the joints in oligoarticular JIA (generally less aggressive arthritis) than in polyarticular JIA. More recently, two additional CD4 Th subsets, regulatory T cells (Tregs) and Th17 cells, are being examined as potential players in JIA pathology.

$CD4^+$, $CD25^{high}$ Tregs are characterized by the transcription factor FoxP3 and by the ability to suppress immune activation (Chapter 13).[18] The ability of Tregs to suppress other T cells likely occurs by both cell-contact dependent (through the surface protein cytotoxic T-lymphocyte antigen-4 [CTLA-4]) and independent (via suppressive cytokines) mechanisms.[18] Tregs secrete the antiinflammatory cytokines IL-10 and transforming growth factor-β (TGF-β). Th17 cells, characterized by the transcription factor retinoid orphan receptor (ROR)γT, produce the proinflammatory cytokine IL-17.[19] IL-17 is thought to contribute to a variety of autoimmune disorders, including JIA. The balance between these two juxtaposed Th subsets may determine whether autoimmunity develops (Th17-dominant) or a state of immune tolerance to self (Chapter 10) persists (Treg-dominant). Indeed, recent studies have identified a predominance of Th17 cells and associated proinflammatory cytokines in the inflamed joints of children with JIA.[19] Thus, a balance of proinflammatory cytokines and suppressive cytokines may dictate the expression of autoimmunity in the form of JIA.

Cytokines

Cytokines (Chapter 14) and, particularly, their inhibition have taken a prominent status in the pathology and treatment of chronic arthritis, including JIA. The bench-to-bedside translation of anti-TNF therapy to the treatment of chronic arthritis has revolutionized the care of adults with chronic arthritis as well as children with JIA. Inhibition of this proinflammatory cytokine in the circulation (via specific monoclonal antibodies [mAb] or receptor fusion proteins) rapidly and effectively treats most forms of JIA.[1] The one exception is sJIA, which may or may not respond well to anti-TNF treatment. However, other proinflammatory cytokines, including IL-1, -6, and -18, are thought to be central to sJIA pathogenesis.[1] Indeed, serum from sJIA patients was shown to induce transcription of a variety of innate immunity genes, including IL-1, in normal peripheral blood mononuclear cells. Fortunately, novel therapies that target either IL-1 or IL-6 have proven highly successful in treating even the most severe forms of sJIA, including associated MAS.[1,6]

Macrophage Activation Syndrome

The sometimes-fatal complication MAS is most commonly seen in sJIA among rheumatic diseases. Clinically, MAS resembles many features of a sJIA disease flare-up, and it has been suggested that MAS may be inherent to sJIA disease pathology in up to half of all patients with sJIA.[6] MAS is likely part of the spectrum of HLH disorders. Primary HLH, or fHLH, typically presents in infancy following infection and results from homozygous mutations in genes involved in the cytolytic pathway employed by NK cells and CD8 T cells. Recent evidence suggests that patients with sJIA who have MAS have heterozygous defects in these same cytolytic pathway genes.[20] MAS can be triggered by a variety of infectious organisms, particularly

KEY CONCEPTS

Macrophage Activation Syndrome

- Macrophage activation syndrome (MAS) is present in up to 50% of children with systemic juvenile idiopathic arthritis (sJIA) in a subclinical (hemophagocytosis) or overt (systemic inflammatory response, 10%) form.
- MAS manifests as fever, liver dysfunction, pancytopenia, central nervous system disturbance, hyperferritinemia, hemophagocytosis, and coagulopathy.
- MAS resembles hemophagocytic lymphohistiocytosis (HLH) and is thought to result from defects in perforin-mediated cytolysis by CD8 T cells and natural killer (NK) cells.
- Patients with sJIA and MAS have been noted to have NK-cell defects and mutations in perforin-1 and MUNC13-4 cytolytic pathway genes.
- MAS can be fatal if not recognized and treated early. Mainstays of therapy include high-dose corticosteroids and cyclosporine.
- Recently, blocking interleukin-1 (IL-1) signaling with biological therapies has been found to be quickly and dramatically beneficial in treating MAS associated with sJIA.

members of the herpes virus family, but the precise role of infectious triggers of MAS in children with sJIA remains unknown. Nevertheless, the inability to effectively shut down an immune response via cytolytic mechanisms results in a "storm" of proinflammatory cytokines, such as IL-1, IL-6, IL-18, TNF, and IFN-γ. Mouse models of MAS/HLH have suggested that IFN-γ is the pivotal cytokine in MAS. In practical terms, inhibition of IL-1, and potentially IL-6, has proven rather effective at treating MAS in children with sJIA.[1,6,20] It is quite remarkable how dampening of one critical cytokine can help restore the immune imbalance of multiple proinflammatory cytokines and rapidly reverse the life-threatening clinical scenario of MAS.

JUVENILE IDIOPATHIC ARTHRITIS CLINICAL SUBTYPES

There is heterogeneity of clinical presentation and progression of the various subtypes, which is attempted to be addressed by the current ILAR classification schema (see Table 54.1), but reclassification efforts are ongoing. An elegant report by Eng et al.[21] has suggested five distinct groups of patients categorized based on clinical disease trajectories, all with subsets different from those defined by the ILAR classification. Nevertheless, the current ILAR classification is the most widely accepted for the time being.

Oligoarticular Juvenile Idiopathic Arthritis

Oligoarticular JIA is likely the most common category of JIA with involvement of one to four joints, most commonly knees, ankles, the TMJ, and fingers.[1] The majority of these children are girls of preschool-age, blonde-haired, blue-eyed with morning stiffness and swollen joints, which can be painless in 25% of cases. Thus, by the time abnormalities are noted by caregivers, the child may already have developed contractures, bony hypertrophy, and limb length discrepancy as chronic articular inflammation stimulates the osteoblasts of the nearby growth plates, resulting in temporary acceleration of growth. Decreased muscle group recruitment around the affected joint leads to muscle wasting, and can affect joint function, gait, and mobility for years to come. The oligoarticular JIA category has the highest percentage of positive ANA blood tests and is associated with potentially damaging silent/painless uveitis.[16] While involvement of a single joint is common in JIA, careful differential diagnosis consideration is necessary. Oligoarticular JIA rarely presents with isolated hip involvement on the contrary to toxic synovitis, septic hip, and malignancies. Monoarticular involvement in middle and high school aged children is more commonly associated with reactive arthritis, IBD-related arthritis, and Lyme disease. The ILAR classification has a separate subcategory for children with oligoarticular JIA who develop additional joint involvement after the first 6 months based on clinical presentation, extended oligoarticular JIA,[1] which might be a variant of the RF-negative polyarticular category. Wrist involvement is considered to be a bad prognostic factor, as is the extended oligoarticular phenotype and elevated laboratory indicators of inflammation.

Polyarticular Juvenile Idiopathic Arthritis

Inflammation of greater than four joints appear in two main JIA categories (see Table 54.1) based on the presence of serum RF, an IgM antibody against the IgG Fc receptor. RF-positive serum on two occasions at least 3 months apart is required for a child to be diagnosed with *RF⁺ polyarticular JIA*. Joint involvement is typically bilateral, symmetrical, involving the small joints of hands and feet.[1] However, large joints and cervical involvement are often present. RF⁺ polyarticular JIA usually presents in adolescent girls and is considered a form of early-onset adult RA.[1] It is a relatively infrequent category with less than 5% of all JIA patients. Antibodies to CCP are much less common in children than in adults with RA,[17] but just like RF⁺ patients, they also herald a more destructive/erosive disease calling for early aggressive therapy. Similar to its adult counterpart, this category comes with arthritis of the wrists and fingers that can lead to ulnar deviation and boutonniere and swan neck deformities. Destructive TMJ involvement is also common.[3] Extraarticular manifestations, such as low-grade fever and occasionally rheumatoid nodules over bony surfaces seen in adults with RA, are less common in children.

RF-negative polyarticular JIA usually presents as symmetrical involvement of the large and medium-sized joints, mostly knees, wrists, and ankles but also the TMJ.[3] As in psoriatic JIA, small joint involvement tends to occur later in life, and there is a bimodal distribution in preschool children and early adolescent patients.[1] There is more frequent silent uveitis in the younger age group, and this form of JIA is often difficult to distinguish from ERA in the latter.

Psoriatic Arthritis

Arthritis with concurrent psoriasis, or arthritis with two of the three criteria—dactylitis (tenosynovitis causing swelling of the digit beyond the joint capsule), psoriatic nail changes, or family history of a first-degree relative with psoriasis—comprises a separate category of JIA. As mentioned previously, there seems to be a bimodal distribution of age at onset for psoriatic JIA.[22] Preschool-aged children have mostly small joint involvement and positive ANA but may also have dactylitis, whereas middle school–aged patients have JIA that resembles ERA with enthesitis, sacroiliac joint involvement (albeit milder), and even spondylitis.[8] In general, initially there is asymmetrical involvement of the joints, and if untreated, it will progress to polyarticular joint disease. Since up to 50% of the patients develop psoriatic skin findings several years after arthritis presentation, it is often difficult to classify this condition as such at onset. Psoriatic JIA

seems to be more resistant to therapy, and approximately 40% of children have active disease into adulthood while on medications. Insidious onset of anterior uveitis is more typical for the younger age group, whereas the older—those with enthesitis—have JIA that resembles the adult type of psoriatic arthritis with an associated HLA-B27 genotype and chronic symptomatic, often painful, eye disease (see Table 54.1).

Enthesitis-Related Arthritis

In general, ERA affects boys more than girls[1] and may sometimes be a manifestation of IBD. Inflammation can present in both joints and entheses, attachments of the tendons, ligaments, or joint capsules to bone. Individual entheses can be tender even in healthy children, but three or more of them involved at the same time points to pathology (see Table 54.1). ERA often occurs in boys 8 years of age and older.[1,8,23] They report stiffness after inactivity and more pain, including back pain, than limitations in comparison to other JIA categories. Most of the time they maintain their activities, with worsening pain reported towards the end of the day. Many consider ERA a potential prelude to ankylosing spondylitis (Chapter 58), an HLA-B27–associated inflammatory condition resulting in irreversible fusion of the vertebrae and of the sacroiliac joints. Therapeutic efforts targeting TNF and IL-17 pathways are focusing on treatment of early stages of inflammation, thus preventing the calcifying hypercorrection of inflamed vertebral edges leading to the above-mentioned fusion using TNF blockade and maintaining mobility.[23] Outcomes are still under investigation but appear promising with early aggressive treatment.

Systemic Juvenile Idiopathic Arthritis

Approximately 10% of children with JIA belong to the sJIA category, also known previously as *Still disease*. The peak incidence of sJIA is ages 1 to 5 years, but it can present in adulthood as adult-onset Still disease (AOSD). The ILAR classification criteria require fever for 2 weeks, with at least three episodes of daily spiking (quotidian) fever, with at least one of the following features: fleeting salmon-colored macular rash, arthritis, lymphadenopathy, and hepatosplenomegaly.[1] When febrile, children appear rather ill, and the rash is more prominent and can be evoked by mechanical contact (Koebner phenomenon). Typically, the fever subsides, and children are visibly better in the morning hours. High levels of indicators of systemic inflammation are typical at onset and may subside later in the disease. Arthritis is often very aggressive and frequently involves wrists, ankles, and knees but also causes ankylosis of the hip and neck, leading to long-term damage and gait abnormalities. Occasionally, joint involvement begins months after fever onset, making timely sJIA diagnosis more difficult. The initial presentation mimics those of infections and malignancies, which have to be excluded. Fifty percent of children may develop (only 10% clinically overt) MAS, described previously.[6]

Laboratory Evaluation

Diagnosis of JIA is established by history and physical exam, and laboratory indicators have only a supportive role. The complete blood count (CBC) is largely normal in oligoarticular involvement, as is the erythrocyte sedimentation rate (ESR). White blood cells (WBCs) are highly elevated in sJIA but are mostly within normal limits in other groups. Anemia of chronic disease presents as normocytic and normochromic and is often found in polyarticular involvement. In those cases, ESR can also be elevated. Intermittent joint effusion of a single large joint with an elevated ESR necessitates further evaluation, and IBD should be considered, especially if there is a low serum albumin level and/or growth delay. Of note, elevated ESR on presentation predicts a worse outcome for those with the oligoarticular subtype. The platelet count, as a marker of inflammation, can be elevated in polyarticular disease and substantially so in sJIA without MAS.

Liver function tests are used for monitoring certain disease-modifying anti-rheumatic drugs (DMARDs), such as methotrexate and leflunomide. They can be elevated as a result of prolonged, and frequently concomitant, use of nonsteroidal antiinflammatory drugs (NSAIDs).

As mentioned above, in 10% of patients, sJIA can progress to overt MAS. Ferritin, an acute-phase reactant, is a very sensitive indicator of this condition. A sudden drop of at least two cell lines in the CBC, a rising C-reactive protein (CRP) level with decreasing ESR, elevated liver transaminases, prolonged prothrombin or partial thromboplastin times, high D-dimer levels, elevated triglycerides, and low fibrinogen should all alert caregivers about the likelihood of MAS in a child with sJIA.[6]

Although 75% to 85% of adult patients with RA have either a RF or CCP antibodies, often both, less than 5% of patients with JIA have the RF, and those are mostly patients with early-onset RA, often teenage girls with symmetrical small joint involvement. Serum anti-nuclear antibody, while widely used, is not suitable for screening as it is of no diagnostic utility in either making or excluding a diagnosis of JIA. ANA serves as a prognostic factor by identifying patients already diagnosed with JIA who have the highest risk for developing uveitis.[3,16] In addition, ANA levels may alert the clinician to the possibility of juvenile Sjögren disease or SLE being the etiology for the chronic arthritis.

The prevalence of the HLA-B27 antigen is 8% in the general Caucasian population but nearly 90% in the ankylosing spondylitis group.[8] HLA-B27 is useful to predict axial involvement in ERA, psoriatic JIA, and IBD-related arthritis but should be evaluated in patients with inflammatory back pain, clinically established arthritis, and/or enthesitis rather than as a routine screening test during a work-up for any back pain without morning stiffness.

Additional laboratory indicators, such as elevated serum lactate dehydrogenase and uric acid levels, may indicate malignancy. Elevated angiotensin converting enzyme (ACE) and lysozyme levels are useful when considering sarcoidosis as the etiology of childhood arthritis and uveitis in early-onset sarcoidosis cases, but non-caseating granulomas seen on histology are more diagnostic.

Imaging Evaluation

Radiography can help evaluate persistent joint pain for bony disease processes (e.g., osteochondral lesions or malignancies). Chronic subtle clinical arthritis can result in finding periarticular osteopenia. Bony erosions seen in adult RA patients or those with psoriatic arthritis are less common in children. Radiographic findings of sacroiliac joint involvement need confirmation by magnetic resonance imaging (MRI) without intravenous contrast material. The role of ultrasonography for diagnosis and monitoring of disease progression in pediatric patients is promising, but further establishment of normative data is still required. MRI, with and without intravenous contrast, may help identify synovitis, but even this imaging modality can some-

times yield false-positive results in certain joints in otherwise healthy children.[8,24,25] MRI with contrast is the gold standard for diagnosing TMJ arthritis in JIA.[3]

DIFFERENTIAL DIAGNOSIS

A wide variety of conditions can mimic the symptoms and signs of JIA. A single acutely involved joint at onset should be considered of infectious origin until proven otherwise and calls for arthrocentesis. Septic arthritis frequently has an erythematous discoloration of skin, whereas JIA does not. Infection of the joint may lead not only to rapid destruction of the joint but also to systemic dissemination of infection. Specifically, *Kingella* species infection as a differential diagnosis for oligoarticular JIA should be considered in painful monoarticular cases of young children when symptoms have sudden onset without prolonged morning stiffness.

Parainfectious arthritis, often resulting from viral disease, is usually short-lived and typically requires only NSAID treatment. In contrast, Lyme disease is characterized by a chronic extensively swollen joint(s), commonly the knee.[15] It appears several weeks to months after the usually unnoticed tick bite and should be considered in areas of high incidence (e.g., northeastern United States). Migratory arthritis is associated with malignancies, *Neisseria* sp. infection, ANCA-associated vasculitis, and rheumatic fever—the last having typically very tender, red, hot joint involvement persisting in each location for a couple of hours before moving to another.

When evaluating for sJIA, multiple other etiologies of systemic inflammation should be considered. Fever and elevated WBCs, platelets, and ESR may accompany polyarteritis nodosa, Kawasaki disease, Henoch-Schönlein purpura, and other vasculitides. Ehrlichiosis and recurrent fever syndromes (e.g., familial Mediterranean fever, TNF receptor–associated periodic fever syndrome) may also manifest as systemic inflammation, arthralgias, and rashes. A typically nonerosive symmetric polyarthritis may occur in SLE, often with cytopenias. Polyarthritis is also seen in SLE-related diseases (e.g., SS, MCTD). Evidence of specific antibodies to extractable nuclear antigens in SLE (anti-Smith, anti–double-stranded DNA [dsDNA]) and MCTD (anti-ribonuclear protein [RNP]) help distinguish these cases from JIA.

Patients presenting with joint pain only, especially after activities or toward the end of the day, without associated swelling or morning stiffness, most commonly have overuse/overload syndromes with or without benign hypermobility syndrome. Structural bony involvement resulting in joint pain occurs with little league shoulder and elbow in middle school–aged baseball players; wrist pain occurs in gymnasts frequently. Pain in the hip, without morning stiffness, may indicate Legg-Calvé-Perthes disease or slipped capital femoral epiphysis. Relentless knee pain without improvement in teenagers could be caused by osteochondritis dissecans. Other common causes of teenage knee pain include Osgood-Schlatter disease and patellofemoral syndrome.

Bone malignancies present with constant pain in the corresponding area of the skeleton. Hematological malignancies typically cause referred hip pain, as does neuroblastoma. Nighttime skeletal pain, back pain in little children, migratory character, and systemic symptoms such as fever, weight loss, and metaphyseal tenderness all should raise suspicion for oncological process. On the other end of the spectrum, unrelenting, diffuse body pain with minimal clinical findings and negative laboratory and imaging findings should be evaluated for pain amplification syndrome.

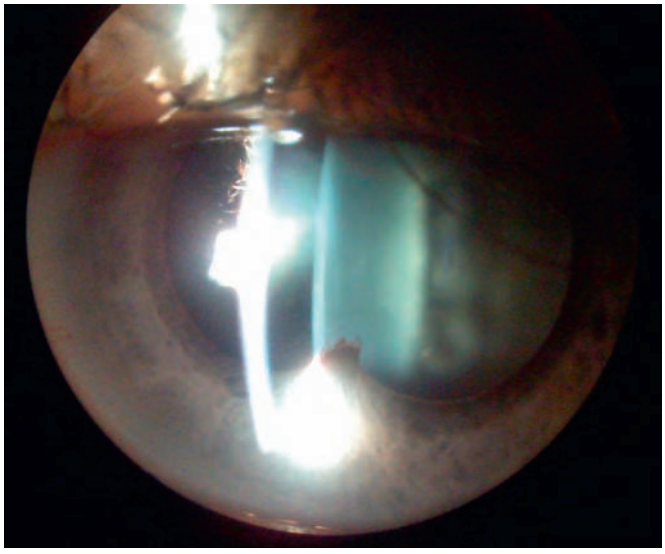

FIG. 54.2 Posterior Synechia, a Complication of Chronic Anterior Uveitis, is Associated with Several Categories of Juvenile Idiopathic Arthritis. The irregularities of the inner margins of the iris reflect fibrous adhesions between the iris and lens capsule. (Courtesy of Dr. Scott Olitsky.)

"Growing pains" or benign nocturnal limb pains of childhood is one of the most common misconceptions when evaluating joint pain. Typical "growing pains," while not associated with growth per se present at night, waking the child up with excruciating shin or leg pain; it is not joint centered and resolves with nonsteroidal (NSAID) therapy, heat, or massage. A different etiology should be investigated for when other parts of the body are involved. Rapid skeletal growth periods in the child's life can come with musculoskeletal pain, especially that of the back, when potentially delayed muscle tone and mass development cannot keep up with change of biomechanics.

Clinically Silent Complications

There are two common manifestations that present insidiously during the course of JIA and yet can cause major damage/morbidity—uveitis and TMJ arthritis. Uveitis is a relatively common complication of JIA with potentially long-term morbidity. Risk factors for uveitis among patients with JIA include young age of onset, positivity for ANA, oligoarticular disease, and female sex.[16] It usually presents as iridocyclitis, but the choroid may also be affected. Although extremely rare in sJIA, approximately 20% of patients with oligoarticular JIA and 5% of patients with RF-negative polyarticular JIA develop eye inflammation.[16] Some children with psoriatic JIA are also at risk of developing silent uveitis, especially in the ANA-positive subgroup.[22] Uveitis may lead to a great deal of morbidity, including cataracts, increased intraocular pressure, band keratopathy, and posterior synechiae (Fig. 54.2), with decreased vision developing in up to 40%.[16] The danger of most JIA-associated uveitis is its asymptomatic presentation, with the exception of symptomatic uveitis in children with ERA. Considering that the highest prevalence is in patients with oligoarticular JIA, which is most common in preschool and younger children, it is not surprising that many of the cases go unnoticed. A routine vision examination may fail

to detect uveitis, and children need to have a formal slit-lamp examination to identify inflammatory cells.[16] The most common presenting signs are synechiae (an irregular iris border resulting from adhesions to the lens), hypopyon, and band keratopathy (see Fig. 54.2). Uveitis may develop many months or years after joint symptoms, and, therefore, close follow-up is warranted. ANA positivity and young age are associated with increased incidence; thus, ANA-positive children with oligoarticular JIA need to be screened the most often, but those in other categories should be followed up on a set schedule as well.[16] Failure to do so and missed diagnosis of eye involvement may lead to the occurrence of cataracts, glaucoma, impaired vision, and even blindness.

KEY CONCEPTS

Temporomandibular Joint Arthritis

- Temporomandibular joint (TMJ) arthritis is common, present in up to 80% of children with juvenile idiopathic arthritis (JIA). It is typically asymptomatic at onset and thus requires early screening with magnetic resonance imaging (MRI) with contrast.
- TMJ arthritis can be active despite therapy with disease-modifying anti-rheumatic drugs (DMARDs) and biologicals (e.g., methotrexate plus tumor necrosis factor [TNF] inhibitors) and might require intensification of treatment.

Another frequently asymptomatic complication of JIA is TMJ arthritis. TMJ arthritis in children with JIA has been recognized increasingly in recent years as a joint inflammation, leading to silent destruction and facial deformity despite systemic therapy.[3] TMJ arthritis is quite common, with 40% to 80% of all patients with JIA patients affected.[3] The overall true prevalence is likely closer to the higher range, since not all children with JIA receive TMJ MRI screening, which frequently reveals synovial thickening (Fig. 54.3) at disease onset, and premicrognathic arthritis may be missed.[3,22] The highest rates of TMJ arthritis have been found in the extended oligoarticular JIA and RF-negative polyarticular JIA groups, as well as in children with upper extremity and neck involvement and those with an elevated ESR.[3] TMJ arthritis needs to be recognized early in children with JIA so that it can be treated prior to growth disturbance.

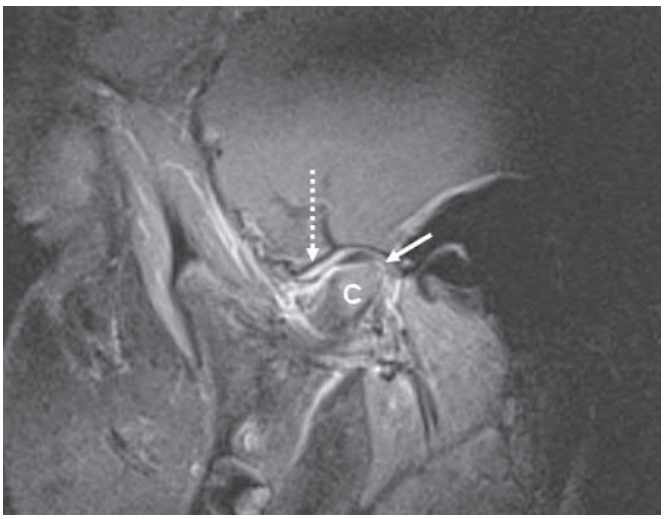

FIG. 54.3 Acute and Chronic Temporomandibular Joint Arthritis in a Child with Juvenile Idiopathic Arthritis. Synovial thickening and enhancement *(long dashed arrow)* and mandibular condyle *(C)* flattening with contour irregularity/erosion *(short arrow)* are noted in this parasagittal postcontrast T1-weighted magnetic resonance image. TREATMENT

Overview

Despite significant advances in the understanding of the pathogenesis of JIA, there are currently no curative treatments. JIA frequently persists into adulthood and may result in significant morbidity, including physical disability. The objective of treatment is to prevent disability and preserve normal growth and development while providing relief of symptoms and improved quality of life by controlling the inflammatory process.[1]

Over the past 20 years, remarkable advances have been made in the treatment of JIA.[1] Chief among these advances was the advent of targeted biological therapeutic agents (Table 54.2) (Chapter 86). These agents have been shown to be quite beneficial against active disease and are generally well tolerated.[1] The early initiation of biological therapeutic agents may, in fact, alter and improve the subsequent disease course.[1] These new breakthroughs have prompted pediatric rheumatologists to "invert the treatment pyramid": that is, to rapidly incorporate more effective therapeutic agents instead of slowly progressing to them in a stepwise fashion.[1]

THERAPEUTIC PRINCIPLES

Early Aggressive Therapy

- Accumulating evidence suggests that early aggressive therapy that includes targeted biological agents near the time of clinical diagnosis (during the "window of opportunity") may improve the future disease course.

In response to the growing number of treatment options for JIA and the advent of the biological therapeutics, the American College of Rheumatology (ACR) issued Recommendations for the Treatment of JIA that were updated in 2019.[26,27] These recommendations were developed by using a rigorous methodology to produce evidence- and consensus-based guidance that reflected the current state of the field.

With new and effective therapies continuing to be introduced to the therapeutic armamentarium, treatment goals have become elevated and more stringent. The current goal is to achieve a status of clinically inactive disease[28]: that is, the absence of any significant signs or symptoms of active arthritis.

Recent advances in the treatment of adults with inflammatory arthritis have elucidated some differences in the effectiveness of specific biological agents for specific forms of arthritis. For example, many non-TNF inhibitor biologicals, such as abatacept, rituximab, and tocilizumab, are highly effective in the treatment of RA but are far less effective in the treatment of ankylosing spondylitis. In contrast, some of the more recently introduced biological agents, such as the IL-17 inhibitor secukinumab, appear effective against ankylosing spondylitis but are likely less effective for RA.[29]

Despite these recent advances, the treatment of JIA is not yet strongly influenced by the distinct categories of JIA, with the exception of sJIA. For example, there are no specific therapies currently approved for the treatment of children with psoriatic

TABLE 54.2 Biological Therapeutic Agents Used in the Treatment of Juvenile Idiopathic Arthritis

Biological Target	Name	Structure	Frequency of Administration	Route of Administration
Tumor necrosis factor (TNF)	Etanercept	TNF receptor–immunoglobulin G (IgG) fusion protein	Twice weekly to weekly	Subcutaneous (SQ) injection
	Infliximab	Monoclonal antibody (chimeric)	Every 4–8 weeks	Intravenous (IV) infusion
	Adalimumab	Monoclonal antibody (humanized)	Every 1–2 weeks	SQ injection
	Golimumab	Monoclonal antibody (humanized)	Every 4 weeks Every 8 weeks	SQ injection IV infusion
	Certolizumab pegol	Monoclonal antibody (humanized and PEGylated)	Every 2 weeks	SQ injection
CD80/86	Abatacept	Cytotoxic T-lymphocyte antigen-4 (CTLA-4–IgG fusion protein	Every 4 weeks Weekly	IV infusion SQ injection
Interleukin-1 (IL-1)	Anakinra	Receptor antagonist	Daily	SQ injection
	Canakinumab	Monoclonal antibody (humanized)	Every 8 weeks	SQ injection
	Rilonacept	Receptor-fusion protein	Weekly	SQ injection
IL-6 receptor	Tocilizumab	Monoclonal antibody (humanized)	Every 2–4 weeks Every 1–2 weeks	IV infusion SQ injection
$CD20^+$ B cells	Rituximab	Monoclonal antibody	2 infusions 2 weeks apart, repeat every 6 months	IV infusion
IL-12 and IL-23	Ustekinumab	Monoclonal antibody	Every 12 weeks	SQ injection
IL-17A	Secukinumab	Monoclonal antibody	Every 4 weeks	SQ injection

arthritis as opposed to RF-negative polyarthritis. Accordingly, the discussion of treatment in this chapter does not detail all categories of JIA but focuses rather on the "treatment groups" as defined by the 2011 ACR Recommendations for the Treatment of JIA.[30] As our knowledge about pathophysiology and response to treatment continues to expand, differential therapeutic approaches for the disparate JIA phenotypes are eagerly anticipated.

Nonsteroidal Antiinflammatory Drugs

NSAIDs formed the foundation of the treatment of JIA for decades, and numerous NSAIDs have been shown to have beneficial effects. In the absence of significant numbers of head-to-head trials, it is believed that in general all NSAIDs are similarly effective,[1] although indomethacin is considered by some to be the most effective NSAID (especially in sJIA). One NSAID may be found to be more effective than another for a particular child.

In general, NSAIDs are not considered to be disease-modifying agents: that is, they are not felt to slow the progression of disease or prevent the appearance of radiographic damage. For this reason, monotherapy with NSAIDs initially began to decline with the advent of agents such as methotrexate that have been shown to modify the disease process. NSAIDs are frequently used for symptomatic relief, but the ACR Recommendations for the Treatment of JIA strongly recommend treatment with a DMARD over NSAID monotherapy for patients with active polyarthritis.[27] Gastrointestinal (GI) discomfort is a frequent adverse effect of NSAID therapy, although frank GI bleeding appears to occur at a lower incidence than in adults. Scarring pseudoporphyria of sun-exposed skin is another risk associated with NSAID use. The long-term cardiovascular effects of NSAIDs in children have not been studied.

Glucocorticoids

Similar to many rheumatological diseases, JIA has been shown to respond to treatment with glucocorticoids (Chapter 83). Intraarticular glucocorticoid injections typically result in a near-immediate decrease in inflammation that is maintained for many months.[31] Accordingly, intraarticular injections may form the foundation of therapy for children with mild or limited oligoarthritis. In addition, intraarticular injections may be effective in children with more extensive arthritis and in those who are receiving concurrent systemic therapy. Randomized trials have shown unequivocally that injected triamcinolone hexacetonide has the longest duration of effect.[30]

JIA also may be effectively treated with systemic glucocorticoids. They are frequently used in the treatment of systemic features of JIA and may form the foundation of the treatment for the sJIA category, although biological therapies may significantly lessen the need for this practice.[28] The use of systemic glucocorticoids for the treatment of synovitis in children with JIA is not an uncommon practice. However, the risks, benefits, and appropriate use of this approach are less clear. The ACR Recommendations for the Treatment of JIA state that a limited course of systemic glucocorticoids (i.e., so-called "bridging therapy" while awaiting the benefits of newly initiated nonbiological or biological DMARDs) may be acceptable, but the use of chronic systemic glucocorticoids is strongly recommended against.[27] The anticipated adverse effects of long-term use of moderate doses of glucocorticoids includes growth failure, osteoporosis, cataract formation, glaucoma, hyperglycemia, hypertension, avascular necrosis of bone, striae, and others.[31]

Nonbiological Disease-Modifying Anti-Rheumatic Drugs

The use of DMARDs was introduced in the 1980s. The most widely used and studied is methotrexate, which has been shown in randomized clinical trials to be efficacious in treatment of JIA.[1] Following these studies, methotrexate became the cornerstone of therapy for many children with JIA. Methotrexate is typically administered weekly through either the oral or the

subcutaneous route, although studies have shown subcutaneous methotrexate to be better absorbed and more effective.[1]

Methotrexate may be associated with several typically minor adverse effects, such as nausea and fatigue. Occasionally, methotrexate may cause liver toxicity, necessitating periodic measurement of serum aminotransferase levels for routine monitoring.

Leflunomide has been shown to be slightly less efficacious than methotrexate in the treatment of JIA.[1] It may serve as an alternative therapy for children who are intolerant of methotrexate. Sulfasalazine is used, to varying degrees, by pediatric rheumatologists and may be of particular benefit to children with JIA of the ERA category.[1] Hydroxychloroquine monotherapy has been demonstrated inefficacious in treating polyarthritis in JIA.[1]

Biological Disease-Modifying Anti-Rheumatic Drugs

The use of biological DMARDs for the treatment of JIA began in the late 1990s. Etanercept, a TNF inhibitor, was the first studied and was shown to be efficacious in a randomized clinical trial.[1] Additional TNF inhibitors have been introduced and used in the treatment of JIA; adalimumab was also shown to be efficacious in a randomized clinical trial.[1] Notable differences have been discovered regarding the effectiveness of the TNF receptor fusion protein (etanercept) and the mAbs (adalimumab, infliximab, and others). Monoclonal antibody TNF inhibitors have been shown to be effective against two important JIA-associated conditions—anterior uveitis and IBD. Receptor fusion proteins have been shown to be far less effective in treating these conditions. The precise mechanism for these differences in treatment effectiveness is not clear but may be related to the ability of etanercept to bind lymphotoxin or the ability of mAb to bind surface membrane–bound TNF.[32]

Because the TNF inhibitors are large proteins, they must be administered parenterally, either by subcutaneous injection or intravenous infusion (see Table 54.2). TNF inhibitors are not generally associated with common medication adverse effects, such as headache or nausea, although they may result in injection site or infusion reactions. There appears to be a modest increase in the incidence of bacterial infections associated with TNF inhibitor use[33] and a significant risk of reactivation of latent tuberculosis.[32] Therefore, individuals should be screened for tuberculosis infection prior to initiating treatment with TNF inhibitors.[30] A possible association between TNF inhibitors and an increased rate of malignancy in JIA has been proposed, but there is no convincing evidence of a strong increased risk of overall malignancy.[34]

In addition to TNF inhibitors, the T-cell costimulation modulator abatacept has been shown in a randomized clinical trial to be efficacious in the treatment of JIA.[1] Presumably, because of the effectiveness of TNF inhibitors and their earlier availability, the use of abatacept has remained relatively limited in clinical practice.

The B-cell–depleting agent rituximab has been minimally studied in the treatment of JIA.[1] However, it appears effective in some instances, particularly in children who appear to have early-onset RA (teenagers with RF^+ and CCP-positive polyarthritis).

The IL-1 inhibitor anakinra has been shown in both uncontrolled and controlled studies to be particularly effective in the treatment of sJIA.[1,35] Similar to the experience in adults with RA, anakinra appears less effective in treating synovitis among children with the other categories of JIA. Additional IL-1 inhibitors (rilonacept, canakinumab) are also now commercially available and have been shown beneficial in clinical trials treating sJIA.[1]

Unlike other biological agents, the IL-6 inhibitor tocilizumab has been shown in randomized clinical trials to be efficacious in the treatment of both sJIA and polyarticular JIA.[1]

Treatment of Oligoarthritis (Arthritis of ≤4 Joints)

Because of fewer involved joints, oligoarthritis may generally be viewed as a milder form of JIA. However, significant disability can still occur, and children with this condition should not be assumed to have had good clinical outcomes without proper evaluation and therapy. The foundation of treatment for this JIA phenotype is intraarticular glucocorticoid injections. These injections may be administered in multiple joints concurrently and may be repeated, as needed.[31] A good response typically results in resolution of clinical signs and symptoms of arthritis for 4 to 12 months. DMARD therapy should be initiated in children who do not respond as desired to injections or who have more significant arthritis.[30] Methotrexate is typically the agent of first choice. Significant arthritis that does not respond adequately to methotrexate can be treated with TNF inhibitors.[30]

Treatment of Polyarthritis (Arthritis of ≥5 Joints)

Methotrexate is currently recommended for nearly all children with polyarthritis.[27] If a brief trial of methotrexate proves inadequate to control the arthritis, then TNF inhibitors are frequently recommended.[27] If an adequate response to the initial TNF inhibitor is not seen, then switching to a different mechanism of action (e.g., abatacept or tocilizumab) is slightly preferred over switching to a different TNF inhibitor.[27] However, the most appropriate role of non-TNF inhibitor biological DMARDs in the treatment of polyarticular JIA has yet to be clearly defined.

Treatment of Arthritis Involving Specific Joints

Arthritis involving the TMJ, hip, and sacroiliac joints may deserve special therapy. Destructive arthritis of the TMJ among children with JIA has been noted for decades. Clinical evaluation of this joint is particularly challenging, as symptoms are often absent initially, and physical examination findings may be normal. Accordingly, the optimal treatment for TMJ arthritis is unclear. Although TMJ arthritis has been known to demonstrate radiographic progression despite treatment with systemic TNF inhibitors and, in the absence of signs of active synovitis of other joints, increased systemic therapy is likely appropriate.[3,25]

The presence of hip arthritis in JIA has been shown in several studies to portend a poor prognosis.[30] Accordingly, many authors advocate early intraarticular glucocorticoid injections and increased systemic therapy when active hip arthritis is identified.

Sacroiliac arthritis is strongly associated with the development of ankylosing spondylitis. Because axial arthritis has been shown to be less responsive to methotrexate therapy, current recommendations are for the use of TNF inhibitors over methotrexate monotherapy when sacroiliac arthritis is present.[27] It is believed that early treatment with TNF inhibitors, or perhaps even newer biological agents that inhibit IL-17 or IL-12/IL-23, may be optimal for the treatment of spondyloarthritis to help prevent progression of ankylosis in children.[29]

Treatment of Erosive Arthritis

It appears that not all children with JIA have the propensity to develop an erosive arthritis that is similar to that frequently seen

in adults with RA. Children who develop erosions visualized on plain radiographs are considered to have a worse prognosis, and the current recommendation is to increase the intensity of their treatment accordingly.[27]

Treatment of Systemic Features of Systemic Arthritis

For decades, the mainstay of therapy for sJIA has been systemic glucocorticoids and NSAIDs. Nearly all children with sJIA will respond favorably to systemic glucocorticoids, if given in sufficient doses. However, often children become "steroid dependent," and efforts to decrease the glucocorticoid burden to minimize adverse effects have been unsuccessful. Presumably because of its different pathogenesis, sJIA has not been shown to respond to TNF inhibitors as favorably as the other categories of JIA. Instead, IL-1 and IL-6 appear to be key cytokines in the disease process. Accordingly, IL-1 (anakinra, canakinumab) and IL-6 (tocilizumab) inhibitors are recommended as the first line in treatments for sJIA.[35]

The appearance of clinically significant MAS generally requires directed therapy. The typical treatment approach involves increased systemic glucocorticoids. The calcineurin inhibitor cyclosporine is frequently added,[1,6] and some authors advocate IL-1 and IL-6 inhibitors for treatment of MAS.[1,6] In severe refractory cases, cytotoxic chemotherapeutic agents, such as cyclophosphamide or etoposide, may be warranted.

Treatment of Arthritis of Systemic Arthritis

Some children with sJIA will develop a chronic course of polyarthritis with a relative absence of concurrent systemic features. In general, it is recommended that these children be treated as those with polyarthritis who did not have systemic features at onset.[30] Based on clinical trial results, the IL-6 inhibitor tocilizumab may be the most effective treatment for these patients.

Treatment of Uveitis

JIA-associated anterior uveitis frequently requires directed therapy. Topical glucocorticoid eye drops—such as prednisolone acetate 1%—are frequently initiated at the time of diagnosis by the treating ophthalmologist.[16] Although effective in decreasing the inflammation of uveitis, glucocorticoid eye drops cannot be tolerated in high doses for extended periods because of the risk of cataracts and glaucoma.[16] For this reason, systemic medications are frequently employed in the treatment of JIA-associated uveitis. Methotrexate has been shown to be effective for uveitis and is the most commonly used systemic medication.[1,16] The mAb TNF inhibitor adalimumab has been shown to be highly effective in the treatment of anterior uveitis in a randomized clinical trial.[36] Other biological agents (e.g., rituximab, abatacept, tocilizumab) appear to be effective in some children with refractory uveitis, but their overall role remains unclear.

Duration of Therapy

As stated, the current goal of therapy is the attainment of clinically inactive disease. However, once this goal is reached, the appropriate next steps in management are less clear. Although none of the currently available therapies is believed to be curative, many children can successfully decrease or discontinue therapies after attaining inactive disease status without immediate recurrence of active disease. Many pediatric rheumatologists will consider decreasing the level of therapy if inactive disease status is maintained for a prolonged period, such as 12 months, although this approach is arbitrary. Further study of the appropriate management of children who attain prolonged inactive disease status will be an important future focus.[37]

TRANSLATIONAL RESEARCH

ON THE HORIZON

- Novel criteria for identifying macrophage activation syndrome (MAS) among children with systemic juvenile idiopathic arthritis (sJIA) have been developed using real patient data that are diagnostically highly sensitive and specific.
- Genetic screening for mutations in cytolytic pathway genes will help identify those individuals at risk for developing MAS.
- Murine models are paving the way for a better understanding of MAS immunopathology and potential pathways for clinical intervention.
- Clinical trials involving treatment of MAS with inhibitors of proinflammatory cytokines are underway.

The explosion in advances in immunology and genetics is leading to major breakthroughs in therapy for rheumatic diseases, including JIA. Challenges remain, however, in diagnosing and treating MAS complicating sJIA. To distinguish a sJIA disease flare-up from MAS, expert opinion and Delphi techniques are currently being used to explore novel criteria for diagnosing MAS in children with sJIA. Data collection regarding clinical, laboratory, and pathological features of children with sJIA—with and without MAS—have been used to develop new classification criteria.[38,39] Furthermore, genetic mutations and polymorphisms in genes linked to the defective cytolytic pathway in lymphocytes from patients with MAS are being explored to identify patients with sJIA with a propensity to develop MAS.[20] Mouse models of MAS are helping to better understand MAS immunopathology and the role of proinflammatory cytokines in the process.[40] Early recognition of MAS and a better understanding of the role of various cytokines in the pathogenesis of MAS will allow for improved targeted therapy for this often fatal condition.

Sjögren's Syndrome

Vasiliki Koulouri, George Fragoulis*, and Clio P. Mavragani*

Sjögren's syndrome (SS) is a chronic autoimmune disease characterized by chronically inflamed exocrine tissues resulting mainly in oral and ocular dryness. Beyond the local manifestations, systemic features affecting virtually any organ system frequently occur. Malignant disease in the form of lymphoproliferation is a well-established disease complication and comorbidities such as accelerated atherosclerosis and mental health issues are also increasingly recognized. SS has been traditionally classified as primary (pSS) and secondary depending on the presence or absence of an underlying autoimmune disease. Given the wide spectrum of clinical manifestations, disease diagnosis can be often challenging. Despite the progress in understanding underlying pathogenetic mechanisms, effective therapeutic strategies remain limited for both local and systemic disease manifestations.

ETIOPATHOGENESIS

Similar to most autoimmune conditions, the exact etiology of SS remains unclear. The impact of environmental, hormonal, and/or stress factors in a genetically predisposed individual is considered the cornerstone of immune dysfunction. Aberrant activation of epithelial cells appears to be a distinctive element in SS.

KEY CONCEPTS

Pathogenesis of Sjögren's Syndrome

Etiopathogenesis	Pathophysiology
• Genetic predisposition • Epigenetic modifications • Viral infection • Endogenous viral elements • Gastrointestinal dysbiosis • Hormonal imbalance • Stress	• Epithelial cell activation • Lymphocytic infiltration • T-cell and B-cell autoreactivity • Autoantibody production—immune complex formation • "Interferon signature"

Environment

The role of viruses as the potential initiators of the immunologic cascade giving rise to SS has long been discussed. Among the offending agents, cytomegalovirus (CMV), Epstein-Barr virus (EBV), human herpes virus-6 (HHV-6), HHV-8, human T-lymphotropic virus-1 (HTLV-1), human immunodeficiency virus (HIV), hepatitis C virus (HCV), Coxsackie viruses, as well as endogenous retroviral elements have all been suspected to be implicated in disease pathogenesis. Activation of type I interferon (IFN) pathways, presence of cross-reactive autoantibodies and viral nucleic acid in patient tissues, in addition to clinical manifestations reminiscent of SS in viral illnesses, have been proposed as indicators of a viral involvement in SS origin.[1,2] Aside from viruses, evidence of irregular gut microbiota composition in SS patients displaying significant associations with disease activity have recently emerged.[3]

Hormones—Stress

High prevalence of SS in women of menopausal age is suggestive of insufficient estrogen production as a potential contributor to disease development. This hypothesis is further supported by evidence of low estrogen and androgen levels in SS patients together with the development of SS-like symptomatology in estrogen-deficient murine models. Moreover, high-stress conditions are considered to be a trigger of SS manifestations in predisposed individuals with ineffective stress management techniques and indolent hypothalamic–pituitary–adrenal axis.[2]

Genetics—Epigenetics

The significant role of genetic predisposition in SS pathogenesis is supported by the well-known presence of familial aggregation and increased prevalence of genetic polymorphisms in SS. Family members of SS patients, especially siblings, display an increased risk for development of SS or other autoimmune diseases compared with controls. Several major histocompatibility complex (MHC) class II gene alleles have been strongly associated with SS susceptibility, most notably the human leukocyte antigen (HLA) HLA-DR and HLA-DQ encoding antigens, with varying haplotypes depending on the studied population/ethnicity. Genome-wide association studies have also revealed non-HLA genetic variants as risk factors for SS. The latter pertain to genes involved in B-cell activation, nuclear factor (NF)-κB–mediated inflammatory and apoptotic processes, as well as in IFN signaling pathways.[4] The most compelling associations include polymorphisms in genes shown in Table 55.1.

Finally, epigenetic alterations, such as DNA methylation, histone modification, and posttranscriptional gene regulation mediated by noncoding ribonucleic acids (RNAs) have also been associated with a potential pathogenetic role in SS. Specifically, analyses conducted in whole blood, peripheral blood mononuclear cells (PBMCs), and salivary gland tissues of SS patients have revealed disease-associated deoxyribonucleic acid (DNA) methylation patterns, such as hypomethylation of IFN-induced genes. Demethylating mechanisms and alteration of methylating enzymes have been shown to be related to increased long interspersed nuclear element 1 (LINE-1) transcripts in salivary gland tissues.[5] Several studies have reported that alterations of microRNA (miRNA) expression, such as miR-146, miR-16, miR-200b-3p, and miR-181a, may impact immune cell regulation and thus contribute to disease pathogenesis.[6]

PATHOPHYSIOLOGY

Lymphocytic periepithelial infiltrates and B-cell hyperactivity are the key features in SS immunopathology and are associated

with several glandular and systemic manifestations. Lymphocytes initially form periductal focal aggregates that eventually advance to the whole tissue. The composition of these infiltrates appears to be dependent on lesion severity; CD4 T cells are the main lymphocytic population of mild lesions, while more advanced ones are characterized by B-cell predominance. Imbalance in T helper 1 (Th1)/Th2 cytokine production along with a prominent Th17 lymphocyte component are the central elements of T-cell involvement. Autoreactive B lymphocytes are primarily responsible for disease-specific autoantibody (anti-Ro, anti-La) and rheumatoid factor (RF) production; together with T cells, they contribute to the formation of germinal center–like structures. Innate immunity cells (natural killers, dendritic cells, macrophages) constitute less than 10% of the infiltrates; they contribute to tissue damage and cytokine and chemokine production.

Lymphocytic accumulation around epithelial tissue and extraglandular manifestations due to epithelial damage (i.e., interstitial nephritis, primary biliary cirrhosis, bronchiolitis) are indicative of a substantial role of epithelial cells in SS pathogenesis, to the extent that the term "autoimmune epithelitis" has been suggested.[7] Epithelial cells are actively involved in immune cell stimulation and recruitment, autoantibody production, and perpetuation of inflammation in various manners:

- They supply autoantigens via increased apoptosis or exosome release (i.e., Ro [SSA], La [SSB]).
- They act as antigen-presenting cells
- They produce proinflammatory cytokines and chemokines, such as interleukin (IL)-1, IL-6, IL-8, tumor necrosis factor-α (TNF-α), CXCL13, CXCL21.
- They release B cell–activating factor (BAFF), an important agent in B-cell survival, proliferation, and activation

Antigen-driven autoantibody production generates immune complex formation, responsible for many of the systemic manifestations in SS. Immune complexes are suspected to ultimately trigger type I IFN production by plasmacytoid dendritic cells. Excess IFN production is evident by the increased expression of IFN-inducible genes in both peripheral blood and glandular tissue of SS patients, also known as the "IFN signature." Type I IFNs further stimulate BAFF production and epithelial cell activation, perpetuating a vicious cycle of aberrant immune activity. Prolonged B-cell autoreactivity as a result of chronic antigenic stimulation, immune complex formation, and long-lasting inflammatory processes in affected tissue act as a "prologue" to lymphomagenesis in SS.

Evidence of discordance between the degree of glandular dysfunction and lymphocytic infiltration in both humans and animal models is suggestive of pathogenetic processes beyond the spectrum of tissue inflammation. Ineffective neurotransmission due to anti–muscarinic receptor antibodies, deficient expression of aquaporins, and structural anomalies owing to altered protein concentrations are some of the mechanisms found to affect salivary and lachrymal secretion.[2]

DIAGNOSIS AND CLASSIFICATION

Diagnosis of SS can be achieved through a combination of detailed medical history, meticulous clinical examination, appropriate laboratory work-up, and evaluation of lachrymal and salivary gland involvement (Fig. 55.1).

Medical History and Clinical Examination

SS should be suspected in any patient presenting with persistent sicca symptomatology: dry eyes and/or mouth. Patients usually complain of burning or foreign body sensation in their eyes, difficulty swallowing, poor dental health, and recurring oral candidiasis. The patient should be questioned for previous parotid gland enlargement (PGE) and family history of SS or other systemic autoimmune disease. Extraglandular manifestations include arthralgias, Raynaud's phenomenon, peripheral neuropathy, and vasculitis, commonly presenting as purpura. Chronic fatigue is a rather common and debilitating SS symptom.[8]

Laboratory Work-Up

Laboratory work-up for evaluation of suspected SS should include complete blood count, basic metabolic panel, urinalysis, erythrocyte sedimentation rate (ESR), serum protein electrophoresis (SPEP), antinuclear antibodies (ANAs), RF, cryoglobulins, C3 and C4 levels, anti-Ro, and anti-La autoantibodies, thyroid autoantibodies, and chest x-ray to exclude sarcoidosis. Evaluation for HCV, HIV, and immunoglobulin G4 (IgG4)-related disease (IgG4-RD) should also be performed as they are included in the differential diagnosis of SS. On clinical suspicion of underlying systemic lupus erythematosus (SLE), testing for anti-dsDNA (double-stranded DNA) antibodies should be offered. Other autoimmune diseases with SS manifestations include rheumatoid

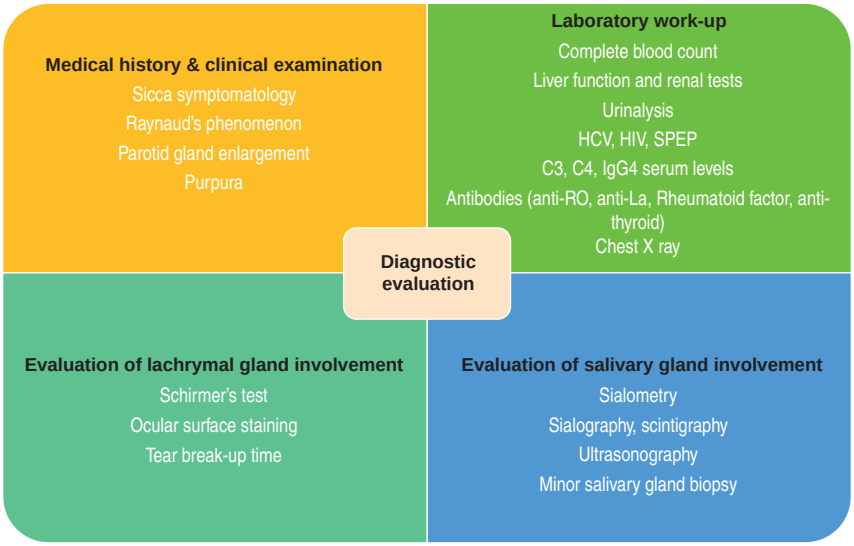

FIG. 55.1 Diagnostic Work-Up in a Patient With Suspected Sjögren's Syndrome. *HCV*, Hepatitis C virus; *HIV*, human immunodeficiency virus; *IgG4*, immunoglobulin G4; *SPEP*, serum protein electrophoresis.

arthritis (RA), primary biliary cirrhosis (PBC), and systemic sclerosis (SSc) (see Clinical Features, later). Common abnormal laboratory values in SS patients are the following:

- Cytopenias. Mainly anemia of chronic disease and leukopenia (white blood cells <4000/μL).
- Increased ESR.
- Hypergammaglobulinemia.
- Positive ANAs. ANAs by indirect immunofluorescence on the classic Hep2 cell line may be negative because Ro60 reactivity can be lost during cell preparation, whereas modified Hep2 cell line (enhanced for better Ro60 reactivity) still lacks adequate sensitivity for this antigen. If positive, the pattern is usually nuclear speckled. Anti-Ro52 positivity produces a cytoplasmic immunofluorescent pattern.[9] If there is strong suspicion of SS, a solid-phase immunoassay for anti-Ro should always be requested.
- RF positivity (approximately in 50% of SS patients) with or without cryoglobulinemia (type II or III).
- Low C4 serum levels.
- Anti-Ro/La positivity. Anti-Ro positivity is present in approximately two-thirds of SS patients. It is included in the classification criteria.
- Mild proteinuria, hyposthenuria, and alkaluria in case of interstitial nephritis/renal tubular acidosis.
- Proteinuria and hematuria in case of glomerulonephritis (GN; rare in SS—associated with vasculitis).[8,10]

Evaluation of Lachrymal Gland Involvement—Ocular Dryness

Ophthalmologic examination of dry eyes is carried out with three main tests, two of which are also items of the 2016 classification criteria for pSS:

- *Schirmer's test*: paper strips are placed in the pouch of both inferior eyelids for 5 minutes. Normally, both eyes produce enough tears to moisten more than 15 mm of paper; 5 mm or less of paper moisture in either eye is a sign of severe objective dryness and raises the possibility of SS.
- *Ocular surface staining*: it is performed with a slit lamp examination using fluorescein and lissamine green dye to assess conjunctival damage indicative of ocular dryness.
- *Tear break-up time (TBUT)*: it is not included in the SS classification criteria. Fluorescein dye is placed on the patient's eye, and the time it takes for the first dry spot to appear is measured. A TBUT less than 10 seconds is considered abnormal.[11]

Evaluation of Salivary Gland Involvement—Xerostomia/Parotid Gland Enlargement

- *Sialometry* is implemented to objectively measure the amount of saliva produced by an individual. A flow rate of 0.1 mL/min or less of unstimulated whole saliva (UWS) production constitutes a positive classification criterion for pSS.
- *Sialography* and *scintigraphy* are used to evaluate the morphology and function of salivary glands, respectively. Both of these methods tend to be replaced by less-invasive techniques.
- *Ultrasonography (US)* is a very useful tool in the assessment of salivary gland pathology in SS patients, and great efforts have been made towards the development of a universal US scoring system. Furthermore, recent evidence supports association of morphologic US abnormalities with systemic manifestations and immunologic markers of SS considered to be prognostic markers of progression to lymphoma.[12]
- *Elastography*, a modality that uses either US or magnetic resonance imaging (MRI) to evaluate the elastic properties of the affected tissue, can improve US specificity of SS diagnosis.[13]
- *Minor salivary gland biopsy (MSGB)* remains an invaluable diagnostic and prognostic tool in SS evaluation and management, although not a prerequisite for SS diagnosis (Fig. 55.2). Glandular lymphocytic infiltration is measured with the use of Focus score (FS) and tissue architectural disorganization is estimated with the Tarpley score. Positive FS is the presence of greater than or equal to 50 lymphocytes/4 mm^2 of tissue and is indicative of SS. Another notable histopathologic feature is the presence of germinal center–like structures, although their association with increased risk for lymphoma development is still a matter of controversy. Still, it is advisable that a patient with a high FS and Tarpley score

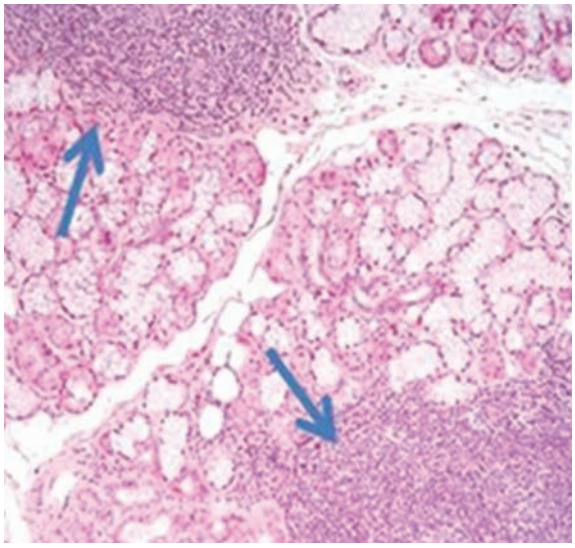

FIG. 55.2 Periepithelial mononuclear cell infiltrates *(arrows)* in labial minor salivary gland biopsy in a patient with Sjögren syndrome.

and germinal center–like structures in their MSGB be closely monitored and further evaluated for lymphoma development. A recent study revealed that SS patients with an FS of zero (essentially lacking histopathologic SS diagnosis) were less likely to have increased expression of IFN-induced genes, high IgG levels, anti-La antibodies or excessive conjunctival damage compared with those with positive FS. However, the two groups did not differ significantly in manifestation of either sicca or constitutional symptoms, asserting the significance of the immunologic criteria in SS diagnosis.[14]

Classification Criteria for Primary Sjögren Syndrome

The 2016 classification criteria for pSS (Table 55.2) were developed and published by the American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR), with a reported sensitivity of 96% and specificity of 95%. Even though they are intended as a classification tool, they are also widely used in diagnosis.[15]

CLINICAL FEATURES

SS usually displays a benign course, with nonspecific manifestations preceding the full development of the syndrome by approximately a decade. The main SS-related symptoms are dry eyes and dry mouth, reflecting lachrymal and salivary gland inflammation, respectively. Dryness of other tissues (e.g., dry skin, dry vagina leading to dyspareunia) is also commonly observed. Approximately one-third of SS patients exhibit extraglandular manifestations. These are subdivided to those linked with periepithelial mononuclear cell infiltrates (e.g., liver involvement, interstitial nephritis) and those in which vasculitis is the underlying pathogenetic mechanism (glomerulonephritis, peripheral neuritis, purpura) (Table 55.3). Importantly, 5% to 10% of SS patients develop lymphoproliferative disease (LPD), which is combined with increased mortality.[16,17]

Glandular Manifestations

As mentioned earlier, dryness of mouth and dryness of eyes are the most characteristic symptoms of SS. Ocular dryness can be expressed with many different symptoms such as blurred vision, burning, itching, or gritty sensation in the eyes. Oral dryness can present as difficulty in chewing or swallowing, abnormalities of taste and smell, or adherence of food to the buccal surfaces. In

CLINICAL MANIFESTATIONS OF SJÖGREN'S SYNDROME

- Glandular
  - Salivary glands
  - Lacrimal glands
  - Other exocrine glands (xerotrachea, bronchitis sicca, pancreatic insufficiency, dyspareunia)
- Extraglandular
  - Nonspecific (fatigue, arthralgias, Raynaud phenomenon)
  - Periepithelial (liver, lung, renal involvement [interstitial nephritis])
  - Immunocomplexes-associated disease (purpura, peripheral neuritis)
  - Lymphoproliferative disease

TABLE 55.2 2016 ACR/EULAR Classification Criteria for Primary Sjögren's Syndrome

2016 ACR/EULAR Classification Criteria for Primary Sjögren's Syndrome (pSS)

Inclusion Criteria: at least one positive answer — **To determine whether an individual has symptoms and/or signs suggestive of pSS**

1. Have you had daily, persistent, troublesome dry eyes for more than 3 months?
2. Have you had a daily feeling of dry mouth for more than 3 months?
3. Do you have a recurrent sensation of sand or gravel in the eyes?
4. Do you have to wake up at night to drink water because your mouth is so dry?
5. Do you use tear substitutes more than three times a day?
6. Do you frequently drink liquids to aid in swallowing dry food?

Exclusion Criteria: any positive answer — **Any of these conditions automatically excludes the possibility of pSS**

1. History of head and neck radiation treatment
2. Active hepatitis C infection (confirmed by PCR)
3. AIDS
4. Amyloidosis
5. Sarcoidosis
6. Graft-versus-host disease
7. IgG4-related disease

Primary Sjögren's Syndrome Criteria: A Total Score of ≥ 4

1. Labial salivary gland with focal lymphocytic sialadenitis and focus score of ≥ 1 foci/4 mm²	**3**	The histopathologic examination should be performed by a **pathologist experienced in the diagnosis of focal lymphocytic sialadenitis and focus score count**, using the **protocol described by Daniels et al**.
2. Anti-Ro/SSA positivity	**3**	
3. Ocular staining score ≥ 5 (or van Bijsterveld score ≥4) in at least one eye	**1**	Patients who are normally taking **anti-cholinergic** drugs should be evaluated for objective signs of salivary hypofunction and ocular dryness after a **sufficient interval without these medications** for these components to be a valid measure of oral and ocular dryness.
4. Schirmer test ≤ 5 mm/min in at least one eye	**1**	
5. Unstimulated whole saliva flow rate ≤ 0.1 mL/min	**1**	

ACR, American College of Rheumatology; *AIDS*, acquired immunodeficiency syndrome; *EULAR*, European League Against Rheumatism; *IgG4*, immunoglobulin G4. *PCR*, polymerase chain reaction; *SSA*, sjogren syndrome related antigen A

TABLE 55.3 Major Clinical Manifestations of Sjögren's Syndrome.

Major Clinical Manifestations of Sjögren's Syndrome (Frequency %)
1. Arthritis/arthralgia (75%)
2. Parotid gland enlargement (50%)
3. Raynaud's phenomenon (30%–40%)
4. Pulmonary involvement (20%)
5. Purpura (10%)
6. Renal involvement (usually interstitial nephritis) (10%)
7. Liver involvement (5%–10%)
8. Lymphoproliferative disease (usually mucosa-associated lymphoid tissue lymphoma) (5%–10%)
9. Peripheral neuropathy (2%–10%)
10. Central nervous system involvement (2%–10%)

Apart from dry eyes and dry mouth, a wide range of clinical symptoms can be encountered in sjögren's syndrome

addition, oral infections, mostly candidiasis, and dental caries are frequent. Various conditions are included in the differential diagnosis of sicca symptomatology and should be thoroughly excluded. These include head and neck radiation, drugs (antidepressants, parasympatholytics, neuroleptics), metabolic conditions (malnutrition, alcohol abuse, diabetes mellitus, lipoproteinemia), viral infections (HIV, HCV, HTLV), graft-versus-host disease, sarcoidosis, IgG4-RD, and other autoimmune conditions (e.g., autoimmune thyroid disease, PBC) (Table 55.4). Salivary gland (usually parotid) enlargement is observed in approximately 40% of SS patients over the course of the disease and in approximately 15% as a first symptom (Fig. 55.3). PGE is usually intermittent, bilateral, firm to palpation, and asymptomatic. It should be considered as an adverse prognostic factor for lymphoma. Furthermore, a rapid increase in the size of the enlarged parotid glands suggests a superimposed infection or development of lympho-proliferative disorder. The differential diagnosis of bilateral PGE includes diabetes mellitus, lipoproteinemia type IV and V, alcoholism, malnutrition, infection (HIV, HCV, mumps), sarcoidosis, and IgG4-RD. Unilateral PGE can be seen in salivary gland neoplasms (e.g., Warthin tumor), lymphomas, bacterial infections, and salivary duct obstruction (e.g., sialolithiasis) (Table 55.5).

Other glandular manifestations include dry skin, dry nasal mucosa, and trachea (xerotrachea) as well as dry vagina in premenopausal women, observed in approximately 10%, 20%, and 40% of the patients, respectively.[17]

TABLE 55.4 Differential Diagnosis of Dry Eyes and Dry Mouth Symptomatology

Differential diagnosis of sicca symptomatology

IgG4, Immunoglobulin G4; *PBC*, primary biliary cirrhosis; *RA*, rheumatoid arthritis; *SLE*, systemic lupus erythematosus.

FIG. 55.3 Parotid Gland Enlargement in a Patient With Sjögren's Syndrome.

Extraglandular Manifestations

Musculoskeletal

Musculoskeletal manifestations are quite common in SS, affecting more than half of the patients. They usually present in the form of muscle aches and pain in the small joints, without causing erosive arthritis as seen in RA. Fatigue associated with functional disability is a common and devastating symptom in SS, present in up to 70% of the patients.

Raynaud's Phenomenon

Raynaud phenomenon is encountered in 30% to 50% of SS patients. It may precede sicca symptomatology, is of milder expression compared with that seen in other autoimmune diseases, and is associated with increased prevalence of extra-glandular manifestations.

Respiratory Tract Involvement

Manifestations from the respiratory tract are observed in approximately 20% of the patients and include dry cough and more rarely dyspnea. Pleurisy can occur but is more common in SS associated with systematic lupus erythematosus. In chest computed tomography, peribronchial thickening is a common finding, probably related to peribronchial and/or peribronchiolar mononuclear inflammation. In pulmonary function testing, a small airway obstructive pattern is most commonly diagnosed.[17,18] Interstitial lung disease (ILD), most commonly lymphocytic interstitial pneumonia (LIP) can also be observed and is usually of benign course. ILD in the setting of SS is associated with the presence of anti-Ro but may also be encountered in seronegative patients without sicca symptomatology.

TABLE 55.5 Differential Diagnosis of Parotid Gland Enlargement

Usually Bilateral
Diabetes mellitus
Lipoproteinemias (type IV and V)
Alcoholism
Malnutrition
Infections (human immunodeficiency virus, hepatitis C virus, mumps)
Sarcoidosis
Immunoglobulin (Ig)G4-related disease
Usually Unilateral
Warthin tumor
Lymphoma
Bacterial infection
Salivary duct obstruction

Hepatobiliary and Gastrointestinal Manifestations

Liver involvement in SS is not rare. It is usually expressed as PBC, while autoimmune hepatitis and sclerosing cholangitis are uncommon. PBC is encountered in approximately 5% to 10% of patients with SS. Cholestatic enzymes are elevated and antimitochondrial antibodies (AMAs) are usually positive. The natural course of PBC in the context of SS is benign, because the disease remains stable over time. Ursodeoxycholic acid is the anchor treatment. Finally, it is worth mentioning that dry eyes and dry mouth are common manifestations in patients diagnosed with PBC, found in approximately 50% to 70% of the latter. Indeed, PBC and SS share many common histopathologic and immunopathogenetic features, leading some investigators to coin the term "Sjögren's syndrome of the liver" for PBC.[19]

In regard to other gastrointestinal symptomatology, dysphagia and unexplained hoarseness may occur. These relate to esophageal dysmotility, decreased saliva volume, and gastroesophageal reflux, respectively.

Renal Involvement

Renal involvement in SS can be expressed by either tubulointerstitial nephritis or GN. The former is more common and is usually seen in young patients. It manifests with hypokalemia, low urine specific gravity, alkaline urine pH, and nephrocalcinosis. GN in the setting of SS is usually associated with vasculitis, hypocomplementemia, and cryoglobulinemia. Hypertension, mild proteinuria, and hematuria are the most common presenting manifestations. As pertains to histopathologic findings, membranoproliferative and membranous GN are the most common types. In addition, in contrast to the "full-house" pattern encountered in SLE, IgM and complement deposits are usually seen. In contrast to interstitial nephritis, GN is associated with poorer outcomes and survival.[20]

Vasculitis

Vasculitis is observed in approximately 15% of SS patients. Common findings are low serum complement levels and cryoglobulinemia, and it is associated with increased risk for lymphoma development and mortality. The skin (cutaneous vasculitis) is the most commonly affected organ, presenting with palpable purpura and more rarely with urticarial lesions. However, other tissues such as the glomeruli and vasa nervorum can be affected, producing GN and vasculitic peripheral neuropathy, respectively.

Neuropsychiatric Involvement

Peripheral neuropathy in SS is encountered in approximately 2% to 10% of patients, depending on the diagnostic methodology applied. Peripheral neuropathies in SS include (a) pure sensory neuropathies, (b) sensorimotor neuropathies, and (c) other rare types such as demyelinating neuropathy, mononeuritis multiplex, and autonomous neuropathy. Sensory neuropathies are expressed as distal symmetric sensory loss attributed to axonal degeneration of sensory fibers and rarely as sensory ataxia, which is due to loss of proprioceptive large fibers (ganglionopathy). Painful and burning paresthesias are also frequently observed in SS and are attributed to degeneration of cutaneous axons, representing a clinical condition called small fiber neuropathy. Importantly, physical and electrophysiologic examination is usually normal, and skin biopsy is required to make the diagnosis.[21] Sensorimotor neuropathies in SS patients, including axonal sensorimotor polyneuropathy, are associated with adverse prognostic factors for lymphoma development such as palpable purpura, cryoglobulinemia, and low serum complement levels.

The frequency and the type of central nervous system (CNS) involvement in SS are still debatable. Several manifestations such as hemiparesis, sensory deficits, seizures, aseptic meningitis, transverse myelitis, and multiple sclerosis–like lesions have been reported to occur in the context of SS. However, whether these are mechanistically linked to the index disease remains to be defined. Presence of anti-Ro antibodies has been associated with CNS involvement in SS and anti-aquaporin four antibodies have been detected in patients with SLE or SS and transverse myelitis along with optic neuritis.[10] Psychopathologic morbidities such as anxiety, distinct personality traits (e.g., neuroticism, psychoticism, and obsessiveness), and other features such as nocturia are also more commonly observed in SS patients.[22] Interestingly, the presence of certain autoantibodies has been linked to psychopathologic manifestations in SS patients.[10]

Lymphoproliferative Disease

LPD is probably the most severe complication of SS, associated with higher mortality rates.[16] Non-Hodgkin lymphoma (NHL) is the most common LPD seen in SS and is encountered in approximately 5% to 10% of this population. Risk factors for LPD in SS include: PGE, generalized lymphadenopathy, splenomegaly, palpable purpura, peripheral neuropathy and GN, cryoglobulinemia, low serum levels of C3 and/or C4, hypergammaglobulinemia, monoclonal gammopathy, lymphopenia, and presence of germinal centers in salivary gland biopsies (Table 55.6).[23] Thus close follow-up is required for these patients. Histologically, NHLs in the context of SS are usually mucosa-associated lymphoid tissue (MALT) lymphomas followed by nodal marginal zone and diffuse large B-cell lymphomas (DLBCLs). It is usually extranodal and is encountered in the salivary glands. However, other tissues/organs, such as the stomach or the lungs, can also be involved. The course of localized MALT in SS is usually benign and watch-and-wait policy is often followed. However, more aggressive treatment is needed especially for DLBCLs (see Therapy section).

Overlapping Autoimmune Entities and Comorbidities

Sicca symptomatology (dry eyes and dry mouth) is seen in other autoimmune rheumatic diseases (ARDs) as well, such as RA, SLE, and SSc. The term "secondary SS" has been adopted

TABLE 55.6 Prognostic Factors for Lymphoma Development in Sjögren's Syndrome

Clinical
Tongue atrophy
Salivary (usually parotid) gland enlargement
Lymphadenopathy
Splenomegaly
Palpable purpura
Peripheral neuropathy
Glomerulonephritis
Serologic
Cryoglobulinemia
Low levels of serum C3 and/or C4
Hypergammaglobulinemia
Monoclonal gammopathy
Lymphopenia
Histopathologic
Germinal centers in salivary gland biopsy

to describe these clinical situations. However, criticism has been raised whether this is indeed secondary to other ARD or a true overlap. In RA, sicca symptomatology is present in approximately 30% of the patients. Positive findings in MSGB are rare. It seems that the lesion composition in MSGB is different between SS and RA-sicca patients. In the context of SLE, patients with sicca symptoms have distinct clinical, serologic, pathologic, and immunogenetic characteristics that are similar to SS. Similarly, comparable antibody and histopathology profiles as well as frequencies of sicca symptomatology were found between patients with SS and those with dry eyes/dry mouth in the context of SSc.[24] Therefore the term "secondary SS" tends to be abandoned.

Like in other ARDs, patients with SS are currently recognized to have a higher burden of cardiovascular disease. A recent meta-analysis showed that SS patients compared with controls had increased risk for coronary, cerebrovascular, and thromboembolic events as well as for heart failure.[25] Along the same lines, data are accumulating that SS is associated with arterial stiffness and subclinical atherosclerosis, as measured by pulse wave velocity (PWV) and intima-media thickness (IMT).[4,26]

THERAPY

Therapeutic management of SS is complex, especially when severe extraglandular manifestations occur and often requires collaboration with other disciplines and specialties, such as dentists, ophthalmologists, hematologists, and others. Compared with other autoimmune diseases, there are not many randomized controlled trials (RCTs) assessing treatment options for SS. However, the EULAR 2019 recommendations for management of SS have been published. This paper, along with the respective systemic literature review, comprehensively addresses therapeutic options for SS.[27,28]

Treatment in SS aims mainly to alleviate clinical symptomatology and to prevent complications such as dental caries and mouth candidiasis. As outlined later, topical treatment for dry eyes and dry mouth is the first line of treatment, and immunosuppressants/immunomodulators and biologic drugs may be given in patients with active systemic disease.[28]

Glandular Manifestations

Eye lubricants containing either sodium hyaluronate or hydroxypropylmethylcellulose and preservative-free natural tears are used for dry eyes. In severe cases, referral should be made to ophthalmologists. The latter might prescribe cyclosporine drops (0.05%) or more rarely nonsteroidal antiinflammatory drugs (NSAIDs) or glucocorticoid drops. Future studies will define whether topical tacrolimus could also be an option. Immunosuppressive/immunomodulatory treatments are not recommended for ocular dryness.[27,28]

For oral dryness the following is suggested: meticulous oral hygiene, saliva substitutes, and local (sugar-free gum, citrus juice, xylitol, lozenges) and/or systematic (pilocarpine and cevimeline, both are muscarinic M3 receptor agonists) stimulation of salivary secretion. In patients who cannot tolerate or do not respond to muscarinic agonists, choleretic (e.g., anetholtrithione) or mucolytic (e.g., bromhexine, N-acetylcysteine) agents may be considered.[28] Moist heat and NSAIDs are also suggested as a treatment option in SS patients with PGE.[10]

KEY CONCEPTS

Treatment of Sjögren's Syndrome

1. Topical treatment is preferred for ocular and oral dryness
2. For systemic disease: glucocorticoids, immunosuppressants (e.g., azathioprine) and biologic drugs might be used
3. Glucocorticoids: keep at the minimum dose and length of treatment duration
4. No hard evidence in favor of a specific immunosuppressant
5. B-cell targeted treatment for manifestations in which vasculitis is the underlying pathogenetic mechanism and for lymphoproliferative disease
6. For lymphoproliferative disease: stratify according to type and stage

Extraglandular Manifestations

Arthralgias/Arthritis

For arthralgias/arthritis, evidence is limited and in some cases contradictory. Analgesics and short courses of NSAIDs are the first line of treatment. Low doses of glucocorticoids, hydroxychloroquine, and/or methotrexate (0.2 mg/kg/week) can also be administered, although data to support their use are inadequate. In refractory arthritis, treatment with anti-CD20 therapy could be considered.[27,28] In addition, as stressed in the recent EULAR 2019 recommendations, arthritis should be distinguished from noninflammatory pain and/or fibromyalgia. For the latter, exercise and/or antidepressants may be beneficial.[28]

Other Extraglandular Manifestations

No well-designed RTCs exist, but the following recommendations have been made for the management of active disease: start with glucocorticoids. Minimum dose and treatment duration are advised. In case of nonresponse or adverse events, glucocorticoid-sparing agents (e.g., azathioprine, methotrexate) and/or biologic treatment (rituximab) can be added. Treatment of NHL in the context of SS ranges from a watch-and-wait policy for low-grade lymphomas limited in exocrine glands to chemotherapy (mainly with B cell–depleting agents). Radiotherapy might also be considered for specific types of lymphomas.[27,28] Therapeutic decisions are based on the histologic type and the extent of the LPD.

Biologic Treatments

With regards to biologics, treatment with TNF inhibitors have failed in SS, both in terms of sicca symptomatology as well as re-
