PART X Transplantation

PART XI Diagnostic Immunology

PREFACE TO THE FIRST EDITION

Clinical immunology is a discipline with a distinguished history, rooted in the prevention and treatment of infectious diseases in the late nineteenth and early twentieth centuries. The conquest of historical scourges such as smallpox and (substantially) polio and relegation of several other diseases to the category of medical curiosities is often regarded as the most important achievement of medical science of the past fifty years. Nevertheless, the challenges facing immunologists in the efforts to control infectious diseases remain formidable; HIV infection, malaria, and tuberculosis are but three examples of diseases of global import that elude control despite major commitments of monetary and intellectual resources.

Although firmly grounded in the study and application of defenses to microbial infection, since the 1960s, clinical immunology has emerged as a far broader discipline. Dysfunction of the immune system has been increasingly recognized as a pathogenic mechanism that can lead to an array of specific diseases and failure of virtually every organ system. Paradoxically, although the importance of the immune system in disease pathogenesis is generally appreciated, the place of clinical immunology as a practice discipline has been less clear. As most of the noninfectious diseases in the human immune system eventually lead to the failure of other organs, it has been organ-specific subspecialists who have usually dealt with their consequences. Recently, however, the outlook has begun to change as new diagnostic tools increasingly allow the theoretical possibility of intervention much earlier in disease processes, often before irreversible target organ destruction occurs. More importantly, this theoretical possibility is increasingly realized as clinical immunologists find themselves in the vanguard of translating molecular medicine from laboratory bench to patient bedside.

In many settings, clinical immunologists today function as primary care physicians in the management of patients with immune-deficiency, allergic, and autoimmune diseases. Indeed many influential voices in the clinical disciplines of allergy and rheumatology support the increasing coalescence of these traditional subspecialties around their intellectual core of immunology. In addition to his or her role as a primary care physician, the clinical immunologist is increasingly being looked to as a consultant, as scientific and clinical advances enhance his or her expertise. The immunologist with a "generalist" perspective can be particularly helpful in the application of unifying principles of diagnosis and treatment across the broad spectrum of immunologic diseases.

Clinical Immunology: Principles and Practice has emerged from this concept of the clinical immunologist as both primary care physician and expert consultant in the management of patients with immunologic diseases. It opens in full appreciation of the critical role of fundamental immunology in this rapidly evolving clinical discipline. Authors of basic science chapters were asked, however, to cast their subjects in a context of clinical relevance. We believe the result is a well-balanced exposition of basic immunology for the clinician.

The initial two sections on basic principles of immunology are followed by two sections that focus in detail on the role of the immune system in defenses against infectious organisms. The approach is two-pronged. It begins first with a systematic survey of immune responses to pathogenic agents followed by a detailed treatment of immunologic deficiency syndromes. Pathogenic mechanisms of both congenital and acquired immune deficiency diseases are discussed, as are the infectious complications that characterize these diseases. Befitting its importance, the subject of HIV infection and AIDS receives particular attention, with separate chapters on the problem of infection in the immunocompromised host, HIV infection in children, anti-retroviral therapy, and current progress in the development of HIV vaccines.

The classic allergic diseases are the most common immunologic diseases in the population, ranging from atopic disease to drug allergy to organ-specific allergic disease (e.g., of the lungs, eye, and skin). They constitute a foundation for the practice of clinical immunology, particularly for those physicians with a practice orientation defined by formal subspecialty training in allergy and immunology. A major section is consequently devoted to these diseases, with an emphasis on pathophysiology as the basis for rational management.

The next two sections deal separately with systemic and organ-specific immunologic diseases. The diseases considered in the first of these sections are generally regarded as the core practice of the clinical immunologist with a subdisciplinary emphasis in rheumatology. The second section considers diseases of specific organ failure as consequences of immunologically mediated processes that may involve virtually any organ system. These diseases include, as typical examples, demyelinating diseases, insulin-dependent diabetes mellitus, glomerulonephritides, and inflammatory bowel diseases. It is in the management of such diseases that the discipline of clinical immunology will have an increasing role as efforts focus on intervention early in the pathogenic process and involve diagnostic and therapeutic tools of ever-increasing sophistication.

One of the major clinical areas in which the expertise of a clinical immunologist is most frequently sought is that of allogeneic organ transplantation. A full section is devoted to the issue of transplantation of solid organs, with an introductory chapter on general principles of transplantation and management of transplantation rejection followed by separate chapters dealing with the special problems of transplantation of specific organs or organ systems.

Appreciation of both the molecular and clinical features of lymphoid malignancies is important to the clinical immunologist regardless of subspecialty background, notwithstanding the fact that primary responsibility for the management of such patients will generally fall to the hematologist/oncologist. A separate section is consequently devoted to the lymphocytic leukemias and lymphomas that constitute the majority of malignancies seen in the context of a clinical immunology practice. The separate issues of immune responses to tumors and immunological strategies to treatment of malignant diseases are subjects of additional chapters.

Another important feature is the attention to therapy of immunologic diseases. This theme is constant throughout the chapters on allergic and immunologic diseases, and because of the importance the editors attach to clinical immunology as a therapeutic discipline, an extensive section is also devoted specifically to this subject. Subsections are devoted to issues of immunologic reconstitution, with three chapters on the treatment of

immunodeficiencies, malignancies, and metabolic diseases by bone marrow transplantation. Also included is a series of chapters on pharmaceutical agents currently available to clinical immunologists, both as anti-allergic and anti-inflammatory drugs, as well as newer agents with greater specificity for T cell-mediated immune responses. The section concludes with a series of chapters that address established and potential applications of therapeutic agents and approaches that are largely based on the new techniques of molecular medicine. In addition to pharmaceutical agents, the section deals in detail with such subjects as apheresis, cytokines, monoclonal antibodies and immunotoxins, gene therapy, and new experimental approaches to the treatment of autoimmunity. The book concludes with a section devoted to approaches and specific techniques involved in the diagnosis of immunologic diseases. The use of the diagnostic laboratory in the evaluation of complex problems of immunopathogenesis has been a hallmark of the clinical immunologist since the inception of the discipline, and many clinical immunologists serve as directors of diagnostic immunology laboratories. Critical assessment of the utilization of techniques ranging from lymphocyte cloning to flow cytometric phenotyping to molecular diagnostics is certain to continue as an important function of the clinical immunologist, particularly in his or her role as an expert consultant.

In summary, we have intended to provide the reader with a comprehensive and authoritative treatise on the broad subject of clinical immunology, with particular emphasis on the diagnosis and treatment of immunological diseases. It is anticipated that the book will be used most frequently by the physician specialist practicing clinical immunology, both in his or her role as a primary physician and as a subsequent consultant. It is hoped, however, that the book will also be of considerable utility to the non-immunologist. Many of the diseases discussed authoritatively in the book are diseases commonly encountered by the generalist physician. Indeed, as noted, because clinical immunology involves diseases of virtually all organ systems, competence in the diagnosis and management of immunological diseases is important to virtually all clinicians. The editors would be particularly pleased to see the book among the references readily available to the practicing internist, pediatrician, and family physician.

PREFACE TO THE SIXTH EDITION

At the time this preface was prepared, our world was being arguably faced with its worst infectious pandemic since the global influenza A infection of the early 20th century. That pandemic infected ~500 million people, or ~1/3 of the total world population, and caused at least 50 million deaths. The current 21st century COVID-19 pandemic was estimated in September 2021 to have infected >230 million individuals out of 7.7 billion (~3%), causing ~4.71 million deaths; and these numbers are also staggering and are necessarily incomplete. But as we learn more about the prevention, diagnosis, and care of persons with COVID-19 infections (both symptomatic and asymptomatic), we have reason to believe that despite the enormous case load, we will not approach the death rate of the 1918–20 pandemic.

This improved survival reflects in part the knowledge that has been gained over the past century from research in immunology, which has been contributed by investigators and clinicians throughout the world. This knowledge has advanced our ability to prevent and manage pandemics in general, giving us hope to face future emerging infectious disease challenges as well.

Although clinical immunology and this book are strongly grounded in the study of and application to microbial infections, both the book and the discipline are far broader. Dysfunction of the immune system is recognized as a pathogenic mechanism that can lead to diseases and failure of virtually every organ system. Fortunately, advances in the prevention and treatment of immunologic diseases also offer enhanced intervention, often before irreversible target organ damage or destruction has occurred. Thus, clinical immunologists are frequently in the vanguard of translating molecular medicine from the laboratory bench to the patient bedside.

In the United States, clinical immunologists often function as primary care providers for patients with a wide variety of disorders of immune function, including immune deficiency, allergic disease, and autoimmunity. As a result, although clinical immunology has not been constituted in this country as a formal subspecialty, many influential voices in the "official" disciplines of allergy and rheumatology regard themselves foremost as clinical immunologists. We trust that this textbook will prove useful to both clinical generalists and clinical immunology subspecialists.

The book opens with three sections dedicated to the fundamental sciences that underlie clinical immunology. However, authors of the basic science chapters were asked to cast their chapters in a context of clinical relevance. We believe this has been accomplished. The basic science chapters are followed by sections on Immune Deficiency and Immune Regulatory Disorders; Allergic Diseases; Systemic Immune Diseases; Organ-Specific Inflammatory Disorders; Immunology and Immunotherapy of Neoplasia; Medical Management of Immunologic Diseases; Transplantation of Tissues and Organs; and the Technologies of Diagnostic Immunology.

We have preserved features in the book that were well received in previous editions. Chapters are generously illustrated, and all chapters contain a Key Concepts summary Box (commonly in bulleted form) as well as an *On the Horizon* box, in which authors look to research opportunities for important advances over the next five to ten years. Furthermore, due to the extraordinarily cross-disciplinary nature of clinical immunology, it is our hope that investigators working in one area might find new ideas and opportunities in the *On the Horizon* boxes outside their primary area of focus. Other boxes similarly summarize content with *Clinical Relevance, Clinical Pearls*, and *Therapeutic Principles*.

Now in its 6th edition since it was first published in 1996, this book represents the achievements and provides access to the expertise of ~200 individual contributors. As editors, we are deeply grateful for the thousands of hours of work put into this effort by our colleagues in Clinical Immunology around the globe. We also note the exceptional support that the preparation of this edition has received from publishing experts at Elsevier, in particular Robin Carter, Louise Cook, Jennifer Ehlers, and Andrew Riley. Thank you so much, Robin, Louise, Jennifer, and Andrew. The task would have been impossible without your expertise.

The Human Immune Response

Robert R. Rich and Randy Q. Cron

Clinical immunology is a medical subspecialty largely focused on a specific physiologic process, inflammation, which is essential to good health, particularly in defense against pathogenic organisms, recovery from injury, and containment of neoplasms. However, inflammation, which is mediated by the cells and soluble products of the immune system, is also a powerful contributor to the pathogenesis of diseases that affect virtually every organ system. A consequent challenge for clinical immunologists, both clinicians and basic scientists, is to reduce a dizzying array of disease descriptions to a systematic understanding of pathogenic mechanisms in order to facilitate translation of fundamental concepts and new discoveries into more effective disease prevention or treatment.

This introductory chapter is directed to nonimmunologist clinicians and researchers. It is structured as an introduction to the interacting elements of the human immune system and their disordered functions in diseases. The subtleties, including immunologic or molecular genetic jargon unavoidably used, are described in detail in the chapters that follow.

THE HOST-MICROBE INTERACTION

The vertebrate immune system is a product of eons of evolutionary relationships between rapidly evolving microbial organisms and their much less rapidly reproducing, and hence less adaptable, hosts.[1] In general, the relationship is mutually beneficial, each providing nutrients and other materials essential to the well-being of their partner—the host and its microbiome (Chapter 22). Occasionally, however, a normally beneficial relationship becomes pathologic. Pathogenic microbes can overwhelm the microbiome, invade host tissues, and result in host morbidity or even death. Because the vertebrate host cannot win a battle with microbial invaders by rapid mutation and selection, the immune system uses a strategy of complexity and redundancy, which involves both the individual organism and its collective population.

Reflecting plasticity of the response, specific defenses differ, depending on the nature of the infectious agent and its point of entry and distribution within the body. Regardless of the defense mechanism, an intended outcome is destruction or neutralization of the invading organism. However, a secondary consequence can be collateral damage to host cells. These unfortunate cells can be targeted for damage because they are sites of microbial residence and replication, or they can be damaged as "innocent bystanders." Depending on the site and severity of the host's defensive response, it may be accompanied by local and/or systemic symptoms and signs of inflammation, which may lead to long-lasting tissue dysfunction as a result of tissue remodeling and partial repair.

Adaptive and Innate Immunity

Immune responses are traditionally classified as adaptive (also termed *acquired* or *specific*) and innate (or *nonspecific*) (Table 1.1). The adaptive immune system, present uniquely in species of the phylum Chordata, is specialized for development of an inflammatory response based on recognition of specific "foreign" macromolecules that are predominantly, but not exclusively, proteins, peptides, and carbohydrates. The vast majority of chordate species are jawed vertebrates, and this book addresses adaptive immunity of that subphylum. Its primary effectors are antibodies, B lymphocytes, T lymphocytes, innate lymphoid cells (ILCs), and antigen-presenting cells (APCs). T and B lymphocytes express surface antigen receptors that are clonally specific as a consequence of receptor-gene rearrangements. Expansion of clones of lymphocytes specific for any particular antigen is induced by antigen encounter and consequent activation and proliferation, thereby constituting the basis of immunologic memory.

Innate immune responses are phylogenetically far more ancient, being widely represented in multicellular phyla.[2] Rather than being based on exquisitely specific recognition of a diverse array of macromolecules (i.e., antigens), they are focused on recognition of common molecular signatures of microbial organisms that are not present in vertebrates (Chapter 3).[3] Among these structures, which are termed *pathogen-associated molecular patterns* (PAMPs) or *danger-associated molecular patterns* (DAMPs), are bacterial cell wall constituents, such as mannose-rich oligosaccharides, lipopolysaccharides, peptidoglycans, and several nucleic acid variants, including double-stranded RNA and unmethylated CpG DNA. For both innate and adaptive immune responses, defense effector mechanisms can require either direct cell-to-cell contact or the activity of cytokines (Chapter 14) and chemokines (Chapter 15), which are hormone-like soluble molecules that act in the cellular microenvironment (cell-mediated immunity). Most immune responses include participation of both modes of response.[2–4]

The elements of innate immunity are diverse. They include physical barriers to pathogen invasion (e.g., skin, mucous membranes, cilia, and mucus), as well as an array of cellular and soluble factors that can be activated by secreted or cell surface products of the pathogen, including PAMPs. Recognition of PAMPs by cells in innate immunity, which also commonly function as APCs to the lymphocytes of adaptive immunity, is via cell membrane or cytoplasmic receptors known as pattern recognition receptors (PRRs). PRRs can be either membrane bound or cytoplasmic. Membrane-bound PRRs include Toll-like receptors (TLRs) and C-type lectin receptors (CLRs). Humans express 10 distinct TLRs, which recognize (among others) specific bacterial glycolipids, lipopolysaccharide; viral single-stranded

TABLE 1.1 Features of Innate and Adaptive Immune Systems

Distinguishing Features	
Innate Immunity	**Adaptive Immunity**
Germline-encoded receptors targeting pathogen molecular patterns	Clonally variable receptors generated somatically by rearrangement of gene elements
Does not require immunization	Consequence of B- and/or T-cell activation
Limited memory	Immunologic memory well developed
Includes physical barriers to pathogen	Antibody and cytotoxic T cells

Common Features

Cytokines and chemokines
Complement cascade
Phagocytic cells
Natural killer (NK) cells
"Natural" antibodies

RNA; and bacterial and viral unmethylated CpG DNA. CLRs are particularly important in antifungal innate immunity but also have important roles in defenses against bacteria, viruses, and parasites. They comprise a large family that commonly recognizes microbe-specific carbohydrate ligands or structurally similar lectin-like domains. Cytoplasmic PRRs include RIG-1–like receptors (RLRs) and nucleotide oligomerization domain (NOD)-like receptors (NLRs). RLRs are involved in recognition of viruses through interaction with intracytoplasmic viral double-stranded RNA (dsRNA), and NLRs recognize bacterial peptidoglycan motifs.[4]

Cells of the innate immune system are commonly triggered through activation of the nuclear factor-κB (NF-κB) transcription factor via the MyD88 signaling pathway, thereby inducing an inflammatory response using mechanisms that are broadly shared with those of the adaptive immune system. These include activation of various types of ILCs (e.g., natural killer [NK] cells [Chapter 12]), which are characterized by absence of clonally expressed receptors for specific antigen (see later), activation of granulocytes and other phagocytes (Chapter 39), the secretion of inflammatory cytokines and chemokines, and interactions of the many participants in the complement cascade (Chapter 40). In addition, activation of cells of innate immunity that also act as APCs for the adaptive immune system results in upregulation of membrane molecules such as CD80 and CD86 (among others) that provide the second signal, which along with the T-cell receptor (TCR) for antigen (Chapter 4), can activate antigen-specific T cells (Chapter 10).[5]

Finally, because recognition of pathogens by the innate immune system relies on germline encoded, non-rearranged receptors held in common by the specific cell type, innate immunity is more rapidly responsive. It can initiate in minutes to hours and generally precedes development of a primary adaptive immune response by at least several days.

CELLS OF THE IMMUNE SYSTEM

The major cellular constituents of both innate and adaptive immunity originate in bone marrow, where they differentiate from multipotent hematopoietic stem cells (HSCs) along several pathways to become granulocytes, lymphocytes, and APCs (Chapter 2).

Granulocytes

Polymorphonuclear leukocytes (granulocytes) are classified by light microscopy into four types. By far the most abundant in the peripheral circulation are neutrophils, which are principal effector cells linking the innate and adaptive responses by virtue of their expression of surface receptors for antibody and complement (Chapter 40). They are phagocytic cells that ingest, kill, and degrade microbes and other targets of an immune attack within specialized cytoplasmic vacuoles that contain potent antimicrobial enzymes and oxidative pathways. The phagocytic activity of neutrophils is promoted by their surface display of receptors for antibody molecules (specifically the Fc portion of immunoglobulin G [IgG] molecules) (Chapter 8) and activated complement proteins (particularly the C3b component) (Chapter 40). Neutrophils are the predominant cell type in acute inflammatory infiltrates and are the primary effector cells in immune responses to pyogenic bacteria (Chapter 27).

Eosinophils (Chapter 45) and basophils (Chapter 44) are the other circulating forms of granulocytes. A close relative of the basophil, but derived from distinct bone marrow precursors, is the tissue mast cell, which does not circulate in blood. Eosinophils, basophils, and mast cells are important in defenses against multicellular pathogens, particularly helminths (Chapter 30). Their defensive functions are not based on phagocytic capabilities but on their ability to discharge potent biologic mediators from their storage granules into the cellular microenvironment. This process, termed *degranulation*, can be triggered by antigen-specific IgE molecules that bind to basophils and mast cells via high-affinity receptors for the Fc portion of IgE (FcεR) on their surfaces. In addition to providing a mechanism for anthelmintic host defenses and certain antibacterial responses, this is also the principal mechanism involved in acute (IgE-mediated) allergic reactions (Chapters 43–50).

Lymphocytes

Three broad categories of lymphocytes are identified on the basis of display of particular surface molecules: B cells, T cells, and ILCs. Each of these categories can be further subdivided according to specific function and display of distinguishing cell surface molecules (Chapter 2). All lymphocytes differentiate from common lymphoid stem cells in bone marrow. B cells create their Ig receptors in bone marrow and differentiate into antibody-producing cells in the periphery (Chapter 7). T-cell precursors move from bone marrow to the thymus (or, in some cases, to extrathymic tissue compartments), where they complete their differentiation and selection (Chapter 9).

T cells and B cells are the heart of immune recognition, a property reflecting their clonally specific cell surface receptors for antigen (Chapter 4). The TCR is a heterodimeric integral membrane molecule expressed exclusively by T lymphocytes. B-cell receptors (BCRs) for antigen are membrane immunoglobulin (mIg) molecules of the same antigenic specificity that the B cell and its terminally differentiated progeny, plasma cells, will secrete as soluble antibodies. Memory B cells and nondividing, long-lived plasma cells may account substantially for persistence of antibody responses (including production of autoantibodies) over many years.[6]

Receptors for "antigen" on the third class of lymphocytes, ILCs, are not clonally expressed. ILCs are subdivided into three major groups according to the cytokines that they produce. For example, group 1 ILCs, including NK cells, produce interferon-γ (IFN-γ) and tumor necrosis factor (TNF).[7] ILCs express receptors

for PAMPs and, as such, serve as major effectors of innate immunity. They also recognize target cells that might otherwise elude the immune system (Chapters 2 and 12). Thus recognition of NK cell targets is based substantially on what their targets lack rather than on what they express.

NK cells express receptors of several types for major histocompatibility complex (MHC) class I molecules via killer immunoglobulin-like receptors (KIRs).[8] KIRs are expressed on the plasma membrane of NK cells (and some T cells), which interact with class I molecules to alter NK-cell cytotoxic function. Most KIRs express in their intracellular domain a tyrosine-based inhibitory motif (ITIM) that suppresses NK activity, thereby preventing NK cell activity directed against normal self-cells. In contrast, some KIRs express a tyrosine-based activation motif (ITAM), which amplifies their activity. NK cells will kill target cells unless they receive an inhibitory signal transmitted by an ITIM receptor. Virus-infected cells and tumor cells that attempt to escape T-cell recognition by downregulating their expression of class I molecules become susceptible to NK cell–mediated killing because the NK cells receive an activation signal and/or fail to receive an inhibitory signal through the ITAM- and ITIM-containing MHC class I receptors. The balance between ITIM and ITAM is regulated by the microenvironmental milieu, increasing expression of ITAM in the presence of virus-infected or cancer cells and of ITIM as necessary to maintain self-tolerance and prevent autoimmunity. A high frequency of ITAM-expressing cells has been reported in some patients with autoimmune diseases.[9]

Although NK cell–mediated innate immunity has been long considered to lack immunologic memory, studies suggest that NK cells can exhibit memory of previous encounters with microbes or other antigens, the molecular basis of which remains to be fully elucidated.[10] NK cells can also participate in antigen-specific immune responses by virtue of their surface display of the activating ITAM receptor CD16, which binds the constant (Fc) region of IgG molecules. This enables them to function as effectors of a cytolytic process termed *antibody-dependent cellular cytotoxicity* (ADCC), a mechanism exploited clinically with monoclonal antibody (mAb) therapeutic agents.[11]

In general, pathways leading to differentiation of T cells, B cells, and ILCs are mutually exclusive, representing a permanent lineage commitment. No lymphocytes express both mIg and TCRs. However, a subset of T cells, termed *NKT cells*, exhibit both NK-like cytotoxicity and αβ TCR with limited receptor diversity.

Antigen-Presenting Cells

KEY CONCEPTS

Features of Antigen-Presenting Cells

- Capacity for uptake and partial degradation of protein antigens
- Expression of major histocompatibility complex (MHC) molecules for binding antigenic peptides
- Chemokine receptors to allow colocalization with T cells
- Expression of accessory molecules for interaction with T cells
- Receptors for pathogen- or danger-associated molecular patterns
- Secretion of cytokines that program T helper (Th) cell responses

A morphologically and functionally diverse group of cells, all of which are derived from bone marrow precursors, is specialized for presentation of antigen to lymphocytes, particularly T cells (Chapter 6). Included among such cells are dendritic cells (DCs), monocytes (present in the peripheral circulation), macrophages (solid tissue derivatives of monocytes), cutaneous Langerhans cells (Chapter 23), and constituents of the reticular endothelial system within solid organs. B lymphocytes that specifically capture antigen via their clonally expressed mIg can also function efficiently in antigen presentation to T cells.

Cardinal features of APCs include their expression of both class I and class II MHC (Chapter 5) molecules as well as requisite accessory molecules for T-cell activation (e.g., B7-1, B7-2/CD80, CD86). Upon activation, APC elaborate cytokines that induce specific responses in cells to which they are presenting antigen. In addition to processing and presenting antigen, APCs can regulate activation of the immune system via innate cell surface receptors, which contribute to determination of whether the antigen is pathogen associated.

APCs differ substantially among themselves with respect to mechanisms of antigen uptake and effector functions. Immature DCs show high phagocytic and pathogen-killing activity but low ability to present antigen and activate T cells. DCs that have ingested a pathogen or foreign antigen can be induced to mature by inflammatory stimuli,[12,13] especially via cells of the innate immune system and by direct activation through receptors for PAMPs or DAMPs. Monocytes and macrophages are actively phagocytic, particularly for antibody and/or complement-coated (opsonized) antigens that bind to their surface receptors for IgG and C3b. These cells are also important effectors of immune responses, especially in sites of chronic inflammation. Upon further activation by T-cell cytokines, they can kill ingested microorganisms by oxidative pathways similar to those used by polymorphonuclear leukocytes.

The interaction between B cells acting as APCs and T lymphocytes is notable because the cells are involved in a mutually amplifying circuitry of antigen presentation and response. The process is initiated by antigen capture through B-cell mIg and ingestion by receptor-mediated endocytosis. This is followed by proteolytic antigen degradation and then display to T cells as oligopeptides bound to MHC molecules. Like other APCs, B cells display CD80 and thus provide a requisite second signal to the antigen-responsive T cell via CD28, its accessory molecule for activation (Fig. 1.1; Chapters 4 and 10). As a result of T-cell activation, T-cell cytokines that regulate B-cell differentiation and antibody production are produced. T cells are stimulated to display the surface ligand CD40L (CD154), which can serve as the second signal for B-cell activation through its inducible surface receptor.

BASIS OF ADAPTIVE IMMUNITY

The essence of adaptive immunity is molecular distinction between self constituents and potential pathogens. For simplicity, this is typically summarized as self/nonself discrimination. However, more precisely the issue is one of discrimination between molecular species that are perceived as signaling potential "danger" versus those that are not. This discrimination is a major responsibility of both T cells, B cells, and cells of the innate immune system. This process is more complicated for T cells because it reflects the selection of thymocytes that have generated specific antigen receptors that can bind to self-antigens below a certain threshold of activation and then, upon later encounter, can bind nonself antigenic peptides bound to self-MHC molecules and be activated to engage in effector function.

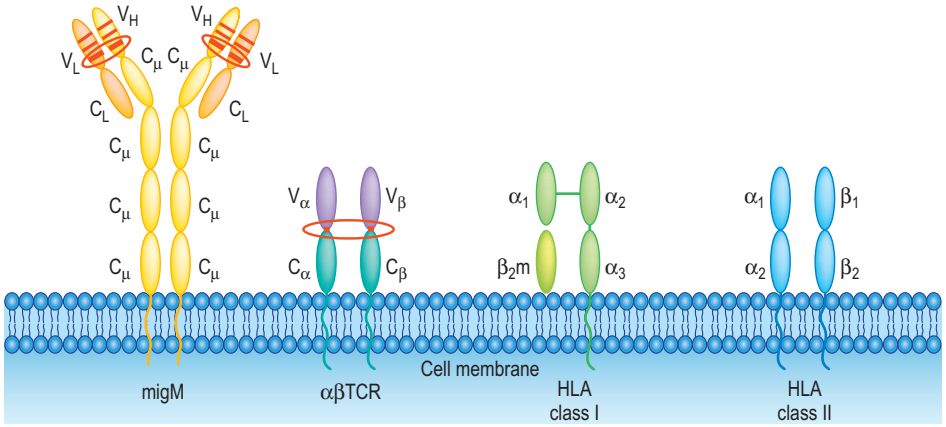

FIG. 1.1 Antigen-Binding Molecules. Antigen-binding pockets of immunoglobulin (Ig) and T-cell receptor (TCR) comprise variable *(V) segments of two chains translated from transcripts that represent rearranged V(D)J or VJ gene elements. Thin red bars* designate two of the complementarity determining regions (CDRs) that form portions of the Ig antigen-binding site. The *red ovals with thick red bars designate the regions of very high sequence variability in both Igs and TCRs that are generated by r*ecombination of the 3′-end of the V gene element with the D and J gene elements or with the J gene element. In the Ig molecule this is designated CDR3. Antigen-binding pockets of Ig molecules are formed by the three-dimensional folding of the heavy and light chains that juxtapose the CDRs of one heavy chain and one light chain. Antigen-binding grooves of MHC molecules are formed with contributions from α_1 and β_1 domains of class II molecules and from α_1 and α_2 domains of class I molecules. All of these molecules are members of the immunoglobulin superfamily. *β_2m*, β_2-Microglobulin; *C*, constant-region domain; *HLA*, human leukocyte antigen; *MHC*, major histocompatibility complex; *mIgM*, membrane immunoglobulin M.

More subtly, the consequence of this selection process is that foreign proteins are recognized as antigens in terms of their ability to initiate an active immune response, whereas self-proteins are tolerated (i.e., are not perceived as antigens). B cells that express self-reactive antibodies are subjected to negative selection in the bone marrow and the periphery. Through PAMPs/DAMPs and other, still undefined, mechanisms, the cells of innate immunity contribute to the essential distinction between commensal (not dangerous) and potentially pathogenic (dangerous) microbes.

T lymphocytes generally recognize antigens as a complex of short linear peptides bound to self-MHC molecules on the surfaces of APCs (Chapter 6). The source of these peptides can be either extracellular or intracellular proteins, and they can be derived from either self or foreign (e.g., microbial) molecules. With the exception of superantigens (SAgs; see later), T cells neither bind antigen in native conformation nor recognize free antigen in solution. The vast majority of antigens for T cells are oligopeptides. However, the antigen receptors of NKT cells can recognize lipid and glycolipid antigens that are presented to them by MHC-like CD1 molecules.[14]

Antigen recognition by T cells differs fundamentally from that by antibodies, which are produced by B lymphocytes and their derivatives. Antibodies are oriented toward recognition of extracellular threats and, unlike T cells, can bind complex macromolecules in their native conformation at cell surfaces or in solution. Moreover, antibodies show less preference for recognition of proteins; antibodies against carbohydrates, nucleic acids, lipids, and simple chemical moieties can be readily produced. Although B cells can also be rendered unresponsive by exposure to self-antigens, particularly during differentiation in bone marrow, this process does not define foreignness within the context of self-MHC recognition.

Clonal Basis of Immunologic Memory

An essential element of self/nonself discrimination is the clonal nature of antigen recognition. Although the immune system can recognize a vast array of distinct antigens, all of the receptors of a single T cell or B cell (and their clonal progeny) have identical antigen-binding sites and hence a particular specificity (Chapter 4). A direct consequence is the capacity for antigen-driven immunologic memory. This phenomenon derives from the fact that, after an initial encounter with antigen, clones of lymphocytes that can recognize the antigen proliferate and differentiate into effector cells. After interaction with their target, most of these effector cells are consumed or undergo programed cell death. However, a smaller population of long-lived memory cells persists. These memory cells constitute a pool of cells larger than the initial naïve responders. They can elicit a greater and more rapid response upon subsequent antigen encounter. These two hallmarks of adaptive immunity, clonal specificity and immunologic memory, provide a conceptual foundation for the use of vaccines in prevention of infectious diseases (Chapter 87).

Immunologic memory involves not only the T cells charged with antigen recognition but also the T cells and B cells that mediate the efferent limb of an inflammatory response. In its attack on foreign targets, the immune system can exhibit exquisite specificity for the inducing antigen, as is seen in the epitope-specific lysis of virus-infected target cells by cytolytic T cells.

ANTIGEN-BINDING MOLECULES

KEY CONCEPTS

Features of the Immunoglobulin (Ig) Superfamily

- Large family of ancestrally related genes (more than 100 members)
- Most products involved in immune system function or other cell-cell interactions
- Ig superfamily members have one or more domains of ~100 amino acids, each usually translated from a single exon
- Each Ig domain consists of a pair of β-pleated sheets usually held together by an intrachain disulfide bond

Three sets of molecules are responsible for the specificity of adaptive immune responses by virtue of their capacity to bind foreign antigen. These are Igs, TCRs, and MHC molecules (see Fig. 1.1; Chapters 4 and 5). All are products of a very large family of ancestrally related genes, the Ig superfamily, which includes many other molecules essential to induction and regulation of immune responses.[15,16] Members of the Ig superfamily exhibit characteristic structural features. The most notable of these is organization into homologous domains of approximately 110 amino acids that are usually encoded by a single exon with an intradomain disulfide bond. These domains are characteristically configured as antiparallel strands, forming two opposing β-pleated sheets.

Immunoglobulins and T-Cell Receptors

The remarkable specificity of Ig and TCR molecules for antigen is achieved by a mechanism of genetic recombination that is unique to Ig and TCR genes (Chapter 4). The antigen-binding site of both types of molecules lies at the tip of the two juxtaposed, constituent polypeptides and contains contributions from each of the two. In the case of Igs, these are a heavy (H) chain and one of two alternative types of light (L) chains, κ or λ. In the case of TCRs, either of two alternative heterodimers can constitute the antigen-binding molecule, one composed of α and β chains, and the other of λ and δ chains. In the case of the TCR, this antigen-binding site is relatively flat, permitting association between the TCR and the MHC:peptide complex. In the case of Ig, the antigen-binding site can be concave, flat, or form a projection. This permits the Ig to bind to a variety of surface structures, including projections and nooks and crannies.

The polypeptides contributing to both Igs and TCRs can be divided into an antigen-binding amino-terminal variable (V) domain and one or more carboxy-terminal constant (i.e., nonvariable) domains. Ig constant region domains generally include specific sites responsible for the biologic effector functions of the antibody molecule (Chapter 8).

KEY CONCEPTS

Comparison of T- and B-Cell Receptors for Antigen

Similarities

- Members of the immunoglobulin (Ig) superfamily
- Each chain divided into variable and constant regions
- Variable regions constructed by V(D)J rearrangements
- Nongenomic N-nucleotide additions at V(D)J junctions
- Both polypeptide chains contribute to the antigen-binding site
- Exhibit allelic exclusion
- Negative selection against receptors with self-antigen specificity
- Transmembrane signaling involving coreceptor molecules

Differences

- Ig can be secreted; T-cell receptor (TCR) is not
- Ig recognizes conformational antigen (Ag) determinants; TCR recognizes linear determinants
- Ig can bind antigen in solution; TCR binds antigen when presented by a major histocompatibility complex (MHC) molecule on an antigen-presenting cell (APC)
- TCRs are positively selected for self-MHC recognition
- Somatic hypermutation of Ig genes can enhance antigen-binding affinity
- Ig genes can undergo isotype switching
- Ig constant domains express inflammatory effector functions

The most noteworthy feature of the jawed vertebrate immune system is the process of recombination-activating gene (RAG) mediated genetic recombination that generates a virtually limitless array of specific antigen receptors from a rather limited genomic investment. This phenomenon is accomplished by the recombination of genomic segments that encode the variable domains of Ig and TCR polypeptides (Chapter 4).[17] The products of these rearranged gene elements provide a specific B or T cell with its unique antigen receptor. The variable domain of the mature receptor is created by the rearrangement of two or three separate gene segments. These are designated V (variable) and J (joining), for IgL chains and TCR α and γ chains, and V, D (diversity) and J, for IgH and TCR β and δ chains. In addition to rearrangement, N-nucleotide addition also contributes substantially to receptor diversity. N-nucleotide addition results in the insertion, at the time of rearrangement, of one or more nongenomic nucleotides at the junctions between V, D, and J segments through the action of terminal deoxynucleotidyl transferase (TdT).[17] This permits receptor diversity to extend beyond germline constraints. Analysis of the linear sequences of many Ig V region domains has shown that they contain three sites of high sequence variability that have been designated *complementarity determining regions 1–3 (CDR1–3)* to indicate that they are the sites that contact antigen (see Fig. 1.1).

DNA rearrangement involved in generating TCRs and BCRs is controlled by recombinases that are active in early thymocytes and in B precursor cells in bone marrow. The process is sequential and carefully regulated, generally leading to translation of one receptor of unique specificity for any given T or B lymphocyte. This result is achieved through a process termed *allelic exclusion*, wherein only one member of a pair of allelic genes potentially contributing to an Ig or TCR molecule is rearranged at a time.[18]

The process of allelic exclusion is not absolute, and a small number of lymphocytes will express dual functional Ig or TCR transcripts and, in some cases, two distinct surface receptors. However, B cells exclusively rearrange Ig genes, not TCR genes, and vice-versa for T cells. Moreover, after producing a functional heavy chain, B cells sequentially rearrange L chain genes, typically κ before λ. Thus, in normal individuals, the vast majority of B cells express either κ or λ chains, with 1% or less expressing both. Similarly, thymocytes express α and β genes, or γ and δ genes.

There is one feature of V region construction that is essentially reserved to B cells. This is somatic hypermutation (SHM), a process that can continue at discrete times throughout the life of a mature B cell at both the $V_HD_HJ_H$ and V_LJ_L gene exons.[19,20] Because these rearranged gene exons encode the antigen-binding site that contains the specific points of contact with antigen, on occasion the random process of SHM will result in cells expressing mIg with increased affinity for the antigen they recognize. Typically, cells with increased affinity for antigen are activated preferentially, particularly at limiting doses of antigen. Thus the average affinity of antibodies produced during the course of an immune response tends to increase, a process termed *affinity maturation*.

TCRs do not show evidence of SHM. This absence may be related to the focus on selection in the thymus involving corecognition of a self-MHC molecule and self-peptides,[21] (Chapter 9) rather than the continuous process of antigen-driven selection in the periphery by B cells after SHM. Thymic selection results in deletion by apoptosis of the vast majority of differentiating

thymocytes by mechanisms that place stringent boundaries around the viability of a thymocyte with a newly expressed TCR specificity. Once a T cell is fully mature and ready for emigration from the thymus, its TCR is essentially fixed, reducing the likelihood of emergent autoimmune T-cell clones in the periphery.

Receptor Selection

The receptor expressed by a developing thymocyte must be capable of binding with low-level affinity to some particular MHC self-molecule, either class I or II, expressed by a resident thymic epithelial cell or APC. Because their receptors are generated by a process of semirandom joining of rearranging exon segments coupled with N-nucleotide additions, most thymocytes fail this test. They are consequently deleted as not being useful to an immune system that requires T cells to recognize antigen that is bound to self-MHC molecules. Thymocytes surviving this hurdle are said to have been "positively selected" (Fig. 1.2A).[21] Conversely, a small number of thymocytes bind with an unallowably high affinity for a combination of MHC molecule plus antigenic peptide expressed by a thymic APC. Because the peptides available for MHC binding at this site are derived almost entirely from self-proteins, differentiating thymocytes with such receptors are intrinsically dangerous as potentially autoimmune. This deletion of thymocytes with high-affinity receptors for self-MHC plus (presumptively) self-peptide is termed "negative selection" (see Fig. 1.2B),[21] a process that may also involve activity of regulatory T cells (Tregs; Chapter 13).[22,23]

Another feature that distinguishes B cells from T cells is that the cell surface antigen receptors of the former can be secreted in large quantities as antibody molecules, the effector functions of which are carried out in solution or at the surfaces of other cells. Secretion is accomplished by alternative splicing of Ig messenger RNAs (mRNAs) to include or exclude a transmembrane segment that is encoded by the Ig heavy-chain genes.

Immunoglobulin Class Switching

In addition to synthesizing both membrane and secreted forms of Igs, B cells also undergo class switching. Antibody molecules are composed of five major classes (isotypes). In order of abundance in serum, these are IgG, IgM, IgA, IgD, and IgE (Chapters 4 and 8). In humans the IgG class is further subdivided into four subclasses and the IgA class into two subclasses. The class of Ig is determined by the sequence of the constant region of its heavy chain (C_H). The H-chain constant region gene locus is organized with exons that encode each of the Ig isotypes and subclasses located downstream (3′) of the variable (V_H) genes. Thus an antibody-producing cell with a successfully rearranged $V_HD_HJ_H$ exon can change the class of antibody molecule that it

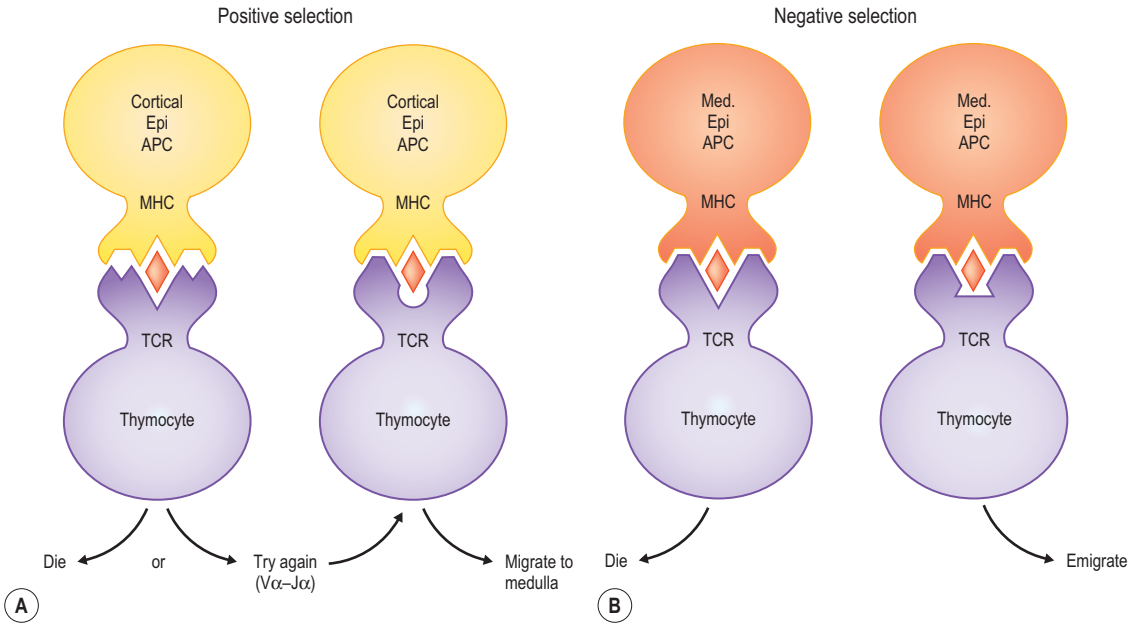

FIG. 1.2 Two-Stage Selection of Thymocytes Based on Binding Characteristics of Randomly Generated T-Cell Receptors. (A) *Positive selection.* "Double-positive" ($CD4^+$, $CD8^+$) thymocytes with T-cell receptors *(TCRs)* capable of *low* avidity binding to some specific self-MHC molecule (either class I or II) expressed by thymic cortical epithelial cells *(Epi)* are positively selected. This process may involve sequential attempts at α gene rearrangement to express an αβ TCR of appropriate self-MHC specificity. If binding is to a class I molecule, the positively selected thymocyte becomes CD8 single-positive, and if to a class II molecule, a CD4 single-positive. Thymocytes that are unsuccessful in achieving a receptor with avidity for either a class I or II self-MHC molecule die by apoptosis. The *solid diamond* represents a self-peptide derived from hydrolysis of an autologous protein present in the thymic microenvironment or synthesized within the thymic epithelium itself. (B) *Negative selection.* "Single-positive" ($CD4^+$ *or* $CD8^+$) thymocytes, positively selected in the thymic cortex, that display TCRs with *high* avidity for the combination of self-MHC plus some self (autologous) peptide present in the thymus are negatively selected (i.e., die) as potentially "autoimmune." Those few thymocytes that have survived both positive and negative selection emigrate to the periphery as mature T cells. *APC*, Antigen-presenting cell; *MHC*, major histocompatibility complex.

synthesizes by utilization of different C_H genes without changing its unique antibody specificity. This process, termed *class switch recombination*, is regulated by cytokines and is accomplished through the action of activation-induced cytidine deaminase.[24]

There is no process comparable to class switch recombination in T cells. The two types of TCRs are products of four independent sets of V-region and C-region genes. A large majority of peripheral blood T cells express αβ TCRs, with a small fraction expressing γδ TCRs (usually ≤5% in peripheral blood). There is a higher representation of γδ T cells in certain tissues, particularly those lining mucous membranes, where they may be specialized for recognition of heavily glycosylated peptides or nonpeptide antigens that are commonly encountered in these tissue compartments. Thymocytes are committed to the expression of either αβ or γδ TCR, and their differentiated progeny (T cells) never change their TCR type in the periphery.

Major Histocompatibility Complex

MHC molecules constitute a third class of antigen-binding molecules. When an MHC class I molecule was initially crystallized, an unknown peptide was found in a binding groove formed by the first two (α_1 and α_2) domains of the molecule. This binding groove has since been established as a general feature of MHC molecules.[25] It is now known that the function of MHC molecules is to present antigen to T cells in the form of oligopeptides that reside within this antigen-binding groove (Chapter 6). The most important difference between the nature of the binding groove of MHC molecules and those of Ig and TCR is that the former does not represent a consequence of gene rearrangement. Rather, all the available MHC molecules in an individual are encoded in a linked array, which in humans is located on chromosome 6 and designated the human leukocyte antigen (HLA) complex.

MHC molecules are of two basic types, class I and class II. Class I molecules are found on the surface of almost all somatic cells, whereas cell surface expression of class II genes is restricted primarily to cells specialized for APC function. Class I molecules have a single heavy chain that is an integral membrane protein composed of three external domains (see Fig. 1.1). The heavy chain is noncovalently associated with β_2-microglobulin, a nonpolymorphic, non–membrane-bound, single-domain Ig superfamily molecule that is encoded in humans on chromosome 15, not linked to the MHC. In contrast, class II MHC molecules comprise two polypeptide chains, α and β (or A and B), of approximately equal size, each of which consists of two external domains connected to a transmembrane region and cytoplasmic tail. Both chains of class II molecules are anchored on the cell by a transmembrane domain, and both are encoded within the MHC. Class I and class II molecules have a high degree of structural homology, and both fold to form a peptide-binding groove on their exterior face, with contribution from the α_1 and α_2 domains for class I molecules and from α_1 and β_1 domains for class II.

There are three class I loci (HLA-A, -B, and -C) and three class II subregions (HLA-DR, -DQ, and -DP) that are principally involved in antigen presentation to T cells (Chapter 5). The functions of other class I and class II genes within this complex are less clear. Some, at least, appear to be specialized for binding (presentation) of peptide antigens of restricted type, source, or function (e.g., HLA-E),[26] and others (e.g., HLA-DM and HLA-DO) appear to be involved in selective antigen processing and loading of antigenic peptides into the binding cleft of the HLA-DR, -DQ, and -DP molecules (Chapter 6).[27] In addition, members of a family of "nonclassic" class Ib molecules, $CD1_{a–d}$, which are encoded on chromosome 1 outside the MHC, are specialized for binding and presentation of lipid and lipid-conjugate antigens to T cells.[14,28]

The HLA complex represents an exceedingly polymorphic set of genes (Chapter 5). Consequently, most individuals are heterozygous at each major locus. In contrast to TCRs and Igs, the genes of the MHC are co-dominantly expressed. Thus, at a minimum, an APC can express six class I molecules and six class II molecules (the products of the two alternative alleles of three class I and three class II loci). This number is, in fact, usually an underestimate, as a consequence of additional complexity in the organization of the class II region.

ANTIGEN PRESENTATION

Because MHC genes do not undergo recombination, the number of distinct antigen-binding grooves that they can form is many orders of magnitude less than that for either TCRs or Igs. Oligopeptides that bind to MHC molecules are the products of self or foreign proteins. They are derived by hydrolytic cleavage within APCs and are loaded into MHC molecules before expression at the cell surface (Chapter 6). Indeed, stability of MHC molecules at the cell surface requires the presence of a peptide in the antigen-binding groove; cells mutant for the loading of peptide fragments into MHC molecules fail to express MHC molecules on their cell surfaces.[29] Because in the absence of infection most hydrolyzed proteins are of self-origin, the binding groove of most MHC molecules contains a self-peptide.

Class I and class II molecules differ from one another in the length of peptides that they bind, usually 8 to 9 amino acids for class I and 14 to 22 amino acids for class II. Although important exceptions are clearly demonstrable, they also generally differ with respect to the source of peptide. Those peptides binding to class I molecules usually derive from proteins synthesized intracellularly (e.g., autologous proteins, tumor antigens, virus proteins, and proteins from other intracellular microbes), whereas class II molecules commonly bind peptides derived from proteins synthesized extracellularly (e.g., extracellular bacteria, nonreplicating vaccines, toxins/allergens). Endogenous peptides are generated by the immunoproteasome and then are loaded into newly synthesized class I molecules in the endoplasmic reticulum following active transport from the cytosol. In contrast, proteolytic breakdown and loading of exogenous peptides into class II molecules occurs in acidic endosomal vacuoles. As a consequence of proteolytic processing and binding into an MHC molecule, T cells see linear peptide epitopes. In contrast, because B-cell antigen recognition requires neither proteolytic processing nor binding into an MHC molecule, B cells recognize native, three-dimensional epitopes.

In addition to the recognition of lipids and lipid-conjugates presented by CD1 molecules, there are other exceptions to the generalization that MHC molecules only present (and T cells only recognize) oligopeptides. It has been known for many years that T cells can recognize haptens, presumably covalently or noncovalently complexed with peptides residing in the antigen-binding groove. This phenomenon is familiar to physicians as contact dermatitis to nonpeptide antigens, such as urushiol (from poison ivy) and nickel ion (Chapter 48). In addition, a newly recognized subset of T cells designated mucosal-associated (semi-) invariant T (MAIT) cells recognize vitamin B_2

(riboflavin) and vitamin B_9 (folate) derivatives bound to MR1, a nonpolymorphic MHC class I–like molecule; these vitamin derivatives are expressed by many strains of bacteria and yeast. Because MAIT cells constitute approximately 5% of human T cells and up to 25% of CD8 cells, their binding specificity suggests a role for these cells in host defenses.[30] In addition, certain human γδ T cells can recognize a variety of nonpeptide phosphoantigens, such as phosphorylated nucleotides, other phosphorylated small molecules, and alkylamines. The role of APCs and MHC-like molecules in presentation of phosphoantigens to γδ T cells remains a subject of investigation.

Another exception to the generalization of T-cell recognition of oligopeptides is represented by a group of proteins termed *superantigens*.[31] SAgs, of which the staphylococcal enterotoxin A represents a prototype, are produced by a broad spectrum of microbes, ranging from retroviruses to bacteria. They differ from conventional peptide antigens in their mode of contact both with MHC class II molecules and TCRs (Chapter 6). They do not undergo processing to oligopeptide fragments. Instead, they bind as intact proteins to class II molecules and TCRs outside the antigen-binding grooves. Their interaction with TCRs is predominantly determined by variable residues of the TCR V_β region. Because SAgs bind more or less independently of the TCRs α chain and the other variable segments of the β chain, they are capable of activating much larger numbers of T cells compared with conventional peptide antigens—hence their name. SAgs cause a wave of T-cell activation, proliferation, and production of proinflammatory molecules that can have profound clinical consequences, leading to development of such diseases as toxic shock syndrome.[31]

LYMPHOCYTE ADHESION AND TRAFFICKING

The capacity to continuously survey the antigenic environment is an essential element of immune function. APCs and lymphocytes must be able to find antigen wherever it occurs. Surveillance is accomplished through an elaborate interdigitated circulatory system of blood and lymphatic vessels that establish connections between the solid organs of the peripheral immune system (e.g., spleen, lymph nodes, and lymphoid structures in mucosal tissues) in which the interactions between immune cells predominantly occur (Chapter 2).

The trafficking and distribution of circulating cells of the immune system is largely regulated by interactions between molecules on leukocyte surfaces and ligands on vascular endothelial cells[32] (Chapter 16). Leukocyte-specific cellular adhesion molecules can be expressed constitutively or can be induced by cytokines (e.g., as a consequence of an inflammatory process).

Several families of molecules are involved in the regulation of lymphocyte trafficking. Particularly important are selectins and integrins, which ensure that mobile cells home to appropriate locations within lymphoid organs and other tissues. Selectins are proteins characterized by a distal carbohydrate-binding (lectin) domain. They bind to a family of mucin-like molecules, the endothelial vascular addressins. Integrins are heterodimers essential for the emigration of leukocytes from blood vessels into tissues. Members of the selectin and integrin families are involved in lymphocyte circulation and homing and are also important in interactions between APCs, T cells, and B cells in the induction and expression of immune responses. Certain endothelial adhesion molecules, mostly members of the Ig superfamily, are similarly involved in promoting interactions between T cells and APCs, as well as in leukocyte transmigration from the vasculature. Receptors for chemokines are important determinants of lymphocyte migration, particularly in guiding tissue-selective cell trafficking.[33]

LYMPHOCYTE ACTIVATION

For both B cells and T cells, initial activation is a two-signal event (Chapters 4 and 10).[34] This generalization is particularly true for immunologically naïve cells that have not been previously exposed to antigen. The first signal is provided by antigen. Most commonly, antigens for B cells are proteins with distinct sites, termed *epitopes*, which are bound by membrane Ig. Such epitopes can be linear, defined by a contiguous amino acid sequence or (more frequently) can be conformationally defined by the three-dimensional structure of the antigen. Epitopes can also be simple chemical moieties (haptens) that have been attached, usually covalently, to amino acid side chains (Chapter 6). In addition to proteins, some B cells have receptors with specificity for carbohydrates and, less commonly, lipids or nucleic acids. Antigens that stimulate B cells can be either in solution or fixed to a solid matrix (e.g., a cell membrane). As previously noted, the nature of antigens that stimulate T cells is more limited. TCRs do not bind antigen in solution but are usually stimulated only by small molecules, primarily oligopeptides, which reside within the antigen-binding cleft of a self-MHC molecule.

The second signal requisite for lymphocyte activation is provided by an accessory molecule expressed on the surface of the APC (e.g., B7/CD80) for stimulation of T cells or on the surface of a helper T cell (e.g., CD40L/CD154) for activation of B lymphocytes. The cell surface receptors for this particular second signal on T cells is CD28 and on B cells is CD40 (Fig. 1.3). Other cell surface ligand-receptor pairs may similarly provide the second signal (Chapters 7 and 10). The growth and differentiation of both T cells and B cells additionally require stimulation with one or more cytokines, which are peptide hormones secreted in small quantities by activated leukocytes and APCs for function in the cellular microenvironment.[35] In the absence of a second signal, cells stimulated only by antigen become unresponsive to subsequent antigen stimulation (i.e., *anergic*) (Chapter 10).[36]

Signal transduction through the antigen receptor is a complex process involving interactions between the specific receptor and molecules coexpressed in the cell membrane.[37] For B cells, this is a heterodimer, Igα/Igβ; and for T cells it is a macromolecular complex, CD3, usually comprising γ, δ, ε, and ζ chains.

Within the cell membrane, antigen receptor stimulation induces phosphorylation of Igα/Igβ or CD3 and hydrolysis of phosphatidylinositol 4,5-bisphosphate by phospholipase C, leading to generation of diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP_3). As a consequence of signal transduction and secondarily of DAG and IP_3 generation, tyrosine and serine/threonine protein kinases are activated. In turn, these kinases catalyze phosphorylation of a number of signal-transducing proteins. This leads to activation of cytoplasmic transcription factors NF-AT in T cells and NF-κB in both T cells and B cells. These transcription factors then translocate to the nucleus, where they bind to 5′ regulatory regions of genes that are critical to generalized lymphocyte activation (Chapter 10).[38]

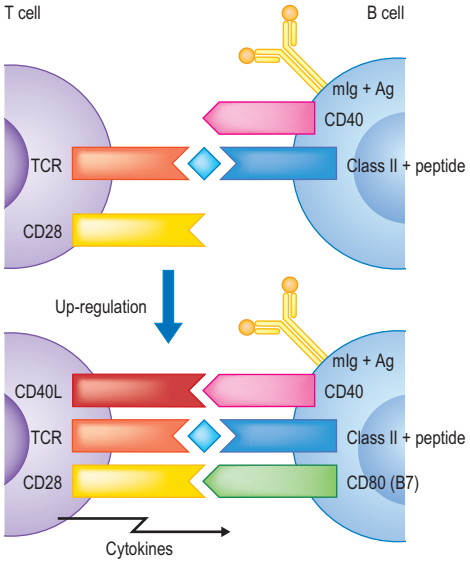

FIG. 1.3 Reciprocal Activation Events Involved in Mutual Simulation of T and B Cells. T cells constitutively express T-cell receptors *(TCRs)* and CD28. B cells constitutively express mIg and major histocompatibility complex (MHC) class II. Antigen bound to mIg is endocytosed and processed to peptide fragments that bind to MHC class II molecules for presentation to TCRs. Activation of B cells by antigen *(Ag)* upregulates their expression of CD80 that interacts with CD28 to activate T cells. This upregulates CD40L (CD154) on the T cell and induces cytokine synthesis. Costimulation of B cells by antigen CD40L and cytokines leads to Ig production. *mIg,* Membrane immunoglobulin.

CELL-MEDIATED IMMUNE RESPONSES

T-Cell Subsets

T lymphocytes expressing an αβ TCR can be divided into two major subpopulations based on the class of MHC molecule that their TCR recognizes and the consequent expression of one of a pair of TCR accessory molecules, CD4 or CD8 (Chapters 4 and 9). Binding of CD4 to class II MHC molecules or CD8 to class I MHC molecules on APCs contributes to the overall strength of intercellular molecular interactions. The ratio of CD4 to CD8 cells in peripheral blood is usually approximately 2:1.

CD4 T Cells, Cytokines, and Chemokines

The activities of CD4 T lymphocytes, commonly referred to as *T helper (Th) cells*, are mediated predominantly through the secretion of cytokines (Chapter 14). Cytokine activity can include autostimulation (autocrine function) if the cell producing the cytokine also expresses a surface receptor for it, or stimulation of other cells in the microenvironment of the cytokine-secreting cell (paracrine function) including B cells, APCs, and other T cells. Although it is now recognized that their biologic effects are broader than implied by their name, many of the principal cytokines active in the immune system are known as *interleukins* (ILs), implying that they are produced by a leukocyte to act on other leukocytes.

The specific profile of cytokines produced by CD4 T cells allows further functional subdivision (Chapters 11 and 14).[35,39] CD4 T cells elaborating the "inflammatory" cytokines involved in effector functions of cell-mediated immunity, such as IL-2 and IFN-γ, are designated Th1 cells. Th2 CD4 T cells synthesize cytokines (Chapter 14), such as IL-4 and IL-13, which control and regulate antibody responses and activate cells that are involved in host defense against parasites. Differentiation of Th1 versus Th2 subsets is a process substantially controlled by positive feedback loops, being promoted particularly by IL-12 in the case of Th1 cells and IL-4 in the case of Th2 cells.

It is important to note that generalizations regarding cytokine activity are usually oversimplifications, reflecting a substantial overlap and multiplicity of functions. For example, although IL-2 was initially identified as a T-cell growth factor, it also significantly affects B-cell differentiation. The prototypic inflammatory cytokine, IFN-γ, which promotes differentiation of effector function of cytotoxic T lymphocytes (CTLs) and macrophages, is also involved in regulation of Ig isotype switching. Similarly, IL-4 is known primarily as a B-cell growth and differentiation factor, but it can also stimulate proliferation of T cells.

A distinct subset of cytokines is a large group of highly conserved cytokine-like molecules, smaller than typical cytokines (~7 to 12 kilodaltons [kDa]), termed *chemo*tactic cyto*kines*, or *chemokines* (Chapter 15).[33] Chemokines are classified on the basis of the number and spacing of specific cysteine residues. They regulate and coordinate trafficking and activation of leukocytes, functioning importantly in host defenses, and also broadly in a variety of nonimmunologic processes, including organ development and angiogenesis. They are characterized by binding to seven-transmembrane-domain G protein–coupled receptors. Of particular interest to clinical immunologists are the chemokine receptors CCR5 and CXCR4. Together with CD4, these molecules are used as coreceptors by human immunodeficiency virus (HIV) to gain entry into target cells (Chapter 41).[40]

Cytokines produced by activated T cells can downregulate as well as initiate or amplify immune responses.[41] Downregulating cytokines include IL-10 (produced by both T cells and B cells) and transforming growth factor-β (TGF-β). The functions of IL-10 in vivo are thought to include both suppression of proinflammatory cytokine production and enhancement of IgM and IgA synthesis. TGF-β, which is produced by virtually all cells, expresses a broad array of biologic activities. These include promotion of wound healing and suppression of both humoral and cell-mediated immune responses.

In addition to their central role in initiation and regulation of immune responses, CD4 T cells are important effectors of cell-mediated immunity (Chapter 11). Through the elaboration of inflammatory cytokines, particularly IFN-γ, they are essential contributors to the generation of chronic inflammation, which is characterized histologically by mononuclear cell infiltrates. Here their principal role is thought to be the activation of macrophages. In some circumstances, CD4 T cells can function as cytotoxic effectors, either directly as CTLs, in which case the killing is "restricted" for recognition of antigen-bound self-MHC class II, or through the elaboration of cytotoxic cytokines, such as lymphotoxin and tumor necrosis factor (TNF).

A third subset of Th cells, designated Th17, has been recognized more recently. With differentiation driven particularly by TGF-β and IL-23 and characterized by the production of the proinflammatory cytokine IL-17, Th17 cells are important in the induction and exacerbation of autoimmunity in a variety of disease models, as well as in host defenses against a broad

spectrum of extracellular bacteria, fungi, and other pathogens.[42] Research continues to identify additional examples of CD4 T cells that may become recognized as distinct subsets. Their function is governed by other predominantly expressed cytokines to achieve specialized effector responses.

One final category of CD4 cells, Tregs, plays a crucial role suppressing the functions of other lymphocytes (Chapter 13). Tregs can differentiate either in the thymus (tTregs) or in the periphery (pTregs). A third category of Tregs are induced in vitro (iTregs).[43] Tregs are commonly characterized by surface expression of CD4 and CD25 and by nuclear expression of the transcription factor Foxp3. Peripheral activation of $CD25^+$ Tregs is via the TCRs. The cells are IL-2 dependent and apparently require cell-to-cell contact for suppressive function. They can suppress functions of both CD4 and CD8 T cells, as well as B cells, NK cells, and NKT cells. In contrast to activation, suppressor effects are independent of the antigen specificity of the target cells. Other Tregs are noted for production of inhibitory cytokines. These include IL-10– and TGF-β–secreting Th3 cells and IL-10–producing Tr1 cells.[44,45]

CD8 T Cells

The best understood function of CD8 T cells is that of CTL effectors.[46] CTLs are particularly important in host defenses against virus-infected cells, where they can kill target cells expressing viral peptides bound to self-MHC class I molecules (Chapter 12). This process is highly specific and requires direct apposition of CTLs and target cell membranes. Bystander cells expressing MHC molecules that have bound peptides that the CD8 T cell does not recognize are not affected. The killing is unidirectional; the CTL itself is not harmed and after transmission of a "lethal hit" it can detach from one target to seek another. Killing occurs via two mechanisms: a death receptor–induced apoptotic mechanism and a mechanism involving insertion of perforins into the target cell membrane to create a pore through which granzymes and other cytotoxic enzymes can be transferred from the CTL into the target cell. CTL activity is enhanced by IFN-γ. As CTL function is dependent on target cell surface display of MHC class I molecules, a principal mechanism of immune evasion by viruses and tumors is elaboration of factors that downregulate class I expression (Chapter 25). However, this increases susceptibility of such cells to cytolysis by NK cells that are activated to attack cells expressing low levels of class I MHC molecules.

ANTIBODY-MEDIATED IMMUNE RESPONSES

The structure of antibodies permits a virtually limitless binding specificity of its antigen-binding site. Antigen binding can then be translated into biologic effector functions based on properties of the larger nonvariable (constant) region of its heavy chains (Fc fragment) (Chapter 8). Moreover, in response to cytokines in the cellular microenvironment, the mechanism of isotype switching enables the antibody-producing cell to switch the exons that are used to encode its heavy-chain constant region and thereby alter the biologic effects of its secreted product without affecting its antigen-binding specificity. With functional heterogeneity determined by isotype, antibody molecules provide a broad-based and efficient defense system against extracellular microbes or foreign macromolecules (e.g., toxins and venoms) (Chapters 8, 27, and 87).

KEY CONCEPTS

Biologic Properties of Immunoglobulin (Ig) Classes

- IgM
  - Monomeric on the cell surface, primarily pentameric in soluble form
  - Principal Ig of the primary immune response
  - Generally restricted to the vascular compartment
  - Antigen receptor (monomer) for most naïve B cells
  - Fixes complement potently
- IgG
  - Monomeric
  - Principal Ig of internal secondary immune responses
  - Binds to Fcγ receptors on neutrophils, monocytes/macrophages, and NK cells
  - Four subclasses, each with a different effector function
  - Fixes complement (except IgG4 subclass)
- IgA
  - Monomeric or dimeric
  - Transported into the gut
  - Principal Ig of mucosal immunity
  - Two subclasses
- IgD
  - Antigen receptor for mature B cells
  - Typically expressed on cells that also express membrane IgM
- IgE
  - Binds to Fcε receptors on mast cells and basophils
  - Antibody of immediate hypersensitivity
  - Important in defenses against helminths

Each antibody class contributes differently to an integrated defense system.[47] IgM is the predominant class formed on initial contact with antigen (primary immune response). As a monomeric structure comprises two light (κ or λ) and two heavy (μ) chains, it is initially expressed as a membrane-bound antigen receptor on the surface of B lymphocytes. The avidity of serum IgM for antigen binding is increased by its organization into a pentamer of five of the monomeric subunits held together by a joining (J) chain. IgM is essentially confined to the intravascular compartment. As a multivalent antigen binder that can efficiently activate ("fix") complement, it is an important contributor to immune responses early after the initial encounter with antigen. The synthesis of IgM, compared with other isotypes, is much less dependent on the activity of T lymphocytes.

IgG is the most abundant Ig in serum and the principal antibody class of a secondary (anamnestic or memory) immune response. IgG molecules are heterodimeric monomers with two light (κ or λ) and two heavy (γ) chains and, except for IgG4, joined by interchain disulfide bridges. Because of its abundance, its capacity to fix complement, and the expression on phagocytes of Fcγ receptors, IgG is the most important antibody for systemic secondary immune responses. IgG is the only isotype that is actively transported across the placenta. These transported maternal IgG antibodies provide the neonate with an important level of antibody protection in the first 6 months of life, when its own antigen-driven antibody responses are first developing (Chapter 21).

IgA is the principal antibody in the body's secretions (Chapter 24). It is found in serum in monomeric form of two light and two heavy (α) chains or as a dimer joined by J chain. In secretions, it is usually present in dimeric form and is actively secreted across mucous membranes by attachment of a specialized secretory component (SC) that is recognized by the polyIg receptor on mucosal epithelial cells. Dimeric IgA is found in

high concentration in tears, saliva, and secretions of the respiratory, gastrointestinal, and genitourinary systems. It is relatively resistant to enzymatic digestion. It is particularly abundant in colostrum, where its concentration may be greater than 50 times that in serum, providing passive immunity to the gastrointestinal system of a nursing neonate. IgA does not fix complement by the antibody-dependent pathway and hence does not promote phagocytosis. Its role in host defenses lies in preventing a breach of the mucous membrane surface by microbes or their toxic products.

IgD and IgE are present in serum at concentrations much lower than that of IgG. The biologic role of serum IgD remains controversial.[48] B cells can express both membrane IgM and IgD by alternative splicing of the Ig heavy-chain gene or can secrete only IgD via an apparently atypical form of class switch recombination. These mechanisms do not require T-cell help.

Although IgE is the least abundant isotype in serum, it has dramatic biologic effects because it is responsible for immediate-type hypersensitivity reactions, including systemic anaphylaxis (Chapter 46). Such reactions reflect expression of high-affinity receptors for Fcε on the surfaces of mast cells and basophils. Cross-linking of IgE molecules on such cells by antigen induces their degranulation, with the immediate release of preformed potent biologic mediators and de novo synthesis and secretion of additional proinflammatory molecules. The protective role of IgE is in host defenses against parasitic infestation, particularly with helminths (Chapter 30).

Complement and Immune Complexes

The effector functions of IgG and IgM depend, in part, on their capacities to activate the complement system. Through a cascade of sequential substrate-enzyme interactions, the 11 principal components of the antibody-dependent complement cascade (C1q, C1r, C1s, and C2–C9) cause many of the principal consequences of an antigen-antibody interaction (Chapter 40). These include the establishment of pores in a target cell membrane by the terminal components (C5–C9) leading to osmotic lysis; the production of factors (principally C5a) with chemotactic activity for phagocytic myeloid cells; opsonization by C3b, promoting phagocytosis; and the ability to induce degranulation of mast cells (C3a, C4a, and C5a).

There are three distinct pathways to complement activation.[49] The pathway mediated by the binding of the first component (specifically C1q) to IgG or IgM has been termed the "classical" pathway (CP). The lectin pathway is similar to the CP but is activated by selected carbohydrate-binding proteins, the mannose (or mannan)-binding lectin (MBL), and ficolins, which recognize certain carbohydrate repeating structures on microorganisms. MBL and ficolins are plasma proteins that are homologous to C1q and contribute to innate immunity through their capacity to induce antibody- and C1q-independent activation of the CP. Finally, a large number of substances, including certain bacterial, fungal, and viral products, can directly activate the cascade through a distinct series of proteins also leading to activation of the central C3 component. Although bypassing C1, C4, and C2, this distinct pathway can achieve all the biologic consequences of C3 to C9 activation. Non–antibody-induced activation of C3 is referred to as the "alternative" pathway (AP) or "properdin" pathway. In addition, the central components of the cascade (e.g., C5a) can be directly produced by the action of serine proteases of the coagulation system.[49] Reflecting these separate pathways to activation and the fact that many types of leukocytes express receptors for activated complement components, the complement system is a major contributor to the efferent limbs of both innate and adaptive immune systems.

In addition to their roles in pathogen/antigen elimination, constituents of the complement system, together with antigen-antibody (immune) complexes, act at leukocyte surfaces to regulate immune functions. For example, interaction of immune complexes via FcγR on B cells decreases their responsiveness to stimulation. In contrast, complement activation on B-cell surfaces co-ligates their receptors with BCRs for antigen, rendering the cells more readily activated and resistant to apoptosis.

Essential for the proper function of the complement system is a series of downregulatory mechanisms that prevent unwanted activation of the system and that extinguish its activity when no longer needed. The regulatory pathways are mediated by a combination of both soluble complement-binding and digesting molecules and cell surface binding proteins.

APOPTOSIS AND IMMUNE HOMEOSTASIS

An immune response is commonly first viewed in a "positive" sense—that is, lymphocytes are activated, proliferate, differentiate, and carry out effector functions. However, it is equally important that this positive response be tightly regulated by mechanisms that operate to turn off the response and to eliminate cells no longer required (Chapter 17).[50,51] Under physiologic circumstances, once an immune response fades, commonly as a consequence of antigen depletion, two pathways to terminal lymphocyte differentiation become available: apoptosis or differentiation into memory cells. Memory cells are, of course, a key to the effectiveness of the adaptive immune system, because a second activating encounter with antigen (e.g., pathogen) is both more rapid and more productive. Isotype-switched high-affinity antibodies are rapidly produced, and/or clones of CTL effector cells proliferate. However, the majority of lymphocytes in an active response are not required for maintenance of immunologic memory, and the necessity for homeostasis leads to apoptosis of cells no longer required.

Apoptosis (or regulated cell death [RCD]) is a unique process of cellular death and widely conserved phylogenetically. It is distinguished from death by necrosis by cellular shrinking, DNA fragmentation, and breakdown of cells into "apoptotic bodies" containing nuclear fragments and intact organelles that can be eliminated by phagocytosis without release into the extracellular space of the majority of intracellular, especially nuclear, components. Necrosis can be genetically determined (regulated necrosis [RN]) or unregulated, reflecting some accidental or otherwise inevitable process. Apoptosis depends on the activation of cysteinyl proteases, termed *caspases*, which cleave proteins that regulate DNA repair and the establishment/maintenance of cellular architecture. In the absence of these apoptotic mechanisms, massive proliferation of cells in lymphoid tissues results. This is seen clinically as autoimmune lymphoproliferative syndrome (ALPS), which is characterized by lymphocytosis with lymphadenopathy and splenomegaly as well as autoimmunity and hypergammaglobulinemia (Chapter 51).[52]

MECHANISMS OF IMMUNOLOGIC DISEASES

Immunologic diseases can be classified on the basis of our understanding of normal immune physiology and its perturbations in disease states (Table 1.2). One type of immunologic

TABLE 1.2 Mechanisms of Immunologic Diseases

1. Functional deficiency of key immune system components
   a. Congenital
   b. Acquired
2. Malignant transformation of immune system cells
3. Immunologic dysregulation
4. Autoimmunity
5. Untoward consequences of physiologic immune function

disease results from failure or deficiency of a component of the immune system leading to failure of normal immune function (Chapters 32–42). Such disorders are usually identified by increased susceptibility to infection (Chapter 32). Failure of host defense can be congenital (e.g., X-linked agammaglobulinemia; Chapter 33) or acquired (e.g., acquired immunodeficiency syndrome [AIDS]; Chapter 41). It can be global (e.g., severe combined immunodeficiency [SCID]; Chapter 34) or, quite specific, involving only a single component of the immune system (e.g., selective IgA deficiency; Chapter 33).

A second type of immunologic disease is malignant transformation of immunologic cells (Chapters 77–81). Manifestations of leukocyte malignancies are protean, most commonly reflecting the secondary consequences of solid organ or bone marrow infiltration or replacement of normal cells by tumor cells, with resulting anemia and immunologic deficiency.

The remaining types of immunopathogenesis are more specific to the immune system. Dysregulation of an essentially intact immune system constitutes a third general type of immune disorder. Features of an optimal immune response include antigen recognition and elimination, with little adverse effect on the host. However, both initiation and termination of the response involve regulatory interactions that can go awry when the host is challenged by antigens of a particular structure or presented in a particular fashion. Diseases of immune dysregulation can result from genetic and environmental factors that act together to produce a pathologic immune response, such as acute allergic diseases (Chapters 43–50). Some forms of allergic disease are thought to be a consequence of insufficient exposure to nonpathogenic microbes and other potential allergens in early childhood, resulting in an increased susceptibility to allergy, atopy, and asthma once the immune system has matured. The so-called hygiene hypothesis suggests that mucosal tissue–colonizing organisms play key roles in the initial establishment of immune homeostasis.[53] The importance of establishing immune homeostasis early in life is also supported by studies demonstrating reduction in the likelihood of food allergy associated with feeding of the allergenic foods to infants at high risk for allergy (Chapter 49).[54–56]

A fourth type of immunologic disorder is the result of failure of a key feature of normal immune recognition, the molecular discrimination between self and nonself. Ambiguity in this discrimination can lead to autoimmune tissue damage (Chapters 51–76). Although such damage can be mediated by either antibodies or T cells, the common association of specific autoimmune diseases with inheritance of particular HLA alleles (Chapter 5) suggests that the pathogenesis of autoimmune diseases usually represents a failure of regulation of the anti-self inflammatory response by T cells.

The immunologic attack on self-tissues can be general, leading to systemic autoimmunity, such as systemic lupus erythematosus; or it can be localized, as in organ-specific autoimmune diseases. In the latter instances, the immune system attacks specific types of cells and usually particular cell surface molecules. In most cases, pathology is a consequence of target tissue destruction (e.g., multiple sclerosis, rheumatoid arthritis, or insulin-dependent diabetes mellitus). However, depending on the antigenic specificity of the abnormal immune response, autoimmunity can lead to receptor blockade (e.g., myasthenia gravis or insulin-resistant diabetes) or hormone receptor stimulation (e.g., Graves disease). It is thought by many immunologists that ambiguity in self/nonself discrimination is commonly triggered by an unresolved encounter with an infectious organism or other environmental agent that shares some structural features with self-tissue structures, although this remains a subject of controversy (Chapter 51).[57,58] Insight into mechanisms whereby specific HLA alleles predispose to development of autoimmunity and others may be protective are suggested by studies in HLA-transgenic mice, which suggest that alleles that predispose animals to a particular autoimmune disease may reflect a T-cell phenotype associated with secretion of proinflammatory cytokines. In contrast, protective alleles were associated with elaboration of tolerogenic cytokines by Tregs.[59]

A fifth form of immunologic disease occurs as a result of physiologic, rather than pathologic, immune functions. Inflammatory lesions in such diseases are the result of the normal function of the immune system. A typical example is contact dermatitis to such potent skin sensitizers as urushiol, the causative agent of poison ivy dermatitis (Chapter 48). These diseases can also have an iatrogenic etiology that can range from mild and self-limited (e.g., delayed hypersensitivity skin test reactions) to life threatening (e.g., graft-versus-host disease, organ graft rejection).

HOST IMMUNE DEFENSES SUMMARIZED

The first response upon initial contact with an invading pathogen depends on components of the innate immune system (Chapter 3). This response begins with recognition of PAMPs expressed by cells of the pathogen. These include lipoproteins, lipopolysaccharide, unmethylated CpG-DNA, and bacterial flagellin, among others. PAMPs bind to PRRs on or within effector cells of the host's innate immune system, including DCs, granulocytes, and ILCs.[2,3] The best characterized PRRs are the TLRs, first recognized as determinants of embryonic patterning in *Drosophila* and subsequently appreciated as components of host defenses in both insects and vertebrates. TLR subfamilies can be distinguished by expression either on the cell surface or in intracellular compartments. A second major family of PRRs comprises NLRs, which detect intracellular microbial products. Binding of TLRs or NLRs by PAMP ligands triggers intracellular signaling pathways via multiple "adapters," leading to a vigorous inflammatory response.

The innate immune response also includes the capacity of NK lymphocytes to identify and destroy, by direct cytotoxic mechanisms, cells lacking surface expression of MHC class I molecules, which marks them as potentially pathogenic.[4] In addition, an innate immune response involves elements of the humoral immune system that function independently of antibody, especially the activation of the complement cascade through

the lectin pathway and the AP, with consequent opsonization of particles and microbes to promote their phagocytosis and destruction.

The nature of the adaptive immune response to any particular pathogenic agent is determined largely by the context in which the pathogen is encountered. Regardless, effectiveness depends on the four principal properties of adaptive immunity: (i) a virtually unlimited capacity to bind macromolecules, particularly proteins, with exquisite specificity, reflecting generations of antigen-binding receptors by genetic recombination and, in the case of B cells, SHM; (ii) the capacity for self/nonself discrimination, consequences of a rigorous process involving positive and negative selection during thymocyte differentiation, as well as negative selection during B-cell differentiation; (iii) the property of immunologic memory, reflecting antigen-driven clonal proliferation of T cells and B cells, which results in increasingly rapid and effective responses on second and subsequent encounters with a particular antigen or pathogen; and (iv) mechanisms for pathogen destruction, including direct cellular cytotoxicity, release of inflammatory cytokines, opsonization with antibody and complement, and neutralization in solution by antigen precipitation or conformational alteration plus phagocytosis and intracellular digestion.

Although most acquired immune responses include multiple defense mechanisms, several generalizations may be conceptually useful. T cell–mediated (and NK cell–mediated) effector functions are particularly important in defenses against pathogens encountered intracellularly or at cell surfaces, such as intracellular viruses, intracellular bacteria, and tumor cells. These responses involve the production of inflammatory cytokines by CD4 Th1 cells, as well as the direct cytolytic activity of CD8 CTLs. In contrast, host defenses to most antigens encountered primarily in the extracellular milieu are largely dependent on humoral mechanisms (antibody and complement) for antigen neutralization, precipitation, or opsonization and subsequent destruction by phagocytes. Targets of antibody-mediated immunity include extracellular virus particles, bacteria, and toxins (or other foreign proteins). However, it is worth reiterating that induction of an effective antibody response (including isotype switching) and development of immunologic memory (resulting from B-cell clonal expansion and B memory cell differentiation) require antigen activation not only of specific B cells but also CD4 T cells, particularly of the Th2 type. In addition, antibacterial and antifungal responses that involve prominent responses by neutrophils require CD4 T cells of the Th17 type.

Finally, clinical "experiments of nature" have proven particularly instructive in our efforts to understand the role of specific components of the immune system in overall host defenses (Chapter 32).[60] The importance of T cell–mediated immunity in host defenses to intracellular parasites, fungi (Fig. 1.4), and viruses is emphasized by the remarkable susceptibility of patients with T cell deficiency to pathogenic organisms, such as *Pneumocystis jiroveci* and *Candida albicans*, and by the fact that using attenuated live virus vaccines in such patients can lead to devastating disseminated infections. Indeed, the relationship between susceptibility to particular potential pathogens and specific immunologic deficiencies is nicely illustrated by demonstrations that the pathogenesis of various familial forms of chronic mucocutaneous candidiasis reflect deficiency of IL-17–mediated immunity.[61]

FIG. 1.4 Leg of a 16-year-old patient with chronic mucocutaneous candidiasis as a consequence of a congenital T-cell deficiency associated with hypoparathyroidism and adrenal insufficiency.

Patients with defects in antibody synthesis or phagocytic cell function are characteristically afflicted with recurrent infections with pyogenic bacteria, particularly gram-positive organisms. And patients with inherited defects in synthesis of terminal complement components have increased susceptibility to infection with species of *Neisseria*.

In recent years, immunology has entered the lay lexicon, largely as a result of the HIV and Covid-19 pandemics. People throughout the world are now aware of the tragic consequences of immune deficiency. However, the remarkable progress in understanding this diseases rested substantially on earlier studies of relatively rare patients with primary immunodeficiency syndromes and on genomic definition of their molecular basis. Similarly, cure of patients with primary immunodeficiencies by cellular reconstitution, particularly bone marrow or stem cell transplantation (Chapter 90),[62] presaged recent progress in correction of such diseases by gene replacement therapy (Chapter 91).[63] The "present" of clinical immunology is, indeed, bright, but its future potential to impact prevention and treatment of many challenging diseases, including cancer (Chapters 80 and 81), through specific analysis of genetic mutations and enhancement or suppression of antigen-specific immune responses with chimeric antigen receptor (CAR) T cells and checkpoint blockade (CPB) is even more exciting to contemplate.[64] A few approaches are broadly hinted at here, and it is hoped that readers will enjoy considering such "perspectives" throughout the book. Given the nature of the immune system, it is also hoped it will challenge readers to transform a particular author's views to new and different clinical settings.

ON THE HORIZON

Enhancement of Immune Responses

- Use of CRISPR/Cas9 technology in correction of gene defect in monogenic immunodeficiency diseases
- Enhancement of molecular pathway–specific cancer immunotherapy
- Prediction of molecular targets and improvements in adjuvants for vaccines

Suppression of Immune Responses

- Further development of protocols for prevention of childhood allergic diseases by appropriate environmental exposures in infancy
- Improved allergen-specific immunotherapy of allergic diseases
- Prevention of graft-versus-host disease in allogeneic bone marrow transplantation cases
- Induction of antigen-specific immune tolerance in humans
- Pharmacologic development of specific inhibitors of cytokines, chemokines, and their receptors

Immunodiagnostics and Immunopathogenesis

- Routine use of genomic analysis for development of personalized medicine applicable to immunologic diseases
- Development of novel diagnostic tools based on nanotechnology arrays
- Application of gastrointestinal microbiome analysis in understanding the pathogenesis of inflammatory bowel diseases, leading to novel therapeutic options
- Understanding the role of inflammation in the pathogenesis of leading causes of morbidity and mortality, including myocardial infarction, stroke, and Alzheimer disease

Studies in experimental animals, especially murine studies, have been critical to our understanding of molecular aspects of immune system function and have contributed importantly to our appreciation of how aberrations of such functions are involved in the pathogenesis of disease. Insights gained from use of transgenic mice (including murine expression of human genes) and constitutive or conditional gene-knockout mice are essential to a comprehensive view of the immune system at the advancing edge of its clinical application, implying that future progress in clinical immunology will equally depend on detailed analysis in such systems. However, it has become apparent that there are important differences in aspects of the human and rodent immune systems. Consequently, the carefully studied patient, particularly when coupled with the power of increasingly feasible genome and transcriptome sequencing, will remain the ultimate crucible for understanding human immunity and the roles of the immune system in the pathogenesis of and protection from disease.

Organization of the Immune System

Dorothy E. Lewis, Arthur W. Zieske, and Sarah E. Blutt

The human immune system consists of organs (*e.g.*, spleen, thymus, and lymph nodes) and movable cells (*e.g.*, from the bone marrow, blood, and lymphatics). This design allows central locations for initial production and differentiation of committed cells from naïve precursors, as in the fetal liver, the bone marrow and the thymus; and more dispersed sites used for selection and further differentiation of cells into mature effector cells, as in spleen, lymph nodes and intestinal Peyer patches. This arrangement also allows regulated immune responses at locations peripheral to primary lymphoid organs to provide local control of infectious processes. The mechanisms responsible for the ability of nonspecific leukocytes, innate lymphoid cells (ILCs), natural killer (NK) cells, and antigen-specific T and B lymphocytes to respond rapidly to challenge are discussed in later chapters. This chapter covers the basic features and the ontogeny of cells involved in the immune response. It also reviews the essential structure of lymphoid organs and sites of organized immune cells, including skin, large intestine, and adipose tissues. Immune cell development.

IMMUNE CELL DEVELOPMENT

Ontogeny of the Cells of the Immune System

In humans, in the first three weeks of embryogenesis, primitive hematopoiesis begins from the primitive streak and is limited to erythroid, macrophage, and megakaryocytic lineages. The yolk sac becomes the major source of erythropoietic islands physically associated with, but not inside, the embryo.[1] Specialized endothelial cells give rise to the first progenitor cells. The cells produced in primitive hematopoiesis are phenotypically and functionally different from those that develop later. Definitive hematopoiesis begins in the aorta–gonad–mesonephros (AGM) where the first hematopoietic stem cells (HSCs) are formed.[2] The placenta is also a source of fetal stem cells for both the AGM and the fetal liver.[3] Properties of HSC differ by site. For example, HSCs in the fetal liver are in cycle whereas those in adult bone marrow are not. The progenitor stem cells that first populate the embryonic liver begin blood cell production in the sixth week of gestation, or just after the organ can be identified. By the eleventh week, the liver is the major source of hematopoiesis and remains so until the sixth month of gestation.[1]

The first progenitor cells derived from HSCs are colony-forming cells that can differentiate into granulocytes, erythrocytes, monocytes, megakaryocytes, and lymphocytes.[4] Subsequent to skeleton formation, between the second and fourth months of gestation, white blood cell development shifts to the bone marrow. The transition from liver to bone marrow is completed in the sixth month of gestation. Cells that differentiate from early stem cells begin to populate the primary lymphoid organs, such as the thymus, by 7 to 8 weeks of gestation.[5,6] At 8 weeks gestation, T-cell precursors that have initiated T-cell receptor (TCR) rearrangement (Chapter 9) can be detected in thymus tissue. In the fetal liver, B-cell precursors initiate immunoglobulin (Ig) rearrangements by 7 to 8 weeks gestation (Chapter 7). Late in the first trimester, B-cell development spreads to the bone marrow where B-cell progenitors congregate in areas adjacent to the endosteum and differentiate in the direction of the central sinus. The association of B cells with stromal reticular cells is essential for eventual release of mature B cells into the central sinus. As in the case of T-cell development, a selection process occurs such that many B-cell progenitors die by apoptosis.

In adult humans, the bone marrow is the chief source of stem cells. However, stem cells with different characteristics and limited self-renewal can be induced into the peripheral blood via injection of granulocyte colony stimulating factor (G-CSF) (Chapter 14). Methods to increase HSC self-renewal and expansion are under intensive study, including a search for means to promote *in vitro* expansion.[7] There has been an explosion in information with regard to how HSC develop and maintain self-renewal *in vivo*, including how fetal HSCs migrate to a niche from which adult HSC are derived. A key idea is that there is a nonlinear continuum of development that allows individual HSCs to "sidestep" a designated pathway depending on cytokine cues in their niches.[3] In the bone marrow of aged humans, there is evidence for a myeloid predominance with a restricted diversity of HSCs.[8]

Tools Essential to an Understanding of Immune Cell Biology

Progress beyond morphologic categorization of hematopoietic cells was enhanced by the use of monoclonal antibodies that identify stage-specific leukocyte cell surface antigens and the use of flow cytometry. In the 1980s, the sheer number of monoclonal antibodies to human leukocyte antigens resulted in a complicated nomenclature. In response, leukocyte differentiation antigen workshops developed a more consistent naming system. The workshops grouped monoclonal antibodies that recognized a single molecule on leukocytes by the cluster pattern of cells with which they were identified, hence the term CD, or "cluster of differentiation" antigen (Table 2.1). No formal conferences have been held since 2010, but new CD antigens have been validated. As of 2020, 371 had been identified (https://www.uniprot.org/docs/cdlist.txt) (Appendix 1).

TABLE 2.1 Important Cell Surface Antigens on Hematopoietic Cells.

Cell type	Surface Antigens	Predominant Location
Hematopoietic Stem Cells		
Bone marrow HSC	$CD34^+$, Lin-, 90^+	Bone marrow
Peripheral blood HSC	$CD34^+$, Lin-, $CD38^+$, $CD71^+$	Blood
Myeloid Cells		
Monocytes	CD14, CD35 (CR1), CD64	Blood
Macrophages	(FcRrγ1)CD68, CD13	Tissue
Langerhans cells	CD64,CD35	Skin
Follicular dendritic cells	CD1a, CD207 (Langerin),	B-cell areas, lymph nodes
Interdigitating dendritic cells	CD35, CD64	T-cell areas, lymph nodes
Myeloid dendritic cells	CD21, CD35 FcγRIIb	Mainly tissues
Plasmacytoid dendritic cells	CD80, CD56, Class II CD83	
(IFN-α producing)	CD40	
	CD83, CD80, CD86, CD40	
	CD1a, CD11c	
	CD4, CCR5, CXCR4, CD123	
Granulocytes		
Neutrophils	CD16 (FcγRIII), CD35 CD88 (C5aR)	Blood, tissues
Eosinophils	CD32 (FcγRII)	Blood, tissues
Basophils	CD23, (FcεRII), CD32	Tissues, blood
Mast cells	FcεRI α	Tissues, blood
		Tissues
Lymphocytes		
T cells	CD7, CD3, CD4, CD8, CD28	Thymus, spleen, lymph nodes, MALT, blood
B cells	Surface Ig, class II,	Bone marrow, spleen, lymph nodes, MALT, blood
NKT cells	CD19, CD20, CD22, CD40	Spleen, lymph nodes, mucosal tissues, blood
Tregs	CD16, CD56, CD94	Blood, tissues
Th17	CD3, CD56, Vα24 TCR	Thymus, blood, tissues
Tfh	CD4, CD25, Foxp3, GARP	Intestine, blood, tissues
	CD4, CCR6, IL-17,	Germinal centers of lymph
	RoRγ	nodes
	CD4, ICOS, PD-1, Bcl-6	

HEMATOPOIESIS AND LYMPHOPOIESIS

All mature cells of the hematopoietic and lymphoid lineages are derived from pluripotent stem cells that produce progenitors for lineage-specific cells.[9] Hematopoietic progenitors mature into cells of the granulocytic, erythroid, monocytic–dendritic, and megakaryocytic lineages (GEMM colony-forming units, CFU-GEMM). Likewise, lymphoid progenitors mature into B lymphocytes, T lymphocytes, and innate lymphoid cells including NK cells (Fig. 2.1).

In the adult, hematopoiesis and lymphopoiesis occur in two distinct tissues. The development of hematopoietic lineage cells (*i.e.*, granulocytes, monocytes, dendritic cells, erythrocytes, and platelets) occurs in bone marrow (Table 2.2). B-lymphocyte development through the immature and transitional B cell stages also occurs in the bone marrow (Chapter 7). T cell progenitors arise in the bone marrow but then migrate to the thymus where they differentiate into γδ and αβ T cells, including regulatory αβ T cells (Chapter 9). Some NK cells develop from precursors in the thymus.[10] Other tissue specific NK cells may develop in the bone marrow, lymph nodes, or the uterus.[10]

TABLE 2.2 Normal Distribution of Hematopoietic Cells in the Bone Marrow

Cell Type	Approximate Proportion (%)
Stem cells	1
Megakaryocytes	1
Monocytes	2
Dendritic cells	2
Lymphocytes	15
Plasma cells	1
Myeloid precursors	4
Granulocytes	50–70
Red blood cell precursors	2
Immature and mature red blood cells	10–20

Characteristics of Hematopoietic Stem Cells

The pluripotent stem cell gives rise to all red and white blood cell populations. Human HSCs in the bone marrow are rare: 1 in 10,000 cells. They are found in two proposed niches of the bone marrow that are closest to the bone. One niche also contains osteoblasts (endosteal niche), and the other is associated with the sinusoidal endothelium (vascular niche). Many human HSCs closely associate with perivascular mesenchymal stem cells.[4] It is estimated that human long-term HSC divide once or twice per year. Quiescent HSCs tend to be found near arterioles in the endosteum. Actively dividing HSCs are more likely to be located near sinusoid regions close to central veins.

Many separation methods are used to identify stem cells and their differentiation potential. Early observations showed that HSCs had characteristic flow cytometric light-scattering properties (low side scatter, medium forward scatter), no lineage

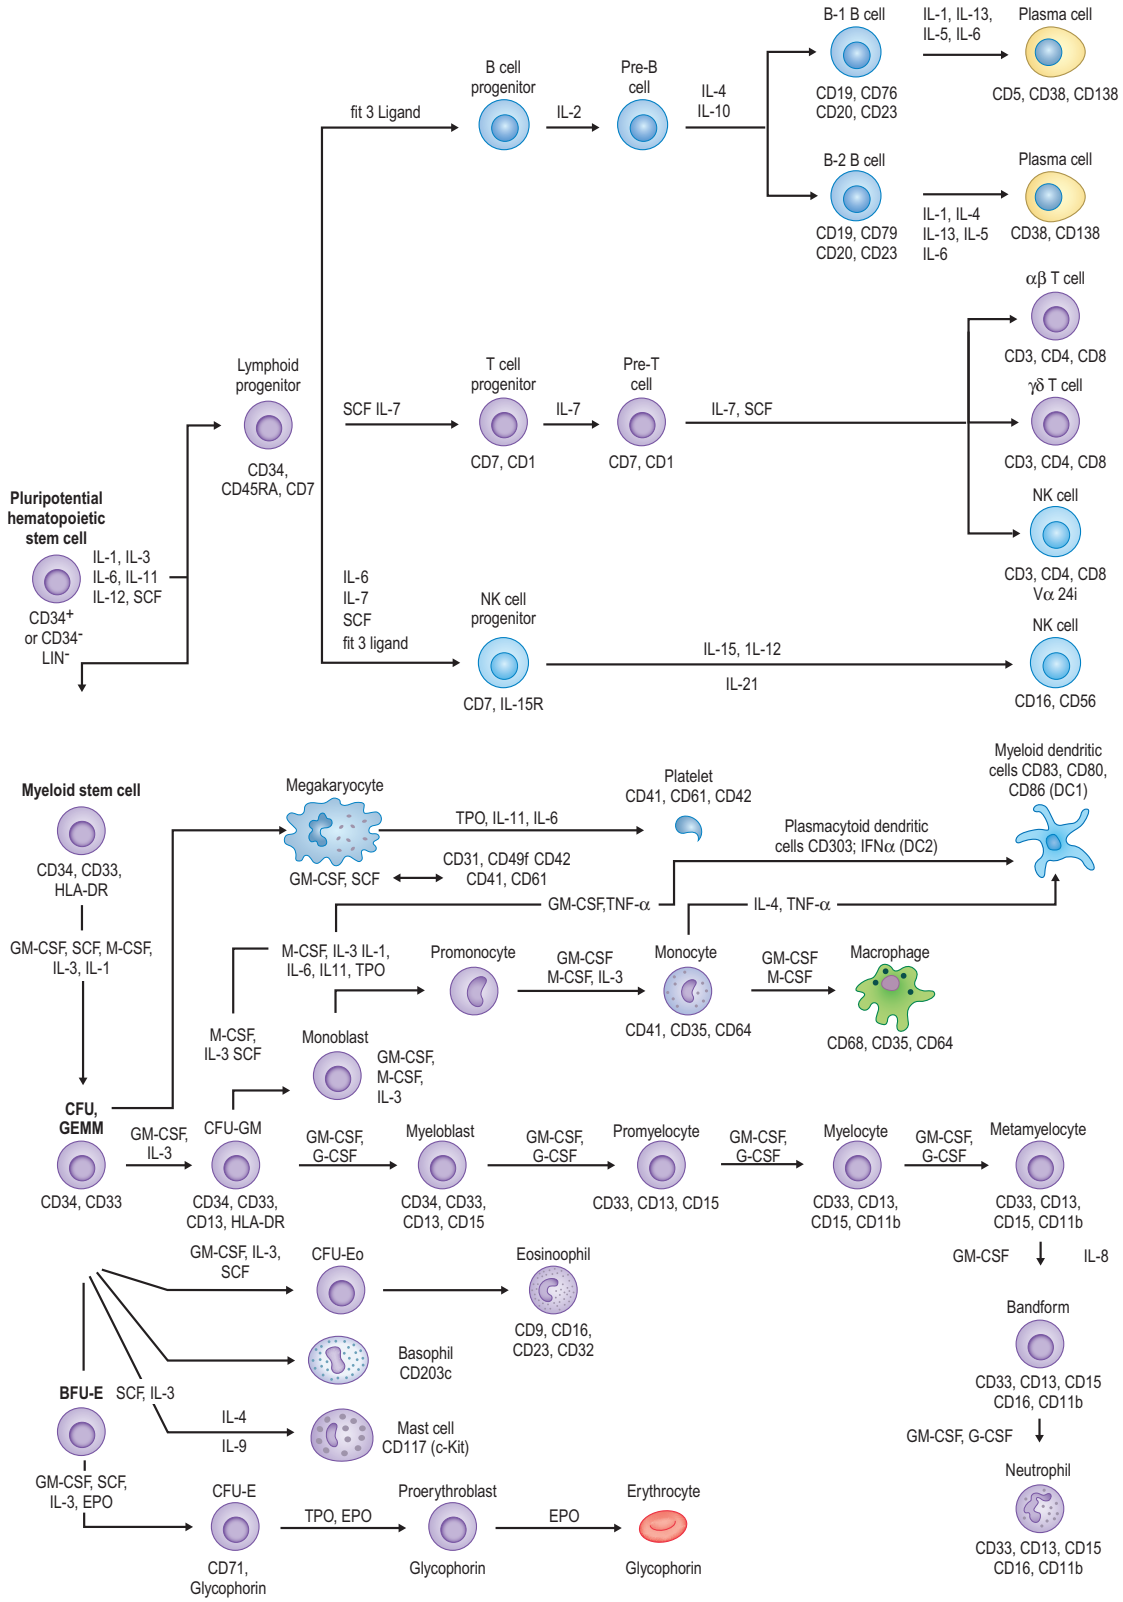

FIG. 2.1 Differentiation pathways for hematopoietic cells.

(LIN)-specific markers (*e.g.*, CD2, CD3, CD5, CD7, CD14, CD15, or CD16), and expressed CD34 on the cell surface. Definitive markers of human HSC are CD34 as well as CD90 and CD49f.[6] As HSC go out of quiescence to become lineage directed, they lose expression of both CD90 and CD49f before they become committed to the myeloid or lymphoid lineage. The lymphoid precursor expresses CD10, CD45Ra, whereas the myeloid precursor expresses CD135. Transcription factors are unique for each population. For the HSC, these include SOX8, SOX18, and NFIB. Out of quiescence, the HSC express MYC and IKZF1. Key signaling pathways include Notch and Wnt/β-catenin.[4]

A long-lived stem cell has capacity for self-renewal via asynchronous division that can be influenced by external factors, including infection.[11] Hematopoietic stem cells circulate in the peripheral blood with 10 to 100 times less frequency than their differentiated progeny. Mobilization of "stem cells" to the periphery is induced with G-CSF. Of these induced cells, although most are Lin^-, only 5% to 20% are true stem cells.[11] Most peripheral blood-induced stem cells express activation antigens (*e.g.*, transferrin receptor, CD71 and CD38). Peripheral blood HSCs engraft 2 to 3 days faster than conventional bone marrow HSCs, and thus can reduce bone marrow transplantation morbidities. However, peripheral blood HSCs are more differentiated than bone marrow HSCs with limited self-renewal.

Regulation of Hematopoietic and Lymphopoietic Cell Growth and Differentiation

Regulation of stem cell differentiation occurs through interactions with a variety of micro-environmental factors in the bone marrow or thymus. Cell surface receptors recognize either soluble ligands (*e.g.*, cytokines) released by other cells, or surface ligands (*e.g.*, cell interaction molecules) expressed on adjacent cells. These receptors can facilitate differentiation. Stem cells can be exposed to spatially and temporally regulated ligands or factors. The differential expression of receptors on the stem cells allows control of proliferation and differentiation along one of the hematopoietic or lymphoid lineages.[6]

Cytokines (Chapter 14) have pleiotropic effects on hematopoietic and lymphoid cell development. They affect both growth and maintenance of pluripotent stem cells, as well as the development and differentiation of specific cell lineages. The effect of the cytokine often differs, depending on whether the cell has previously been or is concurrently being stimulated by other cytokines. The stage of differentiation, as well as the presence or absence of the cytokine's receptor on the cell surface, also affects the cellular response. Although there are several cytokines, such as IL-6 and stem cell factor (SCF), that are classically involved in hematopoiesis, these cytokines have non-hematopoietic functions, as well.

Stromal cells located within the bone marrow and thymus regulate hematopoietic and lymphoid cell growth and differentiation by releasing cytokines. These include the interleukins IL-4, -6, -7, and -11; leukemia inhibitory factor (LIF); granulocyte–macrophage colony-stimulating factor (GM-CSF); granulocyte colony-stimulating factor (G-CSF); and SCF.[4,12] Stromal cells also participate in cell–cell interactions with progenitors that express fibroblast growth factor 1 (FGF-1) and FGF-2 that support HSC expansion. In addition, stromal cells form the intercellular matrix (*e.g.*, fibronectin and collagen) that binds to selectin and integrin receptors present on hematopoietic and lymphoid progenitors.[13]

Cytokines That Affect the Growth and Maintenance of Pluripotent and Multipotent Stem Cells

Pluripotent stem cells can reconstitute cells of the hematopoietic and lymphoid lineages. Maintenance of pluripotent capacity is mediated through factors that keep HSC quiescent. These include c-kit, N-cadherin, osteopontin, TGF-β and Wnt signaling. There are also factors that have a negative effect on quiescence, such as Hedgehog signaling and notch ligands, Delta and Jagged.[4] As progeny differentiate and the stem cell pool is depleted, a low level of stem cell proliferation is required. The entry of stem cells into the cell cycle and subsequent proliferation, as well as commitment to particular lineages, is controlled by cytokines and transcription factors. Data suggest that flt-3 ligand, c-kit ligand, and megakaryocyte growth and development factor (MGDF) all promote long-term stem cell expansion. The combination of c-kit ligand, IL-3 and -6 causes more rapid expansion, but does not allow long-term extension of precursor cells.[12]

Several cytokines, either alone or in combination, promote stem cell growth (Table 2.3).[5] Combinations of cytokines are more effective at inducing stem cell growth. For example, IL-1 promotes stem cell growth by inducing bone marrow stromal cells to release additional cytokines and by synergistically stimulating these cells in the presence of other cytokines. One of these other cytokines, IL-3, promotes the growth of hematopoietic progenitors. The effect is significantly enhanced by the addition of IL-6, IL-11, G-CSF, and SCF. IL-11, a stromal cell-derived cytokine, enhances IL-3-induced colony formation in 5-fluorouracil-resistant stem cells. Similarly, other cytokines secreted by stromal cells (*e.g.*, IL-6, G-CSF, and SCF) also exert their effects by shortening the G0 period in stem cells. In contrast, IL-3 acts on cells after they have left G0. Either by itself or in conjunction with IL-11 or SCF, IL-12 is unable to support the growth of primitive hematopoietic stem cells. However, IL-12 acts in synergy with IL-3 and IL-11, or IL-3 and SCF, to enhance stem cell survival and growth.

Depending on the circumstance, cytokines may either enhance or inhibit the growth or differentiation of hematopoietic and lymphoid cells. For example, IL-6 participates in the development of neutrophils, macrophages, platelets, T cells, and B cells. Thrombopoetin signaling promotes stem cell self-renewal to increase transplantation success.[14] The effects of individual cytokines can be altered when they function in combination. Together, GM-CSF and IL-3 promote development of granulocytes, macrophages, dendritic cells and erythrocytes. In the presence of IL-3, IL-6, and GM-CSF the LIF cytokine can enhance the growth and development of $CD34^+$ bone marrow progenitor cells along multiple lineages. However, in their absence, LIF has little effect. Similarly, while transforming growth factor-β (TGF-β) and IL-4 are potent inhibitors of hematopoietic progenitor cell growth, they enhance granulocyte development. Conversely, tumor necrosis factor-α (TNF-α) inhibits development of granulocytes, but potentiates the effects of IL-3 on hematopoietic progenitor cell proliferation.

Cytokines That Inhibit Hematopoietic Stem Cell Growth

Cytokines produced by mature cells may also downregulate hematopoietic stem cell growth. For example, macrophage inflammatory protein-1α (MIP-1α) can inhibit hematopoietic progenitor cell proliferation, interferon-γ (IFN-γ) and TGF-βpromote terminal differentiation, and TNF-α can induce apoptosis.

TABLE 2.3 Cytokines Important for Hematopoietic Cell Growth and Differentiation

Cytokines	Stem Cells	Thymocytes	B Cells	NK Cells
IL-1	Acts on stromal cells	Differentiation		
IL-2		Pleomorphic	Proliferation	Proliferation
IL-3	Proliferation			
IL-4		Pleomorphic	Promotes (low) Prevents (high)	Inhibits IL-2
IL-5			Proliferation/differentiation	
IL-6	Shortens G_0	Enhances stimulation	Maintains potential	Enhances IL-2
IL-7		Survival/proliferation	Proliferation of pro- and pre-B cells	Activation
IL-10			Survival	
IL-11 (Megakaryocyte development)	Shortens G_0		Maintains potential	
IL-12	Survival			Activation proliferation
IL-13			Activation/division of mature B cells	
IL-15			Proliferation	Development/survival
IL- 21			Proliferation	Expansion
SCF/c-*kit*	Survival	Atrophy	Maintains potential	Expansion
G-CS	Shortens G_0		Maintains potential	
FLt3 ligand	Growth factor		Increases proliferation	Expansion
SDF1-α		Proliferation/regeneration	Chemoattractant	
LIF	Proliferation	Atrophy		
Thrombopoietin	Expansion/regulates self-renewal			
TNF-α	Proliferation: inhibits granulocytes			
TGF-β	Inhibits growth enhanced granulocytes			
MIP-1α	Inhibits			
NGF			Proliferation/differentiation	Expansion

When pathologic conditions exist, these cytokines can have adverse effects on hematopoietic and lymphoid cell development, resulting in various deficiency states.

Cytokines Affecting Development and Differentiation of Specific Cell Lineages

The initial event in differentiation involves the commitment of pluripotent stem cells to a specific lineage. Cytokines are important for this process and appear to have lineage-specific effects that act at particular late stages of differentiation. For example, erythropoietin regulates the later stages of erythrocyte differentiation, whereas G-CSF induces granulocyte differentiation and macrophage colony-stimulating factor (M-CSF) is specific for macrophage maturation.[15]

KEY CONCEPTS

Cells of the Immune System

1. Pluripotent stem cells in bone marrow give rise to all lineages of the immune system as well as platelets and red blood cells.
2. Development and regulation of cells of the immune system is marked by the programmed appearance of specific cell surface molecules and responsiveness to selective cytokines. Most of these cell surface markers have been given a cluster of differentiation (CD) designation.
3. Mature cells of the immune system include antigen-presenting cells (APCs), phagocytic cells, including neutrophils, eosinophils, and basophils, and lymphocytes, including natural killer cells and T, B, or innate lymphoid cells (ILCs).
4. APCs include monocytes, macrophages, dendritic cells, endothelial cells, epithelial cells, and adipocytes. B lymphocytes can also function as potent APCs. APCs can direct the differentiation and function of both innate and acquired immune cells.
5. Polymorphonuclear (PMN) granulocytes are important in the early response to stress, tissue damage, and pathogens. These phagocytes include neutrophils, eosinophils, and basophils.
6. Lymphocyte lineages have discrete subpopulations with specialized functions. These include CD4 and CD8 T cells, T-helper (Th) subsets including T regs, Th9, Th17 and Tfh cells, innate lymphoid cells, and the B-1, conventional B-2, and marginal zone (MZ) B cells.

Mature Cells of the Immune System

The mature cells of the immune system arise mainly from progenitor cells in the bone marrow. They include both nonspecific and antigen-specific effector cells. The central player in both lines of defense is the antigen presenting cell (Chapter 6). In addition to their nonspecific effector functions, these cells are crucial for the development of specific immune responses. With maturation, these cells enter the blood (Table 2.4) where they circulate into the tissues and organs.

Antigen Presenting Cells

APC are found primarily in the solid lymphoid organs and skin (Chapter 23). The frequency of these in tissues varies between 0.1% and 1.0%. Specialized APC in B cell areas of lymph nodes and spleen are termed follicular dendritic cells (FDCs) because they have dendrites, not because they are related to other dendritic cell types. FDCs trap the antigen–antibody complexes that are important for the generation and maintenance of memory B cells. These cells do not express class II molecules, rather they have receptors for IgG and complement component C3b. These are FcγR (CD64) and CR1 (CD35), respectively.

TABLE 2.4 Normal Distribution of White Blood Cells in the Peripheral Blood of Adults and Children

	Approximate Percentage		Range Of Absolute Counts (no./μL)	
Cell type	Adults	Children (0–2 Years)	Adults	Children (0–2 Years)
Monocytes	4–13		400–1000	
Dendritic cells	0.5–1	ND[a]	30–170	ND
Granulocytes	35–73		2500–7500	1000–8500
Lymphocytes	15–52	34–75	1450–3600	3400–9000
As % of lymphocytes				
T cells	75–85	53–84	900–2500	2500–6200
CD4 cells	27–53	32–64	550–1500	1300–4300
CD8 cells	13–23	12–30	300–1000	500–2000
B cells	5–15	06–41	100–600	300–3000
NK cells	5–15	03–18	200–700	170–1100

[a]Not determined.

Child data adapted from Shearer W, Rosenblatt H, Gelman R, et al. Lymphocyte subsets in healthy children from birth through 18 years of age: the pediatric AIDS Clinical Trials Group P1009 study. *J Allergy Clin Immunol.* 2003;12:973–980.

Monocytes-Macrophages

Cells of the monocyte–macrophage lineage comprise approximately 10% of the white cells in the blood. They exist primarily as monocytes, which are large 10- to 18-μm cells with peanut-shaped, pale purple nuclei as determined by Wright's staining (see Table 2.4). The cytoplasm, which is 30% to 40% of the cell, is light blue and has azurophilic granules that resemble ground glass with intracytoplasmic lysosomes. These cells express MHC class II molecules, CD14 (the receptor for lipopolysaccharide), and distinct Fc receptors (FcR) (Chapter 8) for Ig. The latter include FcγRI (or CD64), which has a high affinity for IgG, and FcγRII (or CD32), which is of medium affinity and binds to aggregated IgG. FcγRIII (or CD16) has low affinity for IgG and is associated with antibody-dependent cellular cytotoxicity (ADCC). It is expressed on macrophages, but not on blood monocytes. Monocytes and macrophages also express CD89, the Fc receptor for IgA.[15]

Macrophages are more differentiated monocytes that reside in various tissues, including lung, liver, and brain.[16] Cells of the monocyte–macrophage lineage can be depleted or isolated because they adhere strongly to glass or plastic surfaces. However, this process activates them, which can confound functional studies. Many cells of this lineage phagocytose organisms or tumor cells *in vitro*. Cell surface receptors, including CD14, Fcγ receptors and CR1 (CD35), are important in opsonization and phagocytosis. Cells of this lineage also express MHC class II molecules, and some express the low-affinity receptor for IgE (CD23). Other cell surface molecules include myeloid antigens CD13 (aminopeptidase N) and CD15 (Gal (1–4) or [Fuc (1–3)] GlcNAc) and the adhesion molecules CD68 and CD29 or CD49d (VLA-4). Classical blood monocytes in humans (85%) express high levels of CD14, but no CD16. By contrast, nonclassical monocytes express less CD14, but more CD16. This later subset produces much more IL-12, TNF-α, and IL-1β. In addition to phagocytic and cytotoxic functions, these cells have receptors for various cytokines such as IL-4 and IFN-γ that can regulate their function. Activated macrophages are also a major source of cytokines, as well as complement proteins and prostaglandins.

Macrophages, along with DCs, have been shown to be more plastic in differentiation and function than previously realized. An alternative activation pathway induced by T helper cell 2 (Th2) (Chapter 11) cytokines, IL-4 and Il-13,[16] promotes suppressive anti-inflammatory properties that can reduce responses to cancer as well as maintaining adipose integrity. This macrophage subtype is seen among tumor-associated suppressive macrophages.

Monocytes and macrophages arise from colony-forming unit granulocyte–monocyte (CFU-GM) progenitors that differentiate first into monoblasts, then promonocytes, and finally monocytes.[15] Mature monocytes leave the bone marrow and circulate in the bloodstream until they enter tissues, where they develop into tissue macrophages (alveolar macrophages, Kupffer cells, intestinal gut macrophages and microglial cells). There is evidence suggesting that tissue macrophages actually originate from fetal macrophages and thus seed tissues early in fetal development where they are maintained by longevity and slow self-renewal.[17] Tissue resident macrophages and those derived from monocytes act together to combat infection.[18]

Several cytokines participate in the development of monocytes and granulocytes. For example, SCF, IL-3, IL-6, IL-11, and GM-CSF promote development of myeloid lineage cells from $CD34^+$ stem cells, especially in early stages of differentiation. Another cytokine, M-CSF, acts at the later stages of development and is lineage specific, inducing maturation into macrophages.[15]

Dendritic Cells

Dendritic cells are accessory cells that express high levels of MHC class II molecules and are potent inducers of primary T-cell responses. Except for the bone marrow, they are found in virtually all primary and secondary lymphoid tissues, as well as in skin, mucosa, and blood. DCs are also abundant in the thymus medulla for selection of thymocytes.

Dendritic cells, macrophages, and granulocytes are derived from $CD34^+$ MHC class II-negative precursors present in the bone marrow. GM-CSF and TNF-α are involved in development of DCs from their precursors in bone marrow.[19–21] DCs residing in peripheral sites such as the skin, intestinal lamina propria, lung, genitourinary tract, etc. are typically immature. These cells are more phagocytic and display lower levels of MHC class I, MHC class II, and co-stimulatory molecules. These immature dendritic cells take up antigens in tissues for subsequent presentation to T cells. As they migrate, they mature to become efficient APC.

The predominant APCs of the skin are the Langerhans cells[22] of the epidermis. These cells are characterized by rocket-shaped granules called Birbeck granules. Immature tissue DCs in peripheral tissues engulf and process antigen and home to T-cell areas in the draining lymph nodes or spleen.[23] Mature DCs can directly present processed antigens to resting T cells to induce proliferation and differentiation, a key functional difference between mature DCs and macrophages. The effector cells produced after this presentation then home to the site of the antigenic assault.

TNF-α maintains viability of Langerhans cells in the skin and stimulates their migration. In Peyer patches (Chapter 24), immature dendritic cells are located in the dome region underneath the follicle-associated epithelium (FAE) where they actively endocytose antigens taken up by M cells in the FAE. More mature interdigitating DCs are found in T cell regions. These cells, like their counterparts in the lungs, induce Th2 immune responses. There are at least three types of DC. cDC1 derive from bone marrow,

are found in lymphoid tissues, and express CD141, CLEC-9a and XCR-1. These are similar to murine CD8 α/α DCs in function. cDC2 express CD1c and CD171a. The third type, plasmacytoid DC, are high producers of IFN-α. They express CD123, CD303, CD304 and low levels of CD11c.[21]

All three of the DC types can be derived from either myeloid or lymphoid lineages and are extremely plastic.[19,20] Antigen-presenting cells, especially dendritic cells, are largely influenced by stimulation with Toll-like ligands found on a variety of stimuli, which then direct differentiation and function of innate and acquired immune cells.

Polymorphonuclear Granulocytes

Polymorphonuclear (PMN) granulocytes arise from progenitors that mature in the bone marrow. They are essentially end-stage cells. Their life span after release varies from a few days to 5 to 6 days and is regulated by responses required. PMN constitute 65% to 75% of the white blood cells in the peripheral blood, are 10 to 20 μm in diameter, and are characterized by a multilobed pyknotic nucleus characteristic of cells undergoing apoptosis (see Table 2.4).[24]

PMN cells are also found in tissues. They use diapedesis to gain access from the blood. Granulocytes act as early soldiers in the response to stress, tissue damage, or pathogen invasion. Because of their function in phagocytosis and killing, they possess granules whose unique staining characteristics categorize the cells as neutrophils (Chapter 39), basophils (Chapter 44), or eosinophils (Chapter 45).

Neutrophils. Most circulating granulocytes are neutrophils (90%). Their granules are azurophilic and contain acid hydrolase, myeloperoxidase, and lysozymes. These granules fuse with ingested organisms to form phagolysosomes, which eventually kill the invading organism. In some cases, there is extracellular release of granules after activation via the Fc receptors. Neutrophils express a number of myeloid antigens, including CD13, CD15, CD16 (FcγRIII), and CD89 (FcαR). In response to bacterial infection, there is typically an increase in the number of circulating granulocytes. This often includes the release of immature granulocytes, called band or stab cells, from the bone marrow. In a mild infection, both the number and function of neutrophils are increased. This is associated with a delay in apoptosis. With a more severe infection, there may actually be impairment of function owing to the release of immature cells. Neutrophils form extracellular traps (NETs) that capture microbes and use autophagy to digest them intracellularly.[25] Out of control NET formation (Netosis) occurs in sepsis to enhance tissue destruction. Neutrophils may also act as APC.[26]

Neutrophils derive from CFU-GM progenitor cells and differentiate within a 10- to 14-days period. These progenitors give rise to myeloblasts, which in turn differentiate into promyelocytes, myelocytes, and finally mature neutrophils. The cytokines SCF, IL-3, IL-6, IL-11, and GM-CSF promote the growth and development of neutrophil precursors, whereas certain cytokines are important for differentiation of CFU-GM progenitors into mature neutrophils.[27] For example, G-CSF induces maturation of neutrophil precursors into mature neutrophils. IL-4 enhances neutrophil differentiation induced by G-CSF, while at the same time inhibiting development of macrophages induced by IL-3 and M-CSF.

Eosinophils. Eosinophils typically comprise 2% to 5% of the white cells in the blood. They exhibit a unique form of diurnal variation with peak production at night. This is perhaps due to lower glucocorticoid levels at night. Eosinophils are capable of phagocytosis followed by killing, although this is not their main function. The granules in eosinophils are much larger than in neutrophils and are actually membrane-bound organelles. The crystalloid core of the granules contains a large amount of major basic protein (MBP). MBP can neutralize heparin and is toxic. During degranulation, the granules fuse to the plasma membrane, and their contents are released into the extracellular space. Organisms that are too large to be phagocytosed, such as parasites, can be exposed to cell toxins by this mechanism. MBP can damage schistosomes *in vivo*, but damage is minimized because the MBP is confined to a small extracellular space (Chapter 29). Eosinophils also release products that counteract the effects of mast cell mediators. Whether eosinophils are absolutely required for helminth control is controversial, and more study is needed (Chapter 30).

Eosinophils derive from a progenitor (CFU-Eo) that progresses through developmental stages similar to those of neutrophils.[28] These stages begin with an eosinophilic myeloblast, followed by an eosinophilic promyelocyte, a myelocyte, and finally a mature eosinophil. Three cytokines are important in the development of eosinophils: GM-CSF, IL-3, and IL-5. GM-CSF and IL-3 promote eosinophil growth and differentiation; SCF also has an effect on eosinophil function. The chemokine eotaxin (CCL11) (Chapter 15) also promotes eosinophilia. IL-5 has more lineage-specific effects on eosinophil differentiation, although it also affects some subsets of T and B cells. IL-5 is also essential for eosinophil survival and maturation. These cells are recruited into inflammatory tissue via chemokines that target CCR3. Eosinophils are involved in the pathophysiology of asthma (Chapter 43) by contributing to airway dysfunction and tissue remodeling. IL-5 is a current target to control eosinophilia.

Basophils and mast cells. Basophils represent less than 1% of the cells in the peripheral circulation, and have characteristic large, deep-purple granules. Mast cells are found in proximity to blood vessels and are much larger than peripheral blood basophils. The granules are less abundant, and nucleus is more prominent. There are two different types of mast cells, designated mucosal or connective tissue depending on their location.[29] Mucosal mast cells require T cells for their proliferation, whereas connective tissue mast cells do not. Both types have granules that contain effector molecules. After degranulation, which is effected by cross-linkage of cell surface IgE bound to cells via the high-affinity receptor for IgE, the basophils–mast cells release heparin, histamine, and other effector substances to mediate an immediate allergic attack (Chapter 46).

Since basophils and mast cells share a number of phenotypic and functional features, they have been considered to share a common precursor. They both contain basophilic-staining cytoplasmic granules, express the high-affinity IgE receptor (FcεRI), and release a number of similar chemical mediators that participate in immune and inflammatory responses, particularly anaphylaxis. They both have been implicated in allergic inflammation and in fibrosis. However, basophils and mast cells have distinct morphologic and functional characteristics that suggest they are distinct lineages of cells, rather than cells at different stages within the same lineage. Analysis of human transcription factors places basophils closer to eosinophils than to mast cells.[30]

Basophils mature from a progenitor (CFU-BM) into basophilic myeloblasts, then basophilic promyelocytes, myelocytes, and finally mature basophils. Less is known about the stages of

mast cell development, although they are probably derived from the same CFU-BM progenitor as basophils.[31,32]

In humans, SCF induces the most consistent effects on the growth and differentiation of both basophils and mast cells. Both IL-3 and SCF are important for intestinal mast cell differentiation. IL-6 can also increase mast cell numbers. This probably explains why T cells are needed for their development.[29] While both IL-4 and -9 stimulate mast cell development in mice; in humans, only IL-9 acts in synergy with SCF to enhance mast cell growth.[30] Additional cytokines that affect basophil growth include nerve growth factor and GM-CSF or TGF-β, and IL-5 for basophil differentiation.

Platelets and Erythrocytes

Hematopoietic stem cells also give rise to platelets and erythrocytes. Platelets are necessary for blood clot formation and mediate a number of immune functions. Mature RBCs are necessary for oxygen delivery to tissues.[31] Platelets derive from CFU-GEMM progenitors, which in turn differentiate into burst-forming units for megakaryocytes (BFU-MEG). The BFU-MEG then differentiate into CFU-MEG, promegakaryoblasts, megakaryoblasts, megakaryocytes, and finally platelets.[33] Several cytokines, particularly thrombospondin, IL-1, IL-3, GM-CSF, IL-6, IL-11, and LIF, affect the growth and differentiation of platelets. Platelets are a main producer of exosomes, small 80 micron membranous vesicles with cell surface markers characteristic of their cell source, as well as mRNA encoding for cell-related molecules. Exosomes travel in the blood and the lymph and may be a significant way that cells function at a distance. Other immune cell types, including dendritic cells can transfer information via exosomes.

While erythrocytes also derive from CFU-GEMM progenitors, their progenitors are burst-forming units for erythrocytes (BFU-E), which in turn differentiate into CFU-E, pronormoblasts, basophilic normoblasts, polychromatophilic normoblasts, orthochromic normoblasts, reticulocytes, and finally erythrocytes. Again, several cytokines, notably GM-CSF, SCF, IL-9, thrombospondin, and erythropoietin, regulate erythrocyte development.

Lymphocytes

Lymphocytes, the central cell type of the specific immune system, represent about 25% of white cells in the blood (see Table 2.4). Small lymphocytes range between 7 and 10 μm in diameter. They are characterized by a nucleus that stains dark purple with Wright stain, and by a small cytoplasm. Large granular lymphocytes range between 10 and 12 μm in diameter and contain more cytoplasm and scattered granules. The three types of lymphocytes that circulate in the peripheral blood—T, B, and ILCs, including NK cells cells—constitute approximately 80%, 10%, and 10% of the total blood lymphocyte population, respectively (Chapters 7, 9, and 12). In the thymus, most of the lymphocytes (90%) are T cells. However, in the spleen and lymph nodes, only about 30% to 40% are T cells. The preponderant lymphocytes in these locations are B cells (60% to 70%).[34,35]

T cells. T lymphocytes arise from lymphocyte progenitors in the bone marrow that are committed to the T-cell lineage even before they move to the thymus. Early in embryogenesis, T-cell precursors migrate to the thymus in waves.[36,37] Associated with this migration is the developing ability of thymic education elements, epithelial cells, and DCs to select appropriate T cells.[37] In the thymus, T cells rearrange their specific antigen receptors (TCR) and then express CD3 along with the TCR on their surface (Chapter 9).

Resting T cells in the blood typically range between 7 and 10 μm in diameter and are agranular, except for the presence of a structure termed a Gall body, which is not found in B cells (see Table 2.4). The Gall body is a cluster of primary lysosomes associated with a lipid droplet. A minority of T cells in the blood (about 20%) are also of the large granular type, meaning that they are 10 to 12 μm in diameter and contain primarily lysosomes that are dispersed in the cytoplasm. Golgi apparatus also are found.

The preponderant form of the TCR, found on about 95% of circulating T cells, consists of α and β chains ($\alpha\beta TCR^+$).[38] Some $CD3^+$ cells do not express either CD4 or CD8 (double-negative or DN) and are characterized by having an alternative TCR composed of γ and δ chains ($\gamma\delta TCR^+$). Further differentiation in the thymus occurs from $CD3^+$ cells that express both CD4 and CD8 (double-positive or DP) T cells expressing either CD4 or CD8 but not both. These mature cells then circulate in the peripheral blood at a ratio of about 2:1 (CD4:CD8) and populate the lymph nodes, spleen, and other secondary lymphoid tissues.

T-cell progenitors, which are $CD7^+$, arise in the bone marrow from a multipotential lymphoid stem cell. After migration to the thymus, the $CD7^+$ progenitors give rise to a population of $CD34^+$, $CD3^-$, $CD4^-$, and $CD8^-$ T-cell precursors. These cells undergo further differentiation into mature T cells. Cytokines produced by thymic epithelial cells (*e.g.*, IL-1 and soluble CD23) promote differentiation into $CD2^+$, $CD3^+$ thymocytes (see Table 2.3). IL-7 induces the proliferation of $CD3^+$ DN ($CD4^-$ $CD8^-$) thymocytes, even in the absence of co-mitogenic stimulation. IL-7 is absolutely required for human T-cell development.[39]

IL-2 and -4 demonstrate complex effects on thymocyte development. Both can promote development of pro-thymocytes, as well as antagonizing their development. IL-6 acts as a co-stimulator of IL-1- or -2-induced proliferation of DN thymocytes and can stimulate the proliferation of mature, cortisone-resistant thymocytes alone. Once T cells leave the thymus, a variety of cytokines affect their growth and differentiation.

T cell subsets. T cells can be divided into subsets based on surface expression of CD4 and CD8, as well as by function in an immune response. CD4 and CD8 T cells were originally characterized by expression of the respective antigen and association with functional ability. For example, human T cells expressing CD4 provide help for antibody synthesis, whereas cells expressing CD8 develop into cytotoxic T cells. The distinction is better described as which antigen-presenting molecule is used for TCR interaction. Thus, CD4 T cells recognize antigen in the context of MHC class II molecules, and CD8 T cells recognize antigen presented by class I molecules (Chapter 6).

Memory T cells are divided based on expression of CD45R0, CCR7, CD28 and CD95 that categorize functions of cells as stem cell memory, central memory, transitional memory, effector memory and terminal effector cells. Early memory T cells have high lymph node homing and proliferation potential. Later stage T cells home to the periphery, are effector cells, and do not proliferate.[40,41]

T-helper (Th) cells mature in response to foreign antigens. Their function is dependent on the production of cytokine patterns, which characterize them as Th type 1 (Th1), Th2 or Th17.[39] The precursor Th cell first differentiates into a Th0 cell producing interferon-γ(IFN-γ) and IL-4. The cytokine environment subsequently determines whether Th1 or Th2 cells

predominate. Th1 cells produce primarily IFN-γ, IL-2, and TNF-α and are important in cell-mediated immunity to intracellular pathogens (Chapter 26), such as the tubercle bacillus. Th1 cells primarily use the T-bet transcription factor. Th2 cells produce predominantly IL-4, -5, -6, -10, and -13, as well as IL-2, and predominate in immediate or allergic type 1 hypersensitivity (Chapter 46) and primarily use the Gata-3 transcription factor. IL-33 also enhances production of Th2 cytokines.[39]

Other populations of CD4 T cells can develop and rely on IL-23 or -12 action upon the cells. If T cells are exposed to IFN-γ, they upregulate both IL-12R and -23R, which then produce either conventional Th1 cells or another subset, Th17, which produces IL-17 and is important for controlling immune cell activation in the GI tract (Chapter 24). Overactive function of this subset has been associated with autoimmunity. The Th17 population preferentially uses the ROR γ transcription factor.

T follicular helper cells are those classically determined to help B cell responses in germinal centers. They are $CD4^+$, $ICOS^+$, $PD\text{-}1^+$ and express the transcription factor Bcl-6. It is likely that there are other epigenetically altered T cells that allow diversity of function during an immune response.[41] Th9 cells express the transcription factor, PU.1 and secrete IL-9 and are produced in response to TGF-B and IL-4. These cells are increased in various immune-related diseases.[42]

A minor subpopulation (<5%) of $CD3^+$ cells in the peripheral blood express γδ TCR molecules. Most of these cells do not express CD4 or CD8. However, some intraepithelial lymphocytes that express γδ TCR also express CD8 αα homodimers in place of conventional CD8 αβ heterodimers (see Fig. 2.10). These cells, which are thymus independent, are involved in the initial response to bacterial antigens presented in mucosal epithelium. Another minor subpopulation of T cells, NKT cells (Chapter 12), can be $CD4^+$ or $CD8^+$ and express a single Vα chain, Vα24, which recognizes glycolipids in the context of CD1a rather than a classical MHC molecule (Chapter 6). NKT cells express MIP-1 α and β, have a Th1 bias, but lack Il-10 production. [43,44] The final subset is regulatory T cells (Treg) (Chapter 13), which occur naturally and can be induced *in vitro*. They are $CD4^+$ and express high levels of CD25 and the transcription factor Foxp3. Other definitive markers remain elusive.[45] Tregs are reduced in autoimmunity in adipose tissue during obesity and increased in cancer to aid in immunosuppression.

B cells and plasma cells. B cells represent 5% to 10% of the lymphocytes in the blood (see Table 2.4; Chapter 7). They are typically 7 to 10 μm in diameter and lack Gall bodies and granules. B cells express cell membrane immunoglobulin (mIg), the majority expressing both IgM and IgD.[46] The cytoplasm is characterized by scattered ribosomes and isolated rough endoplasmic reticulum (RER). The Golgi is not prominent unless the cells are activated. A small minority of B cells express either surface IgG or IgA. A number of other cell surface molecules are found on B cells, including CD19, CD20, CD23, CD40, CD72, CD79a and b, MHC class II, Fcγ RII receptors (CD32) and complement receptors C3b (CR1a; CD35) and C3d (CR2a; CD21). Similar to T cells, which surround the TCR with activation effector molecules, B cell mIg associates with CD19, CD21, and CD81 to enhance B cell activation (Chapter 7).

Upon activation and cross-linking of surface Ig by specific antigen, B cells undergo proliferation and differentiation to produce plasma cells. Plasma cells are non-dividing, specialized cells terminally differentiated from B cells, the function of which is to secrete Ig. They lose expression of mIg and MHC class II molecules. Plasma cells (10–15 μm) are not normally found in the blood. They display an eccentric nucleus and a basophilic cytoplasm with a well-developed Golgi. The plasma cell displays parallel arrays of expanded rough endoplasmic reticulum (RER) that contains Ig. B cell proliferation and differentiation processes take place in the germinal centers of the lymph nodes.

Several cytokines influence the development of B lymphocytes. *In vitro* studies of cytokines involved in the development of early B-cell progenitors show that combinations of SCF (but not IL-3) with IL-6, IL-11 or G-CSF can maintain B-lymphoid potential.[47] Stromal cell-dependent differentiation of fetal pro-B cells occurs in conjunction with Flk-2/flt-3 ligand and IL-7 and on several transcription factors, including PU.1, IKAROS, E2A, EBF, PAX5 and IRF8. Unlike in mice, in humans IL-7, is not absolutely required for B cell development.[48]

IL-4 has a variety of important effects on B-cell growth and differentiation. Low doses of IL-4 induce pre-B cells to differentiate into B cells expressing surface membrane IgM, whereas higher doses of IL-4 inhibit differentiation of B cells. In mature B cells, IL-4 increases expression of MHC class II, CD23, and CD40 molecules; promotes activation and progression to the G_1 stage of the cell cycle; enhances proliferation after stimulation through the Ig receptor; and induces immunoglobulin class switch in human to IgG4 and IgE (IgG1 and IgE in mouse). IL-13, which is closely related to IL-4 and has many similar effects on B cells.

Other cytokines, such as IL-2, -5, -6, -11, and nerve growth factor (NGF), act on mature B cells and can either enhance their proliferation or promote their differentiation into immunoglobulin-secreting cells. In addition, IL-10 enhances the viability of B cells *in vitro*, increases MHC class II expression, and augments the proliferation and differentiation of B cells after stimulation through the Ig receptor or CD40. TGF-β1 is a significant switch factor for IgA. This cytokine induces human B cells triggered by mitogen to switch to both IgA1 and IgA2.

SDF-1 (stromal cell-derived factor) attracts early-stage B-cell precursors and is a likely mechanism whereby B cells form islands in the bone marrow. There are at least two major populations of B cells: B-1 in the follicular mantle and peritoneal cavity, and conventional B-2 cells, found in lymphoid follicles. The B-1 lineage predominates early in gestation and produces natural antibodies of the IgM isotype.[47] Local expression of IgA plasma cell precursors in the ileum important for bacterial containment.[48]

Innate Lymphoid Cells

Natural killer cells. Lymphocytes that do not express a T cell receptor but have cytolytic or non-cytolytic function typical of T cells are called innate lymphoid cells see (Chapter 3). The first described were cytolytic natural killer cells, which comprise about 10% to 15% of circulating lymphocytes (see Table 2.4; Chapter 12). These cells are usually larger than typical lymphocytes (10 to 12 μm) with less nuclear material and more cytoplasm small lymphocytes. They possess electron-dense peroxidase-negative granules and a developed Golgi apparatus.

Functional NK cells are found in the fetal liver as early as 6 weeks gestation. Fetal NK cells express cytoplasmic CD3 proteins, but no TCR rearrangements. Evidence suggests that an Fcγ receptor-positive cell that does not express lineage-specific markers (LIN^-) exists in the fetal mouse thymus where it normally gives rise to T cells. However, if removed from the thymus, the cells develop into $CD3^-$ NK cells. Such $CD3^-$ cells with

variable CD16 expression exist in human thymus and can be induced to proliferate, express NK-associated antigens, and exhibit NK cell function *in vitro*. These cells also express substantial levels of CD3δ and CD3ε in the cytoplasm.[49]

Mature NK cells in the blood do not express conventional antigen receptors, such as TCR or Ig, and the genes for these receptors remain un-rearranged. Some express FcγRIII (CD16), and others express CD56, an adhesion molecule. More than 90% of these cells express CD11b but not CD27. In the tissues, subsets of human NK cells express variable levels of CD11b and CD27, which defines their function (tolerant, cytotoxic or regulatory). NK cells, like T cells, also express the CD2 molecule. NK cells express the β chain of the IL-2 receptor, CD122, which allows resting NK cells to respond directly to IL-2.

The function of some NK cells is to provide nonspecific cytotoxic activity towards virally infected cells and tumor cells (Chapter 25). NK cells also can kill specifically when they are provided an antibody. This death delivery mechanism, known as antibody-dependent cellular cytotoxicity (ADCC), occurs via binding of the antibody to the Fcγ receptor CD16. After activation, NK cells produce cytokines, such as IFN-γ, that affect proliferation and differentiation of other cell types, especially DCs. Some of the recognition molecules on human NK cells are activating, some are inhibiting, and some act as receptors for MHC class I molecules.

The ontogeny of NK cells is now better understood. Although they express a number of membrane antigens in common with T cells and share functional properties with some T cell subsets, suggesting a common origin, NK cells are found in fetuses before the development of T cells or the thymus. In addition, NK cells develop normally in nude, athymic mice. NK cells probably develop extrathymically, and data suggest that they can develop from stem cells in lymph nodes. NK cells arise from triple-negative ($CD3^-CD4^-CD8^-$) precursors that are $CD56^+$, but do not express CD34 or CD5. T cells, on the other hand, develop from "triple-negative" precursors that are $CD34^+CD5^+CD56^+$. It is likely that T and NK cells arise from a common "triple-negative" precursor with the phenotype $CD7^+CD34^+CD5^+CD56^+$.

The cytokine receptor that determines lineage specificity is the α chain of the IL-2 receptor, CD25. Once CD25 is upregulated, the cell is destined to become a T cell. The cytokines most important in the early development of NK cells are IL-15 and IL-7. Flt ligand and c-kit also facilitate NK cell expansion. Several cytokines promote the growth and differentiation of mature NK cells. IL-2 induces proliferation and activation of NK cells. This probably occurs via the IL-2 receptor β chain (CD122) as NK cells do not express CD25. IL-2 also induces the growth of NK cells from precursors in bone marrow cultures. Both IL-7 and IL-12 activate NK cells. Although IL-4 inhibits the effects of IL-2 or IL-7 on NK cells, it acts synergistically with IL-12 to induce proliferation of $CD56^+$ cells. IL-6, despite having no effect by itself, enhances NK cell activity in thymocytes cultured with IL-2. Finally, IL-15 is also involved in signaling NK cells for survival.[50] Subsets of human NK cells develop based on responsiveness to TGF-β and IL-10 (tolerant), IL-12 and IGF-1 (cytotoxic) and TGF-β, IL-7 and IL-15.[50] There is now compelling evidence that NK cells can form a type of memory, especially after intense challenge.[51]

Non-cytotoxic innate immune cells. Non-cytotoxic innate immune cells, which are similar in function to T helper subsets, are divided into three main groups: ILC1, ILC2, and IL 3. These groups are defined by the cytokines they produce.[52,53] IlC-1 cells are non-cytotoxic Lin^- cells that produce INF-γ and TNF-α. ILC2's produce Th2 cytokines, such as Il-4, Il-5, Il-9 and Il-13; and some produce amphiregulin. They can be driven by IL-33.53 ILC3's produce IL-17A, IL-17F, IL-22, GM-CSF, and TNF-α. ILC3 are the most heterogeneous subset. They express CCR6 and CD117 and can be divided based on expression of the NCR Nkp44. The role of these cells in normal host function and responses to chronic inflammatory stimuli and cancer indicates that their roles are multifaceted.

KEY CONCEPTS

Tissues of the Immune System

1. Stem cells proliferate and mature into effector cells in the primary lymphoid organs, which include bone marrow and thymus.
2. Mature immune cells reside, undergo additional maturation, and generate immune responses in the secondary lymphoid organs.
3. Spleen and lymph nodes comprise the systemic immune system, which functions to protect the body from antigens in the lymphatic drainage and in the blood stream.
4. The mucosal immune system (respiratory, gastrointestinal, and genital) and the skin and adipose tissues have unique features that differentiate the immune system at these sites from the systemic immune sites, including the mucosal associated lymphoid tissue (MALT).
5. Commensal organisms at mucosal surfaces are an important component of the immune response at these sites.

MAJOR LYMPHOID ORGANS

The primary lymphoid organs are sites where lymphocytes differentiate from stem cells and proliferate and mature into effector cells. From birth to old age, these functions are carried out only in the bone marrow and the thymus.

Bone Marrow

The bone marrow provides the environment necessary for the development of most of the white blood cells of the body (Fig. 2.2). At birth, most bone cavities are filled with actively dividing blood-forming elements known as "red" marrow. By 3 to 4 years, however, the tibia and femur become filled with fat cells, limiting their role in hematopoietic development. The ribs, sternum, iliac crest and vertebrae remain 30% to 50% cellular and produce hematopoietic cells throughout life.[1]

Main components of the bone marrow include blood vessels, cells, and extracellular matrix. The production of cells from HSC occurs in areas separated by vascular sinuses. The walls of the surrounding sinus contain a layer of endothelial cells with endocytic and adhesive properties. These specialized endothelial cells of the sinuses probably produce type IV collagen and laminin for structural support via CXCL-12 (SDF-1) interactions. These cells also elaborate colony-stimulating factors and IL-6. The outer wall of the sinus is irregularly covered with reticular cells, which branch into areas where cells develop and provide anchors by producing reticular fibers. Megakaryocytes lie against this wall, touching the endothelial cells.

A functional unit of marrow, called a spheroid, contains adipocytes, stromal cell types and macrophages. These reticular cell networks compartmentalize the developing progenitor cells into separate microenvironments called *hematons*. Osteoblasts and osteoclasts regulate production of progenitor cell expansion.[4]

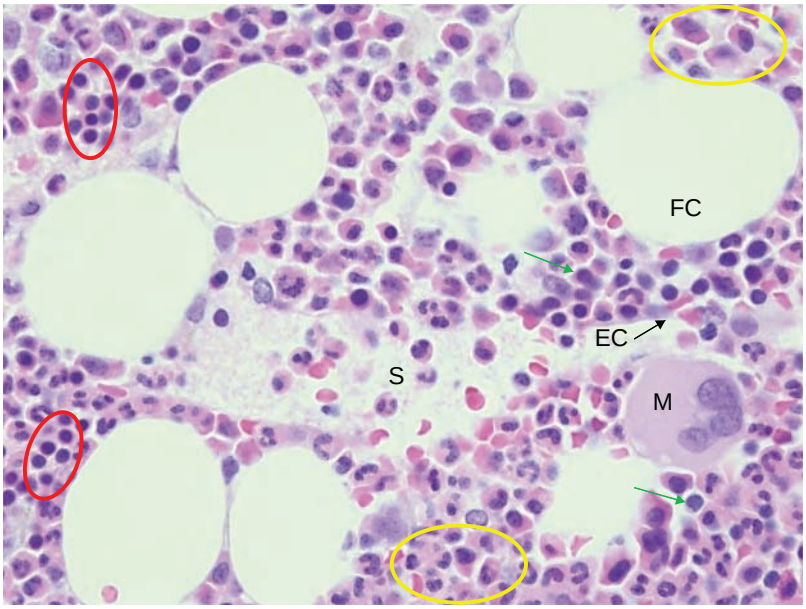

FIG. 2.2 Bone marrow with erythroid precursors *(circled red)*, myeloid precursors *(circled yellow)*, megakaryocytes *(M)*, sinusoids *(S)*, and fat cell *(FC)*.

The kind of distribution of stem and progenitor cells across the radial axis of the bone suggests that the HSC are next to the bone surface, whereas the more mature progenitor cells are nearer the central venous sinus, which facilitates release of mature cells. The production of new progenitor cells from stem cells occurs as a result of interactions between stem cells and stromal cells. Given the right stimulus, most of the progeny proliferate and differentiate further, which may result in migration from the bone marrow. In migrating, the cells become detached from stromal elements and progress toward the central sinus.

Control of hematopoiesis is regulated by both positive and negative cytokines and by up- and downregulation of various adhesion molecules (Chapter 16) in committed progenitor cells. The molecules involved include the fibronectin receptor, glycoproteins IIb and IIIa, ICAM-1 (CD54), LFA-1 (CD11, CD18), LFA-3 (CD58), CD2, and CD44. Adhesion molecules on stromal cell surfaces include fibronectin, laminin, ICAM-1 (CD54), types I, III, and IV collagen, and N-CAM. The most clearly established role for adhesion molecules involves fibronectin, which allows erythroid precursors to bind to stromal cells and thus facilitates progression from erythroblast to reticulocyte. Molecular signals important for the HSC niche include N-cadherin that regulates osteoblastic interactions with HSC, Wnt/B catenin signals important for self-renewal of HSC, VEGF important for coupling osteoblasts with vascular endothelial cells and PDE2, an inflammatory mediator that can increase HSC numbers

Accessory cell populations in bone marrow regulate many aspects of hematopoiesis, both positively and negatively. The upregulation of growth of the earliest progenitor cells is mediated by cytokines. For example, macrophages produce IL-1, which then induces stromal cells to express growth factors such as GM-CSF, IL-6, and IL-11. However, downregulation can occur at any stage. For example, T cells regulate hematopoiesis by producing factors that act on early erythroid progenitor cells, BFU-E. CFU-E, which are later progenitors, are fully differentiated by erythropoietin. By contrast, activated T cells produce factors that suppress BFU-E and CFU-E *in vitro*.

Cells in the bone marrow were originally characterized by morphology. The predominant types are those of the myeloid lineage, which account for about 50% to 70% of the cells. Red blood cell precursors represent from 15% to 40% of the total cells. Other lineages exist in lower proportions (<5%). With the advent of cell surface antigen markers and flow cytometry, a more precise delineation could be made (Fig. 2.3). Thus, we now know that of the mature leukocytes in the bone marrow, approximately 70% are $CD3^+$, $CD14^+$, $CD20^+$, or $CD11b^+$.

Both memory T and B cells return to the bone marrow after generation. These are designated as Lin^+. Of the Lin^- cells, about 6% are $CD33^+$ and primarily of myeloid lineage. A Lin^-CD71^+ population comprises about 18% of the total and is mostly of the red blood cell lineage.

Thymus

The thymus is located below the sternum and in the mediastinum. This bi-lobed organ develops from the third and fourth pharyngeal pouches and is endodermal in origin. It is organized into a loose lobular structure. Areas in each lobe consist of a cortex of rapidly dividing cells and a medulla that contains fewer, but more mature, T cells (Figs. 2.4 and 2.5). This arrangement has long suggested a scenario for differentiation where cells progress from the cortex to the medulla.

Non-lymphocyte cells play very important site-specific roles in development of T cells. Epithelial cells are scattered throughout the thymus. Depending on their location, they are known as nurse cells, cortical epithelial cells, or medullary epithelial cells. Macrophage-type cells and interdigitating cells that are bone-marrow derived are located at the junction between cortex and medulla and are involved in T-cell selection.

Enlarged, activated T-cell precursors from the bone marrow begin by colonizing the subcapsular region of each lobe. These are actively proliferating and can self-renew. Selection begins when their progeny encounter MHC class II molecule-bearing cortical epithelial cells. A further education process probably occurs by interaction with macrophage-like cells found at the cortico-medullary junction and in the medulla.

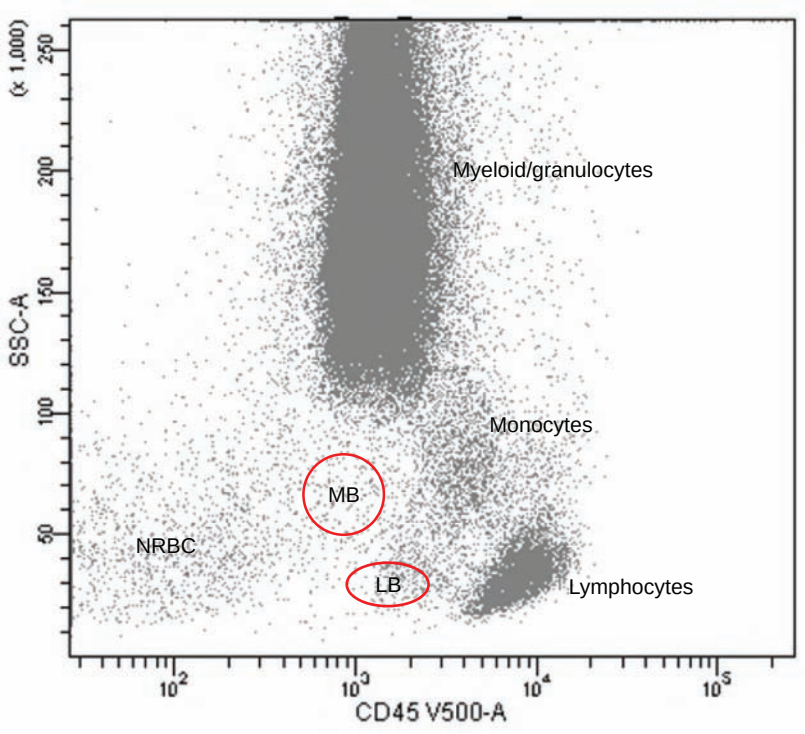

FIG. 2.3 Flow cytometry cytogram of normal human bone marrow based on CD45 expression and light side scatter. This technique separates out the majority of marrow cells, including nucleated red blood cells *(NRBC)*, myeloblasts *(MB)*, and lymphoblasts *(LB)*.

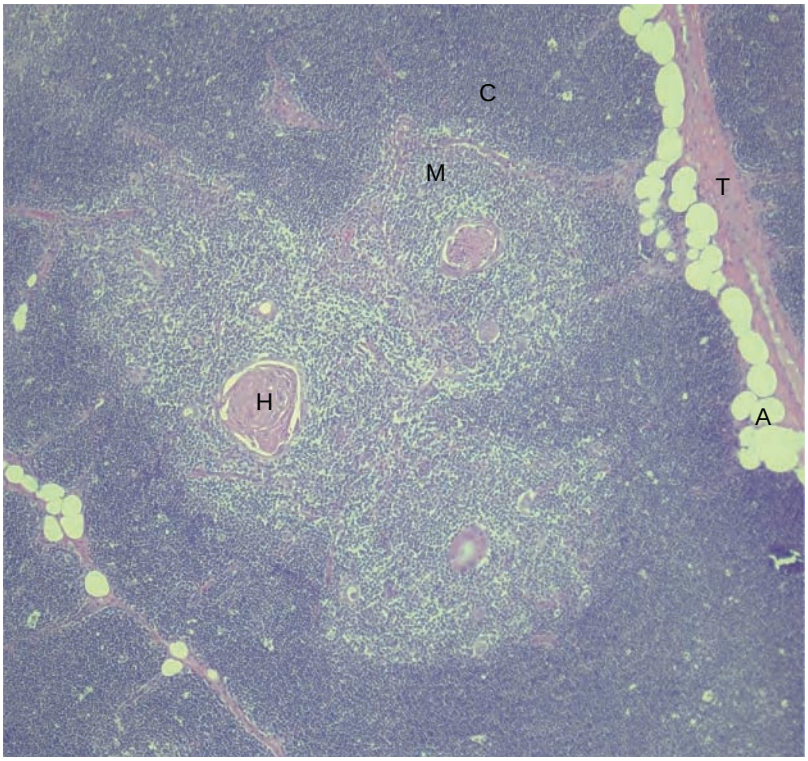

FIG. 2.4 Thymus showing medulla *(M)*, cortex *(C)*, Hassel corpuscle *(H)*, trabecular *(T)*, and mature adipose *(A)*.

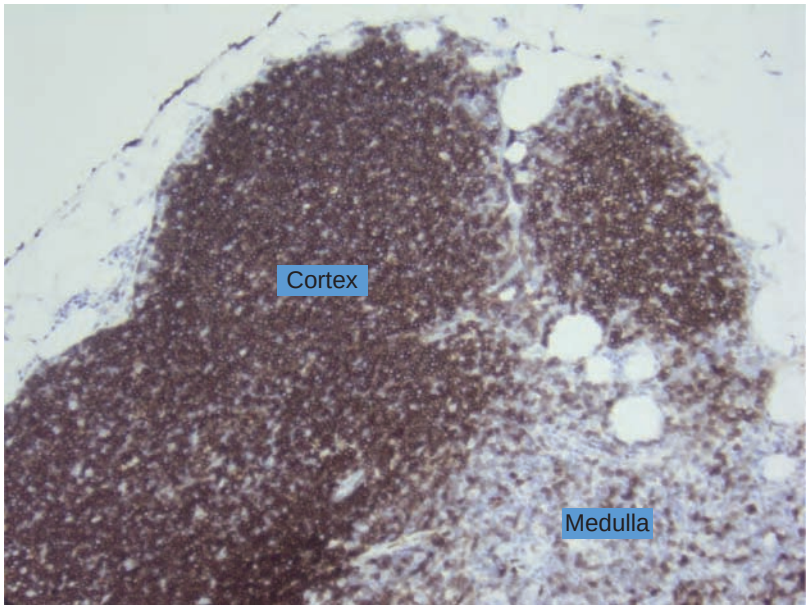

FIG. 2.5 Thymus CD1a immunostain. Cortical thymocytes are extensively positive; medullary thymocytes are focally positive.

Thymus nurse cells, found in the cortex, were originally thought to contribute to the thymic education of T cells. Because large numbers of thymic cells (50 to 200) can be found inside each nurse cell, it was believed that these structures provided an environment where selection and expansion could occur. There is now evidence that secondary rearrangement of Vα can also occur in these structures.[54]

A structure known as Hassall corpuscle, which consists of concentric whorls of epithelial cells, is found in the medulla. Its function remains unclear. The Hassall medullary epithelial cells contain secretory granules, and this network of cells may be active in the production of thymic hormones. For example, thymic stromal lymphopoietin (TSLP) plays a role in production of dendritic cells that select T regs in the thymus.[55] In the fetus, these bundles of cells are widely scattered but become larger as the thymus matures. The center cells eventually become keratinized and die.

The thymic differentiation process (Chapter 9) involves rearrangement of functional TCR, surface expression of CD3, and both positive and negative selection that allows only a small percentage of T cells to survive. Pre-T cells in the thymus express CD2, CD5, and CD7, as well as activation antigens such as CD38 and the transferrin receptor (CD71). Pre-T cells express intracytoplasmic CD3 and exhibit rearrangements in the TCR-β chain. Successful rearrangement of TCR-α allows the cell to progress to the next stage of development with functional TCR and CD3 on the cell surface.[36]

Most cells in the thymus (85%) express both CD4 and CD8 on their surface, termed the "double-positive" stage, as well as CD1 and CD69, an activation marker. CD69 is expressed until the cell reaches the single-positive stage, where it expresses either CD4 or CD8, but not both. T cells are $CD45RO^+$ at the double-positive stage into the single-positive stage. Prior to leaving the thymus, CD45RO is downregulated and CD45RA appears. Mature thymocytes lose CD1 expression and either CD4 or CD8 expression. Most of these mature cells are also negative for activation molecules (CD38 and CD71). However, they acquire an adhesion molecule, CD44, which is necessary for homing. Upon completion of this process of thymus selection and education, mature CD4 or CD8 T cells leave the thymus and enter the peripheral circulation via the post-capillary venules at the cortico-medullary junction.

After birth and during childhood, the thymus continues to grow and to select and educate T cells. This process promotes the development of a robust and diversified repertoire. Prior to puberty, however, the thymus begins to involute. The rapidly dividing cortex is the first to atrophy, leaving medullary areas intact. The sensitivity of cortical thymocytes to hormone-induced death probably accounts for the involution, although human thymocytes are less sensitive to glucocorticosteroids than are murine thymocytes. However, an increase in steroids reduces immature thymocyte numbers and enhances thymus involution. Recent evidence suggests that active TCR rearrangements, and hence T cell development, continue in the adult thymus, albeit at a lower level than during childhood. There is an age-associated decline in new T cell production, such that by age 75 the ability to make new T cells in humans is severely reduced.

Peripheral Development of Hematopoietic and Lymphoid Cells

Although most of the key steps during the growth and development of hematopoietic and lymphoid cells occur in the bone marrow and thymus, additional maturation steps occur after the cells leave those tissues. For example, monocytes and dendritic cell precursors migrate from blood vessels into tissues where they mature into macrophages and dendritic cells, respectively. There is recent evidence for a tissue-associated macrophage that is fetal in origin. Mast cells and eosinophils also undergo further differentiation in resident tissues. After leaving the bone marrow and thymus, B and T cells undergo further maturation and memory cell development in secondary lymphoid organs. There is strong evidence that some T cells, particularly γδ T cells residing in mucosal epithelium, do not develop in the thymus.

SECONDARY LYMPHOID ORGANS

Secondary lymphoid organs are sites where mature lymphocytes reside and where immune responses are generated. Secondary lymphoid organs belong to either the systemic or mucosal immune systems. The systemic immune system includes the spleen and lymph nodes and functions to protect the body from antigens in the lymphatic drainage and circulating in the bloodstream. The mucosal immune system responds to antigens that enter through mucosal epithelium and plays an important role in the inductive phase of the immune response. Unique features differentiate the mucosal immune system from the systemic immune system (Chapter 24). These include efferent, but not afferent, lymphatics, a specialized FAE involved in antigen sampling at the mucosal surface (Fig. 2.6), specialized dendritic cells that rapidly process and present antigens to initiate antigen-specific immune responses, unique distribution and subsets, and an environment that promotes class switching to IgA.

Systemic Immune System

Spleen

The human spleen is surrounded by a capsule of fibrous tissue with many trabeculae traversing from the capsule into the tissue of the spleen. These trabeculae branch and anastomose, forming a complex framework of lobules. Splenic blood vessels enter and exit through the hilum of the spleen and branch into smaller vessels within the trabeculae. Splenic tissue is supported by a fine network of reticular cells and fibers, called the reticulum, which connects and supports the trabeculae, blood vessels, and capsule.

The lobules of the spleen can be functionally divided into two compartments, the red pulp and the white pulp. The largest compartment is the red pulp, which contains numerous venous sinuses situated between arteries and veins. Blood is filtered through these sinuses, which contain many macrophages that phagocytose senescent red and white blood cells, bacteria, and other particulate material. Other leukocytes are found in the red pulp, including neutrophils, eosinophils, and lymphocytes, particularly plasma cells.[56]

The white pulp consists of lymphoid tissue surrounding central arterioles, which are branches of trabecular arteries. The human spleen is structurally different from rodent spleens in that there is no central organization of follicles and the central artery.[56] Rather, a T cell-predominant area is found immediately surrounding a central arteriole, the so-called periarteriolar lymphoid sheath (PALS). The PALS contains both CD4 and CD8 T cells. It is punctuated at intervals by B-cell-predominant areas, termed follicles or so-called malpighian corpuscles. These B-cell-predominant areas include both primary and secondary follicles. Primary follicles consist of only a mantle zone, without germinal centers, whereas secondary follicles contain an inner germinal center in addition to the outer mantle zone (Fig. 2.7). Within the mantle zone are predominantly resting B cells, which express surface IgM/IgD and CD23 (FcεRII). It is within germinal centers that immunoglobulin class switch, affinity maturation through somatic mutation, and the development of memory B cells occurs. Germinal centers are more prevalent at younger ages and diminish with aging. CD4 T cells play a key role in B-cell responses through CD40L and other interactions. The signaling that occurs through this interaction is central to B-cell activation and class switching. In addition to activated B cells and CD4 T cells, the germinal center contains FDCs and macrophages.

At the interface between white pulp and red pulp is an anatomical location known as the marginal zone, which receives blood from branches of central arterioles opening into this region. The marginal zone contains T cells, as well as subsets of macrophages and B cells. Marginal zone B cells (MZB) are distinct from follicular B cells. They express surface IgM, but only low levels of IgD and no CD23. The initial encounter of T cells and B cells with antigen occurs in the marginal zone after blood enters through branches of the central arteriole. Antigen presentation is enhanced by MZB cells, which are important in T-cell-independent responses.

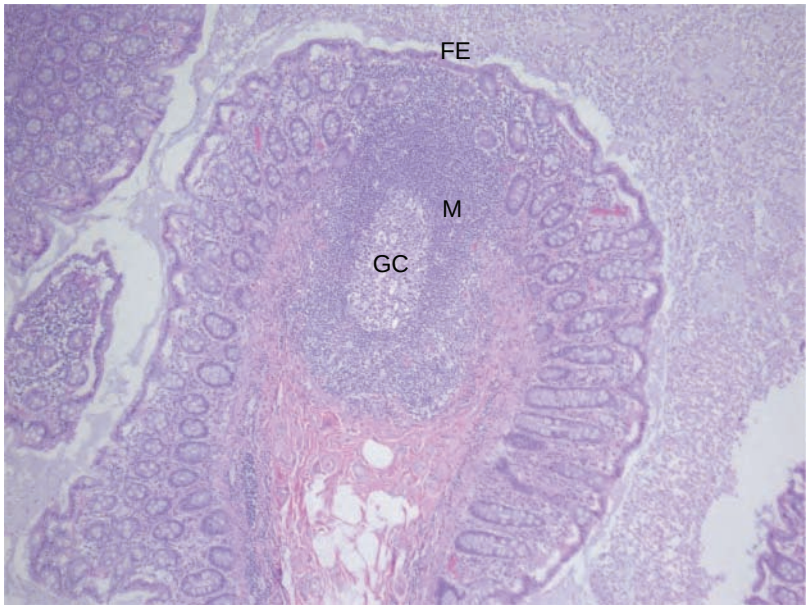

FIG. 2.6 Colon. Shown is a mucosal lymphoid follicle containing a germinal center *(GC)* and mantle layer (M). Follicle associated epithelium is labeled *(FE)*.

Lymph Nodes and Lymphatics

Lymph nodes occur as chains or groups located along lymphatic vessels. Lymph nodes exist in two major groups: those that drain the skin and superficial tissues (*e.g.*, cervical, axillary, or inguinal lymph nodes), and those that drain the mucosal and deep tissues of the body (*e.g.*, mesenteric, mediastinal, and periaortic lymph nodes). Lymph nodes are oval structures surrounded by adipose tissue with an indentation at the region of a hilus, where blood vessels enter and leave the node (Fig. 2.8). A lymph node is surrounded by a fibrous capsule contiguous with trabeculae traversing the node (Fig. 2.9). Blood vessels and nerves, which enter through the hilum, branch through these trabeculae to the various parts of the node. Immediately beneath the capsule is a subcapsular (marginal) sinus. Afferent lymph vessels enter into this sinus opposite the hilum. Dendritic cells process antigen encountered in the skin and migrate into lymph nodes from afferent lymphatics through the subcapsular sinus and into the lymph node. Lymph nodes vary in size, from barely visible in an unstimulated state to several centimeters in size when undergoing an active immune response.

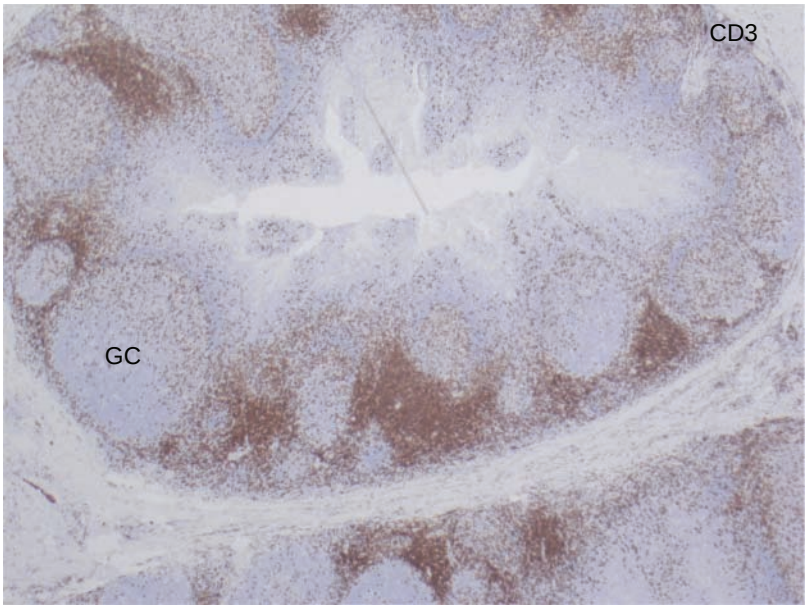

FIG. 2.10 Tonsil CD3 immunostain highlighting T cells predominantly within the interfollicular regions and scattered within germinal centers *(GC)*.

A lymph node is divided into two major regions, the cortex and the medulla. The cortex contains numerous primary and secondary lymphoid follicles, each approximately 0.5 mm in diameter, similar to those in the spleen. Surrounding the lymphoid follicles in the cortex is the paracortical region, which contains mostly T cells along with some macrophages and dendritic cells. Both CD4 and CD8 T cells are present, as are macrophages and B cells (Figs. 2.10–2.13). Accessory cells, including interdigitating dendritic cells, present peptide antigens in association with MHC molecules to the TCR on T cells to activate the T cells (see Chapter 10). Additional accessory molecules (*e.g.*, B7 [CD80] or LFA-3 [CD58]) on the accessory cell, and their ligands (CD28 or CD2, respectively) on the T cell, provide important co-stimulatory signals required for activation of the T cell. Other surface antigens, particularly adhesion molecules such as LFA-1 (CD18) and ICAM-1 (CD54), stabilize cellular interactions, as well as providing additional signals between cells.

In the center of the lymph node, beneath the cortex, lies the medulla, which is divided into medullary cords. Surrounding the medullary cords are medullary sinuses that drain into the hilum. B and T cells migrate from the follicles and paracortical region to the medulla. Medullary cords contain T cells, B cells,

and macrophages, as well as a large number of plasma cells that produce immunoglobulin, which drains into medullary sinuses that empty into the hilum. Efferent lymphatic vessels leave the hilum carrying lipids and antibodies together with mature B and T cells that migrate to other tissues and act as memory B and T cells. The lymphatic vessel system serves to carry lymphocytes derived from various tissue spaces through the network of lymph nodes and eventually to the thoracic duct.

Lymphatic capillaries are lined with lymphatic epithelial cells that serve as valves to move lymph fluid, cells, and nutrients around the body. These epithelial cells express high levels of TLR4, which means they can be activated after LPS delivery to increase lymphaniogenesis.[57] Lymph from the nodes is drawn into the left subclavian vein and back into the circulation. Cancer cells found in lymph nodes may take advantage of this system to seed the body. This system of transport develops early in gestation with both lymphatic muscle cells for propulsion and valves that regulate unidirectional lymph flow. Lymph also serves as a carrier of lipids and the endothelial cells that line the lymphatics are responsive to metabolic signals.[57] Lymph also is recognized as a major carrier of exosomes that may facilitate communication between lymphoid organs.[58]

Gastrointestinal Tract

The organized mucosa associated lymphoid tissue (MALT) of the gastrointestinal system is termed the gut-associated

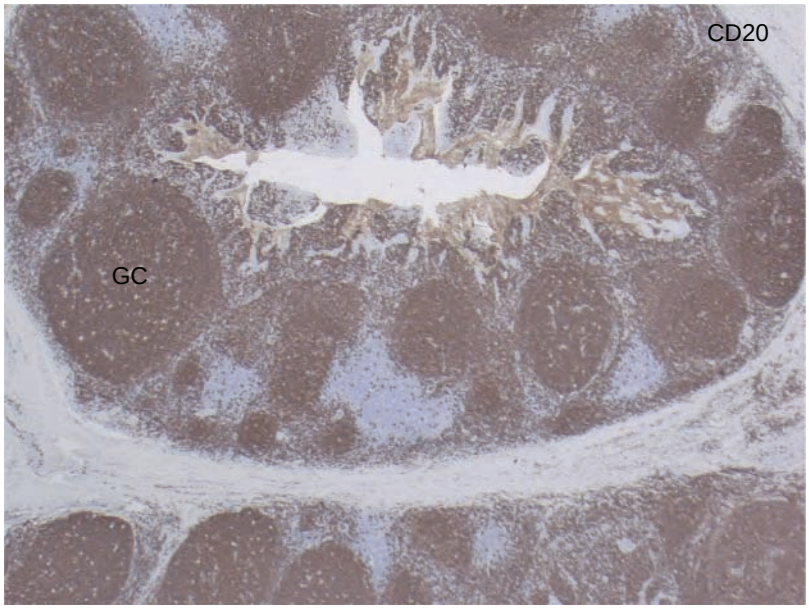

FIG. 2.13 Tonsil CD20 immunostain highlighting B cells predominantly within germinal centers *(GC)*, and scattered within the interfollicular regions.

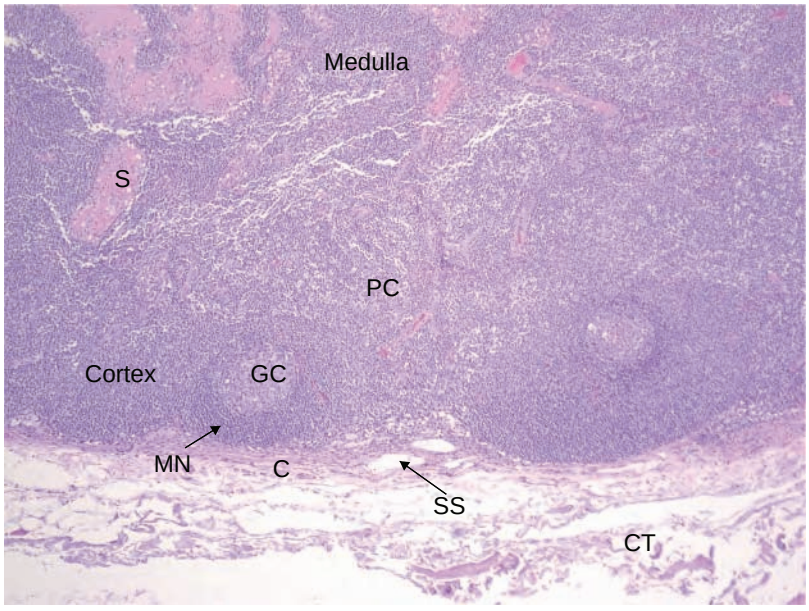

FIG. 2.14 Lymph node showing capsule *(C)* with outer connective tissue *(CT)*, cortex containing follicles with germinal centers *(GC)*, and mantle layer *(MN)*, paracortex *(PC)*, sinusoids *(S)*, and subcapsular sinuses *(SS)*.

lymphoreticular tissue (GALT). It is composed of Peyer patches, cecal and rectal patches, and isolated lymphoid follicles. Isolated lymphoid follicles and cecal and rectal patches are found throughout the lamina propria and are similar to an individual follicle of a Peyer patch. Peyer patches consist of variably sized aggregates of closely associated lymphoid follicles located in the intestinal lamina propria, occurring predominantly in the ileum (Fig. 2.14). These structures arise during fetal life; their full development, with follicles containing germinal centers, does not occur until several weeks after birth, presumably in response to antigenic stimulation. Their number and size increase until puberty and decline thereafter, similar to the thymus.

Virtually all Peyer patch follicles have germinal centers that contain activated B cells, FDCs, CD4 T cells, and tingible-body macrophages (so called because of their appearance after they have phagocytosed cellular debris). Many of the B cells within Peyer patch germinal centers express surface IgA, and it is believed that this is where IgA class switch occurs. An inter-follicular region contains predominantly CD4 and CD8 T cells, as well as dendritic cells, macrophages, and some B cells.

The diffuse tissue of the gastrointestinal tract consists of two components: the lamina propria and intraepithelial lymphocytes (IEL) (Fig. 2.15). The lamina propria is located immediately beneath the epithelium. It contains large numbers of B

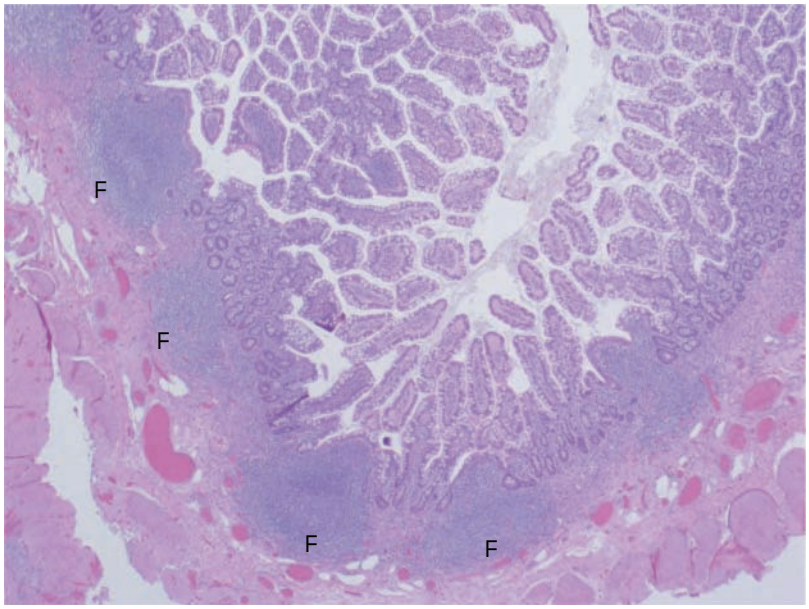

FIG. 2.15 Ileum showing Peyer patches comprised of lymphoid follicles *(F)*.

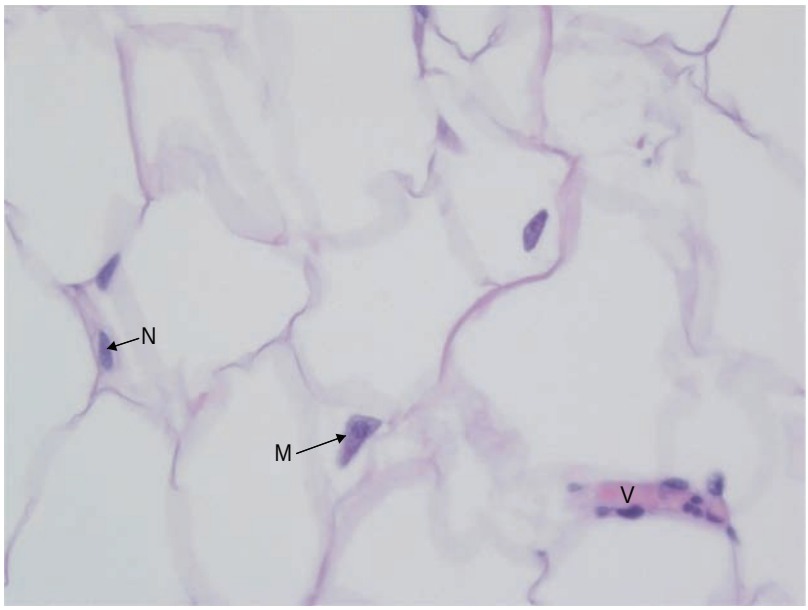

FIG. 2.16 Adipose. The nucleus of a mature fat cell *(N)*, a blood vessel *(V)*, and a macrophage *(M)* are shown.

lymphocytes and plasma cells. A key effector function of the lamina propria is the secretion of antibodies, primarily IgA. IgM represents only 10% to 18% and IgG 3% to 5% of all Ig produced. Two IgA subclasses occur, IgA1 and IgA2. IgA1 represents greater than 90% of IgA in the respiratory tract and greater than 60% in the lamina propria of the small intestine.[51] IgA2 increases in the lower ileum and becomes predominant in the colon and rectum.

Adipose Tissue

In light of the obesity epidemic, adipose tissue has received renewed scrutiny, which has led to the realization that immune cells play central roles in adipose homeostasis and in obesity-associated chronic inflammation (Fig. 2.16). Macrophages are a central component, switching from M2 type to M1 type during obesity. In lean adipose tissue there are numerous T regs, ILC2s and few CD8 T cells, which reverses during obesity when inflammation increases.[59,60]

Epithelial Innate Immunity and Commensal Organisms

It has become clear that epithelial cells have autologous immune capacity and that this property is conserved among epithelial tissues in the body. This immune capacity functions to reinforce the epithelial barrier, stimulate crosstalk within the epithelium, recruit underlying immune cells within the stromal connective tissue, and initiate repair of epithelial damage. In particular, the communication between the epithelium and underlying immune cells, including T cells, B cells, dendritic cells, and

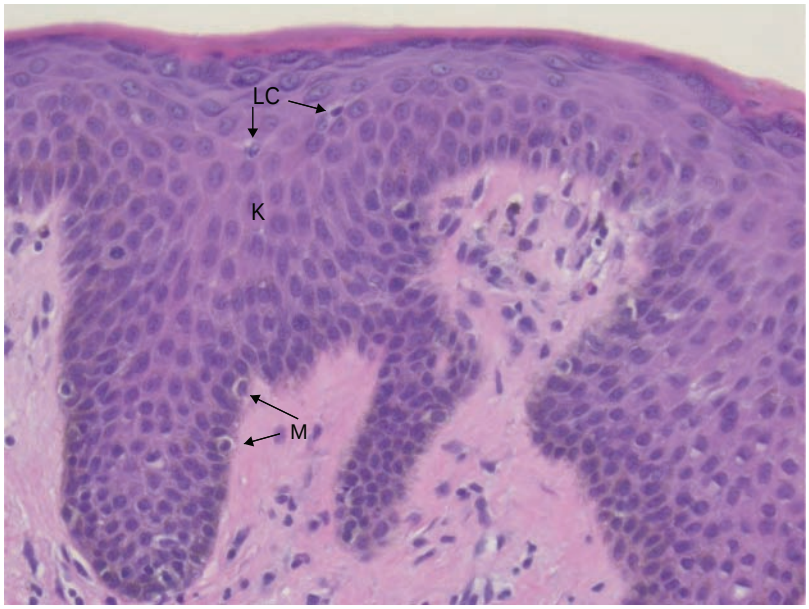

FIG. 2.17 Skin. Keratinocytes *(K)*, Langerhans cells *(LC)*, and melanocytes *(M)* are shown.

macrophages, facilitates the coordination of a tissue and inflammatory response that ultimately can protect the epithelium from external damage (Fig. 2.17).

In some sense, the epithelium is a bidirectional immune mediator of antigens on one side and host on the other. The epithelium has multiple sensors that alert the cells to environmental insults that range from the biologic (bacteria and viruses) to the non-living challenges (pollutants and allergens). These sensors include pattern associated molecular pattern (PAMP) receptors such as toll-like receptors (TLRs) and nucleotide binding and oligomerization domain (NOD) receptors (see Chapter 3).[61,62] Binding of these receptors triggers the epithelial cell production of cytokines and chemokines, hormones, anti-microbial peptides, MHCII expression and antigen presentation, mucous, carbohydrate moieties, and the transport of IgA.[61] Many of these products play an important role in signaling both neighboring cells as well as the underlying stromal immune system to offer a rapid and immediate response to the triggering entity. Additionally, there is some evidence that the induction of the innate immune response of the epithelium can epigenetically rewire the epithelium resulting in the enhancement of epithelial repair upon seeing the insult additional times

All epithelial surfaces live in symbiosis with over 1000 different species of viruses, bacteria, protozoa, and fungi that together outnumber human cells by a factor of 10. Collectively called the commensal microbiota (Chapter 22), these organisms are essential to the development, maturation, organization, and regulation of both the epithelium and the underlying immune system at mucosal surfaces.[63] The commensal microbiota generates a large number of metabolites that have significant effects on both the cells and their functional state and can affect regulation of differentiation, production of cytokines and anti-microbial products, and epithelial barrier function.[64]

Both the epithelium and mucosal immune cells express receptors for these metabolites. Examples of these metabolites include single chain fatty acids (SCFAs), pyruvate, and lactate.[64] These essential interactions activate and prime both innate and specific immune responses such as production of IgA, induction of regulatory T cells, and stimulation of anti-inflammatory cytokines.[64] Microbial metabolites induce metabolite reactive mucosal-associated T cells (MAIT) that are located through all mucosal surfaces.[65] Once activated, the T cell can respond to local cytokines produced by the epithelium as well as other environmental cues. Thus, the types and quantities of microorganisms present at a mucosal surface are an important component of the mucosal immune response.[66–68]

New Modalities to Study Immune System Development and Function

Two new modalities have recently altered the landscape of knowledge on the immune system: single cell sequencing and induced pluripotent stem cell (iPSC)-derived immune cells. Advances in next generation sequencing have overcome a critical barrier in characterization of the immune system and have allowed the immune system to be investigated at the single cell level. Many discoveries using single-cell transcriptomics combined with fluorescent activated cell sorting (FACS) are now resolving immune cell heterogeneity, and what was once believed to be well-defined immune populations are now seen as a compilation of distinct cellular subsets that segregate by function yet express overlapping phenotypic markers. This new approach is indicating that immune cell function is very dependent on environment and tissue context. Using iPSC derived technology, various hematopoietic and immune cells can be successfully generated from a pluripotent precursor. iPSC cultures can provide a constant and continuous production of immune cells from the same genetic individual. These cells are easily amenable to genetic manipulation and, upon stimulation, can produce many immune effectors such as cytokines and chemokines. Applications towards customized immune therapies using iPSC derived hematopoietic cells are in their infancy. Both single-cell genomics and iPSC-derived immune cells help define key processes in immune cell differentiation and maturation, understand hematopoiesis, and ultimately contribute to predicting immune cell function. These approaches hold promise to advance the fundamental knowledge of the human immune system.

ON THE HORIZON

1. Understanding how stem cells self-renew will be a key to exploiting them for gene therapy.
2. Exploiting innate and acquired immune cell function will require an understanding of subpopulations of cells and the manner in which they are induced.
3. Generation of new T and B cells later in life might prolong quality of life in the aged.
4. The role of adipose tissue in HSC development in the bone marrow and control of inflammation in obesity will be fundamental to controlling the obesity epidemic.
5. Exploiting interactions between the mucosal immune system and commensal populations is likely to improve health, prevent inflammation, and allow less antibiotic use.
6. The role of lymphatics in transportation of lymphocytes and exosomes will be crucial for spreading immunologic information; inflammation and cancer spread might be reduced by controlling inflammation of the lymphatics.

ACKNOWLEDGMENTS

We thank Dr. Gregory R. Harriman at BioAdvance for his previous efforts on this chapter; Eleanor Chapman, Anna Wirt, Terry Saulsberry, Yvette Wyckoff and Pamela Love for help with the manuscript; and Dr. Jerry McGhee for critical review of the first edition.

Innate Immunity

Douglas R. McDonald and Ofer Levy

Innate immunity is the first line of host defense against infection. All living organisms are continually exposed to microbes. For example, the human gut is colonized by trillions of commensal bacteria, fungi, and viruses (Chapter 22). The innate immune system must accommodate commensal microbes yet recognize and respond to pathogens. Potentially life-threatening infections can result from naturally occurring defects in the innate immune response (Chapter 3).

A defining characteristic of innate immunity is its existence before microbial exposure. Innate immune responses are induced rapidly by microbes and precede the development of adaptive immune responses. The adaptive immune system is characterized by the tremendous diversity of its receptors and its antigen ligands. The innate immune system responds to a more limited set of antigens that are typically essential and invariant structural components specific to microbes. These microbial components are known as *pathogen-associated molecular patterns* (PAMPs). They include microbial cell wall components and nucleic acids. PAMPs are recognized by pattern recognition receptors (PRRs), and they are highly potent and effective in initiating inflammatory responses.

"Trained immunity" refers to the phenomenon of enhanced innate immune responses following microbial exposure.[1] This increase in host resistance to reinfection can provide "cross-protection" against other infectious agents. For example, macrophages and natural killer (NK) cells can expand and contract their cell populations, upregulate genes involved in pathogen recognition and presentation, and secrete cytokines that augment the antimicrobial activity of bystander cells. Thus, there is an appreciation that the adaptive and innate immune systems have certain similar characteristics.

KEY CONCEPTS

The Innate Immune System

- Composed of barriers to the environment (e.g., skin), antimicrobial peptides and proteins, cells (e.g., neutrophils), and soluble factors (e.g., cytokines, chemokines and complement).
- Provides the initial immune response to microbes and primes the adaptive immune system.
- Differentiates between pathogens and commensals.
- Pathogen detection is mediated by germline-encoded pathogen recognition receptors (PRRs) that recognize invariant microbial structures known as pathogen-associated molecular patterns (PAMPS).
- Has a form of memory termed "trained immunity," whereby activation can modulate subsequent innate immune responses to unrelated stimuli or infections.

BARRIERS TO INFECTION

Skin and Mucosa

The epithelial layers of the skin (Chapter 23) and the linings of the gastrointestinal (GI) (Chapter 24), genitourinary (GU), and respiratory tracts provide a mechanical barrier to microbial entry and thus play an essential role in host defense. The stratum corneum of the skin is the first barrier encountered by microbes. The skin is persistently colonized with numerous microbes. Thus, an intact physical barrier is essential to prevent activation of the immune system under nonpathological conditions. Key cellular components of the skin's immune barrier include keratinocytes, dendritic cells (DCs), macrophages, T lymphocytes, and mast cells. These cells express a wide variety of pathogen recognition receptors and secrete a broad range of cytokines, chemokines, and antimicrobial proteins and peptides (APPs) that mediate inflammatory responses to infection. Genetic disorders of the skin that compromise skin integrity, such as epidermolysis bullosa (Chapter 63), can result in life-threatening infections.

Skin disorders that impair barrier function, such as atopic dermatitis (AD) (Chapter 48) or eczema are common. Filaggrin (FLG) is a key structural component of the outermost layer of the epidermis. Loss of function variants in filaggrin (R510X, 2282del4) is estimated to be present in up to 50% of patients with AD. FLG mutations are a risk factor for the development of early-onset AD and thus for sensitization to food and environmental allergens via increased permeability of allergens, leading to allergic rhinitis and asthma (Chapter 43) (the atopic march). Eczematous skin can lead to reduced expression of APPs and increased susceptibility to cutaneous bacterial (e.g., *Staphylococcus*, *Streptococcus*) and viral (e.g., herpes) infections.

The luminal surfaces of the intestines are sites of continual exposure to numerous microbes. Intestinal epithelial cells (IECs) (Chapter 22) protect against infection by forming a physical barrier through tight junctions and by producing mucus (goblet cells) and APPs. IECs express apical junction complexes, including E-cadherin, ZO-1, claudin, and occludin, which function to form a tight monolayer that prevents penetration by bacteria.[2] A breakdown in epithelial gut homeostasis can lead to inflammatory bowel diseases (e.g., Crohn disease, ulcerative colitis) (Chapter 75) and increased susceptibility to bacterial infection.

Influenza viruses and respiratory syncytial viruses replicate in airway epithelial cells, leading to cell death and inflammation. The subsequent impaired barrier function of the airways can lead to increased susceptibility to secondary invasive bacterial infections by *Streptococcus pneumoniae* and other pyogenic

bacteria. Inflammatory bowel diseases also result in impaired barrier functions of the small and large intestines, which can be associated with increased translocation of bacteria across gut mucosa, potentially leading to serious infection.

CLINICAL RELEVANCE

Innate Immunity: Barriers

- Barrier function is an underappreciated component of the innate immune system.
- Barriers include the epithelial layers of the skin and the gastrointestinal, respiratory, and genitourinary tracts.
- Defects in barriers (e.g., epidermolysis bullosa and atopic dermatitis) increase the risk of infection.
- Production of antimicrobial peptides and proteins at barrier sites helps prevent microbial invasion.

Antimicrobial Proteins and Peptides

Among the APPs produced by the skin and by the epithelia of the gastrointestinal, genitourinary, and respiratory tracts are *bactericidal/permeability-increasing protein* (BPI), *defensins* (β-strand peptides connected by disulfide bonds), and *cathelicidins* (linear α-helical peptides) (Table 3.1).[3] Most APPs have a net positive charge, which enhances their affinity for negatively charged microbial cell membranes. Binding of APPs to microbes can permeabilize microbial membranes, leading to their destruction.

BPI is a ~55-kilodalton (kDa) cationic and hydrophobic protein with high affinity for the lipid A region of lipopolysaccharide (endotoxin). It is found in neutrophil primary (azurophilic) granules and is also inducible in epithelial cells. BPI shields against gram-negative bacteria via its microbicidal, opsonic, and endotoxin-neutralizing properties.[4] Neutralization of endotoxin may serve to limit inflammatory responses to gram-negative bacteria.

Some APPs, such as lysozyme (Lz), have enzymatic activities, which cleave peptidoglycans found in bacterial cell walls. Other APPs bind to and compete for nutrients, a form of so-called nutritional immunity. Lactoferrin (Lf), for example, binds iron, a nutrient essential to bacterial survival.[4]

Defensins are classified by the linking pattern of cysteines and their sizes. Alpha-defensins are expressed in neutrophils and Paneth cells of the small intestine (Chapter 22), whereas β-defensins are expressed by mucosal surface epithelia, including those of skin, eyes, and the oral, urogenital, and respiratory tracts. Defensins exhibit broad specificity of antimicrobial activity against bacteria, mycobacteria, fungi, parasites, and viruses (Table 3.2). They have also been shown to enhance antigen uptake and processing, and to stimulate the chemotaxis of monocytes, macrophages, and mast cells.[5] The expression of several of the defensins is constitutive. For others, inflammatory stimuli (bacterial products, proinflammatory cytokines) will increase defensin expression (human neutrophil proteins 1–3 and human β-defensin-2). Given the increasing incidence of antibiotic-resistant bacteria, there is great interest in the potential uses of APPs as treatment for bacterial infections and infections with multidrug-resistant organisms.[6] Exogenous administration of APPs may be most effective in those with reduced APP expression; for example, in the setting of neutropenia.[7]

TABLE 3.1 Epithelial Antimicrobial Proteins and Peptides

Antimicrobial Peptide	Source	Target Organism
Dermicidin	Eccrine sweat glands	Broad spectrum
Psoriasin	Keratinocytes, sebocytes	G^-
RNase 7	Keratinocytes	Broad spectrum
RNase 5/angiogenin	Keratinocytes	*Candida albicans*
Cathelicidin (LL-37)	Keratinocytes, sebocytes	G^+, G^-
BPI	Epithelia-oral, GI, urogenital tract	G^-, (G^+, fungi)
hBD-1	Keratinocytes, sebocytes	G^-
hBD-2	Keratinocytes, sebocytes	G^-
hBD-3	Keratinocytes	Broad spectrum
hBD-4	Keratinocytes	G^+, G^-
SLPI	Keratinocytes	Broad spectrum
Elafin	Keratinocytes	Broad spectrum
Adrenomedullin	Keratinocytes, hair follicles, eccrine/apocrine sweat glands, sebocytes	G^+, G^-
MIP-3α/CCL20	Keratinocytes	Broad spectrum
Lysozyme	Keratinocytes, sebocytes, hair bulb cells	G^+, G^-
Lactoferrin	Milk, saliva, tears, nasal secretions, neutrophils	Broad spectrum

BPI, Bactericidal/permeability-increasing protein; *CCL*, chemokine ligand; G^+, gram-positive; G^-, gram-negative; *GI*, gastrointestinal; *hBD*, human β-defensin; *MIP*, macrophage inflammatory protein; *RNase*, ribonuclease; *SLPI*, secretory leukocyte peptidase inhibitor.

TABLE 3.2 Neutrophil-Derived Antimicrobial Proteins and Peptides (APPs)

Neutrophil APP	Granule Type	Target Organism
Lysozyme	Azurophil, specific	G^+, G^-
Azurocidin	Azurophil, secretory	G^+, G^-, *Candida albicans*
Elastase	Azurophil	G^+, G^-
Cathepsin G	Azurophil	G^+, G^-
Proteinase 3	Azurophil	G^+, G^-
BPI	Azurophil	G^-, (G^+, fungi)
α-Defensins (HNP-1 to -4)	Azurophil	G^+, G^-, fungi, viruses
Cathelicidin (hCAP-18)	Specific	G^+, G^-, mycobacteria
Lactoferrin	Specific	G^+, G^-, fungi, viruses
SLPI	Specific	G^+, G^-, *Aspergillus fumigatus, C. albicans*
NGAL	Specific	G^+, G^-, fungi
Lysozyme	Azurophil, specific	G^+, G^-
Azurocidin	Azurophil, secretory	G^+, G^-, *C. albicans*
Elastase	Azurophil	G^+, G^-
Cathepsin G	Azurophil	G^+, G^-

BPI, Bactericidal/permeability-increasing protein; G^+, gram-positive; G^-, gram-negative; *hCAP*, human cathelicidin antimicrobial protein; *HNP*, human neutrophil peptide; *NGAL*, neutrophil gelatinase-associated lipocalin; *SLPI*, secretory leukocyte peptidase inhibitor.

KEY CONCEPTS

Humoral Innate Immunity

- Chemokines and cytokines are essential mediators.
- Cytokine influences are both redundant and pleotropic.
- Due to the risk of collateral tissue damage, cytokine synthesis is tightly controlled.
- Acute phase reactants are induced by cytokines and promote opsonization of microbes.
  - The acute phase reactant C-reactive protein (CRP) is induced by IL-6.
  - The CRP plasma level can be used to monitor infections and inflammation.
- The complement system protects against a wide variety of microbes.

HUMORAL INNATE IMMUNITY

The Acute Phase Response

A variety of soluble proteins found in plasma help recognize PAMPs and function as mediators of innate immunity. The cytokines tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) (Chapter 14) induce production of acute phase reactants in hepatocytes, including members of the pentraxin family (e.g., serum amyloid A [SAA], serum amyloid P [SAP], and C-reactive protein [CRP]). These pentraxins bind to components of the bacterial cell wall. TNF-α and IL-1β also induce production of IL-6 (Chapter 14) from mononuclear phagocytes, endothelial cells, and fibroblasts. IL-6 is another potent inducer of acute phase reactants, including CRP and fibrinogen. An *opsonin* is a molecule, including an antibody, that can enhance phagocytosis by marking an antigen for an immune response or marking dead cells for recycling. CRP, SAA, and SAP function as opsonins. They can bind phosphorylcholine and phosphatidylethanolamine expressed on bacteria and apoptotic cells, thereby enhancing phagocytosis by marking these bacteria and apoptotic cells as targets for macrophages.

Lipopolysaccharide-binding protein (LBP) is an acute phase reactant synthesized by the liver in response to gram-negative bacterial infections. LBP binds to LPS and subsequently forms a complex with CD14, TLR4, and MD-2, which functions as a high-affinity receptor for LPS.

Mannose-binding lectin (MBL) is a member of the calcium-dependent (C-type) lectins (collectins) produced by the liver in response to infection. MBL binds to carbohydrates with terminal mannose and fucose residues that are expressed on microbial cell surfaces.[8] MBL can bind to the C1q receptor on macrophages to enhance phagocytosis and can activate the complement system (Chapter 40) via the lectin pathway (discussed below).

Surfactant protein A and surfactant protein D are collectins expressed in the lung and can bind a variety of microbes and inhibit their growth.[6] They also function as opsonins that promote ingestion by alveolar macrophages.

Finally, ficolins are plasma proteins capable of binding to several types of bacteria and can activate complement.

The Complement System

The complement system comprises a collection of plasma proteins activated by microbes (Chapter 40). It helps mediate microbial destruction and inflammation.[9] Complement activation can occur via three pathways: the classical pathway (CP), the alternative pathway (AP), and the lectin pathway (LP).

In the classical pathway, complement C1 detects immunoglobulin M (IgM), IgG1, or IgG3 bound to the surface of a microbe. C1 is composed of the C1q, C1r, and C1s subunits. These form multimeric complexes that recognize IgM or IgG bound to microbial surfaces. C1r and C1s are serine proteases. Activated C1s generates a C3 convertase composed of C4b and C2b (C4b2b) bound to the microbial surface. C3 convertase cleaves C3, generating C3b. C3b binds covalently to C4b2b, generating C5 convertase. C5 convertase then activates the late steps of complement activation, leading to assembly of the membrane attack complex (MAC) and subsequent cytolysis (Fig. 3.1).

The alternative pathway is initiated by small amounts of C3b, which are spontaneously generated in plasma. C3b that remains unbound to a cell surface is rapidly hydrolyzed and inactivated. C3b bound to a microbe becomes a binding site for factor B. Bound factor B is cleaved by factor D, generating factor Bb that binds covalently to C3b, forming the AP C3 convertase, which activates the later steps of complement activation, as in the CP (see Fig. 3.1).

The lectin pathway is activated by MBL or ficolins binding to microbial surfaces. MBL then binds to MBL-associated serine proteases (MASPs)-1, -2, and -3. MASP-2 cleaves C4 and C2 to activate the complement cascade, as in the CP (see Fig. 3.1).

Complement components also function as opsonins. Complement-coated microbes can be phagocytosed via complement receptors on phagocytes. Complement receptor type 1 (CR1) is a high-affinity receptor for the C3b and C4b fragments of complement and mediates the internalization of C3b- and C4b-coated particles. On erythrocytes, CR1 mediates clearance of immune complexes from the circulation. Complement type 2 receptor (CR2, also known as CD21) is expressed on B cells (Chapter 7) and follicular dendritic cells (FDCs) (Chapter 6). It binds C3 proteolytic fragments, including C3d, C3dg, and iC3b. CR2 augments humoral immune responses by enhancing B-cell activation by antigen and by promoting trapping of antigen–antibody complexes in germinal centers.[10] Epstein-Barr virus (EBV) can use CR2 as a receptor, thereby allowing EBV to enter B cells. Complement receptor 3 (CR3) is composed of a heterodimer of CD18 and CD11b and is expressed in polymorphonuclear neutrophils (PMNs), monocytes, and macrophages. CR3 binds to iC3b bound to the surface of microbes, leading to phagocytosis and destruction of the pathogen. Activation of complement via the AP can greatly enhance monocyte-generated TNF-α elicited by gram-positive bacteria, such as group B streptococcus.

KEY CONCEPTS

Humoral Innate Immunity: Complement

- Defects in early complement cascade components paradoxically promote both immune deficiency (invasive infections with encapsulated bacteria) and autoimmunity (lupus-like syndromes).
- Defects in late complement cascade components (C5–9) promote susceptibility to meningitis due to *Neisseria meningitidis*.
- Defects in C1 inhibitor protein (or function) underlie hereditary angioedema.
- Defects in factor H are associated with membranoproliferative glomerulonephritis, hemolytic–uremic syndrome, and age-related macular degeneration.
- Defects in mannose-binding lectin (MBL) create susceptibility to bacterial infection in individuals with comorbid conditions (e.g., chemotherapy, cystic fibrosis).

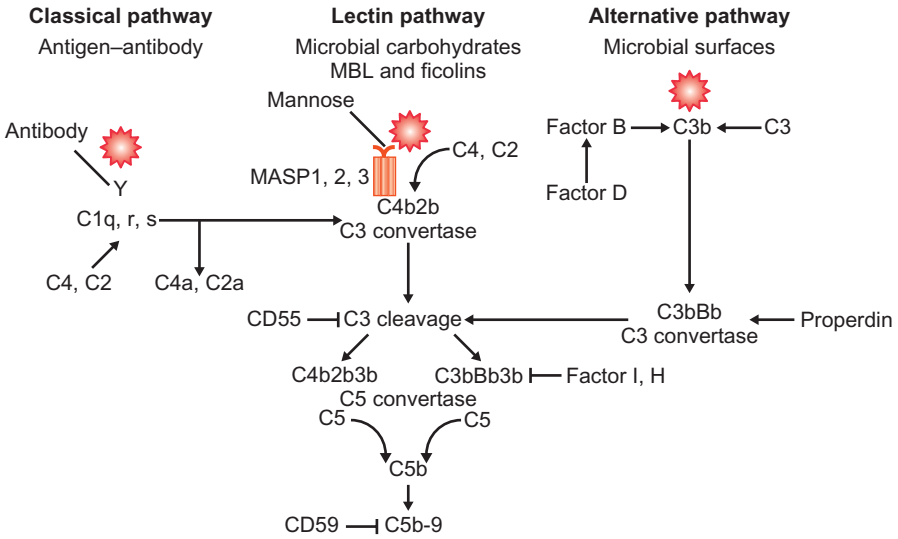

FIG. 3.1 Complement Activation Pathways. The classical complement cascade is activated by antibody bound to microbial surfaces, which is a binding site for the C1 complex. The alternative pathway is activated by the binding of spontaneously generated C3b to microbial surfaces. Microbe-bound C3b binds factor B, which is converted to factor Bb, forming a C3 convertase. The lectin pathway is activated by the binding of mannose-binding lectin (MBL) to mannose residues on microbial surfaces. MBL binds MBL-associated serine proteases, which bind and cleave C4 and C2, forming a C3 convertase.

There are multiple regulatory proteins within the complement pathways (see Fig. 3.1). C1 esterase inhibitor (C1INH) binds to, and inhibits, the enzymatic functions of C1r and C1s within the CP.[11] Properdin stabilizes C3bBb complex, increasing the life span of the AP C3 convertase. Conversely, factor H inhibits the formation of and degrades C3bBb complexes. Factor I inactivates C3b. CD55 (decay accelerating factor) and CD59 are cell surface, glycophosphatidylinositol (GPI)-linked proteins that block complement-mediated cytolysis by inhibiting formation of C3bBb complex and binding of C9 to C5b678 complex, respectively. Paroxysmal nocturnal hemoglobinuria, an acquired defect in the *PIGA* gene that causes a deficiency of GPI-linked proteins, is the result of absent cell surface expression of CD55 and CD59 that leads to hemolytic anemia caused by complement-mediated lysis of red blood cells (RBCs).

Complement Deficiency Diseases

Deficiencies of early components of the complement pathway are associated with invasive bacterial infections caused by encapsulated organisms (Chapter 40). Lack of early components of the complement pathway are also associated with rheumatic disorders, including a lupus-like syndrome that may be caused by impaired immune complex clearance, impaired clearance of apoptotic cells, and loss of complement-dependent B-cell tolerance (Chapter 52). Deficiency of factor I is also associated with increased incidence of invasive infection with encapsulated bacteria (Chapter 27), as well as glomerulonephritis (Chapter 68) and autoimmune disease (Chapter 40).

Deficiency of C1INH protein and function, either hereditary or acquired, leads to hereditary angioedema (HAE) or acquired angioedema (AAE) (Chapter 40). C1INH inhibits C1, factors XIa and XIIa, and kallikrein. Dysregulation of these cascades leads to generation of vasoactive products that result in angioedema. Deficiencies of late components of complement, including C5 through C9, as well as factors B, D, and properdin create susceptibility to meningococcal infections.[12] Deficiency of factor H function is associated with membranoproliferative glomerulonephritis (Chapter 68), hemolytic–uremic syndrome, and age-related macular degeneration (AMD) (Chapter 74). Deficiency of MBL is associated with increased susceptibility to bacterial infections in infancy and particularly in individuals with other comorbid conditions, such as cystic fibrosis.

KEY CONCEPTS

Cellular Innate Immunity

- While short lived, polymorphonuclear leukocytes (neutrophils) are the most abundant and earliest cells of the innate immune system to respond to infection.
- Several days later in an infection, monocytes and macrophages predominate.
- Activated neutrophils, monocytes, and macrophages kill phagocytosed bacteria with reactive oxygen intermediates and antimicrobial peptides and proteins (APPs).
- Dendritic cells take up and present foreign antigens and thus link the innate to the adaptive immune system.
- Natural killer (NK) cells can kill infected or malignant cells without prior activation.
- Mast cells are found at the interface between the host and the environment, are first responders to microbes, and recruit other inflammatory cells.

CELLULAR INNATE IMMUNITY

Polymorphonuclear Leukocytes

PMNs are the most abundant leukocyte (Chapter 39). They have a short life span of ~6 hours in circulation, and in the healthy adult, ~10^9 PMNs are produced per hour. PMNs are readily identified by light microscopy by segmented nuclei divided into 3 to 5 lobules. Their cytoplasm contains four types of granules: azurophilic (or primary), specific (or secondary),

gelatinase, and secretory. PMN granules contain a wide variety of APPs with a broad spectrum of antimicrobial activities (see Table 3.2). Azurophilic granules contain enzymes, such as proteinase 3, cathepsin G, and elastase, as well as α-defensins and BPI. Specific granules contain lactoferrin and the proforms of cathelicidin peptides. Gelatinase granules are rich in gelatinase and are a marker of terminal neutrophil differentiation. Secretory granules contain a variety of receptors that are inserted into the cell membrane upon activation. Exocytosis of these receptors convert PMNs into cells more responsive to inflammatory stimuli. PMNs are the earliest responders to infection. Those not recruited to sites of infection undergo apoptosis and are cleared by the reticuloendothelial system. Individuals with severely low numbers of neutrophils (<500 cells/μL) are susceptible to overwhelming bacterial infections.

KEY CONCEPTS

Defects in Neutrophil Number or Function

- Severe neutropenia (<500/μL) creates susceptibility to overwhelming bacterial infection, regardless of whether it is primary or secondary.
- Defective production of reactive oxygen intermediates leads to chronic granulomatous disease, which is marked by:
  - Susceptibility to invasive bacterial and fungal infections, and
  - Impaired wound healing.
- Myeloperoxidase deficiency is asymptomatic in the majority of affected individuals.
  - Candidal infections (mucocutaneous and invasive) have been reported.

Monocytes and Macrophages

Mononuclear phagocytes include monocytes and macrophages. Monocytes originate in bone marrow and migrate into the peripheral circulation. $CD14^+$ monocytes are efficient in phagocytosis and in the production of reactive oxygen intermediates (ROIs) and proinflammatory cytokines in response to a wide variety of microbial stimuli. A subset of monocytes with low CD14 expression ($CD14^{dim}$), but expressing CD16, is associated with vascular endothelia and appears to be specialized for response to viruses and nucleic acid–containing immune complexes. This subset may also be involved in the pathogenesis of autoimmune disorders.[13] $CD14^+$ monocytes enter tissues where they mature into macrophages.

Distinct macrophage populations in different tissues are given specific names, including Küpffer cells in the liver, alveolar macrophages in the lungs, osteoclasts in bone, and microglia within the brain. Macrophages differ from PMNs in that they are not terminally differentiated and can proliferate at sites of infection. They are longer-lived than PMNs and are the predominant innate immune cell several days after an infection.

Macrophages display considerable plasticity in their functions, depending on the cytokine milieu. Classically activated macrophages (M1) are induced by Th1 cytokines, like interferon-γ (IFN-γ), TNF-α, and bacterial products, leading to enhanced killing of phagocytosed microbes. M1 macrophages secrete higher amounts of TNF-α, IL-1α, IL-1β, IL-6, IL-12, and IL-23, and lower amounts of IL-10. M1 macrophages can cause ROS-induced tissue damage and impair tissue regeneration and wound repair. In contrast, alternatively activated macrophages (M2) are induced by Th2 cytokines (e.g., IL-4, IL-13) and have anti-inflammatory functions and promote healing. M2 macrophages have been shown to inhibit T-cell activation through production of IL-10 and transforming growth factor-β (TGF-β).[14]

Recently, animal models evaluating SARS-CoV infection in macaques has demonstrated that antibodies against the S protein of SARS-CoV can activate FcγR on M2 macrophages in the lung, triggering an exaggerated inflammatory response from classically anti-inflammatory M2 macrophages. This hyperinflammatory response is characterized by the production of large quantities of IL-6 and IL-8 (CXCL-8), and recruitment of inflammatory cells to the lungs, leading to acute lung injury (ALI), diffuse alveolar damage (DAD), and death.[15] Thus, in certain inflammatory conditions, even anti-inflammatory M2 macrophages can contribute to tissue damage.

Neutrophil and Macrophage Microbicidal Mechanisms

Microbicidal Molecules

Activated PMNs and macrophages kill phagocytosed bacteria by releasing microbicidal molecules both extracellularly and within phagolysosomes. Microbes are detected by pattern recognition receptors, as well as by Fc and complement C3 receptors. Bacteria are internalized into phagosomes. Phagosomes fuse with lysosomes containing proteolytic enzymes (e.g., elastase, cathepsin G) to form phagolysosomes.

Reactive Oxygen Intermediates

Activated PMNs and macrophages produce ROIs, which are toxic to microbes. ROIs are produced by phagocyte-derived nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, a multisubunit enzyme. NADPH oxidase consists of five subunits, p22phox, p40phox, p47phox, p67phox, and gp91phox. This phagocyte oxidase is activated following engulfment of opsonized bacteria (oxidative burst). Genetic defects in components of the NADPH oxidase complex create susceptibility to invasive infections with bacteria and fungi (chronic granulomatous disease), as well as impaired wound healing (Chapter 39).

A variety of stimuli activate the phagocyte oxidase complex, including the complement fragment C5a; formylated peptides, such as FMLP (*N*-formyl-methionine-leucine-phenylalanine); LTB4 (leukotriene B4); PAF (platelet-activating factor); and pattern recognition receptors, such as TLR4. Upon cellular activation, p40phox, p47phox, and p67phox are phosphorylated and recruited to cellular membranes, where they associate with membrane-bound gp91phox and p22phox (flavocytochrome b558) and GTP-bound Rac1 (monocytes) or Rac2 (PMNs). The activated enzyme generates superoxide radicals, which are then converted to hydrogen peroxide by superoxide dismutase. Hydrogen peroxide is combined with halide ions by myeloperoxidase to generate hypohalous acids, which are toxic to bacteria.

The phagocyte oxidase complex also generates an environment within the phagolysosome conducive to proteolytic enzyme activation. The oxidase functions as an electron pump that generates an electrochemical gradient across the phagolysosomal membranes, which is compensated by the movement of ions into the vacuole. This results in the increase in vacuolar pH and osmolarity required for activation of the antimicrobial proteases elastase and cathepsin G.[16]

Neutrophil Extracellular Traps

In addition to phagocytosis of microbes, release of neutrophil extracellular traps (NETs) is another mechanism employed by neutrophils to neutralize and kill a variety of pathogens, including

bacteria, fungi, parasites and viruses.[17] NETs are extracellular, web-like structures composed of decondensed chromatin imbedded with a variety of cytosolic and granule proteins. These proteins include neutrophil elastase, myeloperoxidase, calprotectin, cathelicidins and defensins. The composition of NETs may vary, depending upon the stimulus. NET release is triggered by a cell death process, termed NETosis.[17] Generation of reactive oxygen species (ROS) is critical in generation of NETs and neutrophils from patients with chronic granulomatous disease (CGD), who are unable to generate ROS, are unable to produce NETs, likely contributing their susceptibility to invasive bacterial and fungal infections.

A variety of signaling pathways trigger NETosis, including TLR2, TLR4, TLR7, TLR8, Dectin2, complement receptor 3, Siglec-14, FcγRIIIb and receptor for advanced glycation endproducts (RAGE).[17] NETosis is typically triggered by larger, difficult to phagocytose, pathogens, such as fungal hyphae. NETosis is a tightly regulated process and excessive NET formation has been shown to induce lung damage in pulmonary fungal infections. In addition, it is hypothesized that NETs may contribute to the pathogenesis of autoimmune diseases, such as rheumatoid arthritis (Chapter 53) and systemic lupus erythematosus (Chapter 52).

Reactive Nitrogen Intermediates

Macrophages produce reactive nitrogen intermediates in response to microbes. Nitric oxide (NO) is produced by inducible nitric oxide synthetase (iNOS). Expression of iNOS is induced by activation of Toll-like receptors (TLRs), and expression is augmented further by IFN-γ.[18] iNOS catalyzes the conversion of arginine to citrulline, releasing diffusible nitric oxide gas. Within phagolysosomes, NO combines with hydrogen peroxide or superoxide to produce peroxynitrite radicals, which contribute to microbial killing. Although ROIs and NO are effective antimicrobial agents, they are nonspecific and are also capable of inducing damage to host tissues.

Dendritic Cells

Dendritic cells (Chapter 6) have long membranous extensions for surveying the local environment and are highly phagocytic. They link innate to adaptive immune responses after activation by microbes. DCs express a variety of PRRs, which allow them to respond to microbes by phagocytosis and cytokine secretion. Activated DCs rapidly take up antigens and then home to draining lymph nodes where they localize to T-cell zones. During their migration to lymph nodes, DCs mature and become efficient antigen-presenting cells (APCs). Once in the lymph node, DCs express high levels of costimulatory molecules, such as B7 and IL-12p70, and present antigen to naïve T cells, inducing their differentiation into effector T cells (Th1 T cells). Plasmacytoid dendritic cells (pDCs) are specialized for response to viral infection and secrete large amounts of type 1 IFNs.

One subset of DC characterized by $CD11c^{high}CD103^{+}$ expression in the lamina propria of the small intestine (Chapter 24) facilitates the differentiation of regulatory T cells (Chapter 13) in a retinoic acid– and TGF-β–dependent manner. Such DC subsets may play a role in the development of tolerance to commensal bacteria (Chapter 22).

Natural Killer Cells

NK cells are derived from common lymphoid progenitor cells and constitute 5% to 20% of mononuclear cells in the periphery (Chapter 12). They do not express somatically rearranged antigen receptors. Target cells are identified using germline DNA-encoded receptors. NK cells are divided into two subsets, $CD56^{bright}CD16^{-}$ and $CD56^{dim}CD16^{+}$, which have different functions. $CD56^{dim}$ NK cells account for roughly 90% of NK cells in the periphery and express the low-affinity Fcγ receptor (CD16), which mediates antibody-dependent, cell-mediated cytotoxicity (Chapter 8). $CD56^{bright}$ NK cells are poorly cytotoxic but produce large amounts of cytokine and represent the majority of NK cells in peripheral lymphoid organs. NK cells are a major source of IFN-γ, which augments the microbicidal functions of macrophages. Conversely, NK cells are primed by IL-15 derived from DCs and IL-12 or IL-18 derived from macrophages, demonstrating the regulatory interactions that occur between NK cells and other cells of the immune system.

NK-cell function is regulated by a delicate balance between signals generated by inhibitory and activating receptors. NK cells possess the ability to recognize and kill infected or malignantly transformed cells, while leaving healthy host cells unharmed. Inhibitory receptors on NK cells recognize class I major histocompatibility complex (MHC) molecules expressed on most healthy cells in the body, preventing NK-cell activation.

NK inhibitory receptors include three families of receptors: heterodimers composed of CD94 and NKG2A, the Ig-like transcripts (i.e., ILT-2), and the killer cell Ig-like receptor (KIR) family (Chapter 12). The immunoreceptor tyrosine-based inhibition motifs (ITIMs) in their cytoplasmic tails recruit phosphatases (Src homology region 2 [SH2] domain-containing phosphatase-1 [SHP-1], SHP-2, and SHIP [SH2-containing inositol polyphosphate 5-phosphatase]), which oppose the effects of kinases activated by activating receptors. When NK cells encounter host cells expressing MHC class I molecules, protein tyrosine phosphatases are activated, reducing signaling downstream of activating receptors and opposing NK-cell activation (Fig. 3.2).

NK cells also possess activating receptors. CD16 mediates antibody-dependent, cell-mediated cytotoxicity and natural cytotoxicity receptors (e.g., NKp46, NKp30, NKp44, NKG2D, CD94/NKG2C, 2B4). Activating receptors are linked to molecules (e.g., CD3-ζ, FcR-γ, or DAP12) that contain immunoreceptor tyrosine-based activation motifs (ITAMs). Upon ligand binding, tyrosine residues within ITAMs are phosphorylated by Src family kinases. The tyrosine phosphorylated ITAMs serve as binding sites for the activation of other protein tyrosine kinases, such as Syk and ZAP-70, which activate downstream effector molecules in a signaling cascade. Infection of host cells with some viruses can lead to reduced MHC class I expression (Chapter 5), thereby reducing viral antigen presentation to T cells. Reduced expression of MHC class I by infected cells promotes activation of NK cells, which then kill infected cells. Concomitantly, ligands for activating receptors are expressed by the infected cell, also leading to NK-cell activation and killing of the infected cell.

NK cells play an important role in immunosurveillance against tumors (Chapter 80). In humans, NK-cell receptors that mediate tumor recognition include NKp46, NKp30, NKp44, DNAM-1 (DNAX accessory molecule-1), and NKG2D. Ligands expressed on target cells include MHC I-related chain (MIC)-A, MICB, unique long 16-binding proteins (ULBP), poliovirus receptor (PVR), and nectin-2. DNAM-1 specific ligands include PVR and nectin-2, which are expressed in cell lines that include carcinomas, melanomas, and neuroblastomas. Nectin expression is not specific to tumors, since nectins are expressed on normal

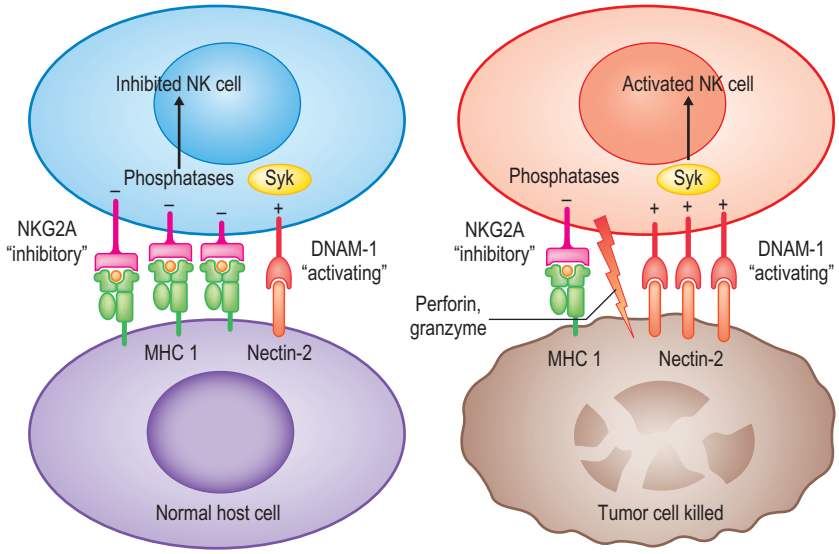

FIG. 3.2 Regulation of Natural Killer *(NK)* Cell Function. Upon encountering normal host cells, inhibitory receptors on NK cells that contain immunoreceptor tyrosine-based inhibitory motifs (ITIMs) preferentially activate phosphatases (e.g., SHP-1/2, SHIP) that send inhibitory signals, inhibiting NK-cell function. NK cells that encounter virally infected cells or tumor cells receive signals through activating receptors that contain immunoreceptor tyrosine-based activation motifs (ITAMs) that activate tyrosine kinases (e.g., Syk), leading to NK-cell activation, release of perforin and granzyme, and target cell death.

cells. DNAM-1–nectin interactions on normal cells do not result in NK-cell lysis because normal cells are protected by MHC class I expression. Conditions favoring NK cell–mediated lysis include tumors in which nectins are overexpressed and/or MHC class I expression is reduced, favoring NK-cell activation (see Fig. 3.2).

Natural killer T (NKT) cells are a small, but highly variable, population of thymus-derived T cells that express NK-cell markers and a restricted repertoire of T-cell receptors (TCRs) that recognize lipids bound to the MHC-like molecule CD1d (Chapter 5).[19] Type 1 NKT cells (also referred to as invariant NKT [iNKT] cells) express the invariant Vα24 and Jα28 TCR α chain, whereas type 2 NKT cells have a more diverse TCR repertoire. Mature human NKT cells can be further divided into three groups, $CD4^+CD8^-$, $CD4^-CD8^-$, and $CD4^-CD8^+$ subsets. The most completely characterized NKT antigen is the lipid α-galactosylceremide (α-GalCer), which is often used to activate NKT cells experimentally.

Identification of natural NKT ligands has proven difficult. NKT cells express perforin and granulysin and are capable of cytotoxic activity. NKT cells are also able to influence innate and adaptive immune responses through release of large amounts of cytokines, including IFN-γ, TNF-α, IL-4, IL-13, IL-10, and granulocyte macrophage–colony-stimulating factor (GM-CSF). In general, NKTs found in blood can produce large amounts of cytokines, whereas NKTs in the thymus are poor cytokine producers.

Decreased NKT cell frequency and/or function may increase susceptibility to some autoimmune diseases, including type 1 diabetes (Chapter 71) and multiple sclerosis (Chapter 66). Mice with NKT defects are susceptible to tumors and adoptive transfer of normal NKTs can provide protection against tumors (Chapter 80). NKT cells may also contribute to the pathogenesis of the airway hyperresponsiveness (AHR) in asthma (Chapter 43), which is dependent on IL-4 and IL-13 production in the airways. iNKT cells are necessary for AHR in several murine models of asthma, since NKT-deficient mice fail to develop AHR following allergen challenge, ozone challenge, or viral infection.[20] iNKT cell deficiency was associated with severe varicella infection, demonstrating a role for iNKT cells in innate antiviral immunity.

Intraepithelial Lymphocytes, B-1 and MZ B Cells, Innate Lymphoid Cells, and Mast Cells

Intraepithelial Lymphocytes

Barrier epithelia of skin and the GI tract contain unique types of lymphocytes, including intraepithelial T lymphocytes (IELs) and B-1 B cells (Chapter 7), which respond to commonly encountered microbes. Because of their more limited diversity of receptors, IELs can be considered part of the innate immune system. The main immune cell populations within the epidermal layer include keratinocytes, melanocytes, a type of DC known as the Langerhans cell, and IELs (Chapter 23).

Keratinocytes and melanocytes express a variety of PRRs, enabling detection of microbes, resulting in secretion of cytokines that can contribute to innate immune responses through recruitment and activation of phagocytes. Langerhans cells form an elaborate network of dendritic processes that allow them to capture antigens that gain access to skin. Following activation by microbes, Langerhans cells migrate to draining lymph nodes and express chemokine receptor-7 (CCR7) (Chapter 15), which allows them to migrate to the T-cell zones within lymph nodes in response to the chemokine ligands CCL 19 and CCL 21 and present antigen to T cells.[21]

Intraepidermal T lymphocytes constitute roughly 2% of lymphocytes within the skin. This lymphocyte subset expresses a more restricted set of antigen receptors, which include both αβ and γδ TCRs (Chapter 4), similar to IELs found in the intestines. These specialized T cells appear to be committed to recognizing microbial peptide antigens commonly found at epithelial surfaces and thus function as components of the innate immune system.

IELs are a significant component of the GI immune system and reside at the basolateral side of the intestinal epithelial cell

layer (Chapters 2 & 24). IELs are among the first immune cells to encounter pathogens that have breached intestinal epithelia. IELs consist of CD8 T cells (Chapter 12), as well as memory-effector T cells bearing αβ or γδ TCRs. IELs contain a greater proportion of TCRγδ$^+$ cells than is found in the peripheral circulation.[22]

CD4$^+$TCRαβ$^+$ and CD8$^+$αβTCRαβ$^+$ IELs are MHC class II and class I restricted (Chapter 5), respectively. These IELs have likely undergone thymic selection (Chapter 9) and subsequently homed to the gut after antigenic stimulation. As such, these IELs are likely specific for foreign antigens.[22] They have a memory phenotype and an oligoclonal TCR repertoire. IELs in the small intestine frequently express CD8$^+$αα (CD4$^+$CD8$^+$αα or CD8$^+$αβCD8$^+$αα), a characteristic of activated mucosal T cells within the gut microenvironment. Upon antigenic stimulation, CD8$^+$αβTCRαβ$^+$ IELs are cytolytic and kill via granzymes and perforin or through engagement of Fas (Chapter 17).[22]

TCRγδ$^+$ IELs emigrate from the thymus and subsequently take up residence in the intestinal epithelium (Chapter 24). They constitute approximately 10% of intestinal IELs in humans, and the majority expresses CD8αα. TCRγδ$^+$ IELs recognize nonclassic MHC molecules (Chapter 5), such as thymus leukemia antigen or MHC class I–like molecules, MICA (MHC I–related chain [MIC]-A) and MICB, and may help modulate inflammatory immune responses. These IELs can be cytolytic and express FasL. TCRγδ+ IELs can produce keratinocyte growth factor and promote intestinal epithelial integrity.[22]

B1 and Marginal Zone B Cells

The B1 and marginal zone (MZ) subsets of B lymphocytes have been characterized as innate-like B cells (Chapter 7). They express antigen receptors enriched for germline sequence. These cell types have been mostly studied in mice. Their identity in humans is less clear. B1 cells and MZ B cells can function as APCs, but unlike conventional B cells, B1 cells and MZ B cells do not develop into memory B cells. B1 cells and MZ B cells share characteristics: (i) they are the main source of natural antibodies; (ii) they express high surface levels of IgM and low surface levels of IgD; and (iii) they are rapidly activated by microbes through pattern recognition receptors to produce large amounts of natural antibodies. B1 cells and MZ B cells produce IL-10 upon activation, which may downregulate immune responses. The natural antibodies produced by B1 cells and MZ B cells function as the first line of defense against invading microbes.

Innate Lymphoid Cells

Innate lymphoid cells (ILCs) are a heterogeneous population of cells. ILCs do not express rearranged antigen-specific receptors. This lymphoid subset includes killer ILCs (e.g., NK cells) and helper ILCs. Helper ILCs are further classified as ILC1, ILC2, and ILC3.

ILC1 cells express T-bet, similar to NK cells (Chapter 12), and produce IFN-γ but lack cytolytic activity. They are found mainly within tissues and are barely detectable in peripheral blood. Oncogene-induced murine cancer model studies suggest that ILC1 cells may play a role in cancer immunosurveillance.

ILC2 development is dependent on expression of the transcription factor GATA-3 and produces the cytokines IL-5 and IL-13. ILC2 cells were first identified in mice as a source of T-helper (Th2) cytokines (IL-4, IL-5, IL-13). ILC2 cells may play a role in anti-helminthic immunity, immune surveillance, immune regulation, and wound healing. ILC2 cells have been shown to accumulate in the skin of patients with AD and within nasal polyps of patients with chronic rhinosinusitis. ILC2 cells produce IL-4, IL-5, and IL-13 in response to epithelial-derived IL-33, IL-25, and thymic stromal lymphopoietin (TSLP). The production of Th2 cytokines by ILC2 cells may represent an early step in the development of atopic disorders.

ILC3 cells express the retinoic acid receptor–related orphan receptor γt (RORγt) and produce IL-17 and IL-22 (Fig. 3.3). ILC3 cells include fetal lymphoid tissue inducer (LTi) cells, which drive secondary lymphoid organ development during embryogenesis. LTi cells can induce upregulation of adhesion molecules on stromal cells and the release of chemokines involved in the recruitment of T and B lymphocytes and DCs to lymph nodes, leading to the subsequent differentiation of naïve T cells into effector T cells and B-cell activation and the production of antibody-secreting cells. Postnatal ILC3 cells influence tissue homeostasis and host defense against extracellular organisms. ILC3-produced IL-22 induces expression of APPs by

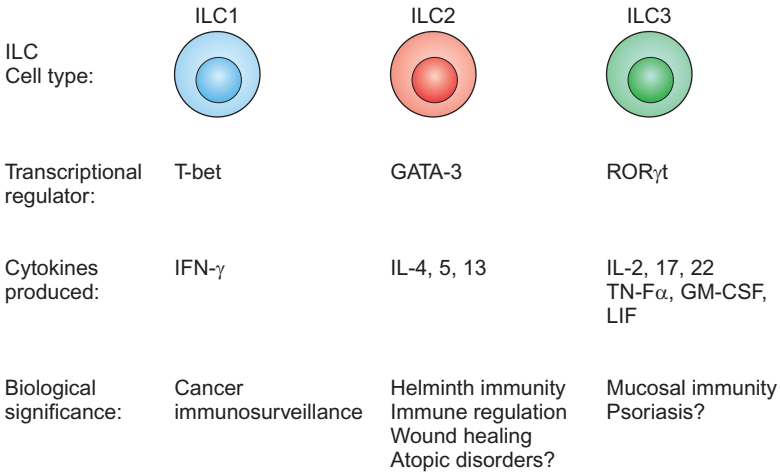

FIG. 3.3 Developmental Regulation and Functions of Innate Lymphoid Cells. The development of innate lymphoid cells (ILCs) is regulated by master transcriptional regulators, including T-bet, GATA-3, and RORγt. Three subsets are recognized: ILC1, ILC2, and ILC3. ILC play roles in tumor immunosurveillance, immune regulation, wound healing, mucosal immunity, atopic disorders, psoriasis, and mucosal immunity.

intestinal epithelial cells. Production of IL-17 by ILC3 cells likely contributes to host defense against *Candida*. ILC3 cells can also produce IL-2, GM-CSF, TNF-α, and leukemia inhibitory factor (LIF). Production of GM-CSF by splenic ILC3 cells is believed to promote survival and activation of splenic neutrophils. A significant population of ILC3 cells have been found in lesional skin of patients with psoriasis.

Mast Cells

Mast cells (Chapter 44) are components of innate immunity that are also commonly found at the interface between host and environment. They are derived from progenitors in bone marrow and circulate as immature precursors to the periphery. Mast cells take up residence and mature in skin, airways, and the GI tract. They are positioned to be first responders to environmental stimuli, including infectious agents. Stem cell factor (SCF, also known as c-kit ligand) is their main survival and developmental factor.

Mast cells express TLR-1 through TLR-9 and therefore are capable of responding to a wide variety of pathogens. TLR-induced mast-cell activation leads to production of proinflammatory cytokines and chemokines. Murine models of peritonitis, such as cecal ligation and puncture, demonstrate that mast cells enhance resistance to bacterial infection. Mast cells are also well known for mediating allergic reactions through IgE-bound allergens that are anchored by FcεRI on the mast-cell surface. Ligation of FcεRI leads to release of tryptase, histamine, leukotrienes, prostaglandins, and cytokines, which cause type 1 hypersensitivity reactions (Chapter 46).

ACTIVATING INNATE IMMUNITY

The innate immune response is initiated when cells of the innate immune system encounter pathogens and recognize them by means of PRRs binding to microbial molecules (e.g., lipopolysaccharide, DNA, RNA). These interactions activate signaling pathways that lead to the production of secreted factors involved in the inflammatory response, including chemokines (Chapter 14) and cytokines (Chapter 15). Characteristics of cytokines include pleiotropism (e.g., the ability to activate a variety of responses on multiple cell types) and redundancy. Cytokines can function locally and distantly and can affect the production of other cytokines. Exposure to cytokines can induce changes in gene expression that affect cell function (e.g., enhanced microbicidal activity or proliferation). Secretion of cytokines (IL-1β, IL-6, TNF-α) is a transient event, thereby limiting potential destruction of host tissue. However, severe infections (e.g., bacteremia, sepsis) can result in overproduction of TNF-α, IL-1β, IL-6, and IFN-γ, which leads to vascular collapse, disseminated intravascular coagulation, and metabolic disturbances (septic shock) that are often fatal.

Cytokine synthesis is a transient process because the messenger RNA (mRNA) of most cytokines is unstable, thus limiting cytokine production. Production of certain cytokines is also regulated by a posttranslational process. For example, TNF-α is a membrane-bound protein that is proteolytically cleaved by a membrane-associated metalloproteinase. IL-1β is a 33-kDa protein that is proteolytically processed by the IL-1β-converting enzyme caspase-1 to generate the biologically active 17-kDa mature IL-1β (described below).

TNF-α and IL-1β can recruit PMNs and monocytes to sites of infection and enhance their ability to eliminate microbes. TNF-α and IL-1β induce expression of adhesion molecules (Chapter 16), such as selectins (P-selectin, E-selectin) and the integrin ligands, ICAMs (intercellular adhesion molecules) and VCAMs (vascular cell adhesion molecules), on vascular endothelial cells near the sites of infection. Expression of selectins on vascular endothelium induces leukocyte rolling on endothelium. Chemokines, such as CXCL8, activate PMNs and monocyte integrins and increase their affinity for ligands (ICAMs, VCAMs) on vascular endothelium, allowing migration of PMNs and monocytes through endothelium to sites of infection. TNF-α and IL-1β both induce prostaglandin synthesis in the hypothalamus, which induces fever.

KEY CONCEPTS

Pattern Recognition Receptors

- Toll-like receptors (TLRs) contain an extracellular domain with leucine-rich repeats (LRRs) and a cytoplasmic Toll/IL-1 receptor domain.
  - The extracellular domain binds ligand.
  - The cytoplasmic domain links to adapter proteins and signaling pathways.
- Nucleotide oligomerization domain (NOD)-like receptors are a family of 22 proteins.
  - LRRs are used for ligand binding.
  - The NOD is used for oligomerization.
  - A caspase activation and recruitment domain (CARD), a Pyrin domain, or a baculovirus inhibitor of apoptosis (BIR) domain is used for initiation of signaling.
- Retinoic acid-inducible gene (RIG)-like receptors contain two N-terminal CARDs for signaling and an RNA helicase domain.
- C-type lectin receptors (CLRs) contain a C (Ca^{2+})-type recognition domain.
  - They mediate diverse functions that depend upon the signaling pathways activated.
- Scavenger receptors and receptor for advanced glycated end products (RAGE) are diverse groups of receptors.
  - They recognize a variety of ligands.
  - They mediate the uptake of oxidized lipoproteins or glycated proteins.
  - They may be involved in atherosclerotic plaque formation.

Pattern Recognition Receptors

Our understanding of the mechanisms by which pathogens are detected has increased greatly over the past decade. Pathogen recognition by the innate immune system leads to engulfment and destruction of invading pathogens, but clearance is often incomplete. The subsequent adaptive immune response is usually required to complete clearance.

The innate immune system expresses a wide variety of PRRs that mediate pathogen recognition. These include TLRs, nucleotide oligomerization domain (NOD)-like receptors (NLRs), and the retinoic acid-inducible gene-I (RIG-I)-like receptors (RLRs). These receptors play an essential role in initiating the innate immune response. Unlike T-cell and B-cell antigen receptors, PRRs are germline encoded, do not undergo somatic recombination, and are expressed constitutively by immune and nonimmune cells. PRRs recognize PAMPs, components of pathogens that are invariant and required for pathogen survival (Table 3.3). Although PRRs detect the PAMPs expressed by microbes, they may also recognize self-molecules (e.g., host nucleic acids), which may underlie some autoimmune diseases such as systemic lupus erythematosus (Chapter 52) and rheumatoid arthritis (Chapter 53).

TABLE 3.3 Classes of Pattern Recognition Receptors

Pattern Recognition Receptor Family	Receptor	Ligand
Toll-like receptors (TLRs)	TLR1/2	Triacyl lipopeptides
	TLR2	Zymosan
	TLR3	dsRNA
	TLR4	LPS, RSV glycoprotein, HSPs, pneumolysin
	TLR2/6	Diacyl lipopeptide
	TLR7	ssRNA
	TLR8	ssRNA
	TLR9	dsDNA, hemozoin
	TLR10	HIV gp41
	TLR11	Profilin-like protein
NOD-like receptors (NLRs)	NOD1	DAP, MDP
	NOD2	MDP
	CIITA	?
	NAIP	*Legionella pneumophilia*, flagellin?
	IPAF	PAMPs
	NLRP1	PAMPs, MDP, microbial toxins
	NLRP2	TBK1 (negative regulator)
	NLRP3	PAMPs, toxins, DAMPs
	NLRP4–14	TBK1 (negative regulator)?
RIG-like receptors (RLRs)	RIG-I	dsRNA, ssRNA
	MDA5	dsRNA, ssRNA
C-type lectin receptors (CLRs)	Mannose receptor	Bacterial carbohydrates
	Dectin-1	Fungal wall glucans
Scavenger receptors	SRA, SRB	Oxidized lipoproteins, apoptotic cells
	CD36, CD68,	β-Amyloid
RAGE		LPS, microbial DNA, β-amyloid

CIITA, Class II major histocompatibility complex transactivator; *DAMP*, damage-associated molecular pattern; *DAP*, meso-diaminopimelic acid; *dsRNA*, double-stranded RNA; *IPAF*, IL-1beta converting enzyme protease activating factor; *LPS*, lipopolysaccharide; *MDA-5*, melanoma differentiation-associated gene-5; *MDP*, muramyl dipeptide; *NAIP*, neuronal apoptosis inhibitory protein; *NLRP*, NOD-like receptor related protein; *PAMP*, pathogen-associated molecular pattern; *RAGE*, receptor for advanced glycation end products; *RSV*, respiratory syncytial virus; *SR*, scavenger receptor; *ssRNA*, single-stranded RNA.

CLINICAL RELEVANCE

Innate Immunity: TLRs, CARDs, NLRs, and Inflammasomes

- TLRs play a non-redundant role in host defense.
  - Defective TLR function (e.g., IRAK-4, MyD88 deficiency) creates susceptibility to invasive, pyogenic infections.
  - Infection in newborns and infants is increased with TLR defects, suggesting the role of TLR is particularly important early in life.
- NOD2 missense mutations have been associated with Crohn disease and Blau syndrome.
- NLRP3 mutations are associated with Muckle-Wells syndrome, familial cold autoinflammatory syndrome, and neonatal onset multisystem inflammatory disease (NOMID).
- CARD9 mutations create susceptibility to chronic mucocutaneous candidiasis.

Toll-Like Receptors

Toll was initially identified in *Drosophila melanogaster* as a receptor required for dorsal–ventral patterning. Subsequently, the Toll pathway was found to be an essential component of *Drosophila* host defense against fungal infection, which led to cloning of mammalian homologues, the TLRs. Mammalian TLRs consist of 11 members that can recognize a wide variety of PAMPs. TLRs are type 1 integral membrane glycoproteins characterized by an extracellular domain with varying numbers of leucine-rich repeats (LRRs) and a cytoplasmic signaling domain homologous to the IL-1 receptor (IL-1R), referred to as the Toll/IL-1R (TIR) homology domain. The TIR domain links the receptor to adaptor proteins (e.g., myeloid differentiation factor 88 [MyD88]) and downstream signaling molecules. This leads to transcription of genes that regulate inflammation (Fig. 3.4).

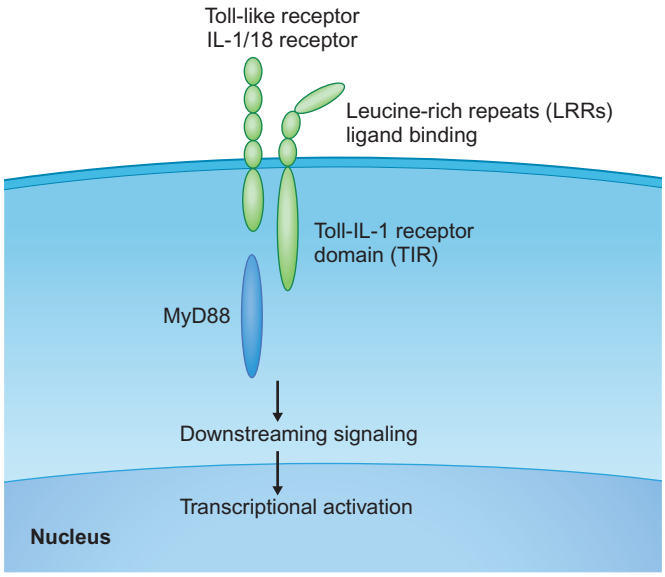

FIG. 3.4 Toll-Like Receptors *(TLRs)* and Interleukin *(IL)*-1/-18 Receptors Share a Common Signaling Pathway. Upon ligand binding, signals are transduced intracellularly by the interaction of the adaptor protein MyD88 with the TIR domain of receptor. MyD88 interacts with IL-1 receptor associated kinase (IRAK)-4 through death domain interactions, activating a signaling cascade, which results in transcriptional activation of genes involved in inflammation.

TLRs are widely expressed on or within cells of the immune system and the epithelia. TLRs detect a wide variety of pathogens (see Table 3.3). They are classified into subfamilies based on their genetic tree. The TLR1, TLR2, and TLR6 subfamily recognizes bacterial lipoproteins, whereas the TLR3, TLR7, TLR8, and TLR9 subfamily recognizes nucleic acids. TLR4, in conjunction with MD-2, recognizes lipopolysaccharide (LPS), TLR5 binds bacterial flagellin, and TLR11, which is functional in mice but probably not in humans. TLR5 recognizes a profilin-like molecule of *Toxoplasma gondii*. However, ligand binding by TLRs can be promiscuous. For example, TLR4 can also bind respiratory syncytial virus F protein and pneumolysin of *S. pneumoniae*; and TLR9 binds malarial hemozoin and hypomethylated CpG-rich DNA.[23] TLRs can also recognize endogenous danger signals: for example, damage-associated molecular patterns (DAMPs) that include heat shock proteins. Recently, TLR10 was found to bind HIV gp41 and high expression of TLR10 was associated with enhanced HIV infection.[24]

The cellular localization of TLRs varies. TLR1, -2, -4, -5, -6, -10, and -11 are found on cell surfaces, whereas TLR3, -7, -8, and -9 are located within endosomes. The cell surface expression of

TLRs, such as TLR4, which recognizes LPS, allows recognition of extracellular molecules released from pathogens. Endosomal expression of TLR3, -7, -8, and -9 allows recognition of microbial nucleic acids following their uptake and degradation in phagolysosomes. Endosomal expression of TLR3, -7, -8, and -9 may prevent activation by host nucleic acids and the development of autoimmunity. The broad cellular expression of TLRs and their diverse and promiscuous agonist recognition allows detection of a wide variety of pathogens despite the existence of a limited number of TLRs.

TLR-mediated cellular responses are essential to host defense. TLR activation stimulates a brief burst of macropinocytosis, which results in antigen uptake at sites of infection and allows antigen presentation to T cells (Chapter 6). TLR activation leads to production of proinflammatory cytokines (e.g., TNF-α, IL-6) and chemokines (e.g., CXCL8). TLR pathway engagement induces transcription and translation of mRNA encoding pro-IL-1β, but production of mature IL-1β requires activation of the inflammasome (described below).

Production of proinflammatory cytokines recruits phagocytes to sites of infection and augments their antimicrobial functions. Production of IL-12p70 by TLR-activated DCs leads to activation of naïve T cells and their subsequent differentiation into effector Th1 cells. Presentation of foreign peptides and increased expression of MHC molecules along with expression of costimulatory molecules (e.g., B7–1, B7–2, IL-12p70) results in subsequent development of adaptive immune responses. IL-12p70 stimulates IFN-γ production by T cells, which further augments the microbicidal activities of phagocytes. Stimulation of TLR3, -7, -8, and -9 elicits the production of proinflammatory cytokines, as well as type 1 IFNs, which play a crucial role in innate antiviral immunity and also influence adaptive immune responses.

Engagement of TLRs activates complex signaling pathways that have been characterized through biochemical analyses and in gene-targeted mice.[25–27] TLRs, IL-1R, and IL-18R share similar signaling pathways (Fig. 3.5). Upon ligand binding, the cytoplasmic adaptor protein MyD88 is recruited to the TIR domain of the receptor for all TLRs, except TLR3.

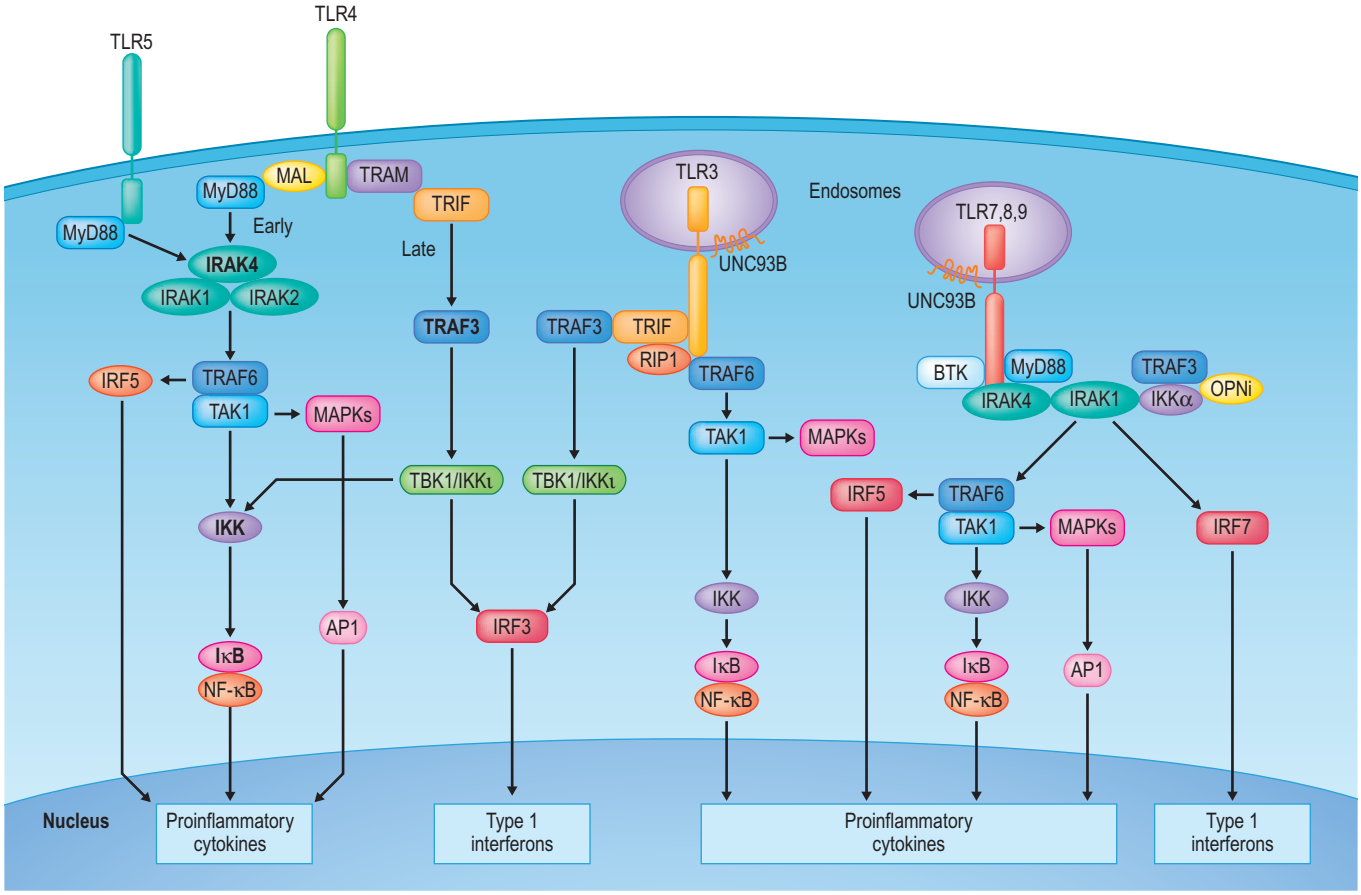

FIG. 3.5 MyD88-Dependent and -Independent Toll-Like Receptor (TLR) Signaling Pathways. Engagement of MyD88-dependent TLR (TLR5) results in activation of IL-1 receptor associated kinase (IRAK)-4 and IRAK-1, IRAK-2, leading to activation of TRAF6 and TAK-1. Subsequently, activation of the IκB kinase (IKK) complex and MAP kinases activates NF-κB and AP1 transcription factors, respectively. The transcription factor IRF5 is also activated downstream of TNF receptor–associated factor 6 (TRAF6). The TLR4 signaling pathway utilizes four adaptor proteins. The adaptors MAL and MyD88 are activated upon ligand interaction at the cell surface, leading to activation of an "early" signaling cascade through the IRAKs. Subsequently, TLR4 is internalized and a "late" signaling cascade, which is dependent on the adaptors TRAM and TRIF, is activated. TLR3 activates a TRIF-dependent pathway that activates RIP1 and TBK1/IKKι, leading to production of proinflammatory cytokines and IFN-β. TLR7, -8, and -9 are MyD88 dependent and activate the transcription factors NF-κB, IRF5, AP1, and IRF7, resulting in production of proinflammatory cytokines and type 1 interferons.

Recruitment of MyD88 leads to recruitment of IL-1 receptor associated kinase-4 (IRAK-4), through death domain interactions. IRAK-4 activation leads to recruitment and activation of IRAK-1 and IRAK-2. In monocytes, IRAK-M is also recruited to this complex and functions as a negative regulator of signaling. Both IRAK-1 and IRAK-2 activation are required for full activation of NF-κB and MAP kinases. IRAK activation leads to interaction with TNF receptor–associated factor 6 (TRAF6), which is an E3 ubiquitin ligase. Along with the E2 conjugating complex of Ubc13 and Uev1a, TRAF6 is K-63 ubiquitinated, recruiting TGF-β–activated protein kinase-1 (TAK-1). TAK-1 then activates the inhibitor of NF-κB (IκB) kinase complex (IKK), which consists of NF-κB essential modifier (NEMO), IKKα, and IKKβ, leading to phosphorylation of IκB (inhibitor of NF-κB) proteins and their subsequent K-48 linked ubiquitination and degradation. NF-κB is subsequently released from inhibition, allowing translocation to the nucleus, where it mediates transcriptional activation of numerous genes involved in inflammation.

The transcription factor interferon regulatory factor-5 (IRF-5) is also activated downstream of TRAF6 and is required for production of proinflammatory cytokines. TAK-1 activation also leads to activation of p38 MAP kinase and c-Jun N terminal kinase (JNK), which then activates the AP1 transcriptional complex (see Fig. 3.5).

TLR signaling can proceed via multiple pathways, impacting both the kinetics and nature of the subsequent innate response. For example, TLR4 also interacts with the adaptors MAL (MyD88-like adaptor protein), TRAM (translocating chain-associating membrane protein), and TRIF (TIR domain–containing adaptor-inducing IFN-β (see Fig. 3.5). TLR4 initially recruits MAL and MyD88 to trigger "early phase" NF-κB and MAP kinase activation. TLR4 is subsequently endocytosed and trafficked to the endosome, where it forms a signaling complex with TRAM and TRIF, which leads to activation of TANK-binding kinase-1 (TBK-1), IKKε, and IRF-3, and "late phase" activation of NF-κB and MAP kinases. Activation of IRF3 induces IFN-β production.

Antiviral TLRs are located in endosomes and interact with an endoplasmic reticulum membrane protein called UNC93B (see Fig. 3.5). Upon activation, TLR3 does not recruit MyD88, but rather TRIF, leading to recruitment of TRAF3 and activation of TBK1, IKKι, IRF-3, and IFN-β production. TRIF also recruits RIP1 and TRAF6, which leads to activation of NF-κB. While the other antiviral TLRs, TLR7, -8, and TLR9, are MyD88 dependent, they activate a pathway utilizing IRAK-1, IKKα, TRAF3, and intracellular osteopontin (iOPN), activating IRF7 and leading to production of IFN-α.[28] TLR7, -8, and -9 also utilize a TRAF6-dependent pathway that leads to NF-κB/MAP kinase activation. Bruton tyrosine kinase (BTK) (Chapter 33) also plays a critical role in TLR8- and TLR9-induced production of TNF-α and IL-6.

Given the ubiquitous expression of TLRs and their essential roles in detection of pathogens, it is not surprising that genetic defects that impair TLR function (e.g., IRAK4 deficiency, MyD88 deficiency) are associated with susceptibility to infections, notably invasive, pyogenic infections (e.g., *S. aureus, S. pneumococcus, P. aeruginosa*) and herpes simplex I (defects in TLR3 function) (Chapter 35).[29] Additionally, numerous single nucleotide polymorphisms (SNPs) in individual TLRs have been identified that have been associated with increased susceptibility to a variety of pathogens or increased susceptibility to autoimmune diseases (e.g., rheumatoid arthritis, systemic lupus erythematosus). However, in many instances the effects of these SNPs on TLR function is unclear and their importance in human health requires further investigation.[30]

The innate immune system in natura encounters intact pathogens that express multiple PAMPs, including bacterial cell wall components as well as microbial DNA and RNA. Thus, DCs and other phagocytes are activated through multiple PRRs. Activation of DCs through combinations of TLRs, such as TLR4 and TLR8, can induce synergistic production of Th1 cell–inducing cytokines, as well as the Th1-inducing ligand, Delta-4, leading to stronger Th1 differentiation of T cells than occurs following activation of a single TLR.[31] Interestingly, the use of combinations of TLR agonists on virus-sized nanoparticles containing antigen induce enhanced and better-sustained antibody responses in mice and nonhuman primates.[32] Thus the use of combinations of TLR agonists as adjuvants in vaccines may result in enhanced efficacy of future vaccines (Chapter 87), as well as in immunotherapy against tumors (Chapter 80).

During an infection, multiple factors can mitigate TLR-induced inflammation. One such factor is adenosine, an endogenous purine metabolite whose levels rise during stress or hypoxia. Adenosine binds receptors expressed on leukocytes, leading to increased intracellular concentrations of cyclic adenosine monophosphate (cAMP), dampening TLR-mediated production of Th1-polarizing cytokines while preserving production of Th2 and anti-inflammatory cytokines. Anti-inflammatory/pro-resolving lipid metabolites, such as resolvins and lipoxins, can differentially regulate TLR4-mediated responses of macrophages, inhibiting TNF response to pure LPS but enhancing uptake, killing, and TNF-α production to whole gram-negative bacteria.[33]

Within the GI tract, the factors that maintain tolerance to commensal host flora while detecting/containing pathogenic bacteria with appropriate inflammatory responses are incompletely understood (Chapter 22). The detection of common PAMPs in pathogenic and nonpathogenic bacteria would be anticipated to activate the same inflammatory response. Nevertheless, the detection of commensal bacteria within the intestines can induce tolerance. TLR signaling can contribute to intestinal homeostasis by regulating intestinal epithelial cell proliferation and epithelial integrity. Expression and localization of TLRs in the intestinal epithelium may directly relate to their role in maintaining homeostasis versus inducing inflammation. For example, within the intestinal epithelium, TLR9 activation through the apical membrane induces tolerance, whereas TLR9 activation via the basolateral membrane induces an inflammatory response through the canonical NF-κB pathway. Differential spatial expression of PRR in epithelia may constitute a critical mechanism of distinguishing nonpathological from pathological bacteria that have breached intestinal epithelium.

NOD-Like Receptors

NOD-like receptors (NLRs) are cytoplasmic PRRs that are unrelated to the transmembrane PRRs. NLRs mediate detection of intracytoplasmic bacterial products. Among the NLRs are five members of the NOD family, 14 members of the NALP family, CIITA, IPAF, and NAIP (see Table 3.3). NLR family proteins possess LRRs for ligand detection; a NOD domain (also referred to as a NACHT domain); a domain for initiation of signaling, such as caspase activation and recruitment domain (CARD); pyrin domains; or baculovirus inhibitor of

apoptosis repeat (BIR) domains. NOD1 and NOD2 were the first NLRs identified. They detect components of bacterial peptidoglycan: NOD1 detects mesodiaminopimelic acid, and NOD2 detects muramyl dipeptide. Direct ligand binding by NLR has not yet been demonstrated, leaving open the possibility that detection of pathogens and other signals by NLRs may be indirect. Following activation, NODs oligomerize and recruit the protein kinase RIP2 and CARD9 via CARD domains, leading to activation of NF-κB and MAP kinases, respectively (Fig. 3.6). NOD2 may also play a role in activation of some inflammasomes (described below).

In humans, missense mutations in NOD2 that impair function have been associated with susceptibility to Crohn disease. Conversely, missense mutations in NOD2 that lead to constitutive activation of NF-κB lead to Blau syndrome, an autosomal dominant disorder characterized by granulomatous arthritis, iritis, and skin granulomas.[34] Although many NLRs function as activators of inflammation, NLRP2 and NLRP4 were found to be negative regulators of innate antiviral inflammation through blockade of TBK1 activation, leading to inhibition of the transcription factor IRF3 and inhibition of type 1 interferon production.[35] Thus, some NLRs play+ homeostatic roles in inflammatory responses.

RIG-I–Like Receptors

RIG-I–like receptors (RLRs) detect the presence of viral nucleic acids generated by intracellular, replicating viruses. The RLRs consist of two receptors: RIG-I and melanoma differentiation-associated gene-5 (MDA-5). Both have two N-terminal CARDs and an RNA helicase domain and mediate virus-induced type 1 IFN expression in fibroblasts and conventional DCs. A third RLR, laboratory of genetics and physiology 2 (LGP2), lacks the N-terminal CARD domains and plays a role in repression of signaling. RIG-I and MDA-5 are activated by double-stranded RNA (dsRNA) generated during viral replication with distinct specificities for viral recognition. RIG-I detects Orthomyxoviridae, Rhabdoviridae, Paramyxoviridae, and Flaviviridae, whereas MDA-5 detects Picornaviridae, Caliciviridae, and Coronaviridae. Polyinosine:cytosine (poly I:C) is a nonspecific dsRNA analogue used experimentally to activate TLR3 and RIG-I/MDA-5. Relatively short poly I:C (<1 kb) is recognized preferentially by RIG-I, whereas long poly I:C (>1 kb) is preferentially recognized by MDA-5.[23]

dsRNA-induced activation of RIG-I and MDA-5 induces their association with a mitochondria-associated adaptor known as interferon-β promoter stimulator-1 (IPS-1) or mitochondrial antiviral signaling protein (MAVS) through CARD domain interactions. Downstream effectors include TBK-1 and IKKι, which activate IRF3 and IRF7, leading to production of type-1 interferons (see Fig. 3.6). It is worth noting that live bacteria are more effective inducers of STAT-1, type I IFN, and inflammasome pathways compared with killed organisms, a property that may reflect the importance of bacterial RNA to innate recognition of live infection.[36] Some viruses have developed strategies to circumvent innate immune responses. For example, the coronavirus that causes severe acute respiratory syndrome (SARS-CoV) expresses a protein encoded by open reading frame-9b (ORF-9b), which targets the MAVS signalosome. ORF-9b causes the degradation of MAVS, TRAF3, and TRAF6, inhibiting host cell interferon production.[37]

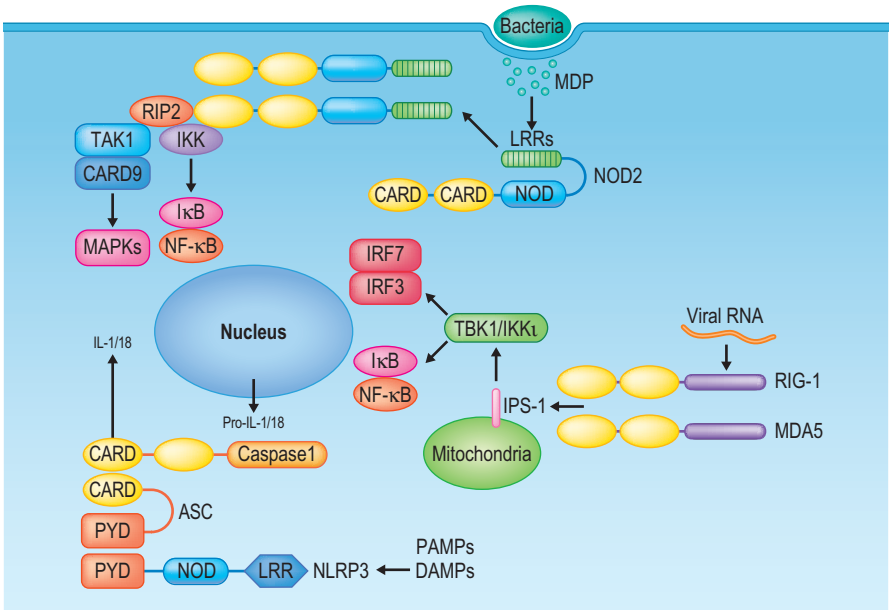

FIG. 3.6 NOD-Like Receptor (NLR), RIG-I–Like Receptor (RLR), and Inflammasome Signaling. NOD2 is activated following exposure to bacterial muramyl dipeptide (MDP) and leads to dimerization and activation of RIP2, TAK1, CARD9, and the IκB kinase (IKK) complex. This results in inflammatory gene transcription. RLRs, like RIG-I and MDA-5, are activated by double-stranded RNA generated by intracellular, replicating viruses, inducing activation of transcription factors, including NF-κB, IRF3, and IRF7, leading to production of proinflammatory cytokines and type 1 interferons. Inflammasomes can be activated by microbial products (PAMPs), as well as endogenous products released by damaged host cells (DAMPs), leading to activation of caspase 1. Active caspase 1 processes pro-IL-1β and pro-IL-18 into mature IL-1β and IL-18. Active caspase 1 also processes GSDMD to form pores in the cell membrane that allows release of IL-1β and IL-18.

C-Type Lectin Receptors

C-type lectin receptors (CLRs) are a diverse group of receptors originally identified as Ca^{2+}-dependent carbohydrate-binding proteins.[38] CLRs are defined as any protein that contains a C-type carbohydrate recognition domain (CRD), regardless of calcium- or carbohydrate-binding ability. CLRs include numerous members with diverse functions, including cell adhesion, regulation of NK-cell function, phagocytosis, endocytosis, platelet activation, complement activation, tissue remodeling, and innate immunity. In myeloid cells, CLRs can mediate internalization of microbes to allow for antigen processing and presentation. Some CLRs function analogously to TLR, resulting in direct cellular activation and generation of inflammatory responses. Other CLRs are capable of binding PAMPs, but function to modulate cell activation. The functions of myeloid CLRs are dictated by the signaling pathways they activate.

Dectin-1 is a CLR expressed on DCs and other myeloid cells that recognizes β-1,3-linked glucans present in the cell wall of fungi, mycobacteria, and plants. Dectin-2 recognizes high mannose structures and α-mannans found in fungi, mycobacteria, and dust mites. Following ligand binding, Dectin-1 and Dectin-2 activate signaling pathways by utilizing the tyrosine kinase Syk, CARD9, and Raf-1, leading to activation of the transcription factors NF-κB, NFAT, and AP1 and production of proinflammatory cytokines (Fig. 3.7). The production of cytokines downstream of Dectin-1 and Dectin-2 (e.g., IL-1, IL-6, TGF-β, IL-23) induces the subsequent differentiation of naïve T cells into Th17 T cells, which play a critical role in antifungal immunity (Chapters 11 and 28). Activation of Syk induces generation of ROIs, which can activate the NLRP3 inflammasome, leading to processing of pro-IL-1β to mature IL-1β. The importance of CLR function in antifungal immunity is demonstrated by inactivating mutations in Dectin-1 and CARD9 that lead to chronic mucocutaneous candidiasis, as well as invasive fungal infections in the case of CARD9 deficiency.[39]

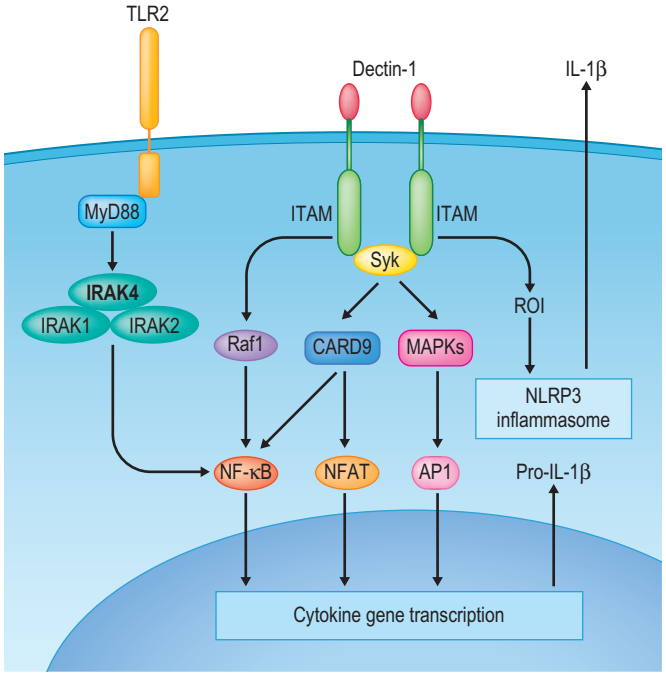

FIG. 3.7 C-Type Lectin Signaling. C-type lectin receptors (CLRs), like Dectin-1, contain immunoreceptor tyrosine-based activation motifs (ITAMs) that interact with the cytosolic tyrosine kinase, Syk, leading to activation of transcription factors including NF-κB, NFAT, and AP1. Dectin-1 activates the serine kinase, Raf1, which contributes to NF-κB activation. Toll-like receptors (TLRs), such as TLR2, can cooperate with Dectin-1 signaling to activate NF-κB, leading to an enhanced inflammatory response.

Mincle (macrophage inducible C-type lectin) recognizes α-mannans and glycolipids and associates with the FcRγ chain. Upon ligand binding, Syk is recruited to the ITAM of FcRγ, leading to cellular activation. Mincle also binds the endogenous nucleoprotein SAP130, which is exposed by dead cells. The Mincle-mediated response to dead cells leads to infiltration of PMNs into damaged tissue and may contribute to tissue repair.

Other CLRs, such as DCIR (DC-inhibitory receptor), possess an inhibitory ITIM motif. DCIR is expressed on myeloid cells, DCs, and B cells. DCIR inhibits TLR8-induced IL-12p70 and TNF-α production by myeloid DCs and TLR9-induced IFN-α/β production by pDCs. Inhibition of TLR responses may reflect inhibition of tyrosine kinases and/or PI3 kinase pathways.

Pathogens express multiple PAMPs that activate a variety of PRRs. Indeed, CLRs and TLRs cooperate in antimicrobial responses. Coordinated activation of Dectin-1 and TLR2, for example, via stimulation with zymosan, enhances production of proinflammatory cytokines via activation of both Dectin-1-Syk and TLR2-MyD88 signaling pathways (see Fig. 3.7). DC-SIGN, which recognizes mycobacteria and viruses, can enhance TLR-induced NF-κB activation through a Raf-1–dependent signaling pathway.

Scavenger Receptors

Scavenger receptors are a diverse group of receptors that include CD36, CD68, SR class A, and SR class B.[40] The receptors mediate the uptake of oxidized lipoproteins into cells. Scavenger receptors also mediate the uptake of microbes and contribute to the response of macrophages to mycobacteria. SR class A can also mediate an inflammatory response to β-amyloid fibrils that may contribute to Alzheimer disease (see Table 3.3). Scavenger receptors play a pathological role in the generation of cholesterol-laden foam cells that comprise atherosclerotic plaques in blood vessels.

Receptor for Advanced Glycation End Products

RAGE is an inflammatory transmembrane receptor that belongs to the immunoglobulin superfamily of receptors (see Table 3.3). RAGE is capable of binding a variety of DAMP molecules, including advanced glycation end products, HMGB1, S100 proteins, and DNA. Additionally, RAGE can bind various PAMPs, including LPS, microbial DNA and respiratory viruses. RAGE preassembles into dimers and multimers at the cell surface. Upon ligand binding, intracellular signaling pathways are activated through the adaptor protein diaphanous-1/mDia-1, which include Rho GTPases, phosphoinositol-3 kinase, mitogen-activated kinases, AKT, and transcription factors (e.g., NF-κB, STAT3), inducing production of proinflammatory cytokines (e.g., TNFβ, IL-6). Chronic activation of RAGE has been implicated in numerous pathological conditions, including cardiovascular disease, diabetic inflammatory complications, Alzheimer disease, and some cancers.[41]

PERSPECTIVES

- While short-lived, polymorphonuclear leukocytes (neutrophils) are the most abundant and earliest cells of the innate immune system to respond to infection.
- Several days later in an infection, monocytes and macrophages predominate.
- Activated neutrophils, monocytes, and macrophages kill phagocytosed bacteria with reactive oxygen intermediates and antimicrobial peptides and proteins (APPs).
- Dendritic cells take up and present foreign antigens and thus link the innate to the adaptive immune system.
- Natural killer (NK) cells can kill infected or malignant cells without prior activation.
- Mast cells are found at the interface between the host and the environment, are first responders to microbes, and recruit other inflammatory cells.

Inflammasomes

A variety of stimuli, including PAMPs, bacterial toxins, the common vaccine adjuvant aluminum hydroxide (alum), and ultraviolet (UV) light, as well as endogenous "danger signals" released by stressed or damaged host cells, referred to as DAMPs (e.g., adenosine triphosphate [ATP], uric acid, hyaluronan), induce the processing of pro-IL-1β to mature IL-1β. The cytosolic cellular multimolecular machinery responsible for IL-1β processing is termed the inflammasome. Prototypical inflammasomes include the NOD-like receptor-related protein-1 (NLRP1) inflammasome, the NLRP3 inflammasome, and the IL-1β-converting enzyme protease-activating factor (IPAF) inflammasome. NLRP recruit ASC (apoptosis-associated speck-like protein containing a CARD) via homotypic PYRIN domain interactions. ASC is an adaptor protein that contains a PYRIN domain and a CARD domain. Caspase-1 is subsequently recruited via CARD domains, leading to proteolytic processing of IL-1β and IL-18 (see Fig. 3.6). Although NLRP1, NLRP3, and IPAF form prototypical inflammasomes, other NLR, including NOD2 and neuronal apoptosis inhibitory protein (NAIP), can also form inflammasomes or modulate their activities.[42]

The mechanism through which mature IL-1β and IL-18 are released has been termed pyroptosis, a form of inflammatory death of the infected cell (Chapter 17). During pyroptosis, inflammatory caspases (caspase 1) cleave gasdermin D (GSDMD), a cytosolic protein in phagocytes and epithelial cells. Cleavage of GSDMD leads to its localization at the cell membrane where it oligomerizes to form membrane pores. Pore formation disrupts membrane integrity, leading to cell death and release of small molecules, such as IL-1β and IL-18 and GSDMD itself (see Fig. 3.6). GSDMD can bind cardiolipin in bacterial cell membranes, perhaps leading to permeabilization of the bacterial membrane and death.[43]

Aberrant inflammasome activation can result in autoinflammatory diseases, characterized by recurrent inflammatory episodes. Mutations in the *NLRP3* gene are associated with a spectrum of autosomal dominant inherited autoinflammatory diseases, including Muckle-Wells syndrome (sensorineural deafness, urticaria, fevers, chills, arthritis), familial cold autoinflammatory syndrome (rash, conjunctivitis, fever, chills, arthralgias elicited by cold exposure), and neonatal-onset multisystem inflammatory disease (NOMID) (rashes, arthritis, chronic meningitis). These disorders are the result of constitutive production of IL-1β. Treatment of these disorders involves anti-inflammatory therapy, including IL-1 antagonists.[44]

INNATE IMMUNITY IN CLINICAL PRACTICE

Our growing understanding of the molecular and cellular basis for innate immunity is paralleled by increasing appreciation of its importance to clinical medicine. Examples include (1) recognition of novel primary immunodeficiencies in the innate immune pathways presenting with heightened susceptibility to bacterial (e.g., MyD88 deficiency, IRAK4 deficiency) and fungal infection (e.g., CARD9 deficiency); (2) appreciation of immune ontogeny (i.e., the change in immune function in a given individual across their life span, which parallels age-specific susceptibility to infection); (3) clinical studies of the potential use of APP congeners to prevent or treat infection; (4) leveraging PRR agonists, such as TLR agonists, as vaccine adjuvants (e.g., the TLR4 agonist monophosphoryl lipid A [MPLA], which is a detoxified form of lipopolysaccharide or endotoxin used in a licensed human papillomavirus [HPV] vaccine [Cervarix]); and (5) employing certain live attenuated vaccines, such as bacille Calmette-Guérin (BCG) or measles, mumps, rubella (MMR) vaccine that activate multiple PRRs to reduce infections to antigenically distinct pathogens—so-called beneficial heterologous or "nonspecific" effects—that may be mediated via epigenetic reprograming of monocytes and enhancement of innate immune responses.[45]

Our understanding of the complexity of innate immunity has advanced considerably over the past decade. The importance of the innate immune system to human health is underscored by single gene mutations, such as IRAK4 deficiency, that result in immune deficiencies and infection, particularly in early life.[29] Continued elucidation of the cell types comprising the innate immune system has expanded our understanding of the delicate balance between tolerance to nonpathogenic commensal bacteria and inflammatory responses to pathogenic, invasive microbes. As innate immunity is expressed in an age-specific manner, a better understanding of the ontogeny of the innate immune system, as well as the mechanisms by which innate and adaptive immunity interact, will guide development of adjuvants, resulting in more effective vaccines and tumor immunotherapy.

Antigen Receptor Genes, Gene Products, and Co-Receptors

Harry W. Schroeder Jr., Laurent Gapin, and Raul Martin Torres

In 1890, von Behring and Kitasato reported the existence of an agent in the blood that could neutralize diphtheria toxin. The following year, glancing references were made to "*Antikörper*" in studies describing the ability of the agent to discriminate between two immune substances, or bodies. The term *antigen* (Chapter 6) is a shortened form of *Antisomatogen* + *Immunkörperbildner*, the substance that induces the production of an antibody. Thus, the definition of *antibody* and *antigen* represent a classic tautology.

In 1939, Tiselius and Kabat used electrophoresis to separate immunized serum into albumin, α-globulin, β-globulin, and γ-globulin fractions. Absorption of the serum against the antigen depleted the γ-globulin fraction, yielding the terms *gammaglobulin*, *immunoglobulin* (Ig), and *IgG*. Subsequently, "sizing" columns were used to separate Igs into those that were "heavy" (pentameric IgM), "regular" (IgA, IgE, IgD, IgG, or monomeric IgM), and "light" (light-chain dimers), culminating with the discovery of the last major class of Ig, IgE, in 1966.

In 1949, Porter used papain to digest IgG molecules into two types of fragments, termed Fab (fragment antigen binding) and Fc (fragment crystallizable) (Chapter 8). The constancy of the Fc fragment permitted its crystallization, and thus the elucidation of its sequence and structure. The variability of the Fab fragment precluded analysis until Bence Jones myeloma proteins were identified as clonal, isolated light chains.

In 1976, Hozumi and Tonegawa demonstrated that the variable portion of κ chains was the product of the rearrangement of a variable (V) and joining (J) gene segment. In 1982, Alt and Baltimore reported that terminal deoxynucleotidyl transferase (TdT) could be used to introduce non-germline encoded sequence between rearranging V, D for diversity, and J gene segments, potentially freeing the preimmune heavy-chain repertoire from germline constraints. In 1984, Weigert and colleagues determined that during affinity maturation variable domains could undergo mutation at a rate of 10^{-3} per base pair, per generation. These discoveries clarified how lymphocytes could generate an astronomically diverse antigen receptor repertoire from a handful of gene elements.

In 1982 Allison and colleagues raised antisera against a cell-surface molecule that could uniquely identify individual T-cell clones. A year later, Kappler and a consortium of colleagues demonstrated that these surface molecules were heterodimers composed of variable and constant region domains, just like Ig. Subsequently, Davis and Mak independently cloned the β chain of the T-cell antigen receptor (TCR). Initial confusion regarding the identity of the companion α chain led to the realization that there were two mutually exclusive forms of TCR, αβ and γδ.

PARATOPES AND EPITOPES

Igs and TCRs both belong to the eponymous immunoglobulin superfamily (IgSF).[1] The study of antibodies precedes that of TCR by decades; hence much of what we know is based on knowledge first gleaned from the study of Igs.

Ig–antigen interactions typically take place between the *paratope*, the site on the Ig at which the antigen binds, and the *epitope*, which is the site on the antigen that is bound. Thus, lymphocyte antigen receptors do not recognize antigens; they recognize epitopes borne on those antigens. This makes it possible for the cell to discriminate between two closely related antigens, each of which can be viewed as a collection of epitopes. It also permits the same receptor to bind divergent antigens that share equivalent or similar epitopes, a phenomenon referred to as *cross-reactivity*.

Although both Igs and TCRs can recognize the same antigen, they do so in markedly different ways. Igs tend to recognize intact antigens in soluble form, preferentially identifying surface epitopes that are often composed of conformational structures that are noncontiguous in the antigen's primary sequence. In contrast, most TCRs recognize fragments of antigens, both surface and internal, that have been processed by a separate antigen-presenting cell and then bound to a major histocompatibility complex (MHC) class I or class II molecule (Chapters 5 and 6).

THE B-CELL AND T-CELL RECEPTOR ANTIGEN RECOGNITION COMPLEX

Both B-cell antigen receptor (BCR) and TCR cytoplasmic domains are exceptionally short. In order for surface binding of antigen to elicit a response from the cell, the BCR and TCR each associate noncovalently with signal transduction complexes: heterodimeric Igα:Igβ (also known as CD79a:CD79b, respectively) for B cells, and multimeric CD3 for T cells. Loss-of-function mutations in either of these complexes leads to cell death, which becomes clinically manifest as hypogammaglobulinemia in the case of B cells (Chapter 33), or severe combined immune deficiency (SCID) in the case of T cells (Chapter 34).

IMMUNOGLOBULINS AND T-CELL RECEPTOR STRUCTURES

The Immunoglobulin Domain, the Basic Immunoglobulin Superfamily Building Block

Igs consist of two heavy (H) and two light (L) chains (Fig. 4.1). The L chain can be either a κ or a λ chain. TCRs consist of either

an αβ or a γδ heterodimer. Each component chain contains two or more IgSF domains, each of which consists of two sandwiched β pleated sheets "pinned" together by a disulfide bridge between two conserved cysteine residues.[1] Considerable variability is allowed to the amino acids that populate the external surface of the IgSF domain and the loops that link the β strands. These solvent-exposed surfaces offer multiple targets for docking with other molecules.

Two types of IgSF domains, "constant" (C) and "variable" (V), are used in Igs and TCRs (see Fig. 4.1). C-type domains, which are the most compact, have seven antiparallel strands distributed as three strands in the first sheet and four strands in the second. Side chains positioned to lie between the two strands tend to be nonpolar in nature, creating a hydrophobic core of considerable stability. V-type domains add two additional antiparallel strands to the first sheet, creating a five-strand–four-strand distribution. The two additional strands, which encode framework region 2 (FR2), are used to steady the interaction between heterodimeric V domains, allowing them to create a stable antigen-binding site.[2]

While each Ig and TCR chain contains only one amino-terminal V Ig domain, the number of carboxy-terminal C domains varies. Ig H chains contain between three and four C domains, whereas both Ig L chains and all four TCR chains contain only one C domain each. IgH chains with three C domains tend to include a spacer hinge region between the first (C_H1) and second (C_H2) domains. Each V or C domain consists of approximately 110 to 130 amino acids, averaging 12,000 to 13,000 kDa. A typical L or TCR chain will thus mass approximately 25 kDa, and a three C domain Cγ H chain with its hinge will mass approximately 55 kDa.

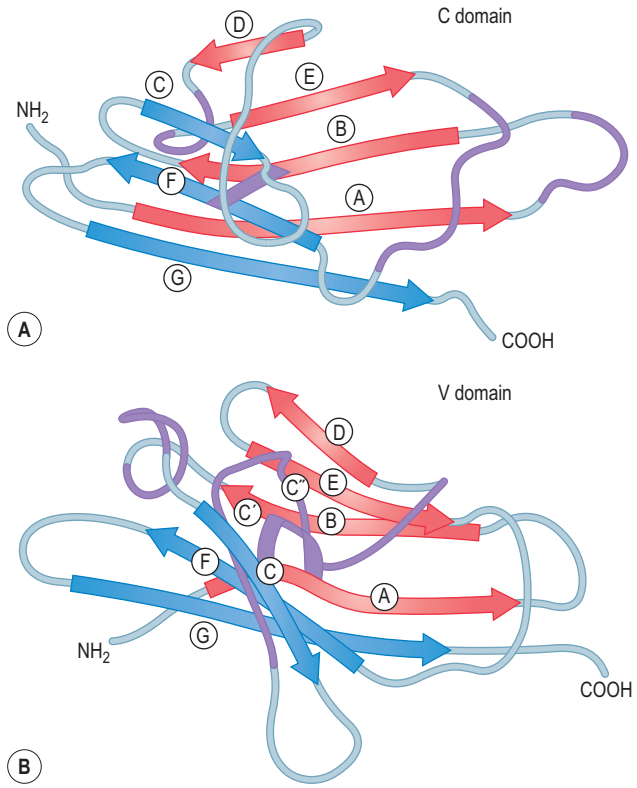

FIG. 4.1 Immunoglobulin Superfamily Domain Structures. (A) A typical compact C domain structure. The β strands are labeled A through G. The sequence at the core is conserved and nonpolar. The external surface and the β loops are available for docking and often vary in sequence. (B) A typical V domain structure. Two additional strands, C′ and C″, have been added. Note the projection of the C–C′ strands and loop away from the core.

Idiotypes and Isotypes

Immunization of heterologous species with monoclonal antibodies (mAbs; or a restricted set of Igs) has shown that Igs and TCRs contain both common and individual antigenic determinants. Individual determinant(s), termed *idiotype(s)*, are contained within V domains. Common determinants, termed *isotypes*, are specific for the constant portion of the antibody and allow grouping of Igs and TCRs into recognized classes. Each class defines an individual type of C domain. Determinants common to subsets of individuals within a species, yet differing between other members of that species, are termed *allotypes* and define inherited polymorphisms that result from allelic forms of the genes.[3]

The V Domain

Three hypervariable intervals, termed complementarity-determining regions (CDRs), that are situated between four framework regions of stable sequence (Fig. 4.2) can be distinguished by comparisons of the primary sequences of V domains.[4] The international ImMunoGeneTics information system, or IMGT, maintains an extremely useful website, http://www.imgt.org that contains a large database of Ig and TCR sequences as well as a multiplicity of software tools for their analysis.

Antigen Recognition and the Fragment Antigen Binding

Initial studies of Ig structure were facilitated by the use of papain and pepsin to fragment IgG molecules. Papain digests IgG into two antigen-binding fragments (Fab) and a single crystallizable (or constant) fragment (Fc). Pepsin splits IgG into an Fc fragment and a single dimeric $F(ab')_2$ that can cross-link as well as bind antigens. The Fab contains one complete L chain in its entirety and the V and C_H1 portion of one H chain (see Fig. 4.2). The Fab can be further divided into a variable fragment (Fv) composed of the V_H and V_L domains, and a constant fragment (Fb) composed of the C_L and C_H1 domains. Single Fv fragments can be genetically engineered to recapitulate the monovalent antigen-binding characteristics of the original, parent antibody.[5] The extracellular domains of TCRαβ and TCRγδ correspond to Ig Fab.

Effector Function and the Fragment Crystallizable

The Fc portion (see Fig. 4.2) encodes the effector functions of the Ig. These functions are generally inflammatory reactions that include fixation and activation of complement, and binding of antibody to Fc receptors on the surface of other cells (Chapter 8). Each Ig class and subclass exhibits its own set of effector functions.[6] For example, the IgG C_H2 domain plays a key role in complement fixation and in binding to class-specific Fc receptors on the surface of effector cells. Both these interactions are important in initiating the process of phagocytosis, in allowing certain subclasses to traverse the placenta, and in influencing the biologic functions of lymphocytes, platelets, and other cells.

Gm Allotype System

A series of serologically defined C-domain allotypes have been identified. In the case of the H chain, they are termed Gm for

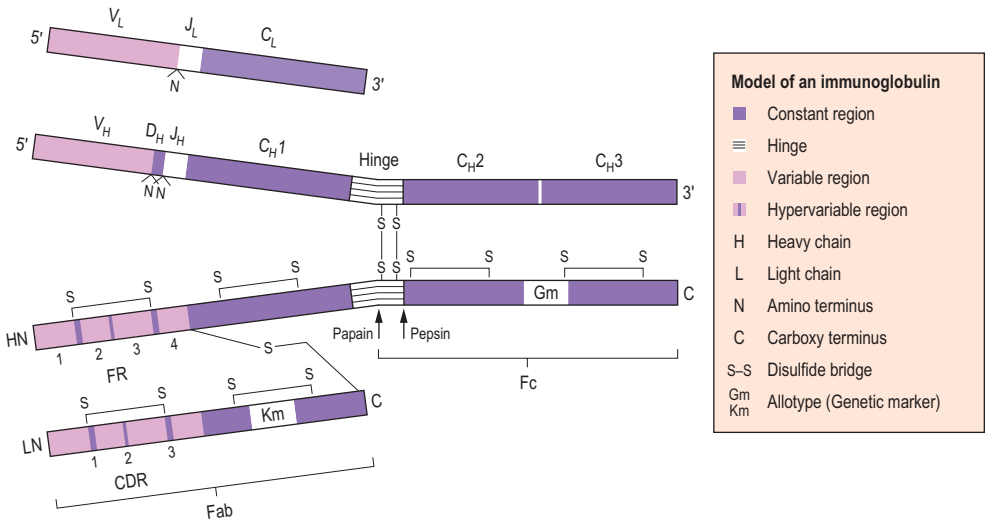

FIG. 4.2 A Two-Dimensional Model of an Immunoglobulin G Molecule. The top H and L chains illustrate the composition of these molecules at a nucleotide level. The bottom chains illustrate the nature of the protein sequence. See text for further details. *CDR*, Complementarity-determining region; *Fab*, fragment antigen binding; *Fc*, fragment crystallizable; *FR*, framework region.

TABLE 4.1 Selected Properties of Immunoglobulin (Ig) Classes

	IgG	IgA	IgM	IgD	IgE
Molecular weight	160,000	170,000 or polymer	900,000	160,000	180,000
Approximate concentration in serum (mg/dL)	700–1500	75–400	50–250	0.3–30	0.0015–0.2

Half-life (days)	23	6	5	3	2.5
Special property	Placental passage	Secretory Ig	Primary response lymphocyte surface	Lymphocyte surface	Immediate hypersensitivity reactions

KEY CONCEPTS

Immunoglobulin and T-Cell Receptor Structure

- Both Igs and TCRs are heterodimeric proteins.
  - Igs consist of two identical H and two L chains.
  - αβ TCRs consist of one α and one β chain.
  - γδ TCRs consist of one γ and one δ chain.
- Ig and TCR contain two or more IGSF domains, which are identified by their characteristic beta barrel structure.
  - Each Ig and TCR chain contains a V-type IgSF domain that will form one-half of the antigen-binding site.
  - Each V domain contains three hypervariable intervals known as CDRs.
- The CDRs of paired heterodimers chains are juxtaposed to form the antigen-binding site.
- The C domains of Ig H chains define the Ig class or subclass.
- The two distal C IgH domains determine the effector function of the antibody.

the gammaglobulin fraction of the serum in which they were first identified.[3] Allotypes have been identified for γ1, γ2, γ3, γ4, α2, and ε H chains and for the κ L chain. Associations between certain Gm allotypes and predisposition to develop certain diseases of immune function have been reported.

IMMUNOGLOBULIN CLASSES AND SUBCLASSES

The constant domains of the H chain define the class and subclass of the antibody. Table 4.1 lists the five major classes of Igs in human and describes some of their physical and chemical features. Two of the five major H-chain classes, α and γ, have undergone duplication. IgG1, IgG2, IgG3, and IgG4 all have the same basic structural design and differ only in the primary sequence of their constant regions and in the location of their interchain disulfide bonds. The H chain in each of these subclasses is referred to as γ1, γ2, etc. IgA consists of the two subclasses, α1 and α2. Table 4.2 compares the four subclasses of IgG, the two of IgA, and the classes of IgM, IgD, and IgE from the standpoint of their biologic functions. In humans, the two L-chain classes, κ and λ, are expressed at roughly equal frequencies. No specific effector function has been identified for either L-chain class.

Immunoglobulin M

IgM exists in monomeric, pentameric, and hexameric forms. The 8 S monomeric 180 kDa IgM has the molecular formula μ_2L_2. It is a minor fraction in serum, but in its transmembrane form IgM plays a key role in B-cell development and function as the antigen recognition portion of the B-cell antigen receptor. The major form in serum is the 19 S, 900 kDa pentameric IgM, which contains five

subunits [$(\mu_2L_2)_5$] linked together by disulfide bridges, and by one molecule of an additional polypeptide chain, the J chain, which joins two of the subunits by a disulfide bridge.[7]

IgM is the first Ig to be secreted (as pentameric IgM) during development and in the absence of antigenic challenge. It is also the predominant Ig produced during the primary immune response. Occasionally, particularly in the case of carbohydrate antigens such as isohemagglutinins, it will remain the major or sole antibody class. IgM differs from most other Igs in having an extra C_H domain in place of a hinge.

IgM avidly fixes complement. This property is focused in CH3, the homologue of IgG CH2.[8] Although the valence of each μ_2L_2 subunit is 2, when binding to large protein antigens 5 of the 10 antigen-binding sites in pentameric IgM appear blocked due to steric hindrance. As a consequence, the valence for large antigens is five.

Immunoglobulin G

IgG, the major Ig class, generally exists in a monomeric form (γ_2L_2) in the serum, although it can form hexameric assemblies at cell surfaces.[9] IgG accounts for the bulk of serum antibody activity in response to most protein antigens.

The four IgG subclasses are numbered in relation to their serum levels relative to each other, with IgG1 predominant and IgG4 the least common.[10] IgG1 and IgG3 fix complement and bind phagocyte Fcγ receptors well, whereas IgG2 fixes complement but binds Fcγ receptors more poorly. Recently it has been shown that IgG1 can use non-covalent Fc-Fc interactions to form hexameric assemblies, which facilitate complement activation. IgG4 does not fix complement effectively in the native state but has been reported to do so after proteolytic cleavage. IgG1 and IgG3 are most frequently elicited by viral antigens, IgG2 by carbohydrates, and IgG4 by helminthic parasites.

IgG4 can attenuate allergic responses by inhibiting the activity of IgE.[11] IgG4 can function as a blocking antibody, preventing cross-linking of receptor bound IgE. It can co-stimulate the inhibitory IgG receptor FcγRIIb, which can negatively regulate FcεRI signaling and thus inhibit effector cell activation. Finally, the disulfide bonds of the IgG4 hinge are easily reduced, which allows the H chains to separate and randomly re-associate to produce a mixed population of IgG4 molecules with randomized heavy-chain and light-chain pairs. This impairs the ability of IgG4 to form immune complexes and thus has an anti-inflammatory effect, facilitating immunotherapy for allergic diseases (allergy shots).

Overproduction of IgG4 is seen in a disparate group of inflammatory diseases. Fibro-inflammatory masses can develop in virtually all organs except the brain, with an unexplained preference for salivary glands, lymph nodes, and pancreas. Together, these are referred to as IgG4-related disease (IgG4-RD).[12]

Immunoglobulin A

IgA generally exists in a monomeric form (α_2L_2) in the serum. However, it can also interact with J chain to form a polymer $(\alpha_2L_2)_{2,3}$-J. Second in concentration to IgG in serum, IgA functions as the predominant form of Ig in mucosal secretions.[13]

Secretory IgA (SIgA) is largely synthesized by plasma cells associated with mucosal tissues. In the secretions, the molecule typically exists in polymeric form with two subunits in association with the 70 kDa secretory component $(\alpha_2L_2)_2$-SC. SC is synthesized by the epithelial cells that line the lumen of the gut. It appears to render the SIgA complex more resistant to proteolytic digestion and it enhances the immune functions of SIgA.

Immunoglobulin E

IgE is largely found in extravascular spaces. Its plasma turnover is rapid, with a half-life of about 2 days. IgE antibodies help protect the host from parasitic infections (Chapter 30). In Westernized, affluent societies, IgE is primarily associated with allergy. Through their interaction with Fcε receptors on mast cells and basophils, IgE antibodies, in the presence of antigens, induce the release of histamine and various other vasoactive substances, which are responsible for clinical manifestations of various allergic states.[14]

Immunoglobulin D

Although the H chain of IgD can undergo alternative splicing to a secretory form, IgD serum antibodies in human are uncommon and are absent in the serum of mice and primates. Instead, IgD typically is co-expressed with IgM on the surface of mature lymphocytes. The appearance of IgD is associated with the transition of a B lymphocyte from a cell that can be tolerized to antigen to a cell that will respond to antigen with the production of antibody (Chapter 7).

T-CELL RECEPTOR αβ AND γδ

TCR α, β γ, and δ chains are members of the IgSF and thus share a number of structural similarities with Ig. Each chain contains

a leader peptide, and extracellular, transmembrane, and intracytoplasmic components. The extracellular component can be divided into three domains: a polymorphic V domain encoded by VJ (α and γ chains) or VDJ (β and δ chains) gene segments, a C domain, and a hinge region.[15] The hinge region typically contains an extra cysteine (none in γ chains encoded by Cγ2) that forms a disulfide bond with the other partner of the heterodimer. The transmembrane domains all include a lysine plus or minus an arginine residue that facilitate the association of the TCR heterodimer with components of the CD3 signal transduction complex, each of which has a matching negatively charged residue in their own transmembrane portions (see below). The intracytoplasmic components are tiny and play a relatively limited role in signal transduction.

T-Cell Receptor αβ

The TCR α and β chains are glycoproteins with molecular weights that vary from 42 to 45 kDa, depending upon the primary amino acid sequence and the degree of glycosylation. Deglycosylated forms have a molecular mass of 30 to 32 kDa. These chains share a number of invariant residues in common with Ig heavy and light chains, in particular residues that are thought to be important for interactions between heavy and light chains. The structures of a number of partial or full-length TCRs have been solved by X-ray crystallography (Fig. 4.3).[16] In general, the structure of the TCR αβ heterodimer is similar, but not identical, to that of an Ig Fab fragment.

T-Cell Receptor γδ

The TCR γ and δ chains are glycoproteins with a more complex molecular size pattern than α and β chains. TCRs that use the Cγ1 gene segment, which contains a cysteine-encoding exon are disulfide-linked (MW 36 to 42 kDa). TCRs that use Cγ2 exist in two non-disulfide-linked forms, one of 40 to 44 kDa and one of 55 kDa.[17] The differences in molecular size are due to variability of both N-linked glycosylation and primary amino acid sequence. The 55-kDa form uses a Cγ2 allele that contains three (rather than two) exons encoding the connecting piece, as well as more N-linked carbohydrate. The TCR δ chain is more straightforward, being 40 to 43 kDa in size and containing two sites of N-linked glycosylation. The overall architecture of the γδ TCR closely resembles that of αβ TCRs and antibodies, although the angle between the V and C domains, known as the elbow angle, appears more acute.

Ligand Recognitions

TCR αβ T cells primarily recognize peptide-MHC complexes (pMHC) (see Fig. 4.3; Chapters 5 and 6); however, other types of ligands exist. Some αβ TCRs can bind nonpeptidic antigens (atypical antigens) that are bound to "non-classic" MHC class Ib molecules. These specificities tend to define unique populations of T cells. For example, some natural killer T cells (NKT) express a distinctive combination of TCR αβ chains that recognize lipid-based antigens presented by CD1d molecules, while mucosal-associated invariant T cells (MAIT), using other combinations of TCR αβ chains, recognize vitamin metabolites presented by the MHC class-I related gene protein (MR1).[18] Many γδ T cells recognize atypical antigens that may or may not be associated with an antigen-presenting molecule, although some can bind peptides. Finally, many αβ TCRs bind superantigens (SAgs) in a predominantly Vβ-dependent fashion (Chapter 6).

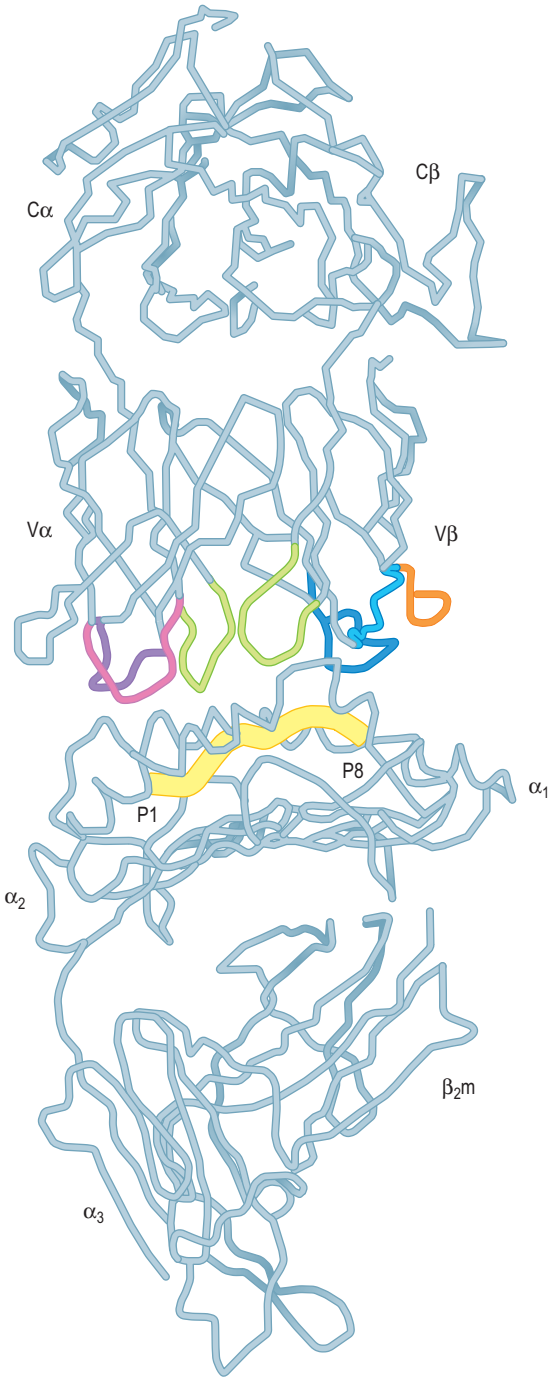

FIG. 4.3 Backbone Representation of Murine αβ T-Cell Receptor Bound to Murine Major Histocompatibility Complex Class I and an Octamer Peptide. The T-cell receptor is above. The Vα CDR1 and CDR2 are *magenta*, Vβ CDR1 and CDR2 are *blue*, both CDR3s are *green*, and the Vβ HV4 is *orange*. β_2m refers to β_2-microglobulin. The peptide is in *yellow*, and the NH_2-terminal and COOH-terminal residues are designated *P1* and *P8*. (Reproduced with permission from Garcia KC, Degano M, Stanfield RL, et al. An alphabeta T cell receptor structure at 2.5 A and its orientation in the TCR-MHC complex. *Science*. 1996;274(5285):209–219.)

Binding to Peptide-Major Histocompatibility Complex

TCRs recognize peptide antigens bound to the binding groove of MHC-encoded glycoproteins (see Fig. 4.3). TCR recognition of pMHC requires a trimolecular complex in which all the components (antigen, MHC, and TCR) contact one another.[16] Thus, recognition is highly influenced by polymorphisms in the MHC molecule (Chapter 5). As in the case of Ig, TCR CDR1 and CDR2 are encoded in the germline V regions, whereas CDR3 is formed at the junction of the V gene with a J gene segment (TCR α and γ) or D and J gene segments (TCR β and δ chains). Vβ also has a fourth region of variability within Framework 3 that is juxtaposed to the other CDRs in the tertiary structure. This region, variously termed hypervariable region 4 (HV4) or CDR4, can participate in SAg binding.

The co-crystallization of different combinations of soluble TCR αβ interacting with MHC class I bound to antigen peptide (pMHC) has made it possible to directly address the manner in which antigen recognition occurs (see Fig. 4.3). The TCR αβ combining site is relatively flat, allowing it to interact with a rather broad surface at the point of contact with pMHC.

The TCR footprint on the pMHC complex tends to occur in a diagonal across the MHC antigen-binding groove, with TCR Vα positioned over the MHC α2 helix and TCR Vβ overlying the MHC α1 helix. This geometry would permit consistent access of the CD8 co-receptors to the MHC class I molecule. The CDR1 and CDR2 loops, which are entirely encoded by germline sequence, tend to interact more with the MHC molecule; whereas the CDR3 loops, which are composed of both germline and somatic (N region) sequence, appear to dominate the interaction with MHC-bound peptide.

The binding of TCR to pMHC appears to be driven by enthalpy: that is, binding increases the stability of the CDR loops, especially CDR3. These results have led to the suggestion that initial binding focuses on the interaction between CDRs 1 and 2 and the MHC. After this initial recognition, the CDR3s change their shape to maximize the area of contact. Conformational flexibility, or "induced fit," would allow TCRs to rapidly sample many similar pMHC complexes, stopping only when their CDR3s are able to stabilize the interaction.

T-Cell Receptor Binding Affinity

The affinity with which the TCR ultimately binds its ligand is a critical determinant of T-cell activation. It is, however, only one factor in determining the overall avidity of the interaction, since other cell-surface molecules of the T cell (e.g., CD4, CD8, CD2, and various integrins) bind to cell-surface molecules on the antigen-bearing cell to stabilize cell–cell TCR–ligand interactions. Furthermore, since both the TCR and the pMHC ligand are surface membrane proteins, each T cell can provide multiple TCRs in the same plane that can bind multiple pMHC molecules on the surface of the antigen-presenting cell. This makes binding of TCR to pMHC functionally multivalent, enhancing the apparent affinity of the interaction.

Atypical Antigens

Some αβ T cells can recognize lipid antigens when they are complexed with members of the CD1 family. There are four members of the CD1 family that are expressed on the cell surface. TCR that recognize CD1a, b, and c likely follow the same recognition scheme as T cells. But crystal structures of NKT TCR that recognize CD1d show binding that is parallel, rather than diagonal. Allelic polymorphism in CD1 is limited, which theoretically would restrict the range of lipid antigens that can be bound. However, a surprisingly large variety of different lipid-based antigens can be accommodated.[19]

Rather than binding to a single groove on the MHC, lipids attach themselves to one of several hydrophobic pockets that can be found on the surface of CD1. Pocket volume can range from 1300 to 2200 $Å^{trs3}$. The number and length of the pockets differ between the various CD1 isoforms. For example, CD1b has three pockets that share a common portal of entry, as well as a fourth pocket that connects two of the three pockets to each other. This connecting pocket permits the insertion of lipids with a long alkyl chain, such as mycobacterial mycolic acid.

MAIT cells are generally low in frequency in laboratory mice. However, they are abundant in humans, on average representing approximately 5% of total blood T cells, 10% of CD8 T cells, and up to 45% of liver T cells. Natural MR1 ligands include derivatives of vitamin B_9 (folate) and also unstable pyrimidine intermediates derived from the vitamin B_2 (riboflavin) synthesis pathway. A range of small organic molecules, drugs, drug metabolites and drug-like molecules, including salicylates and diclofenac, have also been described as MR1-binding ligands.[20] The MR1 Ag-binding cleft is ideally predisposed to bind to these small metabolites, forming an aromatic cradle that closely sequesters the ligands, with some of the ligands forming a covalent bond (Schiff base) with MR1. The MAIT TCR docks in a conserved manner with MR1, analogous to typical TCR–MHC-I–peptide docking, in which the α and β chains of the MAIT TCR are positioned over the α2 and α1 helices of MR1, respectively.

γδ T cells are activated by conserved stress-induced ligands, enabling them to rapidly produce cytokines that regulate pathogen clearance, inflammation, and tissue homeostasis in response to tissue stress.[21] Antigen recognition by γδ TCRs resembles recognition of intact antigens by antibodies more closely than recognition of pMHC by αβ TCR. γδ TCRs can recognize protein antigens, such as nonclassical MHC molecules and viral glycoproteins, as well as small phosphate- or amine-containing compounds, such as pyrophosphomonoesters from mycobacteria and alkylamines.

Binding to nonpeptide antigens plays an important role in the biology of γδ T cells. About 5% of peripheral blood T cells bear γδ TCRs, and most of these are encoded by Vγ9 JγP and Vδ2 gene segments. (In an alternative nomenclature, Vγ9 is known as Vγ2 and JγP as Jγ1.2. See the IMGT database at: http://www.imgt.org.) These Vγ9 JγPVδ2 TCRs recognize nonpeptide pyrophosphate- or amine-containing antigens, such as pyrophosphomonoesters from mycobacteria or isobutylamine from various sources. Other common naturally occurring small phosphorylated metabolites that stimulate γδ T cells include 2,3-diphosphoglyceric acid, glycerol-3-phosphoric acid, xylose-1-phosphate, and ribose-1-phosphate. In addition to mycobacteria, Vγ9 JγPVδ2 T-cell populations are seen to expand in response to listeriosis, ehrlichiosis, leishmaniasis, brucellosis, salmonellosis, mumps meningitis, malaria, and toxoplasmosis.

Superantigens

SAgs are a special class of TCR ligands that have the ability to activate large fractions (5% to 20%) of the T-cell population (Chapter 6). Activation requires simultaneous interaction between the SAg, the TCR Vβ domain, and an MHC class II molecule on the surface of an antigen-presenting cell. Unlike conventional antigens, SAgs do not require processing to allow them to bind class II molecules

KEY CONCEPTS

Features Common to Immunoglobulin and T-Cell Receptor Genes

- Ig and TCR variable domains are created by site-specific V(D)J recombination.
- Starting with a small set of individual gene segments, combinatorial gene segment rearrangement, combinatorial association of H and L chains, or TCR β and α, and mechanisms of junctional diversity generate a broad repertoire of antigen-binding structures.
- Each receptor is assembled in a stepwise fashion
  - Igs: $D_H \rightarrow J_H$; $V_H \rightarrow D_H J_H$; cytoplasmic μ chain expression; Vκ→Jκ and, if needed, $V_\lambda \rightarrow J_\lambda$; surface IgM expression.
  - TCRαβ: Dβ→Jβ; Vβ→DβJβ; cytoplasmic β-chain expression; Vα→Jα; surface αβ TCR expression.
- CDRs 1 and 2 begin with exclusively germline sequence.
- CDR3 is created by the (V[D]J) joining reaction and often includes nongermline N nucleotides between the V and the D, and between the D and the J.
  - Thus, CDR-H3, CDR-B3, and CDR-D3 are the most variable components of IgM, TCRαβ, and TCRγδ; respectively.
- The antigen-binding site is a product of a nested gradient of diversity. Conserved framework regions surround CDR1 and CDR2, which in turn surround the paired CDR3 intervals that form the center of the antigen-binding site.
- The variability of the Ig and TCR repertoires is restricted during pregnancy, limiting the immune response of the fetus and newborn infant.

or activate T cells. Instead of binding to the peptide antigen-binding groove, SAgs interact with polymorphic residues on the periphery of the class II molecule. And, instead of binding to TCR β CDR3 residues, SAg interact with polymorphic residues in CDR1, CDR2, and HV4. Soluble TCR β chains can also bind the appropriate SAg in the absence of a TCR α chain. As a consequence, although SAg link the TCR to the MHC, the T-cell responses are not "MHC-restricted" in the conventional sense,

KEY CONCEPTS

Features Specific to Immunoglobulin Genes

- Variable domain somatic hypermutation (SHM) permits affinity maturation, which further diversifies the B-cell repertoire.
- Class switch recombination (CSR) allows replacement of an upstream C domain by a downstream one, altering effector function while maintaining antigen specificity.

since a T cell with the appropriate Vβ will respond to a SAg bound to a variety of polymorphic class II molecules.

IMMUNOGLOBULIN GENE ORGANIZATION

The component chains of Igs and TCRs are each encoded by a separate multigene family.[22,23] The paradox of variability in the V region in conjunction with a nearly invariable constant region was resolved when it was shown that immunoglobulin V and C domains are encoded by independent elements, or gene segments, within each gene family. As a result, several gene elements are used to encode a single polypeptide chain. For example, while κ constant domains are encoded by a single Cκ exon in the κ locus on chromosome 2, κ variable domains represent the joined product of Vκ and Jκ gene segments (Fig. 4.4).

V_L gene segments typically contain their own promoter, a leader exon, an intervening intron of approximately 100 nucleotides, an exon that encodes the first three framework regions (FR 1, 2, and 3), the first two CDRs in their entirety, the amino terminal portion of CDR3, and a recombination signal sequence (RSS). A J_L (J for joining) gene segment begins with its own recombination signal, the remaining portion of CDR 3, and the complete FR 4 (see Fig. 4.2).

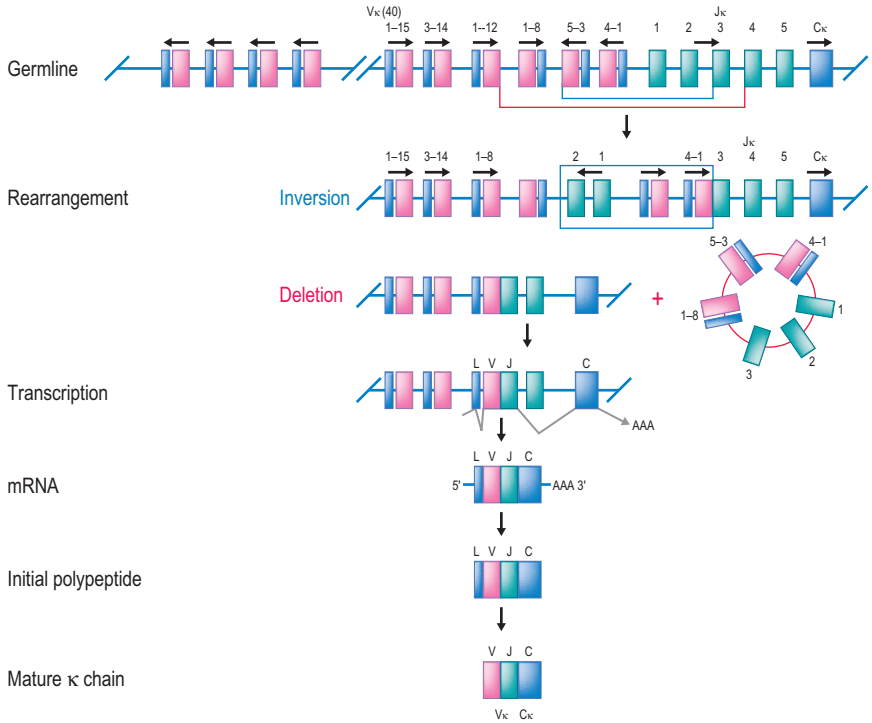

FIG. 4.4 Rearrangement Events in the Human κ Locus. *C*, Constant region of the κ light chain; *J*, joining region; *V*, variable region. See text for further description.

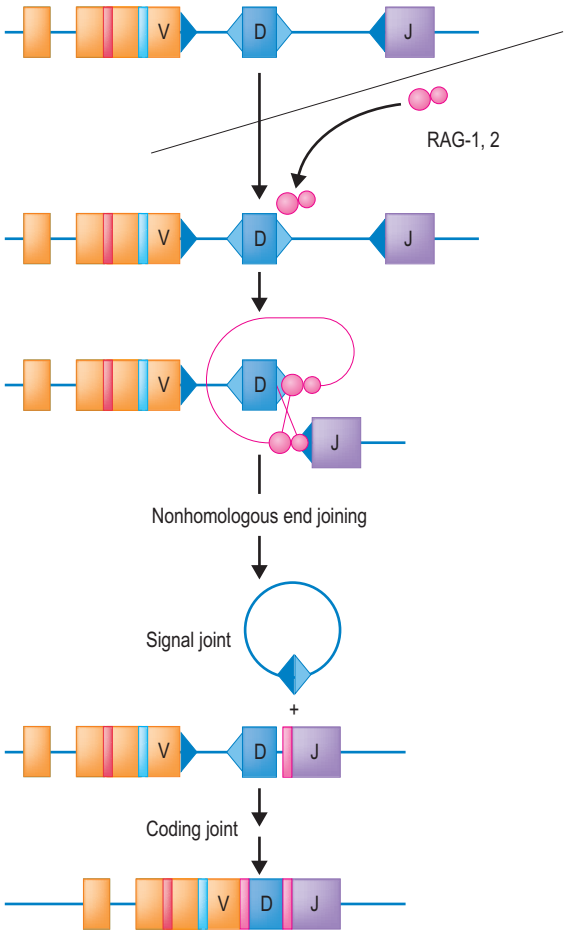

FIG. 4.5 VDJ Recombination. Lymphoid-specific RAG-1 and RAG-2 bind to the recombination signal sequences (RSS) flanking V, D, or J gene segments, juxtapose the sequences, and introduce precise cuts adjacent to the RSS. Components of the nonhomologous end-joining repair pathway subsequently unite the cut RSSs to form a signal joint, and the coding sequences of the rearranging gene segments to form a coding joint.

(Use of the same abbreviation—V—for both the complete variable domain of an Ig peptide chain and for the gene segment that encodes only a portion of that same variable domain is the result of historic precedent. It is unfortunate that one must depend on the context of the surrounding text in order to determine which V region of the antibody is being discussed. The same holds true for the use of J to represent both the J gene segment and the J joining protein.)

The creation of a V domain is directed by the RSSs that flank the rearranging gene segments.[24] Each RSS contains a strongly conserved seven base-pair, or heptamer, sequence (e.g., CACAGTG) that is separated from a less well-conserved nine base-pair, or nonamer, sequence (e.g., ACAAAACCC) by either a 12- or 23-base-pair (bp) spacer. For example, Vκ gene segments have a 12-bp spacer and Jκ elements have a 23-bp spacer. These spacers place the heptamer and nonamer sequences on the same side of the DNA molecule, separated by either one or two turns of the DNA helix. A one-turn RSS (12-bp spacer) will preferentially recognize a two-turn signal sequence (23-bp spacer). This helps prevent wasteful V-V or J-J rearrangements.

Initiation of the V(D)J recombination reaction requires recombination activating genes 1 and 2 (*RAG1* and *RAG2*). These genes are expressed only in developing lymphocytes.[25] The gene products, RAG-1 and RAG-2, act by precisely introducing a DNA double-strand break (DSB) between the terminus of the rearranging gene segment and its adjacent RSS (Fig. 4.5). These breaks are then repaired by ubiquitously expressed components of a DNA repair process that is known as nonhomologous end joining (NHEJ). Lack-of-function mutations in NHEJ proteins yields susceptibility to DNA damage in all cells of the body and can lead to a SCID phenotype (Chapter 34).

The NHEJ process creates precise joins between the RSS ends, and imprecise joins of the coding ends. TdT, which is expressed only in lymphocytes, adds non-germline encoded nucleotides (N-nucleotides) to the coding ends of the recombination product.

Lymphoid-specific expression of RAG-1 and RAG-2 limits V(D)J recombination to B and T lymphocytes. To ensure that TCR genes are rearranged to completion only in T cells and Ig genes are rearranged to completion only in B cells, V(D)J recombination is further regulated by limiting the accessibility of the appropriate gene segments to the specific lineage as well as to the specific stage of development. For example, H-chain genes are typically assembled before L-chain genes.

The RAG-1 and RAG-2 recombinases cooperatively associate with 12- and 23-bp RSSs and their flanking coding gene segments to form a synaptic complex. Typically, the initial event will be recognition of the nonamer sequence of a 12-bp spacer RSS by RAG-1, which appears to function as the catalytic component of the recombinase. RAG-1 binding to the heptamer provides specificity. RAG-2 does not bind DNA independently but does make contact with the heptamer when in a synaptic complex with RAG-1. Binding of a second RAG-1 and RAG-2 complex to the 23-bp, two-turn RSS permits the interaction of the two synaptic complexes to form what is known as a paired complex. Creation of this paired complex is facilitated by the actions of the DNA-bending proteins HMGB1 and HMGB2 and by the presence of a divalent metal ion.

After paired complex assembly, the RAG proteins single-strand cut the DNA at the heptamer sequence. The 3′ OH of the coding sequence ligates to 5′ phosphate and creates a hairpin loop. The clean-cut ends of the signal sequences enable formation of precise signal joints. However, the hairpin junction created at the coding ends must be resolved by re-nicking the DNA, usually within four to five nucleotides from the end of the hairpin. This forms a 3′ overhang that is amenable to further diversification. It can be filled in via DNA polymerases, nibbled back, or may serve as a substrate for TdT-catalyzed N addition. DNA polymerase μ, which shares homology with TdT, appears to play a role in maintaining the integrity of the terminus of the coding sequence.

The cut ends of the coding sequence are then repaired by the nonhomologous end-joining proteins. NHEJ proteins involved in V(D)J recombination include Ku70, Ku80, DNA-PKcs, Artemis, XRCC4, XLF (Cernunnos), and ligase 4.

Ku70 and Ku80 form a heterodimer (Ku) that directly associates with DNA DSBs to protect the DNA ends from degradation, permit juxtaposition of the ends to facilitate coding end ligation, and help recruit other members of the repair complex. The DNA protein kinase catalytic subunit (DNA-PKcs) phosphorylates Artemis, inducing an endonuclease activity that plays a role in the opening of the coding joint hairpin. Thus absence

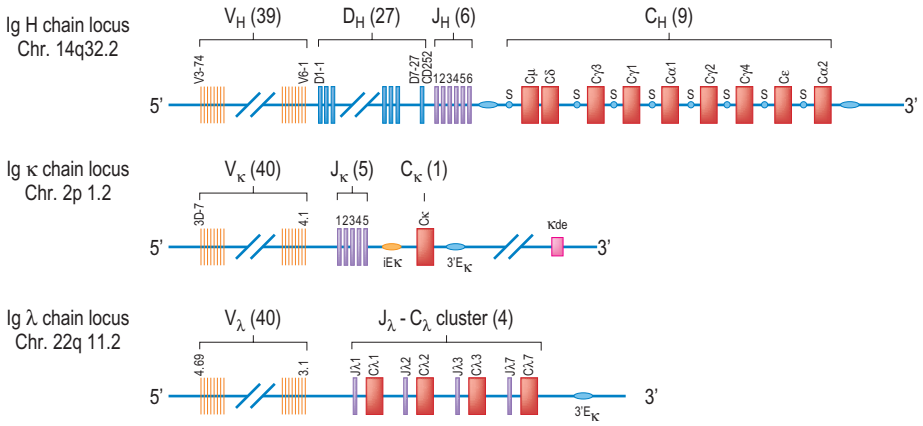

FIG. 4.6 Chromosomal Organization of the Ig H, κ, and λ Gene Clusters. The typical numbers of functional gene segments are shown. The κ gene cluster includes a κ deleting element that can rearrange to sequences upstream of Cκ in cells that express λ chains, reducing the likelihood of dual κ and λ light-chain expression. These maps are not drawn to scale.

of DNA-PKcs or Artemis inhibits proper coding joint formation. Signal joint formation is normal in Artemis deficiency, but it is impaired in the absence of DNA-PKcs. Finally, XRCC4, XLF, and ligase 4 help rejoin the ends of the broken DNA.

Depending on the transcriptional orientation of the rearranging gene segments, recombination can result in either inversion or deletion of the intervening DNA (see Fig. 4.3). The products of inversion remain in the DNA of the cell, whereas deletion leads to the loss of the intervening DNA. The increased proximity of the V promoter to the C domain enhancers promotes the subsequent transcription of the Ig gene product.

There is a price to the use of V(D)J recombination to create antigen receptor diversity. Aberrant recombination in nonreceptor genes can create deleterious genomic rearrangements that promote B-cell and T-cell neoplasias.[24] For example, deletional recombination at the SIL/SCL locus and in *Notch1, Izkf1, PTEN*, and other critical genes appear to be major drivers of lymphoid neoplasms in humans and in mice.

The κ Locus

The κ locus is located on chromosome 2p11.2. It contains 5 Jκ and 75 Vκ gene segments upstream of Cκ (Fig. 4.6). The Vκ gene segments can be grouped into six different families of varying size.[26] Each family is composed of gene segments that share extensive sequence and structural similarity.[27]

One-third of the Vκ gene segments contain frameshift mutations or stop codons that preclude them from forming functional protein, and of the remaining sequences less than 30 of the Vκ gene segments have actually been found in functional Igs. Each of these active Vκ gene segments has the potential to rearrange to any one of the 5 Jκ elements, generating a potential repertoire of more than 140 distinct VJ combinations. Even more diversity is created at the site of gene segment joining. The terminus of each rearranging gene segment can undergo a loss of 1 to 5 nucleotides during the recombination process. In humans, but not mice, N addition can either replace some or all of the lost nucleotides or can be inserted in addition to the original germline sequence. Each codon created by N addition increases the potential diversity of the repertoire 20-fold. Thus, the focus for the diversity of the κ repertoire lies in the VJ junction that defines CDR-L3.

The λ Locus

The λ locus, on chromosome 22q11.2, contains four functional Cλ exons, each of which is associated with its own Jλ (see Fig. 4.6). The Vλ genes are arranged in three distinct clusters, each containing members of different Vλ families.[28] Depending on the individual haplotype, there are approximately 30 to 36 potentially functional Vλ gene segments and an equal number of pseudogenes.

In addition to normal κ and λ peptides, H chains can also form a complex with unconventional λ light chains, known as surrogate or pseudo light chains (SLC). The genes encoding the SLC proteins, VpreB and λ5 (λ14.1), are located within the λ light-chain locus on chromosome 22 and are restricted in expression to discreet B-cell developmental stages (Chapter 7). Together, these two genes create a product with considerable homology to conventional λ light chains. A critical difference between these unconventional SLC genes and other L chains is that VpreB-λ5 gene rearrangement is not required for SLC expression.

The H-Chain Locus

The H-chain locus, on chromosome 14q32.33, is considerably more complex than the κ and λ loci. There are approximately 80 V_H gene segments near the telomere of the long arm of chromosome 14.[29] Of these, approximately 39 are functional and can be grouped into 7 different families of related gene segments. Adjacent to the most centromeric V_H, V6-1, are 27 D_H (D for diversity) gene segments (see Fig. 4.6) and 6 J_H gene segments. Each V_H and J_H gene segment is associated with a two-turn RSS, which prevents direct V→J joining. A pair of one-turn RSSs flanks each D_H. Recombination begins with the joining of a D_H to a J_H gene segment, followed by the joining of a V_H element to the amino terminal end of the DJ intermediate. The V_H gene segment contains FR1, -2, and -3, CDR1 and -2, and the amino terminal portion of CDR3; the D_H gene segment forms the middle of CDR3; and the J_H element contains the carboxy terminus of CDR3 and FR4 in its entirety (see Fig. 4.1). Random assortment of one of approximately 50 active V_H and one of 27 D_H with one of the 6 J_H gene segments can generate up to 104 different VDJ combinations (Fig. 4.7).

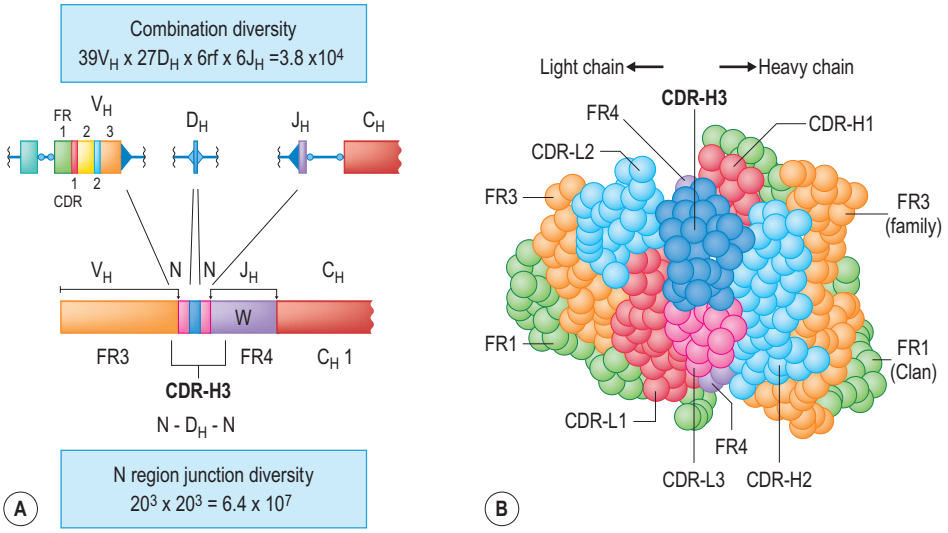

FIG. 4.7 The Antigen-Binding Site Is the Product of a Nested Gradient of Diversity. (A) VDJ rearrangement yields 38,000 different combinations. The CDR-H3 sequence contains both germline V, D, and J sequence and non-germline encoded N nucleotides. The addition of nine N nucleotides on either side of the D gene segment yields 64 million different combinations. (B) The antigen-binding site is created by the juxtaposition of the three complementarity-determining regions (CDRs) of the H chain and the three CDRs of the light chain. The view is looking into the binding site as an antigen would see the CDRs. The V_H domain is on the right side. The central location of CDR-H3, which due to N addition is the focus for repertoire diversity, is readily apparent. *FR*, Framework region.

Although combinatorial joining of individual V, D, and J gene segments maximizes germline-encoded diversity, the major source of variation in the preimmune repertoire is focused on the CDR-H3 interval which is created by VDJ joining (see Fig. 4.7). First, D_H gene segments can rearrange by either inversion or deletion and each D_H can be spliced and translated in each of the three potential reading frames. Thus, each D_H gene segment has the potential to encode six different peptide fragments. Second, the terminus of each rearranging gene segment can undergo a loss of one or more nucleotides during the recombination process. Third, the rearrangement process creates a hairpin ligation between the 5′ and 3′ termini of the rearranging gene segment. Nicking to resolve the hairpin structure leaves a 3′ overhang that creates a palindromic extension, termed a P junction. Fourth, non-germline-encoded nucleotides (N regions) can be used to replace or add to the original germline sequence. Every codon added by N-region addition increases the potential diversity of the repertoire 20-fold. N regions can be inserted both between the V and the D, and between the D and the J. Together, the imprecision of the joining process and variation in the extent of N addition permits generation of CDR-H3's of varying length and structure. As a result, more than 10^{10} different H-chain VDJ junctions, or CDR-H3's, can be generated at the time of gene segment rearrangement. Together, somatic variation in CDR3, combinatorial rearrangement of individual gene segments, and combinatorial association between different L and H chains yields a potential preimmune antibody repertoire of greater than 10^{16} different Igs.

Class Switch Recombination

Located downstream of the VDJ loci are nine functional C_H gene segments (see Fig. 4.7). Each C_H contains a series of exons, each encoding a separate domain, hinge, or terminus. All C_H genes can undergo alternative splicing to generate two different types of carboxy termini: either a membrane terminus that anchors Ig on the B-lymphocyte surface, or a secreted terminus that occurs in the soluble form of the Ig. With the exception of $C_H1\delta$, each C_H1 constant region is preceded by both an exon that cannot be translated (an I exon) and a region of repetitive DNA, termed the switch (S). Through recombination between the Cμ switch region and one of the switch regions of the seven other H-chain constant regions (a process termed *class switching* or *class switch recombination*), the same VDJ heavy-chain variable domain can be juxtaposed to any of the H-chain classes (Fig. 4.8).[30] Thus, the system can tailor both the receptor and the effector ends of the antibody molecule to meet a specific need.

Somatic Hypermutation

A final mechanism of Ig diversity is engaged only after exposure to antigen.[30] With T-cell help, the variable domain genes of germinal center lymphocytes undergo *somatic hypermutation* at a rate of up to 10^{-3} changes per base pair per cell cycle. SHM is correlated with transcription of the locus and current studies suggest that at least two separate mechanisms are involved. The first mechanism targets mutation hot spots with the RGYW (purine/G/pyrimidine/A) motif and the second mechanism incorporates an error-prone DNA synthesis that can lead to a nucleotide mismatch between the original template and the mutated DNA strand. SHM allows affinity maturation of the antibody repertoire in response to repeated immunization or exposure to antigen as B cells bearing receptors that have mutated to higher affinity for the cognate antigenic epitope are preferentially stimulated to proliferate, especially under conditions of limiting antigen concentration.

Activation-Induced Cytidine Deaminase

Activation-induced cytidine deaminase (AID) plays a key role in both CSR and SHM.[31] AID is a single-strand DNA (ssDNA) cytidine deaminase that can be expressed in activated germinal center B cells. Both SHM and CSR require transcription.

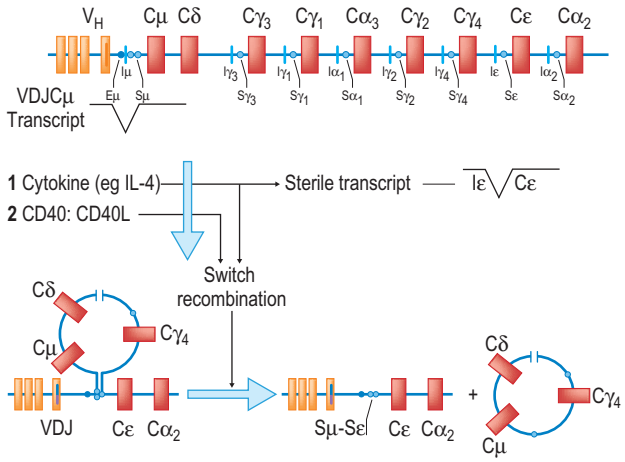

FIG. 4.8 Immunoglobulin H-Chain Class Switching. The molecular events involved in switching from expression of one class of immunoglobulin to another are depicted. At the top is the gene organization during μ-chain synthesis. At the bottom a class switch recombination event has resulted in the deletion of the intervening DNA. Exposure to the appropriate cytokine or T-cell:B-cell interaction through the CD40:CD40L pathway results in activation of the I exon that yields a sterile ε transcript (Iε-Cε) (see Chapter 7). The CD40:CD40L interaction is necessary for the subsequent replacement of Cμ by another constant gene (in this case, Cε). The S loci indicate switch-specific recombination signals.

Transcription helps target AID to the requisite chromosomal location, and also contributes to formation of requisite ssDNA substrates. For example, transcription of an Ig V domain or of the switch region upstream of the C_H1 domain opens the DNA helix to generate ssDNA that can then be deaminated by AID to form mismatched dU/dG DNA base pairs. Both CSR and SHM then co-opt the activities of normal cellular base excision repair (BER) and mismatch repair (MMR) to convert AID cytidine deamination lesions to mutations and/or double strand breaks. The BER protein uracil DNA glycosylase (UNG) removes the mismatched dU base, creating an abasic site. Cleavage of the DNA backbone at this abasic site by an apurinic/apyridimic (AP) endonuclease, generates a ssDNA nick adjacent to the abasic site. The nick is then processed to a single-nucleotide gap. The gap is filled in by DNA polymerase β; and then sealed by DNA ligase 1 or DNA ligase 3. The MMR proteins MSH2 and MSH6 can also bind and process the dU:dG mismatch. Deficiencies of AID, UNG underlie some forms of the hyper-IgM syndrome (Chapter 33). UNG and MMR double deficiency ablates CSR. It also eliminates both C/G transversion mutations and spreading of mutations, leaving only C/G transition mutations.

The benefits of diversity created by AID are balanced by the tendency of AID to target non-Ig genes. AID can create clusters of mutations in a number of genes, including BCL6, CD95, CD79A, CD79B, PIM1, MYC, RHOH, and paired box 5 (PAX5).[32] The process is termed *kataegis*. These mutations clusters can contribute to the development of lymphoproliferative disorders.

Diversity and Constraints on Immunoglobulin Sequence

In theory, combinatorial rearrangement of V(D)J gene segments, combinatorial association of H and L chains, flexibility in the site of gene segment joining, N-region addition, P junctions, hypermutation, and class switching can create an antibody repertoire, the diversity of which is limited only by the total number of B cells in circulation at any one time. In practice, constraints and biases on both the structure and sequence of the antibody repertoire are apparent.

The representation of individual V gene elements is nonrandom. Among Vκ and V_H elements, half of the potentially functional V gene elements contribute minimally to the expressed repertoire. Among Vλ elements these restrictions are even greater, with three gene segments contributing to half of the expressed repertoire.

Particular patterns of amino acid composition in the sequences of the V domains create predictable canonical structures for several of the hypervariable regions. In κ chains, CDR2 is found in a single canonical structure, whereas four structures are possible for CDR1.[33] In the H chain, most germline CDR1 and CDR2 elements encode one of three or one of five distinct canonical structures, respectively.[34] Preservation of these key amino acids during affinity maturation tends to maintain the canonical structure of CDR1 and CDR2 even while they are undergoing SHM.

The enhanced sequence diversity of the CDR3 region is mirrored by its structural diversity. Few canonical structures have been defined for the H-chain CDR3, and even in κ chains 30% of the L-chain CDR3 can be quite variable. However, at the sequence level there is a preference for tyrosine and glycine residues and a bias against the use of highly charged or hydrophobic amino acids in the H-chain CDR3, which reflects preferential use of only one of the six potential D_H reading frames, natural selection of reading frame content, and selection during development.[35]

The T-Cell Receptor αδ-Chain Locus

The α and δ loci are located on chromosome 14q11-12. This region is unusual in that the gene segments encoding the two different TCR chains are actually intermixed (Fig. 4.9). There are 38 to 40 Vα, 5 Vα/Vδ, no Dα, and 50 Jα functional gene segments, as well as one Cα gene.[36]

The δ locus lies between the Vα and Jα gene segments. There are three committed Vδ, five Vα/Vδ, three Dδ, and three Jδ gene segments, as well as one Cδ gene. Vδ3 lies 3′ of Cδ, and thus must rearrange by inversion. Although V-region use by α and δ chains is largely independent of one another, this unusual gene organization is accompanied by sharing of five V gene segments. For example, Vδ1 can rearrange either to Dδ/Jδ or to Jα elements, and thus can serve as the V region for both γδ and αβ TCRs.

In the large majority of αβ T cells analyzed, the α chain on both chromosomes has rearranged. This occurs by the rearrangement of the 5′ RSS δRec to a pseudo-J segment, ΨJα, at the beginning of the Jα cluster (see Fig. 4.9) as well as by the subsequent rearrangement of Vα to Jα on both chromosomes. Both types of rearrangement delete all of the Dδ, Jδ, and Cδ genes, thus preventing co-expression of αβ and γδ TCRs.

The T-Cell Receptor β-Chain Locus

The β locus is positioned at chromosome 7q35.44. It contains 40 to 48 functional Vβ genes, 2 Dβ, 2 Jβ clusters, each containing 6 or 7 gene segments, and 2 Cβ genes (see Fig. 4.9). There is one Vβ immediately downstream of Cβ2, which rearranges by inversion. Each Cβ is preceded by its own Dβ–Jβ cluster. There is no apparent preference for Vβ gene rearrangement to either Dβ–Jβ cluster. Dβ1 can rearrange to the Jβ1 cluster or the Dβ2–Jβ2 cluster. Dβ2 can only rearrange to Jβ2 gene segments.

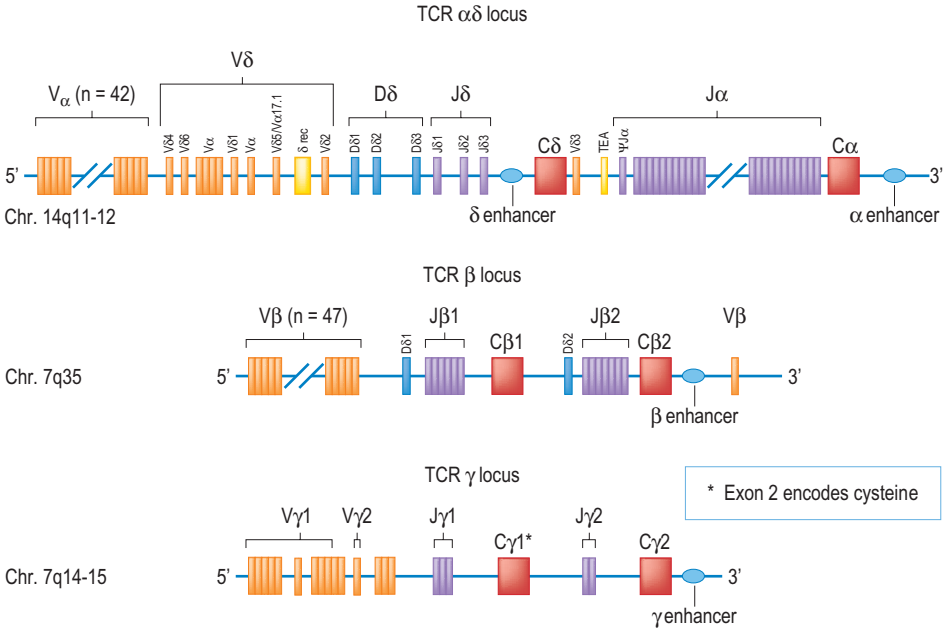

FIG. 4.9 Chromosomal Organization of the T-Cell Receptor αδ, β, and γ Gene Clusters. Typical numbers of functional gene segments are shown. These maps are not drawn to scale. *TCR*, T-cell receptor.

The two Cβ segments differ by only six amino acids and are functionally indistinguishable from each other.

The T-Cell Receptor γ-Chain Locus

The γ locus is located at chromosome 7p14-15. There are four to six functional Vγ region segments intermixed with pseudogenes, no Dγ, and two J clusters with a total of five J segments. Each J cluster is 5′ to its C region (see Fig. 4.9). The Vγ segments have been divided into six families, although only Vγ1 (nine members, five of them functional) and Vγ2 (one member) encode functional proteins. The number of Cγ gene exons varies: Cγ1 has three, while there are two alleles of Cγ2 that have four and five, respectively. The first Cγ exon encodes most of the extracellular portion of this region. The last Cγ exon encodes the intracytoplasmic portion of the molecule. The middle exon(s) (one for Cγ1, two or three for Cγ2) encode the connecting piece, which does (Cγ1), or does not (Cγ2), include a cysteine. Since this cysteine can form a disulfide bond with another cysteine in the δ chain, TCRs using Cγ1 contain a covalently linked γ–δ pair, while TCRs using Cγ2 do not. The nomenclature of the human γ locus differs between laboratories and reports and is extensively cross-referenced on the IMGT website (http://www.imgt.org).

Allelic Exclusion

Because of the inherently imprecise nature of coding joints, only one in three V(D)J Ig or TCR rearrangements will be in-frame and capable of creating a functional protein. Theoretically, one in nine cells might be expected to express two different Ig or TCR chains. However, almost all B cells express the functional products of only one IgH allele and one IgL allele, and mature αβ T cells express only one functional TCRβ gene. The process of limiting the number of receptors expressed by an individual cell is known as *allelic exclusion*.

The mechanisms that ensure monoallelic expression are regulated at the level of gene rearrangement. Mechanisms that have been shown to contribute to allelic exclusion include asynchronous replication of the two alleles, with rearrangement occurring at the allele that replicates early; localization of the active allele to a more central, euchromatic region of the nucleus; and DNA demethylation of the active allele. Once a functional V domain has been generated, rearrangement terminates with the expression of a membrane-bound Ig (mIg) or TCR product capable of transducing a signal. In pre-B cells, a functional μ H chain associates with the surrogate light chain to form the pre-BCR. Similarly, in developing T-cell progenitors a productive TCR β chain associates with pre-Tα to form the pre-TCR. These preliminary antigen receptors signal to shut down RAG expression, promote cell division, and limit the accessibility of the IgH and TCRβ loci to further rearrangement while promoting the accessibility of the IgL and TCRα loci, respectively.

In pre-B cells, the κ locus is the first to rearrange, with λ rearrangement occurring in cells that have failed to produce a proper κ chain. Surface expression of an acceptable membrane-bound IgM BCR invokes the mechanism of allelic exclusion among the L-chain loci, termed *isotypic exclusion*, and promotes further maturation of the B cell.

Productive TCRα rearrangement in $CD4^+CD8^+$ T-cell progenitors allows the expression of a functional TCR αβ heterodimer (Chapter 9). Unlike IgH and TCRβ; TCRα does not undergo allelic exclusion at the level of gene rearrangement. Instead, in cells that express two functional TCRα alleles, one of the two alleles tends to preferentially pair with the one functional TCRβ chain. This is termed *phenotypic allelic exclusion*.

Allelic exclusion can be overcome by selection pressures. Cells that express self-reactive antigen receptors can downregulate IgH or TCR expression and reactivate gene rearrangement to replace one of the two offending chains. This process, termed *receptor editing*, occurs most often in the IgL or TCRα loci, whose gene structures lend themselves to repeated rearrangement. The V_H in the H chain can also be replaced by rearrangement to a cryptic RSS at the terminus of the V_H gene segment.

KEY CONCEPTS

B-Cell Receptor and Co-Receptors

- The BCR–antigen complex consists of a mIg that is responsible for antigen recognition and an Igα/β heterodimer that is responsible for transducing the recognition signal into the cell.
- BCR engagement leads to the phosphorylation of tyrosines in the Igα/β *I*mmunoreceptor *T*yrosine-based *A*ctivation Motifs (ITAMs). This signal is then transmitted to one or more other intracellular signaling pathways.
- Recognition of antigen by B lymphocytes can also involve binding of antigen complexed with C3d and IgG to additional B-cell co-receptors.
- Binding of complexed antigen by individual co-receptors can lead to either positive or negative signals, each of which can influence the ultimate outcome of an antigen-B lymphocyte interaction.
- Deficiency of the components of the BCR–antigen complex impairs B-cell development and can lead to agammaglobulinemia.

B-CELL RECEPTOR COMPLEX: STRUCTURE AND FUNCTION

Although the ability of surface Ig to recognize antigen was appreciated very early, the mechanism by which mIg transmitted an antigen recognition event to the cell took longer to understand. The predominant isotypes expressed on the surface of mature B cells, mIgM and mIgD, contain only three amino acid residues exposed to the cytoplasm. It was thought unlikely that these Ig heavy chains could function as signal transduction molecules by themselves. Subsequently, it was shown that all membrane Ig isotypes associated noncovalently with a heterodimeric complex consisting of two transmembrane proteins, Igα (CD79a) and Igβ (CD79b), each of which is capable of transducing signals into the cell (Table 4.3).

TABLE 4.3 The B-Cell Receptor and Its Co-Receptor Molecules

Molecule	M_r	Chromosome	Function
BCR			
mIgM (μ_2L_2)	180,000	14 (IgH; 14q.32) 2 (Igκ; 2p12) 22 (Igλ; 22q11.2)	Antigen recognition
Igα (CD79a)	47,000	19 (19q13.2)	Signal transducer
Igβ (CD79b)	37,000	17 (17q23)	Signal transducer
Co-Receptors			
CD21	140,000	1 (1q32)	Activating co-receptor Ligand for C3d, EBV, CD23
CD19	95,000	16 (16p11.2)	Activating co-receptor Signal transducer
FcγRIIB (CD32)	40,000	1 (1q23-24)	Inhibitory co-receptor Low-affinity receptor for IgG
CD22	140,000	19 (19q13.1)	Inhibitory co-receptor Adhesion molecule Signal transducer

BCR, B-cell receptor; *EBV*, Epstein–Barr virus; *IgG*, immunoglobulin G; *mIgM*, membrane-bound immunoglobulin M.

Membrane-Bound Immunoglobulin

Igs mediate their effector functions as secreted products of plasma cells. However, Igs also serve as the membrane-bound antigen recognition component of the BCR complex. Although all Ig classes can be expressed at the B-cell surface, the vast majority of circulating mature B cells co-express membrane-bound IgM and IgD. Appropriate activation of a naïve IgM and IgD expressing B cell leads to plasma cell differentiation and antibody secretion. Membrane-bound IgM and IgD are the product of alternative splicing of the Ig transcript at the 3′, or carboxy, terminus of the heavy chain (Fig. 4.10). The two membrane exons encode the transmembrane hydrophobic stretch of amino acids and an evolutionarily conserved cytoplasmic tail encoding lysine, valine, and lysine.

Signal Transduction and the Immunoglobulin-α/β (CD79a/CD79b) Heterodimer

The heterodimeric signal transduction component of the BCR complex that associates with membrane Ig has been designated CD79. It is composed of an Igα (CD79a) and Igβ (CD79b) heterodimer. CD79 is responsible for transporting mIg to the cell surface and for transducing BCR signals into the cell.[37]

CD79a/Igα is encoded by *CD79a/MB-1* (chromosome 19q13.2) as a 226-amino acid glycoprotein of approximately 47 kDa. The exact molecular weight depends on the extent of glycosylation. *CD79b/B29* (chromosome 17q23) encodes CD79b/Igβ, which is a 229-amino acid glycoprotein of approximately 37 kDa. *CD79a* and *CD79b* share an exon–intron structure, which is similar to that of the genes that encode the CD3 TCR co-receptor molecules. These similarities suggest that both BCR and TCR co-receptors are the progeny of a common ancestral gene. Igα and Igβ both contain a single IgSF Ig domain (111 residue C-type for Igα and 129 residue V-type for Igβ). Each also contains a highly conserved transmembrane domain and a 61- (Igα) or 48- (Igβ) amino acid cytoplasmic tail that also exhibits striking amino acid evolutionary conservation.

Igα and Igβ are expressed by the earliest committed B-cell progenitors prior to Igμ H-chain rearrangement. The CD79 heterodimer has been observed on the surface of early B-cell progenitors in the absence of Igμ, although neither protein is required for progenitors to commit to the B-cell lineage.[38] Later in development, Igα and Igβ are co-expressed together with Ig

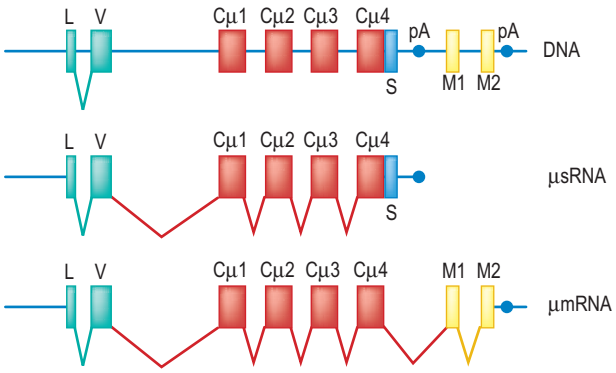

FIG. 4.10 Membrane and Secretory Immunoglobulin M Are Created by Alternative Splicing. Alternative splicing of the Cm carboxy-terminal exons results in mRNA transcripts encoding either secreted IgM (μsRNA) or membrane-bound IgM (μmRNA).

of all isotypes on the surface of B cells as a mature BCR complex.[39] The CD79 proteins are specific to the B lineage and are expressed throughout B lymphopoiesis. This has led to their use as markers for the identification of B-cell neoplasms.[40]

The signaling capacity of both Igα and Igβ resides within an *ITAM* that has the consensus sequence of D/IxxYxxL(x)7YxxL, where x is any amino acid. Similar ITAMs are also found within the cytoplasmic domain of the molecules that associate with, and signal for, the T-cell antigen receptor (CD3) and certain Fc receptors (Chapter 18). The phosphorylation of both tyrosines in both Igα/β ITAMs is considered an obligate initial step in the propagation of antigen receptor engagement to the cell nucleus.[37,41]

Tyrosine-phosphorylated ITAMs serve as efficient binding sites for Src homology 2 (SH2) domains, which are present within a large number of cytosolic signaling molecules. Whether Igα and Igβ make qualitatively different contributions towards BCR signaling or are functionally redundant remains unclear, as evidence exists to support both views. Moreover, the high degree of evolutionary conservation within the non-ITAM portion of the cytoplasmic domains suggests additional, as yet uncharacterized, signaling roles for the cytoplasmic tails of these molecules over and above positive signaling via the ITAMs.

Igα and Igβ are covalently associated by a disulfide bridge via cysteine residues that exist within the IgSF extracellular domains of both molecules. The association of the Igα/β heterodimer with mIg occurs though interaction within the transmembrane domains of these proteins.[39] The core BCR complex consists of a single Ig molecule associated with a single Igα/β heterodimer (H_2L_2/Igα/Igβ) (Fig. 4.11). A current model for the initiation of signals originating from the BCR (see Fig. 4.11) proposes that antigens induce the clustering of BCR complexes, increasing their local density. The increase in density leads to the transfer of phosphate groups to the tyrosine residues of the Ig-α/β ITAM motifs.[37,41]

Src-family tyrosine kinases, of which LYN, FYN, and BLK are most often implicated, are believed to be responsible for ITAM phosphorylation upon aggregation of Igα/β. They have been shown to physically associate with the heterodimer. It has been suggested that only a fraction of Src-family tyrosine kinases are associated with the Igα/β heterodimer and, upon aggregation, transphosphorylate juxtaposed heterodimers. However, the exact mechanism by which Igα/β undergoes initial tyrosine phosphorylation after antigen engagement remains uncertain. Phosphorylated ITAMs subsequently serve as high-affinity docking sites for cytosolic effector molecules that harbor SH2 domains. The recruitment of the SYK tyrosine kinase, via its tandem SH2 domains, to doubly phosphorylated Igα/β ITAMs then appears to propagate a BCR-mediated signal. Association of SYK with the BCR leads to its subsequent tyrosine phosphorylation by either Src-family or other Syk tyrosine kinases, further increasing kinase activity. Together, the concerted actions of the Syk and Src-family protein tyrosine kinases activate a variety of intracellular signaling pathways that can lead to the proliferation, differentiation, or death of the cell.

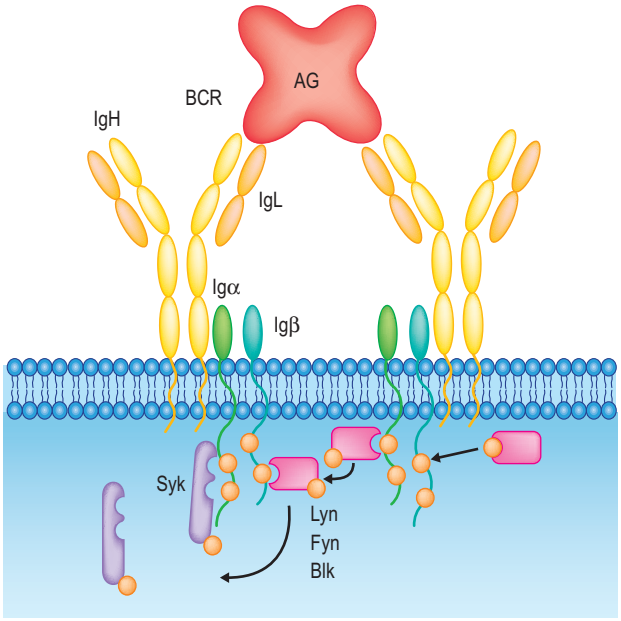

FIG. 4.11 The B-Cell Receptor Core Complex. The B-cell receptor (*BCR*) core complex can be divided into an antigen recognition unit fulfilled by mIgM and a noncovalently associated signal transduction unit composed of the Igα/β (CD79ab) heterodimer. Antigen engagement of membrane-bound immunoglobulin M oligomerizes the BCR, allowing preassociated Src-family protein tyrosine kinases to phosphorylate neighboring Igαβ *I*mmunoreceptor *T*yrosine-based *A*ctivation Motif (ITAM) tyrosines. This promotes association of the SYK tyrosine kinase with the tyrosine phosphorylated ITAMs, allowing SYK to become a substrate for other Syk or Src-family tyrosine kinases, leading to its activation.

Clinical Consequences of Disruptions in B-Cell Receptor Signaling

Both the development of B lymphocytes and the maintenance of the mature antigen-responsive B-cell pool demand the presence of an intact BCR and its downstream signaling pathway(s). Disruption of these pathways can present clinically with hypogammaglobulinemia and an absence of B cells.

The most common such genetic lesions is BTK deficiency, which is an X-linked trait (Chapter 33). BTK plays an important role in BCR signaling both during development and in response to antigen. Loss-of-function mutations in BTK results in the arrest of human B-cell development at the pre-B-cell stage.

BTK is intact in approximately 10% to 15% of patients with hypogammaglobulinemia and absence of B cells. Mouse models where BCR components or signaling pathways have been disrupted by targeted mutagenesis have provided insight into the basis of these atypical hypogammaglobulinemia disorders.[37] These studies have shown that an inability to express either a functional μ IgH chain, Igα, Igβ, or the signaling adaptor molecule, BLNK, lead to an early, severe arrest in B lymphopoiesis, with subsequent agammaglobulinemia.[42] Together, these experimental findings highlight the central role of the BCR in the generation and function of B lymphocytes. Thus, mutations in any component of the antigen receptor complex or immediate downstream effectors have the potential to disrupt B-cell development and create an agammaglobulinemic state.

Besides its important role in the maturation, differentiation, and survival of B lymphocytes, the B-cell antigen receptor is responsible for initiating the humoral response to foreign antigen. Some of the variables that can influence the

ultimate outcome of BCR–antigen interaction include the nature of the foreign antigen, the mode of activation, the developmental stage of the B cell, and the microenvironment in which antigen encounter occurs. Exactly how these variables ultimately result in the differential activation of diverse intracellular signaling pathways with fundamentally divergent outcomes is under study. Emerging from these studies is an appreciation of the role of BCR co-receptors, which have been shown to be capable of modulating antigen receptor signaling in response to antigen.

B-Cell Receptor Co-Receptors

The initiation of a humoral immune response results from antigen interaction with the antigen receptors on mature peripheral lymphocytes. However, the manner in which mature B and T lymphocytes recognize antigen is fundamentally different (Chapter 6). Surface Ig, as a component of the BCR on B lymphocytes, typically recognizes an antigenic epitope in its native three-dimensional configuration, which, upon engagement with mIg, is capable of transmitting a signal to the cell interior. In contrast, the antigen receptor expressed by T lymphocytes typically recognizes an antigen-derived peptide associated with an appropriate MHC structure (Chapter 5). Further, in order for this T-cell recognition event to be productive, a CD4 or CD8 co-receptor must also bind to the MHC structure presenting the foreign antigen.

Antigen recognition by the BCR on B lymphocytes is also influenced by co-receptors present on mature B cells (see Table 4.3). In this case the co-receptors may also recognize antigen, but only in a form that has been modified by other components of the immune system, as described below. In general, these co-receptors and co-receptor complexes can be divided into those that regulate BCR signaling in a positive manner and those that regulate in a negative manner. Thus, the ultimate outcome of signaling via the BCR depends not only on the signals transduced via the Igα/β heterodimer, but also how these signals are perceived by the cell in association with the signals propagated by the various co-receptors that are concomitantly engaged.

Co-Receptors That Positively Regulate B-Cell Receptor Signaling

CD21

Mature B lymphocytes express two receptors for complement C3 components, CD35 (CR1) and CD21 (CR2) (Chapter 40). Of these, CD21 fulfills the requirements of a BCR co-receptor (vide infra). The expression of CD21 is restricted to mature B cells and follicular dendritic cells, whereas CD35 is also found on erythrocytes, monocytes, and granulocytes. CD21 is a 140-kDa surface glycoprotein encoded by the CR2 locus on chromosome 1q32 (see Table 4.3). Expression of CD21 begins at approximately the same time as IgD during B lymphopoiesis (Chapter 7). CD21 is subsequently expressed on all mature B cells until terminal differentiation. Within the mature population, marginal zone B cells express higher levels relative to follicular B cells. The extracellular domain of CD21 is composed of 15 to 16 short consensus regions (SCRs), each composed of 60 to 70 amino acids, and a relatively short 34-amino acid cytoplasmic tail. The two-amino terminal SCRs constitute the region that interacts with one of the third complement component (C3) cleavage products, iC3b, C3d, g, and C3d (Chapter 40).[43]

CD21 is a receptor for Epstein–Barr virus (EBV), which similarly binds the two N-terminal SCRs via its major envelope glycoprotein gp350/220. CD21, through its oligosaccharide chains, also binds CD23, the low-affinity IgE receptor (FcεRII). Whereas EBV utilization of CD21 for cell entry has clear physiologic consequences in terms of infection, B-cell immortalization, and the potential for oncogenesis, the in vivo relevance of any CD21 to CD23 interaction remains unclear.

CD19

CD19 is an IgSF surface glycoprotein of 95 kDa that is expressed from the earliest stages of B-cell development until plasma cell terminal differentiation, when its expression is lost.[44] Follicular dendritic cells also express CD19. *CD19* maps to chromosome 16p11.2, where it encodes a 540-amino acid protein with two extracellular C-type IgSF domains as well as a large, approximately 240-residue, cytoplasmic tail that exhibits extensive conservation between mouse and human. This relatively large cytoplasmic domain includes nine conserved tyrosine residues, which, upon phosphorylation, serve as docking sites for other SH2-containing effector molecules. The signaling capacity of CD19 has been shown to result from tyrosine phosphorylation, which occurs upon engagement of the BCR, CD19 or, optimally, by co-ligation of CD19 and IgM. Known signaling effector molecules that have been identified in association with tyrosine-phosphorylated CD19 include the LYN and FYN protein tyrosine kinases, the Rho-family guanine nucleotide exchange factor, VAV, and phosphatidyl inositol 3-kinase.[44] Although specific ligands for CD19 have been proposed, the physiological relevance of CD19 engagement by putative ligands has not been demonstrated.

In vitro studies using mAbs directed against CD21 or CD19 provided initial evidence that these B-cell surface antigens could influence mIg-mediated signaling.[45,46] Genetic deficiencies of CD21 (CVID7) or CD19 (CVID3) promote the development of common variable immune deficiency, which is characterized by hypogammaglobulinemia (Chapter 33). In mice, CD21 and CD19 deficiency demonstrate impaired antibody response to T-dependent antigens. The paucity of $CD5^+$ B cells in CD19-deficient mice suggests a role for this molecule in the generation and maintenance of the B1 lineage of B cells (Chapter 7). CD19 is expressed from the earliest stages of B-cell ontogeny in both mice and humans and, accordingly, a signaling function for CD19 in B lymphopoiesis has been demonstrated.[47]

CD21–CD19 Co-Receptor Complex

A mechanism by which these molecules could augment BCR-mediated signaling was provided by the identification of a CD21–CD19 co-receptor complex on mature B cells that also includes CD81 (Fig. 4.12). CD81, also known as TAPA-1, is a 26-kDa tetraspan molecule widely expressed on a number of cell types, including lymphocytes. The CD21–CD19 co-receptor model predicted that, as a result of complement activation, C3d would be deposited on an antigen, thereby providing a bridge by which a CD21–CD19 receptor complex could associate with mIgM and the BCR complex.[44,46] Clustering of CD19 close to the BCR by the C3d–antigen complex would effectively recruit the signal transduction effector molecules associated with CD19 to the Igα/β heterodimer. As a consequence, the CD19-associated LYN and FYN tyrosine kinases, VAV, and PI3-kinase signaling effector molecules would be in a position to exert their activities on the Igα/β heterodimer-mediated signaling events initiated by antigen engagement of mIgM.

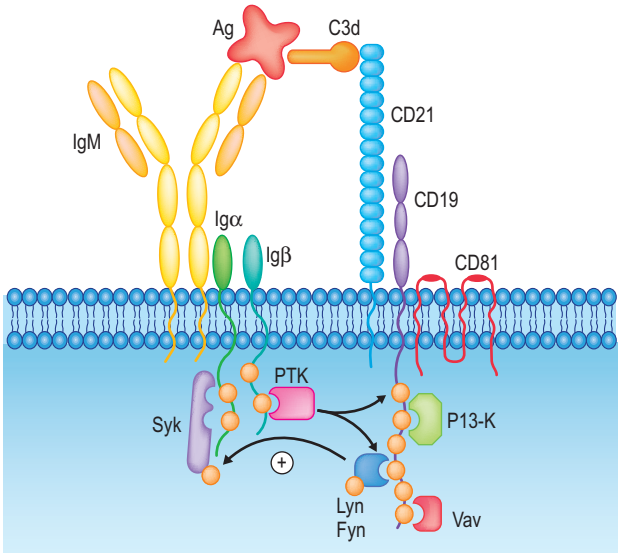

FIG. 4.12 Proposed Mechanisms for the Augmentation of B-Cell Receptor Signaling by the CD21–CD19 Co-Receptor. Co-ligation of the B-cell receptor (BCR) and CD21–CD19 complex by C3d–antigen complex allows a CD79-associated Src-family tyrosine kinase to phosphorylate tyrosine residues within the CD19 cytoplasmic domain. Subsequently, tyrosine-phosphorylated CD19 effectively recruits key SH2-containing signaling molecules to the BCR complex, allowing the initial BCR-mediated signal to quickly disseminate along different intracellular signaling pathways. *Ag,* antigen; *PI3-K,* phosphatidyl inositol 3-kinase; *PTK,* protein tyrosine kinase.

Strong support for CD21–CD19 co-receptor physiological function in BCR signaling was subsequently provided by experiments using a murine model of immune response. Immunization with an antigen covalently attached to C3d dramatically reduced the signaling threshold necessary for antigen to elicit an immune response.[48] Antigen bearing either two or three copies of C3d was, respectively, 1000 and 10,000 times more immunogenic than antigen alone. Thus, the CD21–CD19 co-receptor complex provides a link between the innate and adaptive immune responses. In vivo, CD19-deficient mice appear to have more severely affected T-dependent immune responses than do CD21-deficient animals, suggesting alternative roles for CD19 in regulating BCR signals beyond the CD21–CD19 co-receptor complex.

Co-Receptors That Negatively Regulate B-Cell Receptor Signaling

FcγRIIB

Among the several receptors for the Fc portion of Ig expressed by B cells, the Fc receptor for IgG, FcγRIIB (a member of the CD32 cluster), has an important role in negatively regulating BCR-mediated signal transduction.[49] FcγRIIB is a 40-kDa single-chain molecule that is encoded by single gene located on chromosome 1q23-24. Alternative splicing of different cytoplasmic exons permits expression of three isoforms. The extracellular domain of FcγRIIB is composed of two C-type IgSF domains that can bind with low affinity to IgG. All three FcγRIIB isoforms share a common cytoplasmic region that is important for negatively regulating activation signals delivered by associated surface receptors. The region within the cytoplasmic domain of FCγRIIB responsible for the inhibitory activity of this Fc receptor towards the BCR has been identified as a sequence that contains a tyrosine residue critical for its activity. In analogy to the ITAM, which provides an activation signal, this inhibitory sequence has been referred to as an *I*mmunoreceptor *T*yrosine-based *I*nhibitory Motif, or *ITIM*. The ITIM is carried by the canonical sequence of I/L/VxYxxI/V/L (where x is any amino acid). ITIMs are found in a number of other transmembrane structures, all of which share the ability to negatively regulate signaling by activating receptors.

The ability of passively administered soluble antibody to inhibit humoral responses has long been appreciated and was initially thought to occur by soluble antibody effectively masking all available antigen epitopes. The molecular mechanism accounting for this suppression is now known to be mediated by the binding of IgG to FcRγIIB and the subsequent recruitment of cytosolic phosphatases to the FcRγIIB ITIM upon tyrosine phosphorylation. Thus, the inhibitory effect of IgG on BCR-mediated B-cell activation is explained by the interaction of the FcγRIIB ITIM, and specifically associated phosphatases, with the BCR (Fig. 4.13). Co-ligation of the BCR and FcRγIIB by antigen–IgG complexes results in the tyrosine phosphorylation of the FcRγIIB ITIM, presumably by the BCR-associated tyrosine kinases. Phosphorylated FcRγIIB ITIMs then recruit two different SH2-containing phosphatases, SHIP and SHP-1, which function to remove phosphate groups from inositol lipids or tyrosines, respectively. Although both phosphatases can negatively regulate BCR-mediated signaling events, SHIP appears to be the most relevant phosphatase in FcRγIIB inhibition of BCR signaling (see Fig. 4.13). Thus, once the majority of antigen exists in immune complexes together with antigen-specific IgG, attenuation of an ongoing immune response occurs by the juxtaposition of FcRγIIB with the BCR.

CD22

CD22 is a 135- to 140-kDa transmembrane glycoprotein that is restricted in its expression to the B lineage.[50] CD22 expression is limited to the cytoplasm of progenitor and pre-B cells in early B-cell development. Expression on the surface of the B cell occurs concomitant with the appearance of surface, or membrane, IgD. Upon B-cell activation, CD22 expression is initially transiently upregulated and subsequently down-modulated upon terminal differentiation to Ig-secreting plasma cells. Although the onset of CD22 expression follows a similar pattern during murine B lymphopoiesis, it is not restricted to the cytoplasm in early B lymphopoiesis, but rather is expressed on the surface from the progenitor stage onward. The basis or function of CD22 intracellular retention in human B-cell development is not understood.

CD22 maps to chromosome 19q13.1 and encodes alternatively spliced forms of CD22, CD22α, and CD22β, of which the latter is the predominant species expressed by B cells. The CD22β isoform contains seven extracellular IgSF domains, of which all but one are of the C type. The single exception is the N-terminal domain, which is of the V type. CD22α lacks the IgSF third and fourth domains, although the significance of this minority alternatively spliced product remains unclear. The CD22 murine homolog has only been found as a full-length CD22β isoform. The extracellular domain of CD22 is homologous to the carcinoembryonic antigen subfamily of adhesion molecules, which includes the myelin-associated glycoprotein (MAG) and CD33. CD22 also functions

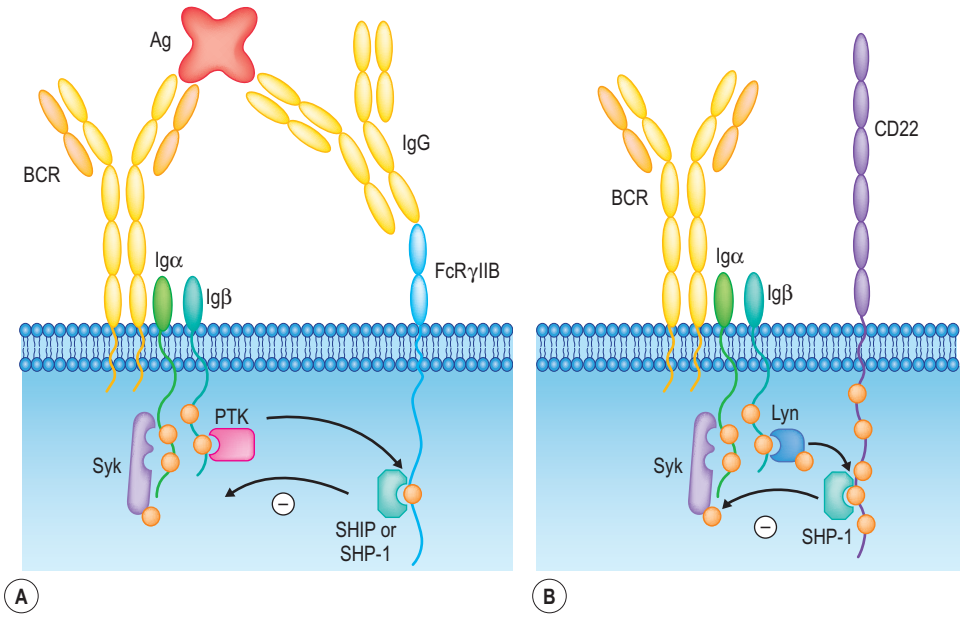

FIG. 4.13 Negative Regulation of B-Cell Receptor Signaling by FcγRIIB and CD22. (A) Soluble IgG–antigen immune complexes juxtapose the B-cell receptor (*BCR*) with FcγRIIB. The BCR-associated LYN tyrosine kinase subsequently tyrosine phosphorylates the FcγRIIB *I*mmunoreceptor *T*yrosine-based *I*nhibitory Motif (ITIM). In turn, this leads to the recruitment of the SH2-containing inositol phosphatase SHIP and tyrosine phosphatase SHP-1 to the phosphorylated FcRγIIB ITIM. Both of these phosphatases have demonstrable inhibitory activity on BCR-mediated signaling. Although SHIP is believed to be the major effector in the FcRγIIB-mediated inhibition of BCR signaling, the exact mechanism of its action in this context has not yet been elucidated. (B) CD22 associated with the BCR is tyrosine-phosphorylated upon antigen–BCR engagement. SH2-containing signaling molecules dock on tyrosine-phosphorylated residues, including the SHP-1 tyrosine phosphatase that can subsequently dephosphorylate signaling molecules previously activated by a membrane-bound immunoglobulin M-mediated signal.

as an adhesion molecule belonging to the Siglec subfamily of the Ig superfamily, whose members function as mammalian sialic acid-binding Ig-like lectins.[51] The two N-terminal IgSF domains have been shown to mediate adhesion to both B and T lymphocytes via the binding of structures carrying α2,6 sialic acids.

In addition to acting as an adhesion molecule, CD22 is also capable of modulating BCR signaling (see Fig. 4.13). A fraction of CD22 associates with the BCR, and CD22 is rapidly tyrosine-phosphorylated upon mIgM engagement. Tyrosine-phosphorylated CD22 associates with several SH2-containing signaling molecules, including the LYN and SYK tyrosine kinases, PI3-kinase, phospholipase C-γ and SHP-1. The 140-amino acid cytoplasmic domain of CD22 includes six conserved tyrosine residues. Three of these tyrosines are located within conserved consensus ITIM sequences and possess a demonstrable capacity to bind the SH2 domain of the SHP-1 phosphatase. The presence of the multiple ITIMs and association with SHP-1 indicated that CD22 might impinge on BCR signaling in a negative manner. Physiological evidence that CD22 could act as a co-receptor to negatively regulate mIgM signaling was provided by the generation of CD22-deficient mice by targeted mutagenesis.[51] CD22-deficient B cells exhibited hyperactive B-cell responses upon BCR triggering, and an increased incidence of serum autoantibodies. This suggests that B-cell tolerance is altered and B cells are more readily activated in the absence of this negative regulator of BCR signaling.

KEY CONCEPTS

T-Cell Receptor/CD3 Complex

- Cell-surface expression of the TCR heterodimers requires association with a complex of invariant proteins designated CD3.
- Each TCR/CD3 complex contains three CD3 dimers.
- Assembly of the TCR/CD3 complex involves interactions between TCR transmembrane basic residues and transmembrane acidic residues in each of the CD3 subunits.
- Signal transduction by the TCR involves the phosphorylation of ITAMs in the cytoplasmic domains of CD3 proteins.
- Phosphorylated CD3 ITAMs recruit and activate the ZAP-70 protein tyrosine kinase.
- Deficiency of CD3 proteins impairs T-cell development and can produce SCID.

THE T-CELL RECEPTOR/CD3 COMPLEX

The αβ and γδ TCR heterodimers, which are responsible for the recognition of specific antigen by T lymphocytes, associate with a complex of invariant proteins designated CD3. This association is necessary for TCR cell-surface expression and enables the TCR heterodimers, which have only short cytoplasmic domains, to couple to the intracellular signaling events that lead to the activation of T-cell effector function.[52] There are four CD3 proteins: γ, δ, ε, and ζ (Fig. 4.14).

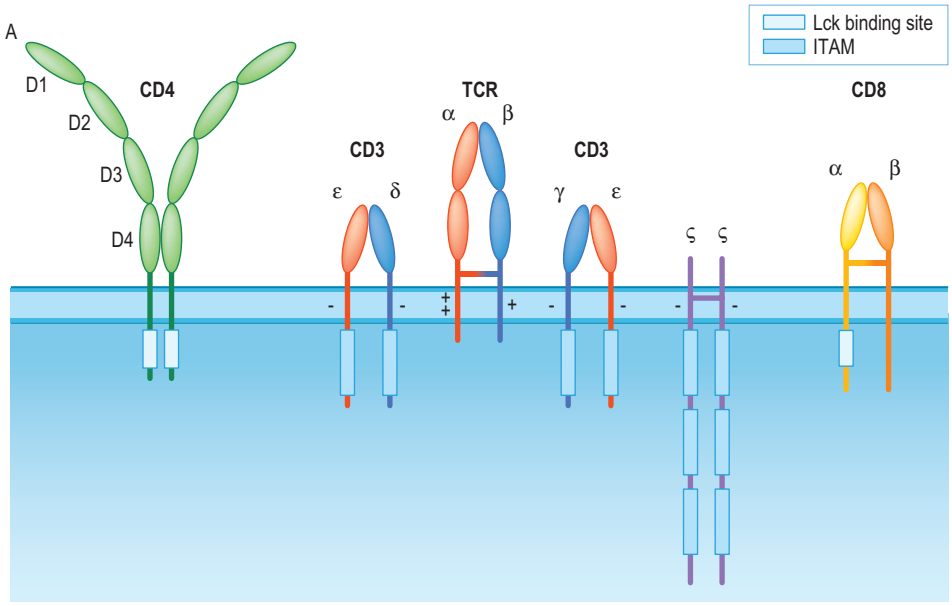

FIG. 4.14 Schematic Representation of the Human T-Cell Receptor and CD4 and CD8 Co-Receptors. IgSF domains are represented by ovals. The four extracellular domains of CD4 are labeled D1–D4. Basic (+) and acidic (–) transmembrane charged residues are indicated, as are known and predicted sites of disulfide bonds. For schematic simplicity the cytoplasmic domains of the CD3 chains are shown as extending into the cytoplasm. The cytoplasmic domains of CD3ε and CD3ζ are positively charged and likely are associated with the inner leaflet of the plasma membrane.

CD3 Proteins

CD3γ, CD3δ, and CD3ε are structurally similar, and the genes encoding them map to a locus in chromosome 11q23. The polypeptides range in size from 20 to 25 kDa. Each has an extracellular C-type IgSF domain, a transmembrane region that contains an acidic residue (aspartic acid in CD3δ and CD3ε, glutamic acid in CD3γ), and a cytoplasmic domain with a single ITAM. The cytoplasmic domain of CD3ε (but not of CD3δ or CD3γ) has a net positive charge and can bind to the negatively charged inner leaflet of the plasma membrane with its ITAM inserted into the lipid bilayer. The CD3 chains are present in the TCR/CD3 complex in the form of noncovalently linked CD3γε and CD3δε heterodimers; interactions between the extracellular IgSF domains lead to the formation of these CD3 heterodimers.

The 16-kDa CD3ζ differs substantially from the other CD3 proteins and is structurally homologous to the γ chain of the high-affinity IgE receptor (FcRγ chain). The extracellular domain of CD3ζ has only nine amino acids and is of unknown structure. As is the case with the other CD3 chains, the transmembrane region of CD3ζ contains an acidic residue (aspartic acid). The large cytoplasmic domain of CD3ζ has 3 ITAMs in tandem, which, like the ITAM of CD3, also associate with the inner leaflet of the plasma membrane.[16] CD3ζ is usually present in the TCR/CD3 complex in the form of disulfide-linked CD3ζζ homodimers that form through interactions within the transmembrane domain.

Stoichiometry of the T-Cell Receptor/CD3 Complex

The αβTCR/CD3 complex is univalent and consists of a single αβ TCR heterodimer together with three CD3 dimers: CD3γε, CD3δε, and CD3ζζ (see Fig. 4.14). The γδTCR/CD3 complex, in contrast, lacks CD3δ. On naïve T cells, this receptor complex contains two CD3γε heterodimers and one CD3ζζ homodimer. Following activation of γδT cells, the TCR/CD3 complex incorporates the FcRγ chain, either as a homodimer or as a heterodimer with CD3ζ.[16,52,53]

Assembly and Cell-Surface Expression of the T-Cell Receptor/CD3 Complex

Assembly begins with formation of the individual TCRαβ, CD3δε, and CD3γε heterodimers, processes that are driven by interactions between the extracellular domains of the pairing polypeptides. The subsequent higher-order assembly of the TCRαβ with the CD3 dimers depends upon interactions between the potentially charged residues within their transmembrane regions. As noted above, each of the CD3 subunits has a transmembrane acidic residue while the transmembrane domains of the αβ and γδ TCRs contain basic residues. Mutation of any of these transmembrane acidic or basic residues to neutral alanine impairs formation of the TCR/CD3 complex. TCRαβ appears to associate first with CD3δε and then with CD3γε. TCRα binds CD3δε, and TCRβ likely interacts with CD3γε. The incorporation of a CD3ζζ homodimer into the complex requires the prior formation of a TTCRαβ–CD3γε–CD3δε hexamer and involves interactions between the arginine residue in the transmembrane domain of TCRα and the two co-localized aspartic acids in the transmembrane domains of the CD3ζζ homodimer.[16,54]

Formation of the TCR/CD3 complex is tightly regulated. For example, when there are deficiencies of CD3γ, CD3δ, or CD3ε, TCRα and β are retained in the endoplasmic reticulum and are rapidly degraded. In the absence of CD3ζ, the TCRαβ–CD3γε CD3δε hexamer is exported to the Golgi but then is targeted to a lysosomal degradation pathway rather than the cell surface.[16,52–54]

A cryoelectron microscopy structure of a human TCRαβ in complex with the CD3 hexamer was obtained at 3.7 Å resolution,

revealing that the octameric TCR/CD3 complex is assembled with 1:1:1:1 stoichiometry of TCRαβ:CD3γε:CD3δε:CD3ζζ.[55] Assembly of the extracellular domains of TCR/CD3 is mediated by the constant domains and connecting peptides of TCRαβ that pack against CD3γε-CD3δε, forming a trimer-like structure proximal to the plasma membrane. The transmembrane segment of the CD3 complex adopts a barrel-like structure formed by interaction of the two transmembrane helices of CD3ζζ with those of CD3γε and CD3δε. Insertion of the transmembrane helices of TCRαβ into the barrel-like structure via both hydrophobic and ionic interactions results in transmembrane assembly of the TCR/CD3 complex.

Clinical Consequences of Altered or Missing Functions of the T-Cell Receptor/CD3 Complex

Homozygous mutations leading to complete deficiencies of either CD3δ, CD3ε or CD3ζ protein produce a form of severe combined immunodeficiency (SCID) (Chapter 34) characterized by severe T-cell lymphopenia, but the presence of phenotypically normal B cells and NK cells ($T^-B^+NK^+$SCID).[56,57]

Mutations in *CD3G* leading to deficiency of CD3γ produce considerable clinical heterogeneity ranging from severe immunodeficiency in infants to mild forms of autoimmunity in adulthood. Homozygous deficiency in CD3γ impairs, but does not abrogate, T-cell development, leading to mild T lymphopenia, reduction in cell-surface expression of TCR/CD3 complex on peripheral T cells by 75% to 80%, and impaired in vitro proliferative T-cell responses to lectins and to anti-CD3 mAbs. In peripheral blood, there are differential effects on phenotypically defined T-cell subsets, with very few CD8 T cells, a 10-fold reduction in $CD45RA^+$ CD4 T cells ("naïve helper" subset), and normal numbers of $CD45RO^+$ CD4 T cells ("memory" cells).[58]

Early Events in T-Cell Receptor/CD3 Signaling

Stimulation of the TCR/CD3 complex by pMHC leads to the phosphorylation of tyrosine residues in the CD3 ITAMs by the SRC-like protein tyrosine kinase LCK.[59] The phosphorylated CD3 ITAMs in turn create high-affinity binding sites for the SH2 domains of the ZAP-70 protein tyrosine kinase, leading to its recruitment to the TCR/CD3 complex and to its activation (Chapter 10).[59,60] The consequences of ZAP-70 deficiency (selective T-cell immunodeficiency in humans) underscore the centrality of its role in T-cell activation (Chapter 34).

The TCR appears to act as a mechanosensor in order to trigger the cascade of complex biochemical events leading to the activation of T-cell effector function. As the T cell migrates over the cell surface of an antigen-presenting cell or target cell, the binding of the pMHC complex to the TCR causes the TCR to act as a lever, converting horizontal force into a vertical force that acts upon the CD3 chains, exposing their ITAMs for phosphorylation. Following the initiation of signaling, sustained signaling appears to involve multimerization of TCR/CD3 complexes and engagement of co-receptors.[16,54]

T-CELL CO-RECEPTORS: CD4 AND CD8

Expression of CD4 and CD8 divides mature T cells into two broad distinct subsets: CD4 T cells (Chapter 9), which recognize peptides in the context of class II MHC molecules, and CD8 T cells (Chapter 9), which recognize antigens presented by class I MHC molecules. Indeed, CD4 binds directly to class II MHC molecules, and CD8 interacts directly with class I MHC molecules (Fig. 4.15) (Chapter 6). The cytoplasmic domains of CD4 and CD8 associate with LCK, and serve to bring LCK into contact with the CD3 chains of the pMHC-engaged TCR/CD3 complexes, leading to the phosphorylation of CD3 ITAMs and initiation of TCR signaling (Chapter 10).

The expression of the CD4 and CD8 co-receptors is highly regulated during T-cell development in the thymus (Chapter 9). Thymocytes initially express neither co-receptor ("double negative"). $CD4^-CD8^-$ thymocytes destined to become TCRαβ T cells progress through a $CD4^+CD8^+$ ("double-positive") stage to become mature CD4 or CD8 T cells. Positive and negative selection of thymocytes on the basis of their TCR specificities and commitment to the CD4 or CD8 lineages occur during the double-positive stage.

CD4: Structure and Binding to Major Histocompatibility Complex Class II Molecules

A member of the IgSF, CD4 is a 55-kDa glycoprotein whose relatively rigid extracellular region contains four IgSF domains (designated D1-4). Its cytoplasmic domain contains two cysteine residues that mediate a noncovalent interaction with LCK through a "zinc clasp"–like structure formed with a dicysteine motif in the N-terminal region of LCK.[59,61–63]

The N-terminal domain (D1) of CD4 binds between the membrane-proximal α2 and β2 domains of MHC class II. Thus CD4 interacts with pMHC class II at a distance from the α-helices and peptide contacted by the TCR, enabling the TCR and CD4 to bind the same MHC class II molecule simultaneously.

Although MHC molecules are highly polymorphic, the CD4 contact sites are highly conserved. In humans, CD4 targets nonpolymorphic residues shared by all three MHC class II molecules (human leukocyte antigen [HLA]-DR, DP, and DQ). The crystal structure of the TCRαβ–pMHC–CD4 ternary complex assumes a V-shape with pMHC at the apex and with TCRαβ and CD4 forming the arms of the V. There is no direct interaction between the co-receptor and the TCR heterodimer, indicating that pMHC brings the TCR and CD4 together. The approximately 70 Å of separation between the membrane proximal domains of TCRαβ and CD4 would allow the CD3 chains to lie within the open angle between TCRαβ and CD4, promoting interactions between CD3 chains and CD4-associated LCK.[59,61,63]

Experiments using soluble forms of CD4 and pMHC reveal that monomeric CD4 binds pMHC with very low affinity (Kd approximately 200 μM). The binding of CD4 to pMHC is of lower affinity than that TCRαβ to pMHC (Kd 1 to 10 μM) and displays a far more rapid off time. Because of the low affinity and the rapid off time, it is unlikely that interactions of CD4 with MHC class II molecules initiate the interaction between a T cell and an antigen-presenting cell (Chapter 6). Rather, these binding characteristics are more compatible with a model in which the initial event is the interaction between the TCR and pMHC, followed by the recruitment of CD4, which acts primarily to promote signaling events through the delivery of LCK.[59,61,63]

CD8: Structure and Binding to Major Histocompatibility Complex Class I Molecules

There are two CD8 polypeptides, α and β, and these are expressed on the cell surface either as a disulfide-linked CD8αα homodimer or as a disulfide-linked CD8αβ heterodimer.

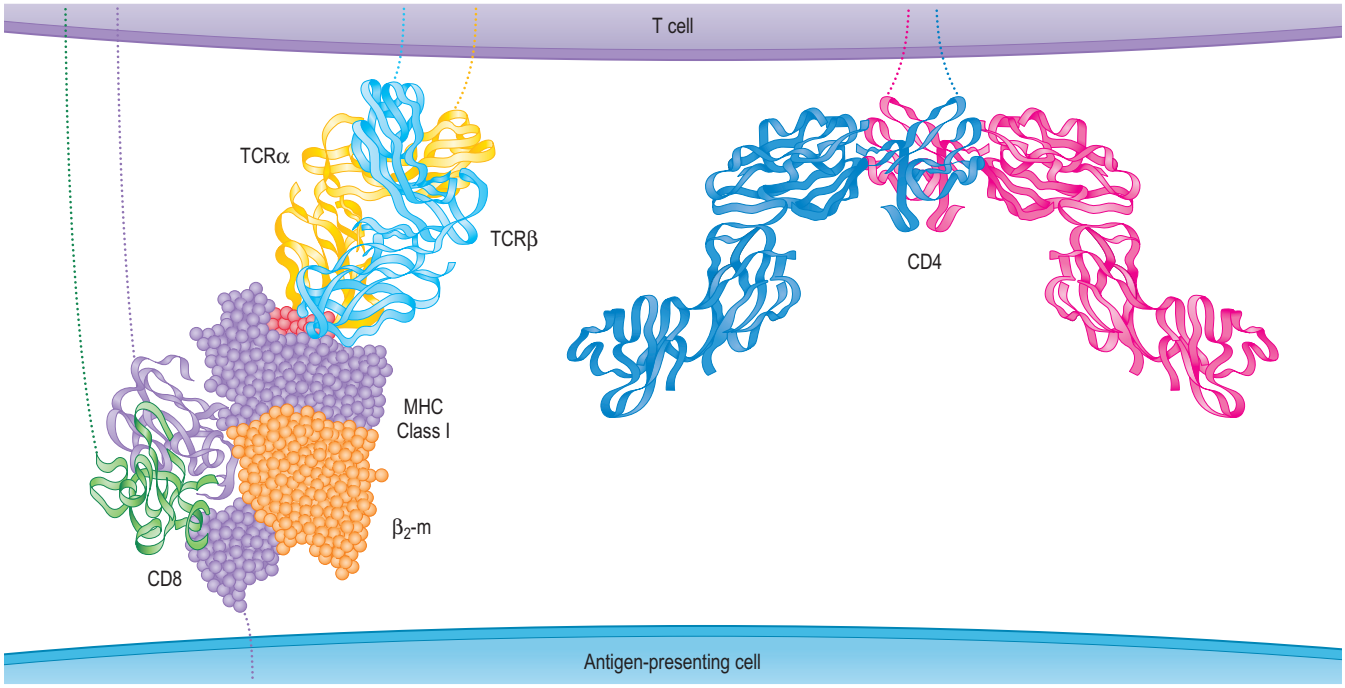

FIG. 4.15 Illustration of the Interactions Between the T-Cell Receptor, Peptide-Major Histocompatibility Complex, and CD8. A composite illustration of the human leukocyte antigen (HLA)-A*0201 structure in complex with a Tax peptide and its cognate T-cell receptor α and β chains (protein data bank [pdb] designation 1BD2) with the human CD8αα/HLA-A*0201 structure (pdb designation 1AKJ) was generated by superposition of the HLA moiety of the two structures. The HLA heavy chain is indicated as major histocompatibility complex *(MHC)*, its light chain (β_2-microglobulin) as β_2-m, the CD8αα homodimer as *CD8*, the T-cell receptor α and β chains as *TCRα* and *TCRβ*. In addition, the *CD4* homodimer (pdb file 1WIO) is shown to scale. Connecting peptides, transmembrane, and cytoplasmic domains are drawn by hand and indicated by *dotted lines*. (Figure courtesy of David H. Margulies, National Institute of Allergy and Infectious Diseases, National Institutes of Health.)

On most αβ T cells, CD8αβ is the predominant form of CD8 while natural killer (NK) cells (Chapter 12), intestinal intraepithelial T cells, MAIT cells, and γδ T cells mostly express CD8αα.[59,61–63]

CD8α, a 34- to 37-kDa protein, and CD8β, a 32-kDa protein, share about 20% amino acid sequence homology. Both are glycoproteins and IgSF members. Although CD8 subserves a co-receptor function similar to that of CD4, in structure it differs substantially from CD4. The CD8 extracellular regions have single N-terminal IgSF V domains at the end of extended mucin-like stalk regions of 48 amino acids (CD8α) or 35 to 38 amino acids (CD8β). A striking difference between the two forms of CD8 lies within the cytoplasmic domain. CD8α, like CD4, contains a cysteine-based motif that enables it to interact with LCK through a "zinc clasp"-like structure. In contrast, CD8β lacks this motif and does not associate with LCK. Interestingly, CD8αβ appears to be a more effective activator of TCR signaling than CD8αα. This may reflect the palmitoylation of the cytoplasmic domain of CD8β, which allows CD8αβ to associate with lipid rafts during T-cell activation.[59,61,63,64]

The structure of CD8αα pMHC class I complexes demonstrates that CD8αα binds to conserved residues in the α3 domain of MHC class I (i.e., a nonpolymorphic, membrane-proximal region of the molecule distinct from the peptide-binding groove engaged by the TCR) (Chapter 5). Compared to the interaction of CD4 and MHC class II, binding is more antibody-like, with a loop of the MHC α3 domain locked between the CDR-like loops of the two CD8α IgSF V domains. Models of the structure of the TCRαβ–pMHC–CD8 ternary complex propose a "V" shape similar to that of the crystal structure of TCRαβ–pMHC–CD4, with pMHC at the apex of the "V" and the TCR and CD8 forming the arms of the "V." CD8 binds to pMHC with lower affinity and with faster kinetics than the TCR. Thus, the binding properties of the CD8 co-receptor, like those of CD4, are consistent with a model in which the TCR initiates pMHC binding, followed by engagement of CD8 to the same pMHC.[59,61–64]

CO-STIMULATORY AND INHIBITORY T-CELL MOLECULES: THE CD28 FAMILY

Although the T-cell response to antigen requires the binding of the TCR and its co-receptors to pMHC, additional receptor–ligand interactions affect the outcome by delivering signals that promote activation (co-simulation) or that inhibit it (Table 4.4). Prominent among these are the interactions of members of the CD28 family with their cell-surface ligands on antigen-presenting cells.[65] This family includes CD28, inducible co-stimulator (ICOS), cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4), B- and T-lymphocyte attenuator (BTLA), and program death-1 (PD-1). CD28 and ICOS are co-stimulatory receptors; the major functions of CTLA-4, PD-1, and BTLA are inhibitory. CD28 and CTLA-4 are T-cell specific, whereas BTLA and PD-1 are also expressed by B cells and ICOS by NK cells. CD28, CTLA-4, and PD-1 are the targets of therapeutic interventions in current clinical practice.

TABLE 4.4 CD28 Superfamily

Receptor	Expression	Ligand	Function on T cells
CD28	Most CD4 T cells	B7-1 (CD80)	Co-stimulation of IL-2 production and proliferation
	50% CD8 T cells	B7-2 (CD86)	Promotes T-cell survival
ICOS	Activated and memory T cells NK cells Not expressed by naïve T cells	ICOS ligand	Promotes T-cell differentiation and effector T-cell function
CTLA-4	Upregulated after T-cell activation	B7-1 (CD80)	Inhibits IL-2 production and proliferation
		B7-2 (CD86)	Promotes peripheral T-cell tolerance
PD-1	Upregulated after activation of T and B cells, myeloid cells	PD-L1 (B7-H1)	Inhibits proliferations and cytokine production
		PD-L2 (B7-DC)	Promotes peripheral T-cell tolerance
BTLA	T and B cells, myeloid cells, dendritic cells	HVEM (herpesvirus-entry mediator)	Inhibits T-cell proliferation

BTLA, B- and T-lymphocyte attenuator; *CTLA-4*, cytotoxic T-lymphocyte-associated antigen-4; *ICOS*, inducible co-stimulator; *IL-2*, interleukin-2; *NK*, natural killer; *PD-1*, program death-1.

All members of the CD28 family have a single extracellular IgSF V domain and have, as their ligands, members of the B7 family of cell-surface molecules. CD28, CTLA-4, and ICOS are disulfide-linked homodimers whose cytoplasmic domains contain the SH2-binding motif YXXM. In contrast, PD-1 and BTLA are monomers whose cytoplasmic domains each contain an ITIM and an *I*mmunoreceptor *T*yrosine-based *S*witch *M*otif (ITSM).

CD28 and Cytotoxic T-Lymphocyte-Associated Antigen-4

Half of CD8 T cells and virtually all human CD4 T cells constitutively express CD28. CD28 binds to B71 (CD80) and B7.2 (CD86) through a MYPPPYY motif in its extracellular domain. Interactions with these ligands leads to the phosphorylation of the YMNM sequence in the CD28 cytoplasmic domain and to the recruitment of phosphatidylinositol 3-kinase and Grb2. CD28 stimulation usually does not elicit a cellular response in the absence of TCR signaling. Rather, CD28 signals act in concert with those of the TCR to promote cytokine production, T-cell expansion, and T-cell survival. TCR signaling in the absence of CD28 co-stimulation can induce T-cell anergy (Chapter 10).

CTLA-4 inhibits the response to TCR and CD28 signals and acts to terminate peripheral T-cell responses. Its importance in human immunology is underscored by observations that *CTLA4* haploinsufficiency produces a syndrome of immune dysregulation characterized by decreased numbers of T regulatory cells (Treg), hyperactive effector T cells, hypogammaglobulinemia, and clinical autoimmunity (Chapter 33).

The majority of CTLA-4 resides in intracellular compartments. T-cell activation promotes the cell-surface expression of CTLA-4 by regulating both its transport to the surface and its subsequent internalization. CTLA-4 also binds B7.1 and B7.2 but does so with substantially greater affinity than does CD28. Moreover, the binding of CTLA-4 to these ligands is divalent, whereas that of CD28 is monovalent. Thus the inhibitory complexes formed by CTLA-4 are more stable than the co-stimulatory interactions involving CD28. CTLA-4 can inhibit T-cell activation by outcompeting CD28 for B7 ligands and, through transendocytosis, by removing B7 molecules from the antigen-presenting cell. In addition, CTLA-4 can induce "reverse signaling" through B7.1 and B7.2 to the antigen-presenting cell, upregulating the enzyme indoleamine 2,3-dioxygenase (IDO), which in turn breaks down tryptophan, a requirement for T-cell proliferation.

The importance of CD28 co-stimulation has made it an attractive target for therapeutic intervention.[66,67] Indeed, two soluble fusion proteins composed of the extracellular domain of human CTLA-4 and the constant regions of human IgG1, abatacept and belatacept, are effective therapies for the treatment of rheumatoid arthritis (Chapter 53) and the prevention of renal allograft rejection (Chapter 89). These fusion proteins are thought to inhibit CD28 co-stimulation through blockade of its B7 ligands, but some of their immunosuppressive effects may be indirect through the induction of IDO and consequent local depletion of tryptophan. Conversely, inhibition of CTLA-4 by mAbs can promote durable immune responses against certain malignancies.

Program Death-1

PD-1 is a key inhibitory receptor that attenuates TCR signaling, promotes T-cell tolerance, and is associated with T-cell exhaustion. PD-1 is not found on resting T cells, and its expression during T-cell activation requires transcriptional activation. PD-1 binds to two ligands: programmed death ligand-1 (PDL-1), which is widely expressed, and PDL-2, which is found primarily on professional antigen-presenting cells. Engagement of ligand induces tyrosine phosphorylation of the ITIM and ITSH motifs in the cytoplasmic domain of PD-1, leading to the recruitment of the tyrosine phosphatase SHP-2. Continued stimulation of T cells by antigen leads to sustained expression of PD-1 and differentiation into a state of hyporesponsiveness termed *T-cell exhaustion*. Blockade of PD-1 has shown considerable promise in the treatment of diverse human malignancies.[68]

The Major Histocompatibility Complex

Dimitri S. Monos and Raja Rajalingam

A primary objective of the immune system is to protect the body against pathogens. The major histocompatibility complex (MHC) comprises a genomic region that has evolved to include many genes responsible for coordinating the immune response. It is named the histocompatibility complex because it was first identified as the site of numerous genes that determined whether transplanted tissue would be accepted or rejected. We now know that this region coordinates immunological functions far beyond those related to histocompatibility. The MHC region includes genes that determine both innate and adaptive immunity and thus influences responses to pathogens (viruses, bacteria, fungi, and parasites), transplantation, autoimmunity, cancer, vaccinations, certain drugs, and possibly other functionalities presently unknown. This chapter describes the genomic organization and immunological importance of the MHC with a special focus on the HLA (*h*uman *l*eukocyte *a*ntigen) genes. These HLA molecules present self and foreign peptides to T cells (Chapter 6) and thus play a central role in adaptive immunity. They also interact with receptors on the surface of natural killer (NK) cells (Chapter 12) and thus also play a role in innate immunity.

The terms HLA and MHC are often used interchangeably. However, in this chapter the term "MHC" is reserved for the broader genomic region, while the term "HLA" refers to the human class I and class II genes and their respective protein products.

CLINICAL RELEVANCE

- HLA molecules regulate antigen-specific immune responses by binding and then presenting pathogen-derived peptides to either CD4 or CD8 T cells.
- Certain HLA alleles are the major genetic determinants of susceptibility to many autoimmune diseases or drug hypersensitivity reactions because they can present specific self-peptides or small molecules (drugs) to T cells.
- HLA molecules play a key role in transplant rejection and appear to regulate placental development in pregnancy.
- Cancerous cells modify expression of their HLA genes in order to avoid immune recognition.

GENOMIC ORGANIZATION OF THE MAJOR HISTOCOMPATIBILITY COMPLEX

The human MHC region includes approximately 3.8 million base pairs (Mbp) of DNA on the short arm of chromosome 6 (6p21.3). It is defined as the region spanning from the gamma-aminobutyric acid type B receptor subunit 1 *(GABBR1)* gene on the telomeric side of the region to the Kinesin Family Member C1 *(KIFC1)* gene toward the centromere (ENSEMBL 86 GRCh38.p7 coordinates chr6: 29555629-33409924).[1] The functional MHC region may include additional downstream and upstream sequences totaling seven or more Mbp.

The classic 3.8 Mbp MHC region is the most gene-dense segment of human genome. It includes 158 protein-coding genes and 86 pseudogenes of unknown functionality (ENSEMBL 86 GRCh38.p7).[2] At least 65 (41%) of the coding genes are involved in innate and adaptive immunity.[2] The MHC is divided into three regions: class I, class II, and class III (Fig. 5.1). The class I region is at the telomeric end and includes the classical HLA class I genes (*HLA-A, -B*, and *-C*), the class I-related (like) genes *(MICA, MICB)*, the nonclassical HLA class I genes (*HLA-E, -F*, and *-G*) and four pseudogenes (*HLA-H, -K, -J*, and *-L*). The class II region occupies the centromeric end and contains the *DRA* and *DRB1* genes and, depending on the DR haplotype, one or none of the *DRB3*, *DRB4, DRB5* genes that code for DR52, DR53, or DR51 molecules, respectively; the *DQA1* and *DQB1* genes that encode the DQ molecule; and the *DPA1* and *DPB1* genes that encode the DP molecule. It also includes the *DM* and *DO* genes encoding the antigen-processing molecules DM and DO that are involved in the class II antigen presentation pathway, and the *TAP* and *LMP* genes encoding proteins that are involved in the class I antigen presentation pathway (Chapter 6). The class III region, interposed between class I and II regions, contains many immune and nonimmune genes. These include complement components, lymphotoxin, tumor necrosis factor, heat shock proteins, *NFKB, NOTCH4*, and 21-hydroxylase *(CYP21)*. Genes within the HLA class I and class II regions variably reflect the mechanisms of insertion, deletion, gene duplication, gene conversion, and mutation used by evolution to expand diversity of function. While the genomic organization of class I and class II genes is quite distinct, the derived molecules share highly similar structures, likely driven by the shared role of these molecules in presenting peptides to T-cell receptors (TCRs).

The MHC is also marked by extensive linkage disequilibrium (LD) between the class I *HLA-A, -B, -C* and class II *HLA-DR* and *-DQ*, but not *–DP*, genes. LD is the phenomenon whereby particular alleles of gene loci on the same strand of DNA are inherited together more often than expected by chance alone. Anthropological population studies suggest that the particular combinations of alleles of the different genes, as distant as they may be, provide a survival advantage. This may reflect functional interdependence of these alleles in antigen-specific immune responses.

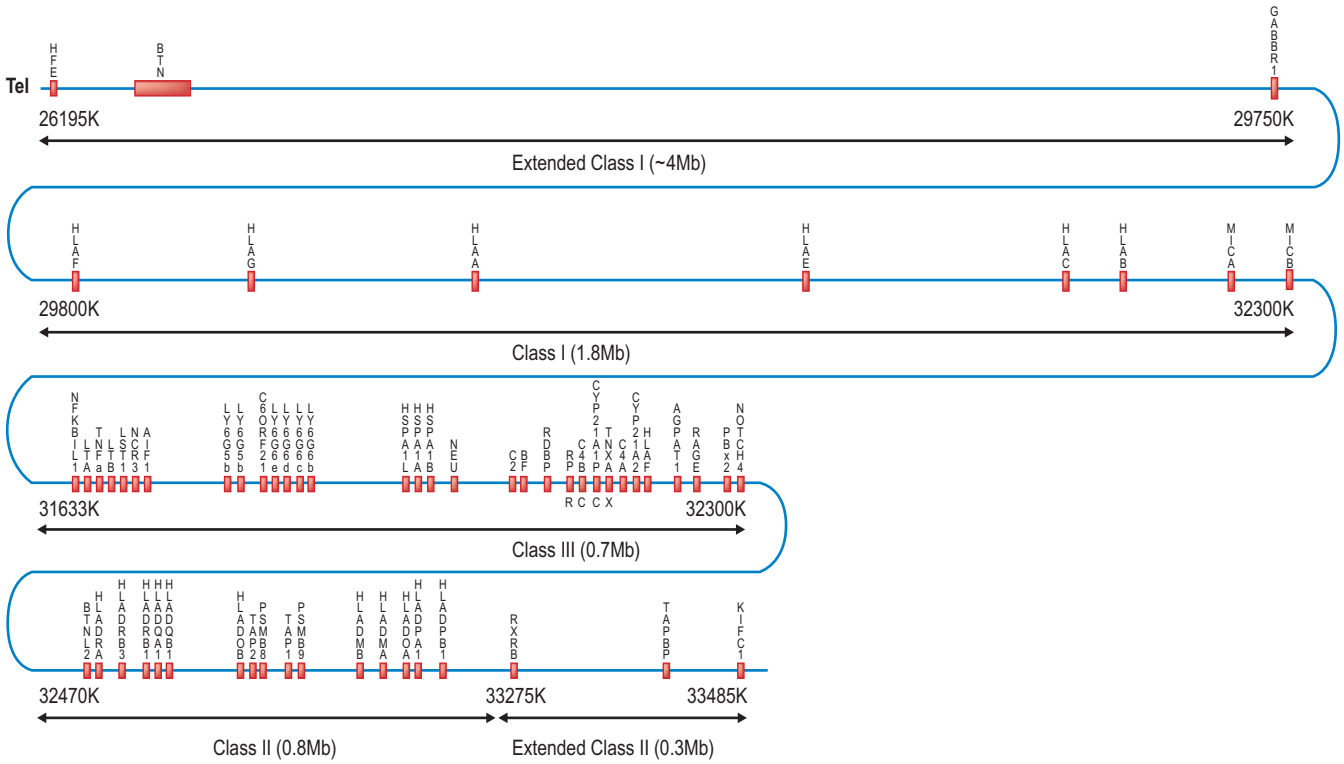

FIG. 5.1 Gene Map of the Extended Major Histocompatibility Complex. The core of the major histocompatibility complex consists of three major regions: class I, class III, and class II. The extended class I and extended class II regions of the complex are labeled. Sequence numbering begins at the telomere. The map depicts immune-related expressed genes as well as certain reference genes. The approximate locations of these selected genes near the start or end of the regions are indicated. (Modified from Beck S, Trowsdale J. The human major histocompatibility complex: lessons from the DNA sequence. *Annu Rev Genomics Hum Genet*. 2000;1:117–137.)

A particular combination of alleles of different loci in LD on the same strand of DNA is called a "haplotype." The frequency of a given haplotype varies among different populations, reflecting distant selection by pathogens, ethnic admixture, and drastic population reductions (genetic bottlenecks). LD is strongest between *HLA-B* and *-C* and between *HLA-DR* and *-DQ*, most likely due to their physical proximity. However, due to a hot spot of recombination between the *DQ* and *DP* there is no LD between *DP* and rest of the HLA genes even though *DQ* and *DP* are relatively proximal to each other in linear distance.

The haplotype is the unit of inheritance of the MHC from either parent. Each parent shares one haplotype with each of their children and typically differs from a child by one haplotype. Two siblings may share two, one, or no haplotypes, and thus range from being HLA-identical, through haplo-identical, to HLA-disparate. A parent is usually only haplo-identical with their child. Exceptions to this rule may occur in inbred populations, where both parents may share an identical HLA haplotype by descent. The HLA alleles originating from the maternal and paternal haplotypes are both expressed.

Ten years of genome-wide association studies (GWAS) have revealed a large number (884) of single nucleotide polymorphisms (SNPs) within the MHC that are associated with many (479) traits and diseases, establishing the MHC as the only region in the genome with this high density of SNPs that is associated with so many diseases.[3] The complexity of the region with its many insertions, deletions, duplications, and LD does not allow an easy dissection of disease-causing variants. However, recent developments in next-generation sequencing (NGS) of the entire MHC[4] will most likely advance our understanding of the principles underlying this complex genomic organization, how this complexity results in so many biological interdependencies, and how it contributes to the pathophysiology of the diseases associated with the MHC.

KEY CONCEPTS

Genomic Organization of the Major Histocompatibility Complex

- The highly complex MHC is associated with more diseases than any other genomic region of comparable size.
- The class I region contains the polymorphic *HLA-A*, *-B*, and *-C* genes, the less polymorphic non-classical class I *HLA-E*, *HLA-F*, and *HLA-G* genes, and the class I-related *MICA* and *MICB*.
- The class II region contains the *HLA-DR A* and *B*, *DQ A* and *B*, and *DP A* and *B* genes. It also contains the *TAP*, *LMP*, *DM*, and *DO* genes, which encode molecules that help process antigens into peptides that can bind class I and class II molecules.
- Genes within the MHC demonstrate extensive LD. A string of linked, polymorphic alleles is termed an MHC haplotype.
  - Haplotypes are preserved by means of natural selection, whose driving force is reproductive fitness.
  - Common haplotypes within a given population appear to reflect functional interdependencies between MHC gene alleles.
  - Different populations can exhibit different haplotypes.
- The HLA genes of the two chromosomes are both expressed.

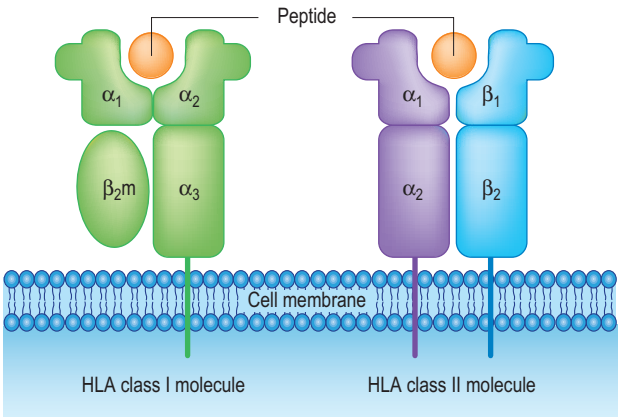

FIG. 5.2 Major Histocompatibility Complex (MHC) Class I and II Domain Organization. Although major histocompatibility complex class I and class II proteins have a different chain structure, the organization of their domains is extremely similar. Both class I and II molecules are expressed on the cell surface where they are accessible to T cells. Both have an outermost domain that contains a cleft where antigenic peptides are displayed. Two of the three class I α domains fold to create a domain with a peptide-binding cleft. The remaining α_3 domain helps support the peptide-binding domain and anchors the molecule to the cell membrane. The class I molecule also contains an extrinsic β chain, β_2-microglobulin ($\beta_2 m$), which is encoded by a separate, invariant gene. β_2-Microglobulin associates with the α_3 domain to support the antigen-binding domain created by the α_1 and α_2 domains. Class II molecules share a similar overall structure, but are the product of two genes, each containing two domains, one relatively constant that is proximal to the cell membrane and one highly variable that interacts with the peptide. *HLA*, Human leukocyte antigen.

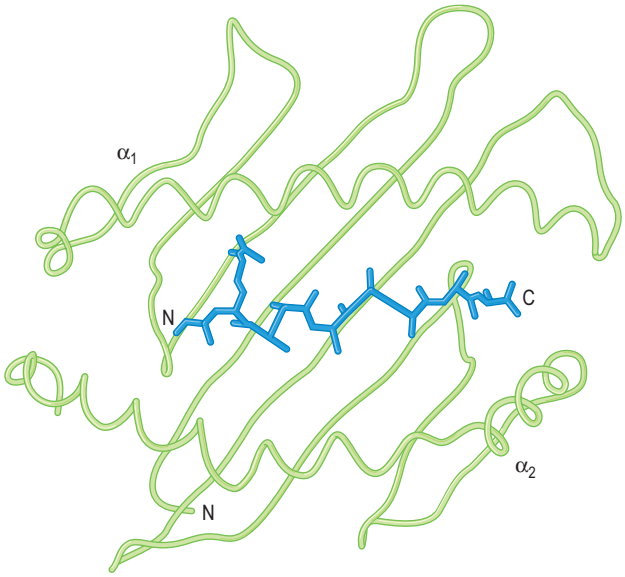

FIG. 5.3 The Three-Dimensional Structure of Human Leukocyte Antigen-B27. The α-helical margins of the peptide-binding cleft contain the bound peptide RRIKAITLK, which is oriented with its amino terminus to the left. There are extensive contacts at the ends of the cleft between peptide main-chain atoms and conserved human leukocyte antigen (HLA) side chains. The peptide amino and carboxyl termini are tethered to the cleft by hydrogen bonds and charge interactions. The peptide reciprocally stabilizes the three-dimensional fold of HLA-B27. The positively charged side chain of arginine in the P2 position of the peptide inserts into the B pocket, which contains a complementary negatively charged glutamic acid at its base. The resulting salt bridge is the dominant anchor for the peptide. Side chains P4, P6, and P8 make minor contributions to the interaction of the peptide with the HLA-B27 molecule. The central region of the peptide is left free to interact with a T-cell receptor. (Modified from Madden DR, Gorga JC, Strominger JL, Wiley DC. The three-dimensional structure of HLA-B27 at 2.1 A resolution suggests a general mechanism for tight peptide binding to MHC. *Cell*. 1992;70:1035.)

STRUCTURE AND FUNCTION OF THE HUMAN LEUKOCYTE ANTIGEN MOLECULES

The main function of both class I and class II HLA molecules is to bind peptides derived from self or nonself-antigens, and then traffic to the cell surface where these peptides can be displayed, or presented, for recognition by the appropriate T cells. Their structure has evolved to satisfy this particular requirement.

Classical Human Leukocyte Antigen Class I Molecules

The classical HLA-A, -B, and -C class I molecules consist of an α and a β chain. The α chain masses 45 kDa and is 362 to 366 amino acids long. It is encoded by the respective class I genes of MHC. The β chain, β_2-microglobulin (12 kDa), is encoded by its respective gene on chromosome 15. The α chain has three approximately 90-amino acid extracellular domains encoded by exons 2, 3, and 4 respectively; a transmembrane segment (approximately 25 amino acids) encoded by exon 5; and a C-terminal cytoplasmic end (approximately 30 amino acids) encoded by exons 6 and 7. β_2-Microglobulin, which is invariant, comprises the fourth domain (Fig. 5.2). The first two α domains (α_1 and α_2) are the most distal to the cell membrane. They combine to form a domain with a peptide-binding groove, or cleft, that is flanked by a surface that interacts with a TCR or a NK cell receptor.[5,6] The ends of the peptide-binding cleft are closed and fix the peptide's orientation. The sides of the peptide-binding cleft are composed of α helices and the floor is composed of symmetric strands of β-pleated sheet (Fig. 5.3). The α_3 domain and β_2-microglobulin create a combined structure that supports the peptide-binding domain and, along with the transmembrane domain of the α chain, attaches the molecule to the cell surface. Class I HLA molecules are ubiquitously expressed in all nucleated cells and in platelets. Expression of class I is significantly reduced on red blood cells and absent on sperm cells.

HLA class I molecules bind peptides derived from processed proteins of a pathogen or other self/nonself-peptides (Chapter 6). These peptides average nine amino acids long, and two or more of the amino acid side chains are used to anchor the peptide to pockets (see Fig. 5.3). Individual HLA class I alleles are generally distinguished by their own distinct pattern of peptide binding, as illustrated for selected HLA-B molecules in Table 5.1.[7] Among class I molecules, one or a few amino acid changes may considerably alter the binding properties of a binding pocket.

In a healthy non-endocytosing cell, HLA molecules are filled with a variety of peptides from self-molecules. The bound peptides are selected according to the binding motif of the particular

TABLE 5.1 Peptide-Binding Motifs Encoded by Different Human Leukocyte Antigen (HLA) Alleles Influence the Number of Peptides in a Protein That Can Be Recognized by a HLA Molecule (e.g., Human Immunodeficiency Virus [HIV] Envelope Protein)

allele. Even during viral infection or upon pathogen phagocytosis, the number of nonself-peptides may not be high. Together, the MHC class I and its peptide create a complex ligand that serves as the target of the TCR on the T-cell surface (Chapter 4).

The expression of class I molecules is upregulated by α-, β-, and γ-interferons, granulocyte-macrophage colony-stimulating factor (GM-CSF), and certain other cytokines (Chapter 14). Class I expression is governed by a regulatory element located ~160 nucleotides upstream from the initiation site of the class I gene. This site binds a number of regulatory factors, including those induced by interferons.

MICA and MICB

Within the class I region are *MICA* and *MICB* (MHC class I chain-related protein A and B). While both MICA and MICB are members of the class I family, neither associate with β_2-microglobulin nor bind peptides.[8] MICA and MICB are expressed as "danger signals" by virus-infected or otherwise stressed cells. Both are ligands for the activating NKG2D molecule *(KLRK1)*, a member of killer cell lectin-like receptors (KLR)[9] that appears on memory-effector T cells and NK cells and provides a signal to activate effector cytolytic responses.

Nonclassical Human Leukocyte Antigen-E, -F, and -G

The HLA nonclassical molecules E, F, and G are less polymorphic, have a limited tissue distribution, and have different functions than classical HLA class I molecules.[10] HLA-E primarily presents self-peptide to the TCR of CD8 T cells. The diversity of these self-peptides is limited and includes the leader peptide of classical class I HLA molecules.

The binding of **HLA-E** to inhibitory receptors (e.g., CD94/NKG2A) is an important part of the surveillance mechanism for missing self. In tumor cells, loss of class I expression results in a survival advantage for the particular tumor cell. In the absence of class I expression, HLA-E molecules no longer form a complex with intracellular class I leader peptides. As a result, HLA-E molecules are not expressed on the cell surface and the inhibitory signals to the NK cells are removed. This licenses the NK cell to kill the tumor target. Thus, HLA-E exists at the interface of innate and adaptive immunity.

HLA-F has a small binding cleft that does not contain peptide and its functions are not well understood. It mainly resides intracellularly and rarely reaches the cell surface.

HLA-G has limited tissue distribution and is primarily expressed by placental trophoblast cells, thymus, cornea, and some erythroid and endothelial precursor cells. HLA-G has a peptide groove, binds a nonamer peptide, and is recognized by the leukocyte immunoglobulin-like receptors (LILR-1 and LLIR-2) and a killer cell immunoglobulin-like receptor (KIR). In melanoma, HLA-G expression can be used by the tumor cells to avoid immunosurveillance by flooding the local microenvironment with soluble HLA-G and compromising the function of immune cells. The expression of HLA-G in the chorionic villi suggests a role in the maintenance of pregnancy. The mechanism appears to involve production of soluble forms of HLA-G. They appear to have an inhibitory role on the immune cells of the mother. Unique among other HLA molecules, HLA-G exists in different isoforms. Of these, four are expressed on the cell membrane, and three others exist as soluble forms. The functional significance of these isoforms is not known.

Class II Human Leukocyte Antigen Molecules

Class II HLA molecules are selectively expressed by professional antigen-presenting cells (e.g., macrophages, dendritic cells, B cells, and activated T cells) (Chapter 6). The HLA class II molecules are heterodimers that consist of two transmembrane glycoprotein α (34 kDa) and β (29 kDa) chains. Together, the α and β chains form a structure that is similar to HLA class I.

Unlike class I, both the α and β chains are encoded by genes within the MHC. Each of the two chains is composed of two extracellular domains. *DR, DQ*, or *DP* α *chain* includes α_1 and α_2 domains that are encoded by exons 2 and 3 of the *DRA, DQA*, or *DPA* gene. *DR, DQ*, or *DP* β *chain* includes β_1 and β_2 domains that are encoded by exons 2 and 3 of the *DRB, DQB*, or *DPB* gene. The α_1 and β_1 domains form the binding groove of the class II HLA molecule and are highly variable. Unlike class I where the peptide-binding domain is encoded by α_1 and α_2 domains in the same gene, trans arrangement of α and β chains derived from the two different haplotypes of the same or even different isotypes permits combinatorial polymorphism in class II. The α_2 and β_2 domains are proximal to the membrane and have limited polymorphisms (see Fig. 5.2).

Although the structure of the peptide-binding cleft in class II is homologous to that of class I, there are several distinct differences that have major functional consequences. Among the most important of these differences are those of length and cleft structure. The binding cleft of class I is closed, limiting peptide length, whereas the binding cleft of class II is open, which permits the peptide to extend on both sides of the class II molecule. Thus, the majority of peptides interacting with class II molecules have a length of greater than 13 amino acids, whereas class I prefers peptides of nine amino acids.

The peptide is bound to the class II molecule through the side chains of the peptide amino acids, which interact with five different polymorphic pockets within the cleft. Loading of the HLA class II molecules with peptides takes place primarily within the endosomes, where the HLA molecule interacts with endocytosed and phagocytosed extracellular antigens (Chapter 6). To prevent binding of intracellular peptides in the class II pocket, when the MHC molecule traffics through the endoplasmic reticulum it interacts with a protein termed invariant chain (Ii). Invariant chain is a trimer. Each of its subunits binds noncovalently with an HLA class II molecule. The MHC:invariant chain complex also interacts with another chaperon protein called calnexin. Upon release of calnexin, the class II molecule moves either directly into the late endosomal MHC class II compartment (MIIC) or is cycled to the cell surface where it is then internalized into MIIC. Once in the endosomal environment, invariant chain is degraded by proteases, including cathepsin S and L. It then leaves a fragment of peptide known as the class II-associated invariant chain peptide (CLIP). Upon dissociation of the CLIP peptide from the class II binding cleft within the endosome and with the assistance of HLA-DM, relevant exogenous peptide associates with the class II molecule prior to transport of the stable HLA class II–peptide complex to the cell surface.

Nonclassical Human Leukocyte Antigen -DM and -DO

The nonpolymorphic nonclassical class II molecules **HLA-DM** and **HLA-DO** are exclusively expressed in endosomes and regulate peptide binding to the classical HLA class II molecules.[11]

Proteasome Elements Within the Class II Region

The products of four genes in the class II region are involved with processing and loading peptides onto class I molecules (see Fig. 5.1). **PSMB8** and **PSMB9** are proteasome subunits generating peptides from the breaking down of proteins. **TAP1** and **TAP2** transport the peptides from the cytoplasm to the endoplasmic reticulum. The presence of these genes, which are related to the functioning of HLA class I molecules, in the midst of genes encoding the HLA class II molecules likely contributes to strong LD within the MHC. Allelic forms of genes in the class I region appear to require the presence of allelic forms in the class II region. Functional interdependencies promote joint transmission across generations.

Principles of Peptide Presentation

The mechanism by which HLA class I and class II molecules present peptides became clear when the structures of these two molecules were determined. A simplified cartoon of the domain structure of MHC class I and class II proteins is depicted in Fig. 5.2. A more intricate ribbon structure of the actual class I molecule interacting with the TCR is presented in Chapter 4. For both class I and class II, the peptide-binding structure takes the shape of a β-pleated floor with two α-helix walls. The peptide lies within the groove created by these structures (Figs. 5.3 and 5.4).

Each HLA molecule, whether class I or class II, binds a single peptide, but the same HLA molecule has a significant degree of promiscuity and can bind thousands of different peptides. Each of the binding grooves is composed of individual polymorphic pockets that dictate the binding of different peptides. Although the mode of TCR docking on HLA molecules is globally conserved, the shapes and chemical properties of the interacting surfaces found in these complexes are so diverse that no fixed pattern of contact has been recognized even between conserved TCR residues and conserved side chains of the HLA α helices.[12] Indeed, of the amino acid side chains not bound to the HLA, only two or three are typically bound to the clonotypic TCR. This limited contact yields considerable TCR plasticity, which has the important evolutionary implication of freeing the HLA molecule and the peptide–HLA complex from the strict stereochemical constraints usually imposed in receptor–ligand interactions. The consequence of TCR plasticity and this unusual receptor–ligand interaction has been the evolutionary development of a uniquely large number of different genes that encode various HLA structures, each of which is able to bind and present a different range of peptides to the same clonotypic TCR.

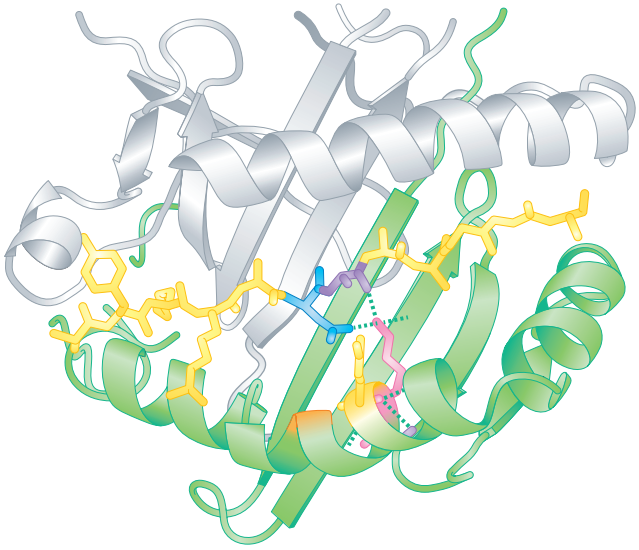

FIG. 5.4 Structure of a Human Leukocyte Antigen (HLA) Class II–Peptide Complex. The structure was prepared using PyMol from published coordinates. The HLA molecule is largely shown as a ribbon, while the peptide is a stick diagram. The peptide-binding groove is delimited by α helices. The upper helix is encoded by the α chain, and the lower helix by the β chain. β-pleated sheets form the saddle-like floor. Side chains are depicted on the β chain at positions 70 and 71, a region involved in specifying the side-chain pocket P4. This pocket binds the fourth side chain of the peptide contained within the HLA molecule. The side chains shown are, respectively, glutamine and lysine, which form part of the "shared epitope" structure associated with susceptibility to rheumatoid arthritis. The lysine is shown forming hydrogen bonds with the peptide antigen.

KEY CONCEPTS

Structure of the Human Leukocyte Antigen Molecules

- HLA class I molecules are involved in both innate (NK cells) and adaptive (T cells) immunity.
- Class I and class II HLA molecules share structures that enable them to bind peptides and present them to TCRs.
- Peptide binding to the HLA molecule is influenced by allele-specific pockets within the HLA binding cleft that interact with peptide amino acid side chains.
  - The HLA–peptide complex is recognized by the TCR of the T cell.

Selection by Self-Peptides in the Thymus

Peptides derived from external antigens, including pathogens, are typically absent during the formation of the T-cell repertoire in the thymus (Chapter 9). Self-peptide–HLA complexes are thus used as surrogates for selecting, or training, individual T cells to recognize nonself-pathogen peptides.[13] For T cells, "immunologic self" is the set of self-peptides and self-MHC molecules that select the TCR repertoire in the thymus. The two-step selection process begins with positive selection and survival of cells whose TCRs interact with the self-peptide–HLA complex. T cells with receptors that fail to recognize any self-peptide–HLA complex are eliminated. This is followed by a negative selection step whereby T cells with high-affinity interactions with self-peptides–HLA complex are eliminated. Negative selection promotes survival of T cells with lower-affinity interactions to self-peptide–HLA complexes. The surviving cells are released from the thymus and into the periphery. Selecting self-peptides expressed in the thymus constitute the T-cell recognition component of an individual's adaptive immune system. This patterning of TCR recognition on self-peptides presented by self-MHC molecules is critical to allorecognition and the avoidance of autoimmunity.

Evolutionary Considerations Driving the Separate Functions of Class I and Class II

One basic task of the T cell is to protect the body from two major types of pathogens: viruses that would commandeer the replicative machinery of a cell (Chapter 25), and bacteria that replicate autonomously and often extracellularly (Chapter 27). These two types of pathogens present very different challenges to the immune system. To terminate viral infection, a cell harboring virus has to be killed by a cytotoxic CD8 T cell (Chapter 12), whereas a bacterium can be eliminated by being phagocytized by a macrophage that has been selectively activated by a CD4 helper T cell (Chapter 11). The necessity of distinguishing between whether the presence of a pathogen peptide should elicit a killer or helper T-cell response is presumed to be the evolutionary drive that resulted in the creation of two specialized forms of HLA molecules, class I and class II (see Fig. 5.2).[12,14]

The specialized antigen processing and presentation intracellular machinery used to load class I molecules offers a means to reflect at the cell surface the molecular profile of antigens within the cell. This allows HLA class I molecules to screen for the presence of an intracellular viral infection. Recognition of the HLA class I–peptide complex is through the TCR of a CD8 T cell, which primarily reacts to the detection of an inappropriate intracellular antigen (i.e., a virus) by cytotoxic activity. In contrast, class II peptide loading occurs in coordination with phagocytosis and lysosomes. HLA class II molecules thus offer a means by which the immune system can be informed of the presence of extracellular antigens, such as bacteria. The recognition of the HLA class II–peptide complex is through the TCR of a CD4 T cell, which leads to the activation of helper T cells and the immune response that results.

Among the evolutionary strategies used for viral survival, some virally encoded genes decrease the expression of the HLA class I surveillance system, which would otherwise alert the immune system to the presence of an infected cell (Chapters 12 and 25).[15] This attempt to escape surveillance by downregulation of HLA class I is countered by the extensive interaction of class I molecules with various NK receptors expressed on NK cells or T-cell subsets. These interactions provide a mechanism for detecting decreases in HLA class I expression, which is termed recognition of "missing self."[16]

KEY CONCEPTS

Human Leukocyte Antigen Molecule Function

- An HLA molecule binds a peptide to create a peptide–HLA complex that serves as a ligand for a clonotypic TCR. The trimolecular peptide–HLA–TCR complex triggers the activation and proliferation of the T cell in an adaptive immune response.
  - HLA class I A, B, and C molecules are expressed on the surface of virtually all nucleated cells.
  - HLA class II DQ, DR, and DP molecules are constitutively expressed on B cells, professional antigen-presenting cells (APC), thymic epithelial cells, and activated T cells.
- The *immunological self* is the set of self-peptides and self-HLA molecules that select the TCR repertoire in the thymus. They constitute the T-cell recognition component of an individual's adaptive immune system.
- During an adaptive immune response, T cells recognize nonself-peptide–HLA complexes and become activated to either initiate an immune response (CD4 helper T cells) or recognize a target (CD8 cytotoxic T cells).
- Through thymic selection, the TCR can adapt to recognize a very large variety of peptide–HLA structures.
  - The plasticity of the recognition permits evolution of a large number of HLA genes encoding duplicated or alternative peptide-presenting molecules with specificity to bind different peptides.
  - The diversification of peptide-presenting structures fosters the development of different T-cell repertoires with completely different recognition properties. This thwarts the possibility that a pathogen will be able to evolve a way to bypass recognition.

GENERATION AND SELECTION OF POLYMORPHISMS; BIOLOGICAL CONSEQUENCES

The hallmark of HLA molecules, both class I and class II, is their extensive polymorphism. HLA polymorphism observed in different human populations is far greater than any other polymorphism observed in any other part of the human genome. This is a direct reflection of their role in the immune response. Pathogens characterized by different proteins and peptides, either in different epidemics or endemic to regions, account for much of the evolutionary drive responsible for the large number of alternative gene forms and their regional diversity across the human race. An individual with an adaptive immune system based on HLA molecules that effectively bind peptides derived from common pathogens is much more likely to have an effective response against that common pathogen. This results in selection of individuals with a particular HLA allele.

A *genetic polymorphism* implies that alleles of a gene are present at a frequency greater than expected from random mutation as a result of selection for diversity. In the case of the HLA genes, there is no preponderant wild-type allele, which would be an example of *balancing selection*. Instead, virtually all alleles qualify as genetically polymorphic. These reflect prior successful selection events. HLA polymorphisms provide a major evolutionary survival benefit, since they equip the species with a large number of very specific, but alternative, HLA molecules that differ in their binding pockets, are highly efficient in presenting different peptides, and select for different T-cell repertoires. A polymorphism that offers a survival advantage in a

given environment would eventually increase in frequency. This illustrates *frequency-dependent selection*, where the fitness of an individual bearing a particular allele increases, if it can manage an effective immune response to the particular pathogen.

Selection is a two-way street. It also operates on the pathogen, encouraging peptide variation. Variation in peptides drawn from common pathogens, and the introduction of novel pathogens with novel peptides, results in pressure on the species to create variation in HLA molecules among individual members of that species. The remarkably different frequency of the HLA alleles in different ethnic subsets tells the history of the successful adaptation of our ancestors' adaptive immune systems to a new environment with different pathogens, as well as bottlenecks resulting from migration and perhaps survival during periods of massive epidemics.

The evolutionary consequence of the diversification of genes encoding HLA molecules is seen at two levels. The first is at the level of the *individual* and is characterized by the presence of different HLA class I and class II loci, each of which codes for one or two different peptide-presenting HLA molecules for each locus. The second is at the level of the *population* and is evidenced by the development of a very large number of alleles at each locus, with each allele coding for alternative polymorphic gene forms and thus for various peptide-presenting allotypes, each of which has the potential to bind a different set of peptides. Duplication of HLA genes involved in peptide presentation is a genetic strategy that increases the range of peptide-presenting structures available to the individual, thus enhancing the variety of presented peptides that can be recognized and bound.[8]

KEY CONCEPTS

The Biological Significance of Polymorphisms; Why So Many?

- HLA class I and class II genes are extremely *polymorphic*.
  - Each HLA allele encodes molecules with different peptide-binding properties that influence the particular peptides recognized by the T cells.
  - The sequence of the HLA gene thereby determines the peptide recognition features of the adaptive immune response.
- HLA allelic polymorphisms are maintained by *frequency-dependent selection*, where the fitness of an individual bearing a novel allele increases as it can respond more effectively to certain pathogens.
- The multiple loci and numerous alleles per locus serve both the fitness of an individual and the survival of the species.
  - The polymorphism of the HLA system reflects the environmental/pathogen challenges to which a particular population has been exposed over evolutionary time.

HUMAN LEUKOCYTE ANTIGENS IN INFECTIONS, TRANSPLANTATION, AUTOIMMUNITY, AND CANCER

Human Leukocyte Antigen in Infections

The first line of defense during a pathogen infection is the triggering of innate immunity. The infectious agent and the foreign peptides generated from that agent then initiate an immune response involving immune cells and signals that subsequently induce adaptive immunity.

During the course of an infection, specialized APCs (dendritic cells, macrophages) are activated to take up antigen (Chapter 6). Increasing synthesis of class II coupled with presentation of a pathogen's peptides by class II to the immune system of the host activates CD4 T cells that recognize the HLA class II–peptide complex. This event triggers adaptive immunity. Eventually CD8 T cells recognize target cells infected with the pathogen by interacting with the HLA class I–peptide complex on their cell surface and the targets are eliminated, therefore containing the infection.

In response, pathogens have evolved mechanisms to overcome the specific attack by the host's immune cells. The first of these mechanisms is antigenic drift or shift, whereby the pathogen by minor (drift) or more substantive changes (shift) evade both humoral and cellular responses. These changes make the pathogen unrecognizable, as some of these new peptides do not form recognizable complexes with the HLA molecules of the host and therefore evade the T-cell responses. Another mechanism frequently adopted by viruses is to persist in vivo by not replicating until the immunity of the host is compromised. By not replicating, they avoid detection and they exist in a dormant state (latency). It therefore becomes evident that the infectivity of a microorganism reflects the interplay between several complex processes. These include the ability of the pathogen to create new molecular forms unrecognizable by the host and thus evade detection. These efforts by the pathogen to avoid immunity are then counterbalanced by molecular polymorphisms between HLA molecules that enable recognition of new molecular forms of the pathogen.[17]

Human Leukocyte Antigen in Transplantation

The large number of different HLA alleles greatly reduces the probability that two unrelated individuals will inherit an identical set of HLA alleles. In transplantation, two basic mechanisms of responses have been described (Chapter 89). The first involves the "direct" recognition of the peptide–HLA complex of the donor tissue by the T cells of the recipient. This is possibly through structural similarities of the HLA molecules of the donor that allow the TCR of the recipient to interact with the peptide–HLA complex. The second involves the "indirect" presentation of donor's HLA antigens processed by the recipient's APCs, generating peptides presented by the recipient's HLA molecules to the recipient's T cells. This indirect mechanism operates the same way as the presentation of a foreign antigen, whereby the HLA molecule is now the foreign antigen processed by the antigen-processing mechanisms of the recipient.

By using appropriate immunosuppressive agents and therapies, T-cell activation by the donor's HLA molecules after clinical transplant can be controlled. However, the major long-term problem is the presence of donor-specific antibodies that develop against mismatched HLA antigens. Controlling the antibody responses to mismatched HLA molecules has been very challenging and there is a need for continuous monitoring of their development. An approach holding some promise for the future is the utilization of regulatory T cells (Chapters 13 and 89), which have an important immunoregulatory role in all immune responses and can possibly induce transplant-specific tolerance.

Human Leukocyte Antigen in Autoimmunity

Selection of T cells on self-peptide presented by self-HLA allotypes in the thymus can predispose to autoimmunity. The inherent autoreactivity of the T-cell system can set the stage for the development of autoimmune diseases associated with the recognition of particular self-peptides, or peptides from external

KEY CONCEPTS

Human Leukocyte Antigen in Infections, Transplantation, Autoimmunity, and Cancer

- HLA and infectious agents participate in a balancing act: pathogens try to avoid the immune response and HLA alleles adapt to secure a robust immune response.
- Transplantation is an artificial system and the transplant is perceived by the immune response to be a foreign element.
  - Induction of tolerance is the objective.
  - Physicians promote immune nonresponsiveness to the transplant by pharmacologically manipulating the immune response.
  - Donor-specific antibodies are most commonly responsible for chronic rejections.
- Three features of the adaptive immune system can set the stage for pathogenic autoimmunity.
  - The TCR repertoire is selected by reactivity to self-peptides and self-HLA molecules.
  - The drive to genetic polymorphism generates alternative forms of peptide-binding HLA molecules that variably influence patterns of self- and nonself-reactivity.
  - Certain HLA allotypes bind particular self-peptides from critical target antigenic molecules that can predispose to autoimmune responses and disease.
- Oncogenesis is associated with the modification of patterns of antigen presentation by the cancerous cells to immune cells and by modification of immune cell responses to the cancerous cells.
- The cancer seeks to avoid immune surveillance and detection by the immune response.

antigens that mimic these self-peptides and are effectively presented by self-HLA.[18] Certain alleles encode HLA molecules that bind peptides from molecules expressed in sites favoring autoimmune recognition by T cells. These molecules become the target of the adaptive immune response. Together, features specific to certain sets of self-peptides and to certain self-HLA molecules can contribute to the progressive development of autoimmunity, and ultimately autoimmune disease.

Human Leukocyte Antigen in Cancer

Immune evasion is a critical process in tumor biology (Chapter 80). It is enabled by several mechanisms that include immunoediting, downregulation of HLA expression, secretion of immunosuppressive mediators, and expression of proteins that modulate immune checkpoints. Somatic mutation of HLA genes is a significantly frequent process in some tumor types. The strategies of immune evasion by cancer cells also include the silencing or aberrant expression of HLA class I and class II molecules, events that have often been associated with high-grade malignancy and metastatic potential in a variety of human cancers.[19]

In patients with solid tumors, HLA-G can contribute to a tumor-escape mechanism that favors cancer progression, and blocking strategies have been proposed to counteract it. Conversely, HLA-G can inhibit proliferation of malignant B cells due to the interaction between HLA-G and its receptor ILT2, which mediates negative signaling on B-cell proliferation. Thus, treatment of some malignancies can benefit by blocking HLA-G, whereas in others HLA-G induction can counteract tumor progression.[20]

The concept of developing cancer-specific immunotherapies involving tumor-specific antigens presented by HLA molecules to T cells has been successfully tested in a number of tumors, including testicular cancer and melanoma. These T-cell immunotherapies require adoptive transfer of T cells that have been expanded ex vivo and transferred back to the patient. Another approach is the use of retroviral vectors to transfer tumor-specific TCR genes into the patient's T cells before reinfusion.[21] Even though HLA molecules are involved in these processes, histocompatibility testing is not necessary in these therapies because the original T cells derive from the patient. However, if the mechanism of immunotherapy involves neoantigens (epitopes of mutated proteins) from tumors presented by specific HLA alleles, such individualized therapy needs to take HLA alleles into account.

Human Leukocyte Antigen Class I Molecules Regulate Natural Killer Cell Responses

The principal function of HLA class I molecules is the presentation of peptides that are expressed either by host-genome normally or dysregulated by tumorigenesis, or by foreign-genome derived from the infecting viruses and intracellular parasites. Cytotoxic CD8 T lymphocytes (CTLs) recognize specific HLA class I–peptide complexes via their TCRs and lyse if the HLA-laden peptides are derived from virus or tumor. If the cell-surface expression of HLA class I is downregulated as a consequence of some viral infection or tumor transformation, NK cells recognize and kill these HLA class I diminished abnormal cells.

NK cells are innate lymphoid cells programmed to kill target cells without a prior antigen "priming" period, as required for CTLs. Therefore, CTLs and NK cells serve as complementary killer cell components that control early immune responses to infection and tumor transformation. NK cells and CTLs are derived from a common lymphoid progenitor. They share several common features in development, morphology, cell-surface phenotypes, cytokine secretion, and lytic mechanism. However, they differ substantially in the tools used to recognize target cells: CTL use unique TCRs that are highly specific to self-HLA class I–peptide complex, while NK cells express an array of polymorphic receptors that bind self-HLA class I molecules.

Unlike TCRs that are generated by somatic genetic recombination, NK cells use a complex and sophisticated repertoire of activating and inhibitory receptors that are calibrated to ensure self-tolerance while exerting early assaults against viral infection and tumor transformation.[22] Human NK cell receptors include KLR, LILR, and KIR. The KIRs are the key receptors of human NK cells. Fourteen KIRs are identified: KIR2DL1, 2DL2, 2DL3, 2DL4, 2DL5, 3DL1, 3DL2, 3DL3, 3DS1, 2DS1, 2DS2, 2DS3, 2DS4, and 2DS5.[23] They are characterized by two or three immunoglobulin-like domains (2D or 3D; D denotes domain) in their extracellular portion and by either a long (L) or a short (S) cytoplasmic tail. Long tails are characteristic of the inhibitory forms and contain immunoreceptor tyrosine-based inhibition motifs (ITIMs) that trigger signals to switch off NK cell response (Chapters 3 and 12). The short-tailed activating KIRs lack ITIMs. Nevertheless, they have a positively charged amino acid residue in the transmembrane region that allows the interaction with the DAP-12, an adopter chain containing immunoreceptor tyrosine-based activation motifs (ITAMs), which trigger signals activating NK cell response.

The KIR gene family consists of 16 highly homologous genes clustered at the leukocyte receptor complex on chromosome 19.[24] Seven of them encode inhibitory KIRs (3DL1-3, 2DL1-3,

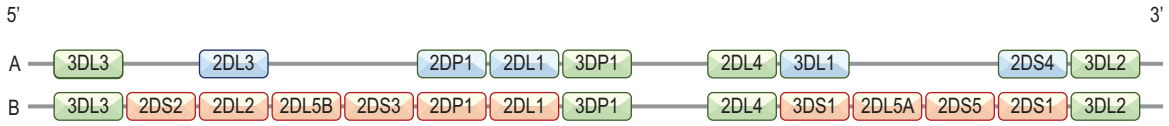

FIG. 5.5 Killer Cell Immunoglobulin-Like Receptor Haplotypes Vary in Gene Composition. Map of two core killer cell immunoglobulin-like receptor (KIR) haplotypes that differ quantitatively as well as qualitatively in gene content. Each box represents a KIR gene. The A haplotype comprises a set of fixed number of genes, most of which encode inhibitory KIR receptors. The B haplotype comprises more genes that are variable and mostly encode for activating KIR receptors. The framework genes conserved on both haplotypes are shown in *green*. A single chromosome may contain KIR genes belonging to either A or B haplotypes. All KIR genes are polymorphic at the nucleotide sequence level.

2DL5), six encode activating KIRs (3DS1, 2DS1-2DS5), one encodes a KIR that can trigger both inhibitory and activating signals (2DL4), and two are pseudogenes (2DP1 and 3DP1). The KIR genome displays a high degree of diversity determined by the variability in KIR gene content between haplotypes. The KIR haplotypes are broadly classified into two groups, A and B (Fig. 5.5). Group A haplotypes have a set of nine fixed genes (KIR3DL3-2DL3-2DP1-2DL1-3DP1-2DL4-3DL1-2DS4-3DL2) encoding for four inhibitory KIRs, 2DL1, 2DL3, 3DL1, and 3DL2, specific for four major HLA class I ligands, C2, C1, Bw4, and A3/A11 respectively. In contrast, the group B haplotypes are variable both in numbers and combinations of KIR genes, and comprising several genes (2DL2, 2DL5, 2DS1, 2DS2, 2DS3, 2DS5, 3DS1) that are not part of the A haplotype. While group A haplotypes contain only KIR2DS4 as an activating KIR, group B haplotypes contain up to five activating KIRs—KIR2DS1, 2DS2, 2DS3, 2DS5, and 3DS1. Random combinations of different gene-containing KIR haplotypes during familial inheritance produce substantial KIR genotype diversity in humans. The KIR A and B haplotypes are present in all human populations, but their frequencies vary considerably. In Africans and Caucasians, the A and B haplotypes are relatively in equal distribution, suggesting a balancing selection. Conversely, the A haplotype is overrepresented in Northeast Asians (Chinese, Japanese, and Koreans), while the B haplotype occurs most frequently in the natives of India, Australia, and America.[25]

In addition to haplotype diversity, each KIR gene exhibits sequence polymorphism, which is generally higher for the inhibitory KIRs than the activating KIRs. The KIR is considered to be second only to HLA in polymorphisms. These polymorphisms can influence cell-surface expression and alter receptor specificity and avidity, signal transduction, and cytokine secretion. The synergistic combination of allelic polymorphism and variable gene content individualize KIR genotypes to an extent where unrelated individuals almost always have different KIR types.

HLA-C is the prominent ligand for inhibitory KIR receptors. Half of the HLA-C allotypes have a lysine residue at position 80 that recognizes KIR2DL1. The remaining half of the HLA-C allotypes have asparagine 80 that binds to KIR2DL2 and 2DL3. KIR3DL1 binds to the Bw4 serological epitope, defined by amino acid residues 77 to 83, present on 40% of the HLA-B allotypes and certain HLA-A allotypes (HLA-A 23, 24, 25 and 32). KIR3DL2 binds certain HLA-A allotypes, such as A3 and A11. Very little is known about the ligands for the activating KIRs. Certain activating KIRs display a high degree of sequence homology with the corresponding inhibitory KIR in their extracellular Ig domains, and therefore activating KIRs would be expected to display a binding specificity similar to their inhibitory counterpart.

During NK cell development, interaction of inhibitory KIR receptor with cognate HLA class I ligand sets the functional threshold for NK cells, a process called "licensing."[26] Given that KIR genes at chromosome 19q13.4 and HLA genes at chromosome 6p21.3 are polymorphic and display significant variations, the independent segregation of these unlinked gene families produce diversity in the number and type of KIR-HLA combinations inherited in individuals,[27] which could potentially influence the health and disease status of a given individual. Consistent with this theory, combinations of certain KIR-HLA genes have been associated with diseases as diverse as autoimmunity, immune deficiency, infection, cancer, and reproductive failure.[28]

KEY CONCEPTS

Human Leukocyte Antigen Class I Molecules Regulate Natural Killer Cell Response

- NK cells arbitrate both innate and adaptive immunity. They are implicated in control and clearance of malignant and virally infected cells, and regulation of adaptive immune responses.
- Human NK cells use variable inhibitory and activating KIR receptors to discriminate between healthy and unhealthy cells.
  - Inhibitory KIRs recognize distinct HLA class I molecules and trigger signals that stop NK killing.
  - Activating KIRs presumably recognize determinants associated with infections and tumors, and trigger signals that activate NK killing.
- The effector function of a given NK cell depends upon the number and type of receptors it expresses and ligands it recognizes on the targets.
- Genes encoding KIRs and HLA ligands are located on different chromosomes and vary in number and gene type.
  - Independent segregation of KIR and HLA genes results in variable KIR-HLA combinations in individuals
  - Variable combinations influence an individual's immunity and susceptibility to a diverse array of diseases including autoimmunity, immune deficiency, infection cancer and reproductive failure.

HUMAN LEUKOCYTE ANTIGEN AND DISEASE ASSOCIATIONS

A large number of studies have established strong associations between certain diseases and individuals carrying particular HLA alleles. However, the mechanisms underlying HLA-disease associations remain unclear.

Hypotheses generated to explain these associations can be grouped into two general categories. The first invokes LD between a particular disease-associated HLA allele and another neighboring genomic element on the haplotype that is actually disease causative. Examples include hereditary hemochromatosis where association with HLA-A alleles is due to mutations in the *HFE* gene that is in LD with *HLA-A*, and congenital adrenal hyperplasia where association with *HLA-B* is due to linkage to a neighboring *CYP 21B* gene allele that causes 21-hydroxylase deficiency.

A second category implicates antigen presentation by the HLA allele. This category deals with diseases that have a strong immunological component. It has been hypothesized that inappropriate immune reactivity to some self-antigens can reflect aberrant T-cell repertoire selection, immune cross-reactivity with foreign antigens, immune attack of "altered self"-antigens, or differences in the expression levels of certain HLA alleles that secondarily influence the course of infections or cancer. MHC cusp theory represents an alternative hypothesis that HLA molecules promote disease due to their auxiliary allele-specific, yet antigen presentation-independent, biological effect.[29]

While many of these associations lie within the highly polymorphic HLA genes,[1] GWAS using SNP markers have established that the MHC region as a whole, and not only the HLA genes, harbors many SNPs associated with a large number of traits/diseases. Indeed, up to 90% of autoimmune disease variants have been located within noncoding regions of the genome.[30] It is therefore possible that disease-association elements may lie not only within the HLA genes but also dispersed within the rest of the MHC.

One possible genomic element that can be located within noncoding regions of the MHC and yet has a significant regulatory role is microRNA (miRNA). A search for functional genomic elements within the noncoding regions of the MHC genes revealed 12 miRNA, including hsa-miR-6891 (miR-6891) that is encoded by intron 4 of *HLA-B*.[31] Thus some, and perhaps many, diseases associated with specific MHC elements, whether HLA alleles or not, may involve noncoding RNAs (miRNAs or long noncoding RNAs) with important biological functions of a regulatory nature (Chapter 19).

Below is a compilation of selected diseases with strong HLA allele associations in different populations. A more extensive list of diseases and reference materials can be found elsewhere.[32–34]

Ankylosing Spondylitis

One of the more extraordinary observations in the MHC field was made in 1973 when the frequency of HLA specificity HLA-B27 was found to be 95% in patients with ankylosing spondylitis (AS), a disease characterized by arthritis affecting the spine and pelvis (Chapter 58). This observation implicated HLA-B*27 in the pathogenesis of AS and propelled the field of HLA and disease associations.[35] HLA-B*27:02 and B*27:05 demonstrate the highest degree of association, making genetic testing useful over and above serological testing. Even though the association of AS to B27 is among the strongest genetic associations with a common disease, the mechanism of action remains uncertain. Twin studies have confirmed that susceptibility to AS is genetically determined. HLA-B27 is found in 8% to 10% of the population, but only a minority of carriers develop the disease. Family studies suggest that less than 50% of the overall genetic risk is due to HLA-B27. A number of GWAS studies have demonstrated that non-HLA genes, including interleukin-23 receptor (IL-23R) and the protein-cleaving enzyme endoplasmic reticulum aminopeptidase 1 (ERAP1), also play a role.

B27 testing can be an instructive component of the diagnostic work-up of AS. Due to the chronicity of the disease and its gradual debilitating nature, a presumptive diagnosis based on B27 carrier status allows institution of treatment early in the disease when patients may have minimal symptoms.

Narcolepsy

Narcolepsy is a long-term neurological disorder characterized by irresistible daytime sleep attacks. These "sleep attacks" can occur at any time, and during any activity. Narcolepsy affects approximately 1 in 2000 people. Often those affected have low levels of the neurotransmitter hypocretin (also known as orexin). Hypocretin is a neuropeptide hormone that is responsible for controlling appetite and sleep patterns. Even though the cause of narcolepsy is unknown, the disease is believed to be of an autoimmune nature.

Family studies have shown that genetic heritability plays a role in narcolepsy. Twin studies show that only 25% to 30% of twins are concordant for the disease, again implicating environmental or other epigenetic events. The *HLA-DQB1*06:02* allele on the *DRB1*15:01-DQA1*01:02-DQB1*06:02* haplotype has been shown to be one of the most important predisposing genetic factors, with 85% to 95% of narcolepsy patients carrying this haplotype.[36] Conversely *DQB1*05:01* and *DQB1*06:01* have a protective effect. The protective associations of these two DQB1 alleles with narcolepsy may provide an insight to the molecular mechanisms for the differential associations of DQB1*06:01 and DQB1*06:02, as the size of P4 pocket of DQB1*06:02 is larger than the DQB1*06:01. This difference possibly influences the binding of larger residues in the DQB1*06:02 allele, which may explain the opposite effect these two alleles have on narcolepsy. Homozygosity for *HLA-DQB1*06:02* increases the risk for narcolepsy as compared to heterozygous persons, as does heterozygosity for HLA-*DQB1*03:01/DQB1*06:02*.

HLA testing for *DQB1*06:02* in narcolepsy is a useful aid to diagnosis. However, as instructive as the association may be, it is not specific as there are many narcolepsy patients without *HLA-DQB1*06:02* and many individuals with *HLA-DQB1*06:02* who do not have narcolepsy.

Type 1 Diabetes

Type 1 diabetes (T1D) is also known as insulin-dependent diabetes mellitus (IDDM) (Chapter 71). This is a disease in which the body fails to maintain normal glucose levels because of the destruction of insulin-producing pancreatic islet cells. The disease is characterized by infiltration of immune cells (CD4 and CD8 T cells) into the islets of the pancreas and by autoantibody production. When over 90% of an individual's beta cells are destroyed, clinical symptoms ensue.

Twin studies have shown that the concordance rate for the disease is 30% to 50%. This suggests that other factors, including environmental triggers (such as diet and viral infection) and epigenetic changes, may be involved. The major heritable risk of T1D comes from the HLA system (about 50%). More than 90% of Caucasian patients with T1D carry the haplotypes *DRB1*03:01, DQA1*05:01, DQB1*02:01* or *DRB1*04:01, DQA1*03:01, DQB1*03:02*. Patients heterozygous for these haplotypes carry a greater susceptibility risk. The critical residues are thought to be position 52 on the DQα chain and position 57 on the DQβ chain. The presence of arginine at position 52 on the DQα and the absence of aspartate on DQβ are strongly associated with

T1D. Conversely, in Caucasian populations resistance to T1D is conferred by *DQA1*01:02*, *DQB1*06:02*. Besides the contribution of the HLA, GWAS studies have identified a number of other genomic regions associated with the development of T1D.[37]

HLA typing is useful as an aid to diagnosis of T1D. Considering that the islet destruction by the autoimmune processes is progressive, associated with the presence of autoantibodies, HLA typing of siblings of T1D-affected patients may help assess risk for the non-symptomatic sibling.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic disease characterized by inflammation of the synovial lined joints leading to joint deformation and disabilities (Chapter 53). The presence of autoantibodies like rheumatoid factor and anti-cyclic citrullinated antibodies (ACPAs) are largely responsible for the autoimmune classification of this disease. It is a multifactorial disease that involves both environmental and genetic factors. RA prevalence in the general population is less than 1%. Studies with monozygotic twins show a 12% to 15% concordance rate for the disease, underlying genetic heritability, but also other factors such as environmental triggers or epigenetic components. Multiple genetic loci have been shown to contribute to the risk of developing RA. Of these, the HLA class II DRB1 is the most important and contributes 30% to 50% of the overall genetic susceptibility risk.

The HLA DRB1 alleles associated with RA share common sequences at positions 70 to 74 of the beta chain.[38,39] This has led to the shared epitope hypothesis. Amino acids in these positions influence both peptide binding and contact between HLA and TCR. HLA-DRB1 alleles associated with RA have any of the following sequences: QKRAA, QRRAA, RKRAA, and RRRAA. In Fig. 5.4, the yellow-colored residue in the α-helical ribbon is glutamine and the magenta residue is positively charged lysine. Hydrogen bonding to two side chains of the peptide is shown. The region around position 70 is involved in the formation of a peptide side-chain binding pocket that binds the fourth amino acid side chain contained within the HLA molecule. The presence of a negatively charged residue at position 71 or 74 removes susceptibility for RA. The presence of two alleles of this group increases susceptibility and favors development of more severe disease.[40]

GWAS have led to the identification of over 100 additional loci associated with RA. Among these is the protein tyrosine phosphatase, nonreceptor type-22 *(PTPN22)* gene, which codes for an inhibitor of T-cell activation. The majority of these additional loci are expression quantitative trait loci (eQTLs) in which genetic variants regulate the level of transcription.

Multiple Sclerosis

Multiple sclerosis (MS) is a complex neurodegenerative disease in which myelin sheath degradation is caused by the immune system (Chapter 66). Based on family and twin studies, the disease has been shown to have a large genetic component. The *HLA-DRB1*15:01*, *DQA1*01:02, DQB1*06:02* disease susceptibility haplotype accounts for up to 35% of the risk of developing the disease. A number of GWAS studies have identified more than 100 additional candidate genomic regions conferring risk, including cell adhesion, leukocyte activation, apoptosis, Janus kinase (JAK)-STAT signaling, nuclear factor-κB (NF-κB) activation, and T-cell activation and proliferation.[41] Although HLA typing is of minimal diagnostic value for MS, genetic testing may provide insights into the mechanism of the disease.

Celiac Disease

Celiac disease (CD) is an autoimmune disorder of the small intestine caused by a combination of genetic and environmental factors (Chapter 75). The disease is characterized by diarrhea and weight loss, among other symptoms. Monozygotic twins demonstrate 90% concordance, indicating a strong genetic component.[42] HLA genes contribute to about 40% of the genetic risk. GWAS studies implicate additional genomic regions. The environmental disease-triggering factor comes from a component of wheat gluten, the protein gliadin (family of closely related proline- and glutamine-rich proteins). CD is a lifelong condition. The only effective treatment is a gluten-free diet.

The implicated HLA molecules are the class II antigens DQ2 and DQ8. The DQ2 molecule mostly associated with CD is encoded by the *HLA-DQA1*05:01-DQB1*02:01* alleles, with a small proportion encoded by the *DQA1*02:01-DQB1*02:02* genotype. The DQ8 molecule associated with CD is *DQA1*03-DQB1*03:02*. Approximately 90% of patients with CD express HLA-DQ2, with the remaining 10% mostly expressing HLA-DQ8. Deaminated by transglutaminase, negatively charged gluten peptides bind strongly to HLA-DQ2 and -DQ8 to present an HLA-gluten peptide complex that activates CD4 T cells. The immune response also includes the development of antibodies against gluten and auto-antibodies to endogenous tissue transglutaminase.

As a complement to histology, genetic testing for HLA-DQ can help confirm the diagnosis in patients not known to be tissue-transglutaminase-antibody positive.

DRUG HYPERSENSITIVITY AND PHARMACOGENOMICS

Severe cutaneous adverse reactions to drugs include syndromes such as Stevens-Johnson syndrome/toxic epidermal necrolysis and drug reaction with eosinophilia and systemic symptoms or drug-induced hypersensitivity syndrome (Chapter 50).[43] Although their incidence is very low, they are severe, life-threatening adverse drug reactions with mortality rates as high as 5% to 12.5%. The associations reported between drug hypersensitivity and specific HLA alleles has been a recent finding and has led to the possibility that hypersensitivity reactions may be predictable and preventable. Drugs associated with immunologically mediated drug-induced hypersensitivity include the anticonvulsant carbamazepine and the antiretroviral agents nevirapine and abacavir. Regulatory agencies have issued relevant and informative pharmacogenomics guidelines: (http://www.fda.gov/Drugs/ScienceResearch/ResearchAreas/Pharmacogenetics/ucm083378.htm).

Carbamazepine

Carbamazepine is an aromatic amine anticonvulsant used for the treatment of epilepsy and other seizure disorders, trigeminal neuralgia, and bipolar disorder. Approximately 10% of patients develop mild cutaneous adverse reactions. Carbamazepine has been shown to be associated with class I *HLA-B*15:02* or *A*31:01*.

Nevirapine

Nevirapine is a non-nucleoside reverse transcriptase inhibitor widely prescribed for HIV-1 infection. Hypersensitivity HLA class I and II associations have been described for *DRB1*01:01, B*35:05, Cw8*, and *B*14:02*.

Abacavir

Abacavir belongs to the family of nucleoside reverse transcriptase inhibitors and is used for the treatment of HIV-1 infection. Two recent abacavir studies have shown that 100% of patients who develop abacavir drug hypersensitivity carry *the HLA-B*57:01* allele. Even though not all of *HLA-B57:01*-positive patients develop hypersensitivity, this predictive value supports the use of *HLA-B*57:01* typing prior to initiating abacavir treatment.

KEY CONCEPTS

Human Leukocyte Antigen and Disease Associations

- In multifactorial immune disorders, HLA alleles frequently confer a higher risk than other genomic factors.
- Most commonly the HLA molecules are directly involved in the disease process.
- Some associations reflect inheritance of an HLA haplotype where the HLA gene is in LD with other, causative, non-HLA genes.
- In some cases, the HLA molecule, the associated peptide, and the TCR are sufficient for disease development.
- In others, the HLA molecule may be necessary, but not sufficient for disease development.
- Twin studies showing less than 100% disease concordance suggest that in addition to the HLA genes, environmental of metagenomic modifications are also likely involved in many HLA-associated disorders.

METHODS OF DETECTING HUMAN LEUKOCYTE ANTIGEN POLYMORPHISMS. THE HUMAN LEUKOCYTE ANTIGEN TYPING PROBLEM

Since the discovery of the HLA genes over 50 years ago, there has been a concerted effort to properly categorize and characterize these very polymorphic genes. Our understanding of the complexity and polymorphic nature of the HLA genes has been substantially improved as the technologies for characterizing these genes have improved.

Serological and cellular testing in the 1960s (antibody and mixed lymphocyte culture [MLC]) was supplemented by two-dimensional electrophoresis and restriction fragment length polymorphism (RFLP) analysis in the 1970s and early 80s. The development of the polymerase chain reaction (PCR) in the mid-1980s revolutionized our understanding of these genes. Methods utilizing sequence-specific oligonucleotide probes (SSOP or SSO) and sequence-specific primers (SSPs) provided the means for further evaluating the highly variable sequence motifs within the HLA genes. Sanger sequencing-based typing (SBT) in the 1990s advanced tissue typing and transplantation genetics by providing an unprecedented molecular view of HLA polymorphism in the context of exonic variation. Most recently, NGS provides entire HLA gene characterization and haploid sequence determination.[44]

To meet the growing demand, clinical HLA typing over the past decade has transitioned from a combination of serological and DNA-based methods to more direct, faster, affordable, and informative DNA-based techniques. Even though serological typing may continue to have some clinical or research-based testing in determining the expression of the HLA molecule at the cell surface (a function that DNA-based testing cannot always verify), direct DNA-based typing techniques have all but replaced serological methods in routine HLA typing.

DNA-Based Typing Techniques: Sequence-Specific Oligonucleotide Probes, Sequence-Specific Primer, and Sequencing-Based Typing

The techniques primarily in use today in clinical immunogenetics laboratories are SSO, SSP, and SBT. The genomic regions analyzed are usually exon 2 and 3 of class I and exon 2 of class II genes. However, this rather limited genomic characterization generates many typing ambiguities.

SSO interrogates polymorphic differences using panels of individual DNA oligo probes that differentially hybridize to the target of interest. The probe either perfectly matches or mismatches the target's polymorphic sites. Drawing upon the sequence database of HLA alleles, the hybridization pattern of the oligoes is compared to an expected pattern and is interpreted as an HLA type.

SSP uses panels of specific primer sets that overlap polymorphic sites. Perfectly matched primers produce an amplification product while mismatched primers do not. The pattern of amplification from multiple primer sets determines the HLA allele.

SBT amplifies and sequences specific gene regions, usually exons, through a process of polymerase-based extension of specific sequencing primers. It uses fluorescently labeled nucleotides that indicate allelic differences base by base.

Next-Generation Sequencing and Its Potential Impact on Human Leukocyte Antigen Typing

Protocols utilizing NGS technology are on the rise as they provide the means for the complete characterization of these genes and the elimination of ambiguities in a cost-efficient manner.[45] Regardless of the platform (Illumina MiSeq; Thermo Fischer Ion Torrent; Pacific Biosciences, Oxford Nanopore), these systems resolve a number of technological barriers that continue to hamper existing molecular techniques, such as inflexibility in typing practices, discovering novel alleles, and the inability to easily resolve phase ambiguities. While HLA typing by NGS has already been adopted by several labs, it is likely that this new method will transform the way HLA typing is performed in the coming years.

KEY CONCEPTS

The Resolution of the Human Leukocyte Antigen Typing Problem

- Currently, HLA typing is primarily performed through DNA-based methodologies.
- The coming dominant methodology most likely will be single molecule DNA sequencing (NGS) the length of each class I or class II gene.

HUMAN LEUKOCYTE ANTIGEN NOMENCLATURE

The HLA genes are very polymorphic (over 27,000 named and close to 30,000 sequence entries that have not been named yet) and expected to further increase, approaching hundreds of thousands, possibly millions. This has led to the development of comprehensive systems for their naming.

The WHO Nomenclature Committee for Factors of the HLA system undertook the first systematic approach for the naming of the HLA alleles in 1968. The HLA naming convention has undergone substantial iteration as earlier naming conventions were unable to address the growing numbers and complexity of alleles (i.e., A*02 and B*15 have more than 100 alleles). The most recent nomenclature was introduced in 2010. Colons (:) were added into the allele names to act as delimiters of the separate fields (field separator). Thus, each HLA allele name has a unique number corresponding to up to four sets of digits separated by colons (Figs. 5.6 and 5.7).

The first field following the asterisk in the allele name (**XX**:xx:xx:xx) describes the allele family and generally corresponds to the serological assignment carried by the allele. HLA typing defined only at the first field is often referred to as "low resolution typing." The second field following the first colon (xx:**XX**:xx:xx) is assigned sequentially as new alleles are determined (e.g., 01, 02, 03,….101, etc.). Together, these two fields (**XX**:**XX**) indicate one or more nucleotide substitutions that change the HLA protein coding sequence and are often referred to as "high resolution typing." Indeed, the Harmonization of Histocompatibility Typing Terms Working Group recently defined a high-resolution typing result "as a set of alleles that encode the same protein sequence for the region of the HLA molecule called the antigen-binding site and that exclude alleles that are not expressed as cell-surface proteins."[46] The third field (xx:xx:**XX**:xx) is for designating synonymous nucleotide substitutions within the coding sequence that do not change the amino acids of the protein, while the fourth field (xx:xx:xx:**XX**) identifies sequence polymorphisms in introns, or in the 5′ and 3′untranslated regions.

All alleles receive at least a four-digit name, which corresponds to the first two sets of fields. At the end of the allele name, specific characters have been added (N=null, L=low expression, S=secreted, C=cytoplasm, A=aberrant, Q=questionable) to

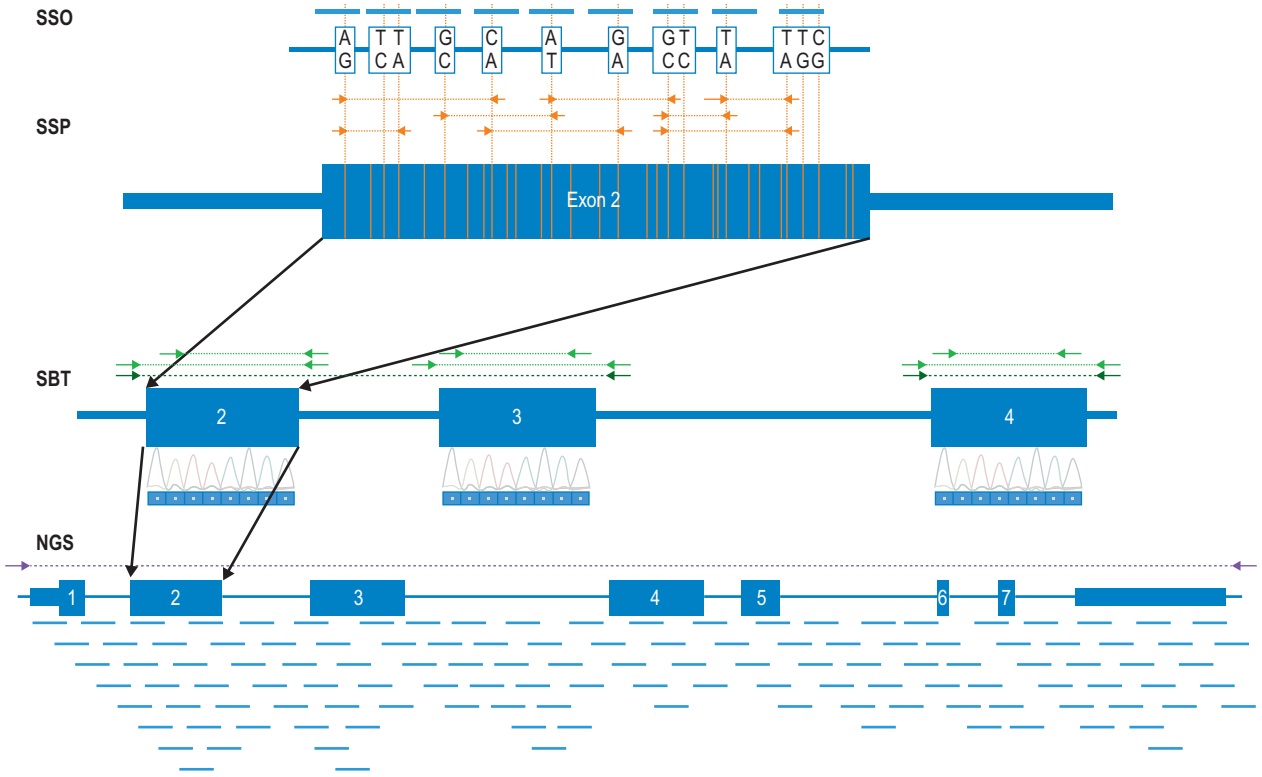

FIG. 5.6 Examples of Molecular Human Leukocyte Antigen Typing Techniques and Their Methods of Interrogating the Human Leukocyte Antigen Genes. For any given human leukocyte antigen (HLA) gene (*dark blue rectangles*), sequence-specific oligonucleotide probes (*SSOs*) of approximately 20 bp (*light blue lines*) can provide single-nucleotide resolution of haplotype differences (polymorphic differences, *red lines* in exon 2). This requires a complex panel of oligonucleotide probes to discern differences between HLA alleles. This probe set is static and therefore cannot adjust to novel alleles. Sequence-specific primers (*SSPs*) *(orange arrows)* can provide haplotype- or allele-specific resolution of nucleotide differences and additionally provide some level of phasing between polymorphic sites. As with SSOs, these oligonucleotide sets are complex and static, limiting their flexibility. Sequencing-based typing (*SBT*) provides whole-exon information on the polymorphic content of the HLA allele (amplification primers *[dark green]* and sequencing primers *[light green arrows]*) but cannot discern phasing, as this method generally does not rely on allele-specific primers for amplification as a first step. Next-generation sequencing (*NGS*) provides whole-gene amplification (amplification primers, *purple arrows*) and detection of polymorphic content for any HLA allele (known or unknown) and provides significant phasing between polymorphic sites that are within the read lengths of the system being used (usually between 200 and 1000 bp). This is accomplished through the alignment of thousands of short overlapping reads that are combined to form a single consensus sequence *(blue lines)*.

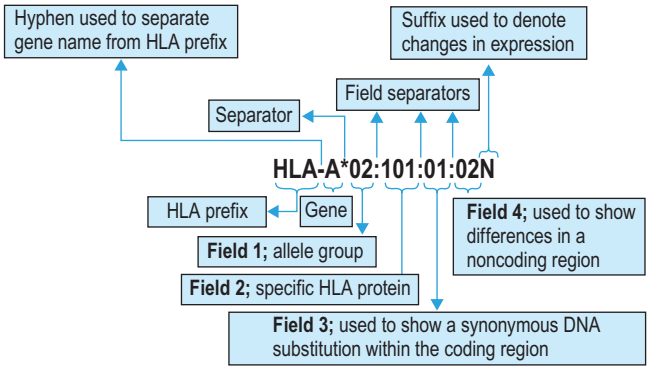

FIG. 5.7 Human Leukocyte Antigen *(HLA)* Nomenclature. (Courtesy Steven G. E. Marsh, Anthony Nolan Research Institute, London, United Kingdom.)

designate unique characteristics for an allele such as whether a protein is not expressed (i.e., HLA-A*24:09N) or whether the expression of the protein is unclear (i.e., HLA-A*32:11Q).[44] For ambiguous allele strings, the codes "P" and "G" were introduced. A group of alleles having nucleotide sequences that encode the same protein sequence for the peptide-binding domains (exon 2 and 3 for HLA class I and exon 2 only for HLA class II alleles) are designated by an upper case "P" that follows the 2-field allele designation of the lowest numbered allele in the group. For example, *HLA-A*01:01:01:01, HLA-A*01:01:01:03*, or *HLA-A*01:37* could be named *HLA-A*01:01P*.

A group of alleles that have identical nucleotide sequences across the exons encoding the peptide-binding domains (exons 2 and 3 for HLA class I and exon 2 for HLA class II) were named after the first allele in the sequence and given a code of "G" as a suffix. The upper case "G" follows the first three fields of the allele designation. For example, *HLA-A*01:01:01:01, HLA-A*01:01:01:03*, or *HLA-A*01:37* could be named *HLA-A*01:01:01G*. More details regarding HLA nomenclature can be found in the site http//hla.alleles.org.

In order to manage and to have access to the sequences of the ever-growing number of alleles, the IMGT/HLA Database project was initiated in 1997 as part of a European collaboration. The database is an invaluable resource, as it provides detailed DNA sequences and protein sequences for all known HLA alleles. It is also interactive as it incorporates tools for data retrieval and analysis so the user can select what segments of the gene/molecule to examine and compare among different alleles. It can also be used for new data submission.

ON THE HORIZON

- Advanced technologies for detailed characterization of the whole MHC should clarify and define functional interrelationships between MHC genes and the genomic elements responsible for many MHC-associated diseases.
- Computational approaches for the accurate definition of peptide-binding properties of individual HLA alleles will enable prediction or manipulation of the trimolecular complex of HLA–peptide–TCR in order to control responses to infectious diseases, autoimmunity, transplantation, vaccine design, and cancer.
- Immunotherapies for cancer involving neoantigens and HLA alleles will be individualized for precision.
- Understanding the genomic organization of the exceedingly complex MHC will most likely reveal and teach us important lessons relevant to the organization and operation of the rest of the genome as well.

FUTURE LEARNING AND RESOURCES

This chapter provides only a limited sketch of this fascinating, but complex, topic. The reader is referred to the *HLA Facts Book* for a more detailed and very accessible presentation, though slightly out of date. There are also a number of websites with extremely useful information. Four stand out in terms of their utility and the curated quality of the information. The IMGT/HLA Database contains all MHC sequences and has a variety of sequence alignments of different alleles as well as specialized sequence searches (http://www.ebi.ac.uk/imgt/hla/index.html and http://hla.alleles.org). The NCBI maintains dbMHC, which includes several components of the International Histocompatibility Working Group (IHWG) that are of interest. Among these are the anthropology database that contains HLA class I and class II allele and haplotype frequencies in various human populations (http://www.ncbi.nlm.nih.gov/projects/mhc/). Information about the genes and the genetic organization of the MHC is contained in several sites, but perhaps the most comprehensive and comprehensible is that using the Entrez search engine (http://www.ncbi.nlm.nih.gov). A comprehensive database of MHC ligands and peptide motifs is located at http://www.syfpeithi.de.

Antigens and Antigen Presentation

Harry W. Schroeder Jr. and Robert R. Rich

ANTIGENS

By the late 19th century, "antibodies" were the hypothesized molecular entities that mediated specific immune memory, could neutralize toxins, and could form precipitates when mixed with the molecular species that induced their formation. In almost all cases, evidence for the presence of such antibodies required the prior exposure of responding individuals to the very substances (or ones closely related, as in the case of toxoids) with which the antibodies reacted. This *specific* relationship of inducing agent and antibody, which is the basis of antigen-specific *adaptive immunity*, led to the concept of an *antigen* as that molecular entity that could induce, in the blood of exposed individuals, the formation of antibodies specific for it. By inventing the concept of the specific *receptor*, with a specificity analogous to the lock-and-key model of enzymes, Paul Ehrlich could explain the specificity of antibodies in molecular terms of a reciprocal interaction between a receptor and its binding partner (*ligand*).[1] This explanation defines a fundamental relationship. An "antigen" is any molecule that binds specifically to the antigen-binding domain of an "antigen receptor" (be it antibody or T-cell receptor—TCR [Chapter 4]). This concept of "antigen" is useful for understanding the molecular basis of recognition and binding and for the practical use of the scientist or pharmacologist who is focused on the use of the antigen/antigen receptor interaction to detect, or purify, or neutralize a molecule of interest.

At the level of the organism, the concept of antigen focuses on its other critical property; that it *can induce* the proliferation and differentiation of the lymphocytes that bear its specific receptor and that it can promote the production of the antibodies that bind it. This view of "antigen" is that of the vaccinologist who wants to induce effective immunity to an organism expressing that antigen, or of the clinician who seeks to understand why a patient does or does not respond to a particular allergen, self-antigen, or tumor antigen. More than a century later, explaining the antigenicity of antigens (i.e., the response at the cellular and organismal level to a given molecule) is one of the fundamental issues in immunology. Why some or all individuals may fail to respond adequately to some pathogen or tumor antigens, why others respond detrimentally to our own self-antigens (autoantigens) or antigens present in tissue grafts (alloantigens), how we can improve the efficacy of vaccines, and how we can prevent or treat autoimmune and tissue-graft-related diseases (graft-*vs.*-host disease [GVHD] and graft rejection) all remain open questions.

Advances in the domain of *innate immunity* have led to the need to distinguish between the antigens that elicit adaptive immunity and the ligands that bind innate immune receptors (Chapter 3). Innate receptor ligands are often described as exhibiting patterns or motifs characteristic of a microbial class or physiological condition. To capture these notions, Janeway[2] and Matzinger[3] coined the terms "pathogen-associated molecular patterns" (PAMPs) and "danger signals," respectively. A prototypical innate ligand is lipopolysaccharide (endotoxin), which is produced by many bacteria and serves as a ligand for Toll-like receptor 4 (TLR4) (Chapter 3).[4] Another is dsRNA, which is an obligatory intermediate in RNA virus replication and serves as a ligand for TLR3. Both have features that are characteristic of a pathogen class. However, a variety of ligands bind to TLR4 that have no obvious "motif" shared with LPS. Moreover, danger signals also do not exhibit an obvious "motif" but instead can be merely characteristic of a physiological state. For example, the receptor for advanced glycan intermediates, RAGE, is also a receptor for HMGB1, a nuclear transcription factor released to function as an inflammatory cytokine by macrophages.[5] Thus, it is problematic to define innate receptor ligands in terms of intrinsic properties. Moreover, ligands for innate receptors can also serve as antigens for adaptive antigen receptors. Consequently, the conceptual difference between antigens and innate receptor ligands depends not on the intrinsic properties of the ligands, but on the properties of the receptors to which they bind.

It has become a cottage industry to reveal "bridges" between innate and acquired immunity, blurring the initial clear-cut distinctions between the two. Moreover, we see a continual expansion of the function of innate receptors as registrars of states of internal stress (Matzinger's "danger") rather than primarily as monitors of external threats (Janeway's "stranger"). It is thus useful to see the categories of innate and acquired immune receptors as a continuum rather than as essentially distinct and in need of "bridges."

At one extreme, purely innate receptors are expressed constitutively among tissues and over time. They are present in the "ground state" of the organism and thus are innate. They function like most other receptors of the body to respond homeostatically to perturbations in the internal milieu of the organism, particularly to an experience of physiologic stress to immunologic homeostasis, but also to a molecular threat of stress as flagged by microbial products.

At the other extreme, the acquired receptors of the adaptive immune system are pleomorphic rather than unimorphic and inducible rather than constitutive. In the case of the two acquired immune receptors defined in jawed vertebrates, antibodies and TCR, the induction is mediated by irreversible changes in the DNA sequence encoding them (Chapter 4).[6] The function of acquired immune receptors (antigen receptors) is to record exposure to an inciting antigen and thus mediate specific immune memory, which permits the "faster, stronger" reaction of a secondary immune response. In particular, many T- and

B-cell responses are accompanied by the rapid proliferation of those cells expressing unique and specific antigen receptors (clonal selection and expansion) (Chapters 7, 9, and 10).

In so-called "bridge" mechanisms, we see aspects of short-term memory (often called "priming") affected by innate mechanisms as well as acquired mechanisms that fail to exhibit memory. For example, pre-exposure to activation of certain Toll-like receptors can lead to enhanced responses through the same or other innate receptors over a period of half a day. Conversely, some T- and B-cell responses exhibit a strong "primary" response to antigen without evidence of an enhanced memory response. Moreover, priming through innate receptors serves as a critical mechanism for enhancing certain aspects of acquired immunity.

This chapter is organized around five themes: *antigen*, how antigens are manipulated by cellular and enzymatic machinery to permit recognition by antigen receptors (*antigen acquisition, processing*, and *presentation*), and, finally, the *antigen-presenting cells* (APCs) themselves. A central function of APC is to present antigens to antigen-receptors on lymphocytes (signal 1) but also to provide costimulatory signals (signal 2) and regulatory signals (signal 3) to those lymphocytes.

Antigens in the sense of *ligand* are defined tautologically as the ligands for antigen receptors (Fig. 6.1). This definition includes the *acquired* antigen receptors found on the surface of B cells (B-cell receptors [BCRs], also known as membrane-bound immunoglobulin [mIg]) and TCR. The closely related category of lymphocytes, natural killer cells, also bear receptors that can recognize antigens, but unlike B cells and T cells, these receptors are encoded in the germline rather than being acquired during development (Chapters 2 and 3).[7]

It is important to distinguish the antigen receptors just described from class I and class II major histocompatibility complex (MHC) *antigen-presenting molecules* (Chapter 5). MHC molecules bind short peptides (*oligopeptides*) and certain other molecules and present them to the TCR on T cells and, in some cases, to innate immune receptors on natural killer cells. MHC molecules themselves are innate receptors in that they are encoded in the germline, and their expression is regulated homeostatically.

The antigen bound by a particular antigen receptor is sometimes called its *cognate antigen*. This makes sense because of the allied concept that the great majority of lymphocytes express only a single antigen receptor due to the mechanism of allelic exclusion, with singular specificity for its own cognate antigen (Chapter 4). This concept is useful even if up to 5% of lymphocytes actually express more than one receptor. Because lymphocytes retain expression of that singular receptor when they divide, we can identify clones of that recognize the same cognate antigen. In turn, lymphocyte clones that bear different antigen receptors can recognize different aspects of the same cognate antigen.

Whether or not a particular molecule will serve as cognate antigen for any receptor depends on many factors. Because of the stochastic mechanisms used to generate the antigen-binding site of forming antigen-receptors (e.g., N region addition [Chapter 4]) and the relatively short life span of most naïve lymphocytes, there is a real possibility that many potential antigens, especially those present at low concentrations, will never encounter a cognate receptor in the lifetime of the individual. Alternatively, the antigen might be sequestered within the cell or body in such a way as to escape detection by lymphocytes.

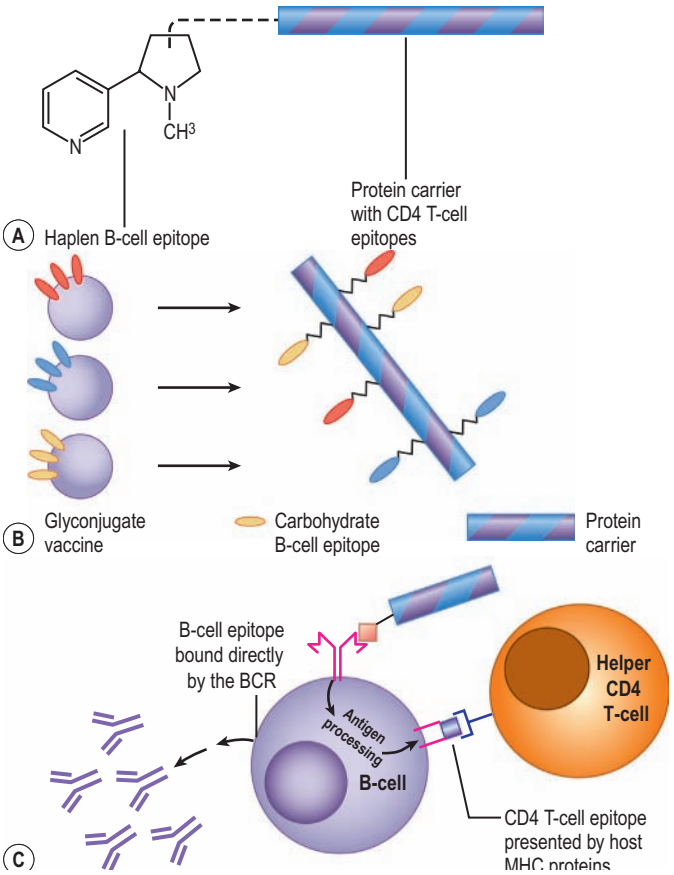

FIG. 6.1 Haptens, Carriers, and Two Kinds of Antigens. (A to C) The antigen-binding site of an antibody binds an antigen through the latter's epitope: this is the biochemical sense of antigen used in ELISA, flow cytometry, and western blot analysis. Haptens are self-conjugating antigen moieties that can modify epitopes and provide new binding specificities. Haptens and many antigens by themselves are not immunogens, the second sense of "antigen." Immunogens (complete antigens) are processed by antigen-presenting cells to reveal T-cell epitopes presented by MHC molecules. *MHC,* Major histocompatibility complex.

Such antigens are sometimes called *cryptic antigens*. Many *self-antigens* are recognized by developing T cells in the thymus or developing B cells in the primary or secondary lymphoid organs, causing the clonal deletion or the development of anergy in responding lymphocytes (Chapter 10). Only a few of these self-antigens escape these tolerance mechanisms and threaten to become disease-causing *autoantigens*.

The term *immunogen* refers to "antigen" in the classic, second sense of an antigen that, when used to immunize, stimulates an immune response to itself. Likewise, an *allergen* is an antigen that stimulates an allergic response.

Facets of antigens, such as their role as ligands for receptors and as inducers of antibodies, are given special terms. For example, "hapten," "epitope," and "determinant" refer to molecular structures that physically engage the antigen receptor (see Fig. 6.1). Antigens that are not also immunogens are "incomplete antigens," whereas immunogens are also called "complete antigens."

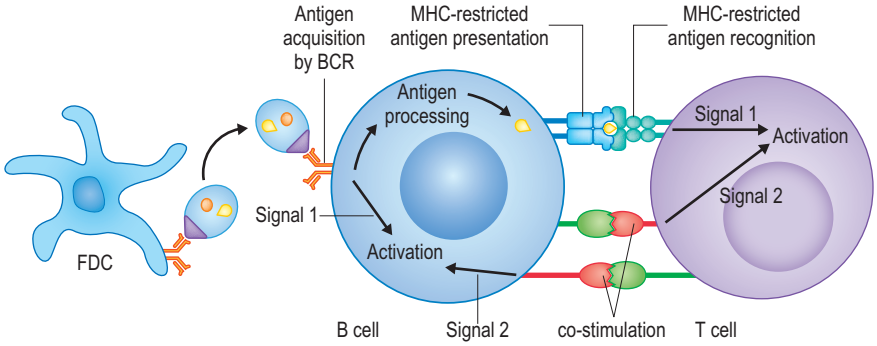

FIG. 6.2 Antigen Presentation. Follicular dendritic cells in germinal centers present antigens bound to local antibodies stored in their surface iccosomes. B cells acquire antigens through their BCR and present processed peptide epitopes via MHC molecules to T cells. T cells recognize antigens presented by MHC molecules on antigen-presenting cells. B and T cells receive signal 1 through the BCR and TCR, respectively. *BCR*, B-cell receptors; *FDC*, follicular dendritic cell; *MHC*, major histocompatibility complex.

Finally, we draw an important distinction between the terms "immunogen" and "adjuvant." Many immunogens are inactive unless mixed with an adjuvant. Adjuvants, such as alum (a form of aluminum hydroxide), have two critical functions in vaccines (Chapter 87): a depot effect and an immunostimulatory effect. As a depot, the adjuvant allows retention of the antigen in the tissue in order to provide steady stimulation. As an immunostimulant, it promotes the acquisition, processing, and presentation of antigen by APC.

Antigens for Antibodies

Antibodies are classically defined as soluble immunoglobulins (Ig). They reside in the blood and lymph fluids, and they permeate the tissues. When imbedded in the membrane of the producing B cells, immunoglobulins serve as the BCRs for antigen. They also have an essentially invariable constant region (termed Fc), which is largely responsible for its biological effects.

Antibodies can bind *via* their Fc domains to Fc receptors (FcRs) or other moieties (e.g., complement receptors) on a variety of other molecules (Chapter 8). Antibodies bind antigens through their highly variable *antigen-binding V domains* that are located at the *N*-termini of the heavy and light chains. BCRs can signal the presence of antigen to an antibody-producing B cell, and antibodies can signal the presence of antigen to cells expressing Fc or complement receptors. Immunoglobulins can also mediate *antigen acquisition* by B cells or FcR-positive APC by receptor-mediated endocytosis (Fig. 6.2).

Immunoglobulins are heterodimeric molecules composed of two heavy (H) chains and two light (L) chains. The *antigen-binding site* of immunoglobulin is formed by the juxtaposition of three highly variable intervals on the H chain and three hypervariable intervals on the L chain (see Chapter 4). The structure of this site can be in the form of a knob, a shallow groove, or a deep pocket. The latter can accommodate molecular structures as small as a single sugar molecule and as large as an oligosaccharide or oligopeptide of six or seven residues. These minimal structures on the antigen that actually bind to antibodies are termed the *epitopes*. Antigens can be much larger—for example, as large as a protein, virus, or bacterium - and can be viewed as collections of epitopes.

Epitopes can be formed by a string of contiguous residues of a protein or other polymer or by a set of non-contiguous residues that are juxtaposed in the three-dimensional structure of the parent antigen. The latter are called *conformational* epitopes because they are present in the antigen only when it is properly folded. They can be destroyed if the protein is denatured as, for example, on a Western blot. Conformational epitopes are typically found on the surface of native proteins and are often important for neutralizing antibodies, which must detect the epitope on a three-dimensional antigen surface. Linear epitopes for antibodies are usually available only when the protein is denatured, as in a Western blot, or if they are present in external loops of a protein. Transitory epitopes can be created when a protein undergoes conformational changes, such as when a protein is undergoing folding or unfolding, when an epitope is exposed by alterations in the structure, or when an epitope is displayed by the association between two different proteins.[8]

The term *hapten* comes from a Greek word meaning "hold" and is drawn from the dye industry, where the word refers to the ability of dyes to *hold fast* to fabrics despite washing. A hapten is the smallest chemical moiety of an epitope that can bind effectively to the antigen-binding site of an antibody and is usually used in relation to the "hapten-carrier" concept. Naturally occurring haptens include contact-sensitizing metals such as nickel and plant products such as urushiol, the toxin from poison ivy (Fig. 6.3).

Haptens, as exemplified by the small molecule trinitrophenol, are not immunogens for two reasons. First, by themselves, they form few electrochemical contacts with the antibody, and so their binding strength is usually very low. Second, they are so small that they cannot be subdivided to produce multiple epitopes, a feature critical to immunogenicity. Haptens are typically monovalent and so do not themselves cross-link BCRs. When chemically conjugated to proteins, they can become multivalent and, by modifying self-peptides, they can create epitopes for T cells.

KEY CONCEPT

Antigens for B cells

- Immunogens contain
  - epitopes that bind to the antigen-binding sites of antibodies
  - Class II epitopes for T helper cells
- Haptens can have almost any chemical nature.
- Epitopes on native proteins are usually amino acids discontinuous in the primary sequence but juxtaposed and found on the surface of the folded molecule.

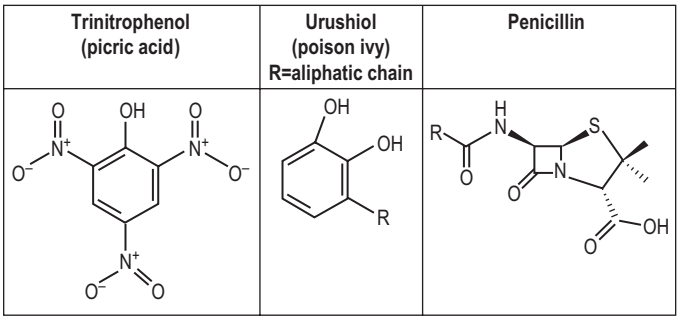

FIG. 6.3 Some Examples of Haptens

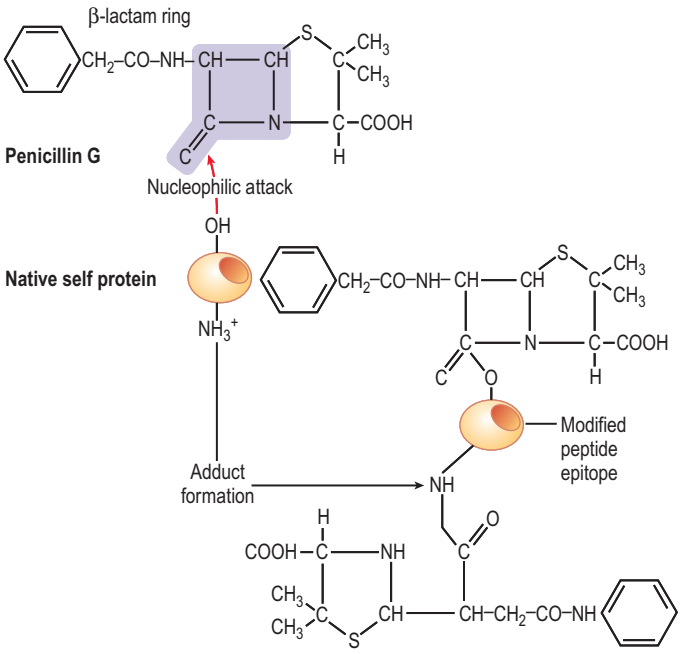

FIG. 6.4 Sensitizing Agents Such as Penicillin Create Neoantigens by Forming Covalent Adducts With Self-Proteins. Penicillin allergies involve both antibodies against penicillin and T-cell responses to penicillin-modified self-proteins. The same chemical reaction that allows penicillin to inhibit peptidoglycan formation in bacteria leads to adduct formation of cellular proteins. Nucleophilic attack by penicillin G *(upper left)* on the β-lactam ring *(shaded)* opens the ring and creates an adduct *(lower left)* with serines and lysines. The lactam adducts can be presented to B cells as modified self-proteins or processed for presentation by MHC molecules to T cells as lactam-conjugated self-peptides.

Immunogens for B cells can be placed into either T cell-dependent (TD) or T-independent (TI) categories. TI antigens come in two flavors. Type 1 TI antigens can stimulate antibody production from even neonatal B cells in the absence of MHC-restricted T-cell help. The prototype of TI antigens is lipopolysaccharide (LPS), also known as *endotoxin*, derived from the cell wall of bacteria. LPS drives polyclonal responses of mouse B cells because it is an activating ligand for the Toll-like receptor TLR4 (Chapter 3) found on B cells. LPS stimulates the proliferation of B cells with LPS-specific antigen-receptors, and it can induce class-switching by B cells and thus produce IgG or IgA. Human B cells normally do not express TLR4 and are unresponsive to LPS. However, TLR4 and LPS-responsiveness is inducible in human B cells by ligands for other TLR molecules, and patients with Crohn disease do express functional TLR4.[9]

Type 2 TI antigens stimulate antibody production from mature but not neonatal B cells. These antigens, which include the ABO blood group antigens, are typically polysaccharides or glycolipids with repeating epitopes.[10] These can cross-link multiple BCR on a single B cell and thereby activate it. B cells activated in this manner usually need help from T cells to undergo class-switching. Thus, antibodies against ABO antigens and other Type 2 TI antigens are of the IgM class. Since IgM cannot be transported across the placenta by the IgG transporter, FcRn (Chapter 8), this explains why incompatible ABO blood groups rarely present a problem for the fetus or newborn.

T-dependent antigens contain epitopes recognized by T cells as well as for B cells (see Fig. 6.1). B cells endocytose the parent antigen through the BCR, then process and present peptide epitopes to helper T cells within germinal centers.[11] The T and B cells provide co-stimulation for each other, inducing class-switching and somatic hypermutation of immunoglobulin genes in the B cells (Chapter 7).[12] Most T-dependent antibody responses quickly switch from initial IgM to IgG, IgA, or IgE. The simultaneous and cooperative responses of T cells and B cells in lymph node *germinal centers* facilitate immune responses of both cell types.

T-dependent antigens can be modeled by the hapten-carrier concept, in which B-cell responses to the hapten require help from T cells responding to the epitopes within a carrier protein (see Fig. 6.1).[13] Experimentally, carrier proteins are typically foreign proteins. However, self-antigens can also serve as carriers in clinically relevant examples. For example, both urushiol, the active ingredient of poison ivy, and penicillin (see Fig. 6.3) readily form covalent adducts with cellular proteins (Fig. 6.4). These haptenated self-proteins constitute *neoantigens*, which in this case elicit both T- and B-cell allergic responses.

Haptens are actually not the smallest moieties that can be recognized specifically by antibodies. *Determinants* are the molecular structures that actually *determine specificity*, and these can be as small as a single-side chain of an amino acid. For example, antibodies can be generated that recognize the difference between a serine and a phosphoserine as part of a larger protein. In this case, the determinant is the phosphate group. A single nitrate group is the determinant differentiating the two haptens dinitrophenol and trinitrophenol.

Using appropriate carriers and adjuvants, antibodies can be raised *in vivo* against almost any chemical moiety. There seem to be only two limitations to what can be an antigen in the sense of ligand. The antigen must be perceived as "foreign" in some sense to the responding animal, and it must provide a surface to which an antibody can form an electrochemical attachment. It is often possible to trick the immune system into generating autoreactive antibodies, and many of these arise in autoimmune reactions. Similarly, bacteriophage libraries of recombinant antibodies (*phage display libraries*)[13] can be screened for almost any chemical specificity without regard for self/non-self discrimination.

The notion that "anything goes" is powerful theoretically but has its practical limitations. On the one hand, the powerful adjuvants and immunization protocols that can be used in experimental animals cannot be used in humans, so that vaccinologists

are still frustrated by their inability to reproducibly stimulate effective immunity to many antigens. On the other, a variety of substances are effectively and fortunately hypoallergenic or hypoantigenic, permitting their use in cosmetic and implantable devices. These substances are non-proteinaceous and so lack T-cell epitopes. They are also chemically inert and thus unable to haptenate proteins. Finally, though sometimes polymeric, they seem to lack a suitable chemical surface for forming high-affinity bonds with antibodies. For example, despite efforts to find contrary evidence, polysiloxane ("silicone") is immunologically inert even in experimental models.[14] This compound is used in contact lenses, breast implants, and other medical devices. These practical comments do not exclude the theoretical possibility that some individuals might generate antibodies reactive with some hypoantigenic substances.

Carbohydrate Antigens

Polysaccharides tend to be type 2 T-independent (TI) antigens.[10] Examples include the pneumococcal capsular polysaccharides targeted by pneumococcal vaccines and the human ABO blood group antigens.[15] The latter are a "family" of related antigens expressed by most tissues and by many kinds of commensal bacteria. The polymorphic *ABO* locus encodes a glycosyltransferase that functions as a haptenating enzyme to modify the H antigen, a polysaccharide found on many different glycoproteins and glycolipids. The common *O* allele is functionally silent so that only the H antigen is generated. Both active enzymes (alleles *A* and *B*) transfer a uridylate diphosphate (UDP)-charged sugar to glycoproteins and glycolipids. The *A* and *B* enzymes use UDP-*N*-acetyl-galactosamine and UDP-galactose, respectively, as sugar donors.

Individuals of genotypes *AA*, *BB*, or *AB* express enzyme A only, B only, or both A and B antigens as self-antigens and are tolerant of them and of bacterial antigens with the same sugars. In contrast, *O*-type individuals make neither *A* nor *B* antigens. As a result, both antigens appear foreign to *O* individuals, and exposure to common bacteria induces both anti-*A* and anti-*B* antibodies. Similarly, *A*-type individuals (genotype *AO* or *AA*) make anti-B antibodies, and B–type individuals (*BO* or *BB*) make anti-A antibodies. These systems are called "blood type," referring to the *type of antibodies the person does not make*. The antigens, however, are found in all tissues, including red blood cells. Infants are exposed to the Type 2 TI A and B antigens through environmental exposure soon after birth. Anti-A and anti-B antibodies consequently begin to accumulate early in life (though use diagnostically is not valid during the first year) and appear as "natural antibodies"[16] of the IgM isotype.

Antigens as Ligands for T-Cell Receptors

Most epitopes recognized by TCR are short peptides generated from proteins through *antigen processing*. Consequently, as peptides rather than native proteins, epitopes recognized by T cells are generally linear. The biochemical definition of antigen indicates that epitopes recognized by TCR should bind directly to them. However, although direct binding of the epitope to TCR can be demonstrated in rare cases, the affinity of these interactions is typically too weak for measurement and probably too weak for biological effects. The weak affinity of a TCR for its epitope reflects, in part, thymic education.[17] which has several mechanisms to select against T cells that recognize epitopes directly (Chapter 9). Instead, epitopes for TCR first bind tightly to MHC molecules (class I for CD8 T cells and class II MHC for CD4 T cells), and it is the molecular complex of MHC plus peptide that is recognized by the TCR (Chapter 5).

Conventional oligopeptide epitopes may include modified amino acids such as phosphoserine or sugar residues. Hapten-modified self-peptides are major determinants of allergic responses to non-protein environmental agents, such as metals, cosmetics, and antibiotics. However, certain class Ib (or "non-classical") MHC molecules (Chapter 5) seem to be specialized for recognizing non-peptide antigens. For example, CD1 presents certain lipids, both endogenous and bacterial, to invariant natural killer (iNKT) cells[18]; MR1 presents unidentified bacterial ligands to mucosa-associated invariant TCR (MAIT) T cells[19]; and HLA-E presents peptide sequences to CD8 T cells and NK cells.[20] With rare exceptions, MHC molecules do not discriminate between self and foreign peptides. Indeed, the vast majority of epitopes bound by MHC molecules are self-epitopes.

The binding site for peptides in both class I and class II MHC molecules is a deep cleft that interacts with the peptide backbone and two or three of the side chains.[21] The latter are considered *anchor* residues and define the *binding motif* of the MHC molecule. The need for terminal anchoring severely limits the length of epitopes for class I MHC molecules to seven to ten amino acids, though longer peptides can sometimes bind by looping out central residues. The short length of peptide epitopes for class I molecules is enforced by a closed-ended binding cleft that binds both amino and carboxyl termini (Fig. 6.5). In class II molecules, both ends of the binding cleft are open. While, theoretically, this allows longer peptides to bind, in practice, the degradation of the ends of these peptides that usually occurs during antigen processing causes the lengths of most peptides presented by class II molecules to be limited to 15 to 20 amino acids.

Three factors generally control whether a given peptide will be recognized by T cells as antigen: foreignness, binding affinity, and antigen processing (Chapter 10). Roughly half of all patho-

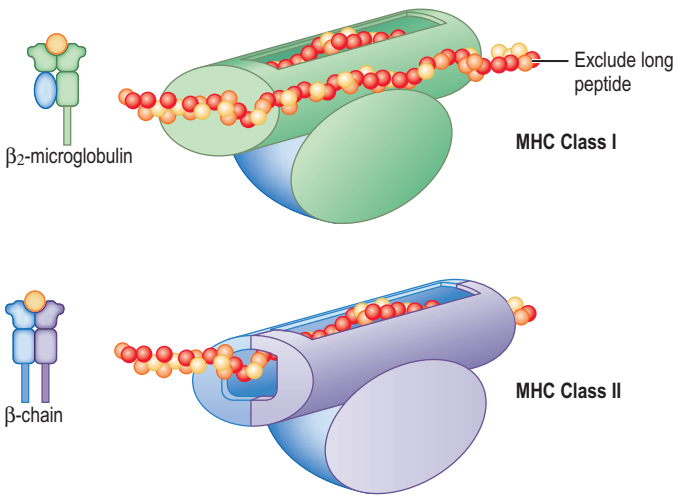

FIG. 6.5 Peptide Binding by MHC Class I and II Molecules. Class I molecules are usually closed at both ends. The peptide termini must interact with terminal sockets. Peptides that are too long must be cleaved *(arrows)* prior to entry into the binding site. The clefts of class II molecules are open at the ends, permitting the binding of longer peptides. *MHC*, Major histocompatibility complex.

gen peptides are identical to self-peptides and, except for cases of autoimmunity, are tolerated by the immune system. The binding affinity of an epitope for most class I MHC molecules can be predicted fairly well.[22] However, naturally occurring proteins must be processed proteolytically (see below), and many sequences that could be good epitopes are either not generated effectively or are destroyed proteolytically.[23] For example, the chicken egg white protein ovalbumin contains three sequences that bind very tightly to class I MHC molecules in the C57BL/6 laboratory mouse, and each of these is a potent antigen on its own. However, only one of these is produced naturally from the parent protein. Identifying the mechanisms and rules governing the proteolytic production of epitopes remains a major challenge.

The fact that any given allelic form of MHC molecule recognizes two or three anchor residues with high specificity severely limits the "universe" of peptides that it can present to T cells. Thus, a given class I allele can recognize only about 0.01% of all possible octamer peptides. Two different MHC alleles may recognize distinct anchors and thus see radically distinct antigenic universes. Nonetheless, most proteins have few potential T-cell epitopes, and some proteins will not be antigenic in certain individuals simply because they do not produce a foreign peptide that binds with sufficient strength to any of the individual's MHC molecules.

Human populations have hundreds of allelic forms of class I and class II MHC molecules. The high polymorphism of MHC molecules has three important biological implications. First, most individuals from unrelated parents are heterozygous for each MHC locus, effectively doubling the size of their antigenic universe. Second, while many individuals may be unable to respond to common or novel pathogens, at least a few individuals are likely to be protected due in part to the promiscuity of their MHC molecules.[24] This may account for the prevalence of certain MHC haplotypes in populations exposed to malaria and for genetic vulnerabilities or resistance to HIV. Finally, epitopes detected by one individual may be invisible to the T cells of another person. Thus, subunit vaccines effective for some MHC haplotypes may be ineffective for others. For example, the hepatitis B surface antigen subunit vaccine is often ineffective in individuals homozygous for certain *HLA* haplotypes.[25]

Major Histocompatibility Complex Restriction

Recognition of peptides by TCR is said to be "MHC-restricted." This has two meanings, molecular and genetic. In both, "restriction" is seen as a limitation or condition on the ability of T cells to recognize their antigens. In the newer, molecular view, the ability of T cells to recognize their peptide epitopes is "restricted" by the MHC molecules that physically present the epitopes to them. Indeed, X-ray crystallography has shown that about 90% of the contacts made between TCR and the MHC:peptide complex are with the MHC molecule.[26] However, the older, genetic meaning of "MHC-restricted" is more severe. T cells can recognize their cognate epitope *only* when it is presented by a particular allelic form of MHC molecule. This property was revealed long ago because of the extraordinary genetic diversity (polymorphism) of most class I and class II molecules in most species, including humans. Most MHC alleles are very distinct from one another, and most of the differences are concentrated in the portions of the MHC molecules that bind peptide and TCR. As a result, different allelic forms of MHC differ both in what peptide they can bind and how they will be seen by the TCR. Due to thymic selection (Chapter 9), TCRs have specificity for both the particular peptide and a particular MHC molecule and are unable to recognize other combinations of peptide and MHC. Thus, unless they happen to be MHC-matched, antigen-specific T cells from one individual are unable to recognize even the same peptide presented by APCs from other individuals.

There are a number of potential benefits for the operation of MHC restriction and for why T cells recognize antigens presented by MHC molecules (Fig. 6.6). Antigen-processing increases the complexity of pathogen antigens by exposing epitopes not available on the surface of pathogens. The exquisite specificity of MHC molecules reduces the universe of detectable foreign peptides, but it also reduces the universe of detectable self-proteins, decreasing the risk of autoimmunity. The requirement that T cells do not respond unless activated by co-stimulation from the APC is enforced by anchoring MHC molecules on the APC. Thus, MHC-restriction forces a T cell to be restricted by antigen-presenting cells, again limiting the risk of pathogenic self-reactivity.

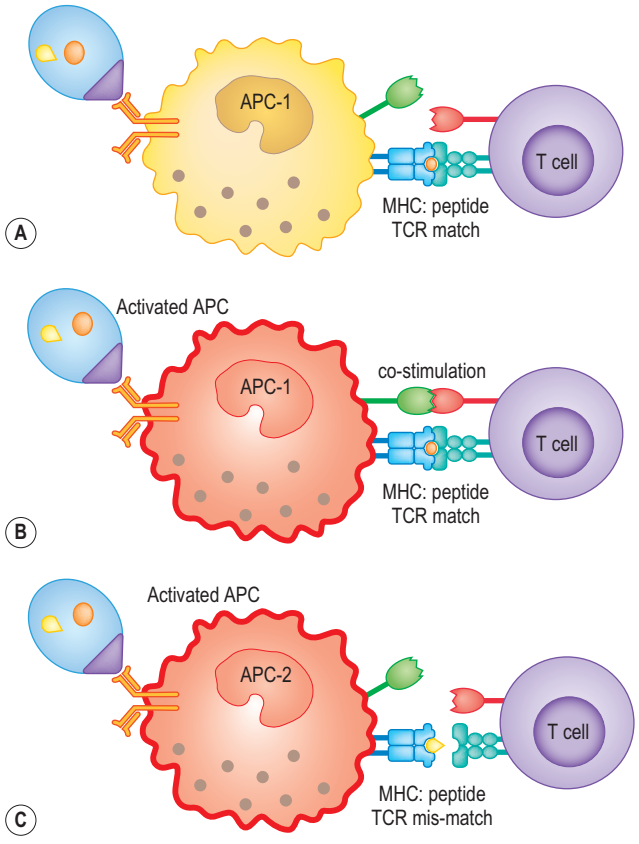

FIG. 6.6 MHC Restriction Carries Out Two Critical Functions. First, by presenting processed peptides derived from within proteins and pathogens, MHC molecules sample a broader antigenic landscape than antibodies, whose epitopes are surface oriented. Second, naive T cells respond to cognate epitopes only when presented by an activated APC (B) but not when the APC is resting (A). Experimentally observed MHC restriction results when an activated APC cannot present the proper MHC/peptide pair (C). *APC*, Antigen-presenting cells; *MHC*, major histocompatibility complex; *TRC*, T-cell receptor.

Alloantigens

Thymic selection ensures that T cells recognize non-self peptides in the context of self-MHC molecules. A clinically important exception to this specificity manifests as "alloreactivity".[27] If lymphocytes from imperfectly matched donors are mixed in a mixed-leukocyte reaction (MLR),[28] about 5% of the T cells from one donor cross-react with some of the MHC:peptide complexes of the other. Thus, a T cell specific for a peptide from cytomegalovirus (CMV) and restricted by the class I molecule HLA-A2 might recognize some other peptide presented by HLA-B7 from the other donor. Disparities in the *major histocompatibility complex antigens* (MHC molecules, also known as *major transplantation antigens*) between an organ donor and recipient are very likely to stimulate graft rejection because of the high probability of cross-reactivity. But even if the donor is perfectly matched for MHC molecules (as happens in one-fourth of full-sibling pairs), minor histocompatibility differences can also cause tissue rejection. The *minor antigens* are proteins that are polymorphic or of limited expression in a species and thus, in humans represent donor-recipient disparities in one or more of the roughly 30,000 different proteins encoded by the genome. A prominent example of a minor histocompatibility antigen is the H-Y antigen, encoded by the Y chromosome, which causes T cell-mediated rejection of male donor tissue by female recipients. The MLR is extraordinarily sensitive to the presence of alloantigens and is a good predictor of whether organ transplants will be accepted.

KEY CONCEPT

Properties of Superantigens

Defining Properties
- Presented and recognized as an unprocessed, native protein.
- Contact TCR and MHC molecules outside the traditional antigen-binding groove.

Specific Properties
- Selectively stimulate T cells expressing certain TCR Vβ chains
- TCR recognition is not MHC allele restricted.
- Stimulate both CD4 and CD8 T cells in an MHC class II-dependent manner.

Superantigens

"Superantigens" are microbial proteins that bind both class II MHC molecules and TCR, causing activation of the T cell.[29] Superantigens include certain bacterial toxins, such as staphylococcal enterotoxin A (SEA) and toxic shock syndrome toxin (TSST), and viral proteins, such as the mouse mammary tumor virus (MMTV) superantigen. Superantigens bind class II MHC molecules as intact macromolecules and bind outside of the peptide-antigen binding groove. Class II binding is independent of the specific MHC allele (though often with a preference for one class II isotype—DR, DQ, or DP). Each type of superantigen also binds TCR belonging to a characteristic subset of Vβ families and, in some cases, also makes contact with the TCR Vα chain. Nonspecific T-cell activation appears to be a bacterial strategy to avoid microbe-specific recognition. However, by stimulating large numbers of clones of a specific Vβ family, bacterial superantigens can also induce an overwhelming T-cell response with massive cytokine release leading, for example, to food poisoning and toxic shock syndrome.

ANTIGEN-PRESENTING CELLS

Cells that Present Antigens to B cells: Follicular Dendritic Cells

In many respects, B cells do not need antigen to be presented to them by any other cell: they express high-affinity antigen-receptors that have no contextual requirement for antigen-binding. However, engaging B cells with soluble, especially monovalent, antigens can tie up the BCR in a non-signaling and even tolerogenic mode. Efficient B-cell activation requires either a polyvalent antigen, as with TI antigens, or some form of additional mechanism that effectively cross-links the BCR and induces signaling. Such cross-linking can be mediated by immune complexes (assemblies of antigens and antibodies), antigens found on the surface of pathogens (thus rendered polyvalent), or antigens fixed by complement. Two complement receptors on B cells (CR1=CD35; CR2=CD21) bind fragments of C3 and C4 attached to antigens (Chapter 4).

Most B cells are activated in the limiting architecture of the germinal center, and clonal activation leads to nearly monoclonal responses in each center. In this context, a unique cell, the *follicular dendritic cell* (FDC; Chapter 2),[30] plays a special role in presenting antigens to B cells. FDCs represent less than 1% of the cells within a germinal center and are tightly associated with B cells and associated macrophages.

FDCs are stromal, not hematopoietic, in origin and are required for the formation of germinal centers. The presence and activity of FDCs in germinal centers require the presence of lymphotoxin, a member of the tumor necrosis family. FDC's play an organizing role by secreting the chemokine CXCL13, which binds to CCR5 on lymphocytes (Chapter 15), inducing the secretion of lymphotoxin.[31] FDCs trap and accumulate antigens through FcR and complement receptors (especially CR1, CR2, and C4bR) and store them in *iccosomes* (immune complex-coated bodies).[32] Antigen in iccosomes is stable for months.

The ability of FDCs to accumulate antibodies secreted by local B cells gives them a high-affinity trapping mechanism with a specificity cognate with those B cells. FDCs are thought to be critical for isotype switching, affinity maturation, and B-cell memory. Because C4b is a surrogate activator of CD40, FDC-presented antigen can drive these processes in the absence of CD40L; likely explaining the efficacy of many T-independent antigens. FDCs are non-phagocytic, do not express MHC class II or T-cell activation molecules such as B7/CD80/CD86, and do not present antigens to T cells. However, by providing antigen to B cells or germinal center dendritic cells, FDCs can activate germinal center T cells indirectly.

FDCs aid in the formation of tertiary lymphoid tissues in inflamed tissues and contribute to unwanted immune reactions, such as in chronic organ rejection and autoimmunity associated with vascular inflammation such as SLE. Fetal and maternal immune cells come into direct contact at the decidua, and the fetus can be considered an allograft to the mother. Uterine dendritic cells (DC) within the decidua have been implicated in the maintenance of pregnancy by inducing tolerance.[33] These observations suggest that manipulating FDCs may be therapeutically useful in controlling autoimmunity.

Cells that Present Antigens to T Cells

Cells that present antigens to and activate *naïve* T cells are called *professional Antigen-Presenting Cells* or, more commonly,

just APC.[34] Unlike class I MHC molecules, which are expressed on almost all nucleated cells in the body, class II molecules are expressed almost exclusively by professional APC. Among human cells, MHC class II and costimulatory molecules can also be expressed by activated T cells and inflamed endothelial cells. In addition, MHC class II is expressed by medullary and cortical epithelial cells in the thymus, where they play an important role during positive and negative selection.

Naïve T cells have a high threshold for activation and require costimulatory ligands found on professional APC. These include B cells, macrophages, mast cells and basophils, and both myeloid and plasmacytoid dendritic cells (DCs). Activated T cells have vastly reduced requirements for co-stimulation, and their responses are proportional to the level of MHC expression. For typical class I molecules, this means almost all nucleated cells are potential targets for CD8 T cells. However, because most cells do not express costimulatory molecules, they do not stimulate naïve T cells.

The different types of professional APCs have distinct but overlapping properties. Conventional (myeloid) DC (cDC) are by far the most potent in terms of their ability to present a wide variety of antigens to naïve T cells.[35] cDC in their immature form are constitutively tissue-resident phagocytes, actively engulfing and digesting any antigen in their vicinity. In this stage, they express few costimulatory or class II MHC molecules. Once activated by a "danger" signal, cDC mature rapidly. They stop phagocytosis and begin to express recently digested antigens through upregulated MHC molecules. They become mobile and follow a chemokine trail from the tissue to nearby draining lymphatics, through which they reach lymph nodes where they begin to present their antigens to T cells. Upregulated costimulatory molecules and cytokines allow the DC to activate naïve T cells and direct their differentiation.

The functions of cDC can be modulated. In the absence of full activation, they tend to be tolerogenic. Once activated by certain innate receptor ligands, cDC express IL-12 and drive a Th1 response (Chapter 11). However, if IL-10 is provided by some other cell type, cDC secrete little IL-12 and drive a predominantly IL-2 response. Other cytokine environments are able to skew cDC functions so that they drive Th-17 or Treg pathways.

Although cDC are extremely potent on a per-cell basis, the activity of other professional APC types should not be underestimated because they vastly outnumber the cDC. Macrophages are active phagocytes and can activate naïve T cells. B cells are not phagocytic but can internalize cognate antigens through their BCR. As a result, they are several orders of magnitude more sensitive than cDC to limiting antigen concentrations.[36] Plasmacytoid DC secrete very high levels of type I interferon but are not potent antigen-presenters. In contrast, mast cells are not phagocytic but may be specialized for presenting antigens acquired through FcR.

Antigen Acquisition

We have hinted that APCs acquire antigens through multiple mechanisms. From a topological perspective, antigens are either exogenous or endogenous. Exogenous antigens (i.e., antigens synthesized externally to the APCs) are acquired by the cells and its associated antigen processing apparatus chiefly through endocytosis. Endogenous antigens (i.e., antigens synthesized within the APC) are already "acquired" by the cell but are often in the wrong cellular compartment. Viral capsid proteins synthesized by an infected cell and inserted into the cell membrane can be internalized by endocytosis for antigen presentation. Autophagy is an important mechanism for digesting internal structures, including invasive bacteria as well as mitochondria and other organelles. It is part of the cellular physiology of most cell types. In APC, autophagy also mediates the presentation of internal antigens. However, most peptides presented by class I MHC molecules are "acquired" through a non-phagocytic mechanism involving ubiquitin, specialized proteases, and both peptide and protein transporters located in the membrane of the endoplasmic reticulum.

Pinocytosis, essentially very small-scale reversible endocytosis of the cell membrane, samples the fluid phase outside the cell.[37] This takes place in many cells and is a property of "ruffled" membrane edges found at the leading edge of mobile cells.

Receptor-mediated endocytosis through clathrin-coated pits internalizes many receptors and their cargo ligands. This is a property of most cell types and is a major mechanism for acquiring antigens for APCs. Typical FcR for IgG, such as found on mast cells, macrophages, and dendritic cells, internalize upon cross-linking (Chapter 8). These cells readily present antigens found in immune complexes. In contrast, B cells express an alternatively spliced form of this receptor that binds antibodies at the surface but does not internalize. Thus, as a group, B cells are not effective at presenting generic antigens acquired through FcR. However, the BCR itself readily internalizes after being cross-linked, and B cells are exquisitely adept at presenting their cognate antigen.

Phagocytosis is a mechanism for internalizing particles that may be as large as the cell itself. Initial engagement of multiple receptors causes a local deformation of the cell surface and a partial invagination of the cell membrane. This deformation, coupled with the triggering of specific receptors, leads to subcellular enzyme activity that changes the lipid composition of the membrane bilayer and remodels the cytoskeleton in the vicinity of the particle. This relaxes the membrane, allowing deeper invagination and creating the *phagocytic cup*. If the particle is small enough, the cup deepens until, when the particle is nearly engulfed, the outer edge of the cup closes like a purse-string, leading to membrane fusion and creating a new external surface and an intracellular vesicle. The endocytic vesicle undergoes successive fusion with other vesicles until fusion with the lysosome. Phagocytosis is a property of phagocytes (DC, macrophages, and neutrophils) and in these cells is accompanied by further inflammatory activation of the phagocyte.

In addition to professional phagocytes, other cell types can also phagocytose apoptotic cells, using a specialized set of receptors that detect apoptotic cells. Many cells can mediate this process, including those that do not possess large lysosomes. Phagocytosis of apoptotic cells by APC is often anti-inflammatory. In contrast, phagocytosis of microbes or necrotic cells, including cells undergoing secondary necrosis after apoptosis, is inflammatory.

Autophagy, found in even the simplest eukaryotes, is a major mechanism for mediating normal protein turnover, protection from intracellular pathogens, and resistance to starvation. It allows a cell to recycle its own organelles. Perhaps 50% of the peptides presented by class II MHC molecules are endogenous peptides acquired through autophagy. Autophagy also mediates presentation by class I MHC molecules of exogenous and some endogenous peptides.[38]

Three broad categories of autophagic mechanisms have been described. *Macroautophagy* mediates the engulfment of microbes or organelles through autophagosomes. *Microautophagy* closely resembles the vesicle fusion described for phagocytosis. *Chaperone-induced autophagy* allows vesicles, including lysosomes, to import proteins directly from the cytoplasm. These three forms of autophagy are linked by their reliance on a set of *ATG* (Autophagy) gene products. ATG8 and ATG12, both ubiquitin-like proteins, nucleate a phagophore attached to an invading microbe or targeted organelle, followed by rapid recruitment of a lipid membrane to seal the object into an autophagosome. Macroautophagy can be induced by bacterial products, such as LPS, and by drugs, including rapamycin. Autophagy can control the activity of specific cellular proteins, complicating the interpretation of many experiments, including NFκB, so that the role of ATG proteins may be very indirect.

Cross-presentation refers to the idea that an APC can present antigens produced by some other cell. Since "cross-presentation by class II MHC molecules" is the norm, the term is used most often to describe cross-presentation by MHC class I, where it is critical for activation of CD8 T cells by APC. Cross-presentation can also inhibit immune responses. For example, antigen-specific B cells present epitopes from their cognate antigens and thereby become targets for CTL. In this way, CTL can suppress B-cell responses to some antigens.

KEY CONCEPT

Antigen Processing and Presentation for Class I MHC

- Peptides presented on most cell types are synthesized endogenously.
- Peptides acquired through endocytosis and autophagy can be cross-presented
- Most epitopes are processed by proteasomes and enter the ER through the TAP transporter.
- Peptides of 8–10 amino acids are bound at both termini within the binding cleft.

ANTIGEN PROCESSING

T cells recognize their cognate antigens in the form of short peptides embedded in MHC molecules (Chapter 5). X-ray crystallography shows that approximately 90% of the molecular surface recognized by the TCR is the MHC molecule. *Antigen processing* excises these peptides from their parent protein antigens and loads them onto MHC molecules.[39] The processing can take place in different cellular compartments but loading takes place chiefly in specialized loading compartments. Class I MHC molecules load chiefly in the endoplasmic reticulum, though some loading might take place in endosomal compartments during *cross-presentation*. In contrast, specific mechanisms prevent class II loading in the ER but facilitate it in the specialized endosomal loading compartments.

Endogenous peptides presented by class I molecules derive from proteins made on the cell's own ribosomes. The chief mechanism for degrading large proteins into small peptides is the *proteasome*,[40] a macromolecular tubular structure containing multiple protease activities that cleave proteins into small fragments of 8 to 14 residues. There are at least four mechanisms that feed proteins into proteasomes. First, nascent cytoplasmic polypeptides that fail to fold properly are attacked by enzymes that attach chains of the protein *ubiquitin* to the protein targeted for destruction. Second, nascent proteins that are translocated into the endoplasmic reticulum endosome, but do not fold properly, can be exported back to the cytosol by a protein transporter called Sec61. This mechanism is called ERAD (endoplasmic reticulum-associated protein degradation). These two mechanisms are the most important and together represent the DRiP (defective ribosome products) model. The "DRiP" pathway is not simply an error-dependent pathway but rather represents a specialized mechanism of sampling open reading frames.[41] Third, properly folded mature proteins are ubiquitinated in the course of normal activity—part of the normal course of protein turnover. Finally, in autophagy and cross-presentation, proteins engulfed by phagocytes are partially degraded in lysosomes before transfer into the cytosol.

The DRiP mechanism provides a conceptual core for understanding how class I MHC molecules can sample internally generated antigens, a key requirement for targeting virus-infected or malignant cells. Degradation of mature proteins has a half-time of hours to months, but virus replication can take place in the order of hours. If MHC molecules were to sample antigens as they degrade through normal channels, surface representation would lag considerably behind internal processes. By sampling proteins during their synthesis, or if they fail to fold properly immediately after synthesis, DRiP mechanisms ensure that cytotoxic T cells receive a timely report of internal states.

All four class I MHC pathways make heavy use of the "UPS" (ubiquitin/proteasome) system for protein degradation found in all cells. UPS is initiated by heat-shock chaperone proteins recognizing a malfolded protein and inducing covalent tagging of the protein with a single copy of ubiquitin, a 76 amino acid protein. This triggers polyubiquitination in which succeeding ubiquitins are attached to the preceding ubiquitin. Polyubiquitin tails are recognized by the regulatory subunit of the proteasome, a multi-subunit cylindrical machine. Substrates are fed through the central channel and digested by proteolytic subunits, producing a residue of peptides roughly 8 to 14 amino acids long.

These products are substrates for the *transporter associated with antigen processing* (TAP), a member of the ATP-binding cassette (ABC) transporter family.[42] Heterodimers of TAP1 and TAP2 subunits form peptide pumps that burn ATP to drive peptides from the cytosol into the lumen of the ER. Without a ready source of peptides in the ER, class I MHC molecules are extruded into the cytosol by Sec61 to be recognized by the UPS. TAP mutations are involved in many cases of type I bare lymphocyte syndrome (BLS) (Chapter 34),[43] and many tumor cells lack class I expression due to mutations in their *TAP* genes (Chapter 5). There are several allelic forms in humans with modest differences in specificity. Cells that are not expressing TAP express low levels of certain MHC alleles and can be highly resistant to specific CTL. However, mice and humans lacking TAP are not profoundly immunodeficient and produce TAP-independent class I MHC-restricted CTL (Chapter 34). These findings suggest alternative mechanisms for loading class I MHC molecules are important, even if not dominant under normal circumstances.

Interferon-γ induces an alternative set of proteolytic and regulatory subunits for the proteasome to create the "immunoproteasome." This has altered specificity and activity and may favor the production of peptides suitable for transport by TAP or alternative pathways.

A minor subset of peptides enters the ER independently of TAP through the protein secretory pathway. Nascent polypeptides bearing a *signal peptide* are recognized and transported into the lumen by the *signal recognition particle* (SRP). The signal peptide itself is cleaved by a *signal peptidase*. By inserting the sequence of a CTL epitope behind a signal peptide, this pathway can be used to deliver the epitope directly into the MHC class I loading compartment. Peptides that are too long to bind MHC class I molecules may be retained temporarily in the ER by additional peptide-binding proteins such as BiP, pumped back into the cytosol by a non-TAP mechanism, or trimmed by cytosolic aminopeptidases

The luminal proteases appear quite efficient, apparently reducing the steady-state concentration of free antigenic peptides in the ER to very low levels. As a result of differences in protease specificities and/or kinetic effects, different epitopes can be carved out of the same protein, depending on whether it follows the proteasome/TAP or the secretory pathway into the ER. Finally, different peptides within a single protein can be degraded or protected at different rates, leading to the immunodominance of a subset of potential epitopes for a given MHC molecule.

The production of an immunodominant epitope from influenza A nucleoprotein (NP) illustrates how extra-epitope residues might affect non-proteasome, non-ubiquitin processing.[44] The optimal NP peptide in one mouse strain is the nonamer TYQRTRALV. The three *C*-terminal residues are efficiently removed from a related 12-mer peptide TYQRTRALVRTG. However, an 11-mer, TYQRTRALVTG, is impotent at producing the epitope. The terminal TG sequence represents a "block" to epitope production. All of these complexities in antigen processing complicate the prediction of which potential epitopes, identified on the basis of their ability to bind to class I molecules, will be immunodominant *in vivo*.

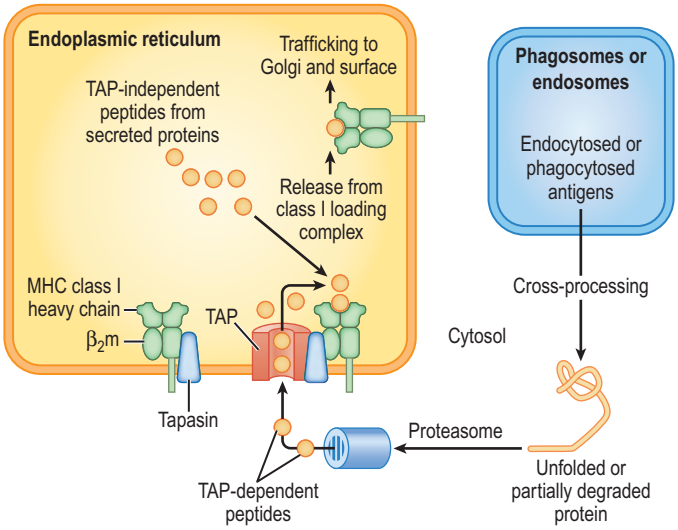

FIG. 6.7 Antigen Processing for MHC Class I. Two chief pathways for antigen processing intersect within the cytosol. Most endogenous antigens are synthesized on ribosomes and then processed by proteasomes into peptides, which enter the ER through the TAP transporter. A minor set of antigens are processed within the ER from proteins secreted into the ER. Professional antigen-presenting cells transfer endocytosed antigens into the cytosol for processing. Autophagy (not shown) can also process endogenous antigens. CD1, MR1, and probably some conventional class I MHC molecules can also acquire ligands in the endocytic compartment itself. *MHC,* Major histocompatibility complex; *TAP,* transporter associated with antigen processing.

Class I Major Histocompatibility Complex Trafficking

Nascent Class I MHC molecules are inserted into the ER membrane via the protein secretory pathway (Fig. 6.7). Nascent chains bind first to the membrane-bound chaperone calnexin until they begin to fold into association with β_2-microglobulin light chains (β_2m). Heterodimers of β_2m and heavy chain are released by calnexin and bind the soluble chaperone, calreticulin. This assembly engages a *class I loading complex*, which includes a 60 kDa thiol reductase, the TAP heterodimer, and another MHC-encoded protein, tapasin.[45] Tapasin retains class I molecules in the complex until they bind peptide. MHC molecules failing to attract peptides misfold and are exported by Sec61 to the cytosol. Only those that bind peptide are released by tapasin from the loading complex, migrate to the Golgi where they undergo glycan maturation, and then traffic to the cell surface for recognition by CD8 T cells.

KEY CONCEPT

Antigen Processing for Class II MHC

- Class II MHC is expressed constitutively only by professional APC (dendritic cells, macrophages, and B cells)
- Epitopes presented by professional APC are acquired mostly through endocytosis and autophagocytosis.
- Peptides (10–15 amino acids) often have terminal extensions, extending outside the antigen-binding groove.

Antigen Processing for Class II-Restricted T Cells

MHC class II molecules assemble in the ER where they associate with *invariant* chain, a 31 kDa protein that chaperones nascent αβ dimers of class II molecules into endosomes. A segment of the invariant chain, called CLIP, blocks class II molecules from binding peptides in the ER. CLIP may be removed along with the rest of the invariant chain once in the endosomes. Alternatively, a CLIP fragment may be left occupying the binding cleft; many class II MHC molecules traffic to the cell surface with CLIP embedded.

MHC class II molecules are loaded with peptides digested by lysosomes. Antigens acquired through endocytosis or autophagy are unfolded and partially degraded in endosomal and acidic lysosomal subcompartments by disulfide isomerase (which unlinks disulfide loops) and a variety of proteases. Most peptides presented by class II molecules are processed from parent proteins and loaded onto class II molecules within a specialized loading compartment of the endosomes. Within this general scheme, there are at least two pathways for epitope production, distinguishable in part by their dependence on the function of DM molecules (Fig. 6.8).[39] DM molecules (heterodimers of DMA and DMB subunits, which are homologous to MHC class II proteins) catalyze the exchange of CLIP for processed epitopes. In the DM-independent pathway, peptides are loaded onto class II molecules recycling from the cell surface in the absence of CLIP.

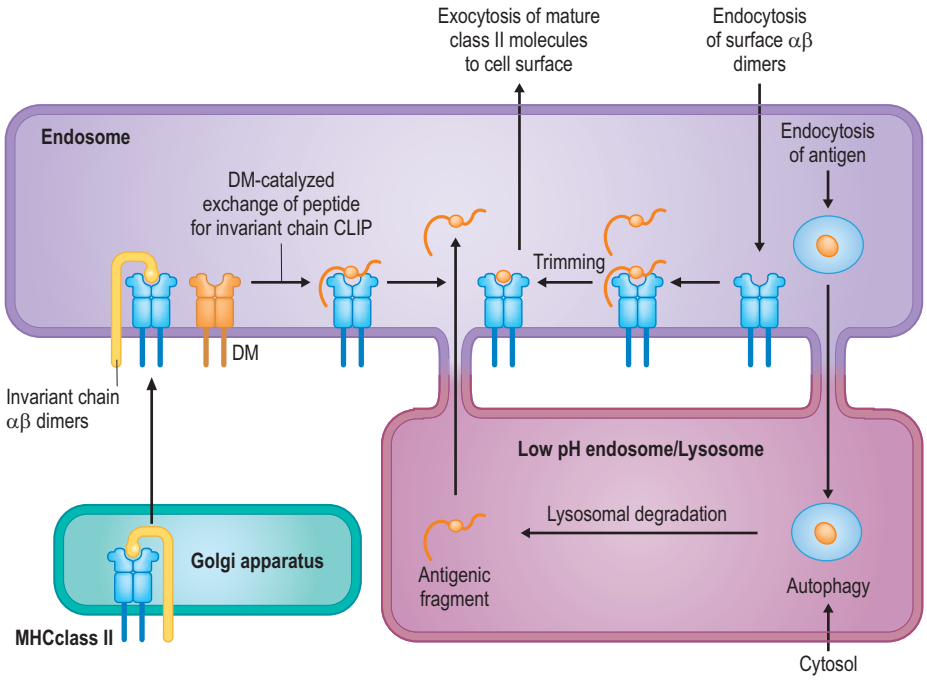

FIG. 6.8 Two Pathways for Loading Antigens Onto Class II MHC Molecules. Autophagy and endocytosis transfer endogenous and external antigens, respectively, into the endosomes. Nascent class II molecules are chaperoned to the endosomes from the Golgi by the invariant chain. The DM molecules catalyze the exchange of antigenic peptides for the invariant chain. Mature class II molecules recycling from the cell surface can acquire peptides in a DM-independent manner. Antigens, initially binding as polypeptides, are trimmed into oligopeptides in the endosomes and at the surface.

The initial ligand for binding class II molecules is a large, unfolded protein or protein fragment rather than the oligopeptide ultimately displayed at the cell surface. This MHC-polypeptide complex is the substrate for trimming exopeptidases. Endosomal aminopeptidases cannot cleave at proline residues; thus, prolines are found near the *N*-terminus of many mature epitopes. Trimming of the extra-cleft residues can continue even after the MHC–peptide complex has reached the surface through the activity of the membrane-bound surface enzyme aminopeptidase N.

As in the case of epitope formation for class I molecules, the initial conformation of the antigen can affect the production of specific linear epitopes. For example, vaccinating mice with synthetic peptides elicits class-II-restricted T cells specific for at least two HIV gp160 epitopes, of which only one is detected on infected cells. Similarly, prior denaturation or mutational destabilization of viral influenza hemagglutinin abolishes its ability to be processed for presentation to some Th clones.

Predicting Epitopes for T-Cell Receptor

The critical role of antigens for T cells in driving both T- and B-cell responses to antigen has fueled attempts to use antigen sequence information to predict T-cell epitopes.[22] The characterization of *binding motifs* for a large number of class I and a smaller number of class II molecules has facilitated computer-based algorithms for predicting potential epitopes from a linear protein sequence. These motifs reflect the chemical affinity of the binding cleft for various amino acid side chains. In many cases, it is possible to show that multiple alleles of class I or class II molecules recognize the same or very closely related epitopes. These groups of MHC alleles are called "supertypes" and can facilitate the prediction of epitopes for a large number of alleles. However, because of the complexity of endoprotease and exoprotease cleavage during the processing of epitopes for both class I and class II MHC molecules, it is difficult to predict whether a given epitope will actually be used *in vivo*.

ANTIGEN PRESENTATION

Once loaded with peptide, MHC molecules move to the cell surface, where they can be recognized by T cells. This is antigen presentation at the bare minimum and is sufficient for triggering effecter responses from pre-activated T cells. Presentation to naïve T cells requires additional factors and efficient activation of the TCR requires adhesion molecules. These additional processes are usually included under the rubric of "antigen processing." Antigen recognition/presentation of both naïve and activated T cells is mediated by the *immune synapse*,[46] although this structure might not be required in all cases.

The immune synapse represents a very close and tight association of APC and T cell resembling tight junctions and may even mediate trogocytosis, through which process peptide-loaded MHC molecules are transferred to the T cell itself (Chapter 4).[47] The synapse is initiated when the leading edge of a T cell engaged in amoeboid motion through a tissue meets a potential APC or target cell. Initial low avidity interactions between the T-cell integrins CD11a and VLA-four mediate a weak approximation of the two cellular surfaces. If MHC molecules on the APC present cognate antigen, the TCR will bind with maximum affinity. The co-receptors CD8 and CD4 bind to class I and class II MHC molecules, respectively (Chapter 5). Their cytoplasmic tails, already loaded with the protein kinase LCK, are swept into proximity with the cytoplasmic domains of the TCR chains, leading to phosphorylation of the latter and

initiating downstream signaling events. An immediate effect is the 1000-fold upregulation of the integrin avidities. The co-stimulatory receptor CD28 migrates to the field, engaging its ligands on the APC. At the surface, the synapse matures as TCR and CD28, and their ligands concentrate at the center of the synapse, surrounded by a ring of integrins. Internally, the ongoing signaling events cause an arrest of cell migration, with a re-organization of the microtubules to permit the trafficking of vacuoles to the synapse. Vacuolar contents are delivered into the intercellular space of the synapse, where, if the T cell is a CTL, they will induce apoptosis in the opposite cell.

Microbial Interference with Antigen Processing and Presentation

Considering the importance of class I-mediated immune responses in antiviral immunity, it is not surprising to find pathogens using a variety of mechanisms for subverting antigen processing. Proteins from several serotypes of human adenovirus, as well as HIV-1 tat protein, inhibit class I MHC transcription. Other viral factors inhibit class I MHC maturation in the endoplasmic reticulum. Proteins US2 and US11 from the human cytomegalovirus (CMV) target nascent class I molecules for destruction through ERAD. The CMV US6 and herpes simplex virus ICP47 proteins inhibit TAP function, indirectly starving MHC molecules of peptide. In contrast, the CMV US3 protein binds class I molecules that have already engaged peptides but retains them in the ER. The HIV-1 protein nef binds the intracellular tails of mature class I MHC molecules, targeting them for increased endocytosis and degradation. Other pathways are also affected by pathogens. For example, the protein ICP345 from the herpes simplex virus inhibits ATG6, a critical autophagy-initiating protein. Also, *Mycobacterium tuberculosis* suppresses the acidification of lysosomes in macrophages to create for itself an environment conducive to its own replication inside lysosomes.

CLINICAL RELEVANCE

Clinical Correlates of Antigen Processing

- The tautological and complementary interaction of antigens and their antigen receptors constitute the recognitive mechanism for acquired immunity to pathogens and tumors and autoimmunity towards the "self."
- Human genetic defects in these antigen processing pathways result in three types of bare lymphocyte syndrome (BLS).
- Structural features of certain antigens may predispose them to induction of allergic (IgE) responses by affecting antigen processing.
- Molecular mimicry and exposure of cryptic self-epitopes are mechanisms leading to autoimmunity.
- Tumor-specific neoantigens can be detected by the immune system, often leading to selection for tumor variants lacking the relevant MHC and/or antigen-processing functions.
- Tumor antigens are typically self-proteins that can be:
  - Products of tumor viruses
  - Over-expressed normal proteins
  - Mutated products of oncogenes
  - Clonally-expressed idiotypes of antigen receptors

CLINICAL RELEVANCE

If microbes can manipulate specific mechanisms of antigen processing and presentation, it should be obvious that human genetic variation in these pathways should also be able to contribute to immune competency or, through deficiency, to immune dysfunction. This may result in specific or global defects in antigen processing and recognition, such as the bare lymphocyte syndrome (BLS) (Chapter 34).[43] Type I BLS involves general loss of class I surface expression, typically the result of mutations in the TAP peptide transporter. Type II BLS reflects the loss of class II MHC expression. Defects in any of at least four different transcription factors can cause this disease. In type III BLS, defects in the RFX transcription factor depress the expression of both class II MHC molecules and the β_2-microglobulin light chain shared by all class I MHC proteins.

Allergens appear to be unusual antigens. It has been long known that allergens inducing delayed-type hypersensitivity are often drugs or environmental compounds able to form covalent adducts with self-proteins, thus generating neoantigens. Many allergens inducing immediate hypersensitivity are or are associated with proteases.[48] These proteases are thought to drive a Th2 response by T cells.

Self-antigens recognized by autoimmunity are so far chemically unremarkable. The principles that govern pathological self-recognition appear to be the same as for healthy self-tolerance or recognition of foreign antigens: the availability of particular processed peptides at appropriate times for tolerance induction of T-cell activation.

Two nonexclusive models have emerged that may begin to account for why certain individuals are predisposed to autoimmunity and why certain self-antigens are likely to become autoantigens (Chapter 51). The first is the concept of *molecular mimicry*.[49] According to this idea, exposure to sufficient doses of a pathogen-derived epitope that cross-reacts with a previously ignored or *cryptic* self-epitope can break self-tolerance to that epitope. A newer concept in autoantigenicity can explain why many autoantigens are proteins normally found intracellularly, where they are involved in nucleic acid and protein metabolism: small nuclear riboproteins, histones, and heat-shock proteins. This involves the observation (discussed earlier with regard to cross-presentation) that apoptotic bodies are efficiently recognized by dendritic cells, and that many intranuclear and intracellular antigens are exposed on the extraverted surfaces of apoptotic bodies. Thus, by inducing apoptosis, it is possible that certain predisposing infections can elicit autoimmune reactions to cryptic self-epitopes.

Finally, tumor-specific and tumor-associated antigens are typically self-proteins.[50] In rare human cases, such as a peptide derived from papillomavirus type 16, they can be encoded by tumor viruses. Some tumor antigens, such as carcinoembryonic antigen (CEA), prostate-specific antigen (PSA), or the MAGE proteins of melanomas, are normal proteins that are merely overexpressed by tumor cells. These can serve as diagnostic markers or as a target for tumor-selective immunity. The antigenic products of mutated tumor suppressor genes and other oncogenes, such as *HER2*, the retinoblastoma protein RB, and the breast cancer–associated antigen BRAC, are also called *neoantigens* and are potentially more specific targets for immunotherapy. The neoantigens expressed by these tumors arise as chance mutations during the many steps of carcinogenesis. The immune system itself provides a unique category of neoantigens that can be targets of immunotherapy, the clonally distributed products of rearranged antigen receptor genes – idiotypes – expressed by malignancies such as myelomas.

Translational Research in Antigen Processing and Presentation

ON THE HORIZON

- Improved definition of the cellular and molecular mechanisms controlling dendritic cell presentation of antigen to T cells and NK cells by classical and non-classical MHC class I molecules as relevant to antiviral and anti-tumor immunity.
- Understanding the role of autophagy to improve vaccine design.
- Clarification of the role of MHC class Ib molecules in the presentation of non-peptide antigens and in the regulation of immune responses.
- Solution to the puzzle of clonally expressed antigen receptors on NK cells.

Several areas are ripe for new insights with probable application to clinical immunology. These include a deeper understanding of peptide processing for presentation by class I MHC molecules, identification of antigenic ligands recognized by CD1- and MR1-restricted T cells, and a better understanding of the mechanisms that control antigen receptor function in NK cells. Although it is now widely accepted that dendritic cells present endocytosed antigens for presentation by MHC class I, the mechanisms and rules governing this process are not clear.

Likewise, autophagy mediates the processing of endogenous antigens in both MHC class I and class II pathways and is likely important in cross-presentation. Pathogens can both be cleared by autophagy but also can wrest control of autophagy for their own purposes, probably including redirection of antigen processing. We expect clarification of the role of autophagy in antigen processing to yield new tools for controlling infection and vaccine design.

The CD1 and MR1 class Ib MHC molecules present non-peptide ligands to specialized invariant NKT cells, and these appear to have important regulatory functions in suppressing autoimmunity, especially in the gut. Ligands for MR1 and for CD1 are poorly understood. This is an area of growth in the next several years and will likely prove important for understanding and treating autoimmunity and some infectious diseases. Finally, NK cells in mice and humans express novel species of antigen receptors in a clonal fashion. These receptors and their mechanism of clonal expression or clonal licensing have opened a new chapter in acquired immunity.

B-Cell Development and Differentiation

Harry W. Schroeder Jr., Andreas Radbruch, and Claudia Berek

B lymphocytes (B cells) are the sole source of antibodies. Each developing B cell creates its own unique immunoglobulin (Ig) that can be expressed on the cell surface as B-cell receptor (BCR) for antigen or secreted as an antibody (Chapter 4). During their development, B cells encounter different microenvironments (Chapter 2) that expose them to a variety of cytokines (Chapter 14), adhesion molecules (Chapter 16), and chemokines (Chapter 15).[1] These processes impose major bioenergetic demands on the cells.[2] Ultimately, however, the fate of the B cell is dependent on the interaction between Ig and antigen (Chapter 6).

EARLY B-CELL DEVELOPMENT BEGINS IN THE PRIMARY LYMPHOID ORGANS

B cells arise from multipotent hematopoietic stem cells that successively populate the yok sac, the endothelium of the major arteries, the fetal liver, and then the bone marrow.[3] Stem cell daughter cells give rise to lymphoid primed multipotent progenitors (LMPPs), which in turn can give rise to either myeloid or lymphoid cells. LMPPs then produce common lymphoid precursors (CLPs), which can generate T cells, B cells, natural killer (NK) cells, or dendritic cells. Final B-cell differentiation requires the exposure of CLP daughter cells to specialized microenvironments in the fetal liver and the bone marrow. These two tissues are the primary B-lymphoid organs. The shift from fetal liver to bone marrow begins in the middle of fetal life and ends prior to birth. The bone marrow continues to produce B cells until the end of life, although the rate decreases with age.

An intact and functional B-cell antigen receptor complex, which consists of membrane-bound immunoglobulin (mIg), the Igα and Igβ co-receptors, and ancillary signal transduction components, must be present in order for the developing B cell to survive (Chapter 7). The composition of the BCR is subject to intense selection. In the primary organs, hazardous self-reactive BCRs, as well as nonfunctional ones, can be culled by changing the L chain (receptor editing), by cell anergy,[4] or by apoptosis of the host cell. Survivors of this initial selection process are released into the blood and thence to the spleen, lymph nodes, and other secondary lymphoid tissues and organs where selection for specificity continues (Chapter 2).

B-cell differentiation (Fig. 7.1) is commonly presented as a linear process defined by the regulated expression of specific sets of transcription factors, Ig, and cell-surface molecules. Given the central role of the BCR (Chapter 4), initial developmental steps are classically defined by the status of the rearranging Ig loci. With the development of monoclonal antibody technology, analysis of cell-surface markers such as CD10, CD19, CD20, CD21, CD24, CD34, and CD38 (Fig. 7.2) has facilitated definition of both early and late stages of development, especially in those cases where Ig cannot be used to distinguish between cell types.[5] Of these, CD19, a signal transduction molecule expressed throughout B-cell development up to, but not including, the mature plasma cell stage[6] warrants special mention as the single best clinical marker for B-cell identity.

In practice, B-cell development is a more complex process than the simple, linear pathways depicted in Figs. 7.1 and 7.2. For example, proB cells typically derive from a common lymphoid progenitor, but they can also develop from a bipotent B/macrophage precursor. Thus, B-lineage subsets identified by one fractionation scheme may consist of mixtures of subsets identified by others. Consequently, when comparing patient findings to the literature, definition of the fractionation scheme used by the reference laboratory is essential.

Initial commitment to the B-cell lineage requires activation of a series of transcriptional and signal transduction pathways. At the nuclear level, the transcription factors PU.1, Ikaros, ID-1, E2A, EBF1, and PAX5 play major roles in committing progenitor cells to the B-cell lineage.[3] After lineage commitment has been established, however, it is generally accepted that the composition of the BCR controls further development.

Each B-cell progenitor has the potential to produce a large number of offspring. Some will develop into mature B cells,

KEY CONCEPTS

B-Cell Development in the Primary Lymphoid Organs

- Commitment to the B-cell lineage reflects differential activation of transcription factors that progressively lock the cell into the B-cell pathway
- B-cell development is typically viewed as a linear, stepwise process that is focused on the assembly and testing of immunoglobulin function, first in the fetal liver and bone marrow, and then in the periphery:
  - Failure to assemble a functional receptor leads to cell death.
  - Expression of a functional receptor subjects the B cell to antigen selection/
  - B cells with inappropriate specificities tend to be eliminated.
  - B cells responding appropriately to external antigen can develop either into immunoglobulin-secreting plasma cells or into memory cells,
- At the clinical level, B-cell development can be monitored by examining the pattern of expression of lymphoid-specific surface proteins.

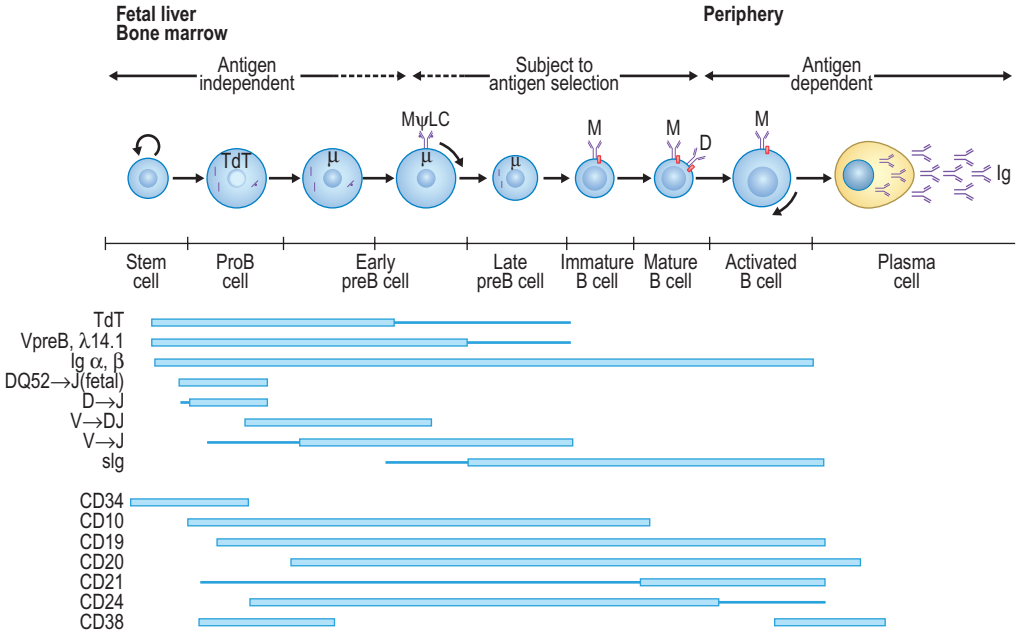

FIG. 7.1 Model of B-Cell Differentiation. B-cell development is typically viewed as a linear progression through different stages of differentiation. The various processes associated with the assembly of the B-cell antigen receptor complex and the expression pattern of surface molecules whose presence or absence are illustrated through use of bars. The various steps in immunoglobulin rearrangement and the pattern of expression of these surface molecules can be used to characterize stages in B-cell development.

	Immature	Transitional T1	Transitional T2	Transitional T3	Naive mature	Memory unswitched (MZ-like)	Memory switched	Plasmablast
IgM	++	+++	++	+	+	+	-	-
IgD	-	+	++	++	++	+	-	-
R123	+	+	+	Int	-	+	+	+
CD10	+	+	+/-	-/+	-	-	-	+/-
CD19	+	+	+	+	+	+	+	lo
CD24	+++	+++	++	+	+	+	-	-
CD27	-	-	-	-	-	+	+	hi
CD38	+++	+++	++	+	+	lo	lo	hi

FIG. 7.2 B-Cell Subsets in the Peripheral Blood. Peripheral blood B-cell subsets can be identified by differential staining for IgM, IgD, CD10, CD19, CD24, CD27, CD38, and use of the rhodamine dye R123, which is extruded by the ABCB1 transporter expressed in naïve, mature B cells and, to a lesser extent, T3 transitional B cells.[36] B cells that are $CD20^{+}CD27^{+}CD43^{+}CD70^{-}$ are currently the best candidates for the human B-1-cell counterparts,[5] but this is subject to change. In addition to these subsets found in the blood, germinal center B cells found in the spleen and lymph nodes are characterized as $IgD^{-}CD38^{++}$ $CD10^{+}$ $CD27^{+/-}$; marginal zone B cells are typically $CD27^{+}$ $CD21^{++}$ $CD23^{+/-}$ $CD1c^{+}$ IgD^{-}; and long-lived plasma cells found in the bone marrow, spleen, and tonsils are $CD138^{+}$ $CD20^{-}$ $CD38^{++}$.

and even fewer into long-lived memory B cells or plasma cells. Others, indeed the majority, will perish.[7] Most of the defined steps in this process of development represent population bottlenecks, developmental checkpoints wherein the developing B cell is tested to make sure that its BCR will be beneficial.[8] In the periphery, exposure to antigen is associated with class switching and hypermutation of the variable domains of the antigen receptor. A few select survivors earn long lives as part of a cadre of memory B cells. These veterans enable rapid engagement of antigens to which they have been previously exposed, providing experienced protection against repeat assaults.

Specialized microenvironments also play a role in peripheral B-cell development (Chapter 2), each of which enables the B cell to properly engage different types of antigens or venues of attack (see below). In the marginal zone (MZ), mature splenic MZ B cells await bacterial pathogens. In the lymphoid follicles, B cells reactive with a given antigen collaborate with follicular T cells and dendritic cells in order to maximize the immune response (Chapter 6). In the germinal centers (GCs) B cells use class switching and somatic mutation to modify and optimize the function and affinity of their Igs. And, underneath mucosal surfaces, B cells are primed to express IgA (Chapter 24).

Generation of a Functioning Antigen Receptor Is Key to the Viability of a B Cell

Ig rearrangement is hierarchical. In proB cells, heavy (H) chain $D_H \rightarrow J_H$ joining precedes $V_H \rightarrow DJ_H$ rearrangement (Chapter 4), followed by light (L) $V_L \rightarrow J_L$ joining in late-stage preB cells.

Production of a properly functioning BCR is essential for development beyond the preB cell stage. For example, function-loss mutations in RAG1/2 and DNA-dependent protein kinase (DNA-PKcs, Ku 70/80) preclude both B-cell and T-cell development (Chapter 34). Each proB cell faces the probability that only one of three possible splices will place the V_H and J_H in the same reading frame. The opportunity to try rearrangement on the second chromosome gives failing proB cells a second opportunity. Together, this provides the cell with five chances out of nine for initial survival ($1/3 + 1/3 \times 2/3$). In-frame, functional VDJ_H rearrangement allows the proB cell to produce μ H chains, most of which are retained in the endoplasmic reticulum. The appearance of cytoplasmic μ H chains marks initiation of the preB cell stage. These early preB cells tend to be large in size.

VpreB and λ14.1 [λ5], which together form the surrogate light chain (ψLC), and Igα and Igβ (Chapter 4) are constitutively expressed by proB cells. The first H chain quality control checkpoint tests for the ability of the μ H chain to associate with surrogate light chain to form a preB cell receptor. In addition to checking to see if the scaffolding (Frameworks) of the L chain can associate correctly with the scaffolding of the H chain, VpreB encodes a sensing site that can test the H chain antigen-binding site. Thus, the surrogate light chain functions as the first, and invariant, antigen to screen for antigen-binding characteristics.[9]

Successful formation of a stable preBCR facilitates termination of further H chain rearrangement *(allelic exclusion)*, which is followed by four to six cycles of cell division, a process associated with a progressive decrease in cell size. Late preB daughter cells reactivate RAG1 and RAG2 and begin to undergo $V_L \rightarrow J_L$ rearrangement. Successful production of a complete κ or λ light chain permits membrane-bound expression of IgM on the cell surface, which identifies the *immature* B cell. Immature B cells expressing self-reactive IgM antibodies may undergo repeated rounds of light chain rearrangement to lessen the self-specificity of the antibody, a process termed *receptor editing*.

Immature B cells that have successfully produced an acceptable IgM BCR extend transcription of the H chain locus to include the Cδ exons downstream of Cμ. Alternative splicing permits co-production of IgM and IgD. These now newly *mature* IgM^+IgD^+ B cells enter the blood and migrate to the periphery where they form the majority of the B-cell pool in the spleen and the other secondary lymphoid organs. The IgM and IgD on each of these cells share the same variable domains.

Tyrosine Kinases Play Key Roles in B-Cell Development

Signaling through the BCR is required for continued development. FLT3 (FLK2) is a receptor tyrosine kinase belonging to the same family as c-FMS, the receptor for colony-stimulating factor-1 (CSF-1). FLT3 ligand, which has homology to CSF-1, is a potent co-stimulator of early proB cells. In mice, targeted disruption of *flt3* leads to a selective deficiency of primitive B-cell progenitors.

Bruton tyrosine kinase is an important component of the phospholipase Cγ (PCLγ) pathway, which is used in BCR signaling. Deficiency of BTK function results in the arrest of human B-cell development at the preB cell stage and is the genetic basis of X-linked agammaglobulinemia (XLA) (Chapter 33). Inhibitors of BTK can be used to treat B-cell malignancies.[10]

BLNK is a SRC homology 2 (SH2) domain-containing signal transduction adaptor. When phosphorylated by SYK, BLNK serves as a scaffold for the assembly of cell-activation targets that include GRB2, VAV, NCK, and PLCγ. Loss of function mutations in BLNK can result in agammaglobulinemia due to the loss of preB and mature B cells.

Cell-Surface Antigens Associated with B-Cell Development

B-cell development is associated with the expression of a cascade of surface proteins, each of which plays a key role in the fate of the cell (see Fig. 7.1, Table 7.1). The timing of the appearance of each of these proteins can be used to further analyze the process of B-cell development. Several of these surface proteins, as well as their ligands and intracellular components, can be targeted for therapeutic interventions. Examples can be found in Table 7.2.

CD34 is a highly glycosylated type I transmembrane glycoprotein that binds to CD62L (L-selectin) and CD62E (E-selectin) and thus likely aids in cell trafficking (Chapter 16). It is expressed on a small population (1% to 4%) of bone marrow cells that includes hematopoietic stem cells. In mice deficient in CD34, the colony-forming activity of hematopoietic progenitors appears reduced. However, the hematopoietic profile of adult blood appears unaffected.

CD10, also known as neprilysin, neutroendopeptidase, and the common acute lymphocytic leukemia antigen (CALLA), is a type II membrane glycoprotein metalloprotease. CD10 has a short N-terminal cytoplasmic tail, a signal peptide transmembrane domain, and an extracellular C-terminal domain that includes six N-linked glycosylation sites. The extracellular

TABLE 7.1 Cell-Surface Proteins Active in Early B-Cell Development

Gene	Class or Alternative Name	Associated or Targeted Genes or Molecules	B-Cell Developmental Phenotype in Human or *Mouse* Associated with Disrupted Function of the Indicated Gene
B-Cell Receptor Complex			
μ chain	Immunoglobulin superfamily	κ, λ L chains, ψL chain, CD79 a,b(Igα, β)	AGM1: agammaglobulinemia and no B cells *Arrest at preB cell stage*
Immunoglobulin lambda-like polypeptide 1; IGLL1 (λ14.1, λ*5*)	Immunoglobulin superfamily	VpreB, μ H chain	AGM2: agammaglobulinemia and reduced B-cell numbers. *Arrest at preB cell stage*
VPREB1 (VpreB)	Immunoglobulin superfamily	λ14.1, μ H chain	*Arrest at preB cell stage*
CD79a,b (Igα, β)	Immunoglobulin superfamily, cytoplasmic ITAM motifs	H chain, LYN, FYN, BLK, SYK	AGM3 (CD79A); AGM6 (CD79B): Agammaglobulinemia and arrest at proB cell stage *Arrest at proB cell stage*
Other Cell-Surface Proteins			
CD10	Type II metalloproteinase	Hydrolyzes peptide hormones, cytokines	*Not expressed in murine B-cell progenitors*
CD19	Immunoglobulin superfamily	mIgM, PI-3 kinase, VAV, LYN?, FYN?	CVID3: panhyperglobulinemia, normal numbers of $CD20^+$ B cells in the blood
CD20	Four transmembrane domain surface molecule	B-cell Ca^{2+} channel subunit; indirectly interacts with LYN, FYN, LCK	CVID5: low IgG, normal IgM, variable IgA *20%–30% reduction in B-cell numbers*
CD21	Complement control protein	iC3b, C3dg, C3d, CD19, CD81, Leu 13, CD23	CVID7: Low IgG, reduced IgA, low normal IgM *Diminished T-cell-dependent immune responses, decreased germinal center formation, reductions in affinity maturation*
CD24	GPI-linked sialoglycoprotein	Ligand for P-selectin (CD62P)	A57V polymorphism associated with increased risk of multiple sclerosis *Deletion in mice leads to reductions in late preB and immature B-cell populations*
CD34	Type I transmembrane glycoprotein	Ligand for L-selectin (CD62L) and E-selectin (CD62E)	*Not expressed in murine B-cell progenitors*
CD38	Type II transmembrane glycoprotein ADP-ribosyl cyclase, cyclic ADP-ribose hydroxylase	ADP ribosylates proteins	*Diminished T-cell-dependent immune responses, augmented responses to T-cell-independent type 2 polysaccharide antigens*

TABLE 7.2 Selected Anti-B-Cell Biologicals and Consequences

Modality and Target	Consequences
Monoclonal antibodies directed against:	
BAFF	Preferentially blocks B cells overexpressing BAFF, including autoantibody-producing B cells in autoimmune diseases
CD20	Destruction of preB cells, B cells including follicular and memory B cells, and some short-lived plasma cells. Left intact are progenitor B cells and long-lived plasma cells
CD40	Blocks isotype switching, GC formation, memory B-cell generation, and class-switched antibody production
FcRn	Permits cellular IgG degradation and blocks IgG recycling, thereby lowering serum IgG levels in general, including autoantibodies
IL-6 receptor	Blocks IL-6 activation of intracellular kinases, reducing inflammation
Inhibitors targeting:	
Proteasomes	Causes cellular accumulation of misfolded or unfolded damaged protein, which is more common in plasma cells, leading to cell death

BAFF, B-cell activating factor of the tumor necrosis family; *GC*, general center; *IL*, interleukin.

domain contains 12 cysteines whose disulfide bonds help stabilize its zinc-binding pentapeptide motif, which is involved in its zinc-dependent metalloprotease catalytic activity. It can inactivate multiple physiologically active peptides such as endothelin-1, bombesin, bradykinin, or oxytocin. Inhibition of CD10 activity on bone marrow stromal cells enhances B-cell maturation. CD10 (CALLA) is used as a marker for preB acute lymphocytic leukemias and for certain lymphomas.

CD19 is a cell-surface glycoprotein of the Ig superfamily that is exclusively expressed throughout B-cell development from the proB cell stage up to the plasma cell stage (see Fig. 7.1). CD19 exists in a complex with CD21 (complement receptor 2 [CR2]: complementarity determining region [CDR]2), CD81 (TAPA-1) and Leu 13 (Chapter 4). With the help of CD21, CD19 can bind the complement C3 cleavage product C3d. The simultaneous binding of sIgM and CD19 to a C3d-antigen complex enables CD19 and the BCR to interact and thereby provides a link between innate and adaptive immune responses (Chapter 3). CD19–BCR interactions permit the cell to reduce the number of antigen receptors that need to be stimulated in order to activate the cell. Co-activation also reduces the threshold required for B-cell proliferation in response to a given antigen.

CD19 is generally considered as a positive B-cell signaling regulator.[11] Co-ligation of CD19 and surface Ig promotes calcium mobilization, enhances MAP kinase and Src PTK

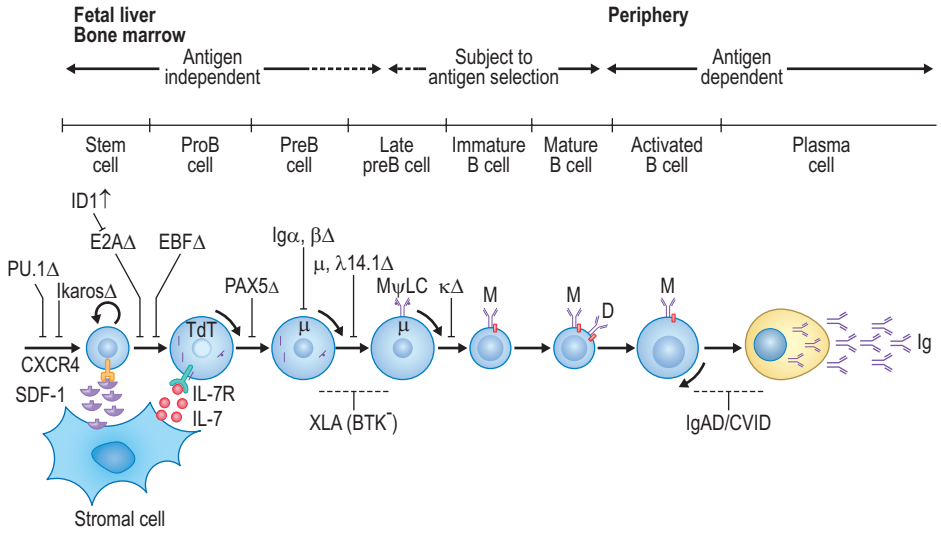

FIG. 7.3 Genes Involved in Early B-Cell Development. The stage of development at which abnormal function of a selected set of transcription factors, cytokines, chemokines, and signal transduction elements can influence B-cell development is illustrated. A *Greek delta* (Δ) or a *dash (–)* indicates a loss of function of the gene in question. An *upward arrow* (↑) indicates an increase in the function of the gene in question. *IgAD/CVID,* IgA Deficiency/Common Variable Immune Deficiency; *XLA,* X-linked agammaglobulinemia.

activation, and prolongs BCR signaling in lipid rafts. Patients deficient in CD19 have normal numbers of $CD20^+$ B cells in the blood but are panhypogammaglobulinemia and are susceptible to sinopulmonary infections (Chapter 33).

CD20 contains four transmembrane domains and cytoplasmic C- and N-termini. It is a member of the CD20/FcεRIβ superfamily of leukocyte surface antigens. Differential phosphorylation yields three forms of CD20 (33, 35, and 37 kDa). Activated B cells have increased fractions of the 35- and 37-kDa forms of the antigen. CD20 appears to function as a B-cell Ca^{2+} channel subunit and regulates cell cycle progression. It can interact directly with Major Histocompatibility Complex (MHC) class I and II molecules (Chapter 5), as well as members of another family of four transmembrane domain proteins known as the TM4SF (e.g., CD43, CD81, and CD82). It also appears to interact indirectly with LYN, FYN, and LCK. A patient, born of consanguineous parents, with CD20 deficiency has presented with normal numbers of B cells, reduced circulating memory B cells, low IgG with normal IgM and IgA, and reduced somatic hypermutation (SHM). Rituximab, a common monoclonal biologic approved for medical use in 1997, is directed against CD20. It is commonly used to treat certain autoimmune diseases and lymphoid cancers (Chapter 84).

CD21 (CR2) is a cell-surface protein that contains a small cytoplasmic domain and an extracellular domain consisting of a series of short consensus repeats termed complement control protein (CCP) domains. These extracellular domains can bind three different products of complement C3 cleavage, iC3b, C3dg, and C3d. When binding these products, CD21 acts as the ligand-binding subunit for the CD19/CD21/CD81 complex, tying the innate immune system to the adaptive immune response. Mice that lack CD21 exhibit diminished T-dependent B-cell responses. However, serum IgM and IgG are in the normal range. A patient lacking CD21 presented with low IgG, low normal IgM, normal IgA, normal responses to protein vaccination, but impaired responses to polysaccharide vaccines.

CD24 is a GPI-linked sialoprotein that serves as a ligand for P-selectin (CD62P). It is expressed on progenitor, immature, and mature B cells. Its expression decreases in activated B cells and is lost entirely in plasma cells. Monoclonal antibodies against CD24 inhibit human B-cell differentiation into plasma cells. In mice, CD24 is also known as HSA, or heat-stable antigen. Mice made deficient for CD24 show a leaky block in B-cell development with a reduction in late preB and immature B-cell populations. However, peripheral B-cell numbers are normal and no impairment of immune function has been demonstrated.

CD38 is a bifunctional enzyme that can synthesize cyclic ADP-ribose (cADPR) from nicotinamide adenine dinucleotide (NAD^+) and also hydrolyze cADPR to ADP-ribose. It is presumed that the enzyme exists to ADP-ribosylate target molecules. CD38 is expressed on preB cells, activated B cells, and early plasma cells, but not on immature or mature B cells or on mature plasma cells. Antibodies to CD38 can inhibit B lymphopoiesis, induce B-cell proliferation, and protect B cells from apoptosis. CD38 knockout mice exhibit marked deficiencies in antibody responses to T-cell-dependent protein antigens and augmented antibody responses to T-cell-independent type 2 polysaccharide antigens.

Transcription Factors and Epigenetic Mechanisms Controlling B-Cell Differentiation

Ultimately, B-cell development is a function of differential gene expression, including epigenetic regulation of specific B-cell-related genes and processes. Deficiencies in the function of the transcription factors that regulate lymphoid-specific gene expression can thus be expected to result in abnormal B-cell development (Fig. 7.3, Table 7.3).

PU.1 belongs to the erythrocyte transformation specific (ETS) family of loop-helix-loop (winged helix) transcription factors, which bind purine-rich DNA sequences. PU.1 regulates CD79a

TABLE 7.3 Nuclear and Cytoplasmic Factors Active in Early B-Cell Development

Gene	Class or Alternative Name	Associated or Targeted Genes or Molecules	B-Cell Developmental Phenotype in Human or *Mouse* Associated with Disrupted Function of the Indicated Gene
Transcription Factors			
PU.1	Loop-helix-loop (winged helix)	CD79a (Igα), μ H chain	*Arrest prior to the proB cell stage*
Ikaros	Zinc finger	RAG1, TdT, IL2R, VpreB, LCK	CVID13: progressive loss of B cells and serum immunoglobulins *Arrest prior to the proB cell stage*
Aiolos	Zinc finger	RAG1, TdT, IL2R	*Aging mice develop symptoms of systemic lupus erythematosus*
E2A	Basic Helix-loop-helix (BHLH)	RAG1, IgH, Igκ, TdT, EBF, PAX5	AGM8: Agammaglobulinemia, reduced numbers of $CD19^+$ B cells that lacked BCRs. *Arrest prior to the proB cell stage*
EBF	EBF/Olf helix-loop-helix (HLH)-like	CD79a (Igα), λ14.1, VpreB, PAX5	*Arrest prior to the proB cell stage*
ID-1	Helix-loop-helix	CD79a (Igα), λ14.1, VpreB, PAX5	*Arrest prior to the proB cell stage*
PAX5	Paired-domain	CD19, λ14.1, VpreB, BLK kinase, J chain, V_H promoters, Vκ promoters	Susceptibility to B-cell acute lymphoblastic leukemia 3. *Arrest at proB cell stage*
The Recombinase Complex			
RAG1, RAG2	Recombinase	Recombination signal sequences of immunoglobulin gene segments	Autosomal recessive SCID *Arrest at proB cell stage*
TdT	Nontemplated DNA polymerase	Coding ends of rearranging immunoglobulin gene segments	*Absence of N nucleotides, diminished production of pathogenic anti-DNA autoantibodies, loss of heterosubtypic immunity against influenza virus*
DNA-PK	DNA repair complex	Multimeric complex consisting of DNA-PKcs, Ku70, Ku80, which repairs double-stranded DNA breaks	SCID *Arrest at proB cell stage, original mouse SCID mutation identified as a loss-of-function mutation in DNA-PKcs*
Protein Tyrosine Kinases			
FLK2/FLT3	Class III receptor tyrosine kinase	GRB2, SHC	Activating mutations contribute to acute myeloid leukemia *Selective deficiency of primitive B-cell progenitors*
BLNK	SH2 adaptor protein	SYK, GRB2, VAV, NCK, phospholipase Cγ (PLCγ)	AGM4: Normal numbers of proB cells, absent preB, and B cells *Arrest at proB cell stage*
BTK	BTK/TEC protein tyrosine kinase	Phospholipase Cγ (PLCγ), SAB	XLA: X-linked agammaglobulinemia–arrest at preB cell stage *Xid: Impaired responses to T-independent antigens.*

(Igα), J chain, μ chain, κ chain, λ chain, RAG1, and terminal deoxynucleotidyl transferase (TdT), the enzyme responsible for *N* addition (Chapter 4). PU.1 requires the presence of other factors in order to activate or repress their target genes. It cooperates with PU.1 Interaction Partner (PIP, LSIRF, IRF4), c-JUN, and c-FOS. PU.1-deficient mice demonstrate defective generation of monocyte, granulocyte, and lymphocyte progenitors, indicating a role in the generation of MPPs as well as LMPPs. PIP-deficient mice lack GCs in peripheral lymphoid organs and exhibit defects in B-cell activation.

Ikaros and Aiolos belong to the same zinc finger transcription factor family. Ikaros is expressed in stem cells and mature lymphocytes. Aiolos is only expressed after commitment to the B-cell lineage. Ikaros can generate several isoforms by means of differential splicing. Isoforms differ in their DNA-binding patterns, tendency to dimerize, and nuclear localization. Ikaros binds TdT, λ14.1 (λ5), VpreB, and LCK genes.

The *E2A* locus encodes two basic helix-loop-helix transcription factors that represent two alternately spliced products, E12 and E47. Targets for E2A include RAG1 and TdT. Although the functions of E12 and E47 overlap; E47 appears to play a greater role in driving TdT and RAG2, whereas E12 is a better activator of EBF and PAX5 and thus helps commit developing cells to the B-cell lineage.

ID-1 has a helix-loop-helix domain but lacks a DNA-binding domain. Thus, it can function as a dominant negative factor, inhibiting the function of helix-loop-helix transcription factors, such as E2A. ID-1 is expressed only in proB cells.

EBF, or early B-cell factor, is a helix-loop-helix like transcription factor. It is expressed at all stages of differentiation except plasma cells and is critical for the progression B cells past the early proB cell stage.

PAX5 is a paired-box, or domain, transcription factor that, among the progeny of hematopoietic stem cells, is expressed exclusively in cells of the B-cell lineage. PAX5 has both a positive and a negative effect on B-cell differentiation. The presence of PAX5 prevents early B-lineage progenitors from transiting into other hematopoietic pathways. Downregulation of PAX5 allows upregulation of BLIMP1 and plasma cell differentiation. PAX5 downregulation in plasma cells permits expression of genes typically expressed in macrophages and neutrophils.

A number of epigenetic modifiers affect numerous aspects of B-cell development.[12] These include polycomb complexes 1 and 2, histone deubiquitinases, histone acetyltransferases, histone deacetylases, and DNA methyltransferases. For example, histone modifications, DNA methylation, DNA looping, and

noncoding RNAs all play crucial roles in V(D)J recombination, classswitching, and SHM.

MicroRNAs, Long Noncoding RNAs, and B-Cell Development

MicroRNAs (miRNAs) are a class of small, noncoding RNAS that downregulate target genes at a post-transcriptional level.[13] These RNAs are derived from longer transcripts by the sequential action of RNA polymerase II, the nuclear nuclease Drosha, and the cytosolic nuclease Dicer. Mature miRNAs are incorporated into the multiprotein RNA-induced silencing complex (RISC), which repress target mRNAs by either inducing mRNA cleavage or mRNA degradation, or by blocking mRNA translation. miRNAs that play a role in both early and late B-cell development include miR-150, miR-155, and miR-17-92. Abnormal function of these miRNAs can contribute to oncogenesis and immune dysfunction.

On the other end of the spectrum, long noncoding RNAs (lncRNA) are transcripts with lengths exceeding 200 nucleotides that are not translated into protein. These transcripts can be cell-stage specific and they can interact with DNA, RNA, proteins, or combinations thereof. In so doing they can modulate three-dimensional chromatin structure, protein scaffolding, interfere with transcriptional gene regulation, and influence posttranscriptional modifications.[14] Mutation of the DNA that encodes these transcripts can have oncogenic or tumor suppressive functions.

Modulation of B-Cell Development by Chemokines, Cytokines, and Hormones

Stromal cells provide the microenvironment for B-cell development and differentiation (see Fig. 7.3). For example, the chemokine CXCL12, also known as preB cell growth-stimulating factor and as stromal cell-derived factor-1 (PBSF/SCF-1), promotes proB cell proliferation. Mice with a targeted disruption of this gene exhibit impaired B lymphopoiesis in fetal liver and bone marrow, and fail to undergo bone marrow myelopoiesis.[15] CXCL12 binds to CXCR4 signaling, which can activate diverse G-protein-coupled receptor (GPCR) pathways and lead changes in cell migration (Chapter 16), adhesion, and transcriptional activation. In IgM^+ IgD^+ mature B cells, CXCR4 associates with surface IgD.

Although in mice interleukin 17 (IL-17) plays an essential role in B-lineage differentiation, in humans IL-7 has a minimal proliferative effect on human B-cell progenitors. Nevertheless, IL-7 enhances CD19 expression, which plays an important role in BCR signal transduction (Chapter 4). IL-7 treatment of human proB cells leads to a reduction in the expression of RAG1, RAG2, and TdT, thereby modulating Ig gene segment rearrangement.

Interferons-α and -β (IFN-α/β) are potent inhibitors of IL-7-induced growth of B-lineage cells in mice.[16] The inhibition is mediated by apoptotic cell death. One potential source of IFN-α/β is bone marrow macrophages. Another macrophage-derived cytokine, IL-1, can also act as a dose-dependent positive or negative modulator of B lymphopoiesis.

Systemic hormones also regulate lymphopoiesis.[17] A role for sex steroids is suggested by the reduction in preB cells during pregnancy. Estradiol can also alter later stages of B-cell development, promoting expansion of the MZ compartment. Prolactin appears to enhance production of both MZ and follicular B cells. *Pit-1* transcription factor deficient mice do not produce growth hormone, prolactin, or thyroid-stimulating hormone. These dwarf mice exhibit a defect in B-cell development that is correctable by the thyroid hormone thyroxine.

KEY CONCEPTS

B-Cell Development in the Periphery

- T-independent activation of naïve B cells results in terminal differentiation into short-lived plasma cells.
- T-dependent activation of B cells:
  - Induces germinal center formation, permitting somatic hypermutation and classswitch recombination.
  - Results in differentiation into high-affinity memory B cells and plasma cells secreting high-affinity antibodies.
  - Generates long-term humoral immune protection.
- The longevity of plasma cells is supported by highly specialized survival niches in the bone marrow.
- T-follicular helper cells control late B-cell differentiation by cell-bound ligands and secreted cytokines.
- Activated B cells control T-cell development by presentation of antigen and co-stimulation.

Organization of the Peripheral Lymphoid Organs

During fetal development, the primary and secondary lymphoid organs follow an organized process of construction. This process involves multiple factors that play various roles in the development, maintenance, and function of these organs. The resultant compartmentalization of the lymphoid organs facilitates the efficiency and regulation of immune responses.

Each secondary lymphoid organ has a preferred route of entry for its constituent B cells.[18] For example, while most lymphocytes enter the spleen through the bloodstream, they enter lymph nodes and Peyer patches through high endothelial venules. Their migration and tissue-specific homing is strictly controlled by chemokines (Chapter 15). Dendritic cells, macrophages, and B cells transport antigens from peripheral sites of entry into the follicle within which circulating lymphocytes survey available antigens. Activation of T cells and B cells by the same antigen (cognate antigen recognition) permits initiation of a T-cell-dependent immune response.

The Spleen

In the secondary lymphoid organs, T cells and B cells are segregated into clearly defined areas (Chapter 2). The pattern observed in the white pulp of the spleen is illustrated in Fig. 7.4. It is within the white pulp that antigen-dependent B-cell activation occurs and where these activated cells subsequently undergo further differentiation. The marginal sinus, a lymphoid structure lined with a mucosal addressin cell adhesion molecule-1 (MAdCAM-1) expressing endothelium (Chapter 16), provides entry for lymphocytes, macrophages, and dendritic cells into the splenic tissue.[19] B cells in the adjacent MZ handle the incoming antigen and transport it in a continuous shuttle to the primary follicles, where it is captured and stored by follicular dendritic cells (FDCs). FDCs are stromal cells that present antigen to B cells (Chapter 6). In contrast to other types of dendritic cells, FDCs do not process antigen. Instead, FDCs have abundant complement receptors and Ig Fc receptors that allow them to accumulate antigen in the form of immune complexes within the B follicle. Antigen presentation by FDCs is crucial for maintenance of B cells as well as for their activation and differentiation (see below).

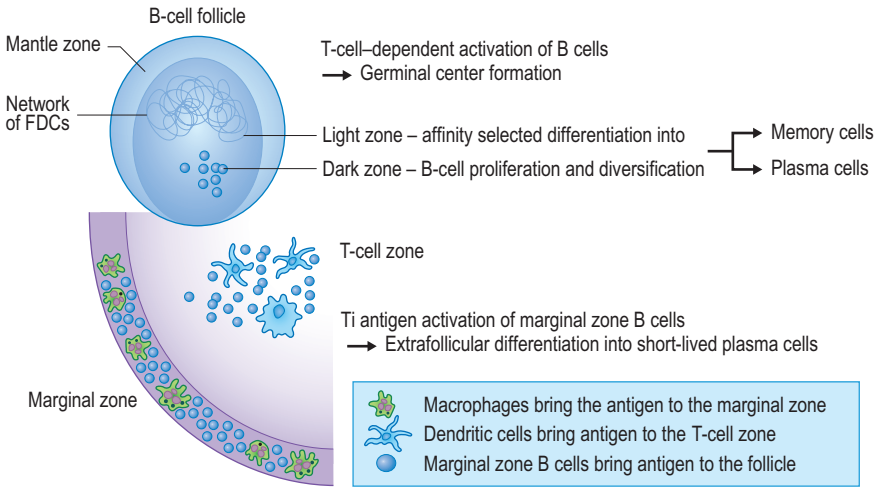

FIG. 7.4 T-Cell and B-Cell Compartments Within the White Pulp of the Murine Spleen. Most splenic T cells can be found in a compartment that surrounds the central arterioles. The compartment is also referred to as the periarteriolar lymphocyte sheath. Most splenic B cells are found in the adjacent follicles, where they are embedded in a network of follicular dendritic cells *(FDCs)*. In addition, there are B cells in the marginal zone, which is located next to the marginal sinus and marks the border of the white and the red pulp. The figure shows a secondary follicle where a dark and a light zone (germinal center) can be distinguished. Primary, follicular B cells are pushed back and form the mantle zone.

B-CELL DEVELOPMENT IN THE PERIPHERY

The life span of mature B cells expressing surface IgM and IgD appears entirely dependent on antigen selection. After leaving the bone marrow, unstimulated cells live for only a few days. Deletion of the transmembrane/intracellular domains of the BCR leads to loss of mature B cells, which indicates that signaling through the BCR is essential for their survival. As originally postulated by Burnet's "clonal selection" theory, a B cell is rescued from apoptosis by its response to an antigen that fits its BCR.

The reaction to antigen leads to activation, which can then be followed by diversification. The nature of the activation process is critical.[19] T-cell-independent stimulation of B cells induces differentiation into short-lived plasma cells with a limited ability to carry out class switching. T-dependent stimulation adds additional layers of diversification, including mutation (SHM) of the variable domains, class switch recombination (CSR) (Chapter 4), and differentiation into memory B cells or into long-lived plasma cells.

B-Cell Activating Factor of the Tumor Necrosis Family and a Proliferation-Inducing Ligand Play Key Roles in the Development of Mature B Cells

Emigrating, recently arisen B cells leave the bone marrow and continue their maturation in the periphery. They demonstrate progressively higher levels of IgD expression with a commensurate reduction of IgM. The splenic environment plays a key role in this maturation process. Immigrant splenic B cells pass through two transitional stages, termed transitional stages 1 (T1) and 2 (T2). Passage through this checkpoint requires the interaction of soluble B-cell activating factor of the tumor necrosis family (BAFF), with its receptor, BAFF-R, which is expressed primarily on B cells. Death signals triggered through interaction of the BCR with self-antigen can be counterbalanced by stimulation of BAFF-R, which enhances expression of survival factors such as Bcl-2 and at the same time downregulates pro-apoptotic factors. Only a minority of these cells successfully make the transition, as this differentiation step is a crucial checkpoint for controlling self-reactivity.[20,21]

BAFF and a second TNF family member APRIL (A Proliferation-Inducing Ligand) are essential factors for the development and long-term maintenance of B cells.[20] As activated B cells develop into plasma cells, BAFF-R is downregulated while the receptors TACI (transmembrane activator and calcium-modulator and cyclophilin ligand interactor) and BCMA (B cell Maturation Antigen) are upregulated. Mutations in TACI and BAFF-R have been associated with hypogammaglobulinemia (Chapter 33). In contrast to BAFF-R, these members of the TNF-R family bind both BAFF and APRIL. APRIL can induce isotype switching in naïve human B cells and—more important—it is a crucial survival factor supporting the longevity of plasma cells.

Marginal Zone B Cells

Functionally and developmentally distinct subsets of mature B cells exist. In the spleen, follicular B cells have a key role in adaptive immune responses that take up to a week to engage. In contrast, MZ B cells lie at the interface between the initial innate and the delayed adaptive immune response[22] with a response that can be measured in hours to a few days. The ability of MZ B cells to rapidly respond to encapsulated bacteria by differentiating into antigen-specific plasma cells helps keep such infections under control. The MZ in the spleen does not fully mature until after the age of 2, which explains why, in addition to individuals lacking a spleen due to a congenital defect or trauma, young infants commonly show a poor response to blood-borne infections with encapsulated bacteria.[23]

B1 B Cells

In addition to "conventional" MZ and follicular B cells (B-2 subset), a small population of innate B cells exists. These B1 B cells are tissue resident cells and are mainly found in the body's

cavities such as the peritoneal cavity.[24] B1 B cells do not participate in adaptive immune responses. Instead, they respond to Toll-like receptor (TLR) (Chapter 3) rather than BCR signaling. B1 cells have been best studied in mice. They preferentially develop from distinct progenitors that comprise a majority of B cells in fetal life. Accordingly, virtually all B cells in mouse fetal liver and 40% to 60% of B cells in fetal spleen are B-1 cells. Later in development, B-1 cells comprise less than 10% of the splenic IgM^+ B cells. Unlike B2 B cells, the B1 subset has self-renewal capacity, which requires autophagy.

Plasma cells originating from B1 B cells secrete IgM antibodies. These natural antibodies (NAb) are found in every serum and provide an important and immediate defense against many infectious organisms. Self-reactivity of these IgM antibodies appears to play a major role in tissue homeostasis.

The frequent presence of CD5 on chronic lymphocytic leukemia (CLL) B cells and their tendency to produce poly- and self-reactive antibodies led many to conclude that CLL was a leukemia of human B-1 cells. When it became clear that CD5 was not a definitive marker for B-1 cells in humans, considerable effort was expended searching for this elusive subset. Currently B cells that are $CD20^+$ $CD27^+$ $CD43^+$ $CD70^-$ appear to be the best candidates.

DIFFERENTIATION AND THE RESPONSE TO ANTIGEN

T-Independent Responses

Unlike T cells, which require presentation of antigen by other cells, B cells can respond directly to an antigen as long as antigen is able to cross-link the antibodies on the B-cell surface. Such antigens, especially those that by nature cannot be recognized by T cells (e.g., DNA or polysaccharides), can induce a B-cell response independent of T-cell help.[19] Depending on the cytokine milieu, the B cells may even undergo class switch, although the range of switching options appears to be restricted. B cells that are activated by antigen alone do not take part in a germinal center reaction (see below).

T-Dependent Responses

Activated B cells express both MHC class I and class II molecules (Chapter 5) on their cell surface. They can thus present both intracellular and extracellular antigens to CD4 T helper and CD8 T cytotoxic lymphocytes. Their role as antigen-presenting cells is enhanced when they present peptides to T cells derived from the same antigen that is bound to their BCR (Chapter 6). Cognate recognition of the same antigen by both a B cell and a T cell permits each of these cells to reciprocally activate the other. In particular, T-cell-activated B cells express the co-stimulatory molecules CD80 and CD86 (Fig. 7.5), which are in turn required for activation of T cells via CD28, and for inactivation by CD152 (CTLA-4). B cells also express the co-stimulator CD40, which interacts with CD40L expressed on T cells. Antigen presentation by B cells is a further requirement for the full differentiation of T cells into T follicular helper cells (Tfh).[19,25]

As Tfh provide cytokines such as IL-4 and IL-21, they have a crucial role in the formation of GCs (see below) and the differentiation of antigen-activated B cells into memory B cells and long-lived plasma cells.[26] These cytokines control divergent outcomes: upregulation of the transcription factor BCL-6 required for the development of GC B cells; activation of AID (activation-induced cytidine deaminase), which is a prerequisite for SHM and class switch (see below); downregulation of PAX-5 and upregulation of transcription factors promoting differentiation into long-lived plasma cells. How these fates are chosen is not yet fully understood (see Fig. 7.5).[19,26,27]

Germinal Center Reaction

T-cell-dependent activation of follicular B cells can induce the formation of GC, which provide the micro-environment in which affinity maturation of the humoral immune response takes place. Within these GC, B cells undergo multiple rounds of SHM and affinity selection after which cells that express BCR of high affinity may differentiate either into memory B cells or long-living plasma cells.[19,28]

During primary immune response, it takes about a week for the complex GC structure to develop in the spleen. A few days after activation of antigen-specific B cells and T cells, small clusters of proliferating B cells are observed at the border between the T-cell zone and the primary B-cell follicle. The rapidly expanding B-cell clone seems to push the naïve B cells toward the edge of the primary follicle so that the naïve B cells form a mantle zone around the newly developing GC. The primary follicle changes into a GC, also referred to as a secondary follicle. Subsequently, the FDC network becomes filled with proliferating, antigen-activated B cells. An influx of antigen activated Tfh follows. Tfh express the chemokine receptor CXCR5, which enables them to enter the B-cell follicle. During this GC reaction, expression of the chemokine CXCL13 by the FDC attracts both antigen activated B and Tfh cells.[25]

In the second week after immunization, the GC matures into a classical structure that contains a dark zone and a light zone (see Fig. 7.4). At this stage of GC development, proliferation is restricted to the dark zone. Within the network of FDC, B cells differentiate into plasma cells and memory cells. In a fully developed GC, dividing cells are termed centroblasts, whereas differentiating cells within the FDC network are termed centrocytes.[28]

In the dark zone, proliferating B cells activate SHM (Chapter 4).[29] This is a highly specific process that targets the gene segments that encode the V domains of the antibody molecule. SHM introduces single nucleotide changes into the sequences of the V domains. This enables production of clones of B cells expressing mutated antigen receptors with varying antigen affinity from a single B cell progenitor. By chance, a few of these mutations result in a receptor with higher affinity for antigen.

A highly efficient antigen-based affinity selection process takes place in the light zone of the GC where FDC present antigen to B cells. Only those B cells with high affinity receptors are able to internalize the antigen via their BCR. Processing of the internalized antigen and presentation of peptides to cognate Tfh cells are prerequisites for B-cell differentiation into memory and plasma cells.[25] The result is that only those B cells with high affinity receptors get adequate help. The cytokine IL-21 (Chapter 14) provided by the Tfh cells is crucial in this differentiation phase (see Fig. 7.5).[26] Upregulation of Bcl6 may support re-entry into the dark zone of the GC and hence further expansion of high-affinity B cell clones. Downregulation of PAX5 and concomitant upregulation of the TF BLIMP-1 will support plasma cell differentiation. Thus, IL-21 together with additional signals provided by Tfh and FDCs, controls the fate of the GC B cells.

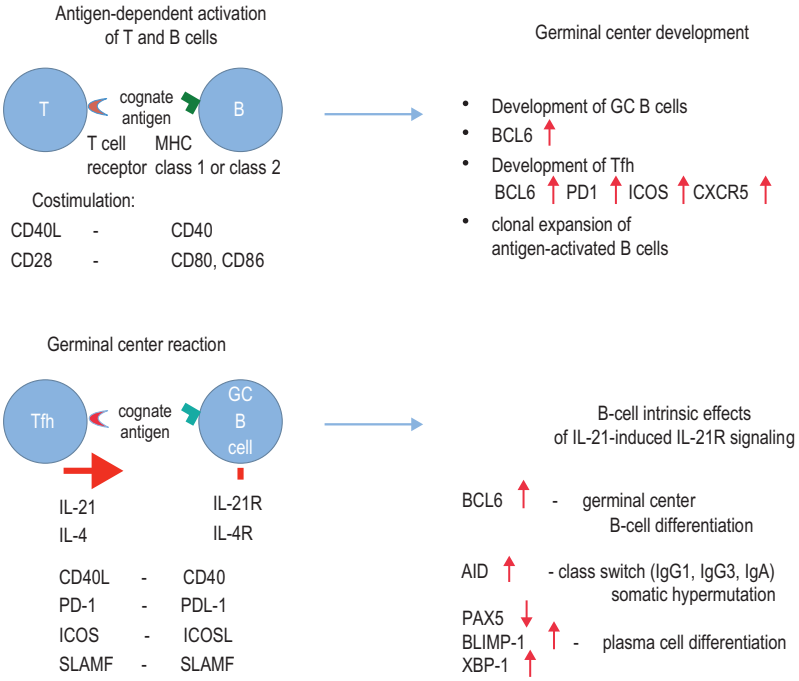

FIG. 7.5 T-Dependent B-Cell Activation and Germinal Centers Formation. Mutual activation of T and B cells requires cognate antigen recognition and co-stimulation. Both antigen activated B cells and T cells upregulate BCL6. Subsequently, the B cells differentiate into germinal center *(GC)* B cells and the T cells develop into T follicular helper cells *(Tfh)* cells. Proliferation of B cells leads to the formation of GC. Under the control of cytokines (e.g. interleukins *IL-21* and *IL-4*), GC B cells differentiate into long-lived memory B cells or into long-lived plasma cells. The differential expression of transcription factors, co-stimulatory factors, and the enzyme activation-induced cytidine deaminase is indicated.

Primary immune deficiencies, such as the hyperIgM syndrome (deficiency in CD40L/CD40 signaling, deficiency in expression of functional AID, failure to signal through the IL-21/IL-21R/STAT3 axis), demonstrated the pivotal role of the GC reaction, for protective humoral immune responses to vaccination or natural infections.

MOLECULAR MECHANISM OF SOMATIC HYPERMUTATION AND CLASS SWITCH RECOMBINATION

Ig SHM and CSR are essential mechanisms for the generation of a high-affinity, adaptive humoral immune response. They allow the generation of effector plasma cells secreting high-affinity IgG, IgA, and IgE antibodies. Both CSR and SHM are dependent on the enzyme AID.[29]

Somatic Hypermutation

Hypermutation occurs only during a narrow window in B-cell development. The mechanism is induced during B-cell proliferation within the microenvironment of the GC. Single nucleotide exchanges are introduced at a rate of about 10^{-3}/base pair/cell generation, into the rearranged V-region and its 3′ and 5′ flanking sequences. Mutations are randomly introduced, although there is a preference for transitions (cytidine <-> thymidine or adenosine <-> guanine) over transversions. Analysis of the pattern of somatic mutations has revealed that the sequence of the six (CDRs; Chapter 4), the loops that form the antigen-binding site, have been selected as mutation hot spots.

Effective hypermutation requires V-gene promoter and transcriptional enhancer sequences. The position of the V-gene promoter defines the start of the hypermutation domain, which spans about 2000 nucleotides. Any heterologous sequence that is introduced into the V-gene segment locus will become a target of the hypermutation machinery. For this reason, SHM can sometimes play a role in the development of lymphomas and leukemia in cases where oncogenes have been linked to Ig promoters and enhancers.

Class Switch Recombination

Upon leaving the bone marrow, the maturing B cell starts to express IgD as well as IgM. Both IgM and IgD antibodies use the same V_HDJ_H-exon and promoter. The molecular basis of co-expression of IgM and IgD by the same B cell is due to differential termination of transcription and splicing of the primary transcripts. Although sequences have been identified that are required for the control of termination and splicing of the Cμ and Cδ transcripts, none of the proteins involved are known. The role of IgD remains unclear, although IgM and IgD appear to create different types of signal transduction structures on the cell surface. In gene-targeted IgD-deficient mice, B cells show a slightly reduced capacity for affinity maturation, although B-cell activation and differentiation appears minimally affected.

Unlike IgD, the other antibody classes are not stably expressed together with IgM. B cells can switch from expression of their V_HDJ_H-exon with Cμ to expression of the same V_HDJ_H-exon with any of the downstream C_H genes (e.g., Cα1,2; Cγ1,2,3,4; or Cε) (Chapter 4) (Fig. 7.6).

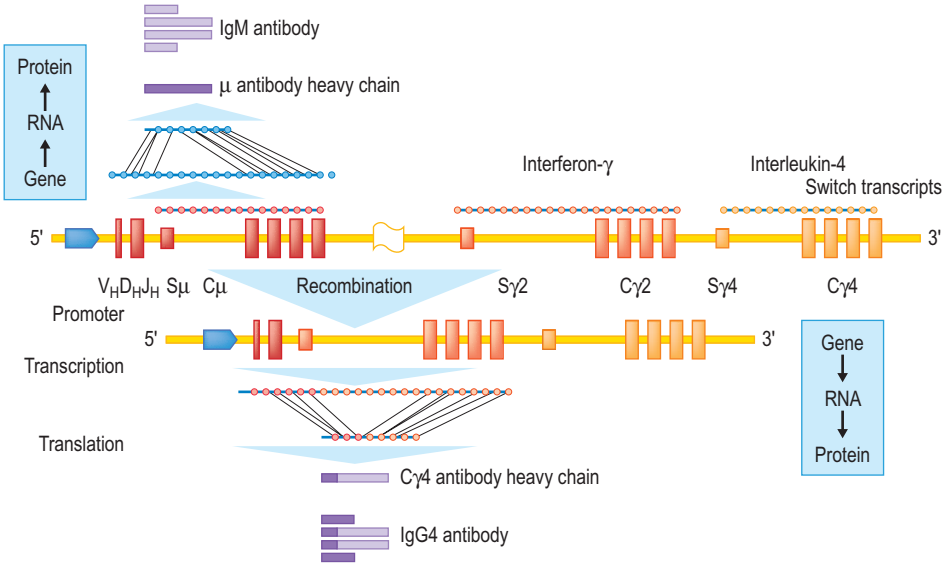

FIG. 7.6 Antibody Class Switch Recombination. Recombination between switch regions (Sμ and Sε) is preceded by transcription of these switch regions. Transcription is targeted by cytokines to distinct switch regions.

TATA-less promoters located in front of the switch regions initiate transcription just upstream of a small I-exon located between the promoter and the switch region. This transcription is essential in targeting CSR, as AID can bind only to single-stranded DNA.

The choice of C_H gene targeted for CSR in a particular B cell appears dependent on external cytokine signals recruiting exactly those classes of antibodies that provide the most useful functions for their respective branches of the immune system (Chapter 14). IL-21 favors class switch to IgG1 and IgG3 in humans, IL-4 to IgG4 and IgE in humans, and IgG1 and IgE in mice. IFN-γ targets CSR to IgG2 in humans and IgG2a in mice, and transforming growth factor-β (TGF-β) to IgA in both humans and mice.

Both Somatic Hypermutation and Class Switch Recombination Require Activation-Induced Cytidine Deaminase

Hypermutation occurs in two steps.[29] The mechanism is induced by AID-catalyzed deamination of deoxycytidine (C) to deoxyuridine (U). The mispairing of U and deoxyguanosine (G) is then processed by uracil DNA glycosylase (UNG) and targeted by repair pathways. This introduces mutations at C–G base pairs. In the second step, mutations at adjacent A–T pairs are induced, probably during a mutagenic patch repair of U–G mismatches introduced by AID. A number of proteins, such as MSH2 and MHS6 (homologues 2 and 6 of the *Escherichia coli* MutS), polymerase η, or exonuclease-1 seem to be involved.

In CSR, AID is targeted to the switch regions located upstream (5′) of each C_H gene.[29] These switch regions are composed of 1 to 6 kilobase-long GC-rich repetitive sequence motifs. Deamination of C and processing by UNG creates an abasic site that facilitates the introduction of double-strand DNA breaks. Joining and repair requires the presence of the DNA-phosphokinases Ku70, Ku80 and probably other members of the general double-strand repair mechanism (Chapter 4).

Both mechanisms, SHM and CSR, need to be tightly controlled, since the introduction of double-strand breaks into the DNA permit translocations involving and activating oncogenes.[30] For example, for Burkitt lymphoma and for plasma cell-derived myeloma, the translocation and ectopic expression of *c-MYC* is an apparent consequence of abnormal SHM and CSR.

B-CELL MEMORY

One of the key features of the immune system is immunological memory for previously encountered antigens. There are two layers of B-cell memory: long-lived memory B cells and protective humoral memory provided by long-lived plasma cells.[19,27,31] Memory B cells provide reactive memory, whereas long-lived plasma cells provide active protective memory. For efficient long-term humoral protection, both are required. Repeat exposure to a high concentration of original antigen may activate memory B cells and induce their differentiation, allowing them to rapidly generate new plasma cells that can secrete antibodies of high quality (Fig. 7.7).

Only plasma cells generated in a GC reaction can migrate to the bone marrow and be housed for long periods in highly specialized niches provided by underlying reticular stromal cells without the need for further activation and proliferation. Their maintenance is dependent on interaction with stromal cells and the survival factor APRIL. Eosinophils have been shown to be the main source of this cytokine and, when they are depleted, plasma cells rapidly go into apoptosis.[32]

The contribution of memory B cells and long-lived plasma cells varies. Some individuals are primarily protected by memory B cells and others by plasma cells.[33] This can be of vital importance in special situations such as transplantation where activation of the immune system should be avoided. For example, treatment of transplant recipients with rituximab, a monoclonal antibody specific for CD20, depletes memory B cells, but has no effect on long-living plasma cells, which may be secreting transplant-specific antibodies.

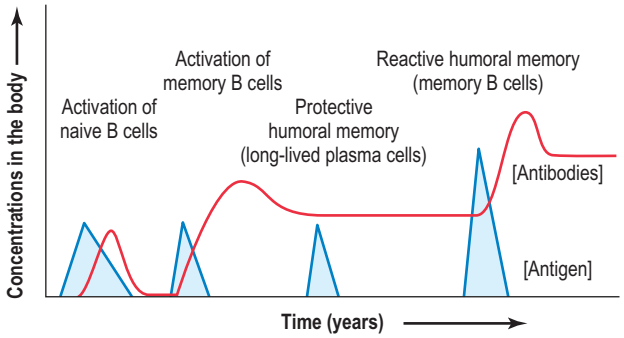

FIG. 7.7 Active and Reactive B-Cell Memory. Memory B cells provide reactive memory, whereas long-lived plasma cells provide active protective memory. The relative concentrations of antibody and antigen over time are indicated.

CLINICAL RELEVANCE

Abnormal B-Cell Development and Diseases of Immune Function

- Failure to generate B cells or a normal repertoire of antibodies leads to humoral immune deficiency, which is commonly marked by recurrent sinopulmonary infections.
- Failure to mount a germinal center reaction may also yield humoral immune deficiency.
- Failure to prevent the formation of antibodies with high avidity or high affinity to self-antigens can lead to autoimmune diseases.
- The process of antibody repertoire diversification lends itself to the creation of mutations that can activate and modify oncogenes as well, promoting leukemia or lymphoma. Mechanisms include:
  - RAG1/2-catalyzed juxtaposition of an oncogene to an immunoglobulin promoter or enhancer, activating the oncogene.
  - AID-induced DNA double-strand breaks and chromosome alterations.
  - AID-induced somatic hypermutation of oncogene, altering its function.

ECTOPIC LYMPHOID TISSUE AND B-CELL DEVELOPMENT

Ectopic lymphoid tissue may develop in the affected tissue or organ in autoimmune diseases, in chronic infection, and in tumors (cancer). Inflammatory cytokines and the presence of B cells support the development of these additional "tertiary" lymphoid tissues.[34]

The growth of ectopic lymphoid tissue in rheumatoid synovium (Chapter 53) offers an excellent example of this disease-related phenomenon. In healthy individuals, the synovium is made up of a thin lining layer of synoviocytes. In contrast, in patients with rheumatoid arthritis the diseased joint is highly infiltrated with varying numbers of T cells, B cells, plasma cells, macrophages, and dendritic cells. In the majority of patients, these mononuclear cells are dispersed loosely throughout the synovium. In some patients, large, well-organized, lymphoid structures can develop that are similar in appearance to the lymphoid follicles seen in the secondary lymphoid organs.[34] At the center of these cell clusters one finds a network of FDCs. Antigen presented by the FDC appears to activate B cells, which induces proliferation. The central B cells are surrounded by a layer of T cells, which may support local B-cell differentiation. A central question concerns the antigens that drive these immune responses and select B cells to differentiate into memory and plasma cells. Ectopic GCs may support an autoimmune response.

ON THE HORIZON

- A better understanding of the regulation of B-cell development by epigenetic modifications and by noncoding RNA as well as the mechanisms and antigens that support the development of ectopic germinal centers could lead to the definition of previously unknown mechanisms of immune deficiency or autoimmunity.
- Elucidation of the mechanisms used to control the antibody repertoire and shape B-cell epitope recognition offer the promise of being able to direct immunity toward production of broadly neutralizing or antitumorigenic antibodies, and away from pathogenic autoantibodies.
- Elucidation of the mechanisms that prevent the development of self-reactivity during affinity maturation could yield new insights into autoimmunity, as well as vaccination.
- A better understanding of the mechanisms that control the production of memory B cells or lead to long-lived plasma cells will pave the way to vaccination strategies that ensure long-term protection.

B-CELL FUNCTIONS IN ADDITION TO ANTIBODY PRODUCTION

B cells play an important function in the activation of T cells, because—like dendritic cells (Chapter 6)—B cells can internalize, process, and present MHC-bound antigen to the TCR on T cells. In cancer, B cells can secrete tumor-associated autoantibodies, inflammatory cytokines, and alter patterns of antigen presentation to T cells. By doing so they may modulate T-cell and innate immune responses to the tumor. By forming antigen–antibody complexes, B cells have the potential to influence immune cells such as granulocytes and natural killer cells that express Fc receptors. In autoimmune diseases, and also in response to inflammation, B regulatory cells (Breg) can have an immune suppressive function.[35] These Breg appear to exert their immunosuppressive effects on Th1 cells via the release of IL-10 and cell–cell contact.

Immunoglobulin Function

Neil S. Greenspan

Antibody-mediated immunity generally requires noncovalent contact between an antibody and the antigen. The ability of an antigen to bind noncovalently to an antibody, termed *antigenicity*, is a physical-chemical property evaluated with respect to a given antibody population. In contrast, *immunogenicity*, the ability to induce the biosynthesis and secretion of soluble antibody molecules, is a biological property requiring in vivo studies.

While antigenicity is necessary for immunogenicity (as defined by the production of antibodies), it is not sufficient. Moreover, the immunogenicity of a given molecule or molecular complex is influenced by host genetic variation.

When an antibody binds to a macromolecular antigen, it directly contacts only a portion of the molecular surface of that antigen. Similarly, only a portion of the antibody molecule makes direct contact with the antigen. By convention, the portion of an antibody or T-cell receptor that makes physical contact with an antigen is referred to as the *paratope* or combining site. Conversely, the region of the antigen in physical contact with the paratope, the antigenic determinant, is termed the *epitope*. Most of the amino acids in an antibody-variable domain that contact a given antigen are located in the hypervariable regions (also termed complementarity-determining regions or CDRs), although some contact residues reside in the framework regions (Chapter 4).[1] Although an epitope (paratope, etc.) is usually defined in terms of intermolecular contact, the region of a molecule involved in physical contact with another molecule may not correspond exactly to the structural correlates for energetics or specificity.[2]

ANTIGEN BINDING AND MOLECULAR IDENTITY

Physical Aspects of Binding

Antibody–antigen interactions are, with some exceptions, noncovalent. This fact is significant in that these interactions are, in principle, spontaneously reversible under the conditions of temperature, pressure, pH, and ionic strength that generally prevail in living organisms.

Several types of noncovalent bonds have been shown to contribute to antibody–antigen binding. These include van der Waals forces, hydrogen bonds, ionic bonds, and hydrophobic interactions. Individually, the strength of these bonds is in the range of one to a few kcal/mole, versus 50 to 100 kcal/mole for covalent bonds. Since the potential to engage in these types of bonds is shared by many of the components of biological macromolecules, individual weak bonds do not usually confer a high degree of specificity, so it is only through the simultaneous action of many such bonds that molecular specificity arises. Hence, the importance of a close fit, often referred to as *complementarity*, between the epitope and the paratope.

Complementarity can be maximized by matching the physical-chemical properties of the epitope and paratope. For example, binding can be facilitated when one molecule is concave and the other is convex, when one molecule is positively charged and the other is negatively charged, or when one molecule is a hydrogen bond donor whereas the other offers a hydrogen bond acceptor. It is expected that the greater the complementarity between receptor and ligand the stronger the interaction (greater affinity) between the two molecules. Complementarity (see below) is also expected to influence specificity.[2] In understanding the strength of interactions between antibodies and antigens, it is relevant that the antibody competes with solvent for binding to antigen. Thus, the thermodynamics of the interaction between these two structures reflects the influence of the interaction on the solvent and other solutes. Moreover, bound water molecules may make important, even crucial, contributions to an interaction between two biomolecules.

Antibody recognition of antigen serves as a paradigm for understanding molecular recognition in the immune system and in biology in general. This fact, coupled with the inducibility of antibodies, permits antibodies to be used as surrogate ligands for almost any receptor (or vice versa).

Affinity is the concept used to convey how strongly two molecules bind to each other. Reflecting the different types of antibody–antigen interaction, two categories of affinity merit consideration: *intrinsic affinity* and *functional affinity*. It should be noted that some immunologists use the term *avidity* in place of *functional affinity*.

Intrinsic affinity is a measure of the strength of the monovalent interaction between a particular paratope and a particular epitope under defined conditions of temperature, pressure, ionic strength, and pH (Fig. 8.1). By convention, the intrinsic affinity is taken to be the equilibrium association constant characterizing the paratope–epitope pair. It is the reciprocal of the concentration of monovalent antigen at which half of the paratopes will be occupied. It is not an intrinsic property of either the paratope or the epitope but rather characterizes the relationship between two molecules under defined conditions.

The intrinsic affinity of an antibody for a small molecule, such as a drug (e.g., digoxin) or a hormone (e.g., insulin), can be clinically important both in vivo and in vitro.[3] For example, the in vivo effectiveness of antibody F(ab) fragments in removing toxic levels of the drug digoxin from patients being treated for congestive heart failure likely depends on the intrinsic affinity of the F(ab) fragments for the drug. Alternatively, antibody intrinsic affinity can limit the analytical sensitivity of an in vitro immunoassay designed to determine the concentration of an

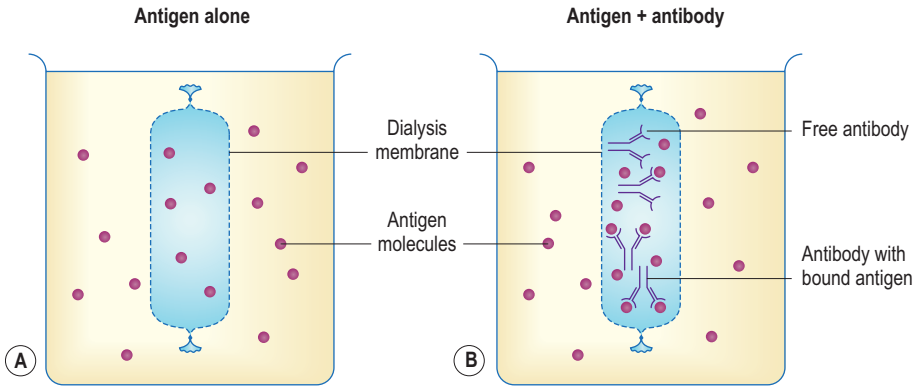

FIG. 8.1 Measurement of the Intrinsic Affinity Characterizing an Interaction Between Antibody and Antigen (Hapten) by Equilibrium Dialysis. At equilibrium (A), the amount of diffusible free hapten inside the dialysis bag will be equal to the amount of free hapten outside of the dialysis bag. However, in the presence of hapten-specific antibody (B) the total hapten concentration will be greater inside of the dialysis bag (free + antibody-bound) than outside of the bag (free). The extent of this difference can be used to determine the intrinsic affinity of the antibody for the hapten. (With permission from Abbas AK, Lichtman AH, Pober JS. *Cellular and Molecular Immunology*. W. B. Saunders Company, Philadelphia, PA; 1991.)

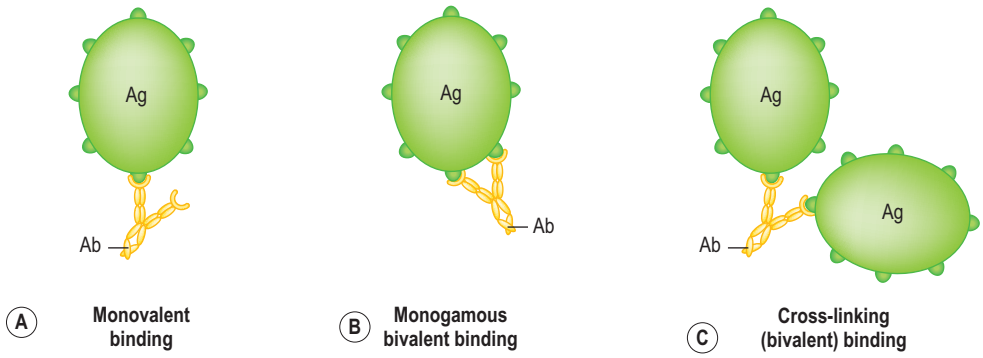

FIG. 8.2 Interaction of a bivalent antibody *(Ab)*, such as immunoglobulin G (IgG), with multivalent antigens *(Ag)* can result in monovalent binding (A), monogamous bivalent binding (B) or cross-linking (C). The complexes in (B) are referred to as cyclic antibody–antigen complexes. *Ag*; antigen; *Ab*; antibody. (With permission from Eisen HN. *General Immunology*. J. B. Lippincott Company, Philadelphia, PA; 1990.)

analyte, such as a hormone (e.g., insulin, parathyroid hormone), or a drug (e.g., digoxin).

In contrast, functional affinity is defined as the equilibrium association constant characterizing the interaction between an *intact antibody* and an *intact antigen*. For a monovalent immunoglobulin G (IgG) antibody–antigen interaction, the intrinsic affinity and the functional affinity will be the same. However, if two paratopes interact simultaneously with two epitopes on the same antigen, referred to as *monogamous* bivalency (Fig. 8.2), the functional affinity of the antibody for the *multivalent* antigen may be substantially greater (as much as 10,000-fold for IgG) than the intrinsic affinity of that antibody for the relevant epitope on that same antigen.[2]

Functional affinity is also influenced by the degree to which the geometric relationships among the epitopes are optimal for the paratopes, which will depend on the quaternary structure and segmental flexibility of the antibody molecule. In the presence of nonoptimal geometry, the average number of engaged sites may be less than maximal, and energy may be expended in achieving some epitope–paratope contacts. Therefore, the functional affinity for a multivalent interaction does not necessarily increase in direct relationship to the maximal number of binding sites that can be engaged simultaneously by an antibody molecule. For example, the effective valency of pentameric IgM with 10 paratopes can be less than 10.

Both concepts of affinity are valuable. Maximization of intrinsic affinity may be of prime importance for antibody-mediated inactivation of toxins or enzymes, which frequently involve monovalent interactions. However, in cases where antibodies bind to repeated epitopes on the surfaces of pathogens or mammalian cells, the functional affinity may play a larger role influencing the biological consequences of the interaction.

Bivalent (IgG, IgE) or multivalent (IgA, IgM) antibodies carry with them the potential to bind simultaneously to two or more epitopes on different antigenic particles, cross-linking them rather than engaging in monogamous bivalency or monogamous multivalency (see Fig. 8.2). This phenomenon has played an important historical role in immunology, such as for typing erythrocyte antigens (e.g., ABO and Rh antigens), which still relies on agglutination of red cells by antibodies (or lectins), and can contribute to host defense by clumping pathogens.

IMMUNOLOGICAL SPECIFICITY

The concept of specificity is fundamental to an understanding of the nature and consequences of interactions between

immunological receptors and antigens. However, in the immunological context, the term specificity encompasses multiple different senses, as discussed below.[2]

One aspect of specificity focuses on the goodness of fit between the paratope and the epitope. Intrinsic affinity is regarded as a reasonable measure of this goodness of fit. However, substantial conformational adjustments of either the paratope or the epitope may be necessary for formation of the complex.[4] Such conformational changes will generally incur energetic costs. Consequently, intrinsic affinity and final complementarity may not be perfectly correlated.

A second aspect of specificity focuses on the ability of a paratope to distinguish among different epitopes. Such specificity is most readily studied when the epitope is in monovalent form and evaluated relative to a specified set of ligands. Thus, one should be cautious about extrapolating claims that one antibody is more or less specific than another antibody without any reference to the relevant universe of ligands. However, there are practical cases where it is justifiable to speak globally of more-or less-specific antibodies. B-1 cells (Chapter 7) often produce polyspecific natural antibodies (NAb).[5] NAb appear to be globally less discriminating than antibodies typical of the B-2 immune repertoire (secondary or later response) when tested on large panels of antigens.

Nevertheless, it is important to note that even antibodies derived from secondary (or later) responses are not,[6] and cannot be, absolutely specific for both thermodynamic and structural reasons.[2] Recent results also indicate that at least some antibodies can adopt two or more different unbound conformations, each of which exhibits a different ligand-binding profile. Such paratopes may undergo further structural adjustment in the process of binding to an epitope.[7] This property can be advantageous to the function of an antibody. Antibodies that react with multiple conformations of a viral surface antigen may be much more likely to interfere with viral infection because they can bind more rapidly to the virus than the virus can bind to its receptor, as demonstrated for human immunodeficiency virus (HIV).[8]

Whereas the first two aspects of specificity focus on the epitope, a third relates to the ability of an antibody to discriminate among antigens that display multiple copies of one or more distinct epitopes. An antigen expressing many copies of one epitope is termed *multivalent*, and an antigen that expresses two or more structurally distinguishable epitopes is referred to as *multideterminant* (Table 8.1). Because two different cells, bacteria, viruses, and so on, may both express multiple copies of the same or nearly the same epitope, an antibody that is highly specific (in the first aspect above) for such a shared epitope may be a poor discriminator between such multivalent particles.[2] Yet, an antibody with a relatively poor degree of complementarity and intrinsic affinity for an epitope found on only one of two or more multivalent targets may be superior at discriminating among these antigens. Furthermore, antibodies (or other molecules) expressing two or more binding sites of identical structure may not discriminate identically among antigens displaying the same epitope in different two- or three-dimensional distributions.[2]

We offer some final points regarding specificity. First, the interactions between molecules such as CD4 (Chapter 9) and major histocompatibility complex (MHC) class II (Chapter 5), which are not clonally distributed, are often described as nonspecific, meaning "not specific for an antigen under consideration." Second, for many purposes immunological specificity has an ultimately biological, not a physical, definition. Third, the enormous utility of antibodies is crucially dependent on the discriminatory abilities of these molecules with respect to other molecules or molecular aggregates, so the usefulness of a particular antibody may depend on the context: for example, what particular antigens or potential antigens, in addition to the preferred target, are available for binding to the antibody. Fourth, apparent antibody specificity may vary with the methods used for analysis, as these methods may differ in sensitivity and in the conditions (pH, ionic strength, temperature) of application, such that the relevant intrinsic affinities may vary among the different assays.

TABLE 8.1 Antigens and Valence

Number of Types of Epitope	Epitope Copy Number	Examples
Monodeterminant	Monovalent	Hapten: DNP, digoxin
Monodeterminant	Multivalent	Polysaccharide: dextran[a]
Multideterminant[b]	Monovalent	Monomeric protein: myoglobin
Multideterminant	Multivalent	Virion: influenza virus

[a]Even a polysaccharide composed of one type of hexasaccharide can have two or more different kinds of epitope: terminal versus internal residues, for instance. However, a given antiserum may preferentially contain antibodies specific for only one such epitope.
[b]Typically, multideterminant recognition occurs with respect to a polyclonal antibody.

PROTEIN EPITOPES

Based on the proximity of the relevant amino acids in the primary structure of the protein, several categories of epitopes have been defined for protein antigens (Fig. 8.3). The simplest is the *linear epitope*, where all of the relevant amino acids are derived from a contiguous, or nearly contiguous, stretch of the polypeptide chain. However, many epitopes on globular proteins involve amino acids from two or more stretches of polypeptide that are distant from one another in the primary structure but juxtaposed in the secondary or tertiary structure. These are referred to as a *conformational*, or *discontinuous*, *epitopes*. A conformational epitope may contain amino acids that are derived from separate but proximate polypeptide chains, as might be the case on nonenveloped viruses.

Another category of protein epitope, the *neo-epitope*, is reserved for those antigenic sites that become recognizable only after a post-translational event, such as phosphorylation or proteolytic cleavage. For example, neo-epitopes have been defined on cleavage products of human C1q, C3, and C9, which are components of the complement pathway (Chapter 40).[9] Antibodies recognizing such neo-epitopes can be used to monitor the extent of activation of the complement pathway.[9] A chimeric antibody ensituximab, which targets colorectal and pancreatic carcinoma–associated neo-epitopes, represents the therapeutic potential of targeting cancer neo-antigens (Chapter 80). In rheumatoid arthritis, autoantibodies to citrullinated epitopes on such antigens as filaggrin can be of diagnostic value (Chapter 53).

Studies in the 1970s on the sizes of epitopes associated with synthetic peptide antigens yielded results suggesting that protein epitopes would maximally involve six or seven amino acids. However, the first x-ray crystallographic structure of an

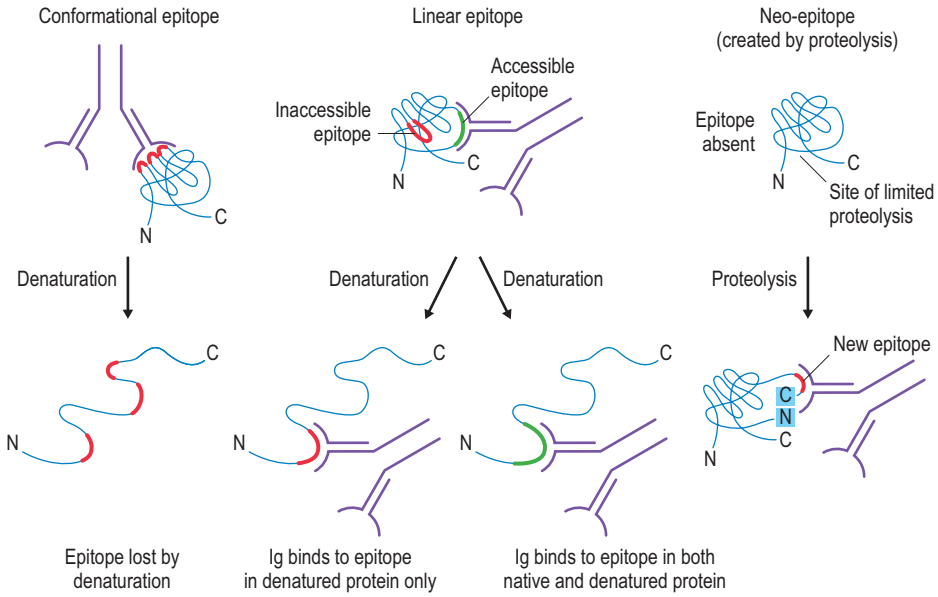

FIG. 8.3 Types of Protein Epitopes. Some antibodies recognize structural features of proteins that arise from the folding of the polypeptide backbone (conformational epitope). Others recognize groups of amino acid residues that are contiguous, or nearly so, in the primary (covalent) structure of the protein (linear epitope). If such a linear determinant is inaccessible in the native structure of the protein, the corresponding antibodies may only be elicited by the denatured form of the protein. Neo-epitopes are created by covalent post-translational modifications, such as phosphorylation or proteolytic cleavage. (With permission from Abbas AK, Lichtman AH, Pober JS. *Cellular and Molecular Immunology*. 3rd ed. W. B. Saunders Company; 1997.)

antibody variable module in complex with a globular protein antigen[1] indicated that protein epitopes, defined on the basis of intermolecular contact, could be as large as 15 to 20 amino acids. A similar number of amino acids in the antibody V domains constituted the paratope. Even peptide antigen–antibody interaction can involve at least 12 peptide amino acids in contact with the antibody. Still, it is possible that there are smaller epitopes on globular proteins, particularly for regions of proteins that protrude or have a high radius of curvature.

Antibodies specific for both linear and conformational epitopes have important practical applications. For example, a synthetic peptide corresponding in amino acid sequence to a segment of the polypeptide chain predicted from the nucleotide sequence can be used to elicit antibodies useful in identifying the protein following expression, electrophoresis, and blotting under denaturing conditions. Antibodies raised by challenge with synthetic peptides that bind to linear epitopes and that recognize a protein in denatured form often do not bind to or alter the function of the native protein.

Antibodies with the ability to neutralize protein function generally recognize conformations accessible to the native protein, usually at discontinuous epitopes. However, antibodies specific for peptides (that correspond in amino acid sequence to a portion of a native protein) or denatured protein, which can cross-react with the protein in a native (folded, functional) state can be extremely valuable. Such cross-reactivity is more likely to occur when the region being recognized is relatively disordered in the native structure.[10]

CARBOHYDRATE EPITOPES

The classical studies of Kabat on the binding of antibodies to dextran led to the concept that epitopes on carbohydrate antigens could be as large as six or seven monosaccharides. However, minimal carbohydrate epitopes can probably be as small as one or two monosaccharides. Even in the case of larger epitopes, it is typical for the terminal groups to play a dominant role in determining antibody specificity for carbohydrate antigens. Recent studies suggest that polysaccharide epitopes can sometimes also result from the conformational properties of the polysaccharides.

In comparison to antibody–protein interactions, interactions between antibodies and polysaccharides have typically been characterized by relatively low intrinsic affinities.[2] Relatively weak antibody–carbohydrate binding can result from biological constraints related to protection against self-recognition and consequent tissue damage, or from physical-chemical constraints related to the conformational freedom and high degree of solvation of unbound carbohydrates. On the other hand, antibodies produced in response to pathogens, such as HIV, may be much more effective at interacting with carbohydrate antigens.[11]

Another important feature of polysaccharide antigens is that they are generally multivalent. Bacterial and perhaps viral polysaccharide epitope densities can approach values in the millions per square micrometer, which is probably one to several orders of magnitude greater than the epitope densities for protein determinants on mammalian cells. Therefore, multipoint attachment and functional affinity are likely to be critical factors in the mediation of immunity by anti-polysaccharide antibodies or other carbohydrate-specific proteins.

IMMUNE COMPLEXES IN VIVO

Interactions between antibodies and antigens in vivo can result in the formation of molecular aggregates, referred to as *immune complexes*. Deposition of immune complexes in tissues, such as blood vessels, renal glomeruli, renal tubules, the thyroid gland,

and the choroid plexus, can result in pathological conditions.[12] Immune complexes can form in the circulation prior to deposition in a given tissue, or they can form directly in the affected tissue. A clinical situation in which immune complex formation can be a cause for concern is the production of anti-antibodies in response to therapy with pooled intravenous IgG (IVIg) (Chapter 82) or therapeutic monoclonal antibodies.

Variables such as concentration, composition, size, charge, and antibody isotype will influence the magnitude and sites of tissue deposition for these complexes. In conjunction with the sites and extent of tissue deposition, the magnitude of complement activation and the extent of interaction with Fc and complement receptors determine the biological properties of the complexes. Antigen–antibody lattice size is determined by antigen valence, epitope geometry, antibody valence, the intrinsic affinity of paratope for epitope, antibody and antigen flexibility, the ratio of antibody to antigen, and the absolute concentrations of antibody and antigen. The potential diversity of immune complex morphologies is illustrated in Fig. 8.4. These complexes, between a monoclonal antibody specific for a bacterial polysaccharide and various anti-idiotypic or anti-isotypic monoclonal antibodies, are visualized by electron microscopy.

Immune complexes have also been found to have immunoregulatory effects,[13] particularly with respect to antibody responses. Immune complexes can bind simultaneously to B-cell surfaces through antigen (to B-cell-surface immunoglobulin), antibody (to Fc receptors [FcR]), and associated complement components (to complement receptors). The interaction with FcγRIIB on the B-lymphocyte membrane has the effect of diminishing the B-cell response (Chapter 4). The molecular events underlying these immunoregulatory effects are being studied, and they have been clinically exploited for many years. Antibody to the erythrocyte Rh antigens is used to prevent immunization of an Rh^- mother by an Rh^+ fetus, thereby avoiding hemolytic disease of the newborn in a subsequent Rh^+ fetus.

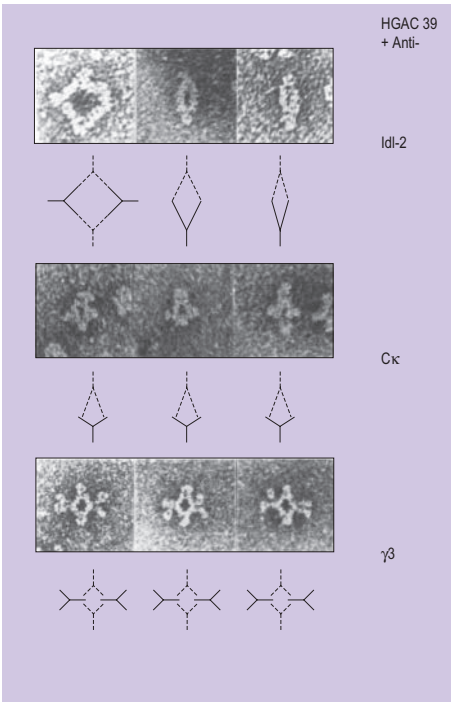

FIG. 8.4 Electron micrographs (*above*; × 350,000) and interpretive diagrams (*below*) of a mouse IgG3 mAb (HGAC 39; specific for a bacterial polysaccharide) in complex with mAbs specific for, respectively, an idiotope (*Idl-2*; *top*), a light-chain isotypic determinant (*Cκ*; *middle*), and a heavy-chain isotypic determinant (γ_3; *bottom*). The different antibodies are not intrinsically distinguishable in the electron micrographs, but the interpretations are based on information in addition to that provided directly by the electron microscopic images. In the top series of micrographs, the choice of which molecules to represent as *solid* or *dotted figures* is arbitrary. *mAb*, monoclonal antibody. (With permission from Greenspan NS. Analyzing immunoglobulin functional anatomy with monoclonal anti-immunoglobulin antibodies. *BioTechniques*. 1989;7:1086.)

CORRELATIONS BETWEEN C_H REGION STRUCTURE AND ANTIBODY FUNCTION

Antibodies are heterodimeric proteins that can be functionally divided into V domains, which bind antigen, and C domains, which define the effector function(s) of the immunoglobulin (Chapter 4). This division of labor allows an antibody to physically link a specific antigen to separate antigen-nonspecific effector molecules. Many features of C_H domain structure exhibited by the immunoglobulin isotypes can be understood in the context of this requirement for physical and/or functional linkage between antigens and antigen-nonspecific effector molecules.

One property of prime significance for antibody function is intramolecular mobility, often referred to as *segmental flexibility*. Hydrodynamic methods, electron microscopy, x-ray crystallography, and fluorescence polarization, have all been used to evaluate the degree of flexibility exhibited by immunoglobulin molecules. In the case of the best-studied isotype, IgG, it is clear that the structural feature most associated with relative motion of one subunit relative to another is the hinge, which connects the C_H1 domain to the C_H2 domain and is encoded by a separate exon(s). The human IgG3 subclass has an extended hinge region that can impart increased flexibility. In the case of IgA, the IgA1 hinge is flexible, such that the F(ab) arms can range from the typical "Y" configuration to a "T" configuration, whereas IgA2 molecules are relatively constrained.

Immunoglobulin flexibility has important functional consequences for the antibody. First, inter-F(ab) movements can play an important role in permitting antibodies to bind in monogamous bivalent (multivalent) fashion to antigenic surfaces that display repetitive epitopes. Second, efficiency in precipitation of multivalent antigen molecules or agglutination of multivalent antigen particles can be correlated with inter-F(ab) flexibility. Third, optimal interactions of effector molecules with IgG antibody Fc regions has been postulated to depend on the ability of the Fc region to bend out of the plane of the F(ab) arms (*dislocation*) (but see discussion on complement activation below).

FUNCTIONS MEDIATED BY ANTIBODY ALONE

While it is clear that in many in vivo situations antibodies mediate their effects with the aid of other molecules and, in some

cases, cells (see next section); there are circumstances where the antibody can influence antigenic targets directly, at least in vitro. The very name "antibody" implies the negation of some activity, and antibodies were first defined as factors that could inactivate or neutralize toxins. Subsequent studies have shown inactivation of viruses, parasites, and enzymes, as well.

Virus Neutralization and Immunity

KEY CONCEPTS

Immunity to Viruses

- Antibodies can neutralize (decrease the replication of) viruses by blocking attachment to the host cell, preventing penetration of the host cell membrane, or interfering with uncoating of the virus within the cell.
- Neutralizing antibodies use their V domains to bind proteins or glycoproteins on the virion surface but may depend on the interaction between their C domains and host Fc receptors to inhibit virus replication in vivo.
- Non-neutralizing antibodies that bind to virion surface proteins or glycoproteins may or may not contribute to immunity, and in some cases may actually enhance infection.
- The magnitude of neutralization mediated by a given antibody may vary with the host cell used for the measurement.
- Neutralization in vitro may not always correlate with protection in vivo.
- Non-neutralizing antibodies can contribute to protection for some viruses based on FcR-dependent mechanisms or via signal transduction.

A phenomenon of fundamental medical and biological importance is the *neutralization* of viruses by antibodies.[14] Although neutralization is defined as the elimination or reduction of the virus's ability to replicate, it does not imply a particular mechanism of interference with the process of replication. Moreover, the measurement of neutralization can depend on the choice of host cell. Thus, the neutralizing activity of a given antibody for a given virus is not an intrinsic property of the antibody but is a property of the relationship between antibody and virus under defined conditions. Consequently, neutralization titers in serum do not always correlate perfectly with protection from infection or disease in vivo.

There are several mechanisms by which antibodies can inactivate viruses. A virus infects a cell via multiple steps: (1) attachment to one or more membrane components, (2) penetration of or fusion with the membrane, (3) uncoating, and (4) genome expression. Although the most obvious mechanism of neutralization is prevention of viral attachment to the host cell surface, some antibodies can block other steps. Neutralizing antibodies for enveloped viruses, such as influenza virus, have been shown to prevent fusion between the virion and cell membranes, and neutralizing antibodies for poliovirus have been shown to interfere with viral uncoating in the host cell.

There is no one-to-one correspondence between isotypes and neutralization mechanisms; different isotypes of antibodies may employ different neutralization mechanisms to varying degrees. In some cases, IgG or IgM antibodies in the blood can mediate protection against a virus directly, or with the assistance of complement components. In mucosal secretions, where complement is less plentiful than in the blood, virus-specific IgA is more likely to utilize virus-inactivating mechanisms that do not require complement, such as prevention of attachment.

Traditional thinking maintains that antibody mediates any protective effects extracellularly. However, it has been reported that IgA antibodies, when transported by the polymeric immunoglobulin receptor (pIgR), can mediate protection against intracellular influenza virus.[15] Similar phenomena have been reported for rotavirus and HIV.

There are several other notable features of antibody–virus interactions. Not all antibodies that bind to molecules on the virion surface will neutralize the virus in all conditions. For the influenza virus hemagglutinin, binding of antibodies to some sites, but not others, will effect neutralization. Some gene products on the virion surface may fail to routinely support viral neutralization (e.g., influenza neuraminidase). However, antibody to influenza neuraminidase, while non-neutralizing, is thought to slow the spread of infection by interfering with the escape of progeny virions from infected cells. Non-neutralizing antibodies, or neutralizing antibodies at suboptimal concentrations, have been found in some instances to enhance the infection of host cells by virus (e.g., HIV-1 or dengue virus). It should be noted, however, that the clinical relevance of this enhancement, at least in regard to HIV, remains to be determined. Finally, some non-neutralizing antibodies, or those antibodies that fail to directly neutralize virus in an in vitro assay, can mediate protective effects in vivo, presumably by engaging antigen-nonspecific effector mechanisms (i.e., complement or FcR-bearing cells), or perhaps through cellular signal transduction.[16]

Neutralization of Toxins and Enzymes

KEY CONCEPTS

Immunity to Bacteria

- By neutralizing exotoxins, antibodies may prevent disease mediated by bacterial pathogens (e.g., *Corynebacterium diphtheriae* and *Clostridium tetani*).
- Antibodies can also bind and inhibit bacterial proteins that perform critical metabolic or virulence-related functions.
- Antibodies alone or with complement-derived split products can opsonize pyogenic pathogens such as *Streptococcus pneumoniae*.
- Antibodies can mediate destruction of some bacteria (e.g., *Neisseria meningitidis* and *Neisseria gonorrhoeae*) through activation of the classical pathway of complement leading to assembly of the membrane attack complex.
- Antibodies can bind to bacterial adhesins and thus interfere with pathogen attachment to mucosal epithelial cells.

In many bacterial infections, the clinical consequences of infection result from toxic molecules liberated by the bacterial cells rather than from the presence of the microorganisms themselves. Antibodies to such toxins can provide life-saving protection from disease, while not directly eliminating the bacteria producing the toxins. A classic example is infection with *Corynebacterium diphtheriae*, which secretes a potentially lethal exotoxin. A more recent example is the emergence of *Clostridium difficile*, which secretes both an enterotoxin (toxin A) and cytotoxin (toxin B). Not only is there a correlate between antibody titers to toxin A and B and prevention of relapse but also passive immunotherapy with antibody prevented relapse.[17]

Bacteria can also produce additional virulence factors, such as enzymes that facilitate pathogen spread through tissues. Host antibodies that inactivate such enzymes can be beneficial. Inactivation of toxins or enzymes is presumed to result from direct

competition between antibody and the target molecule or substrate of the toxin or enzyme, or from the stabilization or induction of conformations incompatible, to some degree, with the normal function(s) of the molecule. However, recent evidence in mice suggests that the protection afforded by exotoxin-neutralizing antibodies can depend on the presence of Fcγ receptors.[18]

FUNCTIONS MEDIATED BY ANTIBODY AND ADDITIONAL MOLECULES OR CELLS

Complement Activation

Antibody bound in vivo can activate antigen-nonspecific effector mechanisms. The exact mechanisms activated, if any, will depend on the isotype of the antibody as well as on other factors. One critical set of these effector mechanisms is encompassed by the classical pathway of complement activation (Chapter 40). Human antibody isotypes vary considerably in their intrinsic ability to activate this pathway. The consensus view is that IgM, IgG1, and IgG3 isotypes are effective activators. While some sources state that IgG2, IgG4, and IgA are weak or nonactivators of the classical complement pathway, evidence suggests that IgG2 can activate the classical pathway effectively when epitope density is high.[19] Of course, complement-fixing ability may not be determined solely by the subclass of an IgG antibody.

One obvious source for the isotype-related variation in complement-activating ability is variation in affinity for C1q (IgG3 > IgG1 > IgG2 > IgG4), the portion of the first component in the classical pathway that physically contacts the C_H2 domains of antibodies. The intrinsic affinity of the C1q globular heads for Fc regions of any isotype is relatively low, which may account in part for the observation that two or more IgG molecules in proximity are required for activation of the classical pathway beginning with C1. Thus, in the activation of the classical pathway, the functional affinity of C1q for antibody Fc regions is a crucial parameter.

IgG subclass–associated differences in some measures of complement activation have been found, under some experimental conditions, to depend on quantitative differences in steps of the cascade subsequent to the binding of C1q to antibody. Regarding the role of segmental flexibility in complement activation, there is no simple correlation between this physical property and activity in fixing the classical complement pathway.[20] Recent studies using a variety of imaging and biophysical methods demonstrate that hexameric assemblies of human IgG1, mediated by noncovalent Fc–Fc interactions, maximally activate complement.[21]

While it is generally agreed that IgA does not activate the classical pathway, its ability to activate the alternative complement pathway has been controversial. Studies with recombinant IgA molecules have suggested that neither IgA1 nor IgA2 activates either complement pathway. However, aberrantly glycosylated IgA and polymeric IgA may activate the lectin or alternative pathway, and this activation has been postulated to be associated with IgA nephropathy.

Antibody-mediated activation of the classical complement pathway has a variety of potential consequences. These include creation of additional sites for attachment to a foreign particle, thereby facilitating ingestion (opsonization), elaboration of substances that mediate leukocyte chemotaxis, additional metabolic changes in leukocytes involved in the destruction of pathogens, and changes in vascular permeability. In this process, it is the antibody that provides the specificity, whereas the other molecules function without specificity for the epitopes involved.

Receptors for Fc Regions

The other major system by which antibodies mediate effector functions is cellular. The specific molecules with which cells recognize antibodies are called FcR.[22] In humans, there are several FcR for IgG (FcγRI, FcγRIIa, FcγRIIb, FcγRIIIa, FcγRIIIb), as well as other FcR for IgA, IgE (FcεRI, FcεRII), and IgM (Fig. 8.5). We describe selected features of FcR that help to illuminate the principles by which they function.

Some receptors (FcγRI, FcεRI) have relatively high intrinsic affinities for antibody molecules and can thus bind significant fractions of monomeric Ig at physiological concentrations. For example, the high-affinity receptor for IgE (FcεRI) binds IgE with an intrinsic affinity of approximately 1×10^{10} M^{-1}. Single IgE molecules can bind to mast cells or basophils through cell-surface FcεRI prior to interacting with allergen (antigen). In contrast, FcγRII and FcγRIII have relatively weak intrinsic affinities for IgG Fc regions. Consequently, multivalent forms of IgG, such as are found in complexes of antibody and multivalent antigens (immune complexes), are much more readily bound to these FcR. Thus, for both the complement-dependent and the FcR-dependent effector function pathways, multivalency of Fc regions (functional affinity) can play a critical role.

Several types of functional consequences can follow ligation of FcR by antibody–antigen complexes. These include activation and metabolic alteration of the FcR^+ cells, phagocytosis of antibody-coated particulate antigens, antibody-dependent cellular cytotoxicity (ADCC), and release of mediators that promote inflammation. The end result of Fc binding depends not only on the receptor but also on the cell on which it is expressed and on concurrent stimulation, if any, of additional receptor types on that cell. As an example, the most studied FcR are those that bind IgG, and these receptors are expressed on many hematopoietic and even non-hematopoietic cells. Within the three classes of receptors (I, II, and III), the latter two FcR exist in two isoforms (A and B). Of interest to the regulation of the immune response, the B isoform for FcγRII transmits an inhibitory signal while the A isoform transmits an activating signal (Chapter 4).

CD89 has been identified in humans as a receptor for IgA and it is expressed on myeloid cells including polymorphonuclear neutrophils (PMNs), monocytes, and a population of dendritic cells.[23] Signaling through CD89 involves an ancillary chain that transmits an activating signal. However, not all CD89 molecules associate with this chain, in which case bound IgA is endocytosed and recycled back to the surface of the cell.[23] Interestingly, Fc binding to CD89 may be more potent at mediating ADCC than Fc binding to one of the FcγR.

Recent data suggest another possible function that depends on the interaction between antibody (IgA) and a cell-surface receptor able to bind to pIgR. Transport of IgA–antigen complexes across epithelial surfaces by pIgR may represent a form of antibody-facilitated antigen excretion.[24]

ANTIBODIES AS SURROGATE LIGANDS

The notion that one molecule can mimic a second molecule, in one respect or another, is of extraordinarily broad applicability and profound biological significance. At least three types of mimicry can be distinguished, and each type is best regarded as a continuous variable[24]: (1) limited structural mimicry of

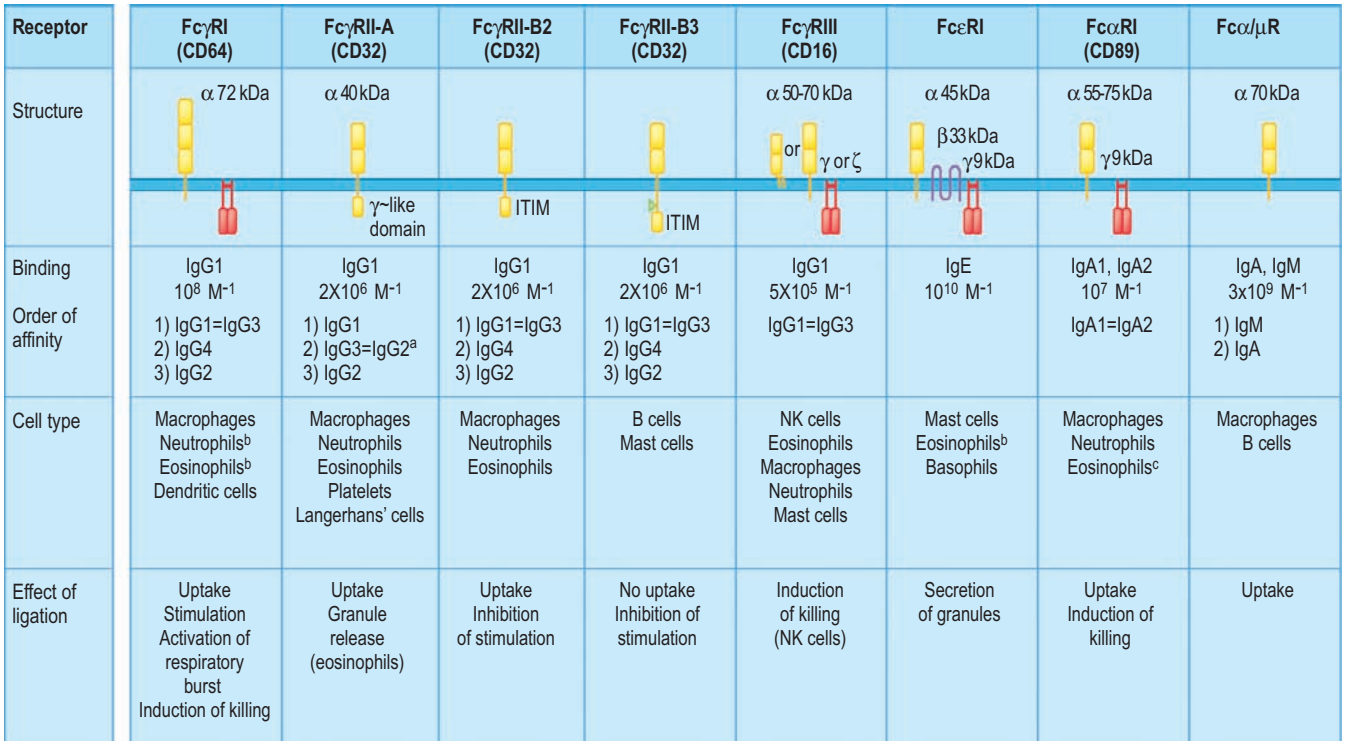

FIG. 8.5 Domain Structures, Binding Properties, Cellular Expression Patterns, and Functional Effects of Human Fc Receptors. A given Fc receptor (FcR) may exhibit differences in composition depending on the cell type expressing it. For example, FcγRIII is expressed on neutrophil plasma membranes bearing a glycosylphosphatidylinositol anchor, without FcR γ chains, while it is expressed on NK-cell plasma membranes as a conventional transmembrane protein in association with FcR γ chains. Similarly, FcγRII-B1 contains an additional stretch of polypeptide encoded by an exon whose product is not represented in the intracellular domain of FcγRIIB2. This additional portion of the polypeptide is believed to prevent the internalization of FcγRII-B1 subsequent to cross-linking. [a]A subset of FcγRII-A allotypes bind to human IgG2. [b]For these cells, FcR expression is inducible, not constitutive. [c]The molecular weight of CD89α chain is 70 to 100 kDa in eosinophils. *ITIM*, immunoreceptor tyrosine-based inhibitory motif; *NK*, natural killer cell. (With permission from Janeway CA Jr, Travers P, Walport M, Shlomchik M. *Immunobiology: The Immune System in Health and Disease*. 6th ed. New York: Garland Science; 2004.)

one molecule by another; (2) mimicry at the level of noncovalent interaction, that is, whether the model (object of mimicry) and the mimic bind the same receptor sites and with the same affinities; and (3) mimicry of more complex biological functions, such as cellular or enzymatic inactivation. It is important to make these distinctions because the extent of mimicry of one type is not a perfect predictor of the extent of mimicry of another. We have already noted that slight changes in structure sometimes have slight effects on binding affinity or specificity, yet in other cases they have dramatic effects on binding affinity or specificity. Thus, structural similarity (mimicry), as we perceive it, is not perfectly correlated with the extent of binding or the elicitation of higher biological function.

There are two aspects of receptor–ligand interaction that antibodies can potentially mimic. First, the inducibility of a vast repertoire of antibody specificities suggests the potential for identifying antibodies that can bind any given target molecule at (near) a given site. Thus, there should be a reasonable probability of obtaining antibodies that bind to a particular receptor at a site bound by some other, perhaps physiological, ligand or co-receptor. Evidence that antibodies can mimic the functional effects of other molecules is provided by many investigations of anti-idiotypic antibodies and conventional anti-receptor antibodies.[25]

Second, the triggering event for many cellular and effector processes in the immune system is the aggregation of receptor molecules by clustered ligands. Therefore, the ability of antibodies, which naturally have a maximal valence of two or greater, to cross-link cell-surface molecules and initiate signal transduction contributes to the abilities of antibodies to serve as surrogate co-receptors for cell-surface molecules. This has greatly facilitated the identification and functional characterization of many of these molecules and is also being exploited for therapeutic uses.[26]

FUNCTIONAL PROPERTIES OF ENGINEERED ANTIBODY MOLECULES

Monoclonal Antibodies

Many modern applications of antibodies in research, medicine, veterinary medicine, and other fields rely heavily on monoclonal antibody technology. By definition, a monoclonal antibody preparation is derived from a clonal population of B-lineage cells. All of the antibodies express identical V domains with identical antigen specificities. It is the homogeneity of the monoclonal V domain structures that most crucially distinguishes a monoclonal from a polyclonal, serum-derived antibody preparation. Both sets of antibodies bind the same antigen, but only the monoclonal preparation will bind the same epitope in the same way. Thus, homogeneous antibodies give more reproducible, and more easily interpreted, results for many kinds of assays.

ON THE HORIZON

Monoclonal Antibodies: Recent Advances

- Production of human monoclonal antibodies from patients who have recovered from infectious diseases could provide new therapeutics for the causative pathogens.
- Genetic engineering of human B cells that make human antibodies able to bind pathogens, pathogen-derived molecules, or other antigens will potentially provide a new pathway for developing cellular therapy for infectious and other diseases.[27]
- If key obstacles can be overcome, vector-mediated expression of antibodies (vectored immunoprophylaxis) will become an option for providing protection against infectious diseases in patients who are not likely to respond effectively to active immunization with standard vaccines due to varying types of immunodeficiency.[28]
- Advances in manipulating glycan structures on antibodies could enhance the efficacy of therapeutic monoclonal antibodies.[29]
- Improved ability to determine the precise geometry of the interaction of antibody with antigen can enable prediction and engineering of mechanisms of therapeutic effect.[30]

Monoclonal antibodies of selected specificity were first produced by cells referred to as *hybridomas*,[31] which are hybrid transformed cells that are created by the fusion of two types of cells. One parent of a hybridoma (the fusion partner) is typically a transformed cell, usually a myeloma cell line, which contributes a metabolism that supports unlimited growth in tissue culture and high rates of immunoglobulin synthesis and secretion, no longer synthesizes an immunoglobulin molecule, and can be selected against in special culture media. The second parental cell is a B lymphocyte that provides the genetic information for the production of a particular antibody. The choice of specificity on the part of the investigator is influenced by both the choice of immunogen and the nature of the screening assay, which permits identification of the minority of cells that secrete a monoclonal antibody of desired specificity, or in some cases, function.

Monoclonal antibodies are useful for the identification and quantitation of diverse molecules of biological or synthetic origin, including human immunoglobulins (e.g., paraproteins), antigens from infectious agents (e.g., HIV p24), hormones, drugs, and toxins. They have also been exploited for therapeutic purposes, such as reversing allograft rejection, killing tumor cells, or preventing cytokine activity contributing to autoimmune disease.

Recombinant Antibodies

ON THE HORIZON

Recombinant Antibodies—Antibody Engineering

- Enhance effector function potency and half-life through Fc modification.
- Reduce or eliminate bystander effects.
- Isolate and express antibody genes using single B-cell cloning or combinatorial libraries.
- Allow expansion of the antibody repertoire and targeting possibilities.
- Facilitate agents for molecular recognition of minimal size (i.e., nanobodies).
- Develop drugs or toxins that can be covalently attached to novel antibodies for therapy.
- Create multispecific or multimeric constructs.
- Guide vaccine design.
- Evaluate the roles of isotypes in protection or other functions.
- Define how differences in glycosylation can alter effector function.

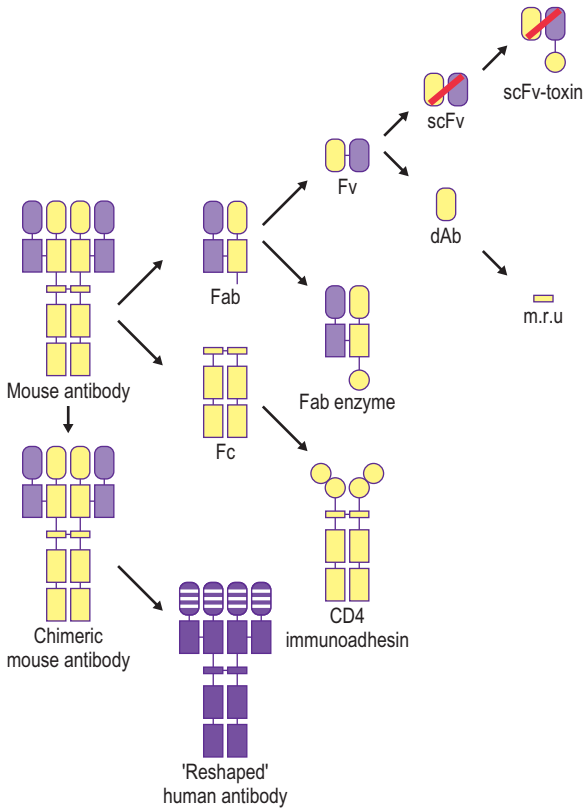

FIG. 8.6 Examples of Engineered Antibodies and Antibody-Derived Fragments That Can Be Created Through the Manipulation of Antibody Genes. Each *closed rectangular (constant)* or *rounded (variable) box* represents a domain. The molecule at the bottom of the figure represents a humanized antibody, where the constant domains and variable domain framework regions correspond to human amino acid sequences. Only the hypervariable regions, and in some cases a small number of framework residues, correspond to mouse or rat antibody amino acid sequences. Other structures depicted include an *Fab* fragment; an *Fv* fragment; a single-chain Fv fragment *(scFv)* in which the C-terminus of the V_H domain is linked covalently by a linker peptide to the N-terminus of the V_L domain; an Fab-enzyme fusion protein; an scFv-toxin fusion protein; an immunoadhesin in which extracellular domains from CD4 have been covalently attached to human heavy-chain constant domains; a single V_H domain *(dAb)*; and a peptide derived from a hypervariable region (minimal recognition unit, or *m.r.u.*). (With permission from Winter G, Milstein C. Man-made antibodies. *Nature*. 1991:349:293.)

The ability to manipulate the genes that encode antibodies, and thereby manipulate the structures of antibodies, has opened a new era in the study and application of antibodies (Fig. 8.6).

Progress includes expression of recombinant intact IgG molecules,[32] expression of Ig fragments [F(ab), Fv] in eukaryotic and prokaryotic host cells, proteomic mining of combinatorial libraries of antibody fragments displayed on the surfaces of filamentous phage[33] or yeast and bispecific or multispecific antibodies. Most recently, the ability to clone immunoglobulin genes from single B cells has revolutionized the production of human monoclonal antibodies. This technology has made possible the identification of broadly neutralizing antibodies for

rapidly evolving pathogens, such as HIV-1 and influenza A viruses. These antibodies may prove to be clinically useful.[34]

Recombinant antibodies are also being designed to improve distribution and half-life of administered antibodies. Antibody engineering is likely to contribute to the design of novel therapeutic agents. And use of these agents is likely to continue to yield new fundamental information. For example, advances in understanding the role of specific effector functions and the influence of the geometry of antibody–antigen interaction in tumor cell destruction have come from using mutant and engineered recombinant antibodies such as rituximab (anti-CD20).

T-Cell Development

S. Thera Lee and Kristin Hogquist

T-CELL DEVELOPMENT

For an effective immune response, antigens from disease-causing agents such as bacteria and viruses are recognized by the adaptive immune system. Two major components of this arm of the immune response are B and T cells, both of which have antigen receptors that respond to a vast range of antigens. These lymphocyte populations, however, develop in different tissues: for T cells, the primary lymphoid organ is the thymus. Like B cells, T cells develop from hematopoietic stem cells (HSCs) in the bone marrow, and during fetal life, in the liver. Lymphoid progenitors access circulation and migrate into the thymus. There, these cells, called thymocytes, differentiate into mature T cells. This process requires passage through a series of developmental checkpoints designed to test the affinity of the thymocyte's T-cell receptor (TCR) to antigens expressed on the surface of thymic antigen-presenting cells (APCs) in the context of a major histocompatibility complex (MHC) (Chapter 6). This process generates a mature repertoire of T cells that is functional—able to protect the organism from pathogens it may encounter, but also self-tolerant.

In the laboratory, this process can be manipulated by exchanging a native T-cell receptor with a synthetic chimeric antigen receptor (CAR).[1] Allogeneic or autologous T cells can thus be genetically modified to express a CAR that may combine an extracellular binding domain, often an antibody-derived single chain variable fragment (scFv), with activating signaling domains from the T-cell-receptor complex, such as CD3ζ, CD28, and 4-1BB (Chapter 4). By so doing, one can take a cytotoxic T-cell clone that has been educated in the thymus to be self-tolerant, and redirect its activity to a protein on the surface of a cancer cell. In this way, one can provide a patient with a personalized immunotherapy.

THYMUS: THE SITE OF T-CELL DEVELOPMENT

In all species with T cells, development occurs in the thymus. If the thymus is surgically removed (thymectomized) early in life or if patients are born with mutations that impact the development of the thymus, there is striking immunodeficiency, leading to increased susceptibility to infection (Chapter 34).[2] Anatomically, the thymus is located behind the sternum. Its distinct lobes are divided into the outer cortex and inner medulla (Fig. 9.1). Although the thymus is primarily composed of developing thymocytes, thymic stromal cells and hematopoietic antigen-presenting cells (Chapter 6) are also present. In the cortex and medulla, the stromal cells and antigen-presenting cells create unique microenvironments. Compartmentalization of thymocytes into these microenvironments provides for the distinct cues that are needed to support T-cell development through the progressive developmental stages.

Initially, thymic precursors enter into the thymic parenchyma near the corticomedullary junction (CMJ). As they develop, immature thymocytes migrate into and through the densely packed cortex, where they are guided by cues from surrounding cells. These cells include large, branched cortical thymic epithelial cells (cTECs), dendritic cells (DCs), and macrophages. Here, thymocytes are committed to the T-cell lineage and progress through sequential differentiation steps. The thymic environment provides chemokines that later guide the developing thymocytes to leave the cortex and enter the thymic medulla.[3] The thymic medulla has distinct thymic epithelial cells, aptly named medullary thymic epithelial cells (mTECs), as well as other antigen-presenting cells. More mature thymocytes reside in the medullary region where αβ thymocytes become MHC class I-restricted CD8 thymocytes or MHC class II-restricted CD4 thymocytes. The thymocytes that survive this process then emigrate from the thymus into the periphery as mature T cells.

Thymic stromal cells, including cTECs and mTECs, form the supporting meshwork needed for thymic structure and proper thymocyte development.[4] Foxn1 is a transcription factor essential for TEC development, and *Foxn1* deficiency leads to a thymic rudiment (athymia) that cannot sustain lymphopoiesis. Defects in *Foxn1* have been described in both mice and humans. The resulting phenotype includes hair loss and T-cell immunodeficiency. In humans, this disorder is referred to as the Pignata Guarino syndrome, and in mice, the *nude* mutation. Functional T cells develop when bone marrow from *nude* mice is transplanted into mice with normal stromal cells, but not when bone marrow from normal mice is transplanted into mice with the *nude* mutation. Thus, the study of *nude* mice has shed particular light on a specific need for thymic stromal cells in normal T-cell development. Patients with DiGeorge syndrome (Chapter 34) exhibit a similar phenotype of athymia and T-cell deficiency. However, these patients have deletions in chromosome 22q11, which encodes *Tbx1*. These experiments of nature have shown that the thymus is the major site of T-cell maturation and that this organ is necessary for the development and production of functional peripheral T cells.

EARLY T-CELL DEVELOPMENT

Early Thymic Progenitors Encounter Notch Ligands

The thymus does not contain a pool of resident pluripotent stem cells. Instead, progenitor cells from the bone marrow enter the blood and then seed the thymus continuously

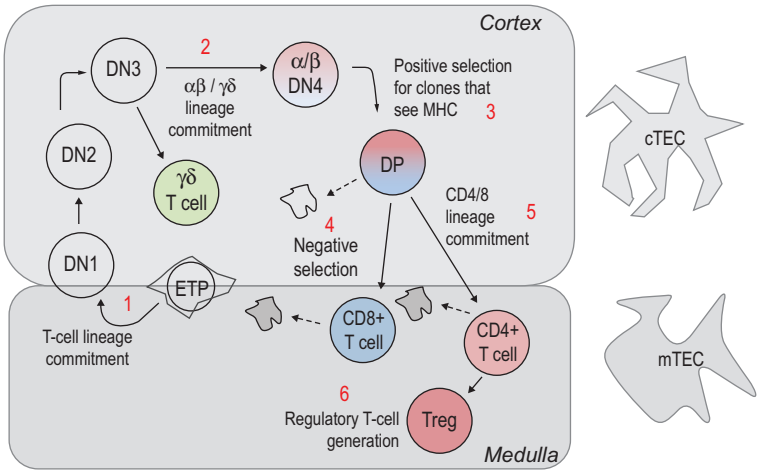

FIG. 9.1 Checkpoints in T-Cell Development Occur in Distinct Locations in the Thymus. The thymus is composed of several lobules, each with outer cortical and inner medullary regions. Thymic antigen-presenting cells localized within a specific anatomical location, such as cortical and medullary thymic epithelial cells *(cTEC and mTEC) (right)*, allow for developing thymocytes to pass through six major checkpoints through the thymus (see Table 9.1). The earliest thymic precursors enter via blood vessels at the cortico-medullary junction and commit to the T-cell lineage (1) before migrating to the outer cortex as immature $CD4^-$ $CD8^-$ double negative *(DN)* cells. As these thymocytes mature, they begin to rearrange their TCRs and diverge into αβ or γδ T cells (2). Cells destined to be αβ T cells upregulate CD4 and CD8 to become DP thymocytes that migrate back through the cortex. At this point, they express T-cell receptors on their surface that engage ligands in the thymus, allowing for T-cell positive (3) and negative (4) selection to occur. Surviving cells will downregulate CD4 or CD8 and commit to either the cytotoxic CD8 or helper CD4 lineage (5) while migrating into the medulla. The medulla contains only mature single positive (either CD4 or CD8) thymocytes, which will continue to undergo negative selection. A fraction of the single positive CD4 cells will become regulatory T cells (6). All fully mature T cells then emigrate to the periphery via blood vessels. *DP*, Double-positive; *ETP*, early thymic progenitors; *Treg*, T regulatory cell.

TABLE 9.1 Critical Checkpoints and Factors in T Cell

	Checkpoint	Role	Critical Factors
1	T-lineage commitment	Progenitors lose potential to generate other cell types	**Notch** signaling
2	γδ/αβ lineage commitment	Progenitor becomes either a γδ or αβ T cell	Depends on which receptor is assembled first
3	Positive selection	Selects for clones that can bind antigens in the context of that individual's MHC alleles	MHC/self-peptide in cTEC full TCR signaling capability
4	CD4/8 lineage commitment	Ensures MHC class specificity is linked to helper or killer function	**Runx** for cytotoxic CD8 T cells, **ThPOK** for helper CD4 T cells
5	Negative selection (clonal deletion)	Ensures "self-tolerance" to prevent autoimmunity	**AIRE** in mTEC **CD80/86+** APCs
6	Regulatory T-cell generation	Ensures "self-tolerance" to prevent autoimmunity	**FoxP3** in Treg
7	Selection of other rare specialized cells	IEL cells NKT cells MAIT cells M3 cells	**PLZF** in NKT cells
8	Emigration	Allows fully mature, selected T cells to leave the thymus and seed peripheral tissues	**KLF2** in all mature T-cell types

AIRE, Autoimmune regulator protein; *APCs*, antigen-presenting cells; *cTEC*, cortical thymic epithelial cell; *IEL*, intraepithelial lymphocyte; *MAIT*, mucosal-associated invariant T; *MHC*, major histocompatibility complex; *mTEC*, medullary thymic epithelial cell; *NKT*, natural killer T; *TCR*, T-cell receptor; *Treg*, T regulatory cell; *APC*, antigen-presenting cell.

throughout life.[3,5] HSC in the bone marrow can give rise to all lineages of blood cells. As stepwise developmental programs progress, downstream progenitors lose the potential to enter non-T lineages.[5,6] T-cell progenitors immigrate into the thymus at the cortico-medullary junction (see Fig. 9.1, step 1). This step involves the chemokine receptors CCR7 and CCR9, and the selectin PSGL-1. At this point, the cell is considered a multipotent early thymic progenitor (ETP).

ETPs experience Notch signaling in the thymus, which is essential for their commitment to the T-cell line (Table 9.1).[5–8] Notch is a heterodimeric receptor that binds to the Delta family and the Serrate family of ligands. In particular, Delta-like 4 is expressed by TEC and is required for the specification of ETP into the T-cell lineage pathway, with a concomitant repression of the B-cell lineage. In the absence of Notch, the thymus fills with B cells. Conversely, if Notch activation is forced in the bone marrow, T-cell development will initiate there. Thus, Notch ligands are an important part of what defines the thymus as a special environment for T-cell development. In the clinic, activating mutations in Notch are a common cause of human T-cell acute lymphoblastic leukemia (T-ALL).

Other Key Transcriptional Regulators

Notch signaling activates several additional transcription factors that are important for T-cell lineage fate and later αβ TCR selection. These include GATA3 (*Gata3*), TCF-1 (*Tcf7*), and

HES1 (*Hes1*). GATA3 is a zinc-finger transcription factor that is expressed as early as the ETP stage. Expression increases until the thymocytes reach the DN3 stage of T-cell development. TCF-1 and HES1 are also highly expressed by the ETP population. HES1 has been shown to be important for restraining the myeloid cell developmental pathway, as ETP cells maintain the potential to develop into natural killer (NK) and myeloid cell populations. Activation of Bcl11b, a transcriptional repressor that is also highly upregulated from the early ETP stage onward, restrains NK cell development.

Fate Commitment Occurs at the Double-Negative Stage

ETP undergo 1000-fold expansion over a period of 10 days.[3] Developing thymocytes eventually go through a series of well-defined stages marked by changes in the co-receptors CD4 and CD8 (see Fig. 9.1). Because ETP and their immature thymocyte progeny express neither CD4 nor CD8, they are called double-negative (DN) thymocytes. As DN thymocytes proceed through developmental checkpoints, they migrate outward from the CMJ into the cortical subcapsular zone, transitioning through so-called DN1, DN2, DN3, and DN4 stages in sequential order. These different stages are marked by differential surface expression of other cell-surface markers: CD44 and CD25.

In mice, DN1 cells express CD44 but not CD25 ($CD44^+CD25^-$). They can give rise to either αβ or γδ T cells but retain the potential to differentiate into NK cells and myeloid cell populations.[5,6] In human, DN cells are distinguished by other cell-surface molecules: $CD34^+CD1a^-$.[7] As DN1 progress, they begin to express CD25. These DN2 cells (mice: $CD44^+CD25^+$ and humans: $CD34^+CD1a^-$) migrate into the thymic cortex. As they mature, they lose their NK and myeloid potential.

T-CELL RECEPTOR GENE REARRANGEMENT BEGINS AT DN2

During the DN2 to DN3 transition, thymocytes are firmly committed to the T-cell lineage. However, they still have the potential to be αβ or γδ T cells. During this stage, the TCR β-chain, γ-chain, and δ-chain loci begin to rearrange (Chapter 4). The TCR α/δ, β, and γ gene loci are on three different chromosomes. The TCR δ-chain locus is embedded within the TCR α locus, which ensures that cells committed to the αβ T-cell lineage cannot express γδ TCR as well—the δ-chain genes are excised in the process of α-chain gene rearrangement as an extrachromosomal circle. The β, δ, and γ (but not α) loci adopt an open conformation at this stage, which allows recombination to initiate simultaneously. Commitment to the αβ or the γδ T-cell fates is dependent on which receptor is expressed first. This race occurs at the DN3 stage (see Fig. 9.1, step 2), where cells are $CD44^-CD25^+$ in mice and $CD34^+CD1a^+$ in humans.

γδ T Cells Diverge at DN3

If a developing thymocyte has productive, in-frame rearrangements at both the TCR γ and δ loci before a productive β-chain rearrangement, the cell is fated to become a γδ T cell. Because of the necessity for successful rearrangements at two loci rather than one, the thymus produces fewer γδ T cells than αβ T cells. Furthermore, the selection requirements for γδ T cells are different from αβ T cells and generally less well understood. After they leave the thymus, γδ T cells are disproportionally represented in nonlymphoid tissues, particularly epithelial tissues such as the skin, lung, and intestine.[9] In addition to T-cell commitment at the ETP stage, Notch signaling regulates the αβ versus γδ cell fate. αβ T cells have a higher requirement for Notch signaling, whereas γδ T cells are less sensitive. ID3, a negative regulator of E2A, plays a key role in integrating Notch and TCR signals to determine lineage commitment.[9] Notch signaling is required for β-selection, and γδ T cells induce higher levels of ID3 compared to β-selected thymocytes.

Beta Selection Generates αβ T Cells

If a productive rearrangement at the TCR β locus occurs at the DN3 stage, the β chain pairs with a nonrearranging pre-T α chain (also known as a surrogate α chain). This β-preTα heterodimer is assembled with CD3 molecules to form a productive pre-TCR complex that is transported to the cell surface. Signaling from this receptor is called β selection, and represents a key checkpoint in committing cells to the αβ lineage (see Fig. 9.1, step 2). At this point, the cell proceeds to downregulate CD25 to become DN4 cells ($CD44^-CD25^-$), where gene rearrangement is halted and rapid proliferation is induced. DN4 is a transient stage, and these cells rapidly begin to upregulate CD4 and CD8 on their cell surface, becoming positive for both (e.g., double-positive or DP) as they proliferate. These DP thymocytes make up the majority of thymocytes (approximately 80%). During this time, there is a second wave of *Rag* gene expression, which allows rearrangements at the TCR α locus. Productive rearrangements at the TCR α locus lead to expression of αβ TCR on the cell surface. The TCR can then recognize self-peptide:MHC (Chapters 5 and 6) to undergo further selection processes.

KEY CONCEPTS

The Thymus is the Anatomic Site Where T Cells Develop

- T-cell development occurs in and requires the thymus.
  - Patients without a thymus due to *FOXN1* mutations or DiGeorge syndrome lack circulating T cells.
- T cells are the progeny of HSC that circulate through blood and seed the thymus.
- ETPs are the first cells to seed the thymus, and their development into T cells requires Notch signals.
- Cells progress through the DN, then DP, stages as they recombine the TCR genes in order to express a surface T-cell receptor.
- Both αβ and γδ T cells are produced in the thymus, and their distinction occurs at the DN3 stage.

POSITIVE AND NEGATIVE SELECTION

The rearrangement and pairing of αβ TCR genes is random, and the TCRs on DP thymocytes have specificities that react to a wide range of antigens (both self or foreign) or don't react at all. Additionally, some receptors, while potentially capable of binding to a peptide antigen, may not bind to the peptide when presented by that individual's MHC molecules. For any individual, a useful T cell is one that can recognize an antigen presented by a self-MHC molecule. Thus, a positive selection step is needed to enrich the T-cell repertoire "with MHC-restricted" TCRs that are specific for antigens only in the context of the host's particular set of MHC molecules (Chapters 5 and 6).[10]

TCRs that bind strongly to self-peptides also present a risk, as these T cells may trigger autoimmunity. Therefore, a negative selection step is required to prune autoreactive clones from the T-cell repertoire. Together, these selection checkpoints permit the production of a diverse repertoire of mature T cells that are MHC-restricted, self-tolerant, and can be exported from the thymus into the periphery.

Positive Selection Generates an "MHC-Restricted" T-Cell Pool

In the thymic cortex, DP thymocytes audition for selection.[10] These immature cells only have a life span of 3 to 4 days and, without engagement of the TCR, their default pathway is one of apoptosis—a form of programmed cell death called "death by neglect" (Chapter 17). It is estimated at anywhere between 85% to over 90% of these precursors are unable to be selected and are eliminated in this manner.[10,11] Cells that avoid this fate undergo positive selection, in which the αβ TCR binds with low to intermediate avidity to self-peptide:MHC complexes presented by cTEC, promoting cell survival (see Fig. 9.1, step 3). As the self-peptides presented in the thymus are displayed on the host's own MHC molecules, positive selection ensures that only self-MHC-restricted DP thymocytes mature into CD4 or CD8 single positive (SP) thymocytes. After undergoing positive selection in the cortex, DP thymocytes up-regulate chemokine receptors such as CCR7 and migrate towards the medulla.[3] As the thymocyte crawls through the CMJ into the medullary region, it interacts with other thymic APCs, which can drive negative selection.

Negative Selection Generates a "Self-Tolerant" T-Cell Pool

Among the TCR expressed by DP thymocytes, some bind strongly to self-peptide:MHC. During the selection processes in the thymus, these autoreactive T-cell clones are removed from the repertoire in a process called *negative selection* (see Fig. 9.1, step 4). Apoptosis by these cells "deletes" them from the T-cell repertoire. The elimination of autoreactive TCRs via cell death is also known as clonal deletion. While the majority of negative selection occurs in the cortex at the DP stage, there is also a second wave of clonal deletion in the more mature thymocytes that are located in the medulla.[10,12] The deletion of self-reactive T-cell clones plays a key role in the establishment of central tolerance. This process is mediated by the different APCs found throughout the thymus (Chapter 6). While self-antigens presented by cTECs promote positive selection, negative selection can be mediated by mTEC as well as hematopoietic APCs such as DC and B cells.[13]

Role of Peptide:MHC in Negative and Positive Selection

The affinity model of selection holds that the strength of signal that results from the interaction between the self-peptide:MHC and TCR underlies positive and negative selection (Fig. 9.2).[10] According to this model, there is a spectrum of strength of signal across the large array of developing thymocytes. At one end of the spectrum are T-cell receptors that do not bind, and thus do not respond, to self-peptide:MHC. These cells will automatically undergo cell death after a few days—which is termed *death by neglect*. At the other end of the spectrum are cells that express T-cell receptors that bind with high affinity and generate a strong signal. These cells undergo cell death by clonal deletion. In the middle is a window of positively selected conventional T cells with receptors that bind to self-peptide:MHC, but with a weaker, more acceptable, affinity.

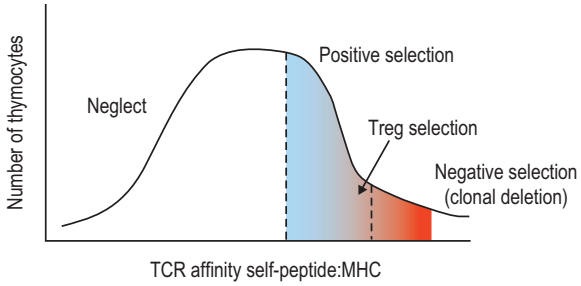

FIG. 9.2 The Fate of Thymocytes is Determined by How Strongly They Bind to Major Histocompatibility Complex (MHC)/Self-Peptide. In the affinity model of selection, the strength of the interaction between the self-peptide:MHC and T-cell receptor (*TCR*) determines whether cells are selected or undergo apoptosis. Cells with TCR that cannot form a stable interaction with self-peptide:MHC will either undergo another round of TCR gene rearrangement in a process termed *receptor revision* or *receptor editing*, thereby expressing another TCR, or they will die by neglect after a few days. T cells with TCRs that interact weakly with self-peptide:MHC will avoid death by neglect and undergo positive selection. These cells can potentially become conventional CD4 or CD8 T cells. T cells with TCR that interact strongly, and thus are highly self-reactive, will undergo negative selection by clonal deletion. Some autoreactive cells, particularly those that recognize the very rare self-peptide:MHC, are able to avoid apoptosis and instead become regulatory T cells, although this is not thought to have a strict affinity threshold. *Treg*, T regulatory cell.

Under this model, thymocytes that have high-affinity interactions with self-peptides will generally undergo apoptosis and be deleted. However, some cell types, such as regulatory T cells and other specialized lymphocytes, are able to avoid this cell fate in spite of being "more" self-reactive (see below). These agonist selected cells depend on other molecular factors, such as CD1d and costimulatory molecules, for their survival. Although the choice of survival or death appears binary, there is some stochastic overlap between agonist selected cells and clonal deletion.[14] This enables the survival of selected T cells with some potentially hazardous T cells.

The different epithelial cells in the cortex and medulla of the thymus are specialized for positive and negative selection. cTECs are essential for positive selection. The crucial role that cTECs have in selection is mediated in part by their peptide processing machinery, which gives them the ability to present a largely unique peptide:MHC repertoire (also known as the *peptidome*).

In APC, peptide fragments are loaded onto MHC molecules after cytosolic proteins are degraded by proteasomes. These proteasomes have a catalytic core that consists of three subunits: β1, β2, and β5. cTECs have the unique proteasome subunit β5t, while other APCs can only express β5 or β5i. This endows cTECs with the ability to present specialized peptides produced by the thymoproteosome (specifically composed of subunits β1i, β2i, and β5t), allowing for a peptide:MHC peptidome that promotes positive selection and shapes the T-cell repertoire.

mTECs, on the other hand, play a crucial role in negative selection. These cells are specialized to express tissue-restricted antigens (TRAs), proteins normally produced only in one or two tissues in the body. An example of a TRA is insulin—a protein otherwise only produced in the pancreas. The thymic expression of TRA is essential to achieve self-tolerance to all proteins in the body. TRA expression in mTECs is largely dependent on a transcriptional regulator called *autoimmune regulator* protein (AIRE) (see Table 9.1).

CD4 AND CD8 T-CELL CHARACTERISTICS ARE SET IN THE THYMUS

Conventional αβ T cells in the periphery are either CD4 helper or CD8 cytotoxic T cells. This divergence of co-receptor expression and effector cell type is determined in the thymus. This decision is made after surface TCR expression: only positively selected DP thymocytes can transition into CD4 or CD8 SP thymocytes (see Fig. 9.1, step 5). A DP thymocyte with an MHC class I-restricted TCR loses CD4 expression and becomes a cytotoxic CD8 SP thymocyte, while a DP thymocyte with an MHC class II-restricted TCR loses CD8 expression and becomes a helper CD4 SP thymocyte.

The molecular pathways by which CD4/CD8 lineage commitment is established and reinforced include two critical transcription factors: ThPOK and Runx3 (see Table 9.1).[6,15,16] ThPOK is essential for differentiation to the CD4 helper lineage, while Runx3 is essential for differentiation to the CD8 cytotoxic lineage. These factors are mutually antagonistic; for example, Runx3 promotes *Cd8* expression while repressing *Cd4* and ThPOK expression.

Specialized Lymphocytes

Conventional αβ and γδ T cells are not the only cells that develop and emerge from the thymus. There are also specialized lymphocyte populations that are numerically fewer but still play important roles in host immune responses. These include lipid-reactive natural killer T (NKT) cells, CD8αα$^+$ intraepithelial lymphocytes (IELs), and mucosal-associated invariant T (MAIT) cells (see Table 9.1). Compared to conventional αβ T cells, NKT cells and IELs express TCRs that are more self-reactive. Thus, their development is referred to as agonist selection in the thymus.[14] These specialized lymphocytes require distinct molecular factors for their development.

NKT cells express an αβ TCR. However, rather than being peptide specific and MHC class I- or II-restricted, they recognize lipid antigens in the context of CD1d molecules.[14,17] The TCR repertoire expressed by NKT cells is highly restricted, consisting of either TCR Vα14-Jα18 (mice) or Vα24-Jα18 (humans) chains paired with limited TCR Vβ chains. Due to this "invariant" TCR, these cells are named invariant NKT (iNKT) cells. Selection of iNKT cells happens in the thymic cortex at the DP stage. However, rather than being positively selected by thymic cTEC like conventional T cells, iNKT cells are selected by other DP thymocytes presenting lipid antigens by CD1d, a nonclassical MHCI-like molecule. Strong TCR signaling at this stage, along with interactions between signaling lymphocyte activation molecule family (SLAMF) receptors. Drives agonist selection of iNKT cells. iNKT cells are specified by the expression of the transcription factor PLZF and can further differentiate into different iNKT effector subsets within the thymus.

Like NKT cells, MAIT cells have a limited TCR repertoire due to restricted TCRα chain usage. These TCR generally consist of either Vα19-Jα33 (mice) or Vα7.2-Jα33 (humans) paired with limited TCR Vβ chains.[18] MAIT cells recognize metabolites of vitamin B in the context of the nonclassical MHCI-like molecule MR1 and are selected for during the DP stage of thymocyte development by other DP thymocytes.

IEL are T cells that reside within the gut epithelium and include a population that express αβ TCR and CD8αα homodimers. These CD8αα$^+$ IEL derive from agonist-selected thymic precursors (IELp) and have a small repertoire size.[14,19] During thymocyte selection, strongly self-reactive DP thymocytes undergo clonal deletion; but without CD28 costimulation, more cells are diverted into the IELp fate. These TCR αβ$^+$ IELp can then be found within DN thymocyte population, and most are localized within the cortex.

KEY CONCEPTS

The Thymus Selects for Clones That Are Useful and Safe

- A positive selection step selects for progenitors with an αβ TCR that can bind to MHC molecules, leading to an "MHC restricted," or useful, pool of T cells in each individual.
  - These MHC molecules must be present on epithelial cells of the thymus.
- CD4 helper and CD8 killer lineage is determined by which class of MHC molecule is recognized—a process called *lineage commitment*.
  - MHC class II recognition by the TCR and CD4 co-receptor generates helper T cells, through the transcription factor ThPOK.
  - MHC class I recognition by the TCR and CD8 co-receptor generates killer T cells, through the transcription factor Runx3.
- A negative selection step eliminates T cells with the most strongly self-reactive TCRs, leading to a "tolerant" or safe pool of T cells.
- The thymus also selects and provides instruction for smaller populations of specialized T cells, such as those that reside at barrier surface (skin and gut), recognize metabolites (MAIT cells), or recognize lipids (NKT cells).

TOLERANCE

An effective immune system is one that can respond robustly to foreign pathogens without having unwanted responses against the host's own cells and tissues (Chapter 10). This immunological tolerance to self-antigens is enforced early during T-cell development in the thymus by the elimination of strongly self-reactive thymocytes by means of clonal deletion. This central tolerance mechanism is not complete. Self-reactive T cells are able to escape into the periphery. However, there is an additional tolerance mechanism, the development of regulatory T cells (Treg), that helps control immune responses.[20]

Regulatory T cells are self-reactive CD4 T cells that express CD25 and the transcription factor FoxP3 (see Table 9.1). They generally suppress immune responses, as opposed to initiating them. They are only a small proportion of both developing CD4 SP thymocytes (approximately 1%) and CD4 T cells in secondary lymphoid organs (approximately 10% to 15%), but they play a key role on immune homeostasis.[21]

Despite being self-reactive, some cells survive and undergo "agonist selection" instead of being deleted.[10,14] This step for Treg development is thought to happen in the thymus at the

CD4 SP stage in the medulla (see Fig. 9.1, step 6). As TCR that have high affinity for self-peptide:MHC can also be clonally deleted, there is some overlap between conventional T cells that undergo apoptosis and Treg selection (see Fig. 9.2). Treg progenitors are able to avoid apoptosis due to pro-survival cytokine signals, such as interleukin-2 (IL-2). Cytokines also play a role in inducing FoxP3 expression, converting progenitors into mature $CD25^+$ $FoxP3^+$ Treg.

Autoimmunity Results From the Lack of Tolerance (AIRE, FoxP3)

Treg can be specific for tissue-restricted antigens. AIRE, which mediates the expression of these TRA by thymic antigen-presenting cells like mTEC, is thus critical for both Treg development and clonal deletion of self-reactive thymocytes.[21] Mice that lack *Aire* have increased numbers of autoreactive T cells in peripheral tissues, leading to multi-organ destruction and autoantibody production. In humans, mutations in *AIRE* lead to multi-organ autoimmune disease, particularly in endocrine organ. This is referred to as *autoimmune polyendocrine syndrome 1* (APS-1) *or autoimmune polyendocrinopathy candidiasis ectodermal dystrophy* (APECED).[20,22] The importance of Treg in immune tolerance is demonstrated by patients that have mutations in *FOXP3*. Such patients develop a fatal lymphoproliferative disease called *immune dysregulation, polyendocrinopathy, enteropathy, X-linked* (IPEX) *syndrome* (Chapter 13).

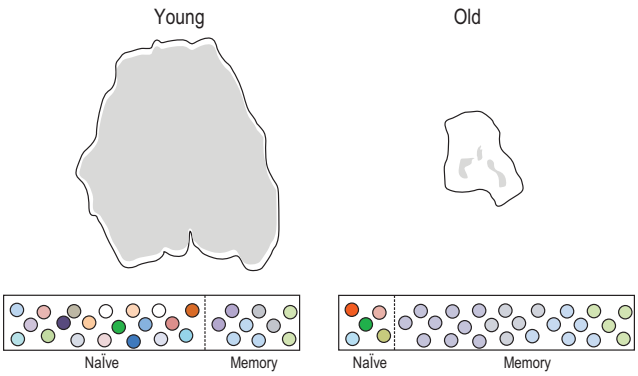

FIG. 9.3 Thymic Atrophy Results in a Less-Diverse Repertoire With Age. The thymus expands early in life, reaching peak size at about puberty. The aging thymus undergoes involution, where reduced tissue mass and altered thymic architecture leads to a decrease in T-cell output. While a young thymus can support robust thymopoiesis, leading to a diverse T-cell repertoire (distinct clones depicted as different colors), an aged thymus is characterized by reduced T-cell output. Due to this change in thymic function with age, the naïve T-cell pool has reduced size and diversity, and, as a consequence, the T-cell pool of an older individual is skewed more towards memory populations.

KEY CONCEPTS

An Important Function of the Thymus is to Make T Cells Tolerant of Self

- Some strongly reactive thymocytes undergo apoptosis, eliminating the most dangerous clones from the repertoire—this process is called *clonal deletion*.
- Other strongly reactive thymocytes upregulate the transcription factor FoxP3 instead, and become regulatory T cells, which also contribute to tolerance.
  - Patients with mutations in the *FOXP3* gene experience lethal lymphoproliferative disease.
- The transcription factor AIRE causes tissue-specific antigens to be expressed in medullary epithelial cells of the thymus, leading to clonal deletion and Treg induction, so that T cells are generally tolerant of tissues.
  - Patients with mutations in the *AIRE* gene experience multi-organ autoimmune disease.

MIGRATION OF THYMOCYTES INTO THE PERIPHERY

Following positive selection, SP thymocytes spend a few days in the thymic medulla perusing APCs there for tolerance purposes and completing their differentiation to become functional T cells, before emigrating via blood vessels at the CMJ.[3,23] The competence to emigrate is signaled by the upregulation of a zinc-finger transcription factor Kruppel-like factor 2 (KLF2) (see Table 9.1). KLF2 upregulates both sphingosine-1-phosphate receptor 1 (S1PR1), a lipid receptor that allows for thymic egress, and CD62L (also known as L-selectin), which allows for entry into peripheral lymphoid tissue. Recent thymic emigrants (RTEs) and other naïve T cells express IL-7 receptor, and IL-7 signaling, along with low or "tonic" levels of TCR signaling, allow for survival and homeostatic cycling.[24] These T cells can then function in adaptive immune responses.

THYMIC ATROPHY

In the young, approximately 10^6 thymocytes in mice and 10^7 to 10^8 thymocytes in humans are exported from the thymus into the circulation every day. These populations account for about 1% of all thymocytes.[3] However, there is a decline in T-cell output by the thymus with age. The decline begins around puberty[25] and accelerates in older adults (Chapter 21). This decrease in T-cell output is due to age-related regression of the thymus, or *thymic involution* (Fig. 9.3).

During thymic involution, there is both a reduction in tissue mass and an alteration in the thymic architecture, with an accumulation of adipose tissue. This leads to reduced thymopoiesis and a loss of diversity among the thymic emigrants that join the naïve T-cell pool. These RTEs are not only fewer in number but also of different quality: aged RTEs have lower proliferative capacity and defective TCR-induced calcium signaling. Taken together, this results in elderly individuals having reduced immune responses, which leads to higher rates of infection, autoimmune disease, and cancer.

Age-related disorganization of thymic stromal cells is associated with accumulation of adipose tissue, and obesity can enhance involution. Furthermore, age and obesity are not the only factors that can drive thymic atrophy. Acute stressors—examples being infections (bacterial, viral, fungal) and medical treatments (such as chemotherapy or stem cell transplantation)—can lead to rapid, stress-induced thymic atrophy.[26] When this stressor is removed, the tissue will often recover. However, reduced thymic output can lead to lymphopenia in patients, and this delay in thymic function during recovery can leave patients vulnerable to opportunistic infections.

KEY CONCEPTS

T-Cell Homeostasis

- Once thymocytes complete maturation in the thymus, they emigrate and become established in lymphoid organs throughout the body.
  - This process requires the sphingosine phosphate receptor, S1PR1, and L-selectin.
- Naïve T cells require the cytokine IL-7 and "basal" TCR signals from continued MHC recognition for long-term survival.
- The thymus atrophies starting after puberty, producing fewer new T cells as individuals age.
  - This contributes to poor immune responses in the elderly.
- T cells are depleted, termed lymphopenia, during some acute and chronic viral infections and some medical treatments.

ON THE HORIZON

- Deducing how the T-cell receptor senses MHC class I versus MHC class II and coordinates the expression of the appropriate CD8 or CD4 co-receptor, respectively.
- Understanding what thymic processes malfunction in common autoimmune diseases, such as type I diabetes.
- Better tools and markers to study αβ T-cell development and the acquisition of innate-like functions prior to thymic export.
- Developing strategies to combat thymic involution with age and increase T-cell development, especially following bone marrow transplantation.

T-Cell Activation and Tolerance

Erik J. Peterson

Activation of T lymphocytes during immune responses triggers a series of gene transcriptional regulatory, proliferation, differentiation, and effector functions. T-cell functions coordinate with other leukocytes to permit the immune system to react against foreign antigens without initiating self-reactivity or autoimmunity. Each of these functions is fully dependent on environmental cues that are recognized by cell surface receptors and are then translated through biochemical alterations within the cell. This chapter discusses signal transduction through one of the best studied of these receptors, the antigen-specific T-cell receptor (TCR) complex. It addresses the mechanisms whereby signals propagated through the TCR combine with those from costimulatory receptors to yield either productive activation or immune tolerance. It also discusses how abnormal TCR signaling, and imbalanced signaling through costimulatory or coinhibitor molecules, can contribute to T-cell dysfunction and disease (Table 10.1). Targeting these molecular pathways has resulted in several clinically relevant drugs currently used to treat autoimmunity, transplant rejection, and cancer.

CLINICAL RELEVANCE

- Dysfunction or deficiency of T-cell signaling proteins (induced or spontaneous) has been causally linked to disease states in animals or humans
- TCR signaling molecules wherein mutations may lead to immune deficiency and/or T-cell hypofunction include:
  - CD45
  - LCK
  - ZAP-70
  - SLP-76
  - LAT
  - Mst1
  - PI3Kδ
  - RasGRP1
- Molecules wherein mutations may lead to exaggerated lymphocyte proliferation include:
  - CTLA-4
  - PD-1
  - SHP-1
  - CD95/CD95 ligand
  - SAP
  - CBL
  - ZAP-70
  - LYP
  - DGK

THE T-CELL ANTIGEN RECEPTOR COMPLEX

The TCR complex consists of a ligand-binding TCR α/β or γ/δ heterodimer (Chapter 4) in association with the CD3/ζ chain complex, which provides transmembrane signal transduction capability.[1] Specificity of the TCR for antigen resides exclusively within the highly polymorphic, clonotypic, ligand-binding α/β or γ/δ heterodimers. Although many of the biochemical events leading to α/β and γ/δ T-cell activation are similar, α/β T cells exhibit a broader spectrum of antigen reactivity and are thought to participate in a wider range of specific immune responses. This chapter focuses on α/β T cells.

The α/β TCR specifically recognizes short (8 to 9 amino acid) polypeptide ligands bound to major histocompatibility complex (MHC) protein (Chapter 5) on the surface of antigen-presenting cells (APCs) (Chapter 6). Coreceptor molecules expressed on subsets of α/β T cells determine whether the TCR recognizes class I or class II MHC. CD4 T cells are stimulated by processed exogenous antigen presented by class II MHC molecules on the surface of professional APCs. CD8 T cells respond to peptides synthesized by APCs and presented by class I molecules. CD4 and CD8 associate with MHC class II and class I molecules, respectively, to stabilize the tripartite interaction between the TCR, antigen, and MHC, which increases the effectiveness of TCR engagement.

Although the α/β chains of the TCR contain all information necessary for antigen/MHC binding, these proteins are not sufficient to initiate the intracellular biochemical events that signal antigen recognition. Instead, signal transduction is accomplished by noncovalently associated CD3 and TCRζ polypeptides, which include several pairs of transmembrane hetero- or homodimers (Fig. 10.1). Each CD3 and ζ chain derives signaling capacity from the presence of one or more cytoplasmic domains known as *immunoreceptor tyrosine-based activation motifs* (ITAMs).[2]

KEY CONCEPTS

T-Cell Receptor Induces Serial Tyrosine Phosphorylation

TCR engagement activates several families of protein tyrosine kinases, which are required for propagation of second messenger-instigated intracellular signaling:

- Src family: LCK, FYN
- Syk family: ZAP-70
- Tec family: ITK, RLK

TABLE 10.1 Phenotypes Associated With Deficient Function of Selected T-Cell Signaling Molecules

		PHENOTYPE	
Molecule	**Affected Signaling Event**	**Mouse**	**Human**
TCR Signaling			
CD3 γ	TCR expression	$B^+T^+NK^+$ SCID	$B^+T^+NK^+$ SCID
CD3 ε	TCR expression	$B^+T^-NK^+$ SCID	$B^+T^{+/-}NK^+$ SCID
CD3 δ	TCR expression	$B^+T^-NK^+$ SCID	$B^+T^-NK^+$ SCID
CD3 ζ	TCR expression, TCR-mediated PTK activation	$B^+T^+NK^+$ SCID	$B^+T^+NK^+$ SCID
ZAP-70	TCR-mediated PTK activation	$B^+T^{+/-}NK^+$ SCID. TCR αβ T cells are absent, but TCR γδ T cells survive. Arthritis occurs in some inbred strains	$B^+T^{+/-}NK^+$ SCID. CD8 T-cell lymphopenia. Overexpressed in some hematological malignancies
LCK	TCR-mediated PTK activation	$B^+T^{+/-}NK^+$ SCID. Impaired thymopoiesis and proliferation	$B^+T^+NK^+$ SCID. CD4 lymphopenia, absent CD28 expression on CD8 T cells, and hypogammaglobulinemia
CD45	Maintenance of SRC family PTK in "open" conformation	$B^+T^{+/-}NK^+$ SCID. Impaired thymopoiesis	$B^+T^{+/-}NK^+$ SCID. Impaired thymopoiesis, decreased cytotoxic T-cell responses, progressive hypogammaglobulinemia, genetic polymorphisms may correlate with increased prevalence of autoimmune disease
SAP	SHP-2 binding to SLAM	Increased susceptibility to lymphocytic choriomeningitis virus, reduced IgE production, NKT-cell deficiency	X-linked lymphoproliferative disease (XLP) with B-cell hyperresponsiveness, NKT-cell deficiency
WASP	Actin polymerization	Decreased T-cell proliferation and interleukin-2 (IL-2) production	Wiscott-Aldrich syndrome (immunodeficiency, atopic dermatitis, thrombocytopenia, bloody diarrhea)
CBL/CBL-b[a]	E3 ubiquitin ligase. Recruitment of CrKL/C3G inhibitory complex	Hyperproliferative T cells[a]	Proto-oncogene for leukemia
LAT	Coupling PTK activation to downstream signals	$B^+T^-NK^+$ SCID. Absolute block in thymopoiesis	
SLP-76	Coupling PTK activation to downstream signals	$B^+T^-NK^+$ SCID. Absolute block in thymopoiesis. Defect in vascular/lymphatic development	
ITK/RLK	Amplification of proximal PTK signals. Activation of PLCγ1	Defective Th2 immune responses	
CTLA-4	Inhibition of CD28-mediated costimulation	Fatal lymphoproliferative disease with myocarditis, pancreatitis	Allelic variants associated with autoimmunity, including Hashimoto thyroiditis, Graves disease, and systemic lupus erythematosus
SHP-1	Downregulation of PTK activity	Autoimmunity, inflammatory lung disease. "Moth-eaten" mice	
LYP (Lymphoid phosphatase; *PTPn22* gene product)	Attenuation of LCK activity	Augmented TCR-stimulated IL-2 production and proliferation	Allelic variants are associated with increased risk of rheumatoid arthritis, systemic lupus erythematosus, type 1 diabetes mellitus
DGKζ	Downregulation of DAG-dependent Ras activation	Impaired T-cell anergy induction	
Mst1 (STK4)	Suppression of Akt, phosphorylation of FoxO transcription factor	Inefficient thymic egress; impaired positive selection; impaired Treg development and function	Recurrent infections; progressive loss of peripheral CD4 T cells; autoimmune hemolytic anemia
IL-2R Signaling			
γc	Coupling IL-2 binding to JAK activation	$B^+T^-NK^-$ SCID	$B^+T^-NK^-$ SCID, X-linked SCID
JAK3	Phosphorylation of STAT proteins	$B^+T^-NK^-$ SCID	$B^+T^-NK^-$ SCID

γc, Common γ-chain (IL2Rγ); *IgE*, immunoglobulin E; *NK*, natural killer; *SCID*, severe combined immunodeficiency; *TCR*, T-cell receptor.
[a]CBL and CBL-b are closely related; CBL-b-deficient mice develop autoimmune features and more severe lymphoproliferative disease compared with mice lacking CBL.

Activation of Protein Tyrosine Kinases by the T-Cell Receptors and the Role of the Immunoreceptor Tyrosine-Based Activation Motifs

The likelihood of a given TCR interaction with peptide/APC ligand to result in productive intracellular signaling is a function of multiple biophysical factors, including TCR-binding affinity ("off rate"), conformational states of TCR components driven by application of mechanical forces, as well as the activation states of membrane-associated enzymatic mediators.[1] Together these factors confer extraordinary sensitivity and selectivity of the TCR for ligand, and determine signal strength. An array of membrane-proximal molecular events translates signals conferred by ligand binding at the cell surface.

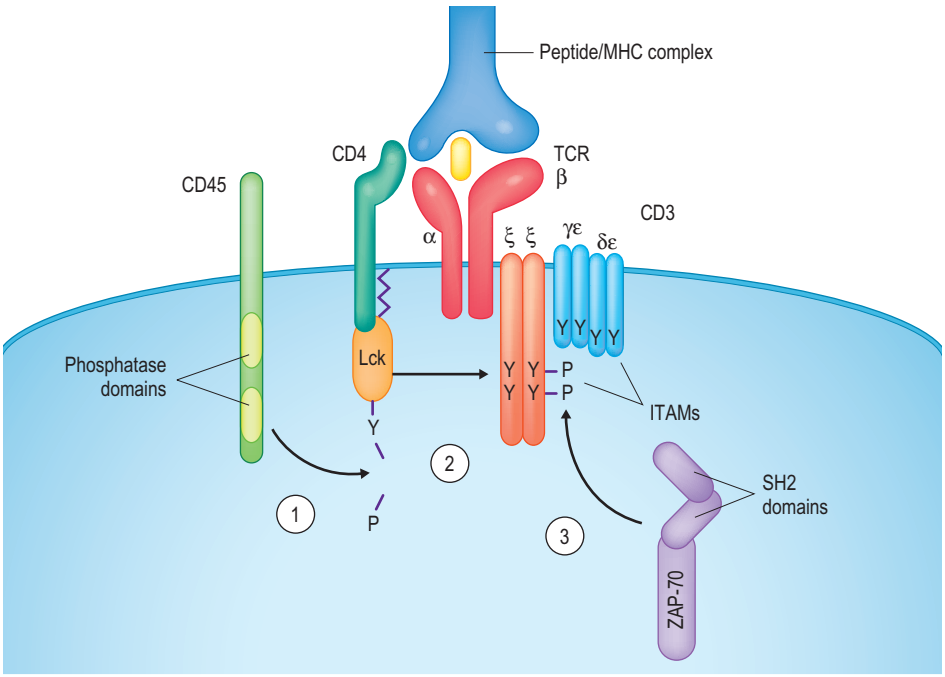

FIG. 10.1 Biochemical Events in Early T-cell Receptor *(TCR)* Signaling. (1) The tyrosine phosphatase CD45 dephosphorylates the negative regulatory tyrosine residue on the CD4-associated protein tyrosine kinase (PTK) LCK, maintaining LCK in an activatable conformation. (2) Engagement of the TCR α/β heterodimer and the CD4 (or CD8) coreceptors by major histocompatibility complex *(MHC)*–bound peptide antigen brings activated LCK into proximity with immunoreceptor tyrosine-based activation motif *(ITAM)*-bearing CD3 chains. LCK phosphorylates the CD3ζ chain within ITAMs. (3) The phosphorylated CD3ζ-chain ITAMs interact with the tandem SH2 domains of the cytoplasmic PTK ZAP-70, permitting activation of ZAP-70 and phosphorylation of downstream substrates.

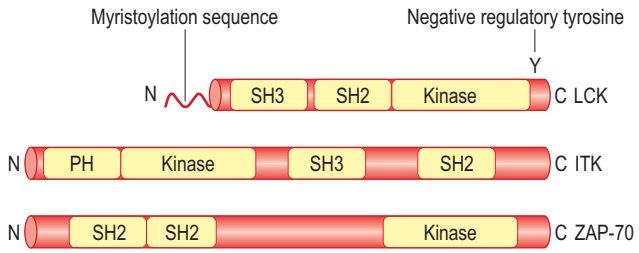

FIG. 10.2 Domain Organization of T-cell Receptor (TCR)-Stimulated Protein Tyrosine Kinases (PTKs). Comparative schematic representation of members of three families of PTKs required for T-cell-activating signals. In addition to catalytic domains, LCK (SRC family), ITK (TEC family), and ZAP-70 (SYK family) each contain regions responsible for mediating protein–protein interactions, including SH3 and SH2 domains. SH3, Src homology 3; SH2, Src homology 2; PH, pleckstrin homology.

Among the earliest biochemical events following engagement of the TCR is the activation of LCK and FYN, two members of the SRC family of protein tyrosine kinases (PTKs).[2] Shared LCK and FYN functional motifs (Fig. 10.2) include an amino-terminal myristoylation sequence that directs membrane localization, a SRC homology 3 (SH3) domain that permits associations with other proteins containing regions rich in proline residues, a SRC homology 2 (SH2) domain that dictates interactions with proteins phosphorylated on tyrosine residues, a catalytic region, and a carboxyl-terminal tyrosine residue. The precise mechanism whereby LCK and FYN are stimulated by the TCR is not clear, but both have been shown to associate physically with TCR CD3 components and/or coreceptors CD4 and CD8.

SRC family protein tyrosine kinase (PTK) enzymatic function is regulated, in part, by the state of tyrosine phosphorylation of the kinase. When the conserved carboxyl-terminal tyrosine residue is phosphorylated, SRC family PTKs adopt a "closed" conformation that is the product of an intramolecular interaction between that phosphotyrosine and the SH2 domain (Fig. 10.3). This intramolecular interaction inhibits the enzymatic activity of the PTK, limiting subsequent tyrosine phosphorylation–dependent signaling events. Phosphorylation of the carboxyl-terminal tyrosine (Y505 in LCK and Y527 in FYN) is dynamically regulated.[3] Phosphate is transferred to the carboxyl-terminal tyrosine by the cytoplasmic negative regulator PTK CSK and is removed by the transmembrane protein tyrosine phosphatase CD45. Current models hold that TCR signal propagation depends upon both recruitment of coreceptor-associated catalytically pre-activated LCK and de novo TCR-induced LCK activation.

Phenotypes of CD45-deficient cells in mice and humans highlight the critical regulatory importance of SRC family PTK carboxyl-terminal tyrosine phosphorylation.[4] TCR signal transduction in cell lines lacking CD45 is blocked at the most proximal step, and CD45 "knock-out" mice exhibit profound defects in thymocyte development and subsequent T-cell activation. CD45 deficiency in humans results in a T^-, B^+, NK^+ severe

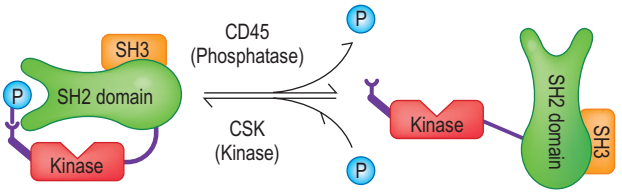

FIG. 10.3 Model for Dynamic Regulation of LCK by Intramolecular Interaction Between an SH2 Domain and Phosphotyrosine. The transmembrane phosphatase CD45 dephosphorylates tyrosine 505 in the carboxyl-terminus of the SRC family protein tyrosine kinase (PTK) LCK. CD45 activity maintains LCK in an "open" conformation, permitting LCK kinase domain access to intracellular substrates. CSK activity opposes that of CD45; phosphorylation of tyrosine 505 results in an intramolecular interaction between the SH2 domain and phosphotyrosine. Inhibition of LCK kinase activity correlates with the "closed" conformation *(left)*.

combined immunodeficiency (SCID) (Chapter 34). These outcomes correlate with markedly impaired LCK enzymatic activity and hyperphosphorylation of Y505, the regulatory tyrosine.

Following TCR engagement and above-described PTK activation, numerous cellular substrates become tyrosine-phosphorylated, including the CD3 and TCR ζ-chain immunoreceptor tyrosine-based activation motifs (ITAMs) (see Fig. 10.1). In resting T cells, key tyrosine residues within the ITAMs are embedded within the hydrophobic core of the plasma membrane lipid bilayer. Upon TCR triggering, conformational changes induced within the CD3 cytoplasmic tails result in enhanced tyrosine accessibility to the action of SRC family kinases.[2] ITAM phosphorylation creates a docking site for another cytosolic PTK, ζ-associated phosphoprotein of 70 kilodaltons (kDa) (ZAP-70). ZAP-70, a member of the SYK family PTKs, contains a catalytic domain that is located carboxyl-terminal to two tandem SH2 domains (see Fig. 10.2). The ZAP-70 SH2 domains have affinity for phosphotyrosine present within ITAMs. Thus inducible phosphorylation of the CD3 and ζ-chain ITAMs results in the formation of docking sites that mediate recruitment of ZAP-70. Upon recruitment to TCR, ZAP-70 enzymatic activity is increased as a result of phosphorylation by LCK as well as autophosphorylation. The net result of these phosphorylations is conversion of the TCR from an enzymatically inactive ligand-binding complex to a potent membrane-associated PTK.

LCK and ZAP-70 are critically important for both thymocyte development and mature T-cell activation. Mice deficient in Zap-70 or Lck exhibit a significant yet incomplete block in early T-cell development (Chapter 9). The pre-TCR (a complex present on immature thymocytes that includes signaling components thought functionally similar to the TCR on mature T cells) appears to require Src and Syk family PTKs to transduce signals. ZAP-70 deficiency and abnormal LCK function in humans create a T^-, B^+, NK^+ SCID.[5]

Downstream of SRC and SYK family PTKs, TCR engagement results in the activation of a third family of cytosolic PTKs, the Tec family, which includes TEC, ITK, and RLK. Tec PTKs contain SH2, SH3, and catalytic domains, as well as pleckstrin homology (PH) domains that mediate interactions with membrane-localized phospholipids (see Fig. 10.2). PH domains permit recruitment of Tec family kinases to the plasma membrane, where they can phosphorylate important substrates.[6] ITK positively regulates antigen-receptor signaling through recruitment and activation of the lipid modulator PLCγ to a "signalosome" nucleated by the cytoplasmic adaptor protein SLP-76, and commencement of signaling via PLCγ and Ras/MAPK cascades. Mice deficient in Tec kinases display variable partial defects in thymocyte development and peripheral T-cell maturation. The role of Itk in effector CD4 T-cell fate is shown by observations that loss of Itk leads to defective Th17 (Chapter 11) and regulatory T cell (Treg) 1 (Tr1) (Chapter 13) subset differentiation, but increased generation of Foxp3-positive Treg cells.

KEY CONCEPTS

T-Cell Receptor Signaling Pathways

TCR engagement leads to the activation of signaling cascades and transcription factors
- PLCγ1 activation →
  - IP3 → calcium flux → NFAT
  - Diacylcglycerol → PKC → NF-κB
  - Diacylglycerol → Ras/MAPK → AP-1

Second Messenger Cascades Downstream of the T-Cell Receptor–Stimulated Protein Tyrosine Kinases

TCR engagement incurs numerous biochemical changes that are dependent on the activation of membrane-proximal PTKs. One intermediate event in TCR signaling is activation of the membrane-associated enzyme phospholipase Cγ1 (PLCγ1) (Fig. 10.4).[7] PLCγ1 is phosphorylated by multiple TCR-dependent PTKs, including both ZAP-70 and members of the Tec family. TCR-stimulated tyrosine phosphorylation alone is not sufficient to activate PLCγ1; relocalization of the enzyme into adaptor-protein nucleated complexes probably plays a critical role.

Activated PLCγ1 catalyzes the hydrolysis of plasma membrane phospholipid phosphatidylinositol-4,5-bisphosphate (PIP_2), giving rise to two second messengers, inositol 1,4,5-trisphosphate (IP_3), a sugar, and the lipid diacylglycerol (DAG). IP_3 binds to a cognate receptor on endoplasmic reticulum (ER) and releases stored calcium from that organelle. Falling calcium ER concentrations are sensed by stromal interaction molecule 1 (STIM1), an EF-hand domain–containing protein localized in the ER membrane.[8] STIM1 aggregation activates membrane-localized store-operated calcium entry channels, including members of the transmembrane protein Orai family.

An Orai-dependent increase in intracellular calcium serves as a second messenger that activates calcineurin, a serine/threonine phosphatase. Activated calcineurin dephosphorylates members of the nuclear factor of activated T cells (NFAT) family, allowing NFAT to translocate from the cytosol to the nucleus in order to activate genes important for T-cell activation. Knowledge of the calcineurin pathway has been exploited clinically in disorders wherein suppression of T-cell activation is desired. Calcineurin inhibitors cyclosporine and tacrolimus have long been employed in the prevention of human solid-organ transplant rejection (Chapter 89) and in treatment of T-cell–driven autoimmune diseases (Chapter 51). Orai regulators include the transient receptor potential melastatin (TRPM) family of membrane ion channels. TRPM4 shapes the magnitude of

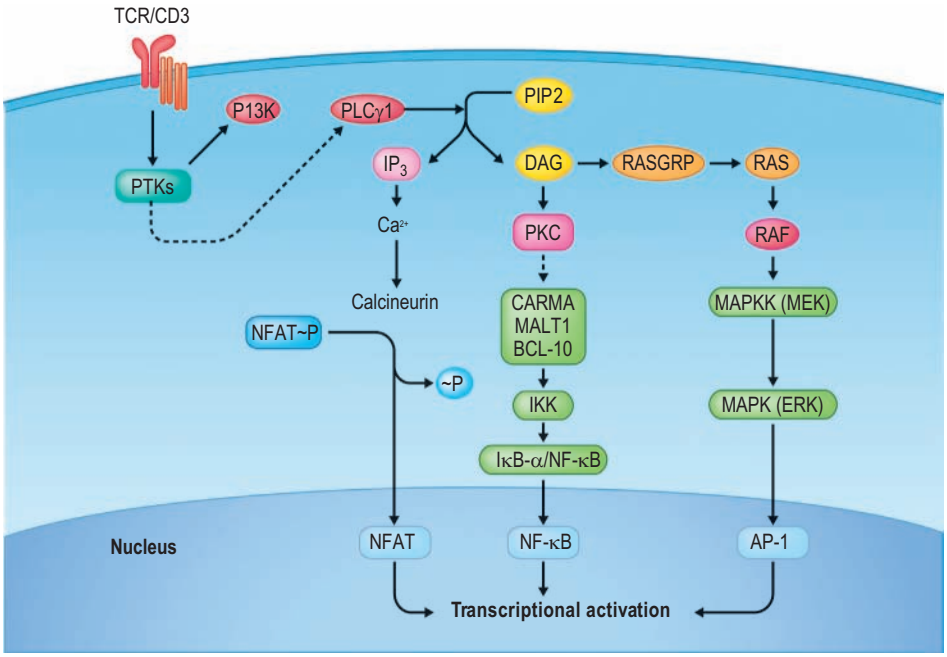

FIG. 10.4 Signaling Pathways Activated by T-cell Receptor *(TCR)* Engagement. TCR ligation results in activation of protein tyrosine kinases *(PTKs)*, such as LCK and ZAP-70. Phospholipase Cγ1 *(PLCγ1)* becomes phosphorylated and activated by PTKs, including ITK. Hydrolysis of phosphatidyl inositol bisphosphate *(PIP_2)* by PLCγ1 releases diacylglycerol *(DAG)* and inositol trisphosphate *(IP_3)*. IP_3 stimulates an increase in intracellular calcium concentration, which activates the phosphatase calcineurin. Calcineurin dephosphorylates nuclear factor of activated T cells *(NFAT)*, thereby signaling NFAT translocation to the nucleus. The formation of DAG leads to activation of RAS-GRP1 GEF activity and RAS activation. Active RAS binds and stimulates the kinase RAF1, initiating a cascade of serine/threonine kinases (MAPK cascade), leading to phosphorylation and nuclear translocation of the extracellular signal-regulated kinase *(ERK)* kinases. DAG formation also results in activation of the CARMA/BCL-1/MALT1 complex, leading to phosphorylation of IκB kinase *(IKK)*. Active IKK phosphorylates IκB-a, leading to IκB-α degradation and release of NF-κB to the nucleus. TCR-activated PI3K catalyzes formation of PIP_3 from membrane-associated PIP_2; the phosphatase PTEN antagonizes PIP_3 formation. PIP_3 binds to the Akt lipid-binding pleckstrin homology domain, a required element in Akt activation. Active Akt both promotes the PKC-CARMA-NFκB pathway and blocks FoxO-dependent transcriptional regulation. Transcription factors NFAT, NF-κB, and those activated by the MAPK pathway cooperate to upregulate transcription of genes, such as *IL-2*, critical for T-cell activation.

TCR Ca^{2+} signals, and TRPM7 plays a key role in TCR signaling termination and T-cell homeostasis. Purinergic ionotropic receptors (P2RX) are membrane channels that are activated by Ca^{2+} entry into mitochondria due to Orai/Stim function. ATP transit through P2RX promotes Th17 differentiation and suppresses Treg development.[8]

Another product of TCR-driven PIP_2 hydrolysis, DAG, functions as second messenger to a parallel cascade of TCR signaling intermediates, including protein kinase D (PKD), Ras guanyl nucleotide releasing proteins (RasGRPs), and members of the protein kinase C (PKC) family of serine/threonine kinases.[9] PKD cooperates with PKC-dependent signals to activate high-affinity binding capacity and clustering of integrins, a family of molecules that mediate TCR signal-augmented cell binding to adhesion molecules on APCs.[10] RasGRP mediates activation of the Ras cascade. PKC is essential for full activation of the Ras/extracellular signal-regulated kinase (ERK) and nuclear factor-κB (NF-κB) cascades that are required to mount a TCR-stimulated gene transcriptional program and drive cellular activation.

In T lymphocytes, RasGRP1 is a guanine exchange factor that mediates exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) bound to RAS.[11] RasGRP1-mediated activation can be envisioned as an analog rheostat, leading to varying intensities of downstream-activated Ras signaling, depending on the strength of upstream stimulus.[11] Genetic loss of RasGRP1 leads to severe defects in thymocyte development in mice, and inactivating RasGRP1 mutations leads to human immunodeficiency associated with decreased TCR-induced ERK activation, highlighting the importance of the RasGRP pathway in TCR signaling.

Active RAS activates and recruits the serine/threonine kinase RAF to the plasma membrane. Active RAF, in turn, phosphorylates MEK, which phosphorylates ERK. ERK translocates to the nucleus and phosphorylates and activates several transcription factors that are critical for TCR-induced transactivation of cytokines and other activation genes. Studies in cell lines and in genetically altered mice attest to the central importance of RAS activation for T-cell function. T-cell lines expressing activated RAS produce more IL-2 after TCR engagement, whereas cell lines carrying inhibitory RAS mutants produce minimal IL-2. Similarly, mice transgenic for activating Ras mutants show alterations in thymocyte development and demonstrate a partially stimulated state in the absence of antigen binding.

TCR stimulation also triggers a cascade headed by phosphatidylinositol 3′-hydroxyl kinase (PI3K) (see Fig. 10.4).[12] PI3Ks are composed of two noncovalently bound subunits. The p85 regulatory subunit activates the kinase activity of the p110 catalytic

subunit. PI3K phosphorylates phosphoinositides, which play an important role in the regulation of several downstream serine/threonine kinases, including protein kinase B (PKB) (Akt). Akt promotes the NF-κB pathway downstream of PLCγ1- and DAG-driven PKC. Although TCR engagement alone can stimulate some degree of PI3K function, full activity of the lipid kinase requires costimulation of the T cell through receptors, such as CD28 (see below). The outcomes of PI3K and Akt signaling play essential diverse roles in T-cell development, differentiation, and effector function, most of which maximize effector T-cell activation responses. These include suppressing the induction of Foxp3$^+$ Tregs and the expression of proapoptotic molecules, including Bim or Bad, and of cell cycle inhibitors. At the same time, PI3K signaling promotes T-cell survival via enhancing metabolic processes, including glucose uptake and glycolysis. The importance of this pathway is suggested by the efficacy of PI3K inhibitors in animal models of T-cell–driven autoimmunity, and in treatment of human malignancies, in which inhibition of PI3Kδ activity can lead to an acute impairment of Treg-mediated suppression at tumor and inflammatory sites.[13]

TCR cross-linking also leads to activation of the cytoplasmic serine/threonine kinase PKC-θ. PKC activation results in nuclear translocation of members of the NF-κB family of transcription factors (see Fig. 10.4).[14] In the basal state, NF-κB family members are sequestered in the T-cell cytoplasm through interaction with inhibitors of NF-κB (IκB). In the TCR-stimulated cell, IκB kinases (IKKs) phosphorylate and degrade IκB, leading to transient NF-κB freedom and translocation to the nucleus. Upstream of IKKs, PKC-θ activation results in the formation of a multimolecular activating complex composed of CARMA1, BCL-10, and MALT1 (CBM). Requirements of CBM assembly for optimal TCR signaling have been established through observation of defects in T-cell activation and survival resulting from deficiencies in CBM proteins.

INTEGRATION OF SECOND-MESSENGER PATHWAYS BY ADAPTOR PROTEINS

Adaptor proteins lack enzymatic or transcriptional regulatory activity. Instead, they possess modular domains responsible for subcellular relocalization and intermolecular interactions. Both constitutive and induced intermolecular interactions mediated by adaptor molecules can promote TCR signal transduction.[15]

Adaptor proteins commonly contain modular domains that exhibit affinity for phosphorylated tyrosine residues (Fig. 10.5A). Such regions include the SH2 and phosphotyrosine-binding (PTB) domains, which recognize phosphorylated tyrosine residues within particular sequence contexts. PTB domains obtain their specificity based on residues amino-terminal to the key phosphotyrosine, whereas SH2 domains recognize sequence motifs carboxyl-terminal to phosphotyrosine. Other adaptor domains that confer binding specificity include SH3 modules, which bind proline-rich regions, WW regions that are responsible for interactions with proline/tyrosine or proline/leucine motifs, and PH domains that have specificity for phospholipids.

Several hematopoietic-specific adaptors play essential roles in T-cell development, in coordinating the signals necessary for mature T-cell activation, and in the process of terminating T-cell responses. Two examples are linker of activated T cells (LAT) and SH2 domain-containing leukocyte phosphoprotein of 76 kDa (SLP-76). Both LAT and SLP-76 were identified during efforts to characterize the substrates of PTKs stimulated by TCR engagement.

LAT is an integral membrane protein that contains tyrosine residues within specific sequence motifs that interact with the SH2 domains of other T-cell signaling molecules (see Fig. 10.5A).[16] In TCR-stimulated T cells, LAT inducibly associates with the SH2 domains of GRB2, GADS (Grb2-related adaptor downstream of Shc), PLCγ1, and the regulatory (p85) subunit of PI3K. It is likely that these induced intermolecular interactions are critical for communicating TCR engagement to downstream second-messenger cascades. The importance of LAT for T-cell activation was suggested by complete loss of TCR signaling events downstream of ZAP-70 phosphorylation in LAT-deficient cell lines. Lat plays an essential role in T-cell development, as Lat-deficient mice have significantly decreased thymocyte numbers. Residual Lat-deficient thymocytes are arrested at an early stage of development; peripheral T cells do not develop.

The cytoplasmic adaptor SLP-76 is absolutely required for both T-cell development and signaling via the mature TCR.[7] By means of a proline-rich region, SLP-76 constitutively associates with the adaptor GADS. Through its SH2 domain, SLP-76 can inducibly interact with other tyrosine-phosphorylated adaptors, such as HPK-1 and ADAP. Following TCR-induced tyrosine phosphorylation, SLP-76 also inducibly binds other SH2-domain-containing proteins, including VAV, an exchange factor for the RAC GTP-binding protein NCK, an adaptor protein, and ITK, the Tec family kinase. In mutant T-cell lines lacking SLP-76, TCR-stimulated Zap-70 phosphorylation is normal, but PLCγ1 and RAS/MAPK signaling cascades are not activated, indicating an early functional niche for SLP-76 in TCR signaling. Mice deficient in SLP-76 show complete block in early thymocyte development and possess no peripheral T cells, indicating an absolute requirement for SLP-76 in T-cell development.

One model for how SLP-76 and LAT functionally interact holds that each contributes multiple molecular interactions to a larger "signalosome" complex at the plasma membrane (see Fig. 10.5B).[16] Following TCR engagement, the two adaptors associate with each other, bridged by GADS and PLCγ1. Inducible movement of SLP-76-bound Itk into complex with LAT brings the kinase into proximity with PLCγ1, resulting in its phosphorylation and activation and leading to the generation of IP_3 and DAG, as described above.

Some adaptor proteins play important roles in restraining TCR-mediated signal transduction events, frequently by dictating subcellular localization of regulatory enzymes. For example, in the absence of TCR stimulation, the transmembrane adaptor PAG binds to the cytoplasmic PTK Csk, bringing it to the plasma membrane.[17] Membrane-localized Csk phosphorylates the regulatory tyrosine of LCK, thus keeping LCK inactive in resting T cells.

Coreceptors Transduce Signals That Are Integrated With T-Cell Receptor Signals

TCR stimulation alone does not lead to full T-cell proliferation or initiation of effector function. Instead, the cell must receive complementary signals via TCR accessory molecules.[18] A requirement for multiple signals to engender full activation allows for an extremely sensitive sensor to detect the presence of specific TCR ligands while protecting against inappropriate

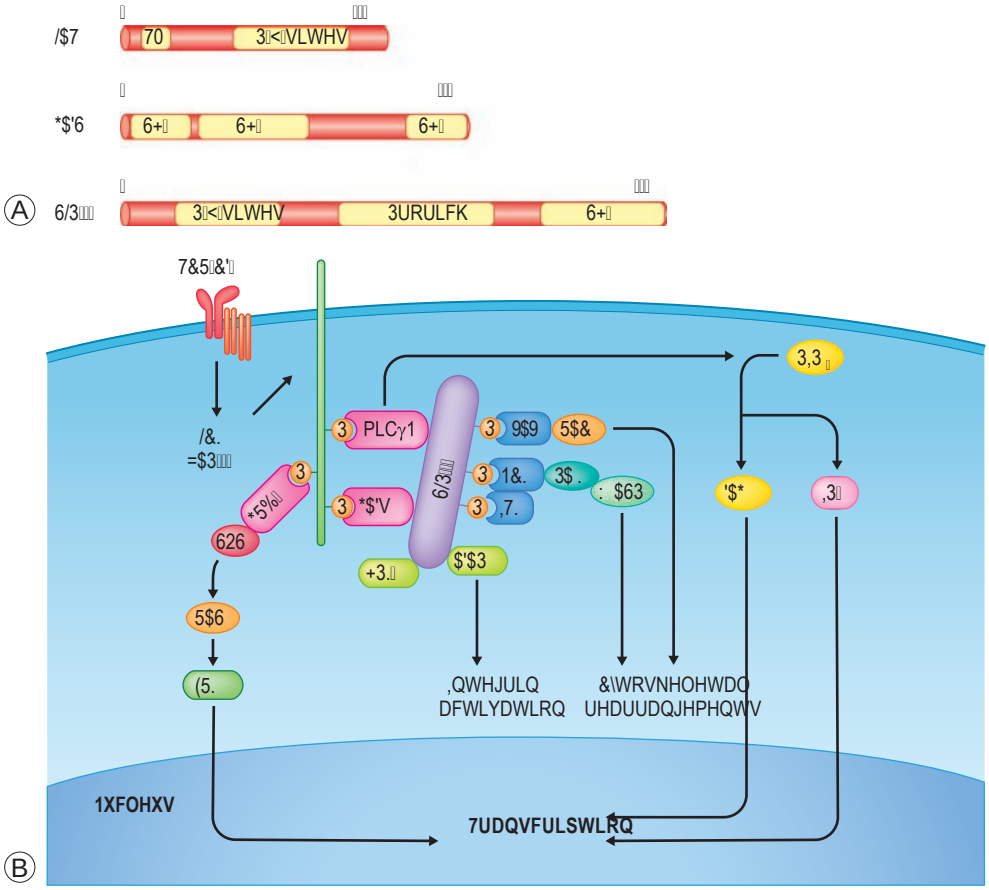

FIG. 10.5 Model for Adaptor Protein-Mediated Coupling of the T-cell Receptor (TCR) to Phospholipase Cγ1 (PLCγ1) Activation. (A) Structural schematics of three adaptors implicated in plasma membrane proximal biochemical events. SH3 domains mediate association with proline-rich regions; SH2 domains associate with phosphorylated tyrosine residues. (B) LAT and SLP-76 are among the substrates of the TCR-activated protein tyrosine kinases (PTKs). When tyrosine residues within the LAT cytoplasmic tail are phosphorylated, GADS binds to LAT through the GADS SH2 domain. Recruitment of GADS results in relocalization of SLP-76, as the proline-rich region of SLP-76 mediates constitutive association with the SH3 domain of GADS. Tyrosine-phosphorylated SLP-76, in turn, becomes associated with ITK via the ITK SH2 domain. ITK is thus brought into proximity with membrane-localized substrates, including PLCγ1. Activation of PLCγ1 leads to hydrolysis of phosphatidylinositol 4,5-bisphosphate *(PIP_2)* and activation of transcription factors, such as nuclear factor-κB (NF-κB), activating protein 1 (AP-1), and nuclear factor of activated T cells (NFAT). SH2 domain containing leukocyte phosphoprotein of 76 kDa *(SLP-76)* also recruits several other signaling molecules, such as VAV, NCK, HPK1, and ADAP, thereby regulating changes in the actin cytoskeleton and adhesion. Phosphorylation of linker of activated T cells *(LAT)* also leads to recruitment of Grb2/SOS and an additional pathway for RAS activation. *TM*, transmembrane domain; *P-Y*, sites for phosphorylation of tyrosine; *pro-rich*, proline-rich regions.

activation of potentially autoreactive—and therefore dangerous—effector T cells. Since T cells respond to antigens presented on APCs, stimulation under physiological conditions involves the potential engagement of multiple coreceptors on the T cell by cognate ligands on the APCs. Some coreceptors may function to increase the avidity of T cells for interacting APCs. However, many coreceptors exhibit intrinsic signal-transducing capacity, both independently of the TCR and via intersection with TCR-driven signaling machinery. Additionally, coreceptors may function to recruit cytoplasmic signaling molecules—for example, enzymes and adaptor proteins—as described above.

The most intensively studied coreceptors are CD4 and CD8 (Chapter 4). Mutually exclusive CD4 or CD8 expression on peripheral T cells defines subsets that respond to MHC class II- or class I-bound peptide antigens, respectively (Chapter 6). Surface-expressed CD4 or CD8 contribute to enhanced TCR signal strength not only because they associate with the extracellular domains of MHC molecules but also because their cytoplasmic domains constitutively associate with LCK, serving to localize a key signal propagator to the TCR complex.[19]

Counterbalanced Costimulatory and Coinhibitory Signals Determine T-Cell Response Thresholds

Productive T-cell stimulation results from a composite of TCR cross-linking and costimulatory signals. Non-TCR activating signals are transduced via a functional family of T-cell surface-expressed proteins termed *costimulatory molecules*. An additional grouping of coreceptors termed *coinhibitors* serve to dampen or restrict potential for TCR-induced cellular activation, and to balance the stimulation-promoting effects of costimulatory molecules.[20] Although functionally divergent,

many costimulatory and coinhibitory molecules share structural features, such as immunoglobulin (Ig)–like extracellular domains.[18] Key costimulatory receptors possessing Ig-like domains include CD28 and ICOS (inducible costimulator); important coinhibitory counterparts include CTLA-4 (cytotoxic T lymphocyte antigen-4, which binds the same ligands as CD28, but with higher affinity), PD-1 (programmed death 1), and BTLA (B- and T-lymphocyte attenuator).[20]

The best-characterized T-cell costimulatory molecule is CD28, a constitutively expressed homodimeric transmembrane glycoprotein.[21] CD28 binds to two ligands expressed on APCs: B7.1 (CD80) and B7.2 (CD86). While ligation of CD28 in isolation has little effect on T-cell activation, when engaged along with the TCR, many TCR signals are augmented. Indeed, concomitant CD28 and TCR engagement is required for activation of naïve T cells.

CD28 ligation engages several signal-transduction pathways implicated in T-cell activation.[21] CD28 contains no intrinsic enzymatic activity, but tyrosine residues within its cytoplasmic tail become inducibly phosphorylated during T-cell activation. These phosphorylated tyrosines recruit several signal-transducing molecules possessing SH2 domains, including GRB2 and the regulatory p85 subunit of PI3K. TCR- and CD28-dependent coactivation of PI3K leads to transactivation of the pro-survival genes *BCL-2* and *BCL-XL*. CD28-driven activation of the GTP-binding protein RAS-related C3 botulinum toxin substrate 1 (RAC1) is crucial for the protein kinase activity of c-JUN N-terminal kinase (JNK), which, in turn, plays an important role in CD28-dependent T-cell cytokine production and apoptosis resistance.

Costimulation with CD28 agonists dramatically augments TCR-driven IL-2 production, both by increasing transcription of the *IL-2* gene and by stabilizing its messenger RNA (mRNA).[21] CD28 is required for T-cell priming during infection and promotes protective secondary T-cell responses during microbial challenge.[22] CD28 is also required for Treg function. Animals engineered to lack CD28 specifically in Treg show splenomegaly, lung inflammation, and accumulation of activated CD4 T cells.[23] These findings suggest that the survival- and activation-promoting function of CD28 costimulation is important for homeostasis of Treg and effector CD4 T-cell subsets. On balance, inhibition of CD28 ligation by cognate ligands CD80/CD86 results in decreased immune responses. In the clinic, blockade of CD28 costimulation using CTLA4-Ig fusion proteins (abatacept; belatacept) can significantly reduce synovial inflammation in human rheumatoid arthritis (Chapter 53) and restrain lymphocyte-driven rejection responses in transplanted kidneys, respectively.

ICOS is an Ig domain-containing costimulatory molecule induced on the T-cell surface after combined TCR and CD28 stimulation.[18] ICOS interaction with APC-expressed ICOS-L is required for development of T-follicular helper (Tfh) cells, a subset required for germinal center formation and for B-cell antibody class switching (Chapter 11). In murine models of rheumatoid arthritis (Chapter 53) and multiple sclerosis (Chapter 66), ICOS antibody blockade results in reduced Tfh and germinal center formation, associated with suppression of autoimmune responses. ICOS deficiency associates with human common variable immune deficiency (CVID) (Chapter 33), suggesting that ICOS is important for protective T-cell-dependent humoral immunity.

Members of the tumor necrosis factor receptor (TNFR) family comprise another large group of costimulatory molecules.[24] OX40 (CD134), 4-1BB (CD137), herpesvirus entry mediator (HVEM), CD30, and glucocorticoid-induced TNF receptor (GITR) all have costimulatory potential. Cytoplasmic domains within these type I transmembrane proteins contain sequences that recruit a family of adaptor molecules known as TNF-receptor–associated factors (TRAFs). A well-characterized member of this group is OX40.[25] OX40 is upregulated on activated CD4 T cells after CD3/CD28 stimulation. Trimerization of OX40 induced by engagement of APC-expressed OX40L leads to recruitment of TRAFS and engagement of a survival-enhancing NF-κB pathway. OX40 deficiency leads to defects in CD4 T-cell proliferation, reduced survival of effector memory T cells, and impaired formation of effective responses to secondary T-cell stimulation with antigen. Antibody-mediated blockade results in reduced induction of experimental autoimmune encephalitis (EAE) and collagen-induced arthritis.

CTLA4 and PD-1 are coinhibitory molecules that can restrain TCR-induced activation. The CTLA4 coinhibitory molecule shares at least two features with CD28: membership in the Ig domain–containing superfamily and high-affinity binding capacity for APC-expressed ligands CD80 and CD86. Unlike CD28, CTLA4 expression is inducible in conventional CD4 T cells. However, CTLA4 is present constitutively on Treg cells. Ligation of CTLA4 induces a biochemical cascade, including the activation of PP2A and SHP-2 phosphatases.[20] CTLA4 functions to antagonize the TCR "stop signal," whereby T cells are induced to pause and maintain lengthy physical contact with antigen-bearing dendritic cells (DCs).[18] Treg can use CTLA4 to limit access of non-Treg conventional T cells to CD80/CD86 by downregulating these ligands on APCs.

CTLA4 represents one of a growing number of molecular "checkpoints" that can negatively regulate natural antitumor T-cell responses.[26] Monoclonal, antagonist anti-CTLA4 antibodies can enhance T-cell antitumor responses against many human malignancies. Approved by the US Food and Drug Administration (FDA) in 2011, such antibodies have resulted in tumor regression and durable remissions in patients with advanced metastatic melanoma and other formerly intractable malignancies.

The coinhibitor PD-1 is an Ig domain-containing surface receptor that functions as a negative regulator of T-cell activation.[26] PD-1 signals attenuation of TCR-driven PI3K and Akt. Ligation of PD-1 by cognate ligand PDL-1 results in recruitment of phosphatases, such as SHP2, to motifs within the PD-1 cytoplasmic tail. Phosphatase-associated PD-1 interacts with TCR microclusters, resulting in dephosphorylation of apical TCR signaling mediators, including ZAP-70 and CD3ζ, thus dampening TCR signal strength. At a cellular level, PD-1 enforces T-cell unresponsiveness by inhibiting TCR-mediated "stop signals" that promote stable, prolonged contact between T cells and APCs. Disruption of PD-1 in mice results in autoantibody formation and glomerulonephritis. In chronic viral infections, CD8 T cells (Chapter 25) display a hyporesponsive "exhausted" phenotype associated with elevated surface expression of PD-1.[27]

Antibody blockade of PD-1/PDL-1 interactions results in restoration of effector functions in exhausted T cells, suggesting that PD-1 manipulation could benefit patients with viral infections. The therapeutic potential of PD-1 has been most dramatically realized in the field of tumor immunotherapy.[26] In many malignancies, both CD4 and CD8 T cells accumulate within the tumor stroma. Tumor-infiltrating lymphocytes

(TILs) are characterized by high expression of PD-1 and other coinhibitory molecules. Tumor-expressed ligands for these molecules are thought to enforce a state of reduced cytolytic or cytokine-secreting functions. Monoclonal anti-PD-1 and anti-PDL-1 antagonist antibodies have been employed to reinvigorate TIL antitumor capacity. PD-1/PDL-1 blockade has sometimes resulted in dramatic tumor regressions of diverse tumors (e.g., metastatic melanoma, non–small cell lung carcinoma, and lymphoma). Other potential targets for checkpoint inhibitor therapy include the T-cell coiinhibitors Lag3 and BTLA.

Knowledge of the additive or synergistic effects of cosignaling by TCR and costimulatory molecules has been exploited for therapeutic purpose through the generation of chimeric antigen receptors (CARs).[28] These engineered molecules possess an antigen-binding extracellular region (often a single-chain variable fragment), a transmembrane domain, and cytosolic domains containing a portion of the CD3 ζ-chain fused to a costimulatory molecule (e.g., CD28, OX40, 4-1BB) cytosolic region. Cross-linking of the CARs thus may provide both "signal 1" (TCR) and "signal 2" (costimulation) for T-cell activation, leading to direct tumor killing. Cytotoxic T cells modified to express CARs that recognize CD19 have been used in successful treatment of B-cell malignancies.

Spatial and Temporal Distribution of T-Cell Receptor Signaling Proteins

Following TCR engagement, a highly organized interface termed the *immunological synapse* (IS) forms between the T cell and the APC (Chapter 6). Within the IS, many transmembrane and cytoplasmic proteins are coordinately polarized and form a structure called the *supramolecular activation cluster* (SMAC).[29] The SMAC is composed of concentric rings with a central region (cSMAC) enriched in TCR and CD3/ζ. The more peripheral ring (pSMAC) is enriched for the integrin leukocyte function–associated antigen-1 (LFA-1). Inhibitory signaling molecules, such as the transmembrane phosphatase CD45, are excluded from the SMAC. These observations initially suggested that formation of the SMAC is required for signal initiation. The subsequent finding of a paucity of active signaling molecules located in the SMAC has led to alternative models in which the SMAC is involved in directed cytokine secretion or in signal termination.

Efficient formation of the T cell IS is heavily dependent on nucleation-promoting factors, such as Wiskott-Aldrich syndrome protein (WASP), which promotes reorganization of the actin cytoskeleton.[29] Complexes composed of TCRs, active kinases, and adaptor molecules, termed *microclusters*, form at the immune synapse within seconds following TCR engagement.[30] TCR microclusters are dynamically regulated in space and time. Within 2 to 3 minutes of formation, microclusters migrate along polymerized actin from the periphery to the center of the IS, where dephosphorylation and dissociation of the components occur. Sustained TCR signaling depends on constant re-formation of microclusters containing SLP-76 and ZAP-70 at the periphery of the central zone. Costimulatory signals generated by CD28 or the integrin very late antigen-4 (VLA-4) can alter the dynamics of microcluster formation and movement and enhance T-cell activation. The functions of either the SMAC or the microclusters in TCR signal initiation and termination remain incompletely understood.

KEY CONCEPTS

Mechanisms of Tolerance: Central and Peripheral

- Central
  - Clonal deletion
  - AIRE-mediated expression of tissue-specific antigens
- Peripheral
  - Immune privilege
  - Anergy
  - Regulation

TOLERANCE

Tolerance is an inherent property of the immune system that governs the ability to respond against foreign antigens (nonself) without attacking the host (self). In normal hosts, tolerance protects against autoimmune tissue injury. The concept of immune tolerance predated understanding of the cellular and molecular bases for the phenomenon. Owen's experiments in cattle showed that a shared blood supply during early development led to lifelong immune tolerance.[31] Billingham et al. later showed that in utero inoculation with foreign tissue resulted in tolerance to foreign skin grafts applied long after birth.[32] Layered and complementary mechanisms of immune system tolerance have developed to calibrate immune responsiveness with maintenance of maximum capacity for protective activation. The remainder of this chapter discusses critical roles played by T cells in the establishment and maintenance of tolerance.

Establishment of immune tolerance to self may occur either during thymocyte development or after T-cell maturation in tissues.[33] *Central tolerance* refers to the phenomenon of induced apoptosis occurring during development of T cells in the thymus (Chapter 9). Despite the presence of mechanisms that promote expression of a comprehensive repertoire of self-peptides in the thymus, central tolerance alone is not sufficient to prevent tissue-damaging autoimmune responses. In healthy vertebrates, a small percentage of newly matured T cells exiting the thymus carry autoreactive TCRs. Control of such "escaped" autoreactive cells in secondary lymphoid organs and tissues is achieved through a series of extrathymic processes. In aggregate, these are referred to as *peripheral tolerance*.

Central Tolerance/Clonal Deletion

Techniques allowing study of clonal populations during T-cell development have opened windows into the molecular mechanisms of thymocyte clonal deletion.[34,35] Fate-mapping experiments that track specific Vβ17 TCR variable regions indicate that clonal deletion of autoreactive cells occurs principally during the transition between $CD4^+CD8^+$ double-positive "DP" to CD4 or CD8 single-positive "SP" transition during thymocyte development. TCR transgenic mice expressing a single specificity TCR potentiated additional investigation into central tolerance. Mice bearing transgenic TCRs reactive with a Y chromosome–encoded antigen (H-Y) are among the oldest models of clonal deletion. Massive deletion of developing thymocytes results in small thymi in self-antigen–expressing (male) mice; only a small number of DP thymocytes avoid the apoptotic cell death induced by TCR engagement. In contrast, transgenic T cells develop normally in littermate female mice that lack H-Y antigen. Additional TCR transgenic models of central tolerance

have shown that autoreactive thymocyte deletion can occur before, during, or after the DP stage.

Deletion due to self-reactivity implies that the extent of autoreactivity of the developing thymocytes is systematically calibrated. A long-held model is that proclivity for deletion due to self-reactivity is a function of the TCR strength of signal.[36] In this model, TCR signals that exceed an intensity threshold lead to clonal deletion of cells bearing that antigen receptor. This model is supported by studies of animals in which the signaling machinery has been genetically altered to increase or decrease TCR signal intensity. For example, an increase in the number of TCR-associated ITAMs (presumably leading to increases in downstream signals) enhances clonal deletion in a TCR transgenic system.[37]

For clonal deletion to establish comprehensive self-tolerance, T cells must come into contact with all potential self-antigens during thymocyte maturation. It is straightforward to imagine how deletion of cells reactive to MHC or to other ubiquitously expressed protein antigens can occur in the thymus. However, thymocytes bearing TCR reactive with self-antigens whose expression is restricted to a specific tissue or developmental time point (e.g., peptides expressed only in the pancreas or testes) would not be expected to encounter such antigens during thymic maturation.

In recent years, mechanisms whereby clonal deletion of developing thymocytes reactive with such tissue-restricted antigens (TRAs) have been described. Some evidence supports the possibility that TRAs are transported to the thymus by APCs, such as migratory DCs.[36] Another, non–mutually exclusive model holds that subsets of thymus-resident APCs may "ectopically" express TRAs. In this regard, the transcription factor AIRE (autoimmune regulator) controls TRA expression within medullary thymic epithelial cells (mTECs).[38] AIRE expression ectopically drives mTEC to express peptides from open reading frames representing TRA. Self-reactive developing T cells are thus exposed to TRA in the thymus and are deleted.

AIRE-deficient humans and mice develop tissue damaging autoimmunity in a syndrome termed polyendocrinopathy–candidiasis–ectodermal dystrophy (APS-1 or APECED in humans; Chapter 34), emphasizing the role of central tolerance in preventing T-cell–mediated autoimmune injury.

TRA presentation by mTEC is unlikely to fully account for successful clonal deletion, given the relative rarity of mTEC in thymic stroma relative to the abundance of autoreactive thymocytes. An additional mechanism for enhancing TRA-reactive thymocytes exposure to deleting TRA-driven signals is "shared" antigen presentation capacity among thymic stromal cells other than mTECS. Intercellular transfer of TRA between mTEC and thymic-resident or migrant DCs has been observed, supporting this model.[36]

Peripheral Mechanisms of Tolerance

Despite highly efficient negative selection in the thymus, significant numbers of autoreactive T cells escape to the periphery, and have potential to cause autoimmune tissue injury. Accordingly, additional mechanisms have evolved to control autoreactivity of T cells that have managed to escape the thymus. These include immune privilege, anergy, and regulation.

Immune Privilege

Medawar first proposed the concept of "immune privilege," whereby intrinsic factors in local tissue engender resistance to autoimmune tissue damage. Tissues that possess features of immune privilege include the anterior chamber of the eye, the brain, and the developing fetus in pregnant females.[39] The eye and the brain are critical organs for basic survival functions and yet have a limited capacity for regeneration. Thus uncontrolled immune responses in these organs could have a detrimental effect on survival. A fetus expresses MHC derived from both parents; thus the mother's immune system must develop tolerance of the paternal antigen-bearing fetus to prevent pregnancy loss.

Immune-privileged tissues evade or suppress immune effector functions through multiple mechanisms. Cells of the eye, brain, and fetal villous trophoblast display low level or absent surface expression of classic MHC class Ia proteins. This feature likely protects them from cytotoxic T-lymphocyte (CTL)–mediated lysis (Chapter 12). Ocular cells express proapoptotic cell surface molecules, such as CD95 ligand (CD95L) and TRAIL (TNF-related apoptosis inducing ligand) (Chapter 17). Since activated T cells or other inflammatory cells may bear high levels of cognate ligands (e.g., CD95, other "death" receptors) for the proapoptotic proteins, they can be induced to undergo apoptosis upon migration to immune-privileged sites, thus limiting their potential for tissue injury.

In mice, the presence of CD95L on ocular cells is critical for the acceptance of corneal allografts. Soluble factors likely also contribute to immune privilege. Ocular DCs can elaborate molecules including the cytokines transforming growth factor-β (TGF-β) and IL-10, which may lead to induction and/or recruitment of Tregs. In addition, ocular DCs may produce high levels of indoleamine oxidase, an enzyme that supports Treg differentiation. Finally, ocular cells can produce migration inhibitory factor (MIF) that suppresses natural killer (NK) cell–dependent cytolytic capacity.

T-Cell Anergy

Cellular proliferation and/or potentiation of T-cell effector function are not inevitable consequences of TCR engagement. Under some conditions, TCR engagement results in *anergy*, a cellular fate characterized by reduced proliferation potential and blunted cytokine production in response to subsequent TCR stimulation.[40] T-cell anergy can ensue either when the TCR is engaged without concomitant costimulation (e.g., CD28 ligands) or when the ligand for the TCR does not possess sufficient affinity to initiate the full spectrum of biochemical second messengers.

Anergy is observed in T cells stimulated with metabolically inactivated APCs incapable of providing costimulation. Conversely, CD28 costimulation prevents the induction of anergy. Treatment of cultured T cells with IL-2 can overcome the anergic state in vitro. In addition to TCR and costimulatory signals, environmental cues (e.g., nutrient and energy store availability) and the products of Tregs (described below) also control the anergy/activation fate choice.

T-cell anergy can be induced by stimuli that engage the calcineurin/NFAT pathway without causing concomitant increases in RAS/ERK pathway–dependent activating protein-1 (AP-1) transcription factor activity (Fig. 10.6A). Experimentally, relatively unopposed NFAT activity can be induced by treatment with calcium ionophore or by stimulation through the TCR while blocking CD28 costimulation. Concurrent treatment of TCR-stimulated cells with protein synthesis inhibitors or with NFAT pathway inhibitors, such as cyclosporine, abrogates the

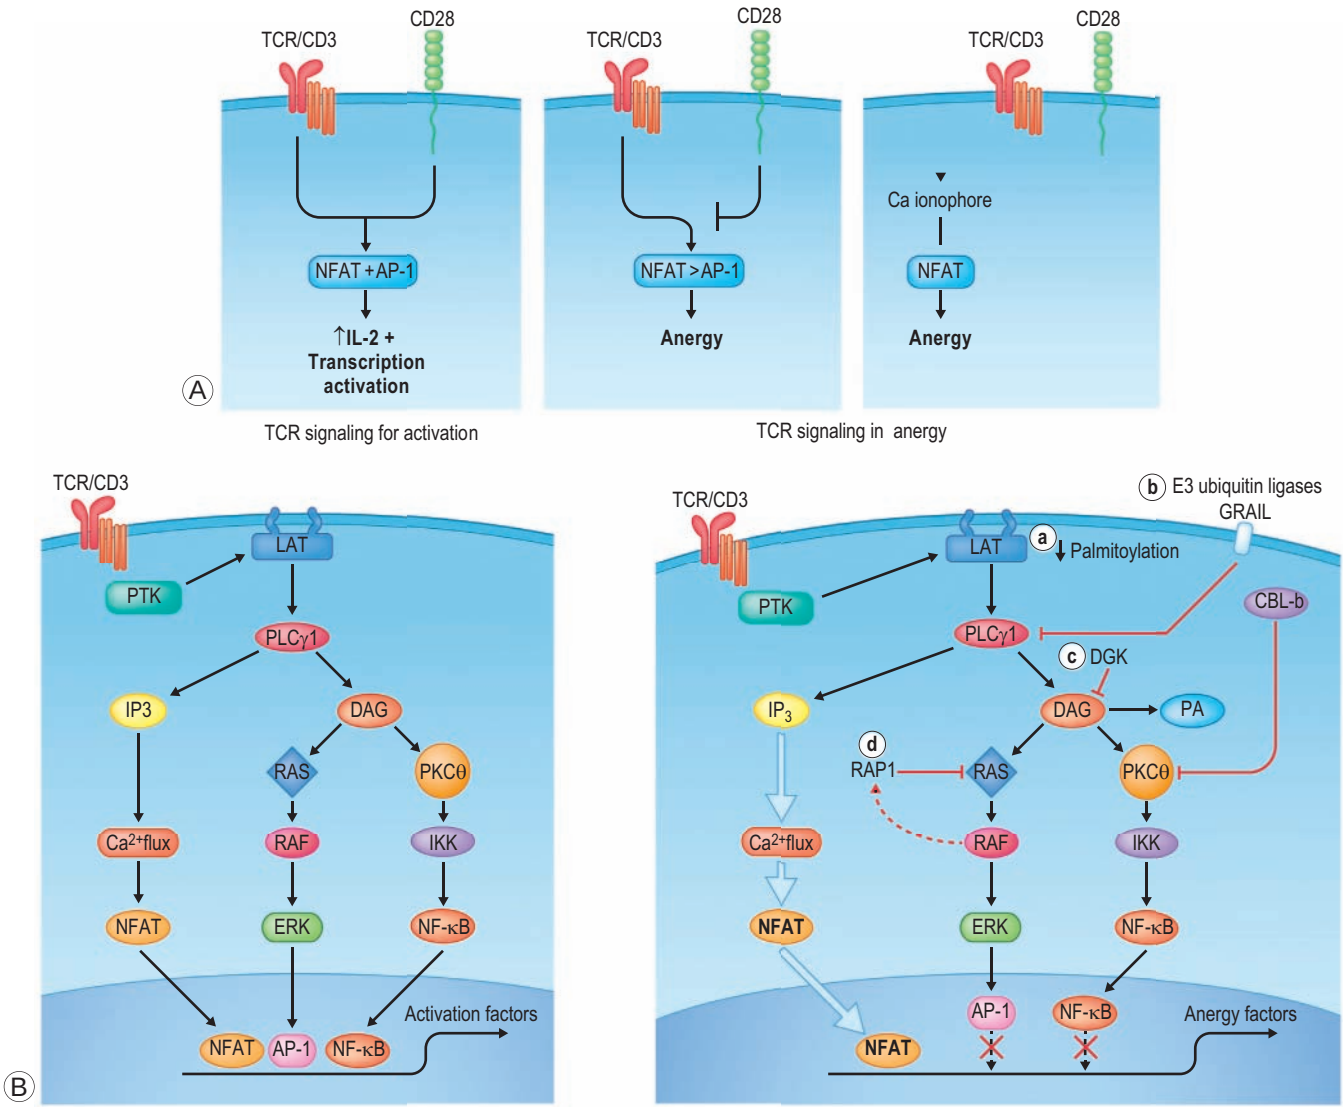

FIG. 10.6 T-cell Anergy Induction and Maintenance Correlates with Differential Activation of T-cell Receptor *(TCR)*–Dependent Second-Messenger Signaling Cascades. (A) Stimulation of T cells by cross-linking of both TCR/CD3 and CD28 lead to upregulation of both the nuclear factor of activated T cells *(NFAT)* and activating protein-1 *(AP-1)* transcription factors, leading to increased transcription of the interleukin-2 *(IL-2)* gene and activation. An imbalance of activated NFAT and AP-1 by blockade of CD28 signals *(middle panel)* or calcium ionophore *(right panel)* leads to an anergic phenotype. (B) TCR signaling required for full T-cell activation features calcium flux-, RAS-, and PKC-dependent biochemical events leading to cooperative transcriptional regulation by NFAT, AP-1, and NF-κB transcription factors *(left panel)*. In energized cells, TCR-dependent signaling is differentially impaired (DAG-dependent events more so than calcium-dependent events) through multiple mechanisms: (a) decreased palmitoylation of linker of activated T cells *(LAT)* results in diminished recruitment to the immunological synapse; (b) upregulated gene related to anergy in lymphocytes *(GRAIL)* and CBL-b degrade positive signaling regulators PLCg1 and PKCθ; (c) diacylglycerol kinases *(DGKs)* convert DAG (PKC and RAS activator) to phosphatidic acid *(PA)*; (d) active RAP1 recruits RAF, thus preventing RAS-mediated signaling to extracellular signal-regulated kinase *(ERK)*. Anergy mechanisms and mediators are highlighted in *red*.

development of later unresponsiveness, supporting the notion that anergy induction and maintenance depend on actively transcribed and translated anergy-associated factors.[41]

Increased NFAT pathway signaling coupled and reduced Ras pathway function in T-cell anergy correlates with a number of biochemical and gene regulatory events (see Fig. 10.6B).[42] First, preferential FYN kinase–dependent activation of c-CBL within anergized cells leads to recruitment of the RAF kinase to the nucleotide exchange factor RAP1. The RAF-RAP1 association prevents RAF recruitment to RAS and thus restricts ERK pathway activation. Second, upregulation of NFAT-dependent transcription factors EGR2 and EGR3 results in transactivation of proteins implicated in the restraint of T-cell activation, including GRAIL (gene related to anergy in lymphocytes), CBL-b, and ITCH.[41] E3 ubiquitin ligase activity associated with a number of the latter factors is responsible for ubiquitin-mediated proteolysis of TCR signal–promoting molecules, such as PKCθ and RAS-GRP. Third, anergic stimuli cause reduced palmitoylation and phosphorylation of the positive TCR signaling mediator LAT, which may reduce LAT membrane

localization in detergent-insoluble lipid rafts and participation in activating signaling.[43] Fourth, increased expression of members of the diacylglycerol kinase family (DGKα and DGKζ) is observed in T-cell anergy. Augmented DGK expression reflects increased capacity for phosphorylation-dependent conversion of DAG, the key lipid mediator upstream of RAS signaling, into phosphatidic acid (PA), an inert metabolite.[44]

Cellular sensing of adequate nutrient and energy stores required for optimal differentiation and proliferation also regulates T-cell fate decisions between anergy and activation. Antagonists of leucine or glucose can cause T-cell anergy if administered in the context of normally activating combined antigen receptor and costimulatory signals, suggesting the importance of amino acid- and energy-sensing pathways in cell fate determination.[40] Several lines of evidence suggest that the cytosolic molecule mechanistic target of rapamycin (mTOR) functions as a switch between activation and anergic states by integrating signals from antigen recognition (TCR), immune (CD28, IL-2 receptor), and metabolic (e.g., GLUT1) receptors and sensors.[45]

TCR and CD28 ligation induce T-cell anergy rather than activation when given in the presence of rapamycin, a selective mTOR inhibitor, suggesting that optimal T-cell activation and anergy avoidance requires activation of mTOR. mTOR is activated by signals that communicate abundant nutrients (e.g., leucine-stimulated RAG proteins). Conversely, mTOR is inhibited by AMP-activated protein kinase (AMPK), an enzyme that responds to low-energy stores reflected by increased ratios of adenosine monophosphate (AMP) to adenosine triphosphate (ATP). Downstream effectors of activated mTOR such as AKT promote cell cycle entry and prevent transcriptional activation of the anergy factors GRAIL and CBL-b.

KEY CONCEPTS

Immunomodulatory Agents That Affect T-Cell Signaling

- Immunosuppressants:
  - Cyclosporine, tacrolimus, and anti-TCR antibodies inhibit TCR-generated signals
  - CTLA4-Ig blocks CD28 signals
  - Rapamycin inhibits mechanistic target of rapamycin (mTOR) activation
- Immunostimulants work through inhibitory receptor blockade, enhancing T-cell antitumor function
  - Anti-CTLA4 antagonist antibodies permit CD28-CD80/86 interactions
  - Anti-PD1/anti-PDL1 antibodies prevent suppressive interactions between tumor-expressed PDL1 and PD1 on tumor-infiltrating Treg and effector T cells

Regulation

Subsets of T lymphocytes can enforce peripheral tolerance through regulation of autoreactive immune responses. Tregs can suppress effector cells of both myeloid and lymphoid lineages (Chapter 13). The most extensively studied Treg-sensitive immune functions—and arguably the most important for maintenance of T-cell tolerance—are proliferation and cytokine production by conventional T cells (Tconv). Tregs inhibit these processes through both cell contact–dependent and soluble molecule secretion mechanisms.[47] By regulating the activation and proliferation of antigen-specific effectors, Tregs promote immune self-tolerance and suppress autoimmunity in vivo. Treg manipulation for therapeutic purposes holds promise for treatment of human autoimmune and malignant disease.

Tregs were initially described on the basis of the correlation between high CD25 expression and the potent suppressive activity of a subset of CD4 T cells. Most Tregs also express GITR, CD103, CTLA-4, lymphocyte activation gene-3 (*LAG-3*), and low levels of CD45RB.[46] No single surface marker specifically identifies Treg. However, features that together correlate tightly with Treg suppressive capacity and a unique differentiation pathway include CD4 T-cell expression of the X chromosome-encoded transcription factor Foxp3, an epigenetic DNA methylation signature that prominently suppresses the *IL2* gene and drives high constitutive CTLA4 expression, and a TCR-driven, antigen-primed activation state.[47]

Absence of Foxp3 occurs either via spontaneous mutation (exemplified by the scurfy mouse, which develops fatal autoimmune disease) or through targeted disruption of the gene, which leads to the complete loss of T cells with regulatory activity. Conditional deletion of Foxp3 in peripheral T cells results in loss of the suppressive phenotype. Conversely, overexpression of Foxp3 leads to an excess of T cells with regulatory activity. Thus, Foxp3 appears both necessary and sufficient for Treg suppressive functions.

The bulk of Foxp3-positive Tregs develop in the thymus. Dynamic Foxp3 expression and development of suppressive capacity can be observed in naïve peripheral CD4 T cells after exposure to TGF-β or retinoic acid. Recent work strongly suggests that inducible Treg may have nonredundant functions in suppressing chronic inflammation.

In humans, mutations in FOXP3 account for a majority of cases of immune dysfunction/polyendocrinopathy/enteropathy/X-linked (IPEX) syndrome.[47] Affected human males develop an autoimmune syndrome consisting of lymphoproliferation, thyroiditis, insulin-dependent diabetes mellitus, enteropathy, and other immune disorders. The signs and symptoms of FOXP3 deficiency are similar in mice and humans.

Mechanisms whereby Treg inhibit conventional T-cell responses include secretion of suppressive cytokines, induction of T-cell apoptosis, and repression of APC function.[48] Key Treg-secreted cytokines include IL-10, TGF-β, and IL-35; each of these molecules has the capacity to induce cell cycle arrest. Tregs, via high expression of CD25 (IL-2Rα), may compete with neighboring T effector cells for limited supplies of IL-2. The resulting growth factor deprivation results in apoptosis of proliferating T cells in a B-cell lymphoma 2–interacting (Bcl2-interacting) mediator (BIM)-dependent manner. Tregs preferentially express galectin-1, a β-galactoside-binding protein that ligates CD45 and other lymphocyte surface molecules and that may suppress lymphocyte activation through induction of cell cycle arrest. Treg surface proteins that work to effectively decrease efficiency of antigen presentation by DCs include CTLA-4, which interferes with CD28-dependent T-cell costimulation; LAG3, which binds to MHC class II molecules and prevents DC maturation; and Nrp1, which mediates prolonged Treg/DC interactions that may restrict access of effector T cells to DCs.

Growing insight into the molecular bases of Treg development and of their suppressive capacities has been exploited in recent manipulations of Treg for therapeutic purpose.[47] Conceptually, strategies to boost Treg hold promise for treatment of human autoimmune and inflammatory diseases, whereas strategies that selectively deplete Treg or impair Treg suppressive capac-

ity may lead to improved efficacy of immunotherapy for malignancy. Supplemental interleukin-2 (IL-2) can selectively drive expansion of Treg in vivo in patients with graft-versus-host disease (GvHD), type 1 diabetes, and hepatitis C-induced vasculitis, with the expectation of ameliorating inflammatory tissue injury. Adoptive cell therapy is another Treg-based approach to autoimmune disease. Tregs isolated from circulation can be expanded in vitro and then transferred back to transplant recipients for treatment of rejection reactions or GvHD prevention.

Tregs can apparently hinder naturally occurring antitumor immunity. Tumor-infiltrating FOXP3$^+$ T cells are in a proliferative activated state, express more T-cell activation molecules compared with Tregs in noncancerous tissues, and confer worse prognosis when present in high numbers.

Treg depletion may be a major mechanism by which ipilimumab (anti-CTLA4 antibody) works, in addition to blocking inhibitory signaling in conventional T cells. Tumor-resident CTLA4-high Treg are opsonized by ipilimumab and rendered susceptible to selective antibody-dependent cellular toxicity. Resultant Treg depletion correlates with greater cytotoxic function of tumor-reactive CD8 T cells, and improved tumor control. Opposite to the effect of anti-CTLA4 treatment, anti-PD-1 therapy may promote Treg function, thus diminishing efficiency of the checkpoint inhibition therapy. Tumor-infiltrating Treg express PD-1 highly, and PD-1-blocking antibody could act to remove restraints on Treg proliferation and suppressive function.

Unwanted enhancement of Treg function may help explain a hyperaggressive tumor phenotype observed in a subset of cancer patients treated with anti-PD-1. Tumor infiltration by enhanced numbers of proliferating and active Tregs is observed in such patients. Current studies are testing whether Treg-depletion strategies, used in combination with or prior to anti-PD-1 therapy, could enhance effectiveness of the checkpoint inhibitor.

ON THE HORIZON

- Promising targets for manipulation of T-cell signaling to treat malignancy include:
  - SYK inhibition
  - PI3K/AKT inhibition
  - Tec kinase inhibition in cancer
- Targets for relief of immune checkpoints on T-cell activation for immune enhancement in cancer or infection include:
  - LAG3, TIGIT, TIM3, BTLA, VISTA
- Harnessing Treg for GvHD, transplant rejection, autoimmunity
  - Cytokine (e.g., IL-2)-driven Treg expansion in vivo
  - Adoptive transfer of ex vivo expanded Treg

SUMMARY AND FUTURE DIRECTIONS

Antigen receptor signaling controls key T-cell developmental checkpoints as well as the fate decisions and behavior of mature T cells. Early TCR signaling depends on tyrosine phosphorylation events coupled to "second messenger" cascades through adaptor proteins. TCR affinity for ligand is the major determinant for life-or-death decisions by immature thymocytes that result in establishment of a broadly self-tolerant mature T-cell repertoire that includes regulatory cells (Treg). In peripheral T cells, auxiliary signals from costimulatory molecules, coreceptors, growth factor receptors, and metabolic sensors all shape the transcriptional regulation programs that govern cell function. T cells proliferate and produce cytokines when members of the CD28 or TNFR families of receptors signal in tandem with the TCR. Immunoreceptor and costimulatory signals are also critical in maintaining immune tolerance through clonal deletion, anergy, and peripheral suppression by Tregs. Co-inhibitory signals, such as CTLA4 and PD1, that restrain T-cell antitumor functions may be antagonized for immunotherapy of cancer. More detailed understanding of T-cell intracellular signaling pathways will likely lead to more specific, targeted immunomodulatory therapies.

Helper T-Cell Subsets and Control of the Inflammatory Response

Todd N. Eagar and Stephen D. Miller

CD4 T cells are an integral part of the immune system, and key regulators of many inflammatory processes involved in health and disease including responses against infectious organisms, anti-cancer immunity, and autoimmunity. Disruption of normal T-cell functions through genetic disease (Chapter 34), such as severe combined immunodeficiency (SCID), or immunosuppressive therapies often results in recurrent bacterial, fungal, and viral infections and certain cancers.[1] Conversely, dysregulated T-cell responses are associated with rampant inflammation and autoimmunity, as seen in patients with such conditions as autoimmune lymphoproliferative syndrome (ALPS), autoimmune polyendocrinopathy syndrome type 1 (APS-1) and immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome.[2]

Thus a balance must be struck between allowing T-cell inflammation to protect the host from pathogens and ensuring control mechanisms to prevent injury from unchecked T-cell–mediated inflammation. The requisite control is established as T cells transit through distinct checkpoints of the immune response. These include activation, clonal expansion, migration, differentiation, and response termination.

T cells are generated in the thymus from lymphocyte progenitor cells (Chapter 9). Mature T cells enter the peripheral immune system as inexperienced or naïve cells that are incapable of carrying out effector immune responses. To participate in inflammation, T cells must go through an instructional process with defined checkpoints. This chapter discusses the functional heterogeneity within the CD4 T-cell compartment in the context of the checkpoints involved in the generation and regulation of T-cell biology.

KEY CONCEPTS

T-Cell–Mediated Inflammation Requires Activated or Memory T Cells

Naïve T Cells
- Low frequency
- Traffic through circulatory and lymphatic systems
- Require professional antigen-presenting cells (APCs) for activation
- Require strong costimulation
- Delayed expansion
- Delayed cytokine production
- Dependent on interleukin-7 (IL-7)

Activated T Cells
- Traffic through most tissues
- Respond to antigen presented by nonprofessional APCs
- Require less costimulation
- Rapidly expand following antigen encounter
- Rapidly produce effector cytokines
- Dependent on IL-2

Memory T Cells
- Traffic through most tissues
- Dependent on IL-7 and IL-15
- Respond to antigen presented by nonprofessional APCs
- Require less costimulation
- Rapidly expand following antigen encounter
- **Activation:** T-cell function requires antigen-specific T-cell receptor (TCR) signals and accessory signals. This provides fine specificity against discrete protein antigens and limits self-reactivity.
- **Clonal expansion:** Activated T cells rapidly expand in number to scale the immune response.
- **Migration:** T cells traffic through blood, lymphatics, and organs. This allows for surveillance and localized effector responses in diverse tissue types.
- **Effector responses:** T cells adapt their phenotypes to tailor the response to the organism and infected tissue. Long-term memory cells provide protection from re-exposure to the same pathogens.
- **Termination:** T-cell responses are limited through inhibitory receptors, cell death pathways, and suppression.

ACTIVATION

T-cell activation is the process by which resting T cells become functional. Due to the fact that activation is required at multiple stages of a T-cell response, activation is the most critical checkpoint controlling T-cell activity (Fig. 11.1). Full activation requires the T cell to integrate signals through distinct receptor types including the T-cell antigen receptor (TCR, signal 1), costimulatory receptors (signal 2), and cytokines (signal 3).[3] TCR signals are essential for T-cell activation. Each TCR is generated through somatic recombination and is selected to recognize linear peptide antigens when presented in the context of self-human leukocyte antigen (HLA) proteins (Chapter 5). Engagement of cognate HLA–peptide complex by the TCR elicits biochemical signal cascades and induces gene transcription that ultimately control T-cell function (Chapter 10). The second set of signals involve costimulatory receptors. Positive costimulation is delivered through receptors such as CD28 and inducible costimulator (ICOS) in response to binding to B7 (CD80 or CD86) or ICOSL, respectively, on neighboring cells. Negative or inhibitory costimulatory signals can also be received by the T cell through receptors such as cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4) or programmed death-1 (PD-1) by engagement of B7 or PD-L1. Costimulation and cytokines regulate T-cell activation by quantitatively modifying TCR-induced signals or qualitatively by inducing

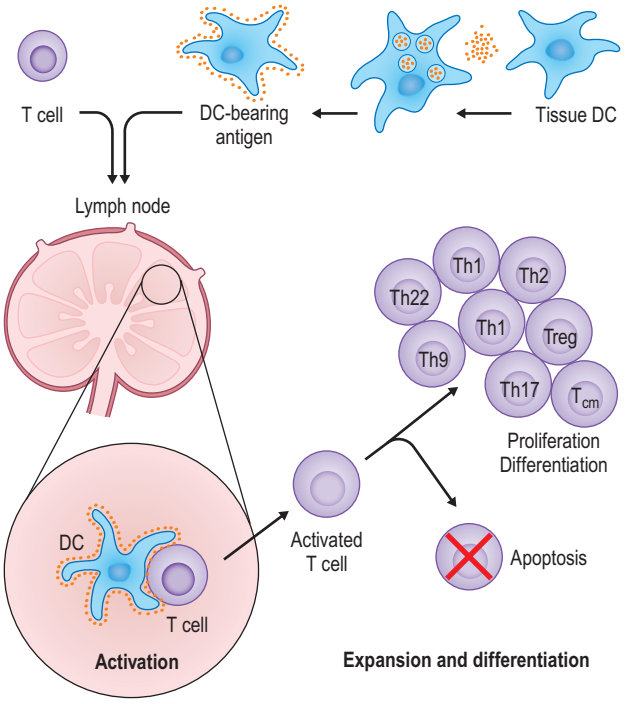

FIG. 11.1 T-Cell Expansion and Differentiation. Following emigration from the thymus, CD4 T cells travel through the lymph nodes. Inflammation results in the recruitment of tissue dendritic cells *(DCs)* into the draining lymph nodes. In the lymph nodes, DCs present antigen to naïve T cells. Effective antigen presentation stimulates the activation, proliferation, and differentiation of T cells into Th1, Th2, Th9, Th17, Th22, or uncommitted T central memory (T_{cm}) cells.

distinct biochemical cascades. Ultimately, the effects of costimulation and cytokine signals are detected at the level of gene expression where they may promote, inhibit, or otherwise alter TCR-induced cell activation.[4]

TCR costimulation and cytokine signals are delivered during interactions between T cells and APCs (Chapter 6) including dendritic cells (DC) and B cells. DCs are considered the primary APC involved in T-cell activation.[5] Mature DCs are potent stimulators of naïve T cells in the lymph nodes and strong activators of memory and effector cell subsets in tissues. In response to infection or damage, DCs migrate from the tissue into the T-cell–rich areas of regional lymph nodes.[6] T cells interact with numerous DCs as they scan for cognate antigen. In the absence of TCR signaling, these interactions are of short duration; however, TCR engagement elicits prolonged T cell–DC engagement leading to full activation.[7] Incomplete stimulation through the TCR, costimulation, or cytokine pathways may prevent T cells from participating in inflammation through altered effector differentiation, induction of apoptosis, or causing functional unresponsiveness such as anergy or exhaustion. Thus, the requirement for TCR stimulation dictates specificity of T-cell responses, and the need for multiple signals during T-cell activation prevents inappropriate T-cell activation. T cells also interact with DCs in non-lymphatic tissues and at sites of inflammation. During this interaction, T cells become activated to elicit effector functions.[8]

Defects in T-cell activation pathways contribute to several immunodeficiency diseases. Patients with mutations in the proximal TCR signaling components lck and Zap70 show defective T-cell activation. T cells from patients with Wiskott-Aldrich syndrome have defects in the formation of stable TCR signaling complexes. T cells in leukocyte adhesion deficiency 1 have a reduced activation capacity due to defects in integrin β_2. By contrast, mutations in inhibitory receptors, including CTLA-4 and PD-1, are thought to contribute to susceptibility in autoimmune diseases.

The T-cell activation process can be targeted for therapeutic immunosuppression. Pharmacological targeting of key biochemical pathways required for activation has been the primary approach to prevent rejection in solid organ transplantation, to treat graft-versus-host disease (GvHD) in bone marrow transplantation, and to reduce the severity of autoimmune diseases or other immune-mediated disorders. Cyclosporine and tacrolimus block calcineurin and thereby inhibit TCR-induced nuclear factor of activated T cells (NFATs) signals. Rapamycin inhibits the kinase mammalian target of rapamycin (mTOR), which is induced by TCR and CD28 or by IL-2 receptor signals.[9] A fusion of the extracellular domain of CTLA-4 with the Fc portion of immunoglobulin G (IgG; CTLA-4-Ig) prevents T-cell activation by blocking the interactions between CD28 and its B7 ligands. Antibodies against the IL-2R block IL-2–driven T-cell activation. Conversely, antibodies blocking the inhibitory receptors PD-1 and CTLA-4 promote or prolong T-cell activation and thereby enhance antitumor T-cell responses.[10]

CLONAL EXPANSION

T-cell activation occurs within hours of antigen exposure; however, days are required until T-cell responses can be detected from a naïve host. This delay partially reflects the need for T-cell expansion to produce a detectable and effective response. The initial frequency of T cells for a single epitope is estimated at approximately one per million total CD4 T cells or approximately 1×10^5 cells per human.[11] It takes several days following antigen exposure for the first cell divisions to occur in the lymph nodes and the spleen; thereafter cell numbers increase rapidly between days 2 and 7, when many T cells have undergone as many as eight rounds of division. This process is known as *clonal expansion* (see Fig. 11.1). A single precursor T cell following eight rounds of division can yield 256 daughter cells, each possessing the same TCR. Through the combined proliferative responses of multiple T-cell clones to the same or different epitopes produced by the same pathogen, a rapid net increase in pathogen-reactive T cells occurs.

In the clinical setting, T-cell proliferation is a target for immunosuppression. Some drugs, such as azathioprine, methotrexate, and mycophenolate mofetil impair T-cell proliferation by inhibiting nucleotide synthesis. Cyclophosphamide suppresses DNA replication by alkylating guanine residues. These agents are used in the treatment of various autoimmune diseases and for the prevention of graft loss in transplantation.

TRAFFICKING

Following activation, T cells change their migration patterns (Chapter 16). T-cell migration relies on the actions of selectins, chemokines (Chapter 15), integrins, and matrix proteases. Together, these permit vessel transmigration into lymphatic tissues or sites of inflammation.[12] The differential trafficking of naïve and effector T cells results from upregulated expression of selectins, chemokine receptors, and integrins upon activation. The circulation of naïve T cells is restricted to blood, lymph nodes, and lymphatic ducts. This pattern of movement relies on the expression of chemokine receptor 7 (CCR7), L-selectin

(CD62L), and leukocyte function–associated antigen-1 (LFA-1; $\alpha_L\beta_2$ integrin, CD11a, CD18). CCR7-expressing T cells follow gradients of CCL21 into T-cell–rich areas in the lymph nodes, Peyer patches, and spleen. L-selectin allows rolling on the high endothelial venule (HEV). LFA-1 and intercellular adhesion molecule-1 (ICAM-1) permit firm adhesion and extravasation. Migration to the Peyer patches also requires $\alpha_4\beta_7$ integrin in addition to LFA-1. T-cell retention in and egress from lymph nodes is regulated by sphingosine 1 phosphate (S1P), a secreted phospholipid. S1P sensitivity is mediated by sphingosine 1 phosphate receptor 1 (S1P1), a G protein–coupled receptor. Recirculating T cells downregulate S1P1. As a result of low S1P levels in the lymph node, S1P1 expression allows exit from the lymph nodes 12 to 18 hours after entry.[13]

During activation, T cells alter the patterns of homing receptors to reduce the cell's ability to migrate within the secondary lymphatic system while gaining receptors needed for trafficking in the peripheral tissues. Very early in the activation process, T cells downregulate S1P1 and express CD69, which suppresses chemotactic migration in response to S1P, shed L-selectin, and express the ligands for E- and P-selectin. Additionally, T cells downregulate CCR7 expression and upregulate expression of a new set of chemokine receptors. Following activation, expression of LFA-1 and additional integrin molecules is markedly increased. One such integrin, very late antigen-4 (VLA-4), is induced by activation and permits T-cell migration into the central nervous system (CNS), lungs, and intestines.[14]

Differential expression of homing receptors by naïve and activated T cells facilitates their diverse functions. Naïve T cells in the lymphatic tissues are in close proximity to DCs from many tissues facilitating antigen encounter. The function of activated T cells in immune surveillance, in contrast, is facilitated by migration through diverse tissues.

The multistep process of migration and the tissue selectivity of migration receptors have been targeted for the treatment of autoimmune diseases. Antibodies targeting CD62L and LFA-1 have been developed to prevent the entry of T cells into lymph nodes. In addition, the S1P1 inhibitor drug fingolimod has been recently approved for the treatment of multiple sclerosis (MS). Fingolimod is thought to prevent the egress of recently activated T cells from the lymph nodes. Natalizumab, a monoclonal antibody against α_4 integrin, a potent inhibitor of T-cell migration into the CNS and intestines, is utilized in the treatment of MS and Crohn disease to prevent the migration of T cells to the CNS and intestines, respectively.

DIFFERENTIATION OF CD4 Th SUBSETS

Naïve T Cells

Naïve T cells are precursors for effector and memory T-cell subsets. Phenotypically, naïve T cells are small cells with little cytoplasm; they express surface markers, such as CD45RA, CCR7, CD62L, CD127, and CD132. They lack expression of markers of previous activation, such as CD25, CD44, CD69, CD45RO, or HLA-DR. Naïve T cells have low metabolism and are unable to mediate effector responses or produce proinflammatory cytokines.[15] Naïve T cells migrate within the secondary lymphoid organs, where they interact with DCs. Because of their role as precursors for all T-effector subsets, their loss is thought to be an important contributor to the immunosenescence seen in older adults.

Early studies demonstrated that CD4 T-cell clones and cell lines would express reproducible patterns of cytokine expression designated T-helper cell-1 (Th1) and T-helper cell-2 (Th2).[16] It is now appreciated that CD4 effector T cells can differentiate into many functional phenotypes (see Fig. 11.1). These can be grouped into four general categories: (i) those possessing proinflammatory effector characteristics, (ii) those possessing regulatory or anti-inflammatory activities, (iii) those that promote B-cell follicle development, and (iv) those that provide long-term memory. Our understanding of the phenotype diversification process is rapidly expanding. T-effector cell differentiation occurs in three steps. First, TCR signals lead to activation and elicit the expression of cytokine receptors.[17] Second, signals through specific cytokine receptors differentially promote the expression of lineage-specific "master" transcription factors that promote expression of genes associated with a particular T-cell phenotype and suppress the expression of genes associated with other T-cell phenotypes. Third, the phenotype-specific transcription factors induce epigenetic changes that control gene accessibility and maintain the T-cell phenotype in a cell-intrinsic manner.

EFFECTOR CELL PHENOTYPES

T-effector cells promote inflammation through the release of cytokines (Fig. 11.2). Cytokine release elicits the activity of accessory cells, which ultimately mediate the inflammation to clear the antigen. The pattern of cytokine production ultimately dictates the type of inflammation (Table 11.1). Effector T cells are divided into five basic groups: Th1, Th2, Th9, Th17, and Th22. Table 11.2 summarizes the T-effector responses associated with selected pathogens.

Th1

Th1 cells are defined by production of the cytokines IFN-γ, GM-CSF, IL-2, and lymphotoxin (LT). Th1 differentiation

KEY CONCEPTS

CD4 Effector Phenotypes

Th1
- Produces interferon (IFN)-γ, IL-2, tumor necrosis factor (TNF), and lymphotoxin (LT)
- Stimulates IgG1 and IgG3 class switching
- Responses mediated by macrophage activity
- Promotes phagocytic activity through:
  - FcγRIII cross-linking
  - Complement deposition
  - Opsonization
  - IFN-γ-mediated macrophage activation

Th2
- Produces IL-4, IL-5, IL-6, and IL-10
- Stimulates IgG4 and IgE class switching
- Responses mediated by mast cells and eosinophils
- Increases degranulation through:
  - FcεRI cross-linking
  - IL-5–mediated eosinophil activation

Th17
- Produces IL-6, IL-17, granulocyte macrophage–colony-stimulating factor (GM-CSF), and TNF
- Activates local endothelium
- Induces cytokine and chemokine production
- Increases infiltration by neutrophils
- Activates cell-mediated inflammation

is elicited in response to infection by intracellular bacteria, fungi, and viruses, products of which stimulate surface toll-like receptors (TLR), leading to the production of cytokines by DCs and natural killer (NK) cells. Th1 differentiation is promoted by IL-12, IL-18, IFN-γ, and type 1 interferons and is inhibited by IL-4, IL-10, and transforming growth factor-β (TGF-β; Fig. 11.3A). During activation, IFN-γ receptor signals activate signal transducer and activator of transcription 1 (STAT1) and promote the expression of the Th1-restricted transcription factor T-bet and IL-12R expression. IL-12R signals through STAT4, which drives the expression of high levels of T-bet. T-bet serves to reinforce the Th1 phenotype by promoting IFN-γ and IL-12Rβ_2 expression.[17] IL-18 plays a dual role in Th1 function by promoting Th1 commitment and eliciting IFN-γ production by fully differentiated Th1 cells.

Th1 cells promote cell-mediated inflammatory responses through inducing the activation of macrophages, NK cells, B cells, and CD8 T cells. Th1 cells regulate macrophage function at several levels. GM-CSF promotes the production of monocyte lineage cells from the bone marrow. IFN-γ is a potent macrophage activator, enhancing microbicidal activity by initiating nitric oxide (NO) production, upregulating production of oxygen radicals, and increasing phagocytic function. IFN-γ also promotes antigen presentation by upregulating major histocompatibility complex (MHC) class I molecules, MHC class II molecules, and costimulatory molecule expression by macrophages (Fig. 11.2). IFN-γ can activate NK cells and also promote humoral responses in B cells to mediate antibody class switching to an IgG1 (IgG2a in mice) isotype.[18] IgG1 activates the classical complement pathway and can bind Fcγ receptors expressed on phagocytic cells, thereby promoting opsonization. Finally, IFN-γ acts in conjunction with another Th1 cytokine, IL-2, to promote the differentiation of CD8 cells into cytotoxic effector cells (Chapter 12). Macrophage-dependent Th1-mediated inflammatory responses are known as *delayed-type hypersensitivity* (DTH) responses. In vivo, DTH responses are critical for protection from intracellular pathogens including bacteria, fungi, and viruses. Individuals with defects in components of the IFN-γ or IL-12 signaling pathways are susceptible to atypical mycobacterial infections and have altered responses to other microorganisms. Additionally, Th1 cells are thought to contribute to the pathogenesis of autoimmune diseases, including MS, type 1 diabetes mellitus, rheumatoid arthritis, and Crohn disease. The Th1 pathway has been explored therapeutically. IL-12 has been studied as a way to boost vaccine immune responses against microorganisms and antitumor immunity. IL-12 neutralizing mAb-based therapies have been investigated in inflammatory and autoimmune diseases, including psoriasis, arthritis, Crohn disease, and MS.

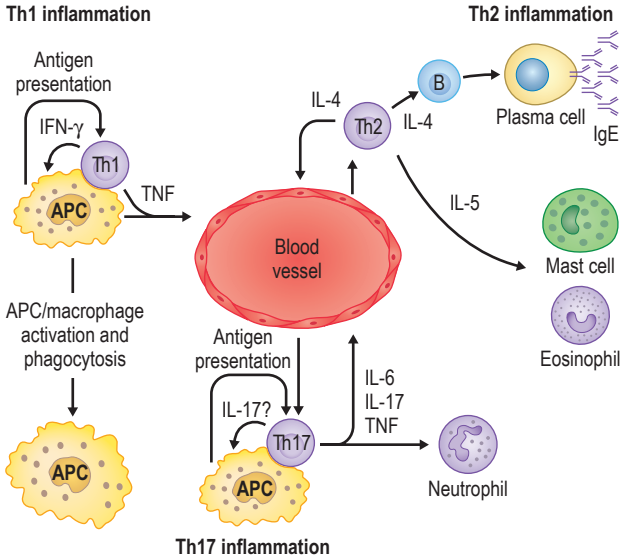

FIG. 11.2 Generalized Model for T Helper–Mediated Inflammation. *Top left.* Introduction of infectious agent stimulates the release of chemokines and tumor necrosis factor *(TNF)* from tissue macrophages, stimulating the recruitment *(upward arrows)* of T cells and monocytes through the local vasculature. Antigen recognition by T cells stimulates the local production of Th1 cytokines. Interferon *(IFN)*-γ activates macrophages, enhancing the clearance of infectious agents. *Top right.* Trafficking to sites of Th2 responses is stimulated by local chemokine expression, leading to T-cell recruitment. Antigen recognition leads to interleukin *(IL)*-4 production by Th2 cells, which stimulates B-cell immunoglobulin *(Ig)E* class switching. Production of IL-5 activates eosinophils. Cross-linking of FcεR1 molecules bound to IgE leads to the degranulation of mast cells and eosinophils. *Bottom.* Recruitment of Th17 cells and restimulation by antigen results in the release of IL-6, IL-17, and TNF, which promotes the recruitment, activation, and function of many cells, particularly neutrophils. *APC,* Antigen-presenting cells.

Th2

Th2 cells are defined by their production of IL-4, IL-5, IL-9, IL-10, and IL-13. In vitro, the critical step in Th2-cell differentiation is the presence of exogenous IL-4 and the absence of IFN-γ during T-cell activation. In vivo, Th2 differentiation is thought to require IL-4 produced by basophils, eosinophils, mast cells, NKT cells, or even previously differentiated Th2 cells. Naïve T cells express the IL-4R, and the combination of TCR, costimulatory (CD28 and ICOS), and IL-4R/STAT6 signaling promotes IL-4 transcription and the production of the transcription factors c-Maf and GATA3. c-Maf helps to establish Th2 polarity by promoting IL-4 and suppressing IFN-γ production. GATA3 also appears to inhibit IFN-γ production, but additionally plays a critical role in establishing Th2 cells by promoting IL-5 and IL-13 production (Fig. 11.3B).[19]

Th2 cells release IL-4 and IL-5, which attract and activate the function of eosinophils and mast cells. Th2-type cytokines enhance B-cell class switching toward IgG2, IgE, and sIgA. High levels of IgE in Th2 reactions combined with antigen exposure and FcεR1 receptor expression by eosinophils or mast cells results in triggering and release of inflammatory factors, such as histamine, platelet-activating factor, prostaglandins, and leukotrienes (Fig. 11.2). These factors act on the local environment, producing vascular dilation and leakage, bronchial constriction, and intestinal hypermotility. On a more systemic level, anaphylaxis may be produced. Eosinophil- and mast cell–dependent reactions are known as *immediate-type hypersensitivity* (ITH) responses. ITH responses are important for ridding the body of intestinal helminths; in fact, components of helminth eggs strongly promote Th2 differentiation. Th2 responses are also associated with atopy and hyperresponsive airway conditions, such as asthma and allergies.

TABLE 11.1 T-Helper Cell Effector Function Through Cytokine Secretion

Th1	
Interleukin (IL)-2	T-cell growth and potentiation of Fas-mediated apoptosis
	Natural killer (NK) cell growth and cytolytic activity
	B-cell growth and antibody production
Interferon (IFN)-γ	Increases class I and II molecule expression on numerous cell types
	Promotes Th1 differentiation
	Activates macrophages; stimulates phagocytic killing and oxidative bursts
	Induces immunoglobulin (Ig)G2α and IgG3 class switching
	Inhibits IgG1 and IgE class switching
	Inhibits Th2 proliferation
	Activates neutrophils
	Activates endothelium to promote CD4 T-cell adhesion
	Stimulates NK cell cytolytic activity
	Required for the activation of CD8 cytotoxic T lymphocytes (CTLs)
Tumor necrosis factor (TNF)	Activates vascular endothelial cells; enhances leukocyte recruitment
	Activates neutrophils, eosinophils, and macrophages
	Stimulates IL-1, IL-6, TNF, and chemokine expression by macrophages
	Protects against viral infections, similar to interferons (IFNs)
	Increases class I molecule expression
	Induces fever
	Activates coagulation
Lymphotoxin (LT)	Activates neutrophils and osteoclasts
	Activates vascular endothelial cells; enhances leukocyte recruitment
	Cytotoxic activity against tumor cells
	Stimulates adhesion molecule expression
	Increases class I molecule expression
Th2	
IL-4	Growth and differentiation of Th2 cells
	B-cell growth and class II molecule upregulation
	Induces IgG1 class switching (IgG4 in humans) and IgE
	Inhibits IgG2a and IgG3 class switching
	Mast cell growth
	Inhibits macrophage activation
	Induces vascular cell adhesion molecule (VCAM) expression on endothelium; recruits eosinophils/monocytes
IL-5	B-cell growth and activation
	Eosinophil differentiation
	Eosinophil activation and survival
IL-10	Inhibits cytokine and chemokine production in monocytes, especially TNF, IL-1, and IL-12
	Inhibits macrophage activation and function
	Inhibits T-cell–mediated inflammation
	Induces IgG4 class switching (IgG1 in mice)
IL-13	Upregulates class II molecules on monocytes and B cells
	Inhibits proinflammatory cytokine production by monocytes
	B-cell costimulation
	Induces IgG4 class switching (IgG1 in mice) and IgE
	Increases class I molecule expression
Th9	
IL-9	Mast cell expansion and recruitment
	T-cell growth factor
IL-21	Promotes Th17 differentiation
	B-cell survival; antibody class switching
	Enhances NK cell proliferation; promotes killer function
Th17	
IL-17	Increases T-cell proliferation
	Promotes neutrophil recruitment and activity
	Promotes cytokine production including IL-6 and TNF
	Induces chemokine production
Granulocyte macrophage–colony-stimulating factor (GM-CSF)	Promotes myeloid cell development and maturation
	Promotes dendritic cell differentiation and survival
	Enhances macrophage activation
IL-6	Activates acute-phase response, inducing fever and antibacterial responses
	Promotes Th2 and Th17 differentiation
	Activates and elicits NK responses
	Promotes plasma cell differentiation and Ig production
IL-21	See above
TNF	See above
Th22	
IL-22	Activates acute phase response, inducing fever and antibacterial responses
IL-13	See above
TNF	See above

TABLE 11.2 T-Cell Effector Responses to Selected Pathogens

Organism	Nature of the Immune Response
Bacteria	
Borrelia burgdorferi	Th1 and Th17 responses associated with protection and joint pathology
Chlamydia trachomatis	Th1 and Th17 responses protective and source of pathology
Helicobacter pylori	Th1 and Th17 responses contribute to protection and pathology. Th2 responses lead to persistence
Legionella pneumophila	Th1 responses associated with immunity
Listeria monocytogenes	Th1 responses are protective: interferon (IFN)-γ from γδ T cells and CD8 T cells is important
Mycobacterium leprae	Severity and phenotype of disease depends on Th1 and Th2 predominance
Mycobacterium tuberculosis	Th1 responses control infection
Treponema pallidum	Th1 resolves infection; Th2 chronic
Yersinia pestis	Th1 and Th17 responses associated with immunity
Fungi	
Aspergillus fumigatus	Th2 production predominates; does Th1 offer protection?
Blastomyces dermatitidis	Th1 protects; Th2 switch in progressive disease
Candida albicans	Th17 responses are protective
Cryptococcus neoformans	Susceptibility associated with Th2 response; Th17 response associated with protection
Paracoccidioides brasiliensis	Infection stimulates Th2 response, but Th1 response protects
Parasites	
Leishmania spp.	Th1 responses are protective; Th2 responses allow chronic infection
Filaria	Initiates Th2 production; Th1 response appears protective
Schistosoma mansoni	Th1 and humoral responses protect; typically Th2 responses directed against eggs
Trypanosoma cruzi	Th1 responses inhibit parasite replication, but protection is not completely CD4 dependent
Giardia lamblia	Th1 and Th2 responses protect
Viruses	
Measles	Th1 responses are protective
Hepatitis B	Th1 responses seen in spontaneous recovering patients
Human immunodeficiency virus	Rapid loss of effector and memory T cells correlates with susceptibility to pathogens.
Respiratory syncytial virus	Th2, Th9, and Th17 responses are associated with reduced lung function

Th17

Th17 T cells are characterized by the production of IL-17a/f, IL-21, IL-22, IL-26, GM-CSF, and TNF. Th17 differentiation is promoted by IL-1β, IL-6, IL-23, and TGF-β, and the absence of type 1 interferons, IFN-γ, and IL-4 (Fig. 11.3C). Much of the potency attributed to Th17 cells derives from the production of IL-17 and GM-CSF. IL-17, together with TNF, strongly promotes inflammation by inducing the expression of adhesion molecules, proinflammatory cytokines (including IL-6, GM-CSF, granulocyte–colony-stimulating factor [G-CSF]), chemokines, prostaglandin E2, and matrix metalloproteinases (see Fig. 11.2). IL-21 regulates B-cell, T-cell, and NK-cell functions.[20]

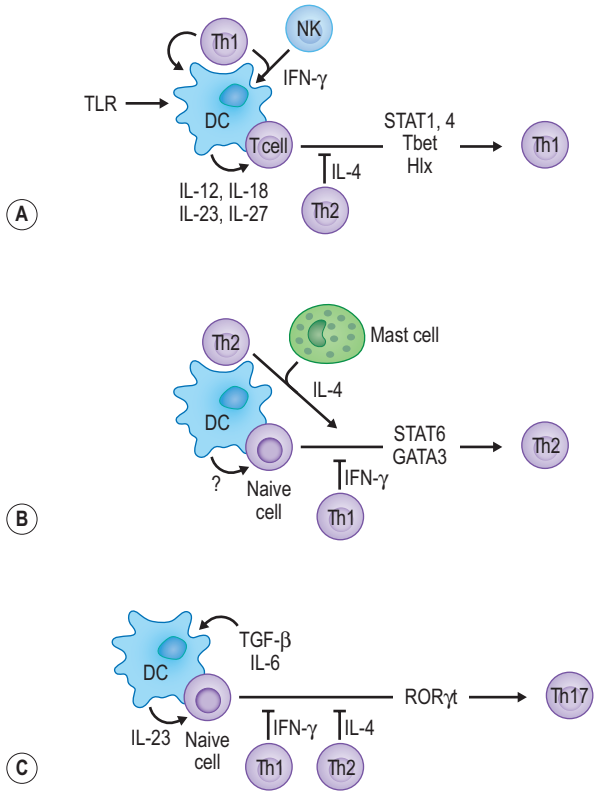

FIG. 11.3 Factors Influencing T-Effector Differentiation. Cytokine exposure during the activation stage of naïve T cells strongly influences T-effector differentiation. Depicted here are the factors promoting and inhibiting Th1 (A), Th2 (B), Th17 (C), and T-follicular helper (Tfh) cells following functional activation of undifferentiated T cells. DC, Dendritic cells; IFN-γ, interferon-γ; IL, interleukin; NK, natural killer; *RORgammat*, retinoic acid related-orphan nuclear receptor gamma; STAT, signal transducer and activator of transcription; TGF-β, transforming growth factor-β. *TLR*, Toll-like receptor.

In B cells, IL-21 has been found to regulate plasma cell differentiation and promote IgM and IgG1 antibody production. IL-21 is a T-cell growth factor, and in the presence of TCR signals, IL-21 promotes T-cell activation, proliferation, and survival. It therefore appears that Th17 cells are important for the recruitment of effector cells, including neutrophils and monocytes.

Th17 cells are potent cell-mediated effectors. Th17 responses are elicited in response to infection with extracellular bacteria and fungi. In addition, Th17 cells have been implicated in transplant rejection, atopic dermatitis, Crohn disease, psoriasis, and MS. Experimental models demonstrate that Th17 cells, via the production of GM-CSF and IL-17, are important mediators of autoimmune diseases, including experimental autoimmune encephalomyelitis (EAE).[21] Patients with impaired IL-17 expression or mutations causing Th17 differentiation experience recurrent infections with *Staphylococcus aureus* and *Candida albicans*. Alleles of the IL-23R have been found to confer protection or susceptibility to Crohn disease and psoriasis. Clinical trials are underway to examine the effects of disrupting Th17 immune responses in patients with autoimmune diseases. Therapeutic mAbs to IL12/23 p40, IL23 p19, and IL-17a have been approved for treatment of psoriasis and are being investigated for application in other conditions.

Th9

IL-9–producing T-cell subsets are a separate lineage. Human Th9 cells produce IL-9 and IL-21. IL-9 is an important growth factor for T cells, mast cells, and hematopoietic stem cells (HSCs). IL-9 functions by preventing apoptosis and by recruiting DC. The differentiation of naïve T cells into a Th9 phenotype is thought to be dependent on the presence of IL-4 and TGF-β and is enhanced by signaling through TNF receptor 2 and costimulation by TNFRSF4 (OX40).[22] Th9 cells express the transcription factor PU.1, which is thought to repress Th2-associated GATA3 and Th1-associated T-bet expression. Similar to Th2 cells, Th9 cells are thought to play a role in protection from helminths and promote airway restriction and mucus secretion in allergic asthma. Experimental and clinical studies indicate that Th9 cells may contribute to immune pathogenesis in inflammatory bowel disease, MS, rheumatoid arthritis, and other autoimmune diseases.

Th22

Although IL-22 was originally described as a Th17 cytokine, research has shown that a distinct CD4 T-cell population expressed IL-22 independently of IL-17. Further work identified IL-22, IL-13, and TNF secreting cells in the skin of patients with inflammatory skin disorders.[3] These IL-22–expressing cell populations also express the cutaneous homing receptors CCR4, CCR6, and CCR10. These Th22 cells have been subsequently found to differentiate in the presence of IL-6 and TNF.[23] Phenotypically, Th22 cells express a different gene profile than other Th cell subtypes, suggesting that they are a distinct effector population. They also produce fibroblast growth factors that promote epidermal repair. IL-22 is a member of the IL-10 family with important functions in regulating skin homeostasis and protection from infection by eliciting anti-bacterial protein production. Experimental models suggest that IL-22 and Th22 cells may play beneficial roles in diverse epithelial tissues.

KEY CONCEPTS

Regulation of T-Cell Responses

- Cell death pathways
  - TNF family receptors: Fas/FasL, TNF-related apoptosis inducing ligand (TRAIL), and TNFR1
- Inhibitory receptor activity
  - CTLA-4 and PD-1
  - Inhibition of TCR signaling
- Cytokine-mediated regulation
  - Anti-inflammatory cytokine production (IL-10, TGF-β)
  - Cytokines that promote and inhibit inflammation at different stages of a response (IFN-γ, IL-2, IL-27)
  - Regulation of apoptosis (LT, TNF)
  - Growth factor withdrawal (IL-2, IL-7, IL-15)

REGULATORY T CELLS

Regulatory T cells (Tregs) possess the ability to suppress or otherwise downregulate the function of other proinflammatory T cells. Although multiple T-cell subsets may possess regulatory T-cell activity, our understanding of regulatory function was greatly enhanced by the discovery of CD25 and FoxP3 as markers for a regulatory subpopulation of CD4 T cells (Chapter 13). This discussion focuses on the involvement of two populations of peripherally derived Treg phenotypes: adaptive Treg and Tr1 cells.

Adaptive Tregs

In mice, the majority of $CD4^+$ $CD25^+$ $FoxP3^+$ Tregs (natural Tregs) are thought to develop regulatory ability in the thymus. Peripherally derived adaptive Tregs are similar in phenotype to natural Tregs in that they express CD4, CD25, CD38, CD62L, CD103, and FoxP3. Adaptive Tregs are thought to be generated in response to prolonged exposure to antigen and are influenced by antigen presentation by immature DCs, plasmacytoid DCs, or nonprofessional APCs. The presence of inhibitory cytokines, such as IL-10 and TGF-β, also favors adaptive Treg differentiation. Similar to natural Tregs, adaptive Tregs are capable of suppressing CD4 and CD8 T-cell responses. Unlike natural Tregs, adaptive Tregs can function through both cell contact–dependent interactions and through the secretion of anti-inflammatory cytokines. These cytokines may directly regulate effector T cells or may inhibit DC activity. The generation of adaptive Tregs is of great interest as a cell-based therapy for inflammatory diseases, including autoimmunity.[24]

Tr1 Cells

Tr1 cells have been defined as a population of CD4 T cells that produce IL-10 in response to stimulation. Unlike adaptive Tregs, Tr1 cells do not express FoxP3 and do not necessarily express CD25. Tr1 cells are produced in the respiratory tract when antigen exposure is coupled with IL-10 and TGF-β. Experimentally, Tr1 cells can be induced by repeated intranasal antigen delivery.[25] Respiratory tract infections with *Bordetella pertussis* have also been found to elicit Tr1 cells in vivo.[26] Tr1 cells function by producing IL-10 to block proliferation of naïve T cells, prevent Th1 differentiation by blocking IL-12 production, and enhance differentiation of T cells toward the Tr1 phenotype.

FOLLICULAR HELPER T CELLS

One of the earliest described roles of CD4 T cells is their ability to promote or "help" generate effective antibody production by B cells. Th1 and Th2 cells have the ability to promote B-cell class switching and effector responses. Evidence supports the role of a distinct subpopulation of T cells, known as *T-follicular helper* (Tfh) cells, as playing a key role in regulating T-cell–dependent B-cell responses. Tfh cells are identified by their surface expression of CXCR5, ICOS), PD-1, CD200, B- and T-lymphocyte attenuator (BTLA), OX40, and serum amyloid P (SAP), while lacking the expression of CD127 and CCR7.[27] Tfh cells also express the transcription factor BCL6, which is essential for their differentiation and function. Interestingly, BCL6 can be co-expressed with T-bet, GATA3, or RORγt, but BCL6 modifies many of their effector lineage functions. The fact that there is an incomplete separation between Tfh and other T-effector lineages might suggest that the Tfh phenotype is generated in parallel with T-effector cell differentiation and in response to inflammatory cues present in lymph nodes.

Tfh differentiation is promoted by signals through ICOS, OX-40, and the presence of IL-6, IL-12, and IL-21. Tfh cells upregulate CXCR5, which enables homing to the interface between the T-cell and B-cell areas of lymph nodes, where they interact with recently activated B cells. This interaction with activated B cells provides signals to the Tfh cell through ICOS and IL-6, while the Tfh cells provide CD40L and IL-21 to the

B cells. Through successive interactions with B cells, Tfh cells promote the survival, proliferation, Ig class switching, affinity maturation and differentiation of B cells into memory B cells, and antibody-producing plasma cells through the germinal center reaction.[28]

Mutations affecting Tfh-associated pathways have been identified in B-cell immunodeficiency disorders. Common variable immune deficiency (CVID; Chapter 33) is often linked to mutations in the ICOS pathway. Recurrent infections in patients with CVID are associated with hypogammaglobulinemia and reduced numbers of Tfh cells. X-linked lymphoproliferative disease type 1 (XLP1) has been associated with mutations in the *SH2D1A* gene. Interestingly, patients with XLP1 have defects in B-cell germinal center formation and decreased memory B-cell numbers, but have normal Tfh numbers. XLP1 Tfh cells have reduced ability to support B-cell function.[29] Tfh cells have been implicated in autoimmune diseases, such as myasthenia gravis, Graves disease, Hashimoto thyroiditis, lupus, Sjögren syndrome, and rheumatoid arthritis, where dysregulated antibody responses are thought to contribute to disease progression. In addition, therapies to target or passively transfer Tfh cells are being studied for treatment of autoimmune disease and some forms of lymphoma.[29]

MEMORY T CELLS

Following an immune response, small numbers of T cells persist over the long term and are called *memory T cells*. Memory T cells protect the host from reinfection by the same microorganisms. Protection correlates with the number of specific memory cells present in the host. Memory cells accelerate responses against repeat antigen for several reasons. First, memory cells are maintained at higher frequencies than are naïve cells. Second, a large portion of memory T cells are maintained in peripheral tissues, allowing for rapid local responses to infection. Third, memory T cells proliferate and produce cytokines in response to stimulation with lower doses of antigen, less costimulation, and much faster kinetics compared with naïve T cells. Fourth, memory cells can promote APC function and produce cytokines that promote the effector differentiation of naïve T cells.

Diverse populations of memory T cells can be defined by surface marker expression, localization, and patterns of migration. Two populations of memory T cells are identified on the basis of their re-expression of the lymph node homing receptors CCR7 and L-selectin following activation. Central memory (T_{cm}) cells are identified as $CD45RA^-$ $CD45RO^+$, $CCR7^+$, $CD62L^+$, and stem cell memory cells (T_{scm}) are identified by the markers $CD45RA^+$ $CD45RO^-$, $CCR7^+$, $CD62L^+$, $CD95^+$.[30] By expressing CCR7 and CD62L, these memory T cells permit recirculation through secondary lymphatic organs, allowing interactions with DCs from diverse tissue sites effectively expanding the area of immune surveillance. T_{cm} and T_{scm} produce IL-2 and rapidly enter the cell cycle upon activation. They are able to acquire effector phenotypes, suggesting that they function as a precursor pool for subsequent immune responses.

Two additional memory cell subsets have been described on the basis of their ability to migrate through peripheral tissues. Effector memory T cells (T_{em}) are identified by the expression pattern: $CD45RO^+$, $CCR7^-$, $CD62L^-$. These cells express chemokine receptors, selectins, and integrins facilitating their recirculation through peripheral tissues. T_{em} cells have previously undergone effector differentiation, and upon stimulation they rapidly express restricted cytokine patterns reflecting their prior phenotype. Additional populations of nonmigratory memory T cells have been identified. These are known as tissue resident memory T cells (T_{rm}). T_{rm} cells are identified by the markers $CD45RO^+$, $CCR7^-$, $CD69^+$. They have been identified in close proximity to epithelial sites in multiple tissues. T_{rm} cells provide rapid and highly localized cytokine production in response to infection. Thus T_{em} and T_{rm} cells bolster immunity by providing immune surveillance at distinct sites.[31]

The processes underlying memory T-cell differentiation are incompletely understood. A number of signaling pathways and APC populations have been proposed to be involved in memory differentiation. It is clear that T_{cm} and T_{em} cells are generated early in the T-cell response. The pathways that lead to the differentiation of Th1, Th2, Th17, and Tfh effector cells are also important in the generation of T_{em} populations.

GENERAL CONSIDERATIONS IN EFFECTOR T-CELL DIFFERENTIATION

Several key concepts of Th maturation should be noted with regard to the cellular differentiation of CD4 T cells. First and foremost, all T-effector, memory, and adaptive Tregs are thought to arise from naïve thymic emigrant precursors. In addition, T-cell phenotype specification is regulated independent of TCR specificity.

Second, differentiation to a specific effector phenotype is self-promoting and inhibitory to other phenotypes through production of effector cytokines (see Fig. 11.3). Early in Th1 or Th2 differentiation, for example, expression of the transcription factors T-bet or GATA3 promote pro-effector differentiation while suppressing alternative cell fates. Once established, T-cell phenotypes are maintained through active signaling and chromosomal modification.

Third, polarization is incomplete at the population level. Following exposure to antigen, responding T cells may collectively possess multiple phenotypes. Heterogeneity of Th phenotypes is a common feature of some diseases, such as asthma, where Th2, Th9, and Th17 responses are thought to contribute to disease; in psoriasis, where Th1, Th17, and Th22 cell types are detectable; and in MS, where Th1, Th17, and Th22 cells are thought to mediate inflammation. A portion of the T cells may persist in a naïve phenotype or as uncommitted T_{cm} or T_{scm}. These cells retain features of stem cells in that they may give rise to T cells of diverse phenotype upon antigen re-exposure.

Fourth, there is limited plasticity in T-cell effector phenotypes. Effector phenotypes are reinforced by "master" transcription factors and epigenetic modifications (Fig. 11.4). For example, established Th1 cells do not express Th2 cytokines despite extended culture in Th2-skewing conditions. There is, however, growing evidence of interconversion between certain T-helper subsets.[32] Experiments tracing T-cell lineage commitment have shown that T cells that once expressed FoxP3 could become effector cells. It is not clear if plasticity occurs between all phenotypes or if phenotype conversion can occur at any stage of phenotype commitment (see Fig. 11.4).

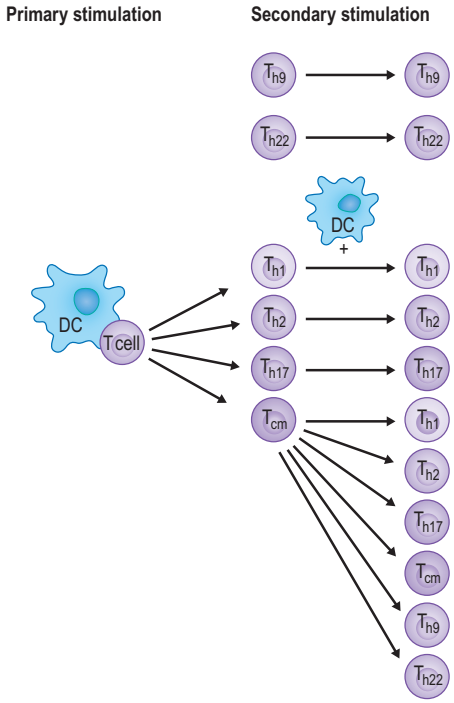

FIG. 11.4 Mechanism of T-Helper Phenotype Shift. Under appropriate conditions, T-cell activation may result in daughter cells adopting one of several T-effector phenotypes. Within a polarized population of Th cells, a subset of undifferentiated T lymphocytes may exist (here referred to in the general category as T central memory *[T_{cm}]*). Fully committed Th1, Th2, or Th17 cells upon restimulation will produce Th1, Th2, or Th17, respectively. T_{cm} or other uncommitted cell types retain the potential to differentiate into T effectors of any phenotype, depending on the context of the secondary stimulation. *DC*, Dendritic cells.

TERMINATION OF T-CELL RESPONSES

CLINICAL RELEVANCE

Diseases Associated With CD4 T-Effector Responses

Th1
- Multiple sclerosis
- Psoriasis
- Type 1 diabetes mellitus
- Tuberculoid leprosy
- Transplant rejection

Th2
- Allergy and asthma
- Helminthic infections
- Lepromatous leprosy

Th9
- Asthma
- Helminthic infections

Th17
- Asthma
- Multiple sclerosis
- Psoriasis
- Rheumatoid arthritis
- Transplant rejection

Th22
- Psoriasis
- Wound healing

As a result of the potential for unregulated inflammation, retention of activated effector T cells presents three risks to the organism. First, with each succeeding infection, the body would be increasingly burdened by the energy requirements of maintaining larger T-cell numbers. Second, there would be loss of TCR diversity resulting from the overrepresentation of clonally expanded T cells. Third, there is an increased risk of damage to self by large populations of activated effector T cells. Thus a return to homeostasis is required at the end of an immune response through reductions in T-cell numbers and activity. Homeostasis is restored through the loss of the initiating stimulus and by active control processes, including cell death, inhibitory signaling pathways, and anti-inflammatory cytokines.

CELL DEATH PATHWAYS IN T-CELL HOMEOSTASIS

Several cell death pathways regulate the processes of activation-induced cell death (AICD; Chapter 17). The primary pathway involved in AICD involves Fas (CD95) and Fas ligand (FasL, CD95L). Fas and FasL are expressed following T-cell activation. Fas-mediated apoptosis can be stimulated by FasL on neighboring cells ("death signal") or on the same cell ("suicide signal"). Mutations in Fas and FasL result in the accumulation of activated lymphocytes and autoimmunity. Another TNF family member, TRAIL, has also been associated with AICD. Mice lacking TRAIL have enhanced susceptibility to autoimmune disease. Some evidence suggests that TRAIL regulates AICD primarily in Th2 cells.[33]

ACTION OF INHIBITORY RECEPTORS

T cells express several Ig family transmembrane proteins containing immune tyrosine inhibitory motifs (ITIMs). Two of these, CTLA4 and PD-1, play important roles in terminating T-cell responses in vivo. CTLA4 is expressed by T cells following activation and regulates T-cell activity in two ways. First, CTLA4 binds to B7 with high affinity and competes with CD28 costimulation. Second, CTLA4 inhibits proximal TCR signaling by recruiting the phosphatases SHP-2 and PP2A. Mice deficient in CTLA4 develop a severe CD28-dependent lymphoproliferative disease, tissue infiltration, and early death.[34] PD-1 interacts with two ligands, PD-L1 and PD-L2, which are differentially expressed in immune and peripheral tissues. PD-1 engagement limits proximal TCR signals by recruiting SHP-2, thereby suppressing activation, cytokine production, and proliferation. Loss of PD-1 has been associated with autoimmune cardiomyopathy, arthritis, and a lupus-like glomerulonephritis.[35] Therapeutic disruption of CTLA-4 and PD-1 signals are exploited as checkpoint inhibitors for treatment of certain cancers.

CYTOKINE-MEDIATED INHIBITION

Cytokines function to terminate immune responses in three basic ways: (i) by loss or withdrawal of growth factors, (ii) by inducing cell death, and (iii) by direct anti-inflammatory properties (Chapter 14). IL-2 functions as a growth factor in early immune responses. Loss of IL-2 signals through decreased production or loss of receptor expression deprives the cell of survival signals, resulting in AICD. Similarly, loss of IL-7 or IL-7 receptor results in increased apoptosis among naive and memory T-cell populations.[36] As discussed in Chapter 17, cell death by growth factor withdrawal results from activation of the mitochondrial pathway of apoptosis.

Cytokines can suppress T-cell responses. This function of cytokines is exemplified by IL-10, IL-27, TGF-β, and TNF. IL-10

is produced by adaptive Tregs and Tr1 cells, as well as B cells, monocytes, and macrophages. IL-10 suppresses inflammation by inhibiting macrophage activation, downregulating chemokine production, and suppressing costimulatory molecule expression by APCs. IL-10–deficient mice develop inflammatory bowel disease caused by dysregulated Th1 responses. Mice genetically deficient for the IL-27 receptor develop exaggerated CD4 T-cell responses and inflammatory diseases. These effects of IL-27 can be attributed to its role in suppressing Th1 responses and CD4 T-cell proliferation.[37] TGF-β_1 is another anti-inflammatory cytokine that is produced by subsets of Tregs and a variety of other cell types throughout the body. Unlike IL-10, which targets APCs, TGF-β_1 directly inhibits T-cell proliferation and Th1 differentiation.[38] Mice deficient in TGF-β_1 have multi-tissue infiltration by activated lymphocytes and macrophages. TNF is well characterized as possessing proapoptotic function. TNFR1 possesses a death domain, and binding of TNF results in the activation of the caspase pathway and apoptosis.

SUMMARY OF THERAPEUTIC REGULATION OF T-CELL RESPONSES FOR TREATMENT OF IMMUNE-MEDIATED DISEASES

T-cell–mediated inflammation is central to immune-mediated diseases. The most effective techniques to control inflammation are aimed at the processes of T-cell activation, differentiation, trafficking, or effector functions (Fig. 11.5). Among many potential approaches currently being employed or in development are the following: (i) blockade of appropriate costimulatory signals or intracellular signaling molecules to prevent T-cell activation (*i.e.*, FK504) or to promote ongoing effector inflammatory responses (*i.e.*, anti-PD-L1); (ii) preventing recruitment of effector T cells into inflammatory sites by targeting pathways required for cellular recruitment (i.e., VLA-4); (iii) neutralizing the cytokines that promote T-effector differentiation (e.g., IL-6, IL-12, or IL-23); (iv) blocking proinflammatory cytokines (*e.g.*, IFN-γ, IL-17, GM-CSF, or TNF) and other effector molecules (e.g., iNOS, reactive oxygen intermediates, etc.) involved in the effector limb of destructive inflammatory processes; (v) the use of regulatory cytokines, such as TGF-β, IL-4, or IL-10 to regulate proinflammatory responses; and (vi) in vivo induction of Treg activity using tolerance strategies or ex vivo expansion and administration of protective or regulatory T-cell subsets.

ON THE HORIZON

- Development of effective techniques to identify antigens targeted in organ-specific autoimmune and allergic diseases and in transplant rejection
- Development and implementation of an effective tolerance-inducing strategy capable of regulating T-cell responses in an antigen-specific manner
- Identification of tolerance-specific biomarkers or assays to clearly delineate successful therapy of inflammatory diseases

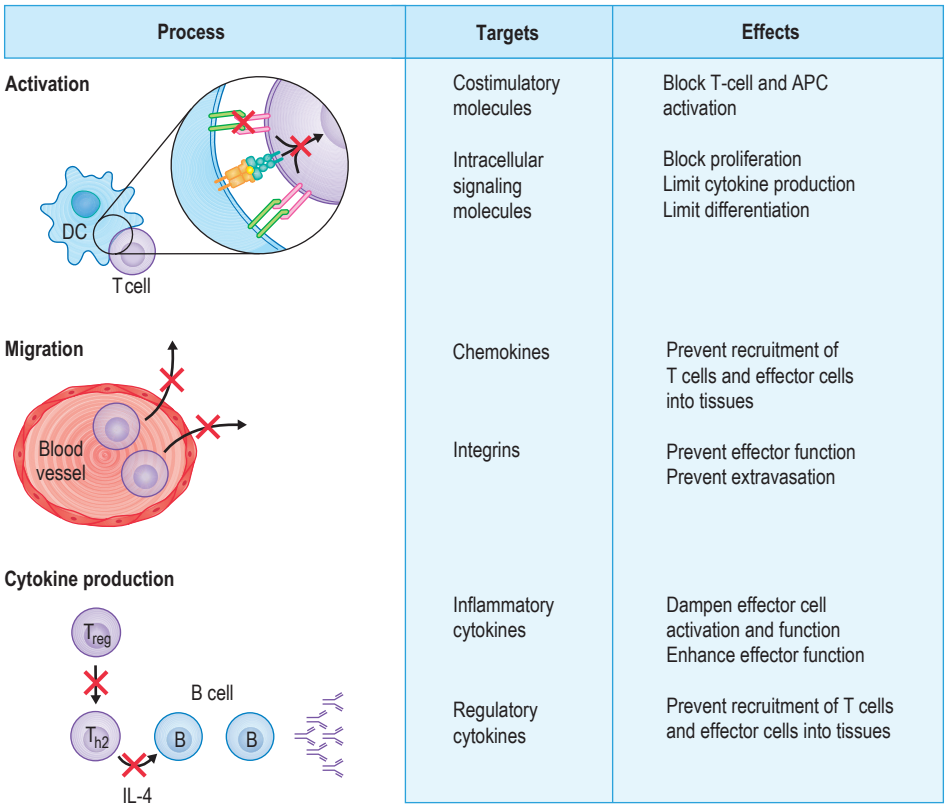

FIG. 11.5 Therapeutic Regulation of Inflammation. Several techniques have been employed to reduce T-cell responses in cases of inflammation. Among these are inhibiting T-cell activation and differentiation by blocking costimulatory interactions with antigen-presenting cells *(APCs) (top)*; inhibiting T-cell and effector-cell trafficking by blocking molecules required for chemotaxis *(middle)*; and limiting the effect of T-helper responses by decreasing the availability of inflammatory cytokines *(bottom)*. *DC*, Dendritic cells; *IL*, interleukin; *Treg*, regulatory T cells.

Cytotoxic T Lymphocytes and Natural Killer Cells

Stephen L. Nutt and Nicholas D. Huntington

Cytotoxic T lymphocytes (CTLs) and natural killer (NK) cells represent two distinct but functionally related lineages that contribute to pathogen and tumor immunity. Although the approaches by which CTLs and NK cells kill their target cells and produce immunomodulatory cytokines are quite similar, the mechanisms by which they recognize their targets are distinctly different. CTLs are CD8 T cells (Chapter 9) that recognize targets via the interaction of a diverse repertoire of polyclonally rearranged T-cell receptors (TCRs) (Chapter 4) with a peptide–major histocompatibility complex (MHC) class I complex (Chapter 6) and are components of the adaptive immune response. MHC class I molecules are expressed on virtually all cells in the body and allow CTLs to scan the tissues for cells expressing foreign or cancer-associated peptides. In contrast, NK cells are members of the innate immune system (Chapter 3) and use an array of invariant activating and inhibitory receptors to control their activity and specificity.[1] These fundamentally distinct approaches to the recognition of antigen allow for complementary functions, with CTLs being specialized in detecting cancerous cells or those infected with intracellular pathogens, such as viruses, whereas a prominent function of NK cells is to eliminate those cells where a pathogen or oncogene has impaired MHC class I expression and/or has induced the expression of stress ligands. As one of the principal immune-evasion mechanisms of viruses and tumors is suppression of MHC class I expression, NK cells provide a key line of defense against this strategy.

CLINICAL RELEVANCE

Functions of Cytotoxic T Lymphocytes and/or Natural Killer Cells

Protective functions include:
- Host defense against:
  - Viruses, including human immunodeficiency virus (HIV), Epstein–Barr virus (EBV), pox virus, herpes simplex virus (HSV), and cytomegalovirus (CMV)
  - Bacteria, including *Listeria monocytogenes*
  - Parasites, including *Plasmodium falciparum* and *Toxoplasma gondii*
  - Primary and metastatic tumors
- Positive regulation of:
  - Graft-*versus*-leukemia (GvL) effect
  - Tumor inflammation by tumor-resident natural killer (NK) cells
  - Placental vascularization by uterine NK cells

Uncontrolled cytotoxicity contributes to:
- Some autoimmune disease, including diabetes and rheumatoid arthritis
- Hypersensitivity reactions
- Graft-versus-host disease (GvHD)
- Transplant rejection

The importance of the lytic function of CTLs and NK cells has been demonstrated in animal models as well as in patients with defective cytotoxicity. A number of recessive genetic syndromes that affect cytotoxic function have been reported, including familial hemophagocytic lymphohistiocytosis (FHL), which results from mutations in the perforin gene.[2] Patients with FHL present with severe immunodeficiency that is often associated with uncontrolled viral infections, including cytomegalovirus (CMV), herpes simplex virus (HSV), and Epstein–Barr virus (EBV) infections. Similarly, mice lacking CTLs and NK cells are overtly susceptible to viral pathogens and display impaired immunosurveillance.[2]

With its potent ability to control pathogen-infected and malignant cells, it is not surprising that modulation of cytolytic activity is an aim of many immunotherapies. These strategies involve either dampening of CTL function in such situations as transplantation or autoimmunity or enhancement of CTL and NK-cell function via vaccination, blocking antibodies to inhibitory receptors, adoptive cell transfer, or cytokine therapy. Tight controls need to be maintained over these effector cells, as deregulated CTL activity can promote autoimmune diseases, hypersensitivity reactions, graft-versus-host disease (GvHD), and transplant rejection. To maintain the discrimination between killing damaged or infected cells and not killing healthy neighboring cells, numerous layers of regulation operate to control cytotoxic functions.

EFFECTOR FUNCTIONS/MECHANISMS

KEY CONCEPTS

Cytotoxic T-Lymphocyte and/or Natural Killer Cell Effector Mechanisms

Cytotoxicity
- Killing by the perforin/granzyme pathway
- Death receptor–mediated apoptosis, including Fas and tumor necrosis factor (TNF)–related apoptosis–inducing ligand (TRAIL)

Immune modulation
- Inflammatory cytokine production, including interferon (IFN)-γ and TNF
- Chemokine secretion
- Immunomodulatory cytokines, including interleukin-10 (IL-10), transforming growth factor-β (TGF-β), and granulocyte macrophage–colony-stimulating factor (GM-CSF)

Cytotoxicity

Cytotoxic cells kill their targets via two major pathways: perforin/granzyme–mediated lysis and death receptor–induced apoptosis. Both require intimate contact between the lytic cell and its target (Fig. 12.1).[3] Although the processes are similar

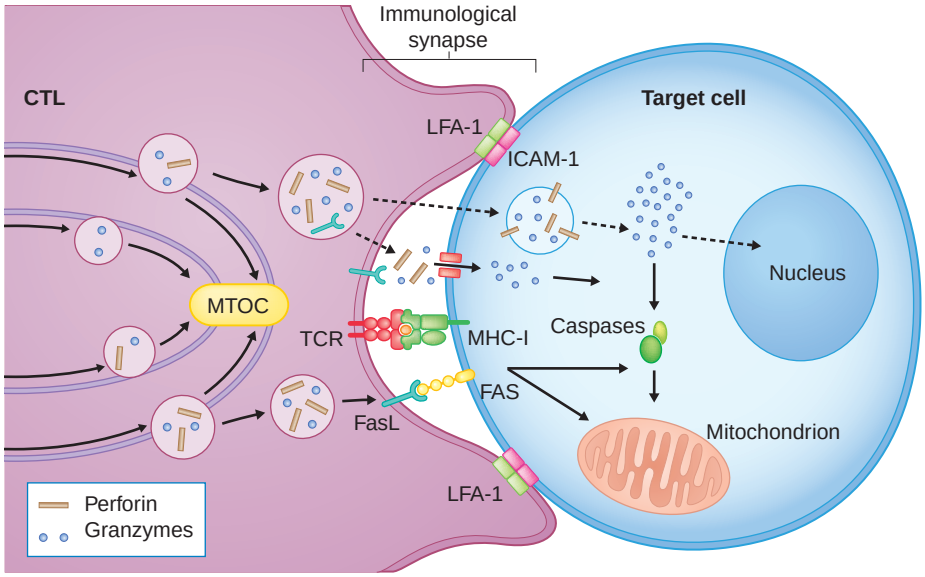

FIG. 12.1 Mechanisms of Cytotoxic T-Lymphocyte *(CTL)*–Induced Cell Death. The CTL recognizes its target via the interaction of the T-cell receptor *(TCR)* and the peptide–major histocompatibility complex class I *(MHC-I)* complex on the target cell. TCR signaling induces the formation of an immunological synapse that is stabilized by the binding of leukocyte function–associated antigen-1 *(LFA-1)* to the intercellular adhesion molecule *(ICAM)* on the target cell. Lytic granules containing perforin, granzymes, and FasL are polarized along microtubules and move toward the microtubule-organizing center *(MTOC)*. Lytic granules are then secreted into the synapse, allowing perforin to form pores in the target cell membrane, which facilitates granzyme access to the target cells. Granzymes induce apoptosis by caspase-dependent and independent pathways that result in DNA cleavage and mitochondrial damage. Membrane-bound FasL can bind to its receptor on target cells and induce apoptosis through an independent pathway. *FasL*, Fas ligand.

for CTLs and NK cells, CTL lytic activity is acquired only after activation and differentiation, whereas NK cells can spontaneously kill target cells. Despite this, NK-cell killing is significantly increased through prior activation by cytokines or inflammatory signals. Both cell types also produce cytokines that further enhance the immune response, most notably interferon-γ (IFN-γ).

Perforin–Granzyme Pathway

Perforin is a membrane-disrupting protein, which, together with a family of serine proteases (granzymes), forms the bulk of lytic granules. The process of lysis has been most extensively studied in CTLs, where, upon interaction between the TCR and an appropriate MHC class I peptide, a synaptic complex forms between the CTL and its target.[3] Lytic granules can then be observed moving along a microtubule network toward the microtubule-organizing center that localizes at the synapse (see Fig. 12.1). This process allows the polarized secretion of lytic granules precisely at the CTL–target cell interface. Perforin forms a pore that disrupts the target cell membrane, including either the plasma membrane or the lysosomal membrane. Once inside the target cell, it is granzymes that are the initiators of cell death. Granzymes function directly by cleaving substrates, such as nuclear proteins and DNA, or indirectly via initiating a protease cascade. One substrate of granzymes is the proapoptotic protein BID (BH3-interacting domain death agonist), which induces cell death via mitochondrial mediators, such as cytochrome c.

Death Receptor–Induced Apoptosis

Cytotoxic cells also have a receptor-based system to induce apoptosis of target cells (Chapter 17). This pathway uses members of the tumor necrosis factor receptor (TNFR) superfamily that are expressed on the target cells. These receptors have an intracellular signaling motif, called the *death domain*, which recruits molecules that transduce the death signal, such as FADD (Fas-associated death domain). The two most prominent apoptosis-inducing TNFR family members are Fas (CD95) and TRAIL (TNF-related apoptosis–inducing ligand).[4] Fas is expressed on a wide variety of tissues, whereas Fas ligand (FasL) expression is restricted to activated CTLs and NK cells, where it is stored in lytic granules and, upon activation, released to the effector cell membrane. The Fas/FasL pathway is important in controlling T-cell numbers through activation-induced cell death, as well as in the rejection of some tumors. Cytotoxic cells also express TRAIL, which, upon binding to TRAIL receptors, induces apoptosis in a wider selection of targets.[4] Of particular therapeutic interest is the fact that a subset of tumor cells are exquisitely sensitive to TRAIL. While each CTL can kill hundreds of tumor cells, most NK cells have the ability to kill <10 tumor cells before their cytotoxicity is lost. A small subpopulation of NK cells are capable of substantial serial killing (>30 tumor cells), primarily through the secretion of TNF superfamily ligands including TRAIL.[5]

Cytokines

Antigen-stimulated CTLs and activated NK cells modulate the immune response by their ability to produce a variety of cytokines, most notably IFN-γ and TNF. These potent inflammatory cytokines activate macrophages, dendritic cells (DCs), and lymphocytes at the site of infection. IFN-γ helps establish a T-helper cell-1 (Th1) response (Chapter 11) and further stimulates differentiated CTLs. NK cells are also a potent source of a diverse

range of cytokines, including GM-CSF, interleukin (IL)-10, and IL-13 (Chapter 14). The capacity to secrete a broad spectrum of cytokines provides NK cells with a wide range of regulatory capabilities. CTLs and NK cells are capable of secreting a number of chemokines (Chapter 15), including chemokine ligand 3 (CCL3), CCL4, and CCL5. These chemokines help recruit additional immune cells such as other lymphocytes and DCs to the response.

CYTOTOXIC T CELLS

Development and Tissue Distribution of Cytotoxic T Lymphocytes

CD8 T lymphocytes develop in the thymus, where they are selected for their ability to recognize nonself peptides in the context of MHC class I molecules (Chapter 9). Upon thymic export, these cells acquire a quiescent state and are referred to as *naïve*. Naïve CD8 T cells circulate between peripheral lymphoid organs, such as the spleen and lymph nodes, via the arterial and lymphatic systems. The tissue distribution of lymphocytes is determined by targeting proteins, which can be divided into three categories: selectins, chemokine receptors, and integrins.[6] Naïve and activated CD8 T cells display distinct sets of these targeting proteins, allowing for the differential homing abilities of these cells (Chapter 16). Naïve CD8 T cells express high levels of the lymph node homing receptor L-selectin (CD62L) and CCR7, a chemokine receptor that recognizes CCL19 and CCL21, which are produced in the T-cell areas of secondary lymphoid organs (Table 12.1; Chapter 2).[6] Here, naïve T cells interact with antigen-presenting cells (APCs). If a naïve CD8 T cell does not encounter its specific antigen, it leaves the lymph node.[6] If, however, a CD8 T cell encounters the correctly presented peptide–MHC I complex, a dramatic change in its localization and homing properties ensues. These cells shut down their egress program and undergo multiple rounds of proliferation to become activated CTLs. After the proliferative phase, the CTLs then reacquire egress capacity and travel via the circulation to nonlymphoid sites, where they tether to endothelial cells and extravasate into tissue. This transmigration occurs in both inflamed and noninflamed sites, such as skin, the gut, or the lung. Many of the effector memory CTLs are retained in nonlymphoid tissues, where they are poised to respond rapidly should the antigen be encountered again. The distinct types of memory T cells are discussed below.

THE CYTOTOXIC T-LYMPHOCYTE RESPONSE

The CTL response to an acute infection consists of three phases: first, the initial activation and proliferation of the CTL; second, the contraction of effector populations; and third, the long-term maintenance of memory cells.

Initial Activation

Naïve T cells constantly circulate through secondary lymphoid organs, where antigen encounter occurs. For a CTL response, antigen is brought to the lymph node via the lymphatic system by APCs (Fig. 12.2). These APCs are typically DCs that mature after antigen acquisition in nonlymphoid tissues and migrate to the lymph node. These antigens are recognized only when complexed to MHC molecules. APCs efficiently degrade self or foreign (pathogen-derived) proteins into shorter fragments (generally 8 to 10 amino acids in length) by the action of proteases in the cytosol. They are then transported into the lumen of the endoplasmic reticulum, where they are loaded onto newly synthesized MHC class I molecules for presentation at the cell surface (Chapter 6). This then enables the APCs to communicate with the antigen-specific CD8 T cells via interactions between the TCR and MHC molecules.

In the lymph node, CTLs scan the APCs for the presence of antigenic peptides complexed with the MHC class I molecules, a process termed *immune surveillance*. In the absence of a specific recognition by the TCR, the encounter is only transient, and the T cell continues on to another APC to repeat the process. If the MHC class I–peptide complex is bound by the TCR and initiates signaling, a more lasting interaction occurs.

TCR activation promotes polarization of the T cell and formation of the "immunological synapse."[3] The immunological synapse is a highly structured body that functions to concentrate TCR signaling in a defined area. It is associated with the selective recruitment of signaling molecules and exclusion of negative regulators. The synapse is stabilized by a ring of adhesion molecules, including, for example, LFA-1, which binds to ICAM1 on the APC (see Fig. 12.1). For a T cell to become fully active, costimulation through a second signaling pathway is required.[3] Many costimulators that have been identified share the common characteristic of being transmembrane receptors, often of the TNFR superfamily, that bind transmembrane ligands on the APC. The most important costimulator, CD28, binds the ligands CD80 and CD86, on activated APCs. Costimulation

TABLE 12.1 Properties of Cytotoxic T-Lymphocyte Populations

CTL, Cytotoxic T lymphocyte.

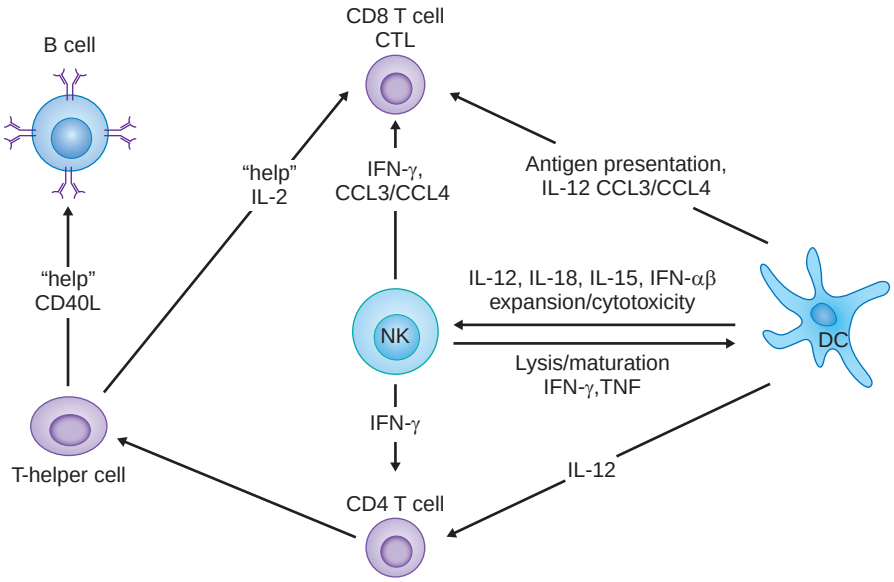

FIG. 12.2 Cellular Interactions During an Immune Response in the Lymph Node. After their encounter with antigen, dendritic cells *(DCs)* move to the draining lymph node, where they initiate an antigen-specific immune response. In the very early stages, natural killer *(NK)* cells are recruited to the lymph node and modulate various aspects of this response. NK cells provide cytokines that induce the maturation of DCs, which enables these cells to efficiently present the antigen to T cells in the context of costimulatory signals. NK cells also have the ability to eliminate immature DCs and to provide "early" interferon *(IFN)*-β for the initiation of a T-helper 1 (Th1)-type CD4 T-cell response. Finally, NK cells produce a range of chemokines, most notably chemokine ligand 3 *(CCL3)*/*CCL4*, which are crucial for the recruitment of CD8 T cells into the immune response. *CTL*, Cytotoxic T lymphocyte; *TNF*, tumor necrosis factor.

results in the clonal expansion of CTLs with the selected antigen specificity. The expression of CD80/86 occurs only after an APC receives activation signals, such as inflammatory cytokines, or components of the pathogens such as bacterial lipopolysaccharide. Naïve T cells that receive TCR stimulation in the absence of costimulatory signals can become nonresponsive to antigen, a state termed *anergy*.

Cross-Presentation and Priming

After it was established that only direct interaction with an APC and appropriate costimulation led to full CTL activity, a problem arose in explaining the mechanism by which antigens in non-APCs were recognized by CTLs. This dilemma was resolved by the discovery that there are two distinct mechanisms by which CTLs encounter peptide–MHC class I complexes.[7] If the APC expresses the antigen—for example, if a virus infects it—then the APC can process the antigen via the endogenous MHC class I pathway for presentation. The more intriguing situation arises when the APC does not express the antigen. In this case, the APC acquires and assimilates the antigen via a process termed *cross-presentation* (Chapter 6).[7] Cross-presentation is initiated by the capture of foreign or exogenous antigens by phagosomes. The antigens are then processed by an unusual mechanism that directs the peptides to the MHC class I pathway and presentation on the cell surface. An encounter of a CTL with an antigen processed in this pathway is termed *cross-priming*.[7] DCs can also acquire preformed peptide–MHC complexes from the plasma membrane through a process called *trogocytosis*. This mechanism acts to significantly amplify the magnitude of priming of T cells, and, like cross-presentation, potentially circumvents immune evasion strategies used by pathogens.[7]

Contraction of Effector Populations

After activation of CTLs in secondary lymphoid organs, an immune response is characterized by the rapid proliferation of antigen-specific cells and their acquisition of effector functions. CTLs proliferate at one of the fastest rates known for mammalian cells, with a cell cycle time of approximately 6 hours. Infection leads to a dramatic increase in the numbers of pathogen-specific CTLs, from almost undetectable initial levels to several million cells in the course of a single week. The expansion phase is followed by a contraction of the CTL population that is independent of both the magnitude of the response and clearance of the antigen. This phase is essential to prevent nonspecific tissue damage through uncontrolled cytokine release and cytolytic activity. Contraction also preserves the flexibility of the T-cell response to new infections while memory of previously encountered antigens is maintained. Typically, less than 5% of the expanded antigen-specific population survives in the long-lived memory pool.

Maintenance of Memory Cells

The production of long-lasting memory cells is essential for a rapid response should reinfection occur. CTL memory provides a more vigorous response than the primary challenge for both quantitative and qualitative reasons.[8] Quantitatively, because of the substantial clonal expansion during a primary infection, the precursor frequency of antigen-specific CTLs is vastly higher in immune individuals than in naïve subjects, thus allowing for a stronger response. Qualitatively, memory CTLs exhibit striking efficiency in elaborating the effector functions associated with the rapid production of IFN-γ. This enhanced response is the result of reprogramming of gene expression profiles by epigenetic changes in DNA methylation or chromatin structure.

The CTL memory compartment is composed of three cell types: effector memory (T_{EM}) cells, central memory (T_{CM}) cells, and tissue-resident memory (T_{RM}) cells. These subsets differ in their surface molecule expression and in their ability to exhibit effector functions (see Table 12.1). Like their naïve counterparts, T_{CM} cells express high levels of CD62L and CCR7 and reside primarily in secondary lymphoid organs. T_{CM} cells are capable of prolonged homeostatic self-renewal in the absence of antigen. T_{EM} cells, in contrast, are characterized by low expression of CD62L and CCR7 and are distributed throughout the body, including peripheral tissues, such as the lung and the gut, where they can immediately confront invading pathogens. T_{RM} cells are the most recently identified memory population that resides in peripheral tissues long after an infection is cleared, providing potent early response to reinfection of the same tissue.[6] CD4 T-cell help and cytokines, including IL-15 and IL-7 and their receptors, have been identified as crucial for the survival and maintenance of the memory T-cell pool.[6,8]

CD4 T-CELL HELP

The final player in the initial activation of CTLs is the "help" provided by CD4 T cells specific for an antigen linked to the CTL epitope (Chapter 11). The processes by which help is provided are poorly understood. It is likely that cytokines, such as IL-2 and IL-21, are involved and that the CD4 T cells influence both DCs and CTLs.[9,10] The cytokines, provided by the CD4 T cells, promote the survival, proliferation, and programming of memory CTLs. CD4 T-cell–deficient mice have been developed to study these CTL responses. Interestingly, "helpless" CD8 T cells resemble CTLs in chronic infections and cancer, in which the targets are not cleared despite a robust CTL response. PD-1 (*p*rogrammed *d*eath 1), an inhibitory receptor, is expressed on both helpless CTLs and on CTL cells during chronic infection and cancer. Blocking the interaction of PD-1 with its ligands greatly enhances the numbers and functions of impaired CTLs, a finding that is the basis for many current immunotherapy regimes in clinical oncology.[11,12]

DETECTION AND ANALYSIS OF CYTOTOXIC T-LYMPHOCYTE FUNCTION

Much progress in our understanding of the generation of CTLs in an immune response has resulted from the development of accurate and sensitive assays for CTL function. Traditional CTL assays were performed on bulk populations of effector cells. In these assays, target cells are labeled with ^{51}Cr or a nonradioactive dye, and then pulsed with peptide-antigen. Peptide-specific CTLs are incubated with the target cells. Lytic activity is then measured by the release of label into the culture supernatant or the loss of target cell viability directly. Although such an approach provides a powerful quantitative assay for CTL activity, it has the disadvantage of requiring prestimulation of the CTL population for 1 to 2 weeks to expand the numbers of antigen-specific CTLs to detectable levels. In mouse models, this limitation was overcome by the development of mouse strains that express a single transgenic TCR that recognizes either MHC class I (CD8)– or MHC class II (CD4)–specific epitopes. Such T cells, which are specific for a single peptide, have proven extremely useful in the study of CTL responses, as antigen-specific cells can be easily detected.

TCR transgenic mouse models do, however, have limitations, as they do not recapitulate the diversity of the normal immune response, and so represent an approach that cannot be broadly used in human studies, although human adoptive T-cell therapy using chimeric antigen receptors (CARs; a form of transgenic TCR) against an antigen specific to B cells has been successfully used to treat some lymphomas (Chapter 81).[13] The development of labeled MHC class I–peptide complexes that bind to the endogenous TCR has made a major contribution to overcoming these previous limitations, as it allows for the detection of rare antigen-specific CTLs within a polyclonal population from patient material or animal tissue.[14] This technique is simple and broadly applicable (Fig. 12.3). The ability to identify antigen-specific CTLs has been combined with single-cell functional assays, such as ELISpot or intracellular cytokine assays.

NATURAL KILLER CELLS

Properties of Natural Killer Cells

NK cells were the founding member of the innate lymphoid cell (ILC) family, which, in contrast to B and T cells, lack somatic antigen–receptor rearrangements. NK cells develop in bone marrow from a common ILC progenitor.[15] IL-15 is essential for most aspects of NK-cell biology, including differentiation, survival, proliferation, and activation in vivo. The IL-15R consists of three components: the IL-2/15β chain (CD122), a unique IL-15Rα chain, and the common γ chain, which contains the intracellular signaling component of the receptor.[16] The importance of this receptor complex is emphasized by the lack of NK cells in patients with X-linked severe combined immunodeficiency (SCID) that have mutations in the common γ-chain gene. The IL-15/IL-15R complex does not function like other cytokines that are produced as soluble ligands and bind to their receptor in a paracrine or autocrine manner. IL-15 is virtually undetectable in body fluids or cell culture supernatants, despite the broad distribution of its mRNA. The solution to this paradoxical observation is that IL-15 function requires the presence of IL-15Rα in the same cell. The IL-15/IL-15Rα complex is then presented on the cell surface in *trans* to the NK cell expressing the IL-15Rβγ complex.[16] In this manner, IL-15 maintains the homeostatic frequency of NK cells in the body. Once NK cells have acquired IL-15 responsiveness in bone marrow, they proceed through an ordered differentiation process that results in an expansion phase and the acquisition of a panel of germline-encoded activating and inhibitory receptors (Table 12.2).[1] It was previously assumed that these bone marrow–derived NK cells were fully functional, but more recent data suggest that multiple mature NK-cell subsets exist, with varying levels of effector function.[15]

Tissue Distribution and Diversity of Natural Killer Cells

In line with their surveillance function, NK cells are found at many sites in the body, including bone marrow, peripheral blood, lymph nodes and the spleen. The broad range of tissue distribution suggests that there is diversity in the function of mature NK cells. Furthermore, NK cells are also found in nonlymphoid organs, such as the liver and small intestine, and in the decidual lining of the uterus along with a closely related innate lymphocyte population, named *group 1 innate lymphoid cells* (ILC1; Chapter 2), which likely have a role distinct from that of NK cells in

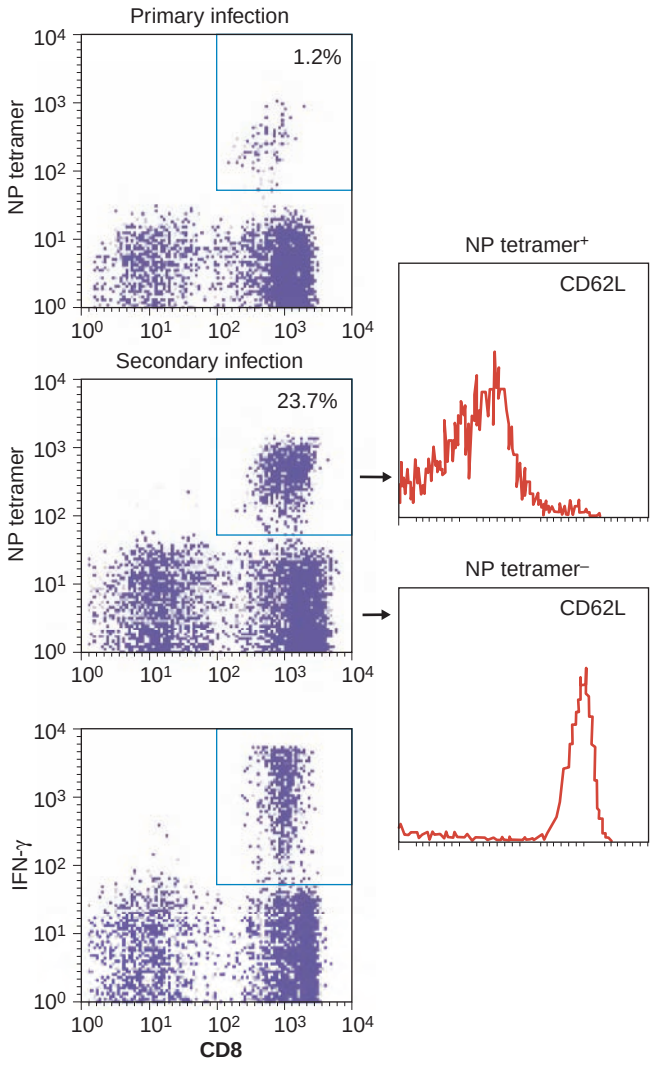

FIG. 12.3 Monitoring a Virus-Specific Cytotoxic T-Lymphocyte (CTL) Response. A fluorescent-labeled tetramer complex comprising a major histocompatibility complex (MHC) class I molecule and a virus-specific nucleoprotein *(NP)* antigen peptide is used to detect NP-specific CD8 T cells in the spleens of mice infected with influenza virus. During the primary response, virus-specific CTLs expand in the draining lymph node of the lung and later exit to the lung and spleen *(upper left)*. After the infection is resolved, a small population of virus-specific memory CTL resides in the spleen. A second infection with influenza results in very high numbers of virus-specific CTLs in the spleen *(middle left)* and the lung. Specific CTLs can be re-stimulated with the NP peptide in vitro, inducing interferon *(IFN)-β* secretion that is detected by intracellular staining with a labeled anti-IFN-β antibody *(lower left)*. Staining with an antibody to CD62L shows the typical profile of effector CD8 T cells in the NP-tetramer–positive CTLs *(upper right)* and of naïve CD8 T cells in the tetramer-negative population *(lower right)*.

host defense. Human NK cells can be divided into subsets based on the expression of CD16 (FcγRIII) and the adhesion molecule CD56 (Fig. 12.4).[17] CD56^{dim} NK cells represent around 90% of peripheral blood NK cells, are CD16^{+}KIR^{+}, and display greater cytotoxicity, especially amongst the CD57^{+} subset. In contrast, their less mature counterparts, CD56^{bright} NK cells, show greater proliferative potential and cytokine production and are the principal NK cell population in secondary lymphoid organs. NK cell progenitors can be found in cord blood and lymph nodes and develop into CD56^{dim} cells via CD56^{bright} intermediaries; this differentiation is also dependent on IL-15.[17] One important limitation in understanding the functional role played by NK-cell subsets has been the inability to identify populations corresponding to the CD56^{bright} and CD56^{dim} populations in rodents, as this molecule is not expressed in mouse NK cells. NK-cell heterogeneity, based on the differential expression of CD11b and CD27, has been dissected in mice. Developing NK cells in bone marrow are CD27^{+}CD11b^{dim}, whereas

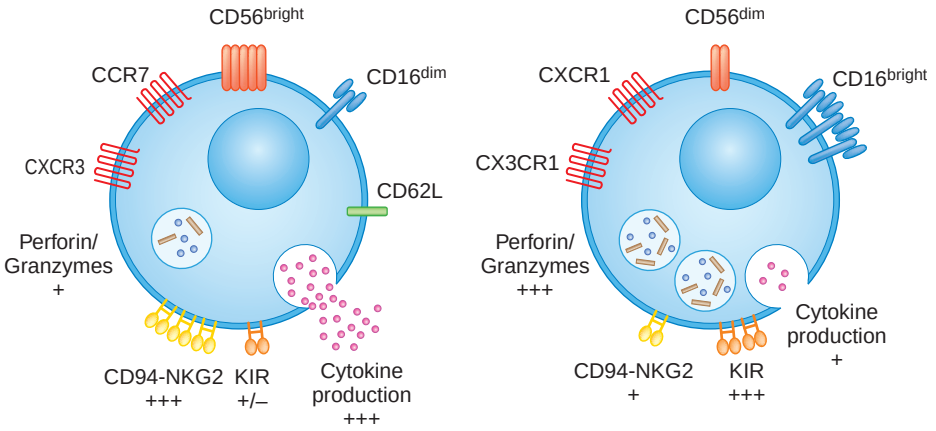

FIG. 12.4 Schematic Representation of Human Natural Killer (NK) Cells. The human NK-cell subsets show distinct receptor expression and effector functions. $CD56^{bright}$ NK cells produce high levels of cytokines and have patterns of chemokine and homing receptor expression that distinguish them from $CD56^{dim}$ NK cells. $CD56^{dim}$ NK cells express high levels of killer immunoglobulin-like receptor *(KIR)* and cytotoxic activity. The relative level of receptors and effector molecules is indicated on an arbitrary scale, with +/– being weak and +++ being strong expression.

these cells differentiate into $CD27^{+}CD11b^{bright}$ and $CD27^{-}CD11b^{bright}$ stages in the spleen. Interestingly, $CD27^{+}$ cells are found in lymph nodes, whereas the $CD27^{-}$ NK cells are localized predominantly in peripheral blood and the lung.[15] Comparative studies of the transcriptomes of human and mouse NK cells have confirmed the similarities between the human and mouse subsets (human $CD56^{bright}$ NK cells correspond to mouse $CD27^{+}$ NK cells, whereas human $CD56^{dim}$ NK cells are the equivalent of mouse $CD27^{-}$ NK cells).[18]

CYTOKINE REGULATION OF NATURAL KILLER–CELL ACTIVATION, FUNCTION, AND HOMEOSTASIS

Mature NK cells also respond to other cytokines in addition to IL-15, with their role being more important for function than homeostasis.[19] IL-2R shares its β and γ subunits with the constitutively expressed IL-15R (Chapter 14). The dimeric IL-2Rβγ is able to respond to the high levels of IL-2 supplied in vitro to induce proliferation of NK cells. IL-2 activation will also induce the IL-2Rα chain to complete the high-affinity trimeric receptor. IL-4 activates human NK cells and promotes the proliferation of a fraction of NK cells characterized by their ability to produce IL-13.

The cytokines IL-12 and IL-18 also have profound effects on NK-cell function.[20] IL-12 and IL-18 are produced by macrophages and DCs during inflammatory immune activation, such as viral infection and within the tumors. Although NK cells are present in IL-12– or IL-18–deficient mice and only marginally reduced in double mutant animals, cytotoxic activity and the ability to proliferate and produce IFN-γ in response to infections, such as mouse CMV (MCMV) infection, is dramatically impaired. Cultivation of NK cells in IL-12 and/or IL-18 induces short-term activation, proliferation, cytotoxicity, and IFN-γ production, whereas longer cultures produce more specialized cytokine-producing cells, sometimes referred to as cytokine-induced memory NK cells.[21]

Another NK cell–activating cytokine is IL-21, a common γ chain family cytokine produced by CD4 T cells. Mouse NK cells treated with IL-21 display a broad-spectrum increase in cytotoxic function and produce cytokines, including IFN-γ and IL-10,[19] whereas IL-21 also promotes the proliferation of human NK cells. Of note, mice treated with IL-21 show a marked increase in NK cell–mediated tumor rejection, highlighting the potential for use of this cytokine as an anticancer therapeutic.[22]

NATURAL KILLER–CELL RECEPTORS

NK cells differ from CTLs in that they do not require the expression of MHC class I to recognize target cells. In fact, the reintroduction of allogeneic MHC class I molecules into previously susceptible cell lines confers resistance to NK cell–mediated killing. These observations led to the missing-self hypothesis, which proposes that NK cells survey tissues for the usually ubiquitous MHC class I expression and react against cells that do not express it.

KEY CONCEPTS

Natural Killer–Cell Receptors

Inhibitory receptors:
- Recognize mostly major histocompatibility complex (MHC) class I ligands with high affinity
- Signal via immunoreceptor tyrosine-based inhibitory motifs (ITIMs)
- Recruit phosphatases (SHP and SHIP) to prevent a cytotoxic response
- Required for natural killer (NK)–cell licensing

Activating receptors:
- Do not bind MHC class I molecules with high affinity
- Ligands include viral molecules and stress-induced proteins
- Signal via immunoreceptor tyrosine-based activation motifs (ITAMs)
- Use several signaling adaptors, including DAP12

The missing-self hypothesis, although altered over time to encompass other observations, has been extremely useful in providing a predictive framework by which to investigate NK-cell receptors and the recognition of target cells (Fig. 12.5).

In the past two decades, a large number of NK-cell receptors and their ligands have been identified, which are classified into either activating or inhibitory types (see Table 12.2).[23]

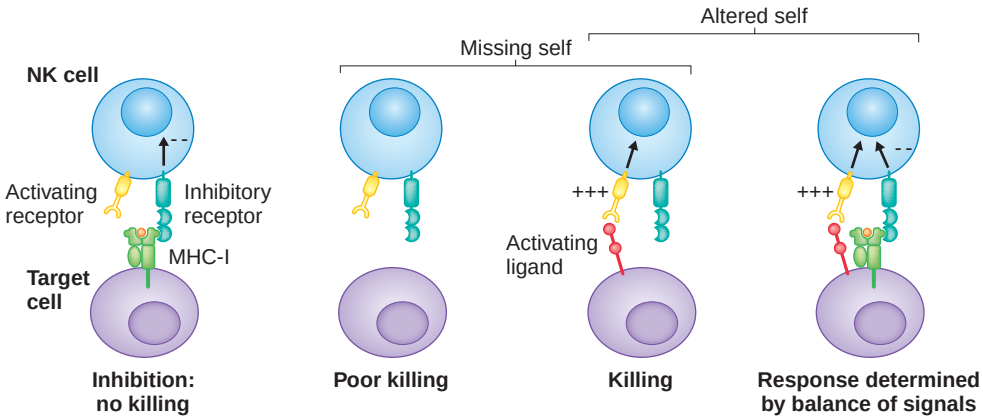

FIG. 12.5 Natural Killer *(NK)*–Cell Recognition of Target Cells. NK cells express inhibitory receptors for major histocompatibility complex class I *(MHC-I)* and activating receptors for a variety of cellular, viral, and stress-induced ligands that alter the outcome of encounter with a target cell. The missing-self hypothesis initially predicted that NK cells would be activated to kill in the absence of MHC-I inhibition. However, an activating signal is also required. This activating signal can be provided by cellular ligands or by viral or stress-induced proteins, termed *altered self*. In the presence of both inhibitory and activating signals, the outcome is determined by quantitative differences in signal strength between the two.

Although many of these NK-cell receptors recognize MHC class I molecules, as predicted by the missing-self hypothesis, there are many other classes of ligands. Interestingly, although this strategy of target recognition is conserved in all mammals tested, in rodents and humans, the receptors have evolved from two independent gene families, killer immunoglobulin-like receptors (KIRs) in humans and the Ly49 family in mice (see Table 12.2).

Natural Killer–Cell Receptor Signaling

The signals derived from NK receptors are defined as *inhibitory* or *activating* in terms of their effect on NK-cell function. Most characterized inhibitory receptors carry an immunoreceptor tyrosine-based inhibitory motif (ITIM) in their intracellular domain. Ligation of ITIM-containing receptors causes tyrosine phosphorylation and the recruitment of a variety of phosphatases, including SHP and SHIP, that act to dampen downstream signaling pathways and NK-cell effector functions.[23] In contrast, most activating receptors use immunoreceptor tyrosine-based activation motifs (ITAMs) to transduce stimulatory signals. Engagement of an ITAM-containing receptor results in tyrosine phosphorylation and recruitment of adaptor molecules, including FcεR1γ, CD3ζ, or DAP12/DAP10. The best-characterized activating receptor is CD16, an Fc receptor that binds IgG and is responsible for the antibody-dependent cellular cytotoxicity (ADCC) of human NK cells. CD16 recruits FcεR1γ and CD3ζ, which, in turn, attract the tyrosine kinases syk and ZAP70. These molecules then promote effector functions via multiple signal-transduction pathways.

NATURAL KILLER RECEPTORS THAT RECOGNIZE MAJOR HISTOCOMPATIBILITY COMPLEX CLASS I MOLECULES

NK cells recognize a wide variety of MHC class I molecules of both classic and nonconventional types. The receptors providing this recognition fit broadly into the immunoglobulin-like and lectin-like superfamilies. They show significant differences between mice and humans.

Killer Cell Immunoglobulin-Like Receptors in Humans

The *KIR* genes are a family of 14 coding genes that are physically linked on chromosome 19.[24] The locus shows a high degree of variation in humans, with both the number of *KIR* genes varying between individuals and extensive allelic polymorphisms. As expected, the inhibitory KIRs contain an ITIM, whereas activating KIRs utilize DAP12 to transduce signals from an ITAM.[23] Surface expression of KIRs is acquired with maturation, driven by IL-15, and as such, NK cells lacking KIRs or expressing combinations of multiple activating and inhibitory KIRs can be found in human blood. Similar to most other NK-cell receptors, some T cells can also express KIRs after activation, in particular in response to IL-15.

KIRs recognize the human MHC class I molecules human leukocyte antigens (HLA, see Table 12.2).[23,24] The specificity of the inhibitory KIRs has been extensively characterized, with, for example, the different KIR2D members that collectively recognize all known alleles of HLA-C. Activating KIRs also bind to HLA molecules, but at a much lower affinity than their inhibitory counterparts. KIR2DL4 is the most evolutionarily distinct member of the family and appears to be expressed in all activated NK cells in culture and on the $CD56^{bright}$ subset in peripheral blood. KIR2DL4 also has some distinct structural features and may act as an unconventional activating receptor binding HLA-G.

There are epidemiological data implicating particular KIRs in a variety of autoimmune pathologies and viral responses.[25] For example, individuals with KIR2DS2 and some HLA-C alleles are predisposed to rheumatoid arthritis with vascular complications. Conversely, individuals with human immunodeficiency virus (HIV) infection who are homozygous for HLA-Bw4 progress to acquired immunodeficiency syndrome (AIDS) more slowly than those with other haplotypes, especially when they have the *KIR3DS1* gene. This activity suggests that KIRs recognize an HIV-associated peptide in the context of HLA-Bw4.[26]

The Ly49 Family in Rodents

In a remarkable example of the power of selection to shape the evolution of the immune system, a multigenic locus with

functional properties almost identical to those of the *KIR* genes evolved independently in rodents.[23] Mice, which have only two *KIR* genes of unknown function, have an analogous cluster of type II transmembrane-spanning lectin-like genes called the Ly49 family on chromosome 6. This family consists of more than 20 members and is highly polymorphic between mouse strains. Like KIR molecules, Ly49 receptors are also variegated in their expression in NK cells. *Ly49* genes encode activating and inhibitory receptors that bind to MHC class I molecules and signal via ITAMs and ITIMs, respectively (see Table 12.2).[23] Ligand-binding studies have revealed that inhibitory Ly49 receptors, such as A, C, and I, function to prevent self-reactivity by NK cells by binding to MHC class I molecules. The function of the activating receptors has proven more difficult to elucidate. Ly49D is known to have high affinity for the MHC class I H-2D^{d} allele and is involved in rejecting bone marrow allografts expressing H-2D^{d}, but the function of Ly49D in the normal immune response is unclear. For one activating receptor, Ly49H, the physiological function is known, as it recognizes the m157 molecule of MCMV and is important in early viral control.[1]

CD94/NKG2 Family

Unlike the KIR or Ly49 families, the CD94/NKG2 complex is present both in rodents and humans. CD94/NKG2 receptors recognize nonclassical MHC class I ligands, such as HLA-E in humans and Qa1^{b} in mice.[25] A single *CD94* gene is physically linked to four *NKG2* (A, C, E, and a truncated F) genes in humans. CD94 is found on the cell surface, either alone or with activating (C, E) or inhibitory (A) forms of NKG2. Interestingly, both the activating and the inhibitory complexes recognize HLA-E, which presents predominantly the leader peptides of other HLA molecules, but not HLA-E itself.[24] This system may provide a mechanism for NK cells to monitor the expression of multiple MHC class I proteins using HLA-E as a surrogate. Human NKG2C-expressing NK cells are enriched in individuals infected with CMV and display fine specificity towards different CMV strains and are often termed *adaptive NK cells* given their ability to rapidly proliferate when stimulated with CMV peptides presented by HLA-E.[24]

NKG2D

NKG2D, which is only distantly related to the NKG2 family, is a single, nonpolymorphic gene that is expressed on all NK cells.[27] In the mouse, NKG2D signals through both DAP12 and another adaptor, DAP10, whereas human NK cells use only DAP10. Activation of NKG2D using a specific antibody results in enhanced cytotoxicity and cytokine secretion. The ligands of NKG2D are a family of molecules with structural similarity to MHC class I proteins, including MICA/B in humans and RAE-1 in mice. These ligands represent a diverse array of sequences, yet all bind with high affinity to NKG2D.[27] Interestingly, the MIC family in humans is highly polymorphic, suggesting that in this receptor–ligand interaction the diversity comes from ligands rather than receptors. Transfection of otherwise resistant tumor cells with NKG2D ligands restores the susceptibility of these cells to NK-cell cytotoxic function. The key to understanding NKG2D function lies in the fact that the ligands are inducible and provide a mechanism for NK cells to detect stressed tissue, such as virally infected or malignant cells, a phenomenon that has been termed *altered self* (see Fig. 12.5).[27] Conversely, certain cancers have been found to downregulate or shed NKG2D ligand expression to evade NK cell immunity. Thus, therapeutic approaches to modulate this pathway in human cancer are being investigated, including antibodies targeting the proteolytic region of NKG2D ligands to block their shedding.[28]

NATURAL KILLER–CELL RECEPTORS THAT RECOGNIZE NON–MAJOR HISTOCOMPATIBILITY COMPLEX I MOLECULES

Beyond the multiple systems of activating and inhibitory receptors that NK cells have evolved to recognize MHC class I molecules and their structural variants, they also have several other receptor families that bind non–MHC class I ligands.[23–25] These include the NKR-P1 family, which is a polymorphic multigene family in rodents consisting of activating (A, C, F) and inhibitory (D) forms, but consists of only a single member in humans, whose activity is inhibitory. The ligands for some family members have been recently reported and are themselves lectin family receptors, including Clr-b and Clr-g in mice and LLT1 in humans. Another NK receptor that is conserved between species is CD244 (2B4, SLAMF4), a pan-NK-cell–expressed molecule whose ligand is CD48 (SLAMF2). SLAM family members are able to switch between inhibitory and activating signaling by recruiting distinct intracellular adaptor proteins. A number of additional activating receptors exist, including the natural cytotoxicity receptors NKp30, NKp44, and NKp46. NKp30 and NKp46 are broadly expressed on human NK cells, and NKp46 is expressed on all mouse NK cells.[29] NKp44 is specifically expressed on activated human NK cells. These receptors can be activated by antibody cross-linking, and although their ligands are unknown, there is evidence that NKp46 binds many pathogen-derived ligands, including hemagglutinin on influenza virus–infected cells and the extracellular matrix component heparan sulfate glycosaminoglycans. Ligands for NKp46 have also been detected on numerous tumor cell lines and NKp46-deficient murine NK cells are poorer at killing these tumor cells, indicating that NKp46 has a direct role in NK-cell activation to various pathogens and cancers.[29]

NATURAL KILLER–CELL LICENSING AND SELF-TOLERANCE

The plethora of MHC class I–binding inhibitory receptors, as proposed by the missing-self hypothesis, explains the influence of MHC class I on NK-cell lytic function against tumors. However, how self-tolerance is achieved has been less clear. The initial theory to explain self-tolerance was the "at least one receptor" model, which proposed that NK cells must express at least one self–MHC class I inhibitory receptor. A second model suggested that the receptor repertoire is shaped by selection by the specific MHC haplotype and the presence of self-ligands. The observation that NK cells are not autoreactive in the absence of any inhibitory ligands (MHC class I–deficient mice) and are actually poor killers suggests that the situation is more complex than these models allow. A concept termed *licensing* was proposed to account for these observations.[30] Under this model, NK cells are initially unresponsive or "unlicensed" and acquire functional competency through binding of at least one inhibitory receptor before they can be activated and display cytotoxic function. An alternative "disarming" model proposes that all NK cells are initially responsive but that chronic stimulation by

normal cells renders these cells unresponsive, or "anergic," unless the stimulation is opposed by MHC class I–specific inhibitory receptors. More recently a third "rheostat" model has also been proposed, whereby the number and affinity of inhibitory receptors it expresses tune NK-cell reactivity in a quantitative manner.[30] Regardless of the exact tolerance mechanism, it is interesting that unlike with T cells, there is no evidence for clonal deletion of autoreactive NK cells.

SPECIFIC NATURAL KILLER–CELL FUNCTIONS

The ability to separate NK cells from T cells both phenotypically and genetically has greatly enhanced the understanding of their functions. Although some cytotoxic and immunomodulatory capacities overlap with those of T cells, it is also apparent that some functions of NK cells are unique. Specific examples of NK-cell functions are discussed below.

Control of Viral Infections

NK-cell activity rises early in the course of viral infection, partly driven by the release of IL-12, -18, and IFN-α, which stimulates activation.[31] The evidence that NK cells are essential for host defense against viruses comes directly from patients and mice lacking NK-cell function and indirectly from viral strategies to avoid NK-cell recognition. Human patients with selective deficiencies in NK cells show a pronounced susceptibility to recurrent severe infections, especially with HSV and CMV.

A powerful example of the role of NK cell–activating receptors in viral control is NK cell–mediated resistance to MCMV. Mouse strains that lack Ly49H are highly susceptible to MCMV, leading to uncontrolled viral replication and death. Importantly, this protection is mediated by the recognition of the m157 protein of MCMV by Ly49H. The rapid accumulation of $Ly49H^+$ NK cells during MCMV infection is the first example of clonal expansion of NK cells in a manner similar to that of B and T cells.[1] These studies also found compelling evidence for the maintenance of a long-lived NK-cell "memory"-like population (described below), blurring the line between innate (NK cells) and adaptive (B and T cells) immune cells.

As mentioned earlier, there is also evidence that NK cells have direct effects on the progression of HIV infection.[32] NK cells are able to lyse HIV-infected target cells either directly or by ADCC. Despite this ability, NK-cell responses are impaired in patients with HIV infection, as infected T-cell blasts selectively downregulate some HLA genes to avoid CTL activity but remain resistant to NK-cell cytotoxicity. These findings are supported by studies that show that high-risk, but uninfected, individuals appear to have increased NK-cell activity and that the combination of the expression of HLA-Bw4 and the *KIR3DS1* gene is associated with delayed progression to AIDS. Finally, HIV viremia induces several functional abnormalities on NK cells, suggesting that this complex virus and NK cells interact at multiple levels.[32]

Control of Malignant Cells

NK cells were named as such during the early 1970s for their potent ability to kill leukemia cell lines and since then have been the focus of immunotherapies to enhance cancer lysis and tumor regression in humans. Evading the immune system is a hallmark of cancer, but the contribution of NK cells in tumor immune surveillance has been difficult to assay, as specific NK cell–deficient mouse models have only recently been generated. There is abundant evidence that NK cells can reduce tumor burden in animal models, and that the administration of cytokines that enhance NK-cell function or number or those that induce IFN-α production, are protective against metastasis.[20]

Melanoma is at the forefront of immunotherapy research in patients since it has high immune infiltration. Bulk and single-cell transcriptomic data have been used to define an NK cell gene signature that infers the relative frequency of tumor-resident NK cell infiltration within metastatic melanoma samples. This study found that greater abundance of tumor-resident NK cells was strongly associated with long-term overall survival in patients with melanoma, and this appears also to be true for head and neck squamous cell carcinoma and lung adenocarcinoma.[31] In light of this, many clinical trials have been conducted to assess either cytokine treatment or the injection of ex vivo cultured healthy or tumor-resident NK cells.[20] Unfortunately, the high doses of IL-2 and IL-15 required for efficacy are relatively toxic, and transferred NK cells have proven difficult to target to tumors. Despite this, some successes have been demonstrated for melanoma, leukemia, and kidney cancer. Numerous immunotherapy trials are ongoing that aim to exploit and boost NK cell–mediated tumor killing, including antibodies against inhibitory receptors on NK cells, modified cytokines, bi- or trispecific antibodies that bind NK cells and tumor antigens, tumor-specific antibodies, in vitro expanded patient-derived NK cells, and irradiated NK cell lines, to name a few.[31]

Role of Natural Killer Cells in Hematopoietic Stem Cell Transplantation

CLINICAL PEARLS

Exploiting Natural Killer Cells in Leukemia Therapy

- Hematopoietic stem cell transplantation requires donor and recipient human leukocyte antigen (HLA) matching to reduce graft-versus-host disease (GvHD) mediated by transplanted cytotoxic T lymphocytes (CTLs).
- Haploidentical donors and recipients (those that share only one HLA haplotype) represent 50% of unrelated transplants and undergo a stronger conditioning regimen to avoid GvHD.
- Alloreactive natural killer (NK) cells are present after haploidentical transplant and provide a potent graft-versus-leukemia (GvL) effect in animal models.
- Transplantation from NK cell–alloreactive donors controls leukemia relapse and improves engraftment without causing GvHD.

In humans, allogeneic bone marrow transplantation can cure leukemia through the reaction of donor CTLs in the graft against the residual leukemic cells. These transferred T cells also mediate GvHD. The need to prevent GvHD as a result of strong immunosuppression is the major cause of transplantation failure because of infection and cancer relapse. It has been proposed that obtaining the transplant from a haploidentical donor (identical at one HLA haplotype and fully mismatched on the other, for example, a parent) provides allogeneic NK cells with an HLA haplotype that supplies more KIR ligand than a matched recipient would provide. Hence it would yield a stronger graft-versus-leukemia (GvL) effect.[33] Indeed, mice treated with alloreactive NK cells tolerate 30 times the lethal dose of mismatched bone marrow cells without developing GvHD, and alloreactive NK cells eradicated human acute myeloid leukemia (AML) transplanted into immune-deficient mice. Retrospective

studies on patients with AML and acute lymphoblastic leukemia who received haploidentical grafts revealed that transplants with alloreactive NK cells showed better engraftment and GvHD protection and less relapse.[33]

These studies suggest that therapeutic treatment with alloreactive NK cells will be effective in eliminating residual cancer cells following frontline treatments or in preventing cancer relapse. Feasibility studies have shown that the production of clinical-grade cultured human NK cells is possible and that the transferred cells persist for some time in the patient. An alternative strategy is the use of monoclonal antibodies directed against inhibitory KIRs. Despite the strong preclinical data for the strong inhibitory effect of KIR2DL1, KIR2DL2, and KIR2DL3 signaling on NK cells when bound to HLA-C-expressing tumor cells,[34] a phase II clinical trial of a KIR2DL1/L2/L3 blocking antibody in AML failed to show any benefit to patients, suggesting that a stronger basic understanding of NK cell target recognition is still required.

ON THE HORIZON

Clinical Trials of Transferred Alloreactive Natural Killer Cells/Chimeric Antigen Receptors

The success of chimeric antigen receptor (CAR) T-cell therapy in treating relapsed refractory B-cell malignancies has given rise to much interest in applying this approach to natural killer (NK) cells. A clear advantage of CAR NK cells is patient safety, as NK cells are well tolerated in the allogeneic setting and, unlike CAR T cells, do not produce cytokine release syndrome, immune effector cell-associated neurotoxicity syndrome, or graft-versus-host disease (GvHD).[31]

A first-in-human phase I trial of allogenic anti-CD19 CAR NK cells has recently concluded and the encouraging results saw 7 out of 11 patients experiencing a rapid response with very little toxicity reported.[35]

Preclinical data suggest that the antitumor activity and persistence of CAR NK cells can be further enhanced by genetic deletion of checkpoint genes that negatively regulate interleukin (IL)-15 signaling.[36] A new-wave of NK-cell therapies are thus on the horizon.

Natural Killer Cell Memory

During the last decade several studies have described the ability of NK cells to generate a "memory" response to pathogens and antigens. Although the original documentation of NK-cell memory was in a cutaneous contact hypersensitivity model, the concept of NK-cell memory has since been extended to viral responses, including MCMV, influenza, vaccinia virus, HSV, HIV, and vesicular stomatitis virus, where NK cells from mice pre-exposed to the virus were more efficiently activated and prolonged survival from lethal infection compared with naïve NK cells. Although the interaction between Ly49H and the viral protein m157 is required for the memory response elicited by MCMV infection, the NK cell receptor–ligands combinations involved in most other antiviral responses are not established. Inflammation, in general, and especially the cytokines IL-12, IL-18, and IFN-α, are likely to be critical for the generation of memory NK cells.

INTERACTIONS OF CYTOTOXIC T LYMPHOCYTE AND NATURAL KILLER CELLS IN THE IMMUNE RESPONSE

Although studies of CTLs and NK cells in isolation have greatly advanced our understanding of their functions, it is obvious that these immune cells function in a system that depends on numerous interactions between the various cell types at multiple levels. In the case of cytotoxic cells, these immunomodulatory interactions are becoming increasingly appreciated (see Fig. 12.2). In particular, it has become apparent that NK cells and DCs interact specifically to promote some outcomes, such as maturation and priming of NK cells. CTL activation by mature DCs is influenced directly by NK cell–derived IFN-γ and indirectly through the role of NK cells in promoting a Th1 response in CD4 T cells (Chapter 11).[37,38]

Increasing evidence has emerged to implicate DC–NK cell cross-talk in various aspects of the immune response. The interactions of mature DCs and NK cells occur at the site of infection, where DCs provide inflammatory stimuli for NK cells, including cytokines such as IL-12 and IFN-α. IFN-α production by DCs promotes MHC class I upregulation by CTLs and their protection from NK-cell killing during viral infections. The other site of encounter is the lymph node, where, during an immune reaction, NK cells are recruited by chemokines and interact with mature DCs and CD4 T cells to induce a Th1 response. This process also requires IFN-γ production from NK cells (see Fig. 12.2).

NK cell–CTL cellular interactions are also important in generating an immune response to tumors. DCs can be recruited into tumors by NK cell derived–chemokines, to influence CTL priming via antigen presentation and NK-cell function via cytokine secretion, particularly IL-12. IFN-γ produced by NK cells and CTLs is important in the rejection of primary tumors and the formation of CD8 T-cell memory to tumors. It is also likely that killing by NK cells and CTLs provides DCs with increased access to tumor antigens and promotes further adaptive immunity. Using DCs to harness the helper function of NK cells as well as the cytotoxic functions of both CTLs and NK cells offers therapeutic promise and is currently being tested in a variety of cancers.

EVASION OF THE CYTOTOXIC RESPONSE

Viruses

As one principal function of CTL and NK cells is the control of viral infections, it is not surprising that viruses have strategies to interfere with the host response (Chapter 25). The multiplicity of these evasion strategies indicates that this is an essential step for long-term viral persistence.

These strategies include:

Latency. This involves minimizing viral gene expression and thereby avoiding detection. Examples include HSV in neurons, HIV in T cells, and EBV in B cells.

Antigenic variation. Viruses possess the ability to rapidly mutate their genomes and produce escape variants that are no longer visible to CTLs. Such mutations were shown for MCMV infection in mouse and HIV infection in humans.[32]

Infection of immune inaccessible sites. Examples include infection of the central nervous system by HSV or rubella virus.

Production of viral defense molecules (immunoevasins). Many viruses, including adenovirus, CMV, and EBV, interfere with cytotoxic activity by producing proteins that either hinder Fas or TNF-mediated killing or inhibit the function of antiviral cytokines, such as IFN-α. A number of viruses, including EBV, produce homologs of antiapoptotic molecules, such as Bcl2, to inhibit killing by CTLs. Members of the poxvirus family have evolved homologs of the naturally occurring IL-18–binding protein that inhibit IL-18 activity and NK-cell function.

Modulation of molecules involved in recognition. A widely utilized viral strategy to evade the cytotoxic response is to interfere with antigen processing, presentation, or the expression of other molecules required for CTL recognition (Chapter 6).[39] Many viruses, including adenovirus and HIV, downregulate MHC class I expression on the cell surface. This can be achieved by a number of mechanisms. For example, adenovirus type 2 E3 protein forms a complex with MHC class I to prevent antigens from being processed; MCMV gpm152 protein causes retention of the MHC class I molecules in the Golgi compartment; and CMV proteins US2 and US11 promote the rapid degradation of newly synthesized MHC class I complexes.[40] An alternative approach is to interfere with antigen processing, either inhibiting the expression of the TAP protein, as is the case for HSV, or producing proteins that are resistant to antigen digestion by the proteasome, such as the EBNA-1 protein of EBV. This inhibition strategy is not restricted to MHC class I, as both human CMV and MCMV express proteins that inhibit the cell-surface expression of NKG2D ligands.

Tumor Cells

Part of the evidence that CTLs and NK cells function to control malignant cells comes from the lengths tumor cells will go to avoid cytotoxic activity. Conversely, promoting the cytotoxic response either through specific tumor antigens, blocking immune checkpoint inhibitors, or through polyclonal stimulation remain successful strategies in cancer immunotherapy (Chapter 80).

Tumors evade cytotoxic function in a number of ways:

Downregulation or loss of MHC class I expression. This strategy is common in solid tumors, including metastatic melanoma and breast cancer, where MHC class I downregulation accounts for up to 50% of samples. MHC class I downregulation is associated with changes in the regulatory mechanisms controlling antigen presentation and can often be corrected by treatment with cytokines, such as IFN-γ.

Induction of immune checkpoint ligands. One mechanism to suppress the infiltrating antitumor CLT/NK cell response is upregulation of ligands to inhibitory receptors expressed on CTLs/NK cells. Two inhibitory receptors, CTLA-4 and PD-1, are expressed on CTLs and to a less extent on NK cells, and blocking of antibodies against these has revolutionized cancer immunotherapy.[11] In particular, IFN-γ upregulates PD-1 ligands (PD-1L and PD-2L) on tumor cells, and their binding to PD-1 potently inhibits tumor-specific CTL activity. Anti-PD-1 therapy offers a high rate of sustained tumor regression in metastatic melanoma and is currently being applied to a huge range of other cancer types.

Antigenic mutation. Tumors can also avoid CTL activity by antigenic loss. This strategy takes the form of silencing or mutating epitopes that are particularly immunogenic to CTL.

Broad-spectrum tumor-derived immune suppression. Tumors express a variety of membrane-bound and soluble factors that can suppress the immune response, including FasL, which protects the tumor by inducing apoptosis in activated Fas-expressing CTLs. This model is not universally accepted, and a role for FasL in inducing the expression of inflammatory cytokines is also possible. Tumors can also express TGF-β, which acts on CTLs and NK cells to inhibit their metabolism, proliferation, and expression of effector molecules, such as perforin and granzymes. TGF-β also acts on NK cells to downregulate the expression of NKG2D. Pharmaceutical inhibitors of TGF-β signaling are being tested in patients with cancer.[20] In addition, tumors can produce soluble decoy ligands, such as MIC, which suppresses NKG2D function. CD73-mediated adenosine production also plays important immunosuppressive roles in the tumor microenvironment. CD73 is a surface receptor expressed on many tumors and catalyzes extracellular adenosine monophosphate (AMP) into adenosine that can bind its receptor (A2AR) on NK cells/CTLs to suppress their activity. As such, A2AR and CD73 antagonists are being developed, and their trials in cancer are ongoing.[20]

Regulatory Immune Cells

James B. Wing and Shimon Sakaguchi

The normal mammalian immune system protects the individual from a myriad of potentially pathogenic microorganisms. However, the immune system must also be tightly regulated to prevent it from attacking self-constituents and thus causing autoimmunity. This is partly achieved through central tolerance and the deletion of T cells that recognize self antigens in the thymus. However, this process is incomplete; that is, some self-reactive T cells are present in the periphery of healthy individuals and are capable of causing autoimmunity. This creates a need for peripheral tolerance mechanisms that control the action of such self-reactive cells.

The mechanisms that suppress harmful immune responses are of interest to both basic and clinical immunologists, as the failure of protective immunity can lead to increased susceptibility to infectious diseases, and loss of self-tolerance may trigger an autoimmune disorder. Furthermore, it is often clinically desirable to enhance an immune response to certain self (or quasi-self) antigens, such as tumor antigens, or to induce immune suppression for the purpose of facilitating organ transplant acceptance. Elucidation of the mechanisms responsible for immune regulation and maintenance of self-tolerance is, therefore, one of the primary goals of current medical immunology.

KEY CONCEPTS

Immunologic Self-Tolerance

Immunologic self-tolerance is actively acquired and maintained throughout life by a series of mechanisms that cooperatively and complementarily operate to prevent the maturation and activation of potentially self-reactive lymphocytes.

The mechanisms include:

- Clonal deletion
- Clonal anergy
- Clonal ignorance
- Dominant suppression

One key feature of the adaptive immune response is that once triggered, it shows essentially the same effector activity, whether the target antigen is a microbe or a self antigen, leading to elimination of the microbe or destruction of self-tissue. To prevent self-destructive immune responses while allowing protective immune responses to nonself antigens, the mammalian immune system has evolved various regulatory contrivances that inhibit the initial generation of potentially harmful self-reactive T and B lymphocytes, termed *central tolerance*, or, after lymphocyte generation, downregulate cellular activation and expansion upon encounter with self antigens, termed *peripheral tolerance*. For T cells, central tolerance is established in the thymus, where many potentially dangerous lymphocytes carrying high-affinity T-cell receptors (TCRs) for self antigens are deleted via negative selection during development. This results in the generation of a peripheral T-cell repertoire that is largely self-tolerant. However, there is abundant evidence that some autoreactive T cells escape thymic deletion, and potentially pathogenic self-reactive T cells are, indeed, present in most individuals. Nevertheless, autoimmune diseases only occur infrequently, indicating that autoreactive T cells are somehow controlled in the periphery. Such peripheral mechanisms of self-tolerance include further deletion of self-reactive T cells, seclusion of self antigen from T lymphocytes, low TCR affinity or lack of costimulation in antigen recognition (clonal ignorance), inactivation of autoreactive T lymphocytes upon encounter with antigen without costimulation (clonal anergy), and active suppression of self-reactive lymphocytes by other lymphocytes (peripheral suppression).[1]

There are various mechanisms of peripheral self-tolerance, and this chapter deals with peripheral suppression mediated by T cells and other suppressive non–T cells. Several types of T cells with regulatory activity have been described, including subpopulations of γδ T cells, natural killer T cells (NKT cells), and CD8 and CD4 T cells (Table 13.1; Fig. 13.1). Some of these suppressive T cells are constitutively produced as a separate lineage in the immune system, whereas others are induced from naïve T cells as a product of a particular mode of antigen stimulation in a particular cytokine milieu. Although it remains to be determined how each cell population is functionally stable and physiologically important, this abundance and apparent redundancy of Treg populations may not be surprising when one considers how essential it is to maintain immune homeostasis and self-tolerance.

This chapter focuses on CD4 regulatory T cells (Treg); in particular, Treg that specifically express the transcription factor Foxp3 and maintain high expression of the interleukin-2 (IL-2) receptor α chain, CD25. $Foxp3^+CD25^+CD4^+$ Treg have been the subject of the majority of recent Treg studies and may have the broadest implication to our understanding of the mechanism of various immunologic disorders. Loss of function or numerical deficiency of Treg function or number can be a primary cause of autoimmune disease, allergy, and inflammatory disorders, such as inflammatory bowel disease (IBD) in humans. Conversely, since these cells can prevent targeting of tumor tissues by conventional CD4 and CD8 T cells, inactivating them is a key goal in cancer immunotherapy. Because of their natural presence in the immune system, they are also a good target for the treatment and prevention of a variety of immunologic diseases.[2]

TABLE 13.1 Subsets of Thymic and Peripheral Foxp3⁺ Tregs and Foxp3⁻ Suppressive T Cells

	Foxp3⁺ Treg	Tr1	Qa-1–Restricted CD8⁺ Treg	NKT Cells	γδ T Cells
Site of generation	Thymus/periphery	Periphery	Periphery	Periphery	Periphery
Marker	Foxp3, CD25, CTLA-4, GITR	IL-10 TGF-β	Nonclassic MHC Ib Qa-1	Invariant TCR chain Va14 (mouse), Va24 (human)	Various subsets Vg5⁺ (mouse) Vg1⁺ (human)
Specificity	Peptide plus MHC class II	Peptide plus MHC class II	Peptide plus MHC class Ib	Glycolipids plus CD1d	Glycolipids plus CD1, Peptide plus MHC class Ib

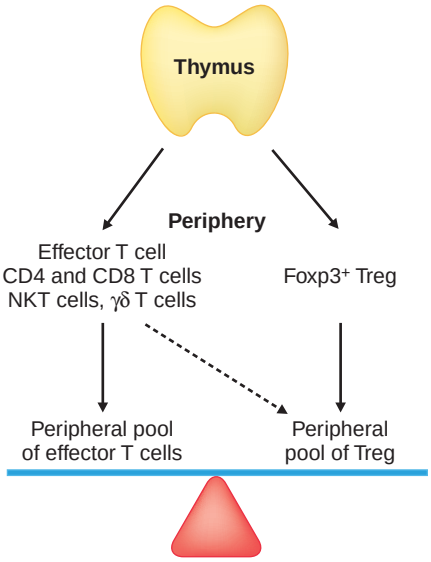

FIG. 13.1 Developmental Pathways of Regulatory T Cells *(Treg).* Treg cells can develop either in the thymus or the periphery and are vital for maintaining tolerance as a counterbalance to effector T cells. Thymically generated Treg express Foxp3 and develop within the thymus following to a specialized combination of T-cell receptor and costimulatory signals. Extrathymic development of CD4⁺ Treg, and CD8⁺ Treg can ensue from a host of different conditions, such as high concentrations of transforming growth factor-β, interleukin-10, or other particular circumstances surrounding antigen priming. The signals that control differentiation of γδ T cells and natural killer T cells *(NKT cells)* to cells with regulatory properties are less well defined.

CD4 REGULATORY T CELLS

The nomenclature used to define Treg has been inconsistent over the years, but recent efforts have been made to standardize the naming of these cells.[3] It is recommended that Foxp3⁺ Treg be clearly separated into thymus-derived tTreg, peripherally in vivo–induced pTreg and in vitro–induced iTreg. Readers should be aware that in the past tTreg have often been referred to as *natural Treg* (nTreg), whereas both pTreg and iTreg were grouped together as *induced* or *adaptive Treg*. Where there is no specific identification allowing confirmation of the cells being specifically tTreg or pTreg, the simple term *Treg* can be used to refer to Foxp3⁺Treg as a group. In this chapter, to avoid confusion, we reserve the term *Treg* for the CD4⁺Foxp3⁺ population rather than other T cells with suppressive function, such as IL-10–secreting type 1 regulatory T cells (Tr1),[4] since they differ in their development, phenotype, and function, and they are thus considered to be of separate lineages (see Table 13.1 and Fig. 13.1).

Thymus-Derived Regulatory T Cells

The first report of autoimmune-preventive, thymus-derived T cells in the normal immune system occurred about 40 years ago when thymectomy on day 3 of life (d3Tx) was shown to cause organ-specific autoimmune diseases, such as oophoritis, in otherwise healthy mice, a finding later attributed to the slightly delayed thymic emigration of tTreg in comparison with effector T cells.[5] Subsequent studies showed that the development of autoimmune diseases could be inhibited if the thymectomized animals were reconstituted with CD4⁺CD8⁻ thymocytes or CD4⁺ splenocytes from histocompatible immune-uncompromised animals. Athymic mice transferred with non-Treg or thymocytes spontaneously develop organ-specific autoimmune diseases, which can be reversed by cotransfer of tTreg from normal adult mice.[2,6] Treg can suppress the proliferation and cytokine production of conventional CD4 or CD8 T cells in vitro. tTreg are thought to arise from T-cell clones with relatively high reactivity to self antigens presented in the thymus.

While for a long time it has been considered that CD25⁺Foxp3⁻ cells in the thymus are the main Treg precursor population, recent evidence also suggests the existence of a second CD25⁻Foxp3⁺ population that forms an alternative

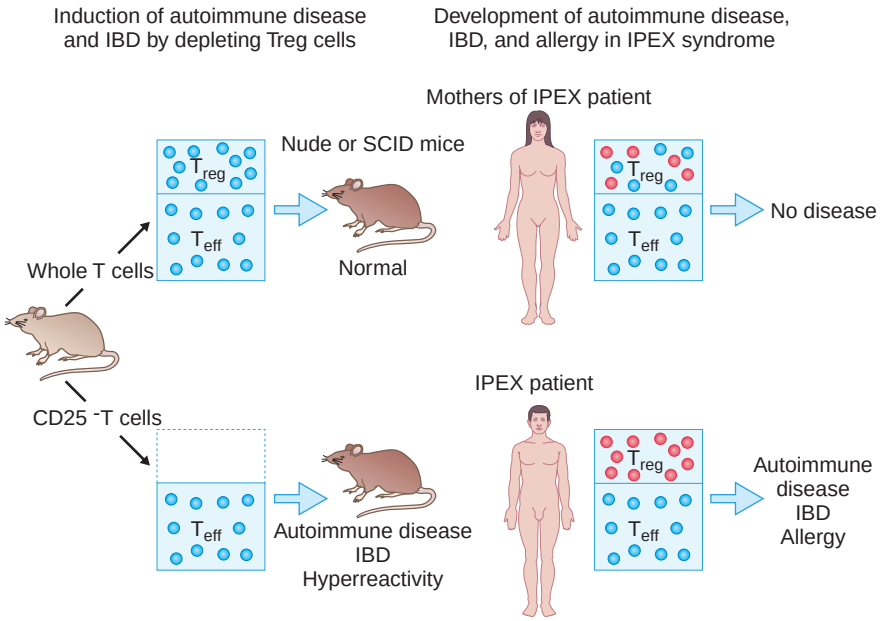

FIG. 13.2 Dominant Self-Tolerance in Rodents and Humans. Transfer of T-cell suspensions depleted of Foxp3$^+$CD4$^+$ Treg induces autoimmune disease and inflammatory bowel disease *(IBD)* and heightens immune responses to nonself antigens in athymic nude or severe combined immunodeficiency *(SCID)* mice *(left)*. Male children are afflicted by infections and immune dysfunction/polyendocrinopathy/enteropathy/X-linked *(IPEX)* syndrome. Their mothers with hemizygous defects of the *FOXP3* gene bear defective and normal Tregs as a mosaic because of random inactivation of the X chromosome in each Treg cell. They are completely normal because normal Treg cells dominantly control the activation and expansion of effector T *(T_{eff})* cells that mediate autoimmune disease, IBD, and allergy *(right)*. *Blue circles* represent intact Treg or T_{eff} cells; *red circles* represent defective Treg cells.

Treg precursor population. These two precursors do appear to result in Treg with no clear difference in their phenotype but they do harbor some differences in their TCR affinity with the Foxp3^{lo}CD25$^-$ population, having generally lower affinity, which suggests a difference in their ability to recognize antigens in the periphery once exported from the thymus.[1]

To pinpoint a specific phenotype for CD4 T cells with regulatory function, surface markers with more restricted expression patterns have been explored. As a high and stable expression of the IL-2 receptor α chain, CD25 has been found to be a useful and specific surface marker of Foxp3$^+$ Treg. Between 5% and 10% of CD4$^+$ T cells express CD25 constitutively in the thymus and periphery of mice. Importantly, transfer of CD4 lymphocytes depleted of CD25$^+$ cells induces autoimmunity in athymic nude mice, whereas cotransfer of CD4$^+$CD25$^+$ cells protects the mice from disease induction (Fig. 13.2). Other markers shown to be associated with Foxp3$^+$ Treg are cytotoxic T-lymphocyte antigen-4 (CTLA-4; CD152) and glucocorticoid-induced tumor necrosis factor receptor protein (GITR). However, these and CD25 are not truly specific markers of tTreg, since conventional T cells upregulate GITR, as well as CTLA-4 and CD25, after activation.[2,6] This dilemma is especially apparent when investigating Foxp3$^+$ Treg in humans, where a significant proportion of CD4$^+$ T cells in peripheral blood express CD25, yet only 2% to 4% of CD4$^+$ T cells, enriched among cells with the highest expression level of CD25 (CD25^{high}), have suppressive properties (Fig. 13.3).[6] The fact that CD25$^+$ Treg are not a discrete population in humans poses a problem both when obtaining cells for experimental purposes and when evaluating their role in a clinical setting. Therefore finding more specific cell-surface markers of CD4$^+$ Treg remains an important goal.

Thymus-Derived Treg Express the Transcription Factor Foxp3

Specific expression of the transcription factor Foxp3 is closely linked with the development and function of Treg.[7] The first hint as to the significance of Foxp3 was given by studies of the Scurfy mutant mouse. This mouse strain suffers from a spontaneous X-linked mutation of the *Foxp3* gene, which leads to fatal lymphoproliferative disease associated with multi-organ infiltrates and early death by 3 to 4 weeks of age in hemizygous males. Similarly, mutations in the human orthologue *FOXP3* are linked to immune dysregulation, polyendocrinopathy, enteropathy, IBD, allergic dermatitis, food allergy, hyperimmunoglobulinemia E, hematological disorders, severe infections and X-linked (IPEX) syndrome, which is an X-linked immunodeficiency associated with organ-specific autoimmune diseases, such as type 1 diabetes (see Fig. 13.2).[2,6] Common features of IPEX syndrome and scurfy mice are deficient levels of both tTreg and pTreg. CD25$^+$CD4$^+$ T cells and CD25$^+$CD4$^+$CD8$^-$ thymocytes specifically express *Foxp3* mRNA in contrast to the cell-surface markers used until now. In addition, other thymocytes/T cells, Th1, or Th2 cells scarcely express *Foxp3* even after stimulation.[7]

Although the majority of Foxp3$^+$ cells in mice reside in the CD4$^+$CD25$^+$ T-cell population, some can be found in the CD4$^+$CD25$^-$ population, particularly in non-lymphoid sites or within the germinal center. Importantly, retroviral transduction of *Foxp3* in naïve CD25$^-$ T cells can convert them to regulatory cells with at least some of the suppressive functions of true Treg. However, although it is essential, it has also become clear that Foxp3 alone is not sufficient to stably maintain the full Treg identity. Another critical factor is the presence of a Treg-type epigenetic pattern in which genes, such as *Foxp3*,

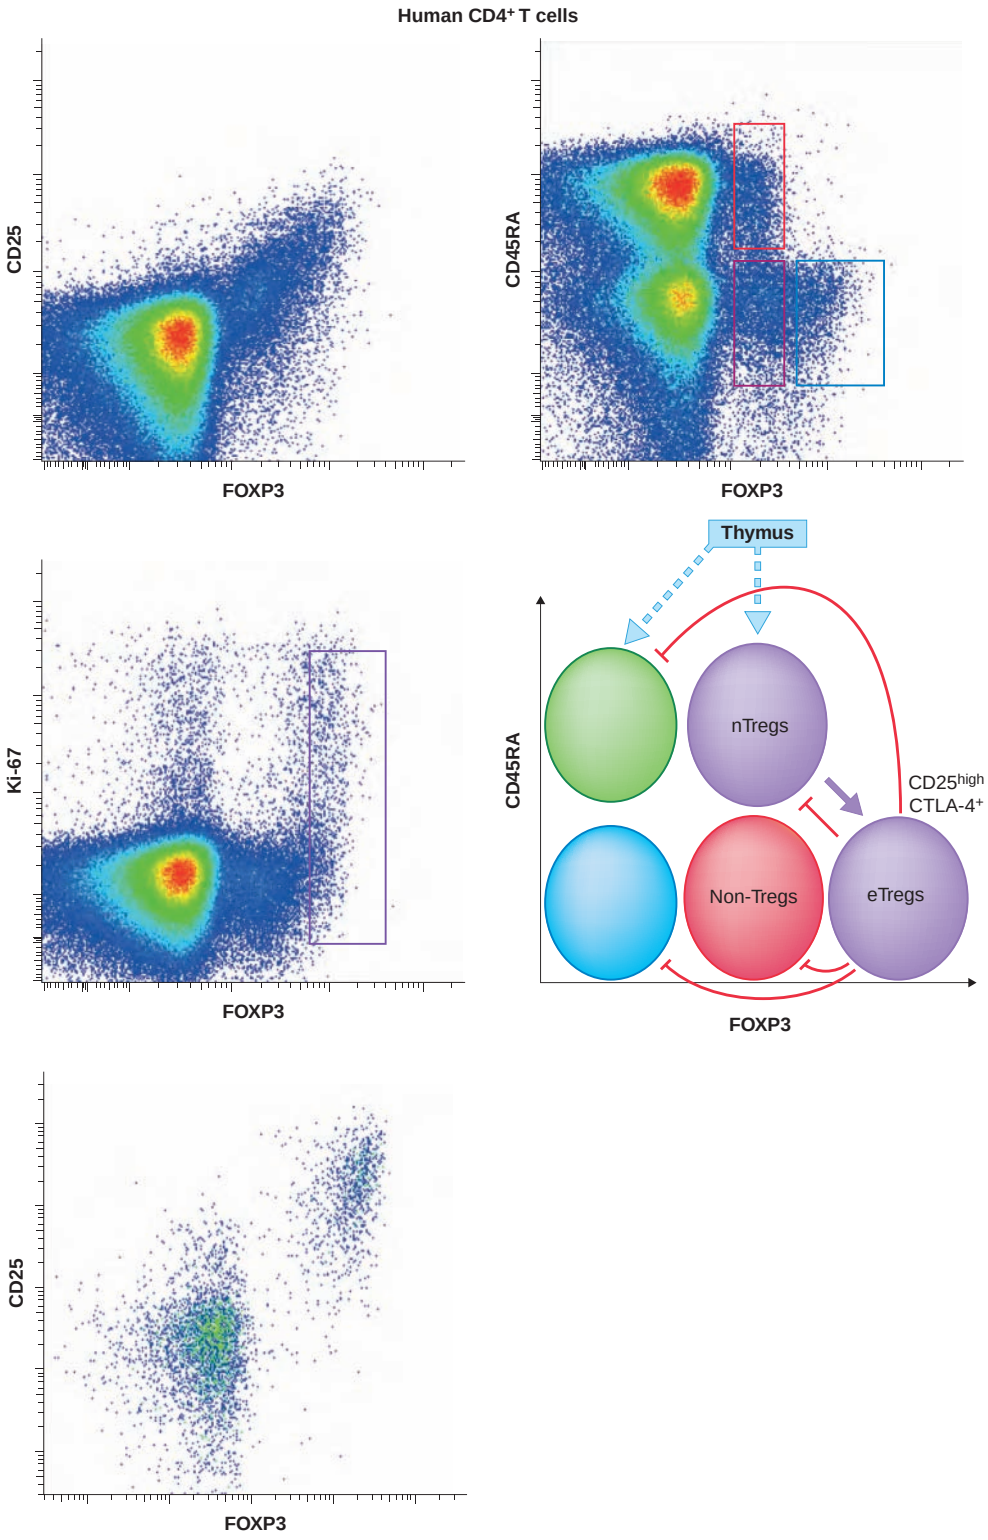

FIG. 13.3 Expression of CD25 and Foxp3 Denotes Treg in Mice and in Humans. In mice, between 5% and 10% of $CD4^+$ T cells express CD25, and among these, almost all are $Foxp3^+$. In addition, a few Foxp3-expressing cells reside among $CD4^+CD25^-$ T cells. In the peripheral blood of humans, expression of surface marker CD25 is well correlated with intracellular FOXP3, especially when the levels of CD25 and FOXP3 are high *(top left)*. CD45RA and intracellular expression of FOXP3 enables the definition of three distinct subsets within $FOXP3^+CD4^+$ T cells: $CD45RA^-$ effector Treg cells with high expression of FOXP3 *(blue box)*, $CD45RA^+$ naïve Treg cells with low expression of FOXP3 *(red box)*, and $CD45RA^-$ non-Treg cells with low expression of FOXP3 *(top right, purple box)*. Effector $FOXP3^{high}$ Treg cells correspond to actively proliferating Treg cells in vivo as they express Ki-67 *(bottom left, purple box)*. The thymus produces $CD45RA^+FOXP3^{low}$ naïve Tregs as well as naïve $CD45RA^+$ non-Treg cells. Upon antigenic stimulation, naïve Tregs differentiate to $CD45RA^+FOXP3^{high}$ effector Tregs, which are potently suppressive and capable of suppressing the proliferation of other Tregs as well as non-Tregs in vitro *(bottom right)*. *CTLA-4*, Cytotoxic T-lymphocyte antigen-4.

CTLA-4, and *GITR*, have stably demethylated CpG residues and a permissive chromatin structure allowing them to be constitutively expressed by Treg. These epigenetic modifications occur independently of Foxp3 expression and maintain a significant proportion of the *Treg* gene expression even in the absence of Foxp3 itself.[8] However, at the same time, Foxp3 expression is still essential, as shown by the severe diseases seen in humans or mice lacking functional Foxp3. A similar pattern of FOXP3 expression can be observed in humans, with most FOXP3$^+$ cells among CD4$^+$CD25^{high} T cells, and a few being CD25$^-$ or CD25^{low} (see Fig. 13.3). However, in humans, but not in mice, low levels of FOXP3 can be transiently induced by TCR stimulation in conventional T cells. These cells can be detected directly in blood as CD4$^+$ T cells with a memory phenotype and a weak expression of FOXP3, but with no suppressive function.[6] However, some true Treg such as CXCR5$^+$ T-follicular regulatory (Tfr) cells may also express lower levels of FOXP3, meaning that great care is required to separate them from non-Treg. As a result, human FOXP3$^+$ Treg with function can be divided into two relatively clearly defined subsets: CD45RA$^+$FOXP3^{low} naïve Treg (nTreg) and CD45RA$^-$FOXP3^{high} effector Treg (eTreg), and a third group of Foxp3^{lo}CD45RA$^-$ cells that contain a mixture of Treg and non-Treg (see Fig. 13.3).

CLINICAL RELEVANCE

Infections and Immune Dysfunction/ Polyendocrinopathy/Enteropathy/X-Linked (IPEX) Syndrome Is a Result of FOXP3$^+$ Treg Deficiency

When the *Foxp3/FOXP3* gene has a loss-of-function mutation, FOXP3$^+$ regulatory T cells (Treg) fail to develop, or Foxp3 protein is dysfunctional, and a fatal autoimmune/autoinflammatory disease develops. This monogenic X-linked disease directly demonstrates how crucial FOXP3$^+$ Treg are for maintaining self-tolerance and immune homeostasis.

Cardinal features of IPEX are:

- Autoimmune diseases (type 1 diabetes, thyroiditis, hemolytic anemia)
- Allergy (dermatitis, hyperimmunoglobulinemia E, food allergy)
- Inflammatory bowel disease

In addition to tTreg, there is abundant evidence from mouse studies supporting the peripheral development of T cells with suppressive properties. For example, Foxp3-expressing CD25$^+$CD4$^+$ Treg, functionally and phenotypically similar to tTreg, can be induced from naïve T cells by in vitro or in vivo antigenic stimulation in the presence of TGF-β.[9] However, it should be noted that in vitro–induced Treg lack the Treg-type epigenetic pattern and so may not be stable Treg, making it important to differentiate between in vivo peripherally induced pTreg and in vitro–induced iTreg.[8] Both murine and human thymus-derived Treg cells express Helios, an Ikaros family transcription factor, and neuropilin-1, whereas most induced Foxp3-expressing CD4 T cells do not. However, some highly activated pTreg and Foxp3$^-$ T cells may express these markers to some extent, making them useful to differentiate between tTreg and pTreg.[9] It has been suggested that tTreg are sufficient for the prevention of widespread autoimmunity but that pTreg have a more specialized function in the prevention of excessive immune responses in mucosal sites, such as the gastrointestinal tract and the lungs.[10]

Maintenance of Foxp3$^+$ Tregs

In addition to TCR interaction, it seems that accessory signals, such as costimulation through CD28-B7 or CD40-CD40L, play an important role in the production of Foxp3$^+$ Treg in the thymus, since animals that lack CD28 or CD40 expression generate only minute numbers of Foxp3$^+$ T cells in the thymus (Table 13.2).[11]

In the periphery, maintenance of Foxp3$^+$ Treg requires antigenic priming and cytokines. It is vital that Foxp3$^+$ Treg encounter specific antigens to remain in the Treg pool. For example, cell transfer experiments in mice thymectomized on day 3 (d3Tx) have demonstrated that Treg from donors of the opposite sex are better at protecting against orchitis or oophoritis compared with Treg from same-sex donors, and that Treg from ovariectomized mice are less competent in preventing oophoritis than those from normal females.[5]

IL-2 is vital for the maintenance of Treg. Thus CD25 is not only a marker but also an indispensable molecule for Treg as a component of the high-affinity IL-2 receptor. Mice genetically deficient in IL-2 or IL-2 receptor α (CD25) or β chain (CD122) develop severe lymphoproliferative disease in multiple organs, resulting in early death.[11] Moreover, genetic deficiencies of CD25 in humans generate a comparable pattern. IL-2–deficient animals have substantially reduced, although not completely depleted, numbers of Foxp3$^+$ T cells, and disease can be prevented by adoptive transfer of normal Foxp3$^+$ Treg (see Table 13.2).

In addition to antigen recognition and cytokines, Foxp3$^+$ Treg require appropriate interactions with antigen-presenting cells (APCs) for their function and survival. Several molecules

TABLE 13.2 Signals With Impact on FOXP3$^+$ Treg Induction, Maintenance, and Suppression

	Development	Maintenance/ Survival	Suppressive Function
Peptide–MHC II interaction	Yes (high affinity)	Yes	Yes, at least initially
CD28	Yes (crucial)	Yes	Not crucial for induction of suppression but high expression on APCs breaks suppression
CD40	Yes	No	No
CTLA-4	No	No	Yes
GITR	No	Modest positive effect	Breaks suppression
TLR ligands	No	Yes	TLR ligands initially break suppression, but this is followed by induction of enhanced suppression
IL-2	Yes (but not crucial)	Yes (crucial)	High levels break suppression
TGF-β	Not required for thymic differentiation but may be involved in peripheral induction	Yes	Yes (not crucial)

APCs, Antigen-presenting cells; *CTLA-4*, cytotoxic T-lymphocyte antigen 4; *GITR*, glucocorticoid-induced tumor necrosis factor receptor protein; *IL-2*, interleukin-2; *MHC II*, major histocompatibility complex II; *TGF-β*, transforming growth factor-β; *Treg*, regulatory T cell; *TLR*, Toll-like receptor.

of cell adhesion and costimulation are important for function and homeostasis of Treg, including CD18/CD11a, GITR, CD28, and CTLA-4.

Effector CD4 T cells differentiate into various subpopulations, such as Th1, Th2, Th17, and Tfh, in response to specific stimulation and cytokine milieus (Chapter 11). It has become clear that Treg somewhat mirror this process and can also differentiate in response to the same stimuli into a subpopulation specialized to control the matching effector population. Consequently, Treg express transcription factors linked to these fates, such as T-bet (Th1), RORγt (Th17), and BCL6 (Tfh), and this allows Treg to gain expression of relevant chemokine receptors, such as CXCR5, in the case of Tfr cells, enabling them to traverse to the germinal center, where they are able to suppress T-follicular helper (Tfh) cells and the germinal center reaction. Similarly, expression of CCR6 and CXCR3 allows a similar process to occur for Th17-Treg and Th1-Treg, respectively. This process lets Tregs respond to the environment, specifically suppressing Th1, Th2, Th17, and Tfh-cell responses.[6] Furthermore, to the development of Treg that specifically mirror effector T-cell subsets, it has also been demonstrated that Treg travel to nonlymphoid sites, such as skin, adipose tissue, and skeletal muscles, to suppress inflammation. Treg from these sites may represent specialized subtypes of Treg with adapted transcriptional signatures, such as adipose tissue Tregs, expressing the transcription factor peroxisome proliferator-activated receptor-γ (PPAR-γ), which regulates fatty acid metabolism and allows their homeostasis and survival.[12]

Another important aspect of Treg responsiveness to the environment is that Tregs are affected by the microbiota (Chapter 22). Recently, it has been demonstrated that certain commensal organisms, such as *Clostridium* spp. in the gut, have large effects on Treg differentiation. In some cases, this may be indirect via induction of TGF-β production, leading to induction of Treg from naïve T cells, whereas in other cases—microbial metabolites, for instance—short-chain fatty acids directly induce Treg proliferation.[9]

Suppressive Function of Foxp3$^+$ Tregs

The standard assay to analyze Treg suppression is to coculture purified fractions of T cells with Treg and then measure proliferation upon antigenic stimulation in the presence of APC. Such assays show that freshly isolated Foxp3$^+$CD25$^+$ Treg cannot suppress T-cell responses in vitro unless they are first stimulated via the TCR. Once activated, they suppress other CD4 and CD8 T cells, irrespective of their antigen specificities.[7] Foxp3$^+$ Treg can inhibit proliferation and cytokine production of naïve T cells. They can also suppress the function of differentiated Th1 and Th2 cells in vitro and reverse ongoing immunopathology, such as colitis, in vivo.[9] In addition to suppressing T-cell function, Foxp3$^+$ Treg can also suppress B cells, NK cells, and NKT cells.

Foxp3$^+$ Treg likely suppress by multiple mechanisms, including both soluble and cell surface–bound mediators (Fig. 13.4). In vitro studies have shown that Foxp3$^+$ Treg need direct cell-to-cell contact with responder cells and that suppression does not occur if Treg are separated from effector T cells by a semipermeable membrane.[2] Moreover, Foxp3$^+$CD25$^+$ Treg are not prominent producers of either IL-10 or TGF-β in vitro. These features differ from those of Tr1 or Th3 cells, which primarily rely on immunosuppressive cytokines, such as IL-10 and TGF-β, for inhibition.

Although Foxp3$^+$ Treg can suppress effector T cells under APC-free conditions in vitro, presumably by absorbing IL-2, it is reasonable that Foxp3$^+$ Treg in vivo control immune responses also by regulating APC. Indeed, by using two-photon laser-scanning microscopy, it has been shown in vivo that although there are limited contacts between Foxp3$^+$ Treg and effector T cells, stable interactions exist between Foxp3$^+$ Treg and dendritic cells (DCs) during ongoing suppression in lymph nodes. One way that Foxp3$^+$ Treg regulate immune responses may be through competition with effector T cells for access to APC. Foxp3$^+$ Treg have, relative to conventional T cells, a more activated phenotype (e.g., high expression of adhesion molecules) in normal individuals, which gives an advantage when engaging with APC and results in prevention of naïve T-cell priming. Interestingly, Foxp3$^+$ Tregs can modify APC function. APC cultured with Foxp3$^+$ Treg downregulate CD80 and CD86 via a CTLA-4–dependent mechanism and become impaired in their ability to stimulate T cells.[13] Additionally, CTLA-4–expressing Treg can induce production of the enzyme indoleamine 2,3-dioxygenase (IDO), which catalyzes tryptophan to the metabolite kynurenine, which represses T-cell responses. Importantly, CTLA-4 expression by Foxp3$^+$ Treg is important for tolerance in vivo, since mice with deletion of this coinhibitory molecule only in Foxp3-expressing cells develop lethal autoimmunity. Other proposed suppressive mechanisms that involve close contact between Foxp3$^+$ Tregs and target cells include surface-bound TGF-β, perforin, and granzyme B (see Fig. 13.4).[2,13]

Although immunosuppressive cytokines are redundant for suppression in vitro, the in vivo situation seems somewhat different. Recently, the immune suppressive cytokine IL-35 has been implicated in Treg-mediated suppression, and both TGF-β and IL-10 expressed by Foxp3$^+$ Treg are important in preventing IBD in mice. Curiously, adoptive transfer of IL-10–deficient CD25$^+$ Treg failed to protect against colitis, although it could inhibit development of gastritis. Furthermore, although perforin- or granzyme B–expressing Foxp3$^+$ Treg are rare in the spleen, they are abundant in a tumor environment. Taken together, Foxp3$^+$ Treg can use several mechanisms of suppression, depending on the local cytokine milieu and the strength and type of immune response.[13]

Tr1 Cells

Some Foxp3$^-$ suppressive T cells have also been identified. The best characterized are IL-10–secreting Tr1 cells, which are present and functional in humans following bone marrow transplantation and in response to allergens (see Table 13.1).

Tr1 cells were initially generated in vitro from CD4 T cells rendered anergic by chronic stimulation in the presence of IL-10, a potent negative regulator of inflammation and lymphoproliferation.[14] T cells so obtained produce a unique pattern of cytokines distinct from Th1 or Th2 cells, with IL-10 as their signature cytokine. Additionally, Tr1 cells secrete some TGF-β, interferon-γ (IFN-γ), and IL-5, but not IL-4 or IL-2. Tr1 cells can be identified by surface expression of CD49b and LAG-3, but lack Foxp3 expression.[14] It remains unclear if Tr1 cells have a master transcription factor but several transcription factors such as c-Maf, IRF4 and EGF2 have a role in their development and function. Also, antigenic stimulation with immature DC (i.e., low levels of costimulatory molecules) or with DC pretreated with IL-10/TGF-β, confers on naïve CD4 T cells an anergic and suppressive phenotype and has further been reported to suppress humoral immunity.[14]

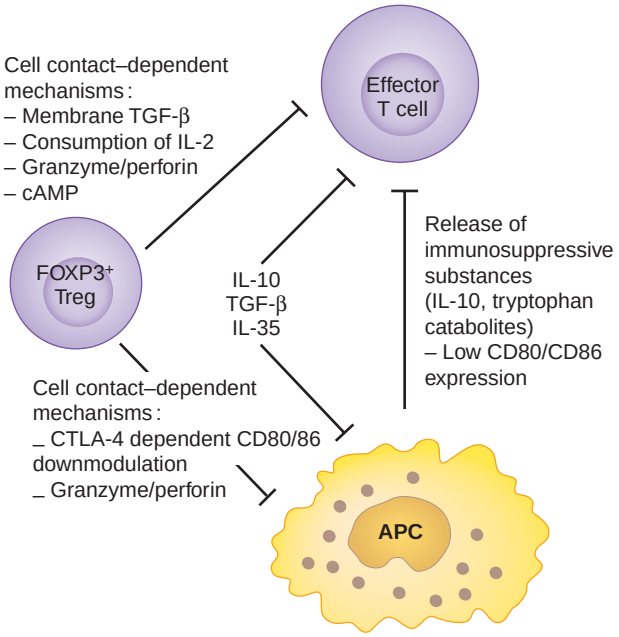

FIG. 13.4 Proposed Suppressive Mechanisms of Foxp3⁺ Regulatory T Cells *(Treg)*. FOXP3⁺CD25⁺ Treg can inhibit many different types of effector cells and can also suppress immune responses at multiple stages, including the initial priming in the lymph node and effector actions at the site of inflammation. The precise mechanism is not known, but numerous theories have been proposed, and it is likely that Foxp3⁺CD25⁺ Treg suppress by several different mechanisms. In vivo Treg can act in a cell contact–dependent manner by competing directly for stimulatory ligands on the antigen-presenting cell *(APC)*, by absorbing essential growth factors, such as interleukin-2 *(IL-2)*, or by directly transmitting an as-yet-uncharacterized negative signal to either the T cell or the APC. Alternatively, Treg can use long-range suppressive mechanisms by means of the cytokines IL-10, IL-35, and transforming growth factor-β *(TGF-β)*. *cAMP*, Cyclic adenosine monophosphate; *CTLA-4*, cytotoxic T-lymphocyte antigen-4; *TGF-β*, transforming growth factor-β.

Tr1 cells also take part in human tolerance. For example, Tr1 cells can be correlated with lack of graft-versus-host disease (GvHD) in bone marrow transplantation, and are also induced after specific immunotherapy in patients with allergies. Data from mice show that Tr1 cells can prevent IBD. Interestingly, Tr1 cells specific for *Escherichia coli* proteins can be isolated from the intestinal mucosa of healthy donors. In pemphigus vulgaris (Chapter 63), Tr1 cells specific for desmoglein-3 can be isolated from pemphigus vulgaris–prone but apparently healthy individuals, whereas patients with pemphigus rarely have such cells. Collectively, Tr1 cells can be induced by autoantigens as well as foreign antigens as a component of the mechanisms that maintain tolerance to both self and nonself.[14]

Treg-of-B cells

Several reports have suggested that repeated contacts with B cells may drive some T cells into a regulatory or suppressive state. These "Treg-of-B cells" produce express CD25 but lack Foxp3 and have IL10-dependent suppressive function.[15] In humans IL10–producing suppressive T cells have also been found among $CD25^+CXCR5^{hi}PD1^{hi}Foxp3^-$ Tfh cells, and these cells, referred to as $CD25^+$ Tf, again appear to have suppressive function dependent on IL-10 and other factors such as CTLA-4; they may have a particular role in suppression of humoral immunity. Initial analysis suggests that $CD25^+$Tf they may not be Tr1 since they lack Lag3 expression.[16] Further work is required to determine the relationship between Tr1, Treg-of-B, and $CD25^+$Tf. They appear to have considerable overlap in phenotype and function and it seems possible that Tconv cells can be driven into a similar suppressive state, with variations in starting cell type and local environment providing some variation in final phenotype.[17]

OTHER SUBSETS OF FOXP3⁻ REGULATORY T CELLS

In addition to CD4 Treg, other types of T cells with immunosuppressive properties have been found; these recognize antigens different from those typically presented to CD4 T cells via MHC class II and may therefore serve to induce tolerance in other settings (see Table 13.1). One example is CD8 T cells with TCR which recognize antigen presented by the mouse MHC class lb Qa-1 molecule (HLA-E in humans; Chapter 5). Qa-1 has limited polymorphisms and can present both foreign and self-peptides. Since Qa-1 peptide complexes on, for example, CD4 T cells can bind to both the inhibitory CD94-NKG2 receptor complex and the TCR on CD8 T cells, total loss of Qa-1 does not lead to development of spontaneous autoimmunity, since loss of CD94-NKG2 inhibitory signaling is largely compensated for by loss of TCR signaling. However, mutation of Qa-1, leading to its loss of CD94-NKG2, but not TCR binding, results in severe lupus-like autoimmunity underpinned by dysregulated Tfh-cell responses. The function of Qa-1–restricted CD8 appears to be largely dependent on perforin expression, as perforin-deficient CD8 T cells fail to mediate the suppression of Tfh cells.[18] While these cells lack expression of Foxp3, it is clear that Helios, a transcription factor also shared by thymic Treg, plays an important role in stabilization of both CD4 Treg and these suppressive CD8 cells; however, despite this area of overlap it appears that CD8 Treg have a closer phenotypic relationship with innate cells such as NKT than with CD4 Treg.[18]

Double-negative T cells are a class of αβ TCR-expressing cells that lack both CD4 and CD8, and make up around 1% of the TCR αβ cells in mice and humans.[19] Much remains unknown about the action of these cells, but it seems that they may be able to suppress CD4 and CD8 T cells by taking up antigen–MHC complexes from APC via trogocytosis, capturing plasma membrane fragments from the immunological synapse and then presenting them to other T cells in the absence of costimulatory signaling and possibly a signal-inducing apoptosis, such as Fas. They may also suppress APCs in a manner similar to Foxp3⁺ Treg by expression of CTLA-4.[19]

γδ T cells with a regulatory phenotype are a subset of the epithelial γδ T cells that can be found in mice. Mice deficient in γδ T cells do not appropriately regulate responses to various pathogens. This inappropriate regulation manifests as immunopathology in conjunction with the robust development of immunity. γδ T cell–deficient mice also show accelerated autoimmune responses in models of systemic lupus erythematosus (SLE) and spontaneously develop dermatitis when bred on certain genetic backgrounds. Commonly, these conditions are driven by αβ T cells, and γδ T cells will inhibit αβ T cells predominantly in the local environment. In humans, who lack an equivalent population of intraepithelial γδ cells, it is plausible

that this immune regulation is provided by other types of suppressive cells. However some forms of non-epithelial γδ cells have also been suggested to have an immunosuppressive role in antitumor immunity.[20]

NKT cells respond to CD1d, the nonclassic class I APC, which binds glycolipids rather than peptides. NKT cells can induce either pro-inflammatory (IFN-γ) or anti-inflammatory (IL-4, IL-10, IL-13) immune responses, but the prerequisites for this choice are ill defined. Nevertheless, under appropriate conditions, NKT cells clearly promote tolerance, which is illustrated in studies of transplantation and oral tolerance (see Table 13.1).[21]

Suppressive Non–T Cells

Recently, interest has also been focused on non–T-cell subsets with suppressive functions. One example of this is B cells with regulatory function (known as *Breg* or *B10 cells*). Breg cells produce the suppressive cytokine IL-10 in both mice and humans. Experiments in mice have demonstrated that these cells have suppressive capacity and can influence the development of autoimmune diseases, such as EAE, collagen-induced arthritis, and colitis. Breg cells appear to be induced in the periphery; to date, a clear transcriptional controller providing a clear transcriptional program has not been identified. This, together with the finding that various subsets of Breg cells differentiate from a wide variety of different B-cell populations (marginal zone, plasma blasts, plasma cells, $CD5^+CD1d^{high}$ B10 cells), has led to the suggestion that Breg cells may not be a lineage in themselves but, rather, a suppressive state that can be induced in all B cells when given the correct stimuli.[22] The suppressive function of Breg cells has largely been attributed to production of IL-10, TGF-β, and IL-35; this may either be via direct action on effector CD4 and CD8 T cells or indirectly by induction of other suppressive populations, such as $Foxp3^+$Tregs and Tr1 cells.[22]

In humans functional or numerical defects in Breg have been found in a variety of autoimmune disease settings such as SLE, rheumatoid arthritis (RA), and psoriasis; this suggests that therapeutic manipulation of Breg may be an attractive strategy for the treatment of autoimmunity.[23]

Myeloid-derived suppressor cells (MDSCs) are broadly divided into polymorphonuclear MDSCs, which are closely related to neutrophils, and monocytic MDSCs, which are related to monocytes, although in both cases, while they share common precursors, mature neutrophils and monocytes cannot convert to MDSCs. MDSCs are often associated with tumor progression and are believed to play an important role in the establishment of the immunosuppressive tumor environment. Accumulation of MDSCs in the tumor environment occurs in a two-step process, with the first being a tumor buildup of immature myeloid precursors and a block on their terminal differentiation to neutrophils or monocytes caused by tumor released growth factors. This is followed by pathological signaling from the tumor stroma, causing the conversion of immature precursors into MDSCs.[24]

MDSCs can be distinguished from other myeloid cells by the high levels of expression of NADPH oxidase (Nox2) and nitric oxide synthase 2 (*nos2*), leading to production of reactive oxygen species (ROS) and nitric oxide (NO) and the transcription factor c/EBPβ. MDSCs have decreased phagocytic capacity, which, in combination with their production of suppressive cytokines, such as IL-10 and TGF-β, leads them to have a suppressive effect on T-cell responses.[25]

DCs have also been demonstrated to have tolerogenic properties in certain circumstances. It is unclear if tolerogenic DC are of a stable lineage or, perhaps like Bregs, represent a particular state of differentiation. Antigen presentation by immature DC may, indeed, be tolerogenic because of lack of costimulation, but antigen presentation by the same cells may be immunogenic once mature and expressing greater levels of costimulatory molecules. Additionally, both pDC found in the tumor microenvironment and $CD103^+$ conventional DC in the lamina propria produce the immune suppressive molecule IDO, which has been demonstrated to aid in the induction of pTreg cells.[26]

CLINICAL RELEVANCE OF REGULATORY T CELLS

Abundant evidence strongly supports Treg as key controllers of self-tolerance, and Treg of various subsets play an active role in the control of almost all types of physiological and pathological immune responses, which also makes them suitable targets for immunotherapy (Tables 13.1 and 13.3).

THERAPEUTIC PRINCIPLES

Adjustment of the Immune Response by FOXP3+ Regulatory T Cell

- Reduction of $FOXP3^+$ Treg suppression or reducing Treg numbers
  - Enhancement of tumor immunity
  - Clearance of infections
  - Improvement of responses to vaccines
- Boosting of $FOXP3^+$ Treg function or increasing Treg numbers
  - Treatment of autoimmunity
  - Treatment of allergic responses
  - Induction of transplantation tolerance
  - Control of excessive immunopathology to foreign antigens (i.e., pathogens)
  - Maintenance of fetomaternal tolerance in pregnancy

TABLE 13.3 Potential Therapeutic Approaches for Treg-Based Therapy

Increase of Treg Numbers or Function	Reduction of Treg Numbers or Function
Ex vivo expansion of pure $FOXP3^+$ Treg with allo- or autoantigens plus growth factors, such as IL-2, and chemicals, such as rapamycin	Transient reduction of $FOXP3^+$ Treg and/or perturbation of suppression in vivo (anti-CD25 antibody, anti-CTLA-4 antibody, or anti-IL-2 antibody)
Ex vivo induction of Treg from conventional T cells by cytokines (IL-10, TGF-β), pharmacological agents, or modified DC	Render effector T cells resistant to suppression (GITR signaling)
In vivo promotion of Treg, rather than effector T cells, using monoclonal antibody treatment or pharmacological agents (anti-CD3 antibody, anti-CD40L antibody, etc.)	

CTLA-4, Cytotoxic T-lymphocyte antigen-4; *DC*, dendritic cell; *GITR*, glucocorticoid-induced tumor necrosis factor receptor protein; *IL-2*, interleukin-2; *IL-10*, interleukin-10; *TGF-β*, transforming growth factor-β; *Treg*, regulatory T cell.

Autoimmunity

As discussed above, Foxp3$^+$CD4$^+$ Treg are engaged in active suppression of autoimmune disease, since their depletion results in spontaneous development of autoimmune diseases in rodents. Furthermore, genetic anomaly of Foxp3 function can be a direct cause of autoimmune diseases in humans, as exemplified in IPEX syndrome.[2] A reduction of Foxp3$^+$ Treg in number or function has been reported in systemic autoimmune diseases, such as SLE, Sjögren syndrome, antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis, Kawasaki disease, systemic sclerosis, psoriasis, autoimmune hepatitis, myasthenia gravis, and IBD.[2,27] Of note, type II autoimmune polyglandular syndrome, which resembles the systemic disease induced in nude mice reconstituted with splenocytes devoid of CD4$^+$CD25$^+$ T cells, is also characterized by Treg functional deficiency. However, studies of MS and type 1 diabetes did not detect any differences between patients and controls, and conflicting data have been reported in RA with regard to both function and numbers of CD25^{high} Treg.[27] The accuracy of the identification of Treg must be taken into account in these human studies, since CD25 and Foxp3 are also expressed to some extent by activated non-Treg T cells in humans.[6]

A general observation is that FOXP3$^+$ Treg increase in number at the site of inflammation. In the case of RA, synovial fluid from patients with ongoing RA was found to contain increased numbers of Foxp3$^+$CD25$^+$ Tregs compared with the levels in peripheral blood. CD25$^+$ Tregs from the synovial fluid of patients with RA are largely functional, although their numbers or suppressive function is apparently not enough to halt the inflammatory process. In contrast, CD25$^+$ Tregs obtained from the blood of patients with MS reportedly have decreased abilities to suppress proliferation of effector T cells. In summary, reduced levels of FOXP3$^+$CD25$^+$ Tregs in peripheral blood are not a general finding in autoimmune diseases and may not necessarily reflect the actual conditions at the site of inflammation. However, if Treg subsets defined by expression levels of CD45RA and Foxp3 are assessed, cytokine-secreting Foxp3^{low} non-Treg cells increase in active SLE.[2] Dynamic changes of Treg subsets in various autoimmune states is an area that still requires further investigation.[6]

Allergic Disease

While Th2 cells play an important role in allergic responses, it is also now clear the IL-4–producing Tfh cells are responsible for the majority of immunoglobulin E (IgE) production. FOXP3$^+$ Treg play an important role in suppressing the development of allergic reactions to innocuous environmental substances. This is best illustrated by IPEX syndrome, which is accompanied not only by organ-specific autoimmune diseases but also by severe eczematous dermatitis, high levels of serum IgE and sometimes eosinophilia.[2] Indeed, FOXP3$^+$ Treg from the blood of healthy donors without allergies suppress both proliferation and production of Th2 cytokines when challenged with specific allergens in vitro. If the same experiment is performed with Treg or Tfr from individuals with allergies, a marked difference is seen, as these Treg fail to downregulate Th2 and Tfh-related responses to allergens. IL-10 production by the FOXP3$^+$ Treg, Tr1 and Breg, has been implicated in the control of allergic responses.[28]

Since the suppressive ability for polyclonal stimuli is retained in patients with allergies, this deficiency is directly related to the allergen the individual is sensitized to, and thus probably does not reflect a general Treg deficiency. The inability to suppress Th2 and Tfh responses induced by birch or grass pollen is aggravated when the allergic reaction is ongoing and effector cells are fully activated, as during spring and summer compared with wintertime. Addition of IL-4 can attenuate the FOXP3$^+$ Treg-mediated suppression of Th2 clones in vitro in the same way as IL-2, which may provide an explanation for the insufficient control of ongoing allergic responses by Treg. Individuals with or without allergies harbor allergen-specific, IL-4–producing effector T cells, IL-10–producing Tr1 cells, and CD25$^+$ Treg, but in different proportions. The balance between Th2, Tfh, and certain Treg populations such as Tfr may, therefore, dictate whether clinical allergy will develop. Indeed, in the setting of curative specific allergy immunotherapy (SIT), allergen-specific IL-10–producing T cells can be induced. Furthermore, children who "grow out" of their allergy to cow's milk have higher numbers of CD4$^+$CD25$^+$ T cells specific for β-lactoglobulin compared with children with clinically active allergies. This suggests that certain allergies can be cured by the induction or expansion of antigen-specific Treg and that the balance between Treg and effector T cells, and Tfr and Tfh in particular, is of importance to prevent allergies.[29]

Transplantation

The ultimate goal of organ transplantation is to establish tolerance of allogeneic organ grafts as effectively and stably as self-tissues, but without the need for continuous general immunosuppression (Chapter 89).[30] Needless to say, Treg have sparked a lot of attention in this area of research. CD25$^+$ Treg were first shown to suppress GvHD in murine models of allogeneic bone marrow transplantation. Similarly, nude mice transplanted with allogeneic skin rejected the graft when reconstituted with CD4$^+$CD25$^-$ T cells alone but retained the graft when large enough numbers of CD25$^+$ Treg were cotransferred. In humans, attempts have been made to prevent GvHD in bone marrow transplantation and induce graft tolerance in organ transplantation with the use of purified FOXP3$^+$ Treg.[30] Another potential way to promote the induction of Treg in organ transplantation is to evaluate the effects of various immunosuppressants in terms of altering the balance between Treg and effector T cells. Different immunosuppressants target different pathways in cell metabolism and can therefore have different effects on cell populations that behave in dissimilar ways, such as effector T cells and Treg cells. Dosage and timing of administration, as well as specific drug combinations, seem to be a promising angle of transplantation immunotherapy with the purpose of inducing graft tolerance and preventing graft rejection. Treg have been shown to home to, and reside within, the graft, which is stably accepted once a dominance of Treg has become established. Treg-mediated transplantation tolerance is not a systemic phenomenon but rather is localized to the graft, and as such, it would not incur the dangers that accompany general immunosuppression.[30]

Tumor Immunity

It is now well known that many of the tumor-associated antigens recognized by a patient's T cells are normal self-constituents, indicating that antitumor immune responses are within the range of FOXP3$^+$ Treg control. Therefore the presence of Treg in the normal immune system may not only prevent autoimmunity but also hamper immune surveillance of cancer.[31] In fact, FOXP3$^+$ Treg, in particular highly

suppressive FOXP3^{high} effector Treg, are abundant in the tumor mass where they likely block any immune response targeting malignant cells. Studies on human malignancies have shown that the frequency of FOXP3$^+$ Treg is increased in tumors of, for example, metastatic melanoma or pancreatic and lung cancers. Moreover, high levels of FOXP3$^+$ Treg cells in the tumor are correlated with a poor prognosis and survival. Treg cells are not only involved in solid tumors but also in hematological malignancies.[31] For example, the architectural pattern of Treg cells in follicular lymphomas is associated with the prognosis of the disease. Whether the elevated levels result from migration of Treg cells into the tumor or from an expansion on the site is not clear, but evidence exists in support of both events. For example, ovarian tumor cells and infiltrating macrophages secrete the Treg-recruiting chemokine CCL22, which binds to CCR4 expressed by Treg cells, and, in addition, many tumors produce TGF-β, which contributes to the maintenance of FOXP3$^+$ Treg cells and may also induce FOXP3 expression in non-Treg cells within the tumor microenvironment. It is now evident that both effector T cells and Treg cells must be assessed in monitoring the efficacy of anticancer immunotherapy.[31]

The involvement of Treg in tumor immunity indicates that antitumor immune responses can be provoked or enhanced by depleting Treg in a host that is otherwise responding poorly. Experimental mouse models have demonstrated that simple depletion of CD25$^+$ Treg cells with anti-CD25 antibody results in tumor eradication, and similar effects can be achieved with in vivo administration of agonistic anti-GITR, anti-CTLA-4–blocking antibodies, or anti-CCR4 cell–depleting antibodies.[31] Depletion of CD25$^+$ T cells also enhances the effect of vaccination with tumor antigens.

Pharmacological agents are another possible way of altering the effector T cell / Treg ratio. For example, fludarabine was shown to selectively decrease the frequency of CD25$^+$ Treg cells in patients receiving chemotherapy. Conversely, previously used regimens, such as administration of exogenous IL-2, are now being reevaluated, since IL-2 may expand Treg cells. As expected from the role of Treg cells in self-tolerance, a caveat of Treg-based therapies of cancer is the possible development of autoimmunity, which may depend on the degree and period of in vivo systemic Treg depletion, as well as the genetic makeup of the host.[31]

In addition to Foxp3-expressing Treg cells, MDSC are believed to have an important role in the establishment and maintenance of the tumor immunosuppressive environment, largely through their production of immunosuppressive cytokines, such as IL-10 and TGF-β, and reactive nitrogen and oxygen species.[32]

Infectious Disease

Immune responses to infectious agents, such as bacteria and viruses, often result in tissue damage, which might be more severe if it were not for the involvement of Treg cells. On the downside, in many cases, Treg cells can contribute to the development of chronic infections. As previously discussed, Treg have the potential to directly respond to microbial products and are believed to be engaged in suppressing responses to infectious agents. A number of studies have shown that the outcome of an infection partly hinges on the proper balance between effector T cells and Treg cells.[33] Adoptive transfer of Treg cells prevents lethal pneumonia in T cell–deficient mice infected with *Pneumocystis jiroveci*, but at the expense of a deficient protective response and microbial clearance. Similarly, Treg suppress Th1 responses in mice infected with *Helicobacter pylori*, thereby limiting the mucosal inflammation but resulting in a higher bacterial load. Human studies have shown that Treg from carriers of *H. pylori* suppress responses to *H. pylori* antigens in vitro and have increased frequencies of CD25^{high} T cells in both the stomach and the duodenal mucosa compared with Treg cells from healthy controls. Taken together, modulation of the infectious response by Tregs can limit tissue damage but may enhance pathogen survival. This sort of compromise may not always be disadvantageous to the host. For example, in murine *Leishmania major* infection, Tregs prevent complete eradication of the parasites, which results in the persistence of low numbers of microbes that have been proven to be essential for the development of T-cell memory and prevention of reinfection. However, this delicate balance can be tipped in favor of the pathogen, which can be seen in the case of malaria and various viral infections such as human immunodeficiency virus (HIV). For example, HIV-specific CD4 and CD8 T-cell responses are substantially suppressed by Tregs in vitro in most individuals with HIV infection. Taken together, future treatments, as well as vaccine design, will need to take Tregs into account, and depending on the pathogen in question, it might be necessary to reduce or enhance the activity of Tregs to achieve a favorable outcome (see Table 13.3).[33]

TRANSLATIONAL RESEARCH

Manipulations of Foxp3$^+$ Treg cells in animal models of, for example, autoimmune disease, cancer, transplantation, and infection, have shown a great potential for modulation of immunological diseases by this subset. The findings in animals have already started to make their way into clinical practice and more is likely to come within the next 5 to 10 years.[2] In cases when immunity needs to be boosted, such as in cancer and during infection, the approach is to identify molecules that inhibit function and differentiation of Treg cells as well as molecules that locally deplete them. Particularly, cancer immunotherapy has proven to be successful (Chapter 80 and 81).[34] Such examples in current therapy are CTLA-4–specific blocking antibody (ipilimumab; MDX-010/Yervoy; Bristol-Myers Squibb, N.Y.); although CTLA-4 expression is not exclusive to Treg cells, it is much more highly expressed and critical to their suppressive function. Furthermore, recent studies have suggested that in addition to blocking the function of CTLA-4, anti-CTLA-4 antibodies may also deplete Treg cells in the tumor environment, but not in the periphery, because of antibody-dependent, cell-mediated cytotoxicity. This depletion specificity to the tumor environment may be attributed to a combination of high levels of CTLA-4 expression and the presence of large numbers of phagocytic cells on the local area.[31] Furthermore, other checkpoint blockade strategies, such as those targeting the cell intrinsic immunosuppressive molecule PD-1 or its ligand PD-L1, have also proven to be effective. Combination therapies are also of great interest. It has been found that anti-CTLA-4 treatment can lead to increased expression of PD-L1 by the tumor itself, which may dampen the effect. Additionally, PD-1 therapy can expand Tregs, enhancing their function and reversing any benefits of PD-1 blocking of effector T-cells.[2] Thus adding both anti-CTLA-4 and anti-PD1 or PD-L1 may have greater benefits, as demonstrated by a recent phase I trial of anti-CTLA-4 (ipilimumab) plus anti-PD-1 (nivolumab) in patients with melanoma.[35] Certain combinations may prove particularly effective, since they target different pathways. Again, in this case,

CTLA-4 may be acting primarily as a cell-extrinsic suppressive molecule on Treg cells, and PD-1 may be acting in *cis* to suppress PD-1–expressing CD4 or CD8 effector cells, and as a result, the combination of the two may provide synergistic effects. As might be predicted, these types of immunomodulatory treatments can lead to severe autoimmune adverse events; however, further studies on both CTLA-4 and PD-1 and other potential checkpoints, such as B- and T-lymphocyte attenuator (BTLA), inducible T-cell costimulator (ICOS), and a range of other inhibitor or stimulatory molecules,[34] either as monotherapies or in combination, may help boost efficacy while reducing adverse events.[34]

Conversely, in cases when tolerance should be reinforced (autoimmunity, transplantation, allergy, fetomaternal tolerance), molecules that either mimic or enhance Treg function and survival are under investigation. In the former case, CTLA-4-Ig (abatacept; Orencia, Bristol-Myers Squibb, N.Y.), a solubilized version of CTLA-4 that, in part, mimics the effect of Treg cells on APC by blocking their expression of B7.1 and B7.2, is currently being used for the treatment of, for example, RA. In addition, cellular therapy, by infusion of ex vivo or manipulated expanded Treg cells, is in small-scale use in patients with GvHD after hematopoietic stem cell transplantation,[2] and early trials of Treg transfer in recent-onset type 1 diabetes are underway. Further to this, transfer of Tr1 cells in patients with Crohn disease is also under investigation.[14] Cell-based therapies are, indeed, a promising strategy for managing various immunological diseases and immune responses; however, several challenges still remain, particularly those relating to the functional stability of ex vivo–expanded or –induced Treg cells.[2]

ON THE HORIZON

- It is clear that regulatory T cells (Treg) in different sites have phenotypic differences, and that a greater understanding of Treg heterogeneity is critical to clarification of their role in human autoimmunity. New approaches such as single-cell RNA sequencing, single-cell epigenomic analysis, and mass cytometry may prove critical to this.
- Specific targeting of tumor-resident Treg without depletion of peripheral Treg is critical to enhancing antitumor therapy while avoiding adverse events.
- Expansion and control of Treg subsets, such as T-follicular regulatory (Tfr) or muscle-resident Treg cells, may be critical to fine control of specific immunological disorders.

Cytokines and Cytokine Receptors

John J. O'Shea, Massimo Gadina, Giuseppe Sciumè, and Françoise Meylan

Cytokines play pivotal roles in controlling the development and functions of a variety of immune and non-immune cells. These include immune regulation, disease pathogenesis, and—increasingly—modulation and treatment of immune-mediated diseases.

The term "cytokine" encompasses factors that are structurally or functionally unrelated. Included among cytokines are a number of different factors produced by lymphoid and non-lymphoid cells that mediate intercellular communication. The term "lymphokine" was originally used to denote products of lymphocytes,[1] whereas "interleukin" was introduced to emphasize the importance of these factors in communication between leukocytes.[2] Although the designation interleukin has remained in use, the term does not accurately convey that many interleukins are made by cells other than leukocytes.

KEY CONCEPTS

Cytokine Characteristics

- Cytokines have pleotropic effects—they bind more than one receptor.
- Cytokines can be redundant—their receptors often share subunits.
- Cytokines can have specific and unique functions—their receptors typically have ligand-specific subunits as well.

Cohen et al.[3] coined the word "cytokine" to emphasize the point that these secreted factors need not be made by one specific cell source. This was an important insight, because many immunologically relevant cytokines are made by non-lymphoid and even non-immune cells, though the argument is easily made that all cells participate in immune responses. Cytokines are thus defined operationally as polypeptides secreted by leukocytes and other cells that act principally on hematopoietic cells, the effects of which include modulation of immune and inflammatory responses. However, there are clear exceptions to even this broad definition (discussed below).

Some definitions distinguish cytokines from hormones and growth factors, which act on non-hematopoietic cells. Cytokines are typically characterized as factors that act locally, whereas hormones are secreted by specialized cells and act at a distance on a restricted set of target cells. Although many cytokines do act locally in an autocrine or paracrine fashion, some enter the bloodstream and can act in a typical endocrine fashion. Consequently, the boundary between cytokines and hormones is rather indistinct. In fact, classic hormones such as growth hormone (GH), prolactin (PRL), and erythropoietin (EPO), and a more recently identified hormone, leptin, are all clearly cytokines, as evidenced by the structure of their receptors and their modes of signaling. Perhaps it is just simplest to accept that cell-cell communication and host defense went hand-in-hand during evolution, and so functional and structural similarities exist among families of molecules that act on the immune, hematopoietic, endocrine, and nervous systems.

CYTOKINE CLASSIFICATION

A major challenge in discussing cytokines is how best to classify them. Due to how they were discovered, complicated nomenclatures and classifications have arisen that can be a barrier to understanding cytokines. Indeed, many were first identified by researchers in different disciplines who derived names based on their original observed functions that may not reflect the full spectrum of a given cytokine's actual biological functions.

One can legitimately group cytokines in different ways, but we have chosen to classify cytokines based on the type of receptor that they bind. Our scheme emphasizes the evolutionary relatedness of cytokines, growth factors, and hormones and highlights similarities in signal transduction. The classification used is adapted from Vilcek[4] and includes the following receptors: the so-called type I (hematopoietin family) and type II (interferon family) cytokine receptors, tumor necrosis factor (TNF) family receptors, interleukin (IL)-1 receptor and the related Toll-like receptors (TLRs), IL-17 receptors, receptor tyrosine kinases, and the transforming growth factor-β (TGF-β) family receptor serine kinases (Fig. 14.1). A seventh group, known as chemokines, forms a separate family and bind seven transmembrane domain receptors (see Chapter 15). This chapter addresses only a selected set of cytokines with important immunological functions.

TYPE I AND II CYTOKINE RECEPTORS (HEMATOPOIETIN FAMILY AND INTERFERON RECEPTORS)

Ligand and Receptor Structure

Cytokines (Table 14.1) that bind the class of receptors termed the type I or hematopoietic cytokine receptor superfamily include hormone-like factors and colony-stimulating factors (CSF) such as GH, PRL, leptin, EPO, thrombopoietin (TPO), granulocyte (G)-CSF, and granulocyte–macrophage (GM)-CSF; and interleukins (IL)-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-11, IL-12, IL-13, IL-15, IL-21, IL-23, IL-27, IL-31, IL-35, and IL-39. Also included in this family are ciliary neurotrophic factor (CNTF), leukemia inhibitory factor (LIF), oncostatin M (OSM), and cardiotropin 1 (CT-1). Closely related are the interferons (IFNs): IFN-αs (13 in humans and 14 in mice), -β, -ε, -κ, -ω (humans), and -ζ (mice) and IL-10-related cytokines: IL-10, IL-19, IL-20, IL-22, IL-24,

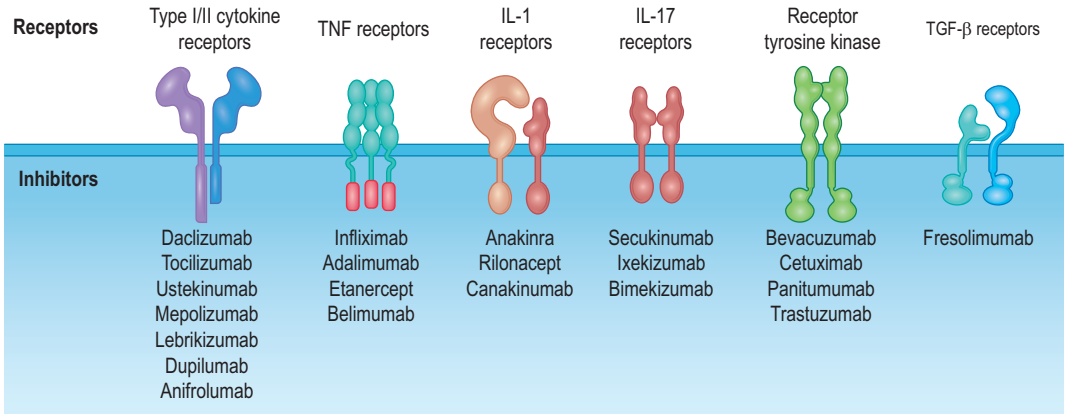

FIG. 14.1 Schematic Representation of Prototypical Receptors of the Six Major Cytokine Receptor Superfamilies and Biological Agents that Block Their Functions.

TABLE 14.1 Selected Cytokines Classified by Receptor Families

Receptor Family	Cytokine	Signaling	Predominant Source	Major Target	Actions	Knockout Phenotype/ Human Mutations
Type I (hemato-poietin)	GH	JAK2, STAT5B	Two GH genes, pituitary, placental	Diverse tissues	Growth, adipocyte differentiation	Dwarfism
	Prl	JAK2, STAT5A	Two Prl genes, pituitary, uterus	Mammary epithelium	Growth, differentiation	Infertility, lactation defects
	Epo	JAK2, STAT5	Kidney, liver	Erythroid precursors	Erythroid differentiation	Embryonic lethal, severe anemia, GOF mutations associated with erythrocytosis
	Tpo	JAK2, STAT5	Liver, kidney	Committed stem cells and megakaryocytes	Platelet growth and differentiation	Severe thrombocytopenia
	Leptin	JAK2, STAT3	Adipocytes	Hypothalamus, thyroid	Satiety, controls metabolic rate	Hyperphagia, obesity
	G-CSF	JAK2, STAT3	Many tissues, macrophages, endothelium, fibroblasts	Committed progenitors	Differentiation, activates mature granulocytes	Neutropenia
	IL-6	JAK1, JAK2, TYK2, STAT1, STAT3	Macrophages, fibroblasts, endothelium, epithelium, T cells, other cells	Liver, B cells, T cells, thymocytes myeloid cells, osteoclasts	Acute-phase reactants proliferation, differentiation co-stimulation	Reduced Ig (esp. IgA), T lymphopenia, impaired acute-phase response, impaired Th17 cell development, reduced estrogen-dependent bone loss *IL6RST* associated with hyperimmunoglobulin E syndrome
	IL-11	JAK1, JAK2, STAT3	Stromal cells, synoviocytes, osteoblasts	Hematopoietic stem cells, hepatocytes, macrophages, neurons	Proliferation	Female infertility *IL11RA* mutations associated with craniosynostosis
	IL-27	JAK1, JAK2, TYK2, STAT1, STAT3, STAT4. STAT5	Activated DCs, macrophages, epithelial cells	T and NK cells, other cells	Enhancement of Th1 responses and IL-10 production; inhibition of Th1, Th2, and Th17 responses	Fatal inflammatory disease during infection
	IL-31	JAK1, STAT3, STAT5	Th2 cells, CD8 T cells	Monocytes, epithelial cells keratinocytes, eosinophils basophils	Induces chemokines, PMN recruitment	
	CNTF[a]	JAK1, JAK2, TYK2, STAT3	Schwann cells	Neuronal	Survival	Progressive atrophy and loss of motor neurons

TABLE 14.1 **Selected Cytokines Classified by Receptor Families—Cont'd**

Receptor Family	Cytokine	Signaling	Predominant Source	Major Target	Actions	Knockout Phenotype/ Human Mutations
	LIF[a]	JAK1, JAK2, TYK2, STAT3	Uterus, macrophages, fibroblasts, endothelium, epithelium, T cells	Embryonic stem cells, neurons, hematopoietic cells	Survival	Decreased hematopoietic progenitors, defective blastocyst implantation, maintenance of stem cell pluripotency, *LIFR* mutations in humans associated with Stuve-Wiedemann syndrome and congenital abnormalities of kidneys and urinary tract
	OSM	JAK1, JAK2, TYK2, STAT3	Macrophages, fibroblasts, endothelium, epithelium	T cells, myeloid cells, liver, embryonic stem cells	Differentiation, acute-phase induction	Thymic hypoplasia, *OSMR* mutations underlie familial primary localized cutaneous amyloidosis
	CT-1	JAK1, JAK2, TYK2, STAT3	T cells, other cells, myocardium	Myocardium	Growth	Motor neuron death
	CRLF1/ CLCF1	JAK1, JAK2, TYK2, STAT3	Lymphocytes, myeloid cells	Neurons	Promotes neuronal cell survival, B-cell growth	Mutations associated with cold-induced sweating syndrome, autonomic dysfunction, kyphoscoliosis, and craniofacial abnormalities
	GM-CSF	JAK1, JAK2, STAT3	T cells, macrophages, endothelium, fibroblasts	Immature and committed myelomonocytic progenitors, macrophages, granulocytes, and DCs	Growth, differentiation, survival, activation	Pulmonary alveolar proteinosis
	IL-3	JAK1, JAK2, STAT5	T cells, macrophages, mast cells, NKT cells, eosinophils	Immature hematopoietic progenitors of multiple lineages	Growth, differentiation, survival	No defects in basal hematopoiesis
	IL-5	JAK1, JAK2, STAT5	Th2 T cells, activated eosinophils, ILCs and NKT cells	Eosinophils, B cells, basophils, mast cells	Proliferation, activation	Decreased eosinophilia, defective CD5, B1-cell development
	IL-2	JAK1, JAK3, STAT5	T cells, NKT cells, ILCs, DCs	T, B, and NK cells, ILCs, macrophages	Proliferation, cytotoxicity IFN-γ secretion, antibody production	Lymphoproliferation[a]
	IL-4[b]	JAK1, JAK3, STAT6	Th2 cells, basophils, mast cells, NKT cells, γ/δ T cells	T cells, B cells, macrophages	Proliferation, Th2 differentiation, IgG1 and IgE production, inhibition of cell-mediated immunity	Defective Th2 differentiation and IgE production, decreased allergic responses
	IL-7	JAK1, JAK3, STAT5	Bone marrow, thymic stromal cells, spleen DCs, keratinocytes, monocytes, macrophages	Thymocytes, T cells, B cells, ILCs	Growth, differentiation, survival	SCID[a]
	IL-9	JAK1, JAK3, STAT5	Th2 and Th9 T cells, ILCs, mast cells, eosinophils	T cells, B cells, mast cell precursors, goblet cells	Proliferation, Th1 inhibition	Impaired goblet cell mucus production
	IL-15[b]	JAK1, JAK3, STAT5	Many cells	T cells (especially memory T cells), NK and NKT cells	Proliferation, survival, activation	Absence of NK and memory cells
	IL-21	JAK1, JAK3, STAT3	T cells, Th17 cells, Tfh cells	T, B, and NK cells, DCs, macrophages, keratinocytes	Isotype switching, plasma cell differentiation, enhancement of CD8 and NK cell responses, promotes Th17 cell differentiation	Decreased numbers of Th17 cells, LOF mutations associated with primary immunodeficiency in humans

Continued

TABLE 14.1 Selected Cytokines Classified by Receptor Families—Cont'd

Receptor Family	Cytokine	Signaling	Predominant Source	Major Target	Actions	Knockout Phenotype/ Human Mutations
	IL-13	JAK1, TYK2, STAT6	Activated T cells, NKT, ILCs, mast cells, basophils	B cells, mast cells, macrophages, epithelial cells, smooth muscle cells	Co-stimulator of proliferation, Increases IgE, CD23 and MHC Class II expression, inhibits cytokine secretion and cell-mediated immunity	Defective Th2 responses and IgE production, decreased allergic responses
	IL-12	JAK2, TYK2, STAT1, STAT3, STAT4, STAT5	Macrophages, DCs, B cells	T cells, NK cells	Th1 differentiation, proliferation, cytotoxicity	Defective Th1 differentiation, susceptibility to bacterial infections* *IL12R* mutations associated with primary immunodeficiency
	IL-23	JAK2, TYK2, STAT1, STAT3, STAT4, STAT5	Macrophages, DCs	T cells, ILCs, macrophages	IL-17 production	Reduced arthritis, inflammation
	IL-35	STAT1 STAT2	Treg cells	T cells	Treg proliferation, suppresses proliferation and function of Th17	Reduced Treg activity
	TSLP	JAK1, JAK2, STAT1 STAT3, STAT5	Epithelial cells, keratinocytes	DCs (human), B cells (mouse)	Th2 differentiation (human)	
Type II	Type I IFNs (IFN-α/β)	JAK1, TYK2, STAT1, STAT2, IRF9	Ubiquitous, but especially plasmacytoid DCs	All cells, immunoregulatory effects on immune cells	Antiviral, anti-proliferative, increases MHC class I activation	Susceptibility to viral infections[a]
	IFN-γ	JAK1, JAK2, STAT1	Th1 T cells, NK cells	Macrophages, endothelium, T cells, NK cells	Activation, increases MHC class II expression, increases antigen presentation	Susceptibility to bacterial infections[a]
	IL-10	JAK1, TYK2, STAT3	Most leukocytes, including macrophages, DCs, T cells, NK cells, and B cells	Myeloid cells, DCs, T cells	Represses immune responses, decreases MHC class II expression, decreases antigen presentation, stimulates mast cells and eosinophils	Exaggerated inflammatory response and autoimmune disease *IL10* and *IL10R* mutations associated with IBD
	IL-19, -20, -24, -26	JAK1, TYK2, STAT1, STAT3	T cells, myeloid cells, NKT cells upregulated in psoriasis and RA	T cells, keratinocytes, epithelial cells	Induces production of inflammatory cytokines, Th2 responses, activation of epithelial cells	
	IL-22	JAK1, TYK2, STAT3	T cells, ILC3	Barrier epithelial cells	Induces anti-bacterial peptides, promotes wound repair, tissue regeneration	Increased gut inflammation
IL-1/TLR	IL-1α/β	IRAK, MyD88, TRAF6, NF-κB	Many cells, esp. macrophages	CNS, endothelial cells, liver, thymocytes, macrophages, T cells	Fever, anorexia, activation of acute-phase reactants co-stimulation, activation, cytokine secretion, differentiation of Th17 cells	Reduced inflammation, cooperates with TNF in host defense
	IL-18	IRAK, MyD88, TRAF6, NF-κB	Many cells, esp. macrophages, keratinocytes, DCs, osteoblasts	T cells, NK cells, macrophages, epithelial cells	Induction of IFN-γ, activation of NK cells, angiogenesis, tumor progression	Increased susceptibility to infection, reduced arthritis
	IL-33	IRAK, MyD88, p38	macrophages, DCs, fibroblasts, adipocytes, smooth muscle cells, endothelial cells, osteoblasts, epithelial cells	T cells, nuocytes, mast cells, basophils, granulocytes, ILC2	Enhances Th2 responses, angiogenesis	
	IL-36	IRAK, MyD88, MAPK	Skin	DCs, T cells	Induce secretion of pro-inflammatory cytokines,	Pustular psoriasis, elevated levels of pro-inflammatory cytokines in skin
	IL-37	IRAK, MyD88, AKT, STAT3	Many cell types and tissues	DCs, macrophages	Suppression of inflammation	

TABLE 14.1 Selected Cytokines Classified by Receptor Families—Cont'd

Receptor Family	Cytokine	Signaling	Predominant Source	Major Target	Actions	Knockout Phenotype/ Human Mutations
	IL-38	IRAK, MyD88, MAPK	B cells	Macrophages	Suppression of inflammation	
IL-17	IL-17A	ACT1, TRAF6, NF-κB, MAPK, C/EBP	Th17 cells, CD8 T cells, γ/δ T cells	Endothelium, many cell types and tissues	Inflammation	Susceptibility to extracellular bacteria
	IL-17B, C, D		Many cell types and tissues	Monocytes, epithelial cells	Inflammation, chondrogenesis	
	IL-17E (IL-25)	ACT1, TRAF6, TRAF2	Mast cells, Th2 cells	Th2 cells	Enhances Th2 responses	Increased susceptibility to helminths
	IL-17 F	ACT1, TRAF6, NFkB, MAPK, C/EBP	Th17 cells, CD8 T cells, γ/δ T cells	Endothelium, many cell types and tissues	Inflammation	
TGF-β receptor serine kinase family	TGF-β 1,2, 3	SMADs	T cells, macrophages, other cell types	T cells, macrophages, other cell types	Inhibits growth and activation, promotes Th17 development	
Receptor tyrosine kinases	Stem cell factor	Ras/Raf/MAPK, stromal cells	Bone marrow	Pluripotent stem cells	Activation, growth	Defective hematopoietic stem cell proliferation, melanocyte production and development
	CSF-1 (M-CSF)	Ras/Raf/MAPK	Macrophages, endothelium, fibroblasts, other cell types	Committed myelomonocytic progenitors	Differentiation, proliferation, survival	Monocytopenia, osteopetrosis, female infertility
	Flt-3 ligand	Ras/Raf/MAPK	Many cell types and tissues	Myeloid cells, especially DCs	Proliferation, differentiation	Reduced repopulating hematopoietic stem cells; reduced B-cell precursors
	IL-32	NF-κB, p38 MAPK	T cells, NK cells, monocytes, epithelia	Monocytes	Induces TNF, IL-1, IL-6, IL-8	
	IL-16		T and B cells, mast cells, eosinophils	CD4 T cells		
	IL-34	ERK, PI3K	Many cell types and tissues	Monocytes	Monocytes, macrophages and osteoclasts differentiation, and proliferation via CSF-1 receptor.	

In cases where STAT5a or STAT5b are designated, the cytokines appear to use both interchangeably.
[a]LIFR is shared by these cytokines.
[b]Note that two forms of the IL-4 and, perhaps, IL-15 receptors exist.

IL-26, and the IFN-related cytokines IL-28A (IFN-λ2), IL-28B (IFN-λ3), IL-29 (IFN-λ1), and IFN-λ4, all of which bind type II receptors. The ligands and receptors in this superfamily are structurally similar and utilize related molecules for signal transduction.[5] A central feature of type I cytokines is the presence of four anti-parallel α helices with two long and one short loop connections arranged in an up–up–down–down configuration, and thus their designation as the α-helical bundle cytokine family.

Structurally, the receptors in the type I family have conserved cysteine residues, a conserved Trp–Ser–X–Trp–Ser motif (where X indicates any amino acid), and fibronectin-like repeats in their extracellular domains. These receptors have a single transmembrane domain and divergent cytoplasmic domains. Within the cytoplasmic portion of these receptors, two segments of homology can be discerned—termed the Box 1 and Box 2 motifs. The membrane proximal domain binds Janus kinases (JAKs; see below). Some of the cytokine receptors are homodimers, such as the receptors for EPO, TPO, PRL, and possibly leptin; whereas other receptors for type I cytokines are heterodimers, containing two distinct receptor subunits. Based on this characteristic, the type I family of receptors can be divided into subfamilies. Each member of the subfamily uses a shared receptor subunit in conjunction with a ligand-specific subunit. For example, the receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 all use a common cytokine γ chain—γc (see Table 14.1)—whereas a common β chain—βc—is shared by IL-3, IL-5, and GM-CSF. Similarly, gp130 is a shared receptor subunit for IL-6 family cytokines: IL-6, IL-11, IL-27, IL-35, IL-39, ciliary neurotrophic factor (CNTF), LIF, OSM, cardiotrophin-1 (CT-1), and cardiotrophin-like cytokine factor 1 (CLCF1). IL-12 and IL-23 also share a receptor subunit, as do members of the IL-10 family.

Other levels of shared receptor usage also exist. For example, the receptors for LIF, CNTF, OSM, and CT-1 all share the LIF receptor subunit. IL-31 and OSM share one receptor chain. IL-2 and IL-15 utilize the same β and γc chains. Conversely, IL-4 can bind two different receptor complexes: one composed of IL-4Rα and γc and a second composed of IL-4Rα and IL-13Rα. IL-13 only utilizes the IL-13 receptor complex for signaling.

The utilization of common receptor subunits explains the phenomenon of shared biological activities (cytokine redundancy) between cytokines that belong to the same subfamily. Within a subfamily, actions distinct for each cytokine can be attributed, at least in part, to the ligand-specific subunits. The pleiotropic effects of a single cytokine can be accounted for by the existence of more than one receptor for a cytokine and expression of receptors on a wide range of cells.

CLINICAL RELEVANCE

Types I and II Cytokine Receptors

- Mutations of genes encoding IL-7R, γc, and JAK3 cause SCID.
- TYK2 and STAT3 mutations cause hyper-IgE syndrome.
- STAT1 mutations cause autosomal dominant chronic mucocutaneous candidiasis with increased susceptibility to mycobacterial and viral infections.
- Mutations of genes encoding IL-12, IL-12R, and IFNγR are associated with susceptibility to intracellular infections.
- Polymorphisms of IL-2R and IL-7R are associated with multiple sclerosis.
- Polymorphisms of IL-23R are associated with IBD.
- Polymorphisms of STAT4 are associated with RA and SLE.
- EPO, G-CSF, and TPO are used to treat cytopenias.
- Anti-cytokine and/or cytokine receptor mAbs are used to prevent transplant rejection and treat several autoimmune and inflammatory diseases.

Family Members and Their Actions

Homodimeric Receptors

Cytokines that use homodimeric receptors include GH, PRL, leptin, EPO, and TPO. EPO is required for erythrocyte growth and development and is widely used to treat anemia. TPO is required for megakaryocyte development and may have a use in the treatment of thrombocytopenia. G-CSF regulates the production of neutrophils (Chapter 39) by acting on committed progenitor cells, supporting the survival of mature neutrophils, and enhancing functional capacity. G-CSF is used clinically to treat patients with granulocytopenia. G-CSF-deficient mice have marked neutropenia, and mutations of the G-CSFR result in severe congenital neutropenia in humans.

Cytokine Receptors Utilizing gp130

Gp130 is ubiquitously expressed and is the shared receptor component for IL-6, IL-11, IL-27, IL-35 IL-39, LIF, OSM, CNTF, CT-1, and the compound cytokine, CRLF1/CLCF1. Targeted disruption of the gene encoding gp130, *Interleukin 6rst (Il6rst)*,[6] is lethal in early embryogenesis, causing defects in myocardial, hematological, and placental development.

Interleukin-6. The IL-6 receptor (IL-6R) consists of an IL-6 binding protein (α chain) (CD126) and membrane-bound gp130. IL-6 associates with IL-6Rα and gp130 to form a hexamer with 2:2:2 stoichiometry. While gp130 is ubiquitously expressed, IL-6Rα is expressed by hepatocytes and immune cells. However, signaling can occur in cells that express IL-6Rα and gp130 as well as cells that express only gp130. In the latter circumstance, IL-6 and the soluble form IL-6Rα can bind gp130, a mechanism termed trans-signaling.[7]

Originally identified as a B cell (Chapter 7) growth factor, IL-6 has a wide array of biological actions on both lymphoid and non-lymphoid cells with the consequences of signaling by the membrane-bound and soluble receptors being distinct. IL-6-deficient mice are susceptible to *Candida* (Chapter 28) and *Listeria* (Chapter 26) infections. IL-6 induces production of immunoglobulins (Chapter 8), including IgE; and $Il6^{-/-}$ mice have normal numbers of B cells with reduced immunoglobulin response to immunization and reduced IgA production (Chapter 33). IL-6 also promotes T-cell growth and differentiation (Chapter 9) and interleukin-6-deficient ($Il6^{-/-}$) mice have reduced numbers of thymocytes and peripheral T cells. IL-6 is important for Th17 differentiation (Chapter 11) and the cytotoxic T-cell response (Chapter 12) to viruses (Chapter 25). IL-6 functions synergistically with IL-3 in hematopoiesis, and $Il6^{-/-}$ mice have reduced numbers of progenitor cells.

IL-6 is a major inducer of fever, inflammation (Chapter 37), and the synthesis of acute-phase proteins (e.g., fibrinogen, serum amyloid A, haptoglobin, C-reactive protein) in the liver. The elevation of the erythrocyte sedimentation rate (ESR) in inflammatory disease largely reflects the accelerated synthesis of these proteins, and IL-6-deficient mice are defective in this response. IL-6 reduces synthesis of albumin and transferrin in the liver and initiates hepatocyte regeneration. IL-6 induces adrenocorticotrophic hormone and anterior pituitary hormones, such as PRL, GH, and luteinizing hormone. IL-6 also plays a role in osteoporosis by affecting osteoclast function. $Il6^{-/-}$ mice are protected from bone loss following estrogen depletion.

Levels of IL-6 in serum are low in the absence of inflammation, but are rapidly increased in response to infection or trauma. Patients with rheumatoid arthritis (RA) (Chapter 53), cardiac myxoma, Castleman disease, and other autoimmune or inflammatory diseases (Chapter 51) have high serum levels of IL-6. This cytokine may also contribute to malignancies such as multiple myeloma (Chapter 79).

IL-6 is produced by many immune and non-immune cells, including fibroblasts, keratinocytes, astrocytes, and endothelial cells. Stimulation of monocytes with IL-1, TNF, or lipopolysaccharide (LPS), in turn, stimulates the expression of IL-6, whereas IL-4 and IL-13 inhibit its production. The *IL6* gene contains binding sites for nuclear factor-κB (NF-κB), nuclear factor for IL-6 (NF-IL-6, or CCAAT element-binding protein), activator protein-1 (AP-1), cAMP response element-binding protein (CREB), and the glucocorticoid receptor.

Monoclonal antibodies (mAbs) targeting IL-6 receptor (tocilizumab, sarilumab) are approved for treatment of RA (Chapter 53), systemic juvenile idiopathic arthritis (Chapter 54), and Takayasu arteritis (Chapter 60). Tocilizumab is also approved for cytokine release syndrome associated with chimeric antigen receptor T-cell therapy (Chapter 81) and is being tested in the treatment of Covid-19-associated cytokine storm (Chapter 31). Satrilizumab is an IL-6R mAb approved neuromyelitis optica. Olamkicept is a soluble gp130 Fc fusion protein being tested presently.

IL6RST mutations are associated with hyper-IgE syndrome (HIES) (Chapter 33).

Interleukin-11. IL-11 and its receptor are widely expressed. IL-11 stimulates stem cells, megakaryocytes, myeloid precursors, and erythroid precursors and promotes B-cell differentiation. It also acts on non-hematopoietic cells, including bone and liver. IL-11 is induced by pro-inflammatory cytokines (IL-1, TNF) and by TGF-β. Oprelvekin is a recombinant IL-11 approved for the treatment of severe thrombocytopenia. *IL11RA* mutations are associated with craniosynostosis.

Interleukin-27. IL-27 is composed of two subunits, designated EBI3 and p28 (also termed IL-30), and signals through gp130 and IL-27Rα (also known as WSX-1/T-cell cytokine receptor). The receptor is expressed on naïve CD4 T cells. IL-27 promotes Th1 differentiation, but also has essential anti-inflammatory properties, inhibiting Th17 differentiation and enhancing IL-10 production.[8]

LIF binds to gp130 in association with the LIF receptor (LIFR), as do OSM, CNTF, and CT-1. Deletion of the *Lifr* gene is embryonically lethal, creating defects in placental architecture and developmental abnormalities in neural tissue and bone. Targeted disruptions of LIF lead to failure of blastocyst implantation. LIF is also critical for the maintenance of stem cell pluripotency in culture. *LIFR* mutations in humans are associated with Stuve-Wiedemann syndrome and congenital abnormalities of kidneys and urinary tract. Deletion of *Osm* in mice results in thymic hypoplasia and decreased bone marrow progenitor activity associated with autoimmunity. *OSMR* mutations underlie familial primary localized cutaneous amyloidosis (Chapter 37) and anti-OSM antibody is being tested in systemic sclerosis (Chapter 56). Mutations of *CRLF1* are associated with cold-induced sweating syndrome, autonomic dysfunction, kyphoscoliosis, and craniofacial abnormalities.

Cytokine Receptors Utilizing the βc Chain

IL-3, IL-5, and GM-CSF bind to a ligand-specific α subunit associated with the common βc receptor subunit (common β subunit, *CSF2RB*, CD131).[9] Mice, but not humans, have a second β chain—βIL3. This species-specific redundancy may explain why gene targeting of βc in the mouse did not result in loss of IL-3 responses, although βc-null mice did have reduced GM-CSF and IL-5 responses. The GM-CSF/IL3/IL5 family is not essential for steady-state production of myeloid cells.

Interleukin-3. IL-3 synergizes with other cytokines to stimulate the growth of immature progenitor cells of all lineages and is termed a multilineage CSF. It promotes survival of macrophages (Chapters 3 and 6), mast cells (Chapter 44), and megakaryocytes. IL-3 is produced mainly by lymphoid cells, mast cells, and eosinophils (Chapter 45). IL-3-deficient mice have no obvious defect in hematopoiesis, suggesting that the major role of IL-3 in vivo may be in the response to stress.

Interleukin-5. IL-5 is unusual in that it is a disulfide-linked homodimer, with each component containing three α-helical bundles. Originally identified as a growth factor for B cells and eosinophils, it is important in allergic disease. *Il5*$^{-/-}$ mice fail to develop eosinophilia in response to parasitic (Chapter 30) or aeroallergen challenge (Chapter 43) and exhibit minimal signs of inflammation and damage to the lungs. IL-5 deficiency does not affect the worm burden of infected mice, indicating that eosinophilia may not play an essential role in the host defense against helminths per se. Both IL-5 and IL-5R knockout mice have decreased numbers of CD5^{+} B cells (B-1 cells) (Chapter 7) and concomitant low serum IgM and IgG3 levels. IL-5 is produced by type 2 innate lymphoid cells (ILC2) (Chapter 3), activated helper T cells of the Th2 phenotype, mast cells, and eosinophils in an autocrine manner and is regulated by neuropeptides.

Mepolizumab and reslizumab are anti-IL-5 mAbs that have been approved for the treatment of severe eosinophilic asthma disease and eosinophilic granulomatosis with polyangiitis. Benralizumab is an anti-IL-5Rα (CD125) antibody approved for treatment of eosinophilic asthma and was granted orphan drug designation for treatment of eosinophilic esophagitis.

Granulocyte–Macrophage-CSF. GM-CSF (encoded by *CSF2*) acts on hematopoietic precursors to support myelomonocytic differentiation and causes rapid expansion of myeloid cells during inflammation. It activates mature neutrophils and macrophages, increasing their microbicidal activity and inducing the production of pro-inflammatory cytokines. Along with IL-4 and IL-13, GM-CSF is important for the in vitro production of dendritic cells (DCs), but also expands immunosuppressive myeloid cells. GM-CSF induces proliferation and activation of eosinophils and upregulates adhesion molecules on fibroblasts and endothelial cells.

Deletion of *Csf2* in mice does not affect steady-state hematopoiesis. Instead, these mice develop lymphoid hyperplasia and alveolar proteinosis due to failure to clear surfactant from the lungs. βc(*Csf2rb*)-deficient mice and humans with *CSF2RA* and *CSF2RB* mutations also develop alveolar proteinosis, characterized by the accumulation of surfactant in the lungs.

GM-CSF is produced by lymphoid cells, including natural killer (NK) (Chapter 12), invariant natural killer (iNKT), T helper 17 (Th17), and ILC3 cells. GM-CSF can be induced by pro-inflammatory cytokines and LPS and is an important driver of immune pathology in murine models of autoimmunity. GM-CSF is not ordinarily detectable in blood except under pathological conditions, such as asthma. Sargramostim is a recombinant form of GM-CSF approved for the treatment of myelosuppression, especially in the context of infection (e.g., fungal). Mavrilimumab and gimsilumab are anti-GM-CSF antibodies being studied in arthritis and Covid-19. Sipuleucel-T is a GM-CSF fusion protein approved for use in a prostate cancer vaccine. Talimogene laherparepvec is an engineered GM-CSF-expressing virus approved for the treatment of melanoma.

Cytokine Receptors Utilizing the γc Chain

IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 all bind to receptors that share a common γc receptor subunit.[10] The γc subunit and the ligand-specific subunits are expressed predominantly on lymphocytes, although they can also be found on other hematopoietic cells. Mutation of the γc gene (*IL2RG*) is responsible for X-linked severe combined immunodeficiency (SCID), characterized by a lack of T cells and NK cells, and poorly functioning B cells (T^{-}B^{+} SCID) (Chapter 34). The lack of γc abrogates signaling by all cytokines that utilize this subunit (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21). The lack of IL-7 and IL-15 signaling is largely responsible for the lack of T and NK cells, respectively.

Interleukin-2. The IL-2 receptor consists of three subunits, α, β, and γc. The latter two are members of the type I cytokine receptor family. NK cells constitutively express these latter two subunits and respond to high doses of IL-2; whereas in T cells, the IL-2Rα subunit is induced upon activation, creating a high-affinity receptor for IL-2. IL-2Rα is also highly expressed on regulatory

T cells (Treg) (Chapter 13), ILC2, and ILC3 cells (Chapter 3) and inducible in activated monocytes and B cells. IL-2Rα, however, is not a member of the type I cytokine receptor family. Rather, it resembles members of the complement family and IL-15R (see below).

IL-2—one of the first cytokines to be intensively studied—is produced by activated T, ILC2, ILC3, and DC (Chapters 3 and 6). It was first identified as an autocrine T-cell growth factor, required for in vitro T-cell proliferation. However, the generation of *Il2*$^{-/-}$ mice and their systemic autoimmune disease unexpectedly revealed the essential role of IL-2 in preserving immune tolerance. IL-2-deficient mice develop massive enlargement of peripheral lymphoid organs, hemolytic anemia, inflammatory bowel disease (IBD) (Chapter 75), and infiltrative granulopoiesis. In addition, the mice have high levels of IgG1 and IgE. The mice succumb to this widespread autoimmune and lymphoproliferative disease, pointing to the nonredundant roles of IL-2 in limiting immune responses. A similar phenotype is seen in humans with IL-2 and IL-2 receptor mutations. Thus, we now appreciate the criticality of IL-2 in promoting the expression of Foxp3 and the development of Treg cells in the thymus and periphery.[11]

Additionally, IL-2 is an important factor in determining the magnitude of T-cell and NK-cell responses in vivo, although other factors also contribute. IL-2 augments the cytolytic activity of T and NK cells, enhances IFN-γ secretion, and promotes Th2 and Th9 differentiation. IL-2 also influences fate determination between follicular helper T (Tfh) cells and non-Tfh effector T cells and inhibits Th17 differentiation.[12] IL-2 is also important in programming CD8 memory T cells, which undergo secondary expansion in viral infections. IL-2 is a growth factor for B cells and induces class switching (Chapter 7) and also activates macrophages.

The *IL2* gene has been extensively characterized and contains binding sites for nuclear factor of activated T cells (NFAT), AP-1, and NF-κB. IL-2 production is also regulated by stabilization of its mRNA.

Recombinant IL-2 (aldesleukin) is approved for the treatment of renal cancer and melanoma; however, its clinical utility is limited by its toxicity, including hepatic dysfunction and capillary or vascular leak syndrome. Given its role in promoting Treg cell homeostasis and inducing Foxp3, low-dose IL-2 is being studied for the treatment of autoimmune disease, with some success in systemic lupus erythematosus (SLE) (Chapter 52). Engineered versions of IL-2 (superkines) and antibodies that preferentially expand Treg cells versus effector T cells have been generated and have been studied in preclinical models.[13] Basiliximab and daclizumab—anti-IL-2Rα mAbs—were approved to prevent rejection of allotransplants. Polymorphisms of *IL2* and *IL2RA* are also associated with autoimmune disease.

Interleukin-4. The two types of IL-4Rs are the type I receptor comprising IL-4Rα in conjunction with γc, which is expressed on hematopoietic cells, and the type II receptor comprising IL-4Rα and IL-13Rα, which is broadly expressed. Type I receptors bind IL-4, and type II receptors bind both IL-4 and IL-13. The loss of IL-4Rα blocks the actions of both IL-4 and IL-13, explaining why gene targeting of IL-4Rα is more severe than IL-4-deficiency. The existence of two receptors helps to explain the diverse actions of IL-4 on both hematopoietic and non-hematopoietic cells. A third receptor subunit, IL13RA2, binds IL-13 with high affinity but not IL-4; it may act as a negative regulator of IL-4 and IL-13 signaling.

IL-4 was discovered as a factor that promotes B-cell differentiation and drives immunoglobulin class switching. More broadly, IL-4, which shares many actions with IL-13, promotes allergic responses and inhibits cell-mediated immune responses. IL-4 promotes differentiation of naïve CD4 T cells into T helper 2 (Th2) cells that produce IL-4, IL-13 and IL-5, and Th9 cells[14] (Chapter 11). In conjunction with CD40 engagement, IL-4 promotes B-cell proliferation and class switching—particularly to IgG1 and IgE in mice and to IgG4 and IgE in humans—and upregulates expression of IgM, MHC class II (Chapter 5), and CD23 (Chapter 77).

In conjunction with GM-CSF, IL-4 is a growth factor for mast cells and basophils, as well as a potent inducer of DC differentiation. IL-4 inhibits macrophage activation and the production of pro-inflammatory cytokines. It antagonizes the effects of IFN-γ, blocks cytokine-induced proliferation of synoviocytes, downregulates the expression of adhesion molecules, and antagonizes the induction of some acute-phase reactants in hepatocytes by IL-6.

IL-4-deficient mice have normal B lymphopoiesis but marked reductions in IgG1 and IgE production in response to parasites. These mice have residual Th2 responses because IL-13, which also binds IL-4Rα, can partially compensate for the defect.

IL-4 is made by the Th2 cells, NK1.1^{+} CD4 T cells, and basophils and mast cells (Chapter 44); ILC2 cells generally do not produce IL-4. A number of transcription factors appear to be important in regulating IL-4 production, including NFAT, NF-IL6, C/EBP, c-MAF, and GATA-3. The *IL4* gene has multiple STAT6 binding sites, consistent with the fact that IL-4 regulates its own expression. Epigenetic control and chromatin remodeling are also important aspects of IL-4 regulation.[15]

Polymorphisms of *IL4* and *IL4RA* are associated with allergy and asthma. The IL-4/IL-13 blocking antibody, dupilumab, is approved for the treatment of atopic dermatitis, asthma, and chronic rhinosinusitis. IL-4 is used to generate DC for tumor vaccines (Chapter 87).

Interleukin-7. The IL-7 receptor consists of the IL-7Rα chain (CD127) in association with γc. It is expressed on both immature and mature thymocytes. Humans with loss-of-function (LOF) mutations of IL-7Rα have T^{-}B^{+} SCID but display normal NK-cell development, unlike individuals with γc mutations (X-SCID) (Chapter 34). Gain-of-function (GOF) mutations of the IL-7Rα chain result in constitutive JAK1 signaling and cell transformation and give rise to T-cell acute lymphoblastic leukemia (Chapter 77).

IL-7 plays an important role in both developing thymocytes and mature T cells, and IL-7Rα expression is tightly regulated during thymocyte development (Chapter 9). IL-7Rα is expressed on double-negative thymocytes, downregulated in double-positive cells, and re-expressed in single-positive thymocytes and mature peripheral T cells. This regulation may relate to IL-7's anti-apoptotic effects and induction of Bcl-2 family members. IL-7 promotes the growth of thymocytes, as well as the expression and rearrangement of TCR genes and the expression of RAG1 and RAG2 (Chapter 4). IL-7Rα is expressed on cutaneous T-cell lymphomas, which also produce this cytokine; thus, the autocrine response to IL-7 may contribute to the growth of these tumors.

IL-7- and IL-7R-deficient mice exhibit impairement in T- and B-cell development. Postnatal B-cell development in *IL7*$^{-/-}$ mice is blocked at the transition to pre-B cells and is arrested even earlier in *IL7ra*$^{-/-}$ mice. Why these B-cell abnormalities do not occur in humans with IL-7Rα mutations is not clear.

IL-7 is produced by a wide variety of cells in the spleen, kidney, stroma, and epithelium. This is consistent with its role in the maintenance of function in both immature and mature lymphocytes.

Clinically, IL-7 may be useful to restore immune function in some congenital immunodeficiencies, after bone marrow transplantation (Chapter 92), or in HIV infection (Chapter 41). Polymorphisms of the *IL7R* gene are associated with multiple sclerosis (Chapter 66) and type 1 diabetes (Chapter 71).

Interleukin-9. IL-9R is expressed predominantly on ILC2, B cells, and non-lymphoid cells, including pulmonary goblet cells. IL-9 has some of the same properties as IL-4. It drives allergic inflammation as well as mucous production in the lungs. IL-9 may also contribute to immunopathology in IBD.

IL-9 synergizes with stem cell factor to promote the growth and differentiation of mast cells and regulate their function. IL-9 potentiates IgE production induced by IL-4 in B cells. IL-9 can inhibit Th1 cytokine production. Although first identified as a T-cell growth factor, a major role of IL-9 in T-cell development has not been established. IL-9 has been reported to have anti-tumor activity, but some lymphoid tumors also produce IL-9, where it may serve as an autocrine growth factor.

IL-9 is produced by activated Th2 cells, ILC2 cells, mast cells, and eosinophils. A subset of Th cells designated Th9 cells preferentially produces IL-9. Their differentiation is promoted by IL-2, IL-4, IL-25, and IL-33. Polymorphisms of *IL9* and *IL9R* are associated with allergy and asthma.

Interleukin-15. The IL-15 receptor consists of the IL-2Rβ and γc subunits in association with a unique ligand-specific subunit, IL-15Rα, which is homologous to IL-2Rα. These receptor proteins contain protein-binding motifs termed "sushi domains." In both human and mouse, the genes encoding receptors are linked.

Given their shared receptor usage, there are many similarities in the actions of IL-2 and IL-15. Like IL-2, IL-15 induces proliferation and cytokine production in T and NK cells. However, IL-15 is critical for NK cell development. In T cells, IL-15 is less efficient than IL-2 in inducing effector memory T-cell differentiation or sensitivity to apoptosis. IL-15Rα is more widely expressed than IL-2Rα, IL-2Rβ, and γc. IL-15Rα is expressed by lymphoid cells, DC, fibroblasts, epithelial, liver, intestine, and other cells and is thought to present IL-15 in *trans* to cells expressing IL-15β and γ chains. IL-15- and IL-15Rα-knockout mice are defective in NK-cell production and in the generation of memory T cells, explaining the absence of NK development in patients with γc mutations.

IL-15 mRNA is expressed in hematopoietic and non-hematopoietic cells but is not typically produced by T cells (HTLV-I-transformed T cells being an exception). Following the pattern seen in IL-7 and IL-9, there are multiple upstream AUGs in the 5′ untranslated portion of the IL-15 message that influence translational regulation. IL-15 protein is also controlled at the level of protein secretion, but this is not completely understood. High levels of IL-15 protein have been reported in patients with RA, sarcoidosis, and ulcerative colitis.

Interleukin-21. IL-21R is broadly expressed on B, T, dendritic, myeloid, and other cells. The genes encoding *IL21* and *IL2* are adjacent to each other in the genome and—like IL-2—IL-21 can activate CD8 T and NK cells, particularly when in conjunction with IL-15 or IL-7. However, IL-21 also opposes a number of actions of IL-2: it promotes Th17 differentiation and, along with IL-6, drives differentiation of Tfh cells. Tfh cells are found preferentially in B-cell follicles where, under control of the transcription factor BCL6, they regulate B-cell development, activation, and class switching. While IL-21 promotes IgG1 production, it represses IgE production. IL-21 also drives terminal B-cell differentiation to plasma cells.

IL-21 is produced by T cells, especially Tfh, Th17, and NKT cells. IL-21 appears to have some anti-cancer properties, and it has been tested in the treatment of melanoma.

Polymorphisms of *IL21* and *IL21R* are associated with multiple autoimmune diseases. LOF *IL21R* mutations are associated with primary immunodeficiency affecting T, B, and NK cells.

Other Heterodimeric Receptors

Interleukin-12. IL-12 is a heterodimer composed of two disulfide-linked polypeptides derived from two distinct genes, p35 (encoded by *IL12A*) and p40 (*IL12B*). While IL-12p35 shares homology with IL-6 and other cytokines, p40 resembles the IL-6 receptor. Thus, IL-12 can be viewed as being produced as a preformed ligand–receptor complex.[8] DC and macrophages are the major producers of IL-12 in response to various pathogens, occupancy of Toll-like receptors, and CD40. IL-12R consists of two chains denoted IL-12Rβ1 and β2, found predominantly on adaptive and innate-like T cells, NK cells, and other ILCs. IL-12Rβ1 and β2 are highly inducible upon T-cell activation, whereas both receptors are constitutively expressed on NK cells and ILC1. IL-12 plays a pivotal role in promoting cell-mediated immune responses. It induces IFN-γ, proliferation and cytolytic activity in innate and adaptive lymphocytes through activation of the transcription factor STAT4.[16,17] In uncommitted CD4 T cells, IL-12 promotes Th1 differentiation.

Humans carrying *IL-12/IL12R* mutations have blunted immune responses and are highly susceptible to infections by intracellular pathogens, typically mycobacteria (Chapter 26).[18] Because of its profound effects on cell-mediated immunity, IL-12 has been used in the treatment of infectious diseases and malignancies. Unfortunately, its utility is limited by toxicity. In this context, clinical trials aimed to selectively deliver IL-12 to tumors are currently under evaluation and IL-12 may have use in vaccines as an adjuvant. IL-12/IL-23 mAb are approved for treatment of psoriasis (Chapter 64) and IBD (Chapter 75).

Interleukin-23. IL-23 is another heterodimeric type I cytokine composed of two disulfide-linked polypeptide chains, p19 (*IL23A*) and IL-12p40 (*IL12B*), which bind to IL-12Rβ1 chain paired to IL-23R. The ability of p19 to complex IL-12p40 to IL-23 helped explain the phenotypic differences observed in mice deficient for IL-12p35 and IL-12p40. These observations ultimately led to the understanding of the role of IL-23 in driving IL-17 expression, providing the missing link between IL-23 and immune-mediated diseases.[19] The IL-23R complex is also expressed by ILCs and innate-like T cells, thereby inducing production of IL-17 and IL-22 via the activation of STAT3.

IL-23 is produced primarily by DC in response to TLR agonists. It regulates epithelial cell barrier functions, host defense against extracellular bacteria, and it contributes to the pathogenesis of autoimmune and autoinflammatory disorders. *IL23R* polymorphisms are associated with IBD, ankylosing spondylitis (Chapter 58), and multiple sclerosis.

Ustekinumab inhibits both IL-12 and IL-23 and is approved for psoriasis, psoriatic arthritis, Crohn disease, and ulcerative colitis; whereas tildrakizumab, risankizumab, and guselkumab

are approved for the treatment of psoriasis and inhibit IL-23 but not IL-12.

Interleukins-35 and -39. IL-35 is a dimer consisting of IL-12 p35 and EBI3. It is preferentially produced by Treg cells. Tregs are also the main cellular target of IL-35, where it induces proliferation and production of IL-10. A synthetic form of IL-35 can reduce the incidence of arthritis in mouse models.

IL-39, a dimer composed of IL-23p19 and EBI3, has been reported to be produced by murine B cells and acts on neutrophils. IL-39's role in humans has not been established.

Interleukin-13. IL-13 has many of the same effects as IL-4 and shares a receptor subunit with IL-4. IL-13-deficient mice have reduced levels of IL-4, IL-5, IL-10, IgE, and eosinophils. In mice deficient for both IL-4 and IL-13, Th2 responses are abolished and parasite clearance is severely impaired. These double-knockout mice default to Th1 responses with concomitant production of INF-γ, IgG2a, and IgG2b. It appears that IL-4 and IL-13 cooperate in promoting Th2 responses, and thus have both overlapping and additive roles.

IL-33 and the neuropeptide neuromedin U promote IL-13 production in ILC2s, whereas another neuropeptide, calcitonin gene-related peptide, limits IL-13 production.[20,21]

IL-13 mAbs include lebrikizumab, tralokinumab, and anrukinzumab and are currently undergoing testing for the treatment of atopic eczema, asthma, and IBD.

Interleukin-31. IL-31 signals through the heterodimeric receptor IL-31RA and oncostatin M receptor (OSMR). IL-31R is expressed on macrophages, DC, eosinophils, basophils, keratinocytes, and peripheral nerves. IL-31 is produced by activated Th2 cells, granulocytes, and mast cells, and its expression is especially prominent in skin. Overexpression of IL-31 results in atopic dermatitis, but surprisingly, IL-31RA-deficient mice showed an increased Th2 response.

Targeting IL-31 with nemolizumab appears to be efficacious in atopic dermatitis and prurigo nodularis.[22] Lokivetamab is approved for use in treating canine atopic dermatitis.

Thymic Stromal:Lymphopoietin. Thymic stromal lymphopoietin (TSLP) is an IL-7-like cytokine expressed by epithelial cells and keratinocytes. Its receptor comprises TSLPR (encoded by *CRLF2*) and IL-7Rα, which is expressed on leukocytes, especially on myeloid and B cells. TSLP exerts its effect through promotion of basophil hematopoiesis. TSLP-treated human DC promote Th2 differentiation. In mice, TSLP contributes to prenatal B-cell development. Elevated TSLP levels have been found in humans and animal models of airway inflammatory disease and atopic dermatitis. Tezepelumab is TSLP mAb being studied in severe asthma.[23]

Interferons

Type I Interferons

The type I IFNs include: IFN-αs, IFN-β, IFN-ε, IFN-κ, IFN-ω (humans), and IFN-ζ (mice).[24] IFN-β and IFN-ω are encoded by single genes, whereas IFN-αs include at least 13 separate genes in humans and 14 in mice, each encoding structurally distinct forms. These intronless genes are all clustered on the short arm of chromosome 9 and appear to have diverged from a common ancestor more than 100 million years ago. All type I IFNs signal via a heterodimeric receptor composed of two subunits—IFNAR1 and IFNAR2. The actions of type I IFNs are similar. These subunits have limited similarity to type I cytokine receptors, although they lack the WSXWS motif.

A major effect of type I IFNs is their antiviral action. Discovered in 1957, they act on all cells to inhibit viral replication and cellular proliferation. It is unclear why there are so many type I genes. Given that their relative potencies differ, it is possible that these genes evolved in response to specific viral pathogens. Alternatively, IFN gene duplication may affect the magnitude of antiviral responses. Type IFNs can also inhibit protein translation. Type I interferons upregulate MHC class I and can block the ability of interferon γ to upregulate MHC class II expression. IFN-α/β increase the cytolytic activity of NK cells. Predictably, *IfnarI* knockout mice are extremely susceptible to infections, even though lymphoid development is normal.

Interferons are produced ubiquitously, although plasmacytoid DC produce exceptionally high levels. Extracellular and intracellular foreign DNA produced by viruses and products generated by bacteria are detected by endosomal pattern recognition receptors including Toll-like receptors, RIG-I like cytosolic sensors (RIG-I/MDA5/MAVS), cyclic GMP-AMP synthase (cGAS), and stimulator of interferon gene (STING), which act to induce transcription of *IFN* genes (Chapter 3). *IFN* genes are bound by multiple transcription factors, including NF-κB, interferon regulatory factors 3 (IRF-3) and IRF7, and STAT1.

Beyond their direct antiviral actions, type I IFNs have broad actions on immune cells, including the regulation of adaptive immune responses. IFNs induce expression of class I and II MHC, co-stimulatory and adhesion molecules, and chemokines. Depending upon timing, type I IFNs can promote or inhibit T-cell proliferation and effector differentiation. B lockade of type I IFN signaling during the chronic phase of viral infection can decrease expression of negative regulatory molecules, enhance IFN-γ responses, and improve viral immunity.

Overproduction of IFNs underlies a collection of heterogenous diseases. Inherited interferonopathies include LOF mutations of genes that metabolize DNA and RNA (TREX1, SAMHD1, RNASEH2, ADAR1) or negatively regulate IFNAR signaling (ISG15, USP18), and GOF mutations in cytosolic RNA or DNA sensors (MDA5 and STING).[25] Human chromosome 21 contains four IFN receptor genes (*IFNAR1*, *IFNAR2*, *IFNGR2*, and *IL10RB*), and interferonopathy is one aspect of Down syndrome. Many autoimmune diseases exhibit high expression of IFN-inducible genes—the "interferon signature"—with lupus being a prominent example.

Anifrolumab—an anti-IFNAR1 mAb—is approved for treatment of lupus.[26] Recombinant IFN-β is approved for the treatment of multiple sclerosis. Recombinant type I IFNαs are approved for the treatment of certain infections (e.g., viral hepatitis). Owing to their anti-proliferative action, IFNαs are also used in the treatment of certain malignancies, particularly hairy cell leukemia.

Interferon-γ

IFN-γ (also termed type II IFN) is a major activator of macrophages and neutrophils, enhancing their ability to kill microorganisms by augmenting their cytolytic machinery. Like IFN-α/β, IFN-γ contributes to antiviral defenses. IFN-γ upregulates MHC class II expression and increases production of reactive oxygen intermediates, including hydrogen peroxide, nitric oxide, and indoleamine dioxygenase. IFN-γ acts on CD4 T cells to promote Th1 differentiation while inhibiting the generation of Th2 cells. It promotes the maturation of CD8 T cells to cytotoxic cells,

augments NK cytolytic activity, regulates B-cell class switching, and activates endothelial cells.

The IFN-γ receptor is a heterodimer composed of IFN-γRα and IFN-γRβ subunits. When one IFN-γ homodimer binds, a complex of two α and two β receptors is created. Mice with a disrupted IFN-γR have normal lymphoid development but are highly susceptible to viral and bacterial infections, especially intracellular microbes. Knockout mice have diminished macrophage MHC class II expression, decreased NK function, and reduced serum IgG2a concentrations. Humans with mutations of *IFNGR* subunits are also susceptible to mycobacterial and *Salmonella* infections.

IFN-γ is produced by Th1 and NK cells. Transcription factors—including STAT4, T-BET, and EOMES—play important roles in *IFNG* gene regulation. IFN-γ has been used to treat patients with immunodeficiencies (e.g., chronic granulomatous disease) and in certain patients with disseminated mycobacterial infections. Emapalumab is an anti-IFN-γ mAb approved for hemophagocytic lymphohistiocytosis (Chapter 36).

Interleukin-10 and related cytokines. The interleukin-10 (IL-10) family of cytokines comprises IL-10, IL-19, IL-20, IL-22, IL-24, IL-26, and type III IFNs and binds to two shared receptors, IL-10RB and IL-20RB.[27] IL-10 binds to IL-10RA and IL-10RB, whereas IL-22 binds to IL-22R and IL-10RB. Type III IFNs bind to IL-28R, IFNLR1, and IL-10RB; IL-26 binds to IL-20RA and IL-10RB; IL-20 and IL-24 bind IL-20RA; and IL-19, IL-20, and IL-24 bind IL-20RA and IL-20RB. The shared usage of receptors helps explain overlapping functions.

Interleukin-10

IL-10R is expressed on macrophages, mast cells, and most other hematopoietic cells. It is inducible in non-hematopoietic cells by stimuli such as LPS. Unlike other cytokines in this family, IL-10 is a disulfide-linked dimer and is made by T, B, NK and DC, macrophages, keratinocytes, bronchial epithelial cells, and other cells. LPS and TNF are inducers of IL-10.

IL-10 serves as an anti-inflammatory and immunosuppressive cytokine, limiting damage during host response to infection. It inhibits macrophage antigen presentation and decreases expression of MHC class II, adhesion molecules, and the costimulatory molecules CD80 (B7.1) and CD86 (B7.2). IL-10 has a direct inhibitory effect on memory Th17 and Th2 cells. It promotes activity of $Foxp3^+$ regulatory T cells and activates mast cells and B cells.

IL-10 is detected in the blood of patients with septic shock and other inflammatory and immune disorders. There is a correlation between levels of IL-10 and autoantibody production in SLE.

IL-10-deficient mice develop autoimmune disease manifested by severe IBD and exaggerated inflammatory responses. Mutations and polymorphism of the *IL10* and *IL10R* genes are associated with IBD in humans. Viral homologues of IL-10 may blunt the immune response to these pathogens.

Interleukin-19, Interleukin-20, Interleukin-22, Interleukin-24, and Interleukin-26. IL-22 acts on tissue epithelial cells, inducing Reg family microbial peptides and promoting tissue regeneration and wound healing. IL-22 is predominately secreted by T cells and ILC3s. IL-22's actions are antagonized by its natural inhibitor, IL-22BP, which is produced by T cells, DC, and eosinophils.

IL-20 subfamily cytokine receptors are preferentially expressed on epithelial cells, including keratinocytes and lung and intestinal epithelial cells. IL-19 and IL-20 are mainly produced by myeloid cells. Myeloid and Th2 cells are cellular sources for IL-24. IL-20 cytokines are upregulated in many diseases, including psoriasis and RA; however, their biological actions remain elusive.

IFN-λs. Type III interferons include IFN-λ1 (IFNL1, IL-29), -λ2 (IFNL2, IL-28A), -λ3 (IFNL3 IL-28B), and IFN-λ4 (IFNL4) in humans; and IFN-λ2 and -λ3 in mice.[24] Receptors for type III IFNs are expressed on barrier epithelial cells and some immune cells. Type III IFNs are less potent and produced at slower kinetics than type I IFNs. Like type I IFNs, type III IFNs induce antiviral responses, but the interferon-stimulated genes induced by type III IFNs are a subset of those induced by type I IFNs. Antiviral responses in the gut are dominated by type III rather than type I IFN signaling. Polymorphisms of *IFNL4* are associated with hepatitis C susceptibility. A frameshift mutation in the promoter of *IFNL4* that results in the loss of IFN-λ4 production is associated with improved clearance of HCV.

Signaling

Neither type I nor type II receptors exhibit intrinsic enzymatic activity. However, the conserved membrane proximal segment of each of these receptors serves as the site at which these receptors bind Janus kinases (JAKs) (Fig. 14.2, Table 14.1).[28] These JAKs play a pivotal role in the downstream signaling via this family of cytokine receptors.

Janus Kinases

There are four mammalian Janus kinases—JAK1, JAK2, JAK3, and TYK2. JAKs have a C-terminal, catalytically active kinase domain that is preceded by a segment termed the pseudokinase domain, which regulates kinase activity. The JAK amino terminus mediates their association with cytokine receptors.

Ligand binding to type I and II receptors induces the aggregation of receptor subunits, which brings JAKs into close proximity, allowing them to phosphorylate and activate each other. After activation, the JAKs phosphorylate tyrosine residues on receptor subunits that recruit proteins with SRC homology-2 (SH2) or phosphotyrosine-binding (PTB) domains. In turn, these proteins are phosphorylated by JAKs resulting in the activation of a number of biochemical pathways. Importantly, phosphorylation of cytokine receptors generates docking sites for a class of SH2-containing transcription factors termed the STATs (see below) (see Fig. 14.2).

The pivotal function of the JAKs is vividly illustrated by mice and humans that are deficient in these kinases. Consistent with the selective association of JAK3 with the common gamma chain, γc; mutations of *JAK3* cause autosomal recessive T^-B^+ SCID (Chapter 34). $Jak3^{-/-}$ mice also exhibit SCID, and mutation of either γc or JAK3 leads to the same functional defects. Multiple JAK inhibitors have been approved as immunomodulatory drugs for various diseases (Chapter 86).[29] The importance of the JAKs is also substantiated by mutations in many leukemias and lymphomas.

$Jak1^{-/-}$ mice die perinatally from neurological defects, but also have a SCID phenotype similar to $Jak3^{-/-}$ mice. This is explained by the fact that γc-containing cytokine receptors utilize JAK1 in association with their ligand-specific receptor subunit. Other cytokines that are dependent on JAK1 include those that use gp130 cytokine receptors and type II receptors (IL-10, IFN-γ, and IFN-α/β). *JAK1* LOF mutations in humans are associated with primary immunodeficiency, whereas GOF mutations are associated with systemic autoimmunity and hypereosinophilic syndrome.

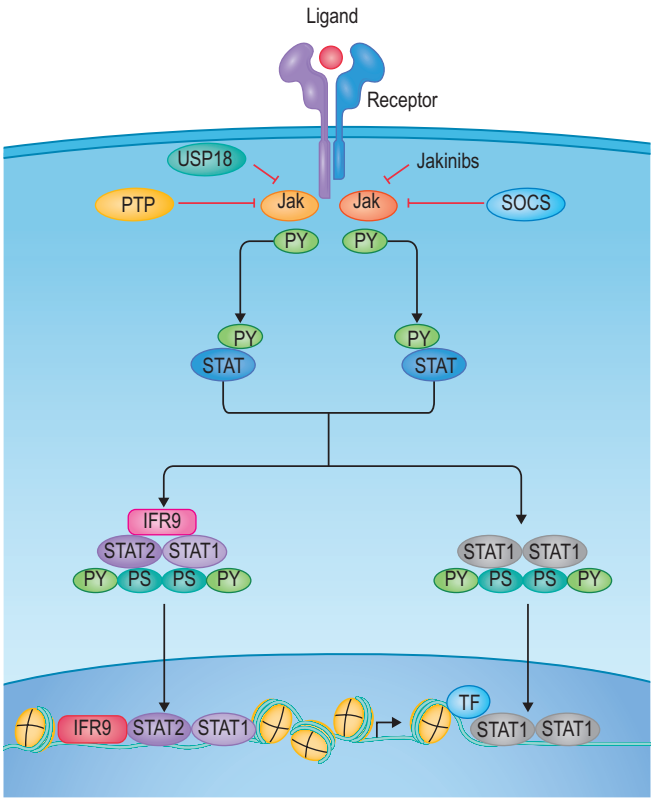

FIG. 14.2 Signal transduction cascade downstream of type I and II cytokine receptors: the role of Janus kinases *(JAKs)*, STATs, and the molecular machinery upstream of cytokine-driven gene regulation. Cytokine binding to this class of receptors activates receptor-associated JAKs. Activated JAKs tyrosine phosphorylate each other and the cytokine receptor *(PY)*, allowing docking of signal transducers and activators of transcription *(STATs)*, which are also tyrosine phosphorylated. STATs dimerize, translocate to the nucleus, bind DNA and regulate transcription. Types I and III interferon activate a complex of STAT1/STAT2/IRF9. Signaling is inhibited by suppressor of cytokine signaling *(SOCS)* proteins, protein tyrosine phosphatases *(PTP)*, and USP18. Janus kinase inhibitors *(Jakinibs)* are small molecule inhibitors approved for the treatment of multiple autoimmune disorders.

Gene-targeting of *Jak2* is embryonically lethal, principally because JAK2 is essential for EPO function and the mice fail to form blood. Conversely, GOF mutations in the pseudokinase domain of *JAK2* underlie most cases of polycythemia vera. A large number of other cytokines signal via JAK2 (Table 14.1).

Tyk2$^{-/-}$ mice have increased viral susceptibility and impaired IL-12 and IL-23 signaling. *TYK2* LOF mutations are associated with immunodeficiency, and *TYK2* polymorphisms reduce the risk of SLE.

STATs

Members of the signal transducer and activator of transcription (STAT) family of DNA-binding proteins serve a key role in transducing signals from cytokine receptors on the cell surface to the nucleus, where they regulate gene transcription. STATs are latent, cytosolic transcription factors that have SH2 domains (phosphotyrosine-binding modules) that allow them to be recruited to phosphorylated cytokine receptors (see Fig. 14.2). Different STATs bind to specific cytokine receptors (see Table 14.1). STATs are themselves tyrosine phosphorylated by JAKs, which promote STAT dimerization. STATs then translocate to the nucleus, bind DNA, and regulate transcription.

There are seven mammalian STATs: STAT1, STAT2, STAT3, STAT4, STAT5A, STAT5B, and STAT6. *Stat* knockout mice document the essential and specific functions of these transcription factors in transmitting cytokine signals. *Stat1*$^{-/-}$ mice develop normally but have extreme susceptibility to viral and some bacterial infections, consistent with the defects seen in mice with mutations of IFNs and IFNRs. *STAT1* LOF mutations in humans result in susceptibility to *Salmonella* and mycobacterial infections. GOF mutations cause chronic mucocutaneous candidiasis, along with viral susceptibility. *Stat2*$^{-/-}$ mice have viral susceptibility, as do humans with *STAT2* LOF mutations. Patients with *STAT2* GOF mutations have autoinflammatory disease and interferonopathy.

Gene targeting of *Stat3* leads to early embryonic lethality, in part due to interference with leukemia inhibitory factor (LIF) function. Conditional knockouts of *Stat3* in myeloid cells display exaggerated inflammatory responses due to failure of IL-10 signaling. STAT3 is also essential for Th17 cells. LOF mutations of *STAT3* underlie Hyper-IgE syndrome or Job syndrome associated with impaired IL-17 production. *STAT3* GOF mutations cause systemic autoimmunity. *STAT3* polymorphisms are associated with IBD (Chapter 75).

STAT4 is activated by IL-12. *Stat4*$^{-/-}$ mice develop normally but have defective Th1 differentiation and IFN-γ production combined with augmented Th2 development. *STAT4* LOF mutations are associated with tuberculosis, atypical mycobacterial susceptibility, and fungal susceptibility. *STAT4* polymorphisms are associated with RA, Sjogren syndrome, and SLE.

STAT5A and STAT5B are highly homologous but nonetheless have different functions. *Stat5a*$^{-/-}$ mice have impaired mammary gland development and failure of lactation, whereas *Stat5b*$^{-/-}$ mice have defective sexually dimorphic growth and growth hormone-dependent regulation of liver gene expression. *Stat5a/5b* doubly-deficient mice manifest increased perinatal lethality, decreased size, female infertility, and impaired lymphocyte development. *Stat5*$^{-/-}$ mice develop lymphoproliferative disease reminiscent of IL-2- and IL-2R-deficient mice related to loss of Treg cells and expansion of Tfh and Th17 cells. Patients with *STAT5B* mutations have short stature and immune dysregulation. Somatic *STAT5* GOF mutations are associated with eosinophilia, urticaria, leukemia, and lymphoma.

STAT6 is activated by IL-4 and IL-13. *Stat6*$^{-/-}$ mice have defective Th2 development with defective IgE responses following parasitic infection. Lack of STAT6 dramatically attenuates allergic and asthmatic disease in animal models.

Attenuation of Type-I and Type-II Cytokine Signaling

Perhaps as important as the triggers that initiate signal transduction are the mechanisms that extinguish responses (see Fig. 14.2). There are several families of proteins involved in downregulating cytokine signaling. Among these are phosphatases, cytokine-inducible inhibitor molecules, and transcriptional repressors. The phosphatase SHP-1 interacts with cytokine receptors and downregulates signaling. Mice with the naturally occurring "motheaten" mutation in SHP-1 die at an early age from autoimmune disease.

Suppressors of cytokine signaling (SOCS) are SH2-containing proteins that bind to either cytokine receptors or JAKs to inhibit signaling. There are at least eight members of this family. Largely

due to systemic hyper-responsiveness to IFN-γ, *Socs-1*$^{-/-}$ mice die within a few weeks of birth. SOCS-2 has been shown to regulate Th2 differentiation and allergic responses and SOCS-3 regulates IL-6's actions including Th17 differentiation.

USP18 and ISG15 negatively regulate IFN signaling. LOF mutations of *USP18* and *ISG15*, along with mutations of *STAT2* that abrogate interaction with ISG15, cause interferonopathy.[30,31]

KEY CONCEPT

Properties of the Tumor Necrosis Factor Receptor Superfamily

- Activation of a TNF receptor can lead to a wide range of effects, from proliferation to apoptosis.
- Transduction of signals through TRAFs leads to the enhancement of survival.
- Signaling through death domains leads to the induction of apoptosis.

THE TNF CYTOKINE AND RECEPTOR SUPERFAMILY

This large family of structurally related ligands, receptors, and inhibitory decoy receptors has various roles in both the immune system and beyond. The first two members of this family discovered were TNF and lymphotoxin-α (LTα; formerly named TNF-β). They are principally secreted by activated myeloid and T cells. They share pro-inflammatory functions and belong to a large family of related molecules that includes CD30 ligand (CD30L), CD40L, FASL, and TRAIL. The TNF cytokine family contains 19 ligands and 29 receptors, each of which exhibits marked differences in tissue expression, ligand specificity, receptor binding, and biological function (Fig. 14.3). This section describes general aspects of TNF and TNFR (TNF receptor) biology, with examples from the best-studied TNF-family members and others that show promising potential in disease intervention and therapy. More complete listings of TNF-family cytokines and their receptors can be found in Tables 14.2 and 14.3. A listing of recombinant cytokines and biological agents currently in clinical use or being tested for clinical application at the time this chapter was written can be found in Table 14.4.

Ligand and Receptor Structure

Much of our understanding of the structural and functional characteristics of the TNF ligand and receptor superfamilies has come from the analysis of TNF (TNFSF2), LTα (TNFSF1), FASL (TNFSF6), and their receptors. All TNF ligands are synthetized as type II transmembrane glycoproteins. TNF and LTα are closely related homotrimeric proteins (32% identity). Human TNF contains an amino-terminal sequence that anchors as a type II cell membrane protein. A secreted form of TNF is generated through enzymatic cleavage of membrane-bound TNF by a metalloproteinase termed TNF-α–converting enzyme (TACE). Both soluble and membrane-bound forms of TNF are homotrimers held together by noncovalent interactions between each subunit's trimerization domain. Both TNF forms are biologically active, but have different affinities for the two TNF receptors and thus can exhibit different biological properties.

Unlike TNF, LTα is synthesized as a secreted glycoprotein homotrimer. It can bind both TNF receptors with affinities comparable to those of TNF and has similar biological effects. LTα1β2 is a heteromeric membrane-bound form of LT (mLT)

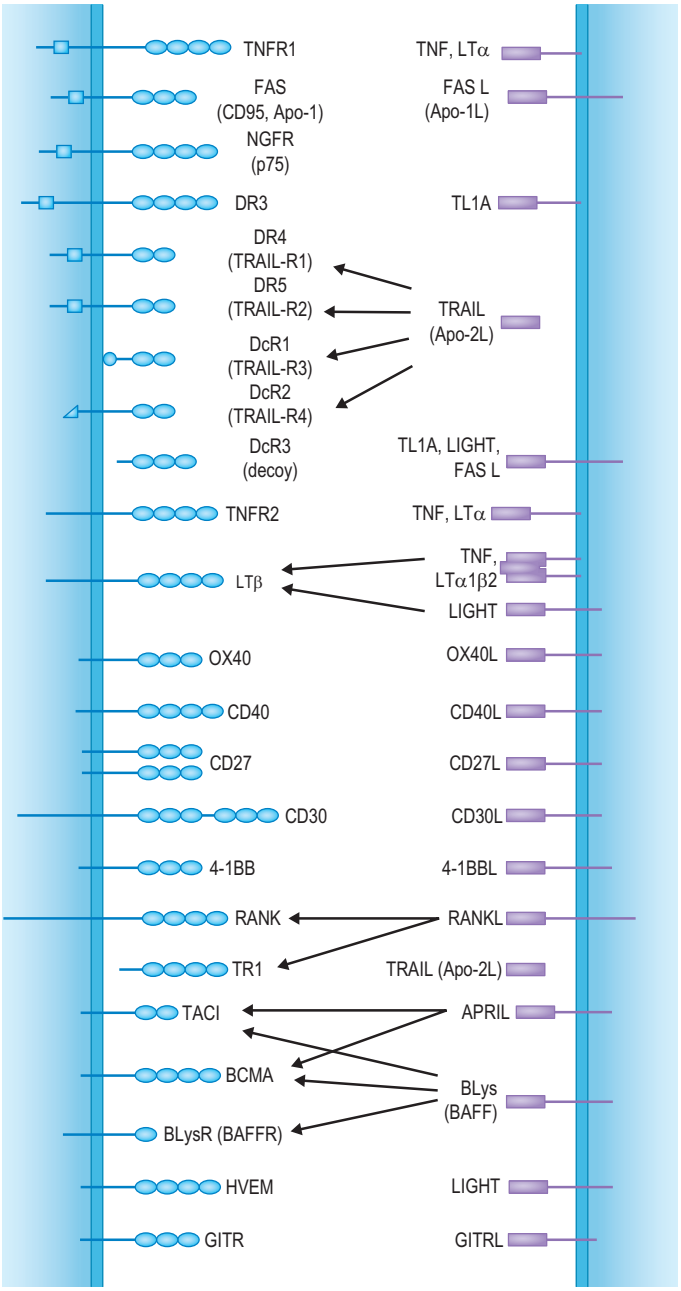

FIG 14.3 Schematic Representation of Tumor Necrosis Factor *(TNF)* Ligand and Receptor Superfamily Members.

composed of LTα subunit noncovalently linked to two molecules of LTβ. mLT is not cleaved by TACE and is thought to exist exclusively as a membrane-bound complex. mLT specifically interacts with another member of the TNF receptor superfamily, the lymphotoxin β receptor (LTβR). TNF and the two LT subunits are encoded by closely linked, single-copy genes situated in the class III major histocompatibility locus at chromosome 6p21.3 in humans (Chapter 5).

All TNF receptor family members are type-I transmembrane glycoproteins. The two receptors for TNF (and LTα) are designated TNFR1 (TNFRSF1A, also known as p60 in humans and p55 in mice) and TNFR2 (TNFRSF1B, also known as p80 in humans and p75 in mice). These receptors are characterized by cysteine repeat domains (CRD) of about 40 amino acids in their amino-terminal extracellular domains, each consisting of

TABLE 14.2 Tumor Necrosis Factor Superfamily Cytokines

Symbol	Common Name	Aliases	Binds to Receptor(s)	OMIM ID	Key Functions	Phenotype Associated With Overexpression	Phenotype Associated With Deficiency	Human Genetic Disease Associations
TNFSF1	Lymphotoxin alpha (Ltα)	LT, TNFB, TNFSF1	TNFR2 (1B), TNFR1 (1A), HVEM (14)	153440	Lymphoid organ formation		Absence of LN and PP, defective GC formation	
TNFSF2	Tumor necrosis factor (TNF)	DIF, TNFA, TNFSF2, CACHECTIN	TNFR2 (1B), TNFR1 (1A)	191160	Inflammation	Wasting syndrome, arthritis	Defective GC formation, resistance to endotoxic shock and experimental arthritis	TNF2 (G-308A) promotor polymorphism associated with increased susceptibility to septic shock, asthma, and RA severity
TNFSF3	Lymphotoxin beta (LTβ)	p33, TNFC, TNFSF3	As a $\beta_2\alpha_1$ heterotrimer with LTα binds to LTβ receptor (3)	600978	Lymphoid organ formation	Ectopic lymphoid organ formation		
TNFSF4	OX40 Ligand	GP34, OX4OL, TXGP1, CD134L, OX-40 L	OX40 (4)	603594	CD4 T-cell expansion, survival, and Th2 development	Increased Th2 responses	Th2 deficiency, blockade improves EAE	Associated with SLE in GWAS
TNFSF5	CD40 Ligand	IGM, IMD3, TRAP, gp39, CD154, CD40L, HIGM1, T-BAM	CD40 (5)	300386	Co-stimulation and differentiation of B cells and APCs	Constitutive expression in B cells or keratinocytes leads to SLE-like syndrome	Immunodeficiency due to defective Ig class switching and germinal center formation	X-linked hyper-IGM syndrome associated with CD40L LOF mutations
TNFSF6	Fas Ligand	FASL, CD178, CD95L, APT1LG1	Fas (6), DcR3 (6B)	134638	Mediator of CD4 T-cell apoptosis due to restimulation and apoptosis in other cell types		Lymphadenopathy and systemic autoimmunity	Autoimmune lymphoproliferative syndrome (ALPS) type Ib
TNFSF7	CD27 Ligand	CD70, CD27L, CD27LG	CD27 (7)	602840	T cell co-stimulation	T cell hyperactivation eventually leading to HIV-like immunodeficiency		
TNFSF8	CD30 Ligand	CD153, CD30L, CD30LG	CD30 (8)	603875

three or four cysteine-rich regions involved in intrachain disulfide bonds. The cytoplasmic domains of these receptors lack intrinsic enzymatic activity. However, the CRDs harbor a specific sequence to which adaptor molecules will bind and activate various signaling pathways that can lead to a remarkably diverse set of cellular responses. These include differentiation, activation, release of inflammatory mediators, and apoptosis.

Family Members and Their Actions

Tumor Necrosis Factor, Lymphotoxin-α, and Receptors

TNF is a major physiological mediator of inflammation and of the physiopathology of septic shock. It is one of the first cytokines made in response to TLR4 stimulation by bacterial (LPS) and other TLR ligands.[32] IFN-γ also induces TNF and augments its effects. TNF upregulates MHC class I and class II expression, activates phagocytes, and induces mononuclear phagocytes to produce IL-1, IL-6, chemokines, and TNF. TNF increases adhesion of cells to endothelium and can be cytotoxic, particularly to tumor cells.

TNF-deficient mice are resistant to septic shock induced by high doses of LPS but have increased susceptibility to bacterial infection. The dual role of TNF in controlling bacterial replication and in septic shock emphasizes the point that, although the goal of an immune response is to eliminate invading microorganisms, the response itself can be injurious to normal host tissues. Septic shock is an extreme example of this. Although the primary source of TNF is mononuclear

TABLE 14.3 Tumor Necrosis Factor Superfamily Receptors (Receptors in Italics Have a C-Terminal Death Domain)

Symbol	Common Name(s)	Aliases	Binds to Ligand(s)	OMIM ID	Key Functions	Phenotype Associated With Deficiency	Human Genetic Diseases
TNFRSF1A	Tumor necrosis factor receptor 1 (TNF-R1)	FPF, p55, p60, TBP1, TNF-R, TNFAR, TNFR1, p55-R, CD120a, TNFR55, TNFR60, TNF-R-I, TNF-R55, MGC19588	TNF-α (2), Lτα (1)	191190	Mediates TNF-induced inflammation (and apoptosis in some cells)	Resistance to TNF-induced arthritis models, resistant to endotoxic shock, increased sensitivity to bacterial pathogens	Periodic fever syndrome (TRAPS) associated with heterozygous extracellular mutations; locus associated with primary biliary cirrhosis and multiple sclerosis in GWAS
TNFRSF1B	Tumor necrosis factor receptor 2 (TNF-R2)	p75, TBPII, TNFBR, TNFR2, CD120b, TNFR80, TNF-R75, p75TNFR, TNF-R-II	TNF-α (2), Lτα (1)	191191	May enhance pro-apoptotic effect of TNFR1	Still susceptible to TNF-induced arthritis models, defective CD8T cell apoptosis after restimulation, increased sensitivity to bacterial pathogens	
TNFRSF3	Lymphotoxin β receptor	LTBR, CD18, TNFCR, TNFR-RP, TNFRSF3, TNFR2-RP, LT-BETA-R, TNF-R-III	LIGHT (14), LTβ (3)	600979	Lymphoid organ formation	No lymph nodes and Peyer patches, defective GC formation	
TNFRSF4	OX40	OX40, ACT35, CD134, TXGP1L	OX40L (4)	600315	T-cell co-stimulation	Defective CD4 T-cell responses	
TNFRSF5	CD40	p50, Bp50, CD40, CDW40, MGC9013	CD40L (5)	109535	Co-stimulation and differentiation of B cells and APCs	Defective Ig class switching and germinal center formation	Autosomal hyper-IgM syndrome associated with LOF mutations; locus associated with RA through GWAS
TNFRSF6	*Fas, CD95*	FAS, APT1, CD95, APO-1	FasL (6)	134637	Apoptosis of restimulated CD4 T cells, B cells, other cells	Defective apoptosis of restimulated CD4 T cells	Autoimmune lymphoproliferative syndrome (ALPS) associated with heterozygous dominant-interfering mutations
TNFRSF6B	Decoy receptor 3	M68, TR6, DCR3, DJ583P15.1.1	FasL (6), TL1A (15), LIGHT (14)	603361	Soluble decoy receptor for FasL, LIGHT, and TL1A; may have a role in tumor immune evasion		Associated with inflammatory bowel disease in GWAS
TNFRSF7	CD27	T14, CD27, S152, Tp55, MGC20393	CD27L (7)	186711	T-cell co-stimulation	Defective T-cell responses	
TNFRSF8	CD30	CD30, KI-1, D1S166E	CD30L (8)	153243	Inhibition of CD8 T-cell effector function		
TNFRSF9	4-1BB, CD137	ILA, 4-1BB, CD137, CDw137, MGC2172	4-1BBL (9)	602250	T-cell co-stimulation	Defective CD8 T-cell responses	Locus associated with ulcerative colitis in GWAS
TNFRSF10A	*Death Receptor 4 (DR4)*	DR4, APO2, MGC9365, TRAILR1, TRAILR-1	TRAIL (10)	603611	Mediates DC and tumor cell apoptosis		
TNFRFRS-F10B	*Death Receptor 5 (DR5)*	DR5, KILLER, TRICK2, TRICKB, ZTNFR9, TRAILR2, TRICK2A, TRICK2B, TRAIL-R2, KILLER/DR5	TRAIL (10)	603612	Mediates DC and tumor cell apoptosis		
TNFRSF10C	Decoy receptor 1	LIT, DCR1, TRID, TRAILR3	TRAIL (10)	603613	GPI-linked decoy receptor, interferes with TRAIL function		
TNFRSF10D	Decoy receptor 2	DCR2, TRUNDD, TRAILR4	TRAIL (10)	603614	Transmembrane decoy receptor, interferes with TRAIL function		

TABLE 14.3 Tumor Necrosis Factor Superfamily Receptors (Receptors in Italics Have a C-Terminal Death Domain)—Cont'd

TNFRSF11A	(Receptor activator of NF-κB) RANK	OFE, ODFR, PDB2, RANK, TRANCER	RANKL (11)	603499	Mediates DC co-stimulation and osteoclast maturation and activation	Osteopetrosis due to osteoclast deficiency, no lymph nodes, impaired B-cell development	
TNFRSF11B	Osteoprotegerin (OPG)	OPG, TR1, OCIF, MGC29565	TRAIL (10), RANKL (11)	602643	Soluble decoy receptor for RANK	Osteoporosis, arterial calcification	
TNFRSF12A	TWEAK-receptor	FN14, TWEAKR	TWEAK (12)	605914			
TNFRSF13B	TACI	TACI	APRIL (13), BAFF (13B)	604907	May inhibit some of the pro-survival effects of BAFF-R	Decreased TI-2 B-cell responses, but B-cell hyperplasia and autoimmunity	LOF mutations associated with familial CVID
TNFRSF13C	BAFF receptor (BAFF-R)	BAFF/BLyS receptor 3	BAFF (13B)	606269		Impaired survival of immature transitional B cells	
TNFRSF14	Herpes virus entry mediator (HVEM)	TR2, ATAR, HVEA, HVEM, LIGHTR	LIGHT (14), herpes viruses	602746			Locus associated with RA and ulcerative colitis in GWAS
TNFRSF16	NGF-R	TNFRSF16, p75(NTR)	NGF (not a TNF family member)	162010	NGF receptor (evolutionary outlier as NGF is not classic TNF family molecule)	Defective sensory neuron innervation, impaired heat sensitivity	
TNFRSF17	B cell maturation antigen (BCMA)	BCM	APRIL (13), BAFF (13B)	109545		Apparently, no B-cell phenotype	
TNFRSF18	Glucocorticoid-induced TNF receptor (GITR)	AITR, GITR, GITR-D	GITRL (18)	603905	T-cell co-stimulation, marker for $CD4^+CD25^+$ Treg cells, modulates Treg function	T-cell hyperactivation	
TNFRSF19	Toxicity and JNK inducer (TAJ)	TROY, TRADE, TAJ-alpha		606122	Similar to EDAR, expressed in skin and brain		
TNFRSF19L	RELT	RELT, FLJ14993			Possible T-cell co-stimulator		
TNFRSF21	*Death Receptor 6 (DR6)*	DR6, BM-018		605732	Negative regulator of B- and T-cell responses	Enhanced T- and B-cell activation	
TNFRSF25	*Death Receptor 3 (DR3)*	*DR3, TR3, DDR3, LARD, APO-3, TRAMP, WSL-1, WSL-LR, TNFRSF12*	*TL1A (15)*	*603366*		Impaired thymic negative selection, reduced immunopathology and T-cell accumulation at site of autoimmune disease	
EDAR	*Ectodysplasin 1, anhidrotic receptor*	DL, ED3, ED5, ED1R, EDA3, EDA-A1R	E1	604095	Tooth, hair, and sweat gland formation	Abnormal tooth, hair, and sweat gland formation	Ectodermal dysplasia
XEDAR	XEDAR: ectodysplasin A2 isoform receptor	EDAA2R, EDA-A2R	EDA-A2	300276

TABLE 14.4 Recombinant Cytokines and Biological Agents Currently in Clinical Use or Being Tested for Clinical Application

Name	Target	Type	Phase	Indications
Anakinra	IL-1 α and β	Human recombinant IL-1Ra	In clinic	Autoinflammatory syndromes, RA
Rilonacept	IL-1 α and β	Human IL-1R–Fc (IgG1) fusion protein	In clinic	Autoinflammatory syndromes, gout, JIA
Canakinumab	IL-1β	mAb	In clinic	Autoinflammatory syndromes, JIA
Bermekimab	IL-1α	mAb	2	AD, HS
Basiliximab	IL-2Rα	mAb	In clinic	Transplantation, uveitis, ulcerative colitis
Mepolizumab, Reslizumab	IL-5	mAb	In clinic	Eosinophilic asthma, EGPA
Benralizumab	IL-5Rα +ADCC	mAb	In clinic	Eosinophilic asthma
Tocilizumab, Sarilumab	IL-6R	mAb	In clinic	RA, JIA, GCA, cytokine release syndrome
Siltuximab	IL-6	mAb	In clinic	Castleman disease
Clazakizumab, Sirukumab	IL-6	mAb	2	RA, Antibody-mediated graft rejection
Ustekinumab	IL-12/23 p40	mAb	In clinic	Psoriasis, PsA IBD,
Tralokinumab, Lebrikizumab, Anrukinzumab	IL-13	mAb	2, 3	AD
Dupilumab	IL-13R/IL4R	mAb	In clinic	Asthma, AD, rhinosinusitis
Secukinumab, Ixekizumab	IL-17A	mAb	In clinic	Psoriasis, PsA, ankylosing spondylitis, HS
Bimekizumab	IL-17A, IL-17F	mAb	3	Psoriasis, PsA
Brodalumab	IL-17RA	mAb	In clinic	Psoriasis
GSK1070806	IL-18	mAb	2	IBD
Tadekinig Alfa	IL-18	IL-18 BP	2	Systemic-onset JIA, Still disease
Guselkumab, Risankizumab Tildrakizumab	IL-23	mAb	In clinic	Psoriasis, PsA, HS (Ph3), IBD (Ph3)
Nemolizumab	IL-31	mAb	2	Prurigo nodularis, atopic dermatitis
Etokimab	IL-33	mAb	2	Chronic rhinosinusitis, atopic dermatitis
SAR440340/REGN3500	IL-33	mAb	2	Asthma

Source: Pipeline (Drug pipeline information database by Citeline, Inc.).

phagocytes, TNF is also produced by T cells, NK cells, and mast cells.

Anti-TNF inhibitor mAbs and recombinant receptors are approved for multiple indications from arthritis to IBD. LTα shares many of the same biological effects as TNF, mainly because of its ability to bind the same receptors. However, LTβR plays a unique role in the development of secondary lymph nodes. As such, unlike with TNF, targeting of lymphotoxin signaling did not result in successful outcomes in clinical trials.

Fas Ligand (FasL) and Its Receptor, Fas/APO-1/CD95

Fas (also known as Apo-1, CD95, or TNFRSF6) is a type I integral membrane protein structurally related to TNFR1. Fas can trimerize and transduce proapoptotic signals upon binding of its ligand, FasL. Similar to TNF, FasL (CD95L) is synthesized as a type II membrane protein, expressed on activated B cells, T cells, and NK cells. Fas-induced apoptosis plays an essential role in the termination of T-cell responses, particularly in the peripheral immune system. Fas can also play a key role in the induction of cell death by cytotoxic T cells (CTLs) and NK cells (Chapter 12), where it functions in conjunction with perforin. Nonapoptotic functions of FasL include lymphocyte costimulation and T-cell differentiation into short-lived effector memory cells.[33,34]

CD40 Ligand and CD40

CD40 is expressed by a variety of cell types, including B cells, DCs, monocytes, macrophages, and endothelial cells. It plays a major

co-stimulatory role in B-cell differentiation, immunoglobulin recombination, and promotes cell survival through the induction of BCL-2 family members. Studies of both CD40-deficient mice and patients with hyper-IgM syndrome (Chapter 33) reveal that its function extends beyond the humoral immune response; CD40 signaling also plays a role in cell-mediated immunity. CD40L (CD154) is expressed by activated CD4 T cells that can bind to and activate CD40 by cell–cell contact.

CD40L on T cells triggers antigen-presenting cell (APC) activation, including the upregulation of the CD28 ligands: B7-1 and B7-2. This indirectly boosts co-stimulation of the T-cell response. Because of its critical role in mediating T-cell help in B-cell class switching and autoantibody formation, blocking CD40L/CD40 interactions has been a therapeutic goal in autoimmune diseases. Clinical trials of a blocking anti-CD40L antibody in SLE showed promising results, but were halted because of thrombotic events likely resulting from the off-target effects of these antibodies on CD40L expressed on platelets. Recent drugs targeting CD40L have been engineered to limit platelet activation. Anti-CD40 mAbs, including iscalimab, are being tested in Sjogren syndrome, SLE, and other indications.[35]

OX40 Ligand and OX40

OX40 is primarily upregulated by T cells upon antigen stimulation, but it is also present on other cell types including NK cells, NKT cells, and neutrophils. OX40L (OX40 ligand) is mainly expressed on APCs, including activated B cells, macrophages, and DCs. Additionally, OX40L has also been found on mast cells, endothelial cells, Langerhans cells, NK cells, and activated T cells. Co-stimulation through OX40 promotes survival, clonal expansion, and cytokine production. Human and mouse studies suggest that OX40 signaling is important in rheumatic diseases, and *OX40L* polymorphisms are associated with Sjögren syndrome. Several blocking antibodies have been generated with encouraging effects in early trials. Given their function, co-stimulatory receptors such as CD40 and OX40 are thought to be strong therapeutic candidates for enhancing the immune response against tumors.

TL1A and DR3

TL1A (TNFSF15) is mainly expressed by APCs upon stimulation by LPS or immune complexes. Its receptor—DR3—is found primarily on activated T cells and innate lymphocytes. This signaling pathway plays critical roles in diverse autoimmune disease models by facilitating T-cell accumulation at the site of inflammation. Both TL1A and DR3 have been reported to be upregulated in human biopsy samples and in animal models of IBD. A blocking TL1A antibody has been developed with a potential application in IBD. The TL1A-DR3 axis appears to play a role in the development of RA. A role for TL1A in host defense against infection has thus far been limited in controlling T-cell responses to *Salmonella* and select viral infections in various mouse models.

Other TNF-Family Cytokines

Other members of the TNF family play various roles in the development and function of the immune system. The vast majority of them participate in co-stimulation of lymphocyte activation. Many of those pathways are now being targeted as therapeutic candidates. The TNF family ligand BAFF (BlyS/TALL1/TNFSF13B) promotes B-cell maturation and antibody secretion and can bind three distinct receptors, TACI (TNFRSF13B), BADD-R (TNFRSF13C), and BCMA (TNFRSF17). BCMA is present on multiple myeloma cells but absent in normal tissue. Belantamab mafodotin—a BCMA mAb conjugated to monomethyl auristatin F—is approved for treatment of multiple myeloma. Brentuximab vedotin is a mAb-drug conjugate targeting CD30, which is approved for the treatment of Hodgkin lymphoma (Chapter 78).

Some TNF members are also involved in development and function outside the immune system. Ectodysplasin A (EDA) affects the formation of tooth germs and sweat glands, and receptor activator of NF-kB ligand (RANKL) regulates bone regeneration and remodeling. The anti-RANKL mAb, denosumab, is approved for treatment of osteoporosis.

Signaling

The TNF receptor superfamily can be divided into three subfamilies on the basis of the types of intracellular signaling molecules recruited (e.g., FADD, TRADD or TRAF) (Fig. 14.4).[36] The cytoplasmic domains of TNFR1, FAS, Death Receptor 3 (DR3), DR4, and DR5 contain a conserved motif termed the death domain (DD). This element is required for recruitment of DD-containing adaptor molecules involved in initiating apoptosis and thus are termed "death receptors" (Chapter 17). The function of some death receptors can be regulated by decoy receptors that bind ligands but lack functional intracellular domains. Other TNF receptors that lack DD (e.g., CD27, CD30, CD40, HVEM, TNFR2, LT-βR, OX-40, 4-1BB) associate with different types of adapter molecules, mostly members of the TRAF (TNFR-associated factor) family.

Death Domains: TRADD and FADD

FAS recruits a Fas-associated protein with death domain (FADD) to its cytoplasmic DD, leading to the rapid formation of the death-inducing signaling complex (DISC), which contains FADD and caspase-8, thereby permitting activation of downstream caspases. Caspase-8 is recruited through a structurally related domain termed the death-effector domain (DED). The FADD DED contains two hydrophobic patches, not present in the DD, that are necessary for binding to the DEDs in the pro-domain of caspase-8 and for apoptotic activity.[37] Under low FASL oligomerization, caspase-8 can participate in preventing necroptosis and can also lead to non-apoptotic signaling.

TNF-induced apoptosis upon TNFR1 ligation is mediated through recruitment of TRADD to the receptor via the DD motifs found in both molecules (Fig. 14.4). In turn, TRADD recruits FADD, also through their DD, leading to the formation of an intracellular DISC.[37] This initiates the apoptotic pathway. TRADD contains a TRAF-binding motif, which contributes to TRAF-dependent activation of inflammatory responses by inducing the NF-kB and mitogen-activated protein kinase (MAPK) pathways. Although cell death in tumor cells can be induced by TNF, the most common result of TNFR1 ligation in primary immune cells is inflammation and, sometimes, protection from TNF-induced apoptosis. Activation of proapoptotic and pro-inflammatory signaling by TNFR1 proceeds in sequential steps.

TNF receptor members lacking DDs contain short peptide consensus sequences that enable recruitment of the TRAF proteins. Structural studies of TRAFs have revealed a mushroom-like structure, with a trimer of the three TRAF subunits stabilized by a stalk-like coiled-coil domain. TRAF proteins recruit and activate protein complexes that ultimately induce

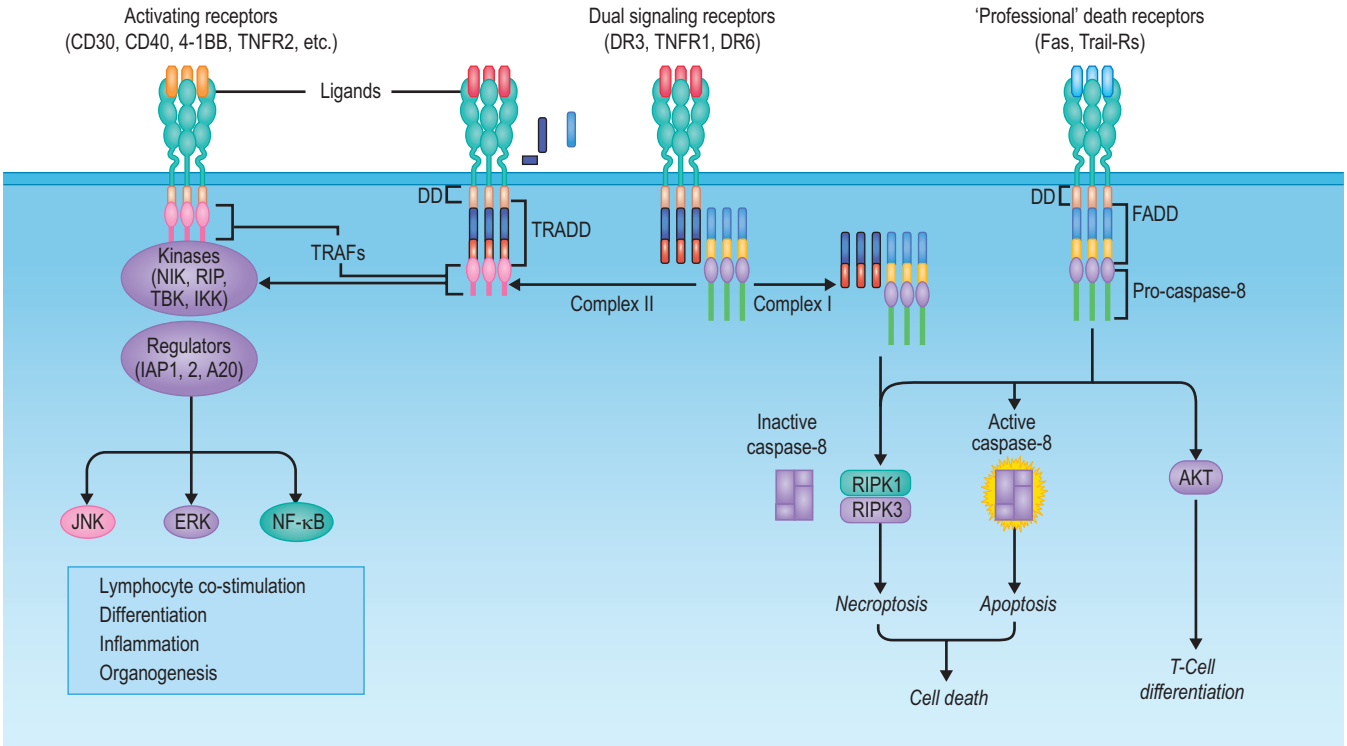

FIG. 14.4 Signal Transduction Cascade Downstream of the Tumor Necrosis Factor *(TNF)* Family of Cytokines and Their Receptors and the Resultant Effects on Immune Cells.

NF-κB and MAPK pathways. Most TRAFs can function as E3 ubiquitin ligases through their RING domain, but detailed mechanisms remain elusive. TRAF6 mediates NF-κB activation by a number of TNF-family receptors. TRAF6 also associates with a protein complex that mediates K63-linked ubiquitination and activation of the inhibitor of κB kinase (IKK) complex, which consists of two catalytic subunits, IKKα and IKKβ, and a regulatory protein IKKγ or nuclear factor κB (NF-κB) essential modulator (NEMO). K63-linked ubiquitination activates IKK, leading to the phosphorylation and degradation of IκB (an inhibitor of NF-κB) and the release of active NF-κB subunits, which translocate to the nucleus and regulate the expression of a wide variety of genes involved in the inflammatory response.

LTβ receptor activates the IKK complex via the serine–threonine kinase NF-κB -inducing kinase (NIK). A naturally occurring LOF NIK mutation in mice termed alymphoplasia (aly) leads to a lack of lymph nodes and Peyer patches and disorganized splenic and thymic structures. This mutation, and the phenotype of LTβR knock-out mice, revealed the critical role of this receptor in normal lymph node development and the formation of "tertiary" lymphoid tissue in inflammation.

When a single TNF-family ligand, such as TNF, binds both a death receptor (TNFR1) and a non–death receptor (TNFR2), a number of mechanisms regulate receptor signaling and the cellular outcome. Rather than functioning in cell death, the physiological function of TNFR2 may be as a co-stimulator of lymphocyte proliferation.[38] Accumulated evidence suggests that TNF-induced death is not only determined by the complex activity of TNFR1-TNFR2 signaling but also from its crosstalk with other, equally intricate signaling networks driven by pattern recognition receptors (PRRs), inflammasomes, and IFNs.[39]

CLINICAL RELEVANCE

TNFR Superfamily Cytokines and Receptors and Disease

- Dominant mutations of the gene encoding TNFR1 are associated with autosomal dominant periodic fever syndromes known as TNFR1-associated periodic syndromes (TRAPS).
- LOF mutations in the gene encoding CD40L are associated with X-linked hyper-IgM syndrome (X-HIM).
- Dominant interfering mutations in *TNFRSF6,* encoding the Fas receptor are associated with autoimmune lymphoproliferative syndrome (ALPS).
- RA often responds to therapeutic use of TNF antagonists.

Clinical Relevance

Mutations affecting *TNFR1* are associated with periodic fever syndromes (Chapter 37). Patients with the TNFR1-associated periodic syndrome (TRAPS) have missense mutations in exons encoding the extracellular regions of the receptor that cause intracellular accumulation and TNF-independent signaling that amplify inflammatory responses through the wild-type TNFR1.[40] Both blocking TNF with etanercept and blocking IL-1 have shown efficacy in reducing symptoms in TRAPS.[41]

The role of Fas signaling in the regulation of the immune system in vivo was confirmed when the naturally arising *lpr* and *gld* mouse strains were found to harbor homozygous mutations of Fas and Fas ligand, respectively. Both of these mouse strains are characterized by lymphadenopathy and splenomegaly due to the accumulation of unusual $CD4^{-}CD8^{-}$ T cells as well as the production of autoantibodies. Heterozygous dominant negative mutations of FAS cause autoimmune lymphoproliferative syndrome (ALPS) (Chapter 34).

The gene encoding CD40 ligand is defective in X-linked hyper-IgM syndrome (X-HIM) in which affected male children generate only IgM antibodies, many of which are autoantibodies (Chapter 33). Patients with X-HIM frequently suffer opportunistic infections, usually bacterial, and have increased susceptibility to cancer.

The physiological role of the BAFF receptor in mouse B-cell development is illustrated by BAFF-R mutations in the A/WySnJ mouse, which lacks peripheral B cells. TACI knockout mice have hyperactive B cells; but in humans, dominant negative TACI mutations have been found in patients with common variable immunodeficiency that affect B-cell numbers and function (Chapter 33), which indicates that in humans TACI serves as a positive modulator of B cells. Belimumab is an anti-BAFF mAb approved for the treatment of SLE.

Polymorphisms of TNFSF15 are associated with susceptibility to IBD. IBD patients have increased levels of TL1A and DR3 at the site of inflammation. In RA, TL1A is specifically elevated early in the disease course and in at-risk first-degree relatives. Interestingly, TL1A levels decline after TNF blockade, placing TL1A downstream of TNF.

The gene encoding EDA is defective in X-linked hypohidrotic ectodermal dysplasia (XLHED), a disorder leading to impaired development of sweat glands and teeth. The most severe clinical outcome for patient with XLHED is lethal hyperthermia occurring after birth. In a small clinical sample, prenatal treatment with protein-replacement therapy *in utero* was able to restore tooth and sweat gland development.[42]

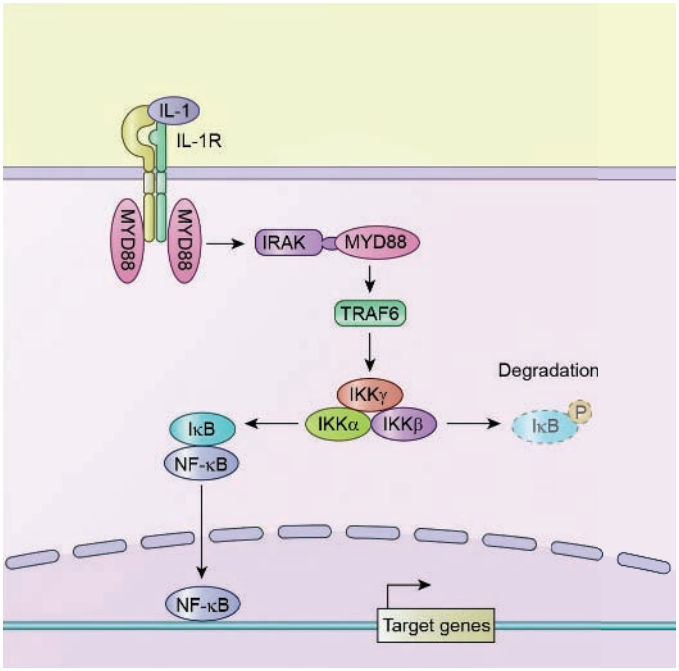

FIG. 14.5 Mechanism of Signal Transduction Downstream of Interleukin (IL)-1R and Related Receptors. IL-1 uses the adapter protein MyD88 to link to TRAF6 to activate inhibitor of kappa B kinases *(IKK)*. Phosphorylated inhibitor of kappa B (IκB) is degraded upon activation, allowing nuclear factor kappa B (NF-κB) to translocate to the nucleus, bind DNA, and regulate transcription.

KEY CONCEPT

Properties of the Interleukin-1R/Toll-Like Receptor Family

- IL-1 plays a key role in fever and acute-phase responses.
- IL-18 augments Th1 differentiation.
- TLRs modulate pro-inflammatory signals in response to bacterial proteins.

INTERLEUKIN-1/TOLL-LIKE RECEPTOR FAMILY

Ligand and Receptor Structure

The IL-1/Toll-like family of receptors comprises 11 members. IL-1 family members are subdivided into three subfamilies based on shared receptor or co-receptor binding. The IL-1 subfamily utilizes co-receptor binding to IL-1R3 and includes IL-1α, IL-1β, IL-33, and IL-1 receptor antagonist (IL-1Ra). The IL-18 subfamily consists of IL-18 and IL-37, both of which bind IL-1R5 (also known as IL-18Rα). The IL-36 subfamily includes IL-36α, IL-36β, IL-36γ, IL-36 receptor antagonist (IL-36Ra), and IL-38, which bind to IL-1R6 (IL-36R). All of these cytokines are produced as pro-peptides and are cleaved to generate the molecule, which binds to the appropriate receptor complex. This excludes IL-1Ra, which possesses a signal peptide and is secreted in a more classical fashion.

Family Members and Their Actions

Interleukin-1

There are two cell surface receptors for IL-1—type I (IL-1R1) and type II (IL-1R2). Both of these bind ligands (Fig. 14.5), but only IL-1R1 transduces signals. Upon ligand binding, IL-1R1 associates with IL-1R accessory protein (IL-1RAcP), which is critical for the initiation of signaling. The IL-1R2 cytoplasmic domain is extremely short and has been suggested to be a "decoy" receptor, competing with IL-1-RI for ligand binding, thus attenuating signaling. Both IL-1Rs are susceptible to proteolytic cleavage near the membrane surface. Thus, they can be found as soluble proteins that can "buffer" IL-1 signaling. These soluble receptors are readily detectable in circulation. IL-1R also associates with a second subunit, IL-1R associated protein (IL-1Rap).

Both IL-1α and IL-1β are synthesized as precursor proteins. IL-1α and IL-1β are structurally similar and have similar actions, but they are regulated differently. IL-1α is processed by a calpain-like converting enzyme but can also be cleaved by granzyme B, neutrophil proteases, and mast cells proteases. The pro-form of IL-1α has biological activity, but cleavage results in increased biological activity.

IL-1β is regulated at the level of mRNA stabilization and translation and it requires proteolytic activation. Pro-IL-1β remains in the cytoplasm until it is cleaved by proteases, such as caspase-1, and then transported out of the cell.

The cleavage of IL-1β occurs in a multi-protein complex called the inflammasome (Chapter 3). The key components of the inflammasome are caspase-1 and a recognition/assembly component NOD-like receptor (NLR). The adapter protein ASC, which contains pyrin and CARD domains, is required to facilitate inflammasome assembly. NLR proteins are intracellular pattern-recognition receptors that contain three domains: a segment with multiple leucine-rich repeats that recognizes the trigger for activation (it remains unclear whether this occurs directly or indirectly), a NACHT domain that leads to ATP-dependent dimerization of the NLR after trigger recognition,

and a protein-protein interaction domain—most commonly a pyrin or a CARD domain—that recruits caspase-1.

The best-studied inflammasome is the NLRP3 inflammasome. Trigger recognition by NLRP3 leads to its dimerization, the recruitment of ASC via interaction of the pyrin domains of NLRP3 and ASC, and the subsequent recruitment of caspase-1 via the CARD domains present in both ASC and caspase-1. Dimerization of caspase-1 upon inflammasome assembly allows for auto-activation by cleavage of its pro-form to generate the active enzyme. The NLRP3 inflammasome can be triggered by ATP, gram-positive bacterial cell wall components, intracytoplasmic DNA, molecules resulting from tissue damage, uric acid crystals, alum, silica, asbestos, and amyloid-β, among others. Cigarette smoke and cholesterol crystals also activate caspase-1.[43] IL-1β secretion can also occur via gasdermin N channels and caspase-8 and caspase-1 cleavage of the precursor gasdermin D. Secretion of IL-1β via gasdermin channels results in cell death via a mechanism known as pyroptosis (Chapter 17).[44]

Similar to IL-1α, IL-β can be cleaved and activated by other proteases, including neutrophil elastase, cathepsin, and proteinase-3 (PR-3). Mast cell proteases, as well as caspase-8, have also been shown to cleave the IL-1β precursor. The mechanism of release of IL-1 and related family members from cells is somewhat mysterious because they lack a classic signal peptide and don't enter the secretory pathway. Although there is some evidence that IL-1β can be cleaved and released from cells without cell death, a large body of evidence suggests that IL-1 family proteins are released from cells upon lysis. Because of the large numbers of cellular insults that result in release of IL-1 and the related proteins that trigger inflammation, it has been proposed that IL-1 family proteins function as "alarmins," acting as sentinels of cellular damage.

Principal functions of IL-1 include the induction of acute-phase protein synthesis, cachexia, and fever. In fact, it was the first endogenous pyrogen to be identified. IL-1 induces the production of IL-6 and chemokines, promotes hematopoiesis, stimulates adhesion of vascular leukocytes to endothelium, and has pro-coagulant effects. Importantly, IL-1 is a critical differentiation factor for Th17 cells, which underscores the significant role of this cytokine in inflammation and inflammatory diseases. IL-1 can activate ILC2s, inducing proliferation and cytokine expression.[45] Unlike Fas and some of the other TNF-family cytokines, IL-1 does not directly induce cell death. Mononuclear phagocytes are the main, but not exclusive, source of IL-1. *IL-1RI*$^{-/-}$ and *IL-1*$\beta^{-/-}$ mice have blunted fever responses to some—but not all—stimuli. Thus, despite the impressive actions of IL-1, it is somewhat redundant in febrile responses.

Interleukin-18

IL-18R is expressed predominantly on T cells, B cells, and NK cells associated with IL-18RacP. IL-18 is primarily produced by DC and macrophages and induces IFN-γ and activates NK cells, acting synergistically with IL-12. These functions are important for its anti-tumor activity, but IL-18 can also promote angiogenesis and tumor progression.[46] IL-18 can induce IL-4 and IL-13 production, indicating a somewhat broader range of action. The IL-18 precursor can be cleaved by the NLR family pyrin domain containing 3 (NRLP3) inflammasome as well as the NLR family CARD domain-containing protein 4 (NRLC4). IL-18-binding protein (IL-18bp) interacts with IL-18 to act as a decoy receptor that attenuates the actions of IL-18.

Interleukin-33

IL-33 (IL-1 F11) binds to the IL-1 receptor-related protein ST2, also designated IL-33R. IL-33 additionally acts as a transcriptional repressor by associating with chromatin. Because of this dual effect, and because of the expression of ST2 on different cell types, IL-33 acts on both immune and non-immune cells. It acts on T and B cells to promote Th2-associated cytokines, including IL-4, IL-5, and IL-13.[47] IL-33 enhances cell survival and promotes degranulation of mast cells, basophils, and granulocytes. Upon cleavage by mast cell proteases, IL-33 can also activate ILC2-inducing cytokine production and eosinophil recruitment.[48,49] IL-33-treated basophils have been shown to suppress arthritic inflammation. IL-33 correlates with RA disease severity, although it is unclear whether IL-33 substantially contributes to RA pathogenesis. IL-33 can act also on endothelial and epithelial cells to induce angiogenesis and production of other cytokines and chemokines.

Interleukin-36

The three members of the IL-36 subfamily—IL-36α, β, and γ—are encoded by separate genes, but all bind to a receptor composed of IL-36R and IL-1RacP. These cytokines are produced by both innate and adaptive immune cells. In turn, IL36s then induce the secretion of other pro-inflammatory cytokines. IL-36-producing cells are highly expressed in the skin and airways and are involved in diseases such as psoriasis and aspergillosis. Anti-IL-36R mAbs are being tested in pustular psoriasis (Chapter 64).

IL-36 receptor antagonist (IL-36Ra, also known as IL-1 F5) antagonizes the three IL-36 family cytokines. LOF *IL-36RA* mutations (deficiency of IL-36 receptor antagonist or DITRA) are associated with generalized pustular psoriasis. Keratinocytes from patients with deficiency of IL-36 receptor antagonist (DITRA) have elevated levels of multiple inflammatory cytokines in lesioned skin.

Interleukin-37

IL-37 (also known as IL-1 F7) broadly and negatively regulates excessive inflammatory responses by suppressing the innate and acquired immune response. IL-37 exists in several splice variants, of which IL-1F 7b has been the most studied. IL-37 binds to IL-18Rα chain, although with a lower affinity than IL-18. IL-37 uses TIR8 (also known as SIGIRR) as a second chain of the receptor. Although IL-18 and IL-37 bind to the same receptor and have a similar capacity to complex with IL-18Acp, IL-37 does not seem to act as a receptor antagonist for IL-18. IL-37 translocates to the nucleus and binds Smad3 (small mothers against dodecaplegia 3), enabling regulation of gene transcription. Cleavage of IL-37 appears to be dependent on caspase-1 and -4. Its anti-inflammatory activity is dependent on mTOR suppression and increased phosphorylation of AMP kinase, thus limiting glycolysis and ATP production. IL-37 tolerizes the DC and macrophages that express IL-37 such that they no longer secrete pro-inflammatory cytokines. IL-37 transgenic mice are resistant to LPS-induced shock.[50]

Interleukin-38

IL-38 (IL-1 F10) has homology with IL-36RA and, similarly, has anti-inflammatory activity. It is released by apoptotic cells to limit macrophage activation and it inhibits IL-17 and IL-22 production. *IL-1F10* polymorphisms are associated with RA, spondyloarthritis and psoriatic arthritis.

Other Members of the Interleukin-1 Family

The remaining members of the IL-1 and IL-1R families are the receptor homologues IL1RAPL2 and TIGIRR. These receptors have limited tissue distribution. TIGIRR is found almost exclusively in the brain, and IL1RAPL2 is found in the brain and a small number of other tissues.[51] Relatively little is known about the function of either TIGIRR or IL1RAPL2; although *IL1RAPL2* mutations cause mental retardation.

Signaling

Ligand binding to IL-1R, IL-18R, and TLRs results in NF-κB activation (see Fig. 14.5). These receptors all associate with the adapter protein MyD88 (Chapter 3). MyD88 has a C-terminal TIR domain and an N-terminal death domain. MyD88 allows the recruitment of IL-1 receptor-associated kinase (IRAK), which also has an N-terminal death domain. In turn, IRAK permits the recruitment and activation of a member of the TNF receptor-associated factor (TRAF) family, TRAF6. This leads to the activation of the serine kinases TAB2, TAK1, and inhibitors of κB kinases, IKKα, and IKKβ. With IKKγ or NEMO, these kinases phosphorylate IκB. The phosphorylated IκB is degraded within proteasomes, thus freeing bound NF-κB for nuclear translocation. Mice deficient in MyD88, IRAK, or TRAF6 have diminished responses to IL-1R/TLR family ligands. Other adapter molecules, including Mal and TRIF, are involved in TLR signaling.

CLINICAL RELEVANCE

Diseases Associated With the Interleukin-1 Family of Cytokines

- Mutations in genes involved in the formation of the inflammasome complexes result in increased secretion of IL-1 and other IL-1-family members.
- Mutations in the gene coding for IL-1 receptor antagonist cause a systemic autoinflammatory disease.

Clinical Relevance

The actions of IL-1 are tempered by the actions of a critical natural cytokine antagonist, IL-1 receptor antagonist (IL-1Ra), which is encoded by the *IL1RN* gene. Mutations in *IL1RN* can cause a systemic autoinflammatory disease, which is denoted Deficiency of IL-1Ra or DIRA.[52] Mutations in *NLRP3* contribute to several hereditary periodic fever syndromes (Chapter 37), including familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome, and neonatal onset multi-organ inflammatory disease (NOMID; in Europe called chronic infantile, neurological, cutaneous, articular syndrome or CINCA). NLRP3 is also called cryopyrin, thus, these disorders have been collectively referred to as cryopyrinopathies.[53] DITRA and other autoinflammatory diseases including NOMID are treated with recombinant IL1Ra, anakinra, and rilonacept, a fusion protein comprising the extracellular domains of IL-1Ra and IL-1RacP linked to the Fc portion of IgG1.

IL-1α, IL-1β, and other members of the IL-1 family are present in the synovial fluid of patients with osteoarthritis. Patients with RA treated with recombinant, human IL-1Ra have reduced joint space narrowing. The anti-IL-1β mAb, canakinumab, is used in the treatment of systemic juvenile idiopathic arthritis. Canakinumab has also been shown to reduce rates of recurrent major cardiovascular events, mortality, hospitalization, and new onset diabetes. The incidence of gout, osteoarthritis, and cancer also appear to be reduced, confirming a role for IL-1β in these pathologies.[54]

Anti-IL-33 mAbs (etokimab, SAR440340) are being tested in chronic rhinosinusitis, atopic dermatitis, asthma, and chronic obstructive pulmonary disease.

Mutations in the alternative inflammasome component, NRLC4, result in autoinflammation due to excessive IL-18 production and, ultimately, macrophage activation syndrome.[55] IL-18bp circulates at serum levels typically 20 to 30 times greater than those of IL-18; thus, IL-18bp is in sufficient excess to block any IL-18 activity. The amount of free IL-18 in the serum correlates with disease severity in several pathologies, including sepsis, SLE, Crohn disease, adult-onset Still disease, and macrophage activation syndrome. Accordingly, neutralization of IL-18 with rIL-18BP can result in the resolution of the hyper-inflammation.

High concentrations of circulating IL-37 have been reported in patients with RA, systemic juvenile idiopathic arthritis, and Still disease. Increased IL-37 and T-cell activation appear to correlate in patients with RA.

IL-38 has been detected in RA synovium and correlates with the expression of the other members of the IL-36 family. Serum concentrations of IL-38 correlate with reduced disease activity in SLE.

INTERLEUKIN-17 RECEPTORS

IL-17 and related cytokines are major inducers of inflammation, serve to recruit inflammatory cells, and provide protection against extracellular fungal and bacterial pathogenic species.

Ligand and Receptor Structure

The IL-17 receptor family comprises five, ubiquitously expressed receptors: IL-17AR, IL-17BR (IL-17RH1), IL-17RL (receptor like), IL-17RD, and IL-17RE.[56] These receptors have a single transmembrane domain and exceptionally large cytoplasmic tails. The ligands in the IL-17 family include IL-17A-F. Structurally, the IL-17 family members contain cystine knots and are structurally related to the nerve growth factor and platelet-derived growth factor.

IL-17A, commonly known as *IL-17*, is the founding member of the *IL-17* family. It is located on human chromosome 6 (mouse chromosome 1)[57] adjacent to the *IL17F* gene. IL-17A and IL-17F are produced by activated CD4, γ/δ, NKT, CD8 T cells, ILC3, and lymphoid tissue-inducer (LTI)-like cells and induced by IL-23 (Chapter 14). Beyond IL-23, Th17 cells are generated by IL-1β, IL-6, IL-21, and TGF-β.

Both IL-17A and IL-17F evoke inflammation largely by inducing the production of chemokines, G-CSF, and GM-CSF, leading to the subsequent recruitment of polymorphonuclear leukocytes. IL-17 also induces production of matrix metalloproteinase by epithelial cells, which may be an important aspect of its pro-inflammatory effects. IL-17 family cytokines are important in host defense against fungi and extracellular bacteria. Abundant data also point to the potential pathogenic roles of IL-17A in models of immune-mediated disease and in human autoimmune disorders.

Less well studied are IL-17B, IL-17C, and IL-17D, which are expressed in a variety of non-hematopoietic tissues, although IL-17D is reportedly produced by CD4 T cells. All of these cytokines are involved in anti-microbial immunity and barrier maintenance, as well as in inflammation promotion and neutrophil recruitment.

IL-17E, also known as IL-25, is constitutively produced by a population of intestinal epithelial cells, termed tuft cells.[58] IL-25 induces the expression of the type 2 cytokines (e.g., IL-4, IL-5, IL-13) in Th2 and ILC2, thereby enhancing mucus production,

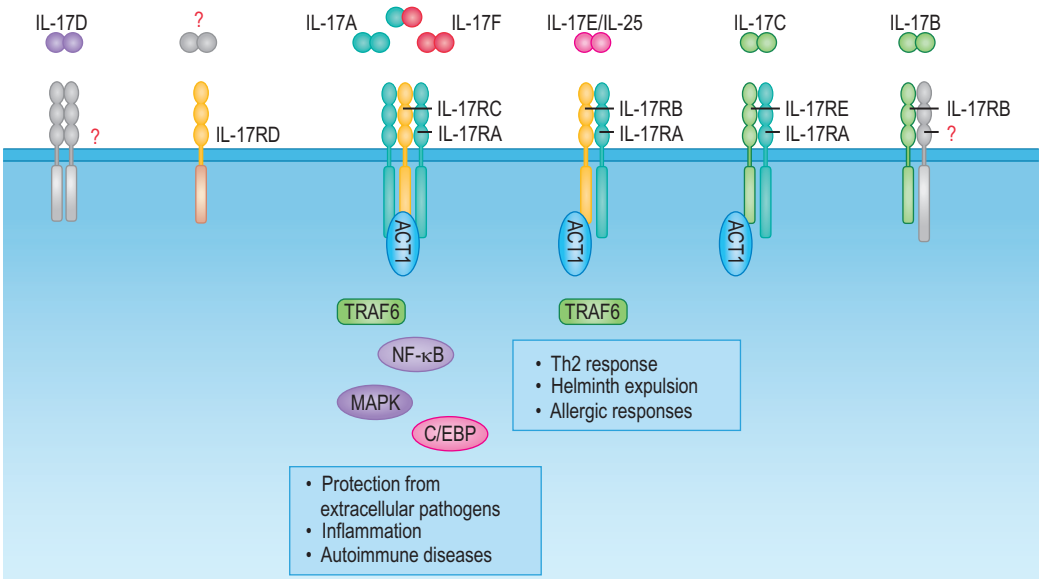

FIG. 14.6 Signal Transduction Cascade Downstream of Interleukin (*IL*)-17 Family of Cytokines and Their Receptors. IL-17 receptor family members recruit the adapter molecule ACT1 to couple to downstream signaling by nuclear factor kappa B (*NF-κB*), MAP kinases, and the transcription factor C/EBP.

epithelial cell hyperplasia, and eosinophilia. IL-25 is essential for the elimination of helminthic parasites.[59]

Signaling

Engagement of the IL-17 receptor activates MAP kinases, the PI3 kinase pathway, and NF-κB via Act-1 and TRAF6 (Fig. 14.6). IL-17 acts synergistically with TNF.[60] The IL-17R associates with an adapter molecule called Act through the SEFIR domains, which are part of both the receptor and the adaptor.[61]

CLINICAL RELEVANCE

Therapeutic Application of Interleukin-17 Blockade

- mAbs neutralizing IL-17 or antagonizing the IL-17 receptor are effective in treating psoriasis and psoriatic arthritis.

Clinical Relevance

Many human diseases and animal models of autoimmune disease have been associated with increased levels of IL-17. Anti-IL-17 and anti-IL-17 receptor mAbs are approved for the treatment of psoriasis, psoriatic arthritis, and ankylosing spondylitis and could represent a useful strategy to limit malignant transformation.[62] IL-17A and IL-17F are essential for mucocutaneous immunity against *Candida albicans*, and mutations of *IL17F*, *IL17RA*, or *IL17RC* result in chronic mucocutaneous candidiasis.[63]

CYTOKINES ACTIVATING RECEPTOR TYROSINE KINASES

Ligand and Receptor Structure

Many growth factors, such as insulin and epidermal growth factor, utilize receptor tyrosine kinases (RTKs). Some—but not all—of these factors can be classified as cytokines, including CSF-1 (colony-stimulating factor-1 also known as monocyte–macrophage-CSF or macrophage-CSF (M-CSF), stem cell factor (SCF, c-KIT ligand, or steel factor), platelet-derived growth factor (PDGF), and FLT3 ligand (FMS-like tyrosine kinase 3 ligand, FLT3-L). All of these have important hematological effects and tend to be included in discussions of cytokines. The structures of SCF and CSF-1 are similar to that of the cytokines that bind type I receptors as they too form four α-helical bundles, even though their receptors are entirely distinct. The similarities in their three-dimensional structures point to a common evolutionary ancestor. The receptors in this subfamily typically have five immunoglobulin-like loops in their ligand-binding extracellular domains. The cytoplasmic domain contains a tyrosine kinase catalytic domain interrupted by an "insert region" that does not share homology with other tyrosine kinases. This region is used to recruit various signaling molecules.

Family Members and Their Actions

KIT and Stem Cell Factor

Bone marrow stromal cells synthesize SCF as a soluble form (sSCF) and membrane-bound form (mSCF) resulting from alternative splicing and proteolytic cleavage. SCF is widely expressed during embryogenesis. Detectable in the circulation of normal adults, it is required to make stem cells responsive to other CSFs. sSCF signaling via c-KIT results in proliferation, differentiation, survival, and migration of stem cells; whereas mSCF prevents endocytosis of the Kit receptor. SCF has effects on germ cells, melanocytes, and hematopoietic precursors, as well as important effects on the mast cell differentiation. Naturally occurring mouse mutations of SCF (Steel) or its receptor (W) result in defects in hematopoiesis and fertility, loss of mast cells, and absent coat pigmentation.

Colony Stimulating Factor Receptor 1 (CSF-1R) and CSF1

CSF-1 is a hematopoietic growth factor that supports the survival and differentiation of monocytic cells. It is produced by a wide variety of cells, including monocytes, smooth muscle cells, endothelial cells,

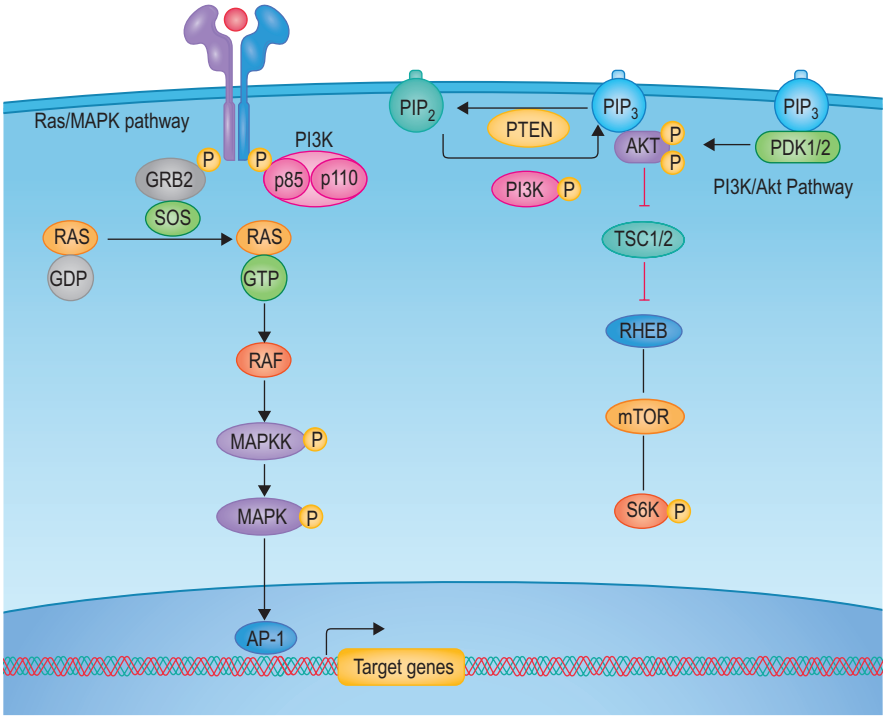

FIG. 14.7 Mechanism of Signal Transduction by Receptor Tyrosine Kinases. Ligand binding to receptor tyrosine kinases activates their enzymatic function leading to autophosphorylation, forming docking sites for adapter proteins that couple to activation of the RAS-Raf mitogen activated protein *(MAP)* kinase pathway. RTKs also activate phosphoinositide 3′ kinase (PI3K) leading to activation mTOR (mammalian target of rapamycin).

and fibroblasts. In humans, overexpression of CSF-1 leads to the recruitment of colony-stimulating factor-1 receptor (CSF-1R) expressing macrophages to the primary cell type within tenosynovial giant cell tumors (TGCTs). TGCT is a rare benign tumor that involves the synovium, bursa, and tendon sheath and results in the reduced mobility of the affected joint or limb. Kinase inhibitors that target CSF-1/CSF-1R have emerged as potential systemic agents for the treatment of TGCT.[64]

FLT and FLT3-L

FLT3-L synergizes with other cytokines, including SCF, to induce proliferation of hematopoietic precursors and is an important regulator of DC.

Signaling

The first step in signaling by the RTKs is ligand-induced receptor dimerization (Fig. 14.7). Dimerization brings the two kinase domains into proximity and results in the activation of phosphotransferase activity. This leads to autophosphorylation of the receptor subunits on the tyrosine residues, which are then bound by a variety of signaling molecules to initiate signal transduction. During this step, the signaling and adapter molecules recognize phosphotyrosine residues on the RTKs through either their SH2 (src homology 2) or phosphotyrosine binding (PTB) domains.

RTKs activate the RAS/RAF/ERK pathway. In some cases, GRB2 binds directly to phosphotyrosine residues on the cytoplasmic tail of the receptor via its SH2 domain. Alternatively, SHC can bind first and then recruit GRB2. In addition to an SH2 domain, GRB2 has two SH3 domains that bind proline-rich segments of the guanine nucleotide exchange factor, son of sevenless protein (SOS), recruiting it to the membrane and allowing it to activate RAS, a small G-protein. Activated RAS binds and activates the serine/threonine kinase RAF, which in turn phosphorylates the dual-specificity kinase MEK. Activated MEK phosphorylates and activates ERK (extracellular signal-regulated kinase), which then translocates to the nucleus where it phosphorylates and modulates the activity of various transcription factors, including ELK-1. GOF *RAS* mutations of RAS are common in a wide variety of human cancers.

RTKs also act through the phosphatidylinositol 3′-OH kinase (PI3-kinase) pathway.[65] PI3-kinase catalyzes the formation of phosphatidylinositol-3,4,5-trisphosphate (PtdIns(3,4,5)P3), and PtdIns(3,4)P2. These phospholipids are recognized by proteins with pleckstrin homology (PH) domains. One such protein is protein kinase B (PKB or AKT), which has been implicated in the regulation of apoptosis. The PI3-kinase pathway is inhibited by the lipid phosphatase PTEN, which dephosphorylates PI3-kinase-generated phosphatidylinositides. Deletion of PTEN has been found in numerous tumor types, demonstrating its role as a tumor suppressor.

Clinical Relevance

GOF c-KIT mutations result in systemic mastocytosis (Chapter 44). Mutations resulting in a fusion between the *PDGFRA* and *FIP1L1* genes underlie hypereosinophilic syndrome.[66,67]

KEY CONCEPT

Properties of the Transforming Growth Factor-β Receptor Family

- TGF-β receptors play a key role in lymphoid homeostasis, with pro- and anti-inflammatory actions.
- TGF-β promotes the differentiation of regulatory T cells and Th17 cells.
- TGF-β receptors transduce signals through SMAD proteins.
- TGF-β receptor function is dysregulated in many forms of human cancer.

TRANSFORMING GROWTH FACTOR-β LIGAND AND RECEPTOR FAMILIES

The transforming growth factor-βs (TGF-β) are a family of over 40 cytokines involved in processes, including tissue remodeling, wound repair, development, and hematopoiesis. Mutations of the elements in this pathway also contribute to malignant transformation and connective tissue and bone disorders. The mammalian ligands that belong to this family include TGF-β1, -β2, and -β3, bone morphogenic proteins (BMPs), growth and differentiation factors (GDFs), activins, inhibins, nodal, leftys, and Müllerian-inhibiting substance. TGF-βs induce collagen and fibronectin production by fibroblasts, which are thought to be responsible—at least in part—for diseases characterized by fibrosis (e.g., systemic sclerosis, pulmonary fibrosis). Functionally, TGF-β inhibits many aspects of lymphocyte function, including T-cell proliferation and CTL maturation. In mice, disruption of TGF-β receptor signaling results in massive expansion of lymphoid organs and development of T-cell lymphoproliferative disorders, indicative of a critical role for TGF-β in T-cell homeostasis.[68]

Ligand and Receptor Structure

The TGF-βs are expressed as biologically inactive disulphide-linked dimers that are cleaved to form active dimers. On translocation into the endoplasmic reticulum, the N-terminal leader peptide is cleaved, and the mature protein is subsequently generated by a second cleavage event that releases an N-terminal pro-region. The pro-region can remain associated with the biologically active C-terminal region, inhibiting its activity.

The biological effects of the TGF-βs and their related ligands are mediated by two classes of receptor, designated type I (RI) and type II (RII).[69] A third group of receptors, denoted type III, also exists (i.e., TGF-βRIII for TGF-β); however, the latter group function as co-receptors.

Similar to the RTKs, the cytoplasmic domains of TGF-β receptors possess intrinsic kinase activity; however, TGF-βRI and TGF-βRII encode serine/threonine kinases. The signaling cascade is initiated by the binding of TGF-β to the type II receptor, inducing the assembly of a ternary complex containing TGF-β, TGF-βRII, and TGF-βRI. The principal type I receptor in the TGF-β pathway is the ~55-kDa activin-like kinase-5 (ALK-5). ALK-1 can also be recruited into the complex and can transduce TGF-β-mediated signals.

TGF-β Family Members and Their Actions

The three known human TGF-βs (TGF-β1, TGF-β2, and TGF-β3) are closely related and have very similar biological functions. TGF-β1, the most abundant form, is the only isoform found in platelets. T cells and monocytes mainly synthesize TGF-β1, a critical function of which is to antagonize lymphocyte responses.

Approximately half of TGF-β1$^{-/-}$ mice survive until birth, but then succumb 3 to 4 weeks later to an overwhelming autoimmune state characterized by lymphoid and mononuclear infiltration of the heart, lung, and other tissues and by autoantibody production. These studies, together with selective inhibition of TGF-β function in T cells, indicate that TGF-β plays a crucial role in T-cell homeostasis and the prevention of spontaneous T-cell differentiation. TGF-β1 induces FoxP3, promotes adaptive Treg cell differentiation, and inhibits IFN-γ production. TGF-β can also regulate T-cell tolerance independently of FoxP3. Conversely, TGF-β1 with IL-6 induces IL-17. TGF-β also promotes IL-22 secretion by Th17 cell through Ahr activation and promoting tumors. TGF-β with IL-4 induces IL-9, a cytokine with pro- and anti-inflammatory actions. Thus, TGF-β1 has both pro-inflammatory and anti-inflammatory activities.

Of the three isoforms, TGF-β2 is the most abundant and TGF-β3 is the least abundant isoform in body fluids. TGF-β2 and TGF-β3-null mice exhibit defects distinct from those observed in TGF-β1 knockouts, particularly in bone and internal organ formation. Their deficiency is embryonically lethal. Thus, although the three isoforms function similarly in vitro, they play distinct roles in vivo.

Signaling

The human type II receptor is an 80-kDa glycoprotein and is the principal receptor for TGF-β. Once TGF-β binds to type II receptor, the type I receptor is recruited into the complex and activated through phosphorylation of its GS domain, a juxtamembrane domain preceding the kinase domain (Fig. 14.8).[69] In turn, the type I receptor is responsible for phosphorylating key signaling intermediates, SMADs, the primary substrates of the receptor.

Small mothers against dodecaplegias (SMADs) are a group of highly conserved proteins that play a critical role in TGF-β signal transduction.[70] Eight SMADs have been identified in mammals. All exhibit a high degree of specificity for conserved motifs in the cytoplasmic tail of type I receptors with no known structural or enzymatic motifs. They are subdivided into three classes based on functional distinctions.

The receptor-regulated SMADs (R-Smads) directly interact with the type I receptor. These include SMAD1, -2, -3, -5, and -8. Smad2 and Smad3 are phosphorylated in response to TGF-β, whereas Smad1, -5, and -8 are primarily activated in response to BMP activation. The interaction of R-SMADs with TGF-β

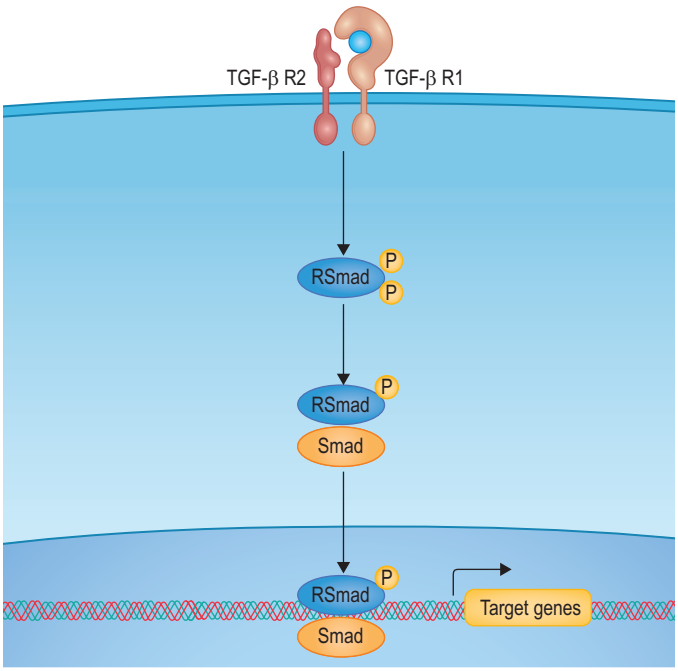

FIG. 14.8 Signaling byTransforming Growth factor-β (*TGF-β*) Family Receptor Serine Kinases. Ligand binding activates enzymatic activity leading to phosphorylation of SMADs, which translocate to the nucleus, bind DNA, and regulate gene expression.

receptors can also be regulated by another molecule termed SARA (SMAD anchor for receptor activation). SARA binds unphosphorylated SMAD2 and SMAD3. Through its lipid-binding domain (FYVE), SARA relocates SMADs to the plasma membrane, facilitating receptor binding.

Once phosphorylated, R-SMADs dissociate from SARA and from the activated type I receptor and associate with SMAD4 in the cytoplasm. This is followed by nuclear translocation of the heteromeric SMAD complex with binding to cognate DNA motifs in the promoters of TGF-β-responsive genes and to concomitant induction of transcription. SMAD2 null mice lack anterior/posterior specification and fail to develop mesoderm, causing embryonic lethality. SMAD3-deficient mice have limb malformations and defective immune function.

Upon recruitment to their cognate activated type I receptor, R-SMADs are phosphorylated on C-terminal serine residues, triggering homodimerization of R-SMADs or heterodimerization of the common SMAD—or C-SMAD. SMAD4 is the only known C-SMAD in vertebrates, functioning as the central and essential downstream mediator of other SMADs in all TGF-β/BMP pathways. SMAD4-deficient mice exhibit severe defects in gastrulation and die early in embryogenesis. SMAD4 specific deletion provided insight into its role in bone development and pathogenesis of chondrodysplasia[71]

SMAD6 and SMAD7 comprise the third subfamily of SMADs in mammals, the inhibitory SMADs (I-SMADs). SMAD6 competes with SMAD4 for binding to an R-SMAD. Studies with SMAD6-deficient mice indicate a role in the development and homeostasis of the cardiovascular system. SMAD7 is induced by TGF-β and binds to TGF-β receptors, inhibiting the phosphorylation of R-SMADs, thus serving as a classic feedback inhibitor.

Although SMADs bind DNA, they also interact with a variety of other transcription factors, transcriptional co-activators, and transcriptional co-repressors to coordinately regulate transcription of a select subset of complex promoters. For example, SMADs can bind ATF2—the vitamin D receptor—and other transcription factors and can recruit the co-activators CBP/p300. SMAD4 can also regulate FZD4, a component of the Wnt network, therefore establishing a bridge between TGF-β and Wnt.[72]

A number of members of the mitogen-activated protein kinase (MAPK) family are activated in response to TGF-β, including ERK, JNK, and p38 MAPK. Another MAPK member, TAK1 (TGF-β-associated kinase-1) can be recruited upon TGF-β stimulation, forming a complex with TAB1 (TAK1-asociated binding protein), leading to downstream activation of p38/MPK2 and c-JUN N-terminal kinase (JNK) through MKK6 and MKK4, respectively. TGF-β can also interact with the PI3K-AKT-mTOR signaling pathway. Thus, TGF-β signaling influences many cellular functions by its ability to crosstalk with other paths.

Clinical Relevance

Loeys-Dietz syndrome is a connective tissue disorder that results from mutations in *TGFBR1*, *TGFBR2*, *TGFB2*, *TGFB3*, *or SMAD3*. GOF mutations of activin receptor-like kinase 2 (ALK-2, encoded by *ACVR1*) underlie the disorder fibrodysplasia ossificans progressive, which is characterized by widespread heterotopic bone formation. SMAD4 is deleted in half of all human pancreatic carcinomas. Mutations in SMAD2 have been identified in patients with colon cancer, and somatic mutations in TGF-β receptors have been identified in colon and gastric cancers. Loss of SMAD3 is associated with leukemia. Oncogenic RAS can repress SMAD signaling by negatively regulating SMAD2 and SMAD3. Variants in SMAD6 are associated with complex cardiovascular pathology. Somatic mutations of *SMAD3* are associated with melorheostosis, a rare genetic bone disease.[73] Activation of the TGF-β network can contribute to pathological fibrosis in most organs and has been associated with multiple skeletal muscle myopathies, including Duchenne muscular dystrophy.

OTHER CYTOKINES

Interleukin-14

IL-14 was identified as a high molecular weight B-cell growth factor produced by T cells and some B-cell tumors. The precise nature of this putative cytokine is still uncertain, although it has been implicated in the pathogenesis of autoimmune diseases, SLE, Sjögren syndrome (Chapter 55), and Graves disease or Hashimoto thyroiditis (Chapter 70).[74]

Interleukin-16

IL-16 was formerly termed lymphocyte chemoattractant factor because of its ability to recruit CD4 T cells.[75] Unrelated to other cytokines, its only known receptor is CD4. Originally identified as a product of CD8 T cells, its message is widely expressed. CD4 T cells, eosinophils, and mast cells as well as epithelial cells, fibroblasts, and monocytes can all secrete IL-16. It is present in bronchoalveolar lavage fluids from asthmatics and sarcoid patients. IL-16 has also been detected in blister fluid from bullous pemphigoid lesions (Chapter 63) and overexpressed in RA, IBD, SLE, and autoimmune thyroid disease.

Interleukin-32

IL-32 is structurally distinct from other families.[76] It is inducible by the combination of IL-12 and IL-18, and nine different isoforms are generated by mRNA splicing. IL-32 induces the expression of various cytokines, including TNF, IL-1, IL-6, and chemokines. It can synergize with muramyl dipeptides and signals via NF-κB and p38. IL-32 is present in rheumatoid synovium and is found at increased serum concentrations in patients with Behçet disease, SLE, and atopic dermatitis (Chapter 48). IL-32 may be a promising approach to the evaluation of the presence of pulmonary arterial hypertension in systemic sclerosis.[77]

Interleukin-34

IL-34 is the second ligand for CSF-1R. Its functions include the differentiation, proliferation, and survival of monocytes, macrophages, and osteoclasts. IL-34 has been associated with the inflammatory process seen in RA, IBD, and Sjogren syndrome. IL-34 levels appear to be elevated in serum and synovial fluid in patients with RA.[78]

CONCLUSIONS AND SUMMARY

Cytokines encompass a wide range of molecules that are essential for communication between cells of the immune system and other non-immune cells. Although the number of cytokines already seems vast, it is likely that more will be discovered in the future. Considerable progress has been made in defining the in vivo functions of various cytokines. Equally impressive have been the advances in our understanding of how the dysregulation of cytokines and cytokine signaling contributes to human disease. While there is no doubt that innumerable advances,

including direct therapeutic triumphs (Table 14.4), have come from understanding the basic science of cytokine biology, there is still much to do. An exciting possibility for the future is engineering synthetic cytokines. Equally, there are many possible bispecific antibodies that target more than one cytokine or cytokine receptor that can be generated. Improved understanding of regulators like SOCS proteins should also offer new therapeutic opportunities. As imaging of cells and macromolecular complexes improve, it will be particularly exciting to really see how cytokines signal. The best advice is to "stay tuned to this station."

Chemokines and Chemokine Receptors

Philip M. Murphy

The large number of leukocyte subsets that populate the immune system, each with distinct and complex trafficking itineraries, places great demands on an operating system. Orderly trafficking (Chapter 16) depends on the specificity of chemokine receptors for chemokines and leukocytes, dynamic temporospatial regulation of chemokine expression in source cells and chemokine receptor expression in responding cells, integration of multiple signal transduction pathways, and signal-modifying factors in individual cells (Fig. 15.1).[1] Accordingly, the chemokines are the largest family of cytokines (Chapter 14), and chemokine receptors are one of the largest families of 7-transmembrane-domain receptors. In order to fine-tune immune responses, combinatorial complexity permits multitasking and back-up by individual system components in a single cell type or among different cell types.

CHEMOKINES

Chemokines are defined by their structure, not their function.[2] Conserved and uniformly spaced disulfide-bonded cysteines help create a highly conserved tertiary structure (Figs. 15.1 and 15.2A). Most chemokines have at least four conserved cysteines. The first two are either adjacent (CC motif, $n = 24$ in human) or separated by one (CXC motif, $n = 16$ in human) or three (CX3C motif, $n = 1$) amino acids. Two chemokines have only two cysteines (XC motif), which correspond to C-2 and C-4 in the other groups. Disulfide bonds link C-1 to C-3 and C-2 to C-4. The chemokine core domain contains 3 β-sheets connected by short loops and arranged in the shape of a Greek key. The core is overlaid by a C-terminal α-helical domain, and flanked by an N-terminal domain that lacks order. The four chemokine cysteine motifs are followed by the letter "L" for *ligand* and a number (e.g., CXCL1) in a systematic nomenclature.[3]

Chemokines may form multiple quaternary structures, including monomers, homodimers, homotetramers, and heterodimers. Complex multimers noncovalently bound to glycosaminoglycans (GAGs) on the endothelial cell surfaces may be important for presentation to leukocytes in vivo. However, structural studies indicate that chemokines probably bind to receptors as monomers, potentially released as a cloud from multimerized deposits at GAG binding sites.[4] CXCL16 and CX3CL1 are exceptional in having a multimodular structure that includes a classic chemokine domain, a mucin-like stalk, a transmembrane domain, and a C-terminal cytoplasmic module. Each can exist as either a membrane-bound form or shed form, enabling either direct cell–cell adhesion or chemotaxis, respectively. CXCL16 also multitasks as a scavenger receptor, binding to phosphatidylserine and oxidized low-density lipoprotein.

KEY CONCEPTS

Chemokine and Chemokine Receptors

Definition
- Chemokines are defined by a common structure, the chemokine fold.
- Chemokine receptors are defined by a common biochemical function: chemokine binding-dependent cell signaling.
  - Most chemokine receptors catalyze guanine nucleotide-exchange on Gi-type G proteins.
  - A small group of so-called atypical receptors do not signal through G proteins; some signal through an arrestin-dependent pathway.

Classification
- Chemokines form four main structural subclasses (C, CC, CXC, and CX3C) and two main immunological subclasses (inflammatory and homeostatic).

Evolution
- Chemokines and chemokine receptors arose in vertebrates and have been copied or mimicked by many viruses.
- Chemokines and chemokine receptor repertoires can differ among species and among individuals of the same species.

Ligand–Receptor Promiscuity
- The majority of chemokine receptors pair promiscuously with chemokine ligands, usually restricted to a single chemokine subclass; these typically mediate inflammatory responses.

Cell Biology
- Chemokines coordinate leukocyte trafficking.
- They can have prominent nontrafficking functions:
  - Immunologic effects: lymphocyte proliferation/apoptosis/differentiation/activation, granulocyte degranulation/superoxide production/direct antimicrobial activity.
  - Nonimmunologic effects: development, cancer, angiogenesis.

Biology
- Chemokines act redundantly or nonredundantly, depending on context.
- Host chemokine receptors mediate antimicrobial defense.
- Some pathogens (e.g., HIV and *Plasmodium vivax*) can exploit chemokine receptors to infect the host.
- Excessive or inappropriate chemokine expression may pathologically amplify immunologically mediated disease.

CHEMOKINE RECEPTORS

Chemokine receptors are defined as signal transducers that trigger cellular responses upon binding chemokines. In humans, 23 subtypes of chemokine receptors have been divided into two main groups, the conventional G protein-coupled chemotactic chemokine receptors (GPCRs; $n = 19$) and the

LXXXIX. Update on the extended family of chemokine receptors and introducing a new nomenclature for atypical chemokine receptors. *Pharmacol Rev*. 2014;66(1):1–79.)

atypical G protein-uncoupled chemokine receptors (ACKRs; $n = 4$) (see Figs. 15.1 and 15.2B). Chemokine binding, membrane anchoring, and signaling domains for receptors from both groups come from a single polypeptide chain, although evidence exists for both homo- and heterodimers.[2,5,6]

Each chemokine has a unique receptor specificity profile, and vice versa. Five chemokine GPCRs (CXCR4, CXCR5, CCR6, CCR7 and CCR9) pair monogamously with a chemokine ligand, all of which support homeostatic trafficking into, within and out of primary and secondary immune organs. The other 14 chemokine GPCRs bind multiple chemokines restricted mainly to one structural group that support inflammatory signaling.

The chemokine GPCRs are systematically named based on ligand group specificity. The distinction between inflammatory and homeostatic chemokines and chemokine receptors can be vague since the same molecule may multitask. For example, CXCR2 is important for both acute tissue neutrophilic inflammation and homeostatic release of newly produced bone marrow neutrophils to the blood.

Almost all chemokines are chemotactic agonists. A few may be agonists at one GPCR, antagonists at another (e.g., CCL11 agonism at CCR3 and antagonism at CXCR3), and also bind to ACKRs. For chemokines acting at the same GPCR, differential receptor usage, differential regulation of expression, and biased agonism all contribute to nonredundant function in vivo.[7] The sheer size and high degree of promiscuity of the chemokine ligand-receptor repertoire help explain why, in complex chronic inflammatory diseases, the response to monospecific drugs that target the system one component at a time has been underwhelming, given the many types of leukocytes, chemokines, and chemokine receptors that can be involved in pathogenesis.[8]

ATYPICAL CHEMOKINE SYSTEM COMPONENTS

There are three main classes of atypical chemokine system components. The first includes the four atypical chemokine receptors (ACKRs). These bind promiscuously to multiple chemokines either without inducing a signal or with signaling occurring through a β-arrestin-dependent G protein-independent pathway. ACKRs are subclassified by the degree of chemokine promiscuity.[9] ACKR1 and 2 bind overlapping sets of many proinflammatory CC chemokines, and ACKR1 also binds multiple proinflammatory CXC chemokines. Prominent expression of both receptors on tissue barrier cells, including vascular and lymphatic endothelial cells and placental trophoblasts, and of ACKR1 on mature erythrocytes, which hugely outnumber leukocytes in blood, has suggested they may function as chemokine sinks to shape more effective chemokine gradients or to dampen excessive inflammatory responses. For example, inflammatory chemokine scavenging by placental trophoblast-expressed ACKRs may contribute to immunologic tolerance during pregnancy. ACKR1 on endothelial cells may also present chemokines to leukocytes by mediating transcytosis of bound chemokine to the abluminal side of the cell. Internalization of bound chemokine is a general property of all chemokine receptors; however, ACKR2 is specialized for chemokine scavenging by extremely rapid internalization of degradation bound ligands and rapid receptor recycling.

In contrast to ACKR1 and 2, ACKR3 and 4 bind only 2 and 3 chemokines, respectively. They coordinate local chemokine gradient shaping with specific GPCRs for which they share ligand specificity (CXCR4 and CCR7, respectively). For example, gradients of CXCL12 shaped by ACKR3 that then signal chemotactically through CXCR4 mediate zebrafish germ cell

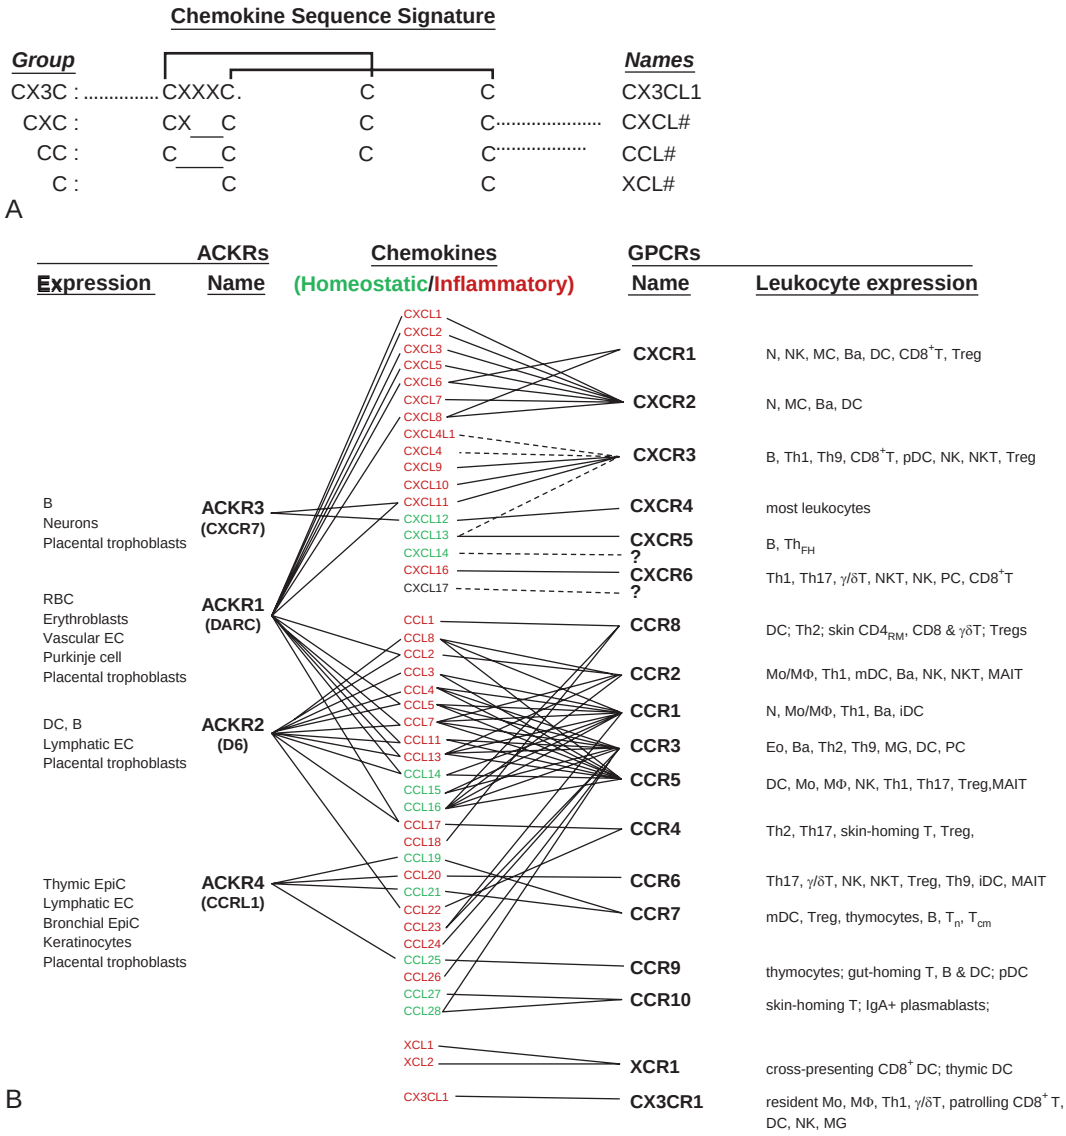

FIG. 15.2 Molecular and Cellular Organization of the Chemokine System. (A) Chemokine classification. Chemokines are defined by the number and arrangement of conserved cysteines, as shown. *Brackets* link cysteines that form disulfide bonds. *X* refers to an amino acid other than cysteine. The *underscore* is a spacer used to optimize the alignment. The N- and C-termini can vary considerably in length (not illustrated). For molecules with four cysteines, there are approximately 24 amino acids between Cys-2 and Cys-3, and 15 amino acids between Cys-3 and Cys-4. At *right* are listed the nomenclature system and the number of human chemokines known in each class (N). (B) Chemokine receptor specificity for chemokine ligands and cells. *ACKR*, Atypical chemokine receptor; *B*, B lymphocyte; *Ba*, basophil; *DC*, dendritic cell; *EC*, endothelial cell; *Eo*, eosinophil; *EpiC*, epithelial cell; *GPCR*, G protein-coupled receptor; *iDC*, immature dendritic cells; *MAIT*, mucosal-associated invariant T cell; *MG*, microglial cells; *Mo*, monocyte; *MΦ*, macrophage; *N*, neutrophil; *NK*, natural killer cell; *NKT*, NKT cell; *PC*, plasma cells; *pDC*, plasmacytoid dendritic cells; *RBC*, red blood cell; T_{cm}, central memory T cells; *Tfh*, follicular helper T cells; *Tmem*, memory T cells; *Treg*, regulatory T cells. *Dashed lines* indicate low affinity and unknown interactions.

migration during development. ACKR4 shaping of gradients for shared ligands signaling through CCR7 may similarly facilitate B, T, and dendritic cell trafficking in mammalian lymph node (Chapter 2). ACKR3 may also function independently of CXCR4: for example, to position marginal zone B cells (Chapter 7) in mouse spleen.

The second class of atypical chemokine system components includes endogenous nonchemokine agonists that act at chemokine receptors (e.g., MIF at CXCR2 and β-defensin-2 at CCR6). The third class includes virally encoded chemokine system mimics, including pirated bona fide chemokines and 7TM chemokine receptors, structurally unique secreted chemokine scavengers, and nonchemokine chemokine receptor agonists or antagonists (see Fig. 15.1).[10] Viral chemokine elements can function to evade the immune system, recruit new target cells, reprogram gene expression for cell proliferation and angiogenesis, and mediate target cell entry. Secreted and structurally unique broadly specific chemokine-binding proteins known as evasins have been identified in tick saliva, which could help explain the lack of inflammation associated with tick bites.

KEY CONCEPTS

Immunologic Classification of the Chemokine System

Homeostatic System

- Constitutively expressed ligands and receptors.
- Important in hematopoiesis and immune surveillance.
- Key receptors: CXCR4 on all leukocytes, especially hematopoietic stem and progenitor cells; CXCR5 on B cells; CCR7 on mature dendritic cells and both naïve and central memory T cells; and gut and skin-specific T-cell homing receptors (CCR9 and CCR10, respectively).

Inflammatory System

- In innate immunity, inducible ligands, and constitutively expressed receptors (e.g., neutrophil CXCR1 and CXCR2, monocyte CCR2 and CX3CR1, eosinophil CCR3, and NK cell CX3CR1).
- In adaptive immunity, inducible ligands and inducible receptors (e.g., CXCR3, CCR4, and CCR6 on Th1, Th2, and Th17 subsets of CD4 T cells, respectively).

Immunologic Classification

Mature hematopoietic cell types express a variably sized signature subset of multiple chemokine receptors. The sole exception is the erythrocyte, which expresses only ACKR1. Several chemokine receptors are consistently and highly expressed on almost all cells of a given subset, acquiring the status of a reliable subset marker (e.g., CXCR1 and CXCR2 for neutrophils, CCR3 for eosinophils, CCR2 and CX3CR1 for different subsets of monocytes, CXCR3 for Th1 cells, CCR4 for Th2 cells, CCR6 for Th17 cells, CXCR5 for B cells, and CCR7 for naïve and central memory T cells and mature dendritic cells).

Homeostatic chemokines are differentially and constitutively expressed in specific microenvironments of primary and secondary immune organs. They direct trafficking of both mature and immature leukocytes (Chapter 16) via constitutively expressed receptors. Noxious stimuli induce inflammatory chemokines in diverse tissue cells and leukocytes. Inflammatory chemokine receptors are constitutively expressed on myeloid (Chapter 39) and NK cells (Chapter 12), and are induced upon activation of effector lymphocytes (Chapter 10). Dynamic shifts in receptor expression occur during dendritic cell (Chapter 6) and NK cell maturation, and during lymphocyte maturation, activation, and differentiation.

The chemokine and chemokine receptor repertoires vary between and within species. For example, the major human CXC chemokine CXCL8 (interleukin-8) is not found in mice and chemokine gene copy number variation and sequence polymorphism in humans affects the risk of acquiring certain diseases (e.g., *CCL3* copy number variation and the *CCR5Δ32* mutation in HIV/AIDS (Chapter 41), and the ACKR1 Duffy mutation in *Plasmodium vivax* malaria (Chapter 29)).

CHEMOKINE PRESENTATION MECHANISMS

Chemokines typically act at the local site of production. They may be presynthesized and stored in granules (e.g., CXCL4 and CXCL7 in platelets) awaiting a proinflammatory release signal, or else be constitutively released, sometimes achieving high concentrations in the blood (e.g., CCL14–16). Others are newly synthesized in response to activation signals (e.g., inflammatory chemokines). Chemokines may be presented to leukocytes as ligands tethered to either extracellular matrix proteins and, as mentioned previously, to endothelial cells either by binding to GAGs or by transmembrane domains in the case of CX3CL1 and CXCL16. The tethering cell may have produced the chemokine or else imported it by transcytosis from neighbors. The ligand binding site includes the receptor N-terminus and one or more extracellular loops, which allow docking of the chemokine core domains, and multiple seven-transmembrane (7TM) domains, which accept the chemokine's N-terminus and are critical for triggering. Additional sites of interaction have been identified by direct structural studies.[2,5,6]

CHEMOKINE ACTIVATION OF CHEMOTACTIC SIGNALING PATHWAYS

Chemokines trigger G protein–coupled chemokine receptors to act as guanine nucleotide exchange factors (GEFs) for heterotrimeric G_i-type G proteins, releasing GDP from and binding GTP to the $G_i\alpha$ subunit (Fig. 15.3).[11,12] The G protein dissociates into α and βγ subunits, which in turn activates diverse G protein–dependent effectors, including phospholipases A2, C (subtypes β2 and β3) and D, phosphatidylinositol-3-kinase γ (PI3Kγ), protein tyrosine kinases (PTK) and phosphatases, low-molecular-weight GTPases, and mitogen-activated protein kinases.

Phospholipase C (PLC) hydrolyzes phosphatidylinositol bisphosphate (PIP_2) to form 1,2-diacylglycerol (DAG) and inositol-1,4,5-trisphosphate (IP_3). IP_3 induces Ca^{2+} release from intracellular stores, which acts with DAG to activate protein kinase C (PKC). PI3Kγ phosphorylates PIP_2 to form PIP_3, which recruits proteins containing pleckstrin homology (PH) or PHOX (PX) domains to lamellipodium, thereby converting shallow analog extracellular chemokine gradients into steep digital intracellular effector gradients. Four PH domain-containing targets—Akt, and GEFs for Rac, Rho, and Cdc42—modulate distinct phases of cell movement in various model systems. Rho regulates cell adhesion and chemotaxis, and myosin contraction. Rac and Cdc42 control lamellipodia and filipodia formation, respectively. Downstream targets of Rac include Pak1, which also regulates myosin contraction.

Chemokine activation of G_i may also inhibit adenylyl cyclase activity via the dissociated $G\alpha_i$ subunit. Chemokine agonists induce phosphorylation of the *C*-tail domain of their receptors to which β arrestin is recruited for alternative signaling and downregulation of the receptor by internalization through a clathrin-dependent mechanism. Chemokines also activate MAP kinases, and PTK with downstream effects on cell migration and gene regulation.

REGULATION OF CHEMOKINE ACTION

Chemokine and chemokine receptor expression can be positively or negatively regulated at the transcriptional level by factors that include proinflammatory cytokines, oxidant stress, hypoxia, viruses, bacterial products such as lipopolysaccharide and N-formylpeptides, cell adhesion, antigen uptake, and T-cell costimulation. Multiple transcription factors regulate chemokine and chemokine receptor expression, including nuclear factor-κB (NF-κB) and cEBP-δ. In innate immunity, proinflammatory cytokines such as interleukin (IL)-1, tumor necrosis factor (TNF), IL-15, and IL-17 (Chapter 14) induce expression of inflammatory chemokines important for recruitment of myeloid and natural killer (NK) cells. In adaptive immunity, signature cytokines of polarized helper T cells (Chapter 11) establish

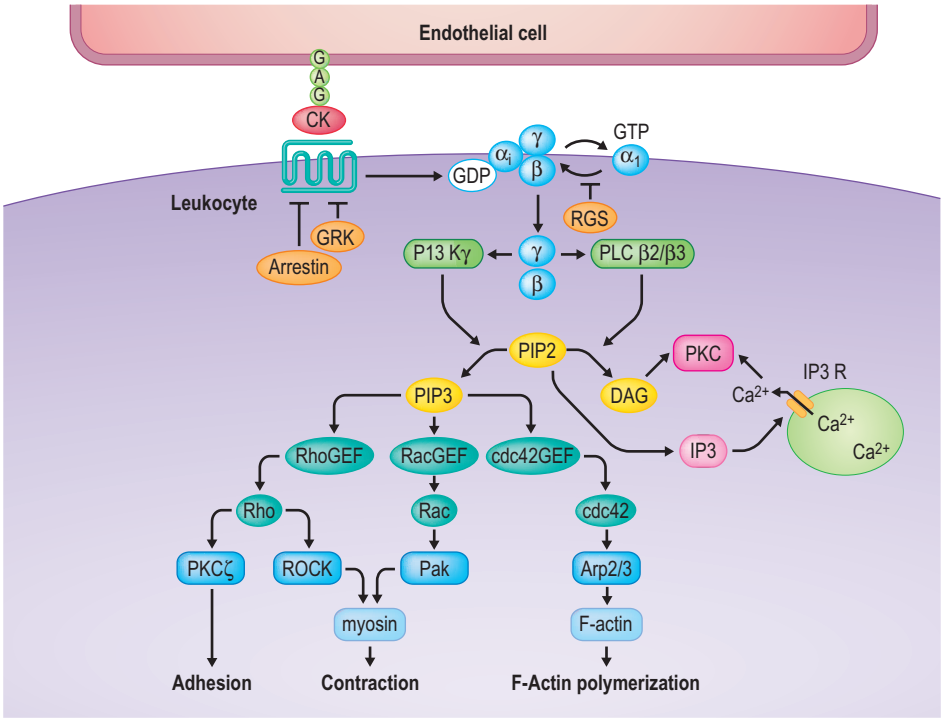

FIG. 15.3 Chemokine Signal Transduction in Chemotaxis. Depicted are key steps in two of the main pathways induced by most chemokines. The PI3Kγ pathway is particularly important for cell migration. Chemokines are able to activate other pathways as well, including non-Gi-type G proteins, protein tyrosine kinases, and MAP kinases. These pathways influence cell proliferation and activation. The model is modified from the Alliance for Cell Signaling (http://www.signaling-gateway.org). *CK*, Chemokine; *DAG*, diacylglycerol; *GAG*, glycosaminoglycan; *GEF*, guanine nucleotide exchange factor *GRK*, G protein-coupled receptor kinase; *IP3*, inositol trisphosphate; *PI3K*, phosphatidylinositol-3-kinase; *PIP*, phosphatidylinositol phosphate; *PKC*, protein kinase C; *PLC*, phospholipase C; *RGS*, regulator of G protein signaling.

positive feedback loops for tissue cell production of signature chemokines able to specifically recruit additional helper T cells, thereby reinforcing polarization of the response. Interferons, glucocorticoids, and antiinflammatory cytokines (e.g., IL-10, transforming growth factor-β [TGF-β]) can inhibit inflammatory chemokine gene expression. Chemokine system components can also be regulated at the level of mRNA stability by *cis* motifs, microRNAs and long-noncoding RNAs (Chapter 19).

Chemokine genes may generate functional variants by alternative splicing and posttranslational modification, especially N- and C-terminal proteolytic trimming.[13] Proteases can target many chemokines (e.g., CD26 [dipeptidyl peptidase IV] and matrix metalloproteinases [MMP]), or few or only one (e.g., TACE [the TNF-α converting enzyme], plasmin, urokinase plasminogen activator and cathepsin G). Chemokines can be scavenged not only by ACKRs, but also by receptor decoys and autoantibodies, or they can be blocked by endogenous receptor antagonists. In addition, cytokines may convert a signaling receptor into a decoy (e.g., IL-10 uncouples CCR2 signaling in monocytes). Chemokine receptors may exist in different functionally distinct conformational states and may be modulated in signalosomes, which may include physical and/or functional interactions with other chemokine receptors and accessory molecules. Likewise, chemokine action may be modulated by binding to other chemokines and accessory molecules: for example, the ability of the chromatin-binding protein HMGB1 released from dying cells to bind CXCL12, thereby enhancing its signaling potential at CXCR4.

LEUKOCYTE RESPONSES TO CHEMOKINES

Whereas all leukocyte subtypes migrate in response to one or more chemokines, each subtype can also respond in additional stereotypical ways. For example, lymphocytes may proliferate or undergo apoptosis (Chapter 17), and strengthen immune synapses (Chapter 10) or release immunoregulatory (Chapter 13) and cytotoxic factors (Chapter 12); and granulocytes (Chapter 39) can release antimicrobial and inflammatory mediators (e.g., superoxide, defensins, proteases, histamine, eicosanoids).

The mechanism of leukocyte migration can vary depending on the leukocyte subtype and the environment. In the classic multistep model of leukocyte transendothelial migration (Chapter 16),[14] an initial chemokine-independent step involves leukocytes rolling on inflamed endothelium by reversible interactions between endothelial selectins (e.g., L-selectin) and leukocyte selectin ligands (e.g., sialyl-Lewis^x). Next, chemokines presented by endothelium via GAGs stimulate cognate chemokine receptors on rolling leukocytes to induce expression of activated β_2 integrins, which mediate firm adhesion of leukocytes to endothelium by binding to endothelial intercellular adhesion molecule (ICAMs).

Leukocytes sense chemokine gradients, polarize, and become poised to crawl. Motion involves shear-dependent coordinated cytoskeletal remodeling, involving expansion of the leading edge (lamellipodium), myosin-based contraction at the trailing edge (uropod), release of the uropod

from substrate, and membrane lipid movement. Navigation across endothelium and through tissue may involve additional steps in which specific chemoattractants and adhesion molecules play differential roles and the steps may vary for different barriers in tissue.[15] For example, some chemokines are specialized in arrest of leukocytes on endothelium and others are critical for terminal transendothelial migration (Fig. 15.4A).[16]

CHEMOKINE REGULATION OF HEMATOPOIESIS

Chemokines play major roles in hematopoiesis (see Fig. 15.4B).[17] Both CXCR2 and CXCR4 are expressed on hematopoietic stem cells (HSCs) and neutrophils, and the balance of CXCR2 and CXCR4 signaling influences homing to and egress from bone marrow niches. CXCL12 is produced by CXCL12-associated reticular (CAR) cells in hematopoietic stem cell (HSC) niches whereas bone marrow microvascular endothelial cells produce oppositely oriented gradients of the CXCR2 agonists CXCL1 and CXCL2.[18] HSCs and neutrophils can both be rapidly mobilized pharmacologically by granulocyte colony-stimulating factor (G-CSF), which induces CXCR4 degradation by neutrophil elastase, or by CXCR4 antagonists and CXCR2 agonists. Mice lacking either CXCL12 or its receptor CXCR4 display defective bone marrow myelopoiesis, whereas CXCR2 knockout mice demonstrate resting peripheral blood and bone marrow neutrophilia and impaired acute neutrophil migration into tissue under inflammatory conditions. The atypical CXCL12 receptor ACKR3 does not regulate hematopoiesis, but instead regulates marginal zone B-cell positioning in spleen (Chapters 2 and 7), among other functions. CCR2 is important for monocyte release from bone marrow.

Chemokines and chemokine receptors are differentially expressed in thymus and coordinate thymocyte migration from cortex to medulla.[19] CCR9 and its sole ligand CCL25 are particularly important in this process. CCL25 is expressed by medullary dendritic cells and both cortical and medullary epithelial cells. CCR9 is expressed on the majority of immature $CD4^+CD8^+$ thymocytes but is downregulated during transition to the $CD4^+$ or $CD8^+$ single-positive stage. Just before thymic egress, thymocytes become CCR9 negative and upregulate L-selectin. $CD4^+CD8^+$ thymocyte transition in the cortex to $CD4^+$ or $CD8^+$ single-positive thymocytes in the medulla involves upregulation of CCR4 and CCR7, receptors for CCL22, and CCL19 and CCL21, respectively, which are expressed in the medullary stroma. Accordingly, these chemokines attract thymocytes between the late cortical and medullary stages of development in vitro. Neutralization studies suggest that egress of newly formed T cells from fetal thymus to the circulation is mediated by CCL19, which localizes to endothelial cells of medullary venules and acts at CCR7 on mature thymocytes.

CHEMOKINE REGULATION OF THE IMMUNE RESPONSE

Innate Immunity

Platelet-Derived Chemokines

Made primarily during platelet development, stored in platelet α granules, and rapidly released during platelet degranulation, CXCL4 and CXCL7 are among the first chemokines to appear at sites of tissue injury and infection, particularly when there is hemorrhage and vascular damage, and can reach high concentrations.[20] CXCL7 can function as an immediate-early mediator of neutrophil recruitment released from platelets at sites of inflammation. Although it is not a prominent leukocyte chemoattractant, CXCL4 complements CXCL7 by inducing neutrophil secondary granule exocytosis and release of matrix-degrading enzymes, which may facilitate neutrophil penetration of infected or injured tissues.

Myeloid Cell Trafficking

Once myeloid cells are released from the bone marrow, they undergo specific trafficking itineraries and, in some cases, become resident in tissue. CXCL14 is important for macrophage (Chapter 3) positioning in lung by a still undefined receptor, and CCL11 and its receptor CCR3 are important for positioning of eosinophils (Chapter 45) in spleen and the gastrointestinal tract (Chapter 24). CX3CR1 regulates localization of myeloid DCs in Peyer patches and may be important for antigen sampling from the intestine.

All seven CXC chemokines containing an N-terminal ELR motif preferentially recruit neutrophils in vitro by binding to CXCR2. CXCL6 and CXCL8 are also potent agonists at the closely related neutrophil receptor CXCR1.[21] CXCR2 chemokines are rapidly inducible in most tissue cells. Temporospatial differences in expression provide a mechanism for graded navigation of neutrophils from blood into tissue. Blocking studies have demonstrated the importance of CXCL8 and CXCR2 in neutrophil accumulation in response to infectious and noninfectious stimuli. CXCR1 does not appear to mediate neutrophil recruitment into infected sites but is instead involved in activation of antimicrobial effector mechanisms.

Intradermal injection of CXCL8 in man causes rapid (<30 minutes) and selective accumulation of large numbers of neutrophils in perivascular regions of the skin (Chapter 23) without causing edema. Tissue-specific transgenic overexpression of mouse CXCL8 paralogues KC and MIP-2 suggests that these factors may recruit cells, but may not independently activate cytotoxic mechanisms. In a human blister model, endogenous CXCL8 peaks at approximately 24 hours, whereas C5a (Chapters 3 and 39) and leukotriene B4, which also recruit neutrophils, appear earlier. Thus, the primary role of CXCL8 may be to amplify early inflammatory responses initiated by other types of chemoattractants. CXCL1, 2, 3, 7, and 8 also induce basophil chemotaxis and histamine release in vitro, which together with other factors, including complement-derived anaphylatoxins C3a and C5a, promote vasodilatation early during innate immune responses.

Monocyte recruitment typically follows neutrophil accumulation with delayed kinetics and can be mediated by multiple inflammatory CC receptors and CX3CR1. CCR2 and CX3CR1 are particularly important and define two monocyte subsets, $CX3CR1^{hi}CCR2^-$ and $CX3CR1^{lo}CCR2^+$, which are referred to as "resident" and "inflammatory" monocytes because of their distinct trafficking characteristics.[22]

NK Cells

Human NK cell subsets (Chapter 12) express unique repertoires of chemokine receptors. The $CD56^{dim}CD16^+$ subset, which is associated with high cytotoxic capacity and low cytokine production, expresses primarily CXCR1 and CX3CR1. The minor subset of $CD56^{bright}CD16^{dim}$ cells,

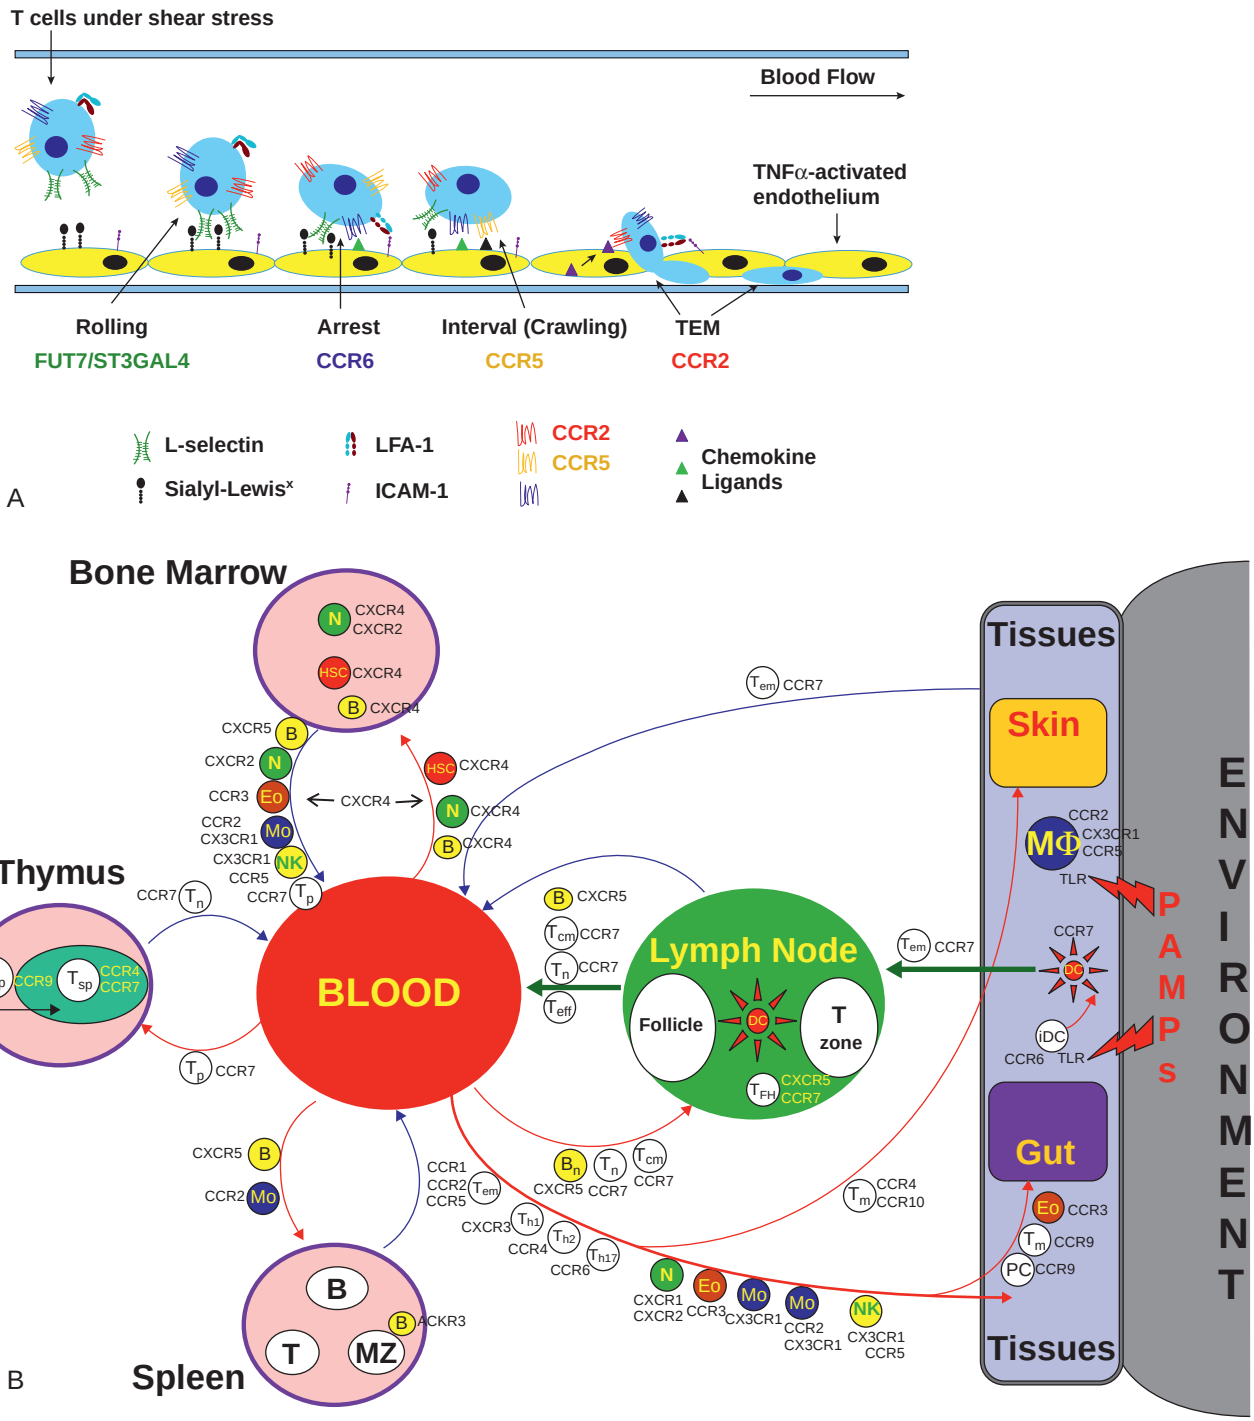

FIG. 15.4 Chemokine Receptor Control of Leukocyte Trafficking. (A) Multistep model of leukocyte transendothelial migration *(TEM)*. An example of MAIT cell trafficking across TNF-activated human umbilical vein endothelial cells *(HUVEC)* is summarized.[16] FUT7/ST3GAL4 is a fucosyltransferase important for biosynthesis of L-selectin ligand. (B) Chemokine regulation of leukocyte trafficking itineraries under homeostatic and inflammatory conditions. Shown are key receptors on the indicated leukocyte subtypes that control trafficking into, within, and out of primary and secondary immune organs and the periphery. *Eo*, Eosinophil; *GC*, germinal center *HSC*, hematopoietic stem cell; *iDC*, immature dendritic cells; *Mo*, monocyte; *Mφ*, macrophage; *N*, neutrophil; *NK*, natural killer cell; *PC*, plasma cell; T_{cm}, central memory T cells; T_{eff}, effector memory T cells; T_{FH}, follicular helper T cells; T_m, memory T cells; T_n, naïve T cells; T_p, precursor T cells. The model is based primarily on studies of mice where the relevant gene has been inactivated by gene targeting. (Panel A was created by Joshua Farber, NIAID.)

which produce large amounts of cytokines but have low killing capacity, preferentially express CCR7. The exact profile of chemokine receptor expression can be modulated by adherence and stimulation ex vivo with IL-2. Cognate chemokines chemoattract NK cells and promote degranulation and killing.

Dendritic Cells and Transition to the Adaptive Immune Response

Transition from innate to adaptive phases of the immune response involves antigen uptake by antigen-presenting cells (Chapter 6), especially dendritic cells, mediated by Fc and complement phagocytic receptors; as well as pattern recognition receptors (PRRs) (Chapter 3), including DC-SIGN and Toll-like receptors (TLRs), which differentially induce inflammatory chemokine expression. Pathogens can skew the nature and magnitude of the immune response in a specific direction by means of specific PRR ligands.

The chemokine receptors expressed on DCs vary depending on the nature of the inflammatory stimulus and type. For example, blood-derived plasmacytoid and myeloid DCs express a similar repertoire of inflammatory chemoattractant receptors, but they are functional only on myeloid DCs. CCL3, CCL4, and CCL5 may be particularly important for recruiting additional mononuclear phagocytes and DCs to sites of infection. This can amplify the late stage of the innate immune response, and, in the extreme, can progress to endotoxic shock. Genetic disruption of the CCL3/CCL4/CCL5 receptor CCR5 renders mice relatively resistant to LPS-induced endotoxemia.

Adaptive Immunity

Afferent Trafficking to Secondary Lymphoid Tissue

The homeostatic receptors CXCR5 and CCR7 and their ligands are major regulators of the immune response, acting at the level of B and T lymphocyte and DC trafficking to and within secondary lymphoid tissue (Chapter 16).[19,23,24] DC maturation in peripheral tissues is associated with downregulation of inflammatory receptors such as CCR6, which is important for recruitment, migration and retention in the periphery, and reciprocal upregulation of CCR7, which mediates mature DC migration to draining lymph nodes. Inflammatory receptors, such as CCR2, may also contribute to afferent lymphatic trafficking. In addition to these general DC receptors, XCR1 is expressed on a niche subset of cross-presenting CD8 dendritic cells. CCR7 is also a major lymph node trafficking receptor for naïve T cells and can mediate activated T-cell exit from inflamed tissue.

The CCR7 ligand CCL21 is constitutively expressed on afferent lymphatic endothelium, high endothelial venules (HEVs), stromal cells and interdigitating dendritic cells in T-cell zones of lymph node, Peyer patch, mucosa-associated lymphoid tissue, and spleen. It is not expressed in B-cell zones or sinuses. CCL19, another CCR7 ligand, is also restricted to the T-cell zone and is expressed on interdigitating DCs.

CCR7$^{-/-}$ mice and the *plt* mouse, which is naturally deficient in CCL19 and a CCL21 isoform expressed in secondary lymphoid organs, have similar phenotypes: atrophic T-cell zones populated by a paucity of naïve T cells. This and the failure of activated DCs to migrate to lymph node from the skin of these mice explain why contact sensitivity (Chapter 48), delayed-type hypersensitivity, and antibody production are severely impaired. However, lymph node trafficking is not completely abolished in these mice, which may develop autoimmune phenomena.

CXCR5 is expressed on all peripheral blood and lymph node B cells as well as on some T cells. Its ligand CXCL13 is expressed constitutively on follicular HEV and controls trafficking of CXCR5 positive B and T cells from the blood into follicles (Chapter 16). In *Cxcr5*$^{-/-}$ mice, B cells do not migrate to lymph node, Peyer patches are abnormal, and inguinal lymph nodes are absent. CXCL13 is also required for B-1 cell homing, natural antibody production, and body cavity immunity (Chapter 7). *Cxcr5*$^{-/-}$ mice still can produce antibody, perhaps in part because B cells and follicular DC, by an unknown mechanism, are able to form ectopic germinal centers within T-cell zones of the periarteriolar lymphocyte sheath of spleen.

Migration Within Lymph Node Microenvironments

CXCR5 is expressed on a majority of memory CD4 T cells (Chapter 11) in the follicles of inflamed tonsils. Follicular helper T cells (T_{FH}), a CD57$^+$ subset of CXCR5$^+$ T cells, lack CCR7, which licenses them to move from the T-cell zone following activation to the follicles where they provide help for B-cell maturation and antibody production. Reciprocally, B cells activated by antigen in the follicles upregulate CCR7 and move towards the T-cell zone. Thus, B-T interaction can be facilitated by reciprocal movement of these cells, which may be influenced by the balance of chemokines made in adjacent lymphoid zones. CXCR4 signaling is also important in naïve and memory B-cell trafficking to germinal centers, and CCR5 ligands can guide antigen-specific CD8 T cells to sites of helper T cell–dendritic cell conjugation for activation in lymph nodes.

Efferent Trafficking

Naïve T cells that do not encounter antigen continue to recirculate between the blood and secondary lymphoid tissue in a CCR7-dependent manner. Most antigen-activated T cells die by apoptosis (Chapter 17). The survivors can be divided into functionally distinct memory and effector cell subsets with characteristic patterns of chemokine receptor expression. The CD4 memory subsets (Chapter 11) include effector memory cells (T_{EM}) and central memory cells (T_{CM}). T_{EM} do not express L-selectin or CCR7 and surveil peripheral tissues, rapidly releasing cytokines in response to activation by recall antigens. T_{CM} express CCR7 and L-selectin and recirculate between blood and secondary lymphoid organs, where they efficiently interact with cognate antigen-presenting DCs and differentiate into effector cells upon costimulation.

Upon antigen activation, effector CD4 T-cell subsets downregulate CCR7 and upregulate inflammatory chemokine receptors that mediate trafficking to tissue sites. Exit from lymph node via efferent lymphatics is mediated by additional mechanisms including S1PR (sphingosine-1-phosphate receptor) signaling, which can be blocked by the immunosuppressive drug FTY720 (fingolimod). CXCR3 is the signature trafficking receptor for Th1 cells, reinforced by CXCR6, CCR2, and CCR5; CCR4 is the signature chemokine receptor expressed on Th2 cells, reinforced by CCR3 and CCR8; and CCR6 is the signature chemokine receptor for Th17 cells.

Polarization is established in each case by positive feedback loops involving subset-specific signature cytokine induction in tissue cells of the chemokine ligands for the corresponding signature chemokine receptor. For example, the Th1 cytokine IFN-γ induces production in tissue cells of the CXCR3 agonists CXCL9–11, which maintain Th1 polarization by recruiting Th1 cells and by blocking the Th2 chemokine receptor CCR3. CCR3 is also expressed on eosinophils and basophils, which participate in Th2-type allergic inflammation. Each co-expressed receptor may have nonredundant function. For example, CCL8 signaling via CCR8 is a nonredundant pathway for recruiting a population of highly differentiated IL-5$^+$ Th2 cells to skin that is important in a mouse model of atopic dermatitis (Chapter 48). Tregs (Chapter 13) also

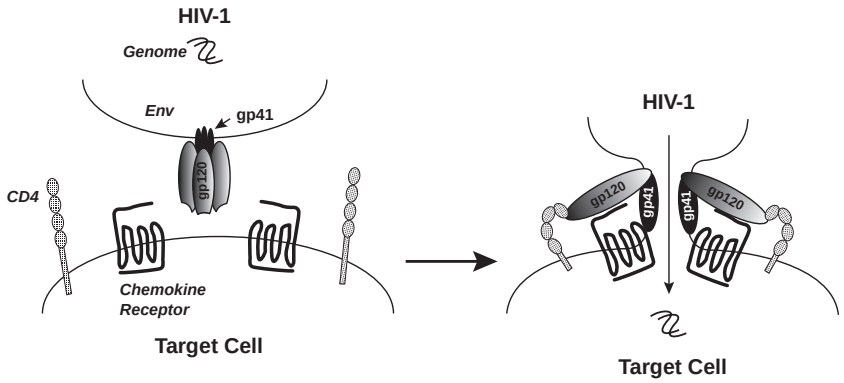

FIG. 15.5 Human Immunodeficiency Virus 1 (HIV-1) Usage of Chemokine Receptors for Cell Entry. See text for details.

express a distinct subset of chemokine receptors. CCR4 and CCR5 are expressed on most freshly isolated natural Tregs, with less consistent expression of CXCR3 and CXCR4.

Mucosa-associated invariant T (MAIT) cells (Chapter 3) are a prominent subset of human CD8 TCR αβ effector/memory cells in the blood and mucosa that express the MHC (Chapter 5) class 1-like molecule MR1 and a semi-invariant TCRα chain specific for riboflavin metabolites. They are thought to be important in innate-like T-cell responses to bacteria, and have been shown to migrate using CCL20/CCR6 as an endothelial arrest system and CCR2 for transendothelial migration (see Fig. 15.4A).[16] Conventional TCR $\alpha\beta^+$ CD8 cytotoxic T cells express CXCR3, CCR2, CCR5 and other inflammatory chemokine receptors. Optimal development of resident memory CD8 T cells in the skin involves signaling by CXCR6 and CCR10.

Tissue-Specific Lymphocyte Homing

Cutaneous lymphocyte-associated antigen (CLA^+) T lymphocytes, which home to skin, preferentially express CCR4 and CCR10. The CCR4 ligand CCL22 is made by resident dermal macrophages and DCs, whereas the CCR10 ligand CCL27 is made by keratinocytes. Blocking both pathways, but not either one alone, has been reported to inhibit lymphocyte recruitment to the skin in a delayed-type hypersensitivity model.

Homing to small intestine is determined in part by T-lymphocyte expression of the integrin $\alpha_4\beta_7$ and CCR9. The $\alpha_4\beta_7$ ligand MADCAM-1 and the CCR9 ligand CCL25 co-localize on normal and inflamed small intestine endothelium. Most T cells in the intraepithelial and lamina propria zones of the small intestine express CCR9. These cells, which are mainly $TCR\gamma\delta^+$ or $TCR\alpha\beta^+$ $CD8\alpha\beta^+$, are reduced in small intestine from $CCR9^{-/-}$ mice.

As B cells differentiate into plasma cells, they downregulate CXCR5 and CCR7 and exit the lymph node. B immunoblasts expressing IgG coordinately upregulate CXCR4, which promotes homing to the bone marrow, whereas B immunoblasts expressing IgA specifically migrate to mucosal sites. Like gut-homing T cells, B immunoblasts that home to small intestine express $\alpha_4\beta_7$ integrin and CCR9 and respond to CCL25.

CLINICAL CORRELATES

Chemokines and Disease

There is a vast literature addressing the presence and potential clinical relevance of chemokines in human disease. This section provides only a sampling of this work, highlighting those diseases with the strongest evidence for a role in pathogenesis in humans, in some cases leading to clinical trials and new treatments.

CLINICAL RELEVANCE

Examples of Chemokine and Chemokine Receptor Determinants of Human Disease

- WHIM syndrome: Mendelian combined immunodeficiency due to gain-of-function mutations in *CXCR4*
- *Plasmodium vivax malaria*: Protection due to a nonfunctional promoter variant in ACKR1/Duffy. Sub-Saharan Africa variant abrogates expression on erythrocytes, preventing parasite cell entry
- HIV: Protection from cell entry by the virus conferred by homozygous loss-of-function mutation *CCR5Δ32* and by FDA-approved CCR5 antagonist maraviroc/Selzentry (Pfizer)
- AIDS disease progression rate: Slowed by heterozygous *CCR5Δ32*
- West Nile virus disease: Increased risk with homozygous *CCR5Δ32*
- Kaposi sarcoma: Human herpesvirus 8 vGPCR
- Age-related macular degeneration: Increased risk with *CX3CR1 M280* allele
- Cardiovascular disease: Decreased risk with *CX3CR1 M280* allele
- Autoimmune heparin-induced thrombocytopenia: Caused by autoantibodies to CXCL4-heparin complexes
- Chronic renal allograft rejection: Reduced risk with homozygous *CCR5Δ32*
- Rheumatoid arthritis: Reduced risk with *CCR5Δ32*
- Eosinophilic esophagitis: Associated with CCL26 variant

HIV/AIDS

Human immunodeficiency virus (HIV) (Chapter 41) envelope glycoprotein gp120 mediates fusion of the viral envelope with the target cell membrane by binding to both CD4 and a specific chemokine receptor, which is referred to in this context as an HIV coreceptor (Fig. 15.5).[25] CCR5 and CXCR4, the most important HIV coreceptors, have been shown to physically associate with both CD4 and gp120, and HIV viruses are classified into three main subtypes (X4, R5, and R5/X4) by their specific usage of these receptors.

Individuals homozygous for *CCR5Δ32*, a nonfunctional allele that occurs in approximately 20% of North American Caucasians, appear healthy and are highly resistant to R5 HIV, the main transmitting strain. HIV-infected heterozygotes experience slower disease progression. The CCR5 antagonist maraviroc (Selzentry; Pfizer, New York, USA) is approved for treatment of patients with HIV/acquired immunodeficiency syndrome (AIDS). Remarkably, two HIV^+ patients (the "London patient" and the "Berlin patient") both developed hematologic malignancies that were fortuitously treated after cytoreductive

CLINICAL RELEVANCE

Examples of Approved Drugs Targeting the Chemokine System

- Maraviroc (Selzentry; Pfizer): Small-molecule oral CCR5 antagonist FDA approved in 2007 that blocked target cell entry by R5 strains of HIV.
- Plerixafor (Mozobil, AMD3100; Sanofi): Small-molecule parenteral CXCR4 antagonist FDA approved in 2008 as combined treatment with G-CSF for HSC mobilization for collection and autologous transplantation in patients with multiple myeloma and non-Hodgkin lymphoma receiving cytoreductive therapy.
- Mogamulizumab-kpkc (Poteligeo; Kyowa-Kirin): Humanized afucosylated monoclonal antibody that blocks CCR4, FDA approved in 2018 for treatment refractory patients with mycosis fungoides and Sezary syndrome.

therapy by rescue bone marrow transplant from *CCR5Δ32* homozygote donors, resulting in sustained undetectable viral load off antiretroviral therapy, suggesting a functional "cure." This has motivated gene editing cure strategies to inactivate *CCR5* in T cells in HIV/AIDS.[26] The creation of germline CRISPR-mutated *CCR5* humans has also been reported and broadly criticized on ethical grounds. CCR5 appears to be important in the pathogenesis of West Nile virus (WNV) infection, but instead of facilitating infection, it plays a protective role by mediating antiviral T-cell and monocyte trafficking to infected brain.

Malaria

The *Plasmodium vivax* Duffy binding protein (PvDBP) is a protein expressed in micronemes of the merozoite form of the parasite that facilitates infection of erythrocytes by binding via a cysteine-rich domain to the N-terminal domain of ACKR1 (originally known as Duffy and later as DARC [Duffy Antigen Receptor for Chemokines]. This promotes junction formation during invasion. *P. vivax*-malaria is rare in sub-Saharan Africa due to genetic deficiency in ACKR1 caused by a single nucleotide substitution in the gene promoter (−46 C) affecting an erythroid-specific GATA-1 site.[27] ACKR1 deficiency is associated with benign ethnic neutropenia.

WHIM syndrome

Autosomal dominant truncating mutations in CXCR4 that inhibit CXCL12-dependent receptor desensitization cause WHIM syndrome, a rare Mendelian disease characterized by the acronymic tetrad of *w*arts, *h*ypogammaglobulinemia, *i*nfection, and *m*yelokathexis (neutropenia without maturation arrest).[28] Myelokathexis and infection reflect the bone marrow retention function of CXCR4 for myeloid cells, inhibiting their egress to blood. Most patients are also lymphopenic. Mechanism-based treatment with the selective CXCR4 antagonists plerixafor (Mozobil, AMD3100; Sanofi, Massachusetts, USA) and mavorixafor (X4-Pharma, Massachusetts, USA) have been advanced to phase 3 clinical trials in WHIM syndrome. Plerixafor is a short-acting parenteral bicyclam FDA-approved drug for use with G-CSF to mobilize HSCs for autologous transplantation in patients with multiple myeloma or lymphoma undergoing cytoreductive therapy. Mavorixafor is a new oral agent.

A patient has been identified who was spontaneously cured of WHIM syndrome as an adult by an acquired second complex mutational event known as chromothripsis (chromosome shattering), which deleted the disease copy of *CXCR4* in a single HSC. The affected $CXCR4^{+/o}$ HSC acquired a selective advantage and repopulated the bone marrow, resulting in durable correction of neutropenia and monocytopenia, clearance of warts, and cessation of recurrent bacterial infections. $CXCR4^{+/o}$ mouse HSCs have enhanced proliferative capacity in vivo and phenocopy the engraftment advantage in the patient, suggesting specific *WHIM* allele deletion as a gene therapy cure strategy.

ON THE HORIZON

Basic Principles

- Elucidation of the stoichiometry, presentation requirements, and mechanisms of receptor activation by chemokines through structural studies of chemokine receptors complexed to chemokines, G proteins, and other effectors.
- A more comprehensive understanding of chemokine immunoregulation by means of systems immunology using proteomics and single cell technologies.
- More precise targeting of the chemokine system in disease through biased agonism.
- Detailed delineation of mechanisms of microbial pathogenesis, including immunomodulation by pathogens, by using microbial chemokine mimics.
- A more comprehensive understanding of chemokine multitasking and for mining natural products as therapeutics through the study of the evolution of the chemokine system.

Clinical Correlates

- More rapid development of novel therapeutics by development of disease validation and targeting pipelines.
- Unbiased systematic surveys of chemokine and chemokine receptor expression in the context of disease models and human disease samples from centralized Biobanks.
  - Targeted interrogation by CRISPR-mediated gene knockout technology in mice.
  - Drug discovery by target structure-based design.
  - Clinical trials drawing patients from large disease registries.
- Cure strategies in HIV/AIDS, WHIM syndrome and potentially other diseases based on chemokine system gene editing.
- Development of a next generation of multi-chemokine receptor blocking agents, based on the recognition that chemokines may drive chronic inflammation in humans in a combinatorial manner.
- Define the contribution of chemokines and chemokine receptors to Covid-19 pathogenesis.

Atherosclerosis

Macrophages are the dominant leukocyte present in atherosclerotic lesions and are associated with the presence of macrophage-targeted chemokines such as CCL2, CCL5, and CX3CL1.[29] $CCL2^{-/-}$, $CCR2^{-/-}$, $CX3CL1^{-/-}$, and $CX3CR1^{-/-}$ mice on the atherogenic $ApoE^{-/-}$ genetic background demonstrate smaller lesions and reduced accumulation of macrophages in the vessel wall, and mice lacking both *Ccl2* and *Cx3cr1* treated with Met-CCL5, a chemically modified variant of CCL5 that blocks CCR1, CCR3, and CCR5, were almost completely protected. Adoptive transfer studies with bone marrow from $Cxcr2^{-/-}$ mice have also revealed a role for CXCR2 in promoting atherosclerosis in mouse models, apparently by promoting monocyte adhesion to early atherosclerotic endothelium through interaction with its mouse ligand KC and activation of the VLA-4/VCAM-1 adhesion system. The CX3CR1 genetic variant CX3CR1-M280, which lacks normal CX3CL1-dependent adhesive function, is associated with reduced risk of atherosclerotic vascular disease. Mechanistic studies suggest that CX3CL1 on coronary artery smooth muscle cells anchors macrophages via CX3CR1.

Kaposi Sarcoma

HHV8 (also called Kaposi sarcoma [KS]–associated herpesvirus) is an example of a virus laden with genes encoding pirated

chemokines and chemokine receptors. It encodes three CC chemokines, vMIP-I, II, and III, as well as a constitutively active CC/CXC chemokine receptor named vGPCR, encoded by *ORF74*. All these factors are angiogenic and may contribute to the pathogenesis of KS, a highly vascular multicentric nonclonal tumor caused by HHV8, typically in the setting of immunosuppression such as in HIV/AIDS. Consistent with this, vGPCR induces KS-like tumors when expressed in transgenic mice. The mechanism may involve activation of NF-κB and induction of angiogenic factors and proinflammatory cytokines. This virus appears to have converted a hijacked receptor, probably CXCR2, into a regulator of gene expression.[10]

Autoimmunity

An established risk factor for thromboembolic complications of heparin therapy, heparin-induced thrombocytopenia occurs in 1% to 5% of patients treated with heparin and is the result of autoantibodies that bind specifically to CXCL4-heparin complexes in plasma. In general, T cell–dependent autoimmune diseases in humans, such as psoriasis (Chapter 64), multiple sclerosis (MS) (Chapter 66), rheumatoid arthritis (RA) (Chapter 53), and type I diabetes mellitus (Chapter 71), are associated with inflammatory chemokines and tissue infiltration by T lymphocytes and monocytes expressing inflammatory chemokine receptors.[30,31] In a mouse model of immune complex–induced arthritis, the specific contributions of Ccr1, Cxcr2, Blt1 (a leukotriene B4 receptor) and the C5a receptor have been dissected in detail in joint venules at the level of adhesion and transendothelial migration. A dominant negative antagonist of CCL2 inhibits arthritis in the MRL-*lpr* mouse model of RA, suggesting a potential role for CCL2 and CCR2. Met-CCL5 treatment was beneficial in a collagen-induced arthritis model in DBA/I mice. The importance of the CCL20/CCR6 axis has been validated in multiple mouse models of psoriasis, working in part through IL-17 produced by recruited γδ T cells in the dermis.

CCR9 is an attractive drug target in Crohn disease (Chapter 75) due its important role in T-cell homing to the gut and proof-of-principle preclinical evidence in mouse models. However, the specific allosteric CCR9 antagonist CCX282-B (ChemoCentryx), also known as vercirnon, has demonstrated mixed results in phase 2/3 clinical trials.

Acute Neutrophil-Mediated Inflammatory Disorders

Many neutrophil-mediated human diseases have been associated with the presence of CXCL8, including psoriasis, gout, acute glomerulonephritis, acute respiratory distress syndrome (ARDS), RA, and ischemia-reperfusion injury.[21] Over 25 years, 8 small-molecule CXCR2- and CXCR1/2-specific antagonists have been tested in 54 registered clinical trials for diverse disease indications, including chronic obstructive pulmonary disease (COPD), inflammation damage after islet cell transplantation, bullous pemphigoid, asthma, respiratory syncytial virus (RSV) infection, psoriasis, cancer, myelodysplastic syndrome, cystic fibrosis, and ulcerative colitis. Most of the inflammation trials were terminated. The CXCR1/2 antagonist reparixin (Dompe) was advanced into phase 3 for islet cell transplantation. The cancer trials opened recently and are enrolling.

Transplant Rejection

The most extensive analysis of the role of chemokines in transplant rejection (Chapter 89) has been carried out in an MHC class I/II-mismatched cardiac allograft rejection model in the mouse, which is mediated by a Th1 immune response. Sets of inflammatory chemokines are found in the mouse model that resemble those in the human disease; these appear in a strict temporal sequence. Analysis of knockout mice has demonstrated that while multiple chemokine receptors contribute to rejection in this model, there is a marked rank order: Cxcr3 > > Ccr5 > Ccr1=Cx3cr1=Ccr2. Most impressively, rejection and graft arteriosclerosis do not occur if the recipient mouse, treated with a brief, subtherapeutic course of cyclosporine, is *Cxcr3*$^{-/-}$ or if the donor heart is *Cxcl10*$^{-/-}$. In humans, CCR5 may be important in chronic kidney allograft rejection, since individuals homozygous for *CCR5Δ32* are underrepresented among patients with this outcome in a large German kidney transplantation cohort.

Allergic Airway Disease

Chemokine receptors associated with asthma (Chapter 43) include CXCR2, CCR3, CCR4, and CCR8. CCR3 is present on eosinophils, basophils, mast cells, and some Th2 T cells. CCR4 and CCR8 identify airway T cells of allergen-challenged atopic asthmatics. Despite extensive preclinical proof-of-principle, clinical trials of 3 CCR3 antagonists, 2 CCR4 antagonists, and 1 CXCR1/2 antagonist in asthma have been disappointing.

Eosinophilic esophagitis has been associated with a CCL26 variant. Although there is no CCL26 homologue in mouse, other mouse CCR3 ligands have been implicated in a mouse model of this disease.

Cancer

Many chemokines and leukocyte subtypes have been detected in situ in tumors, and cancer cells have been shown to produce chemokines and express chemokine receptors.[32] Despite extensive evidence for functional roles in mouse cancer models, the role played by endogenous tumor-associated chemokines in recruiting tumor-infiltrating lymphocytes and tumor-associated macrophages, and in promoting an antitumor immune response, has not been clearly delineated in humans. On the contrary, there are data from mouse models suggesting that the overall effect may be to promote tumorigenesis through additional effects on cell growth, angiogenesis, apoptosis, immune evasion, and metastasis. Controlling the balance of angiogenic and angiostatic chemokines may be particularly important. Chemokine receptors on tumor cells have been shown to directly mediate chemokine-dependent proliferation.

The most extensively studied chemokine receptor in cancer is CXCR4,[33] which is expressed ectopically or normally by multiple cancer types and has been implicated in multiple functions, including proliferation, anchorage, quiescence, and radiation and chemotherapy resistance of leukemic stem cells in bone marrow and breast cancer metastasis. It has been used successfully as a Cu^{64}-AMD3100 positron emission tomography (PET) imaging target for adrenocortical carcinoma metastasis in a patient. Acquired *CXCR4* mutations, including several gain-of-function mutations that cause WHIM syndrome, have been found in most patients with the plasma cell cancer Waldenstrom macroglobulinemia (Chapter 79), and have been associated with poor prognosis and poor treatment responses. A large number of clinical trials are testing CXCR4 inhibitors in various cancers, and seven have been advanced to phase 3.

CCR4 and CCR10 have been associated with several cancers, including melanoma. A humanized afucosylated cell-depleting anti-CCR4 monoclonal antibody named mogamulizumab-kpkc

(Poteligeo; Kyowa-Kirin) was FDA-approved in 2018 for the treatment of treatment-experienced refractory adult T-cell leukemia/lymphoma (Sezary syndrome and mycosis fungoides), which express CCR4 at high levels.

THERAPEUTIC APPLICATIONS

Chemokines and Chemokine Receptors as Targets for Drug Development

Chemokine receptors are the first cytokine receptors for which potent, selective nonpeptide small-molecule antagonists have been identified that work in vivo, including antagonists at CXCR2, CXCR3, CXCR4, CCR1, CCR2, CCR3, CCR5, and CCR9. Many of the compounds share a nitrogen-rich core and may block ligand binding by acting at either orthosteric or allosteric sites. As of 2020, approximately 700 clinical trials of drugs targeting the chemokine system have been registered and/or published, approximately `32 targeting chemokines, the rest targeting chemokine GPCRs. Approximately 70% of the trials targeted just three receptors, CCR4, CCR5, and CXCR4, the only three for which targeted drugs have received FDA approval: maraviroc targeting CCR5 in HIV/AIDS; plerixafor targeting CXCR4 in HSC mobilization; and mogamulizumab-kpkc targeting CCR4 in adult T-cell leukemia/lymphoma. Sixty-five of the approximately 700 trials have been advanced to phase 3, of which 59 were for the three approved drugs. Thus, in contrast to these three niche areas, the enormous effort expended toward targeting the chemokine system one component at a time in acute and chronic disease states has not yet resulted in approved drugs, and many failures have been reported. The fact that viral and tic antichemokines typically block multiple chemokines acting at multiple receptors hints that the most clinically effective chemokine-targeted antiinflammatory strategy may need to provide broad-spectrum coverage or define the key timepoint when intervention is most likely to be successful.[34]

Although small molecules taken as pills are the main goal, other blocking strategies are also under consideration, such as (1) ribozymes, (2) modified chemokines (e.g., amino-terminally-modified versions of CCL5), (3) intrakines, which are modified forms of chemokines delivered by gene therapy that remain in the endoplasmic reticulum and block surface expression of newly synthesized receptors, (4) monoclonal antibodies and llama nanobodies,[35] and (5) specific gene editing using zing finger nucleases, TALENs, and CRISPR/CAS9.

Chemokines as Biological Response Modifiers

Both inflammatory and homeostatic chemokines are being evaluated for therapeutic potential as biological response modifiers, acting mainly as immunomodulators or as regulators of angiogenesis. Studies to date have not revealed major problems with toxicity, and efficacy has been noted in models of cancer, inflammation, and infection. Clinical trials in cancer and stem cell protection have been disappointing. Chemokines are also being developed as vaccine adjuvants. Chemokine gene administration has also been shown to induce neutralizing antibody against the encoded chemokine, which is able to block immune responses and to ameliorate EAE and arthritis in rodent models.

Many chemokines, when delivered pharmacologically as recombinant proteins or by plasmid DNA or in transfected tumor cells, are able to induce immunologically mediated antitumor effects in mouse models and could be clinically useful. Chemokines could also be useful as adjuvants in tumor antigen vaccines and to potentiate leukocyte trafficking to tumor and immune responses that potentiate immune checkpoint inhibitor therapy. Chemokine-tumor antigen fusion proteins represent a novel twist on this approach that facilitates uptake of tumor antigens by antigen-presenting cells via the normal process of ligand–receptor internalization. Non-ELR CXC chemokines such as CXCL4 also exert antitumor effects through angiostatic mechanisms. Lastly, one can conceive of using chemokine-based immunotoxins to target disease cell–associated chemokine receptors, including cells infected with viruses such as human cytomegalovirus (HCMV) that encode chemokine receptors.

CONCLUSION

The chemokine system occupies a central place in immunoregulation and is an attractive source of potential drug targets for any disease with an innate or adaptive immune component. A basic outline for how the system works has been established using mouse models, and there has now been tangible progress translating this knowledge to the clinic. Three major successes, CCR5 inhibition in HIV/AIDS, CXCR4 inhibition for HSC mobilization, and CCR4 targeting in adult T-cell leukemia/lymphoma, are pioneers demonstrating the feasibility of targeting the chemokine system therapeutically in humans. However, all are eccentric indications that address niche roles of chemokine receptors. Chronic immune-mediated diseases remain a major unmet medical need, where the chemokine system offers many targets and difficult challenges for the future that may require targeting of multiple chemokine receptors simultaneously.

Lymphocyte Adhesion and Trafficking

Sirpa Jalkanen and Marko Salmi

EARLY LYMPHOCYTE PRECURSOR TRAFFICKING TO THE PRIMARY LYMPHOID ORGANS

Lymphocyte trafficking begins at an early stage of human ontogeny when lymphocyte precursor cells first appear and migrate into the primary lymphoid organs. The multipotent hematopoietic progenitor and stem cells from the yolk sac and from the aorta–gonad–mesonephros migrate via the circulation to the liver and the spleen, which are important organs that support lymphocyte production in the embryo (Chapter 2), and then into bone marrow.[1] Thereafter, the developmental maturation of B cells takes place solely in bone marrow (Chapter 7). T cells, in contrast, require an additional migratory event, which involves the entry of marrow-derived T-cell progenitors into the thymus (Chapter 9).[2] These early T-cell progenitors enter the thymus via the vessels in the cortical region. Concomitant with their differentiation and maturation via positive and negative selection, they pass from the cortex into the medulla.

MIGRATION OF NAIVE MATURE LYMPHOCYTES FROM BLOOD TO THE SECONDARY LYMPHOID ORGANS

After completing their initial course of development, newly arisen naïve B and T cells exit the primary lymphoid organs, travel through blood, and extravasate selectively to the secondary lymphoid organs.[3–5] These organs include peripheral lymph nodes, organized lymphoid tissues of the gut (e.g., Peyer patches and the appendix), and the spleen (Chapter 2). Interestingly, in mice lymphocyte homing to lymph nodes displays strong circadian regulation, with a peak at the onset of darkness.[6]

In lymph nodes, most lymphocyte trafficking from blood to tissues takes place in specialized postcapillary venules. The endothelial cells of the venule exhibit a characteristic high cuboidal morphology that has given them their name: high endothelial venules (HEVs).[4,7] The protrusion of the surface of these endothelial cells into the vascular lumen promotes the interaction of leukocytes with the endothelial surface membrane in the relatively low-shear venular part of the circulatory system (Fig. 16.1). HEVs carry many unique adhesion molecules that enable the capture of passing lymphocytes. They also have special intercellular connections that facilitate penetration of the vessel walls by these emigrating lymphocytes. It has been estimated that more than 50% of incoming lymphocytes make transient contacts with the vascular lining in the lymph nodes and that as many as one passing cell in four adheres to the endothelium and then extravasates into the tissue.

KEY CONCEPTS

Lymphocyte Recirculation

- Lymphocytes recirculate continuously between blood and lymphoid organs.
- Approximately 80% of lymphocytes enter the lymph nodes via specialized vessels called high endothelial venules (HEVs).
- The remaining lymphocytes enter the lymph nodes together with dendritic cells (DCs) and antigens via afferent lymphatics.
- Lymphocytes leave the lymph nodes via efferent lymphatics.
- Lymphocyte recirculation allows the lymphocytes to meet their cognate antigens and other leukocyte subsets to evoke an efficient immune response.

Antigens gather into these secondary lymphoid organs by a different route. Most antigens in the periphery can be taken up by dendritic cells (DCs) (Chapter 6), which subsequently migrate into the secondary lymphoid organs via the afferent lymphatics.[4] These afferent lymph channels open into the subcapsular sinus of the lymph node. Individual DCs subsequently penetrate the lymphatic endothelium and migrate into the stroma. Unbound, or free, antigens that are being carried via the afferent lymphatics through the body can diffuse into these secondary lymphoid organs, and then they can be captured by the professional antigen-presenting cells (APCs) of the lymph nodes.[8] Lymph nodes thus serve as traps for the immune system, collecting lymphocytes from blood and antigens from lymph (Fig. 16.2). In these organs, lymphocytes percolate through the tissue in search of their cognate antigens.[4,9] If a given lymphocyte does not find its antigen, it will leave the organ by entering the efferent lymphatics that drain the medullary sinuses and is then transported via a major lymphatic trunk, such as the thoracic duct, back into the large systemic veins. After reentering the circulation, the cell can randomly gain access to another lymph node, where it has another chance to extravasate into the tissue and find its cognate antigen. One round of recirculation from blood to the lymph node stroma, to a lymphatic vessel, and then back to blood takes about 1 day. Naïve lymphocytes continue recirculating until they either find their cognate antigen or die.

ACTIVATED LYMPHOCYTES DISPLAY SELECTIVE TISSUE HOMING PATTERNS

In a secondary lymphoid organ, a successful encounter between a lymphocyte and its cognate antigen leads to the proliferation of the cell within the organ and the maturation of its progeny.[4,5,9] Simultaneously, a process called *imprinting* leads to a profound

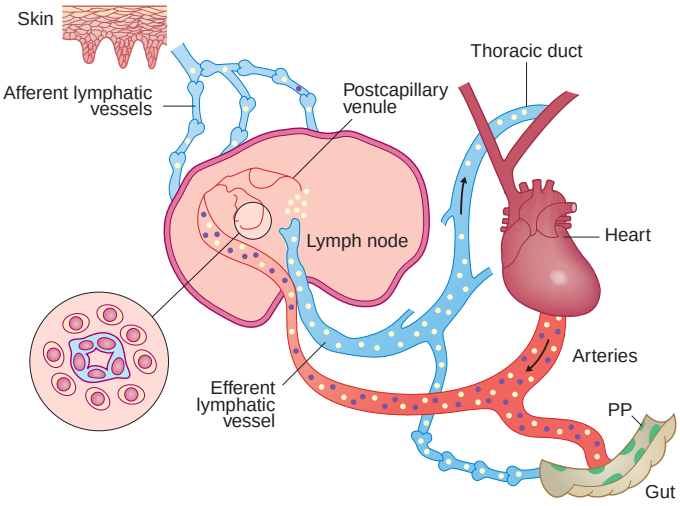

FIG. 16.1 Lymphocyte Recirculation Routes Under Physiological Conditions. A low level of continuous antigenic transport into lymphoid organs takes place via the afferent lymphatics draining the skin and epithelium of the gut. Blood-borne lymphocytes are carried to the organized lymphatic tissues (lymph nodes and Peyer patches *[PP]*) via the arterial tree, flow through the capillary bed, and then extravasate in the postcapillary high endothelial venules (HEVs). The extravasated lymphocytes percolate through the tissue parenchyma, enter the lymphatic vessels, and are then carried via the efferent lymphatics back to the systemic circulation. (Most of the venous circulation has been omitted from the figure.) *Inset:* a cross section of HEV (blue). (From Salmi M, Jalkanen S. How do lymphocytes know where to go: current concepts and enigmas of lymphocyte homing. *Adv Immunol.* 1997;64:139, with permission from Elsevier.)

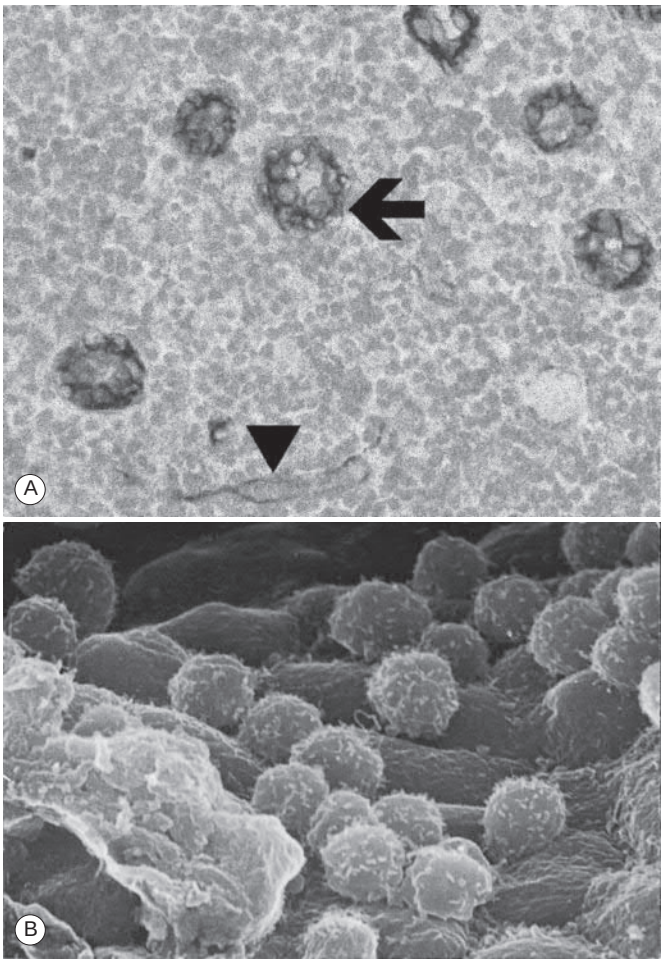

FIG. 16.2 Characteristic Features of High Endothelial Venules (HEVs). (A) In this immunoperoxidase staining with anti-CD31 antibody, six HEVs are seen with typical plump endothelial cells. One HEV is identified with an *arrow*; a vessel with flat endothelium is also seen in this figure *(arrowhead)*. (B) The scanning electron microscopy image shows lymphocytes adhering to the HEV.

change in the subsequent pattern of migration of the antigen-responsive cell. During the imprinting, local DCs give educational clues, such as vitamin A and D metabolites, to the lymphocytes. These lead to changes in the chemoattractant and adhesion receptor repertoire of the lymphocytes (Chapter 15).[10] Although these responding cells leave the node via the lymphatics and are carried back to the systemic circulation, unlike naïve cells, they no longer migrate randomly to any lymphoid tissue. Instead, imprinting primes cells to preferentially seek the peripheral tissues in which the inciting antigen was originally ingested by the DC. In this way, selective homing of lymphocytes according to their previous history allows the organism to focus the immune response to the tissues where the effector cells can do the most good.

Among activated T cells, distinct pools of short-lived T effector cells, long-lived central memory T cells, effector memory T cells, and tissue-resident memory T cells can be distinguished.[5,11] The different profile of adhesion molecule and chemokine receptor expression allows central memory T cells to continue migration through lymph nodes, whereas effector memory T cells are dispersed to patrol the peripheral tissues. In contrast, tissue-resident lymphocytes, including tissue-resident memory T cells, intraepithelial lymphocytes, γδ T cells, and innate lymphoid cells, mostly remain sessile in barrier tissues without the pattern of constant recirculation that is typical for the other lymphocyte subpopulations.

Under normal conditions, two distinct routes of lymphocyte recirculation can be discerned.[4,5] One targets lymphoid cells to the peripheral lymph nodes, and the second targets them to gut-associated lymphoreticular tissues (GALTs; Chapter 24). Although the common gut-associated lymphoreticular system has long been considered to include the intestinal, respiratory, and genitourinary tracts, differences in the fine specificity of lymphocyte homing among these targets do exist.

DISTINCT RECIRCULATION ROUTES IN THE SPLEEN

The spleen holds a unique place in the panoply of secondary lymphoid tissues.[12] It contains more lymphocytes than all of the peripheral lymph nodes combined, and the number of lymphocytes recirculating through it daily is the equivalent of the total pool of circulating lymphocytes. Based on the different anatomical structures of mouse and human spleen, the observations made in mouse are not directly applicable in man. For example, the human spleen does not have the marginal zone surrounding the white pulp, separating red pulp from the white pulp (Chapter 2). This is an important notion from the recirculation point of view, as the marginal zone has been considered to be a main entrance site

for lymphocytes in mouse. Recent studies, however, have demonstrated that lymphocytes can also enter the spleen via the red pulp vessels and thereafter, migrate within the *perivascular channels* to the white pulp in a chemokine receptor, CCR7-dependent manner, promoted by integrins leukocyte function–associated antigen-1 (LFA-1) and very late antigen 4 (VLA-4).

In the white pulp, T cells accumulate in the regions surrounding the central arteriole, a location known as the *periarteriolar sheath*. B cells are scattered in the corona that surrounds these T-cell areas. The spleen does not have afferent lymphatics, but efferent lymphatics may exist. The mechanisms that control the entry and exit of lymphocytes from the spleen remain incompletely understood but include chemokines, oxysterols, sphingosine-1-phosphate, and common lymphatic and vascular endothelial receptor-1 (Clever-1)/stabilin-1.

KEY CONCEPTS

Adhesion Molecules in Inflammation

- Adhesion molecules are important in directing leukocyte traffic to sites of inflammation.
- Numerous inflammatory mediators upregulate and/or induce expression of several endothelial cell adhesion molecules.
- Harmful inflammation can be prevented and cured by blocking the function of adhesion molecules.

INFLAMMATION-INDUCED CHANGES IN LEUKOCYTE TRAFFICKING

During an acute inflammatory response to an antigenic insult, leukocytes can migrate into all nonlymphoid sites. The inflammation-induced leukocyte migration takes place in characteristic waves.[13,14] First, the polymorphonuclear leukocytes rapidly (typically within 1 to 4 hours) infiltrate into the inflammatory focus. They are then followed by mononuclear cells (monocytes and lymphocytes). In a primary challenge, it may take 3 days or more before antigen-specific immunoblasts are seen at the peripheral site of inflammation. However, a secondary response by memory lymphocytes typically has a much shorter lag period. Different CD4 T-helper subpopulations, including Th1, Th2, Th17, and regulatory T cells (Tregs; Chapters 11 and 13), CD8 T-cytotoxic cells (Chapter 12), and B cells (Chapter 7) can all enter the inflamed tissue by using basically the same mechanisms. However, the ratio of these populations and the individual molecules employed can vary.[5,14] Successful resolution of an inflammatory reaction is also dependent on a coordinated program involving specialized proresolving lipid mediators (lipoxins, resolvins, protectins, and maresins), proteins (annexin A1), purines (adenosine), and gaseous mediators (e.g., hydrogen sulfide), all of which serve to halt the inflammatory cell recruitment and to initiate multiple antiinflammatory, tissue-repairing mechanisms.[15]

The normal vascular endothelium in nonlymphoid tissues has a flat, inactive morphology. With inflammation, a series of events renders postcapillary venules in these tissues capable of binding lymphocytes. The most important changes result from the proadhesive effects of a multitude of proinflammatory cytokines that are released by a variety of cell types after being subjected to inflammatory stimuli.[13] If inflammation becomes chronic, marked histological manifestations become apparent in the affected nonlymphoid tissues.[16] Most notably, the venules in these chronically inflamed tissues acquire many of the characteristics of HEVs. Immigrating lymphocytes can form lymphoid follicles that resemble those seen in lymph nodes. These alterations have consequences for lymphocyte recirculation pathways. For example, inflamed skin displays characteristics of lymphocyte homing that are clearly distinct from those of either mucosal or peripheral lymph node systems.[10,17]

MOLECULAR MECHANISMS INVOLVED IN LEUKOCYTE EXTRAVASATION FROM BLOOD INTO TISSUES

The Adhesion Cascade

Dynamic interactions between leukocytes and endothelial cells can be observed both in vitro and in vivo. For example, leukocyte adhesion can be followed in vivo in experimental animals and even in human tissues by intravital microscopy (Fig. 16.3). Leukocyte–endothelial cell interaction during the extravasation cascade can be divided into a series of phases, or steps, that all leukocyte subtypes, including lymphocytes, are thought to follow (Fig. 16.4).[4,5,13,18]

First, the leukocytes marginate out of the main bloodstream and begin to tether and roll on the endothelial cell surface. This step is mediated primarily by selectins and their mucin-like counterreceptors. This slow-velocity movement culminates in an activation phase, during which leukocyte chemokine receptors transmit activation signals by recognizing their chemokine ligands presented on the endothelial cell surface. This leads to avidity and/or affinity changes in leukocyte integrins, which bind leukocytes firmly to their immunoglobulin superfamily ligands on endothelial cells. Leukocytes then begin to crawl on the endothelium. After finding a proper place, they transmigrate through the endothelial cell layer. This transmigration process begins with interactions between leukocyte integrins, their counterreceptors, and other molecules. This step is followed by complex signaling events that lead to protein phosphorylation and dynamic clustering of the cytoskeleton.

Leukocytes typically transmigrate between endothelial cells at the endothelial cell junction (paracellular route), which opens transiently and subsequently closes by localized stimuli.[18] This process requires proteinases, such as matrix metalloproteinase-2 (MMP-2), which is induced in T cells upon adhesion to endothelial cells, as well as other repair mechanisms that are currently not well known. This subsequently closes the path of transmigration. Interestingly, leukocytes can also migrate through endothelial cells (transcellular route) in a subtype-specific fashion. For example, polymorphonuclear leukocytes prefer entering via the interendothelial junctions, whereas nonactivated lymphocytes may choose the transcellular route.[13,18]

KEY CONCEPTS

Leukocyte–Endothelial Cell Interactions

- Leukocytes interact with the vessel wall in a multistep fashion, using several leukocyte surface molecules that recognize their counterreceptors on endothelial cells.
- Selectins mediate the rolling and tethering of leukocytes on the vessel wall.
- Chemokines and their receptors activate leukocyte integrins.
- Only activated integrins are able to mediate firm adhesion between leukocytes and endothelium.
- The transmigration of leukocytes into the tissues requires proteinases and repair mechanisms.

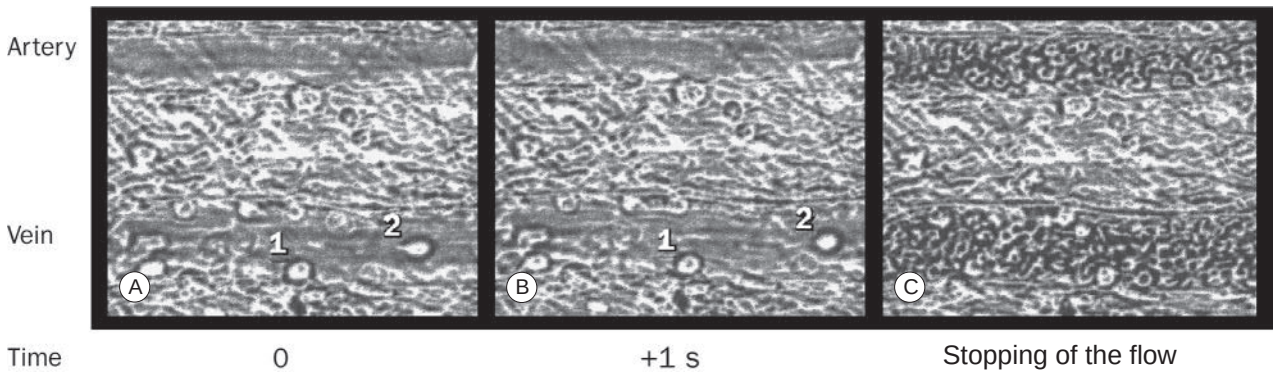

FIG. 16.3 Intravital Microscopy of Mesenteric Vessels. In these video frames taken at indicated intervals from the same field, a vein, an artery, leukocytes, and the transparent mesenteric membrane are seen. Within the vein, rolling and adherent leukocytes are visible, whereas no such cells are seen in the artery. Leukocyte *1* is attached to the vessel wall and leukocyte *2* is slowly rolling. Compare the locations of these cells in A and B to stationary leukocytes outside the vessels. Leukocyte 1 is at the same location in both panels, whereas leukocyte 2 has moved a distance corresponding to roughly the length of its diameter. Under normal conditions, freely flowing cells move so fast that they cannot be visualized. However, in panel C, the flow has been transiently stopped. Under this static condition, the large number of hematopoietic cells (mainly erythrocytes) traveling within the bloodstream can be seen. (Courtesy S. Tohka, University of Turku, Finland.)

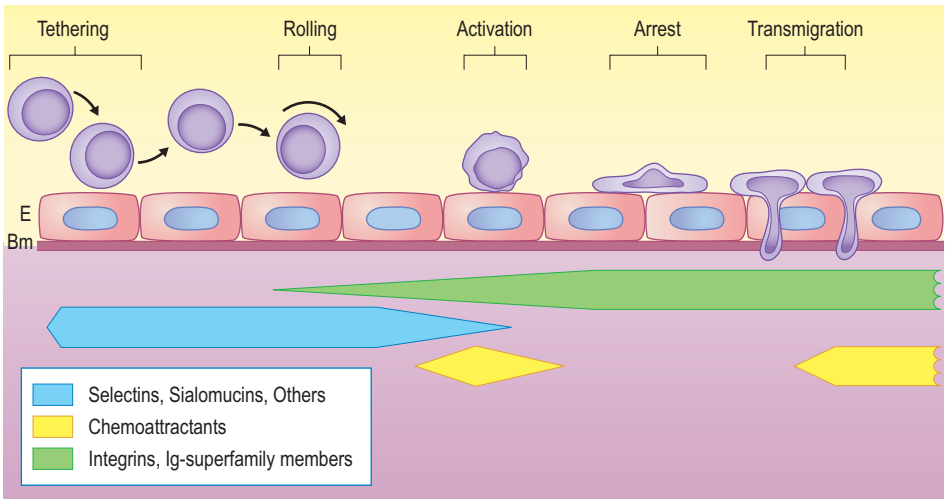

FIG. 16.4 The Multistep Cascade of Lymphocyte Extravasation. The blood-borne cell makes transient initial contacts with endothelial cells (tethering), which leads to the cell rolling along the vascular lining. If the cell becomes activated, it can subsequently adhere firmly to the endothelial cells (arrest). The adherent cell can then penetrate through the endothelial cell cytoplasm (transcellular migration) or seek for interendothelial junctions (crawling). It can then migrate between two endothelial cells (paracellular migration) and finally penetrate the basement membrane to enter the tissue. The contribution of major superfamilies of adhesion-associated molecules at each step is depicted below. *E*, Endothelial layer; *Bm*, basement membrane.

Certain endothelial molecules involved in the adhesion cascade show organ-specific expression patterns. Analogously, leukocyte-associated homing molecules display subtype-specific expression profiles. Only those leukocytes that have the proper set of molecules on their surface can enter a particular tissue because the entering leukocyte must find a correct endothelial partner molecule at each step of the adhesion cascade. Thus leukocyte–endothelial cell interactions take place in a well-coordinated multistep fashion, in which every step must be properly executed before the leukocyte can be guided into the tissue. The multistep nature of the leukocyte adhesion cascade is reminiscent of the cascades involved in blood clotting and complement-mediated killing.

RECEPTORS AND THEIR LIGANDS IN LEUKOCYTE–ENDOTHELIAL CELL INTERACTION

Various molecules belonging to several molecular families are expressed on both leukocyte and endothelial cell surfaces and participate in the complex extravasation process.[18] Most of these molecules exert their function in successive, but overlapping, phases of the adhesion cascade. In addition, proper functioning of multiple intracellular signaling molecules is needed for execution of successful extravasation.[4,18] In the following section, only the best-known surface molecules in this process are discussed (Fig. 16.5).

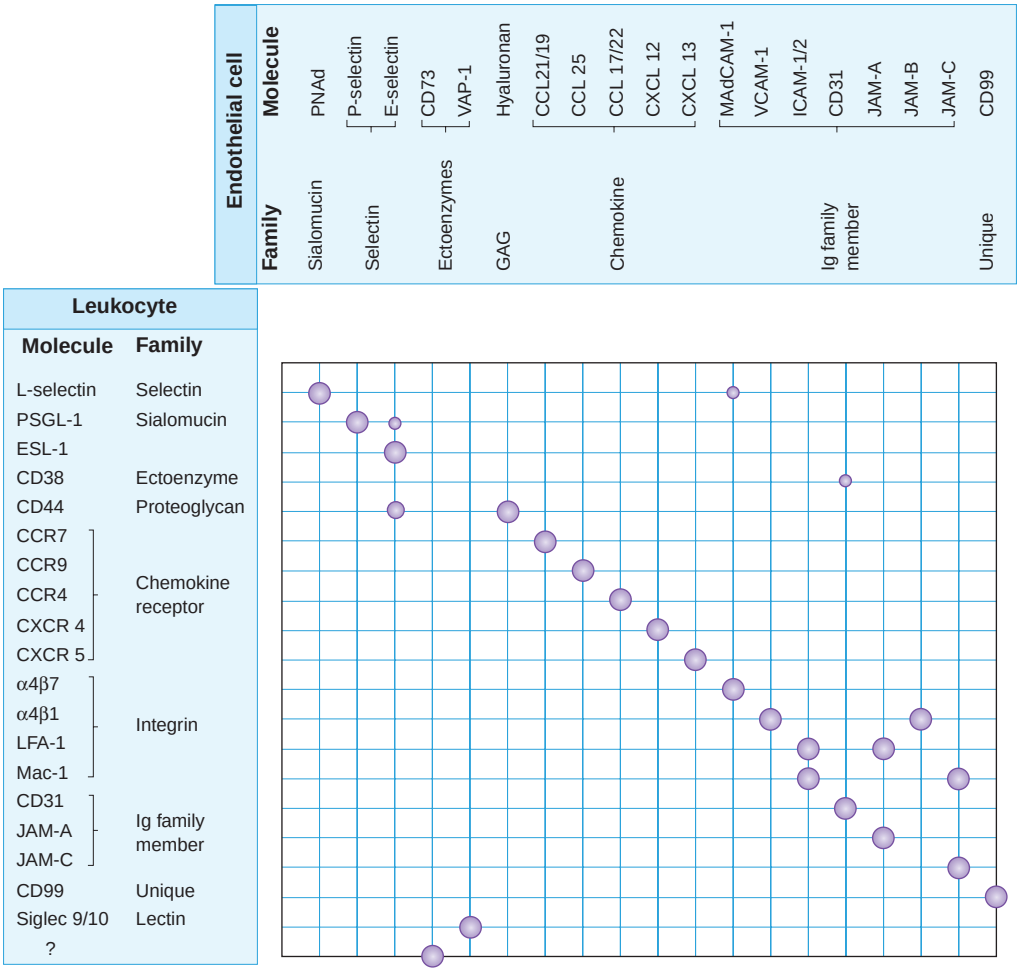

FIG. 16.5 Adhesion Molecules Mediating Leukocyte Traffic. The most relevant proteins involved in leukocyte–endothelial cell interactions are shown as receptor–ligand pairs. *GAG*, Glycosaminoglycan.

Selectins and Their Ligands

Three members of the selectin family mediate leukocyte trafficking. L-selectin is expressed on several leukocyte subpopulations. E-selectin is expressed on the endothelium, and P-selectin is expressed on both platelets and the endothelium. An important structural feature of selectins is the presence of a terminal lectin domain that is used to bind to their counterreceptors. The counterreceptor is typically decorated by a sialyl Lewis X (sLeX) carbohydrate, which is a prototype recognition domain for selectins in general.[19] The interaction between selectins and their counterreceptors is transient and weak, which allows leukocytes to form and break contacts with the endothelium effectively during tethering and rolling under shear stress.

L-selectin preferentially mediates lymphocyte migration to the peripheral lymph nodes.[13,19] However, it also participates in the homing of lymphocytes to organized mucosa-associated lymphoid tissue (MALT; e.g., Peyer patches) (Chapter 24). L-selectin is also an important contributor to the process of leukocyte trafficking to sites of inflammation. Peripheral lymph node addressins (PNAds) are the best-characterized counterreceptors for L-selectin. This group consists of at least six different molecules that are decorated with a sulfated and fucosylated sLeX, which serves as a recognition motif for L-selectin. PNAds include glycosylation-dependent cell adhesion molecule-1 (GlyCAM-1), CD34, podocalyxin, endomucin, nepmucin, and mucosal addressin cell adhesion molecule-1 (MAdCAM-1). MAdCAM-1 is decorated with recognition epitopes for L-selectin on HEVs in the organized lymphoid areas of the gut, but not on the flat-walled vessels in the lamina propria.

The importance of posttranslational carbohydrate modifications for the function of selectin ligands has been well demonstrated in knockout mice deficient in fucosyl, glucosaminyl, galactosyl, sialyl, or sulfotransferases.[19] For example, mice with a targeted disruption of fucosyltransferase VII (Fuc-TVII) are unable to glycosylate L-selectin ligands appropriately. These mice exhibit severe defects in lymphocyte homing and in the extravasation of leukocytes to sites of inflammation. In contrast, core 2 β 1,6-*N*-acetylglucosaminyltransferase (C2 β GlcNAcT) knockout mice that have deficient glycosylation of their P- and E-selectin ligands demonstrate normal lymphocyte homing to lymph nodes, but impaired leukocyte trafficking to sites of inflammation. Interestingly, L-selectin also facilitates entry of leukocytes into tissues by mediating leukocyte tethering and rolling on endothelium-bound leukocytes by binding to P-selectin glycoprotein ligand-1 (PSGL-1).

E- and P-selectin are inflammation-inducible molecules.[13,19] Within minutes, P-selectin can be translocated from intracellular storage granules onto the endothelial cell surface, where it

binds to its leukocyte receptor, PSGL-1 (see Fig. 16.5). P-selectin and PSGL-1 mediate rolling at early time points during inflammation. Platelet P-selectin can facilitate lymphocyte entry into tissues because it can simultaneously bind to PNAd on the endothelium and PSGL-1 on lymphocytes.

E-selectin upregulation requires new protein synthesis. It is maximally expressed about 4 hours after induction of inflammation. E-selectin is needed for slow rolling of leukocytes. It also has an affinity toward PSGL-1, as well as a specific glycoform of PSGL-1, cutaneous lymphocyte antigen (CLA). CLA specifically directs lymphocyte trafficking to inflamed skin.[17] In addition to PSGL-1, E-selectin has other leukocyte counterreceptors such as CD44 and E-selectin ligand-1 (ESL-1) (see Fig. 16.5).

Mice deficient in both E- and P-selectins have more drastic defects in their rolling and leukocyte migration to sites of inflammation than could have been anticipated from mice deficient in only one of the two selectins. This suggests that E- and P-selectins can compensate each other's functions.

Chemokines and Their Receptors

Chemotactic cytokines and their receptors (Chapter 15) are grouped into four different families based on their primary protein structure. The families are defined by a cysteine signature motif—CXC, CC, C, and CX3C—where C is a cysteine, and X any amino acid residue.[20] Most chemokines are small, soluble heparin-binding chemoattractants.

The relevant chemokines for leukocyte extravasation are presented to blood-borne lymphocytes by proteoglycan molecules present on endothelial cell surfaces. During the adhesion cascade, chemokines activate leukocyte integrins by signaling via serpentine receptors, which are pertussis-toxin sensitive and G-protein linked.

Different leukocyte subsets bear their own distinct sets of receptors, which enable them to respond to chemokines presented on the vascular endothelium as well as within tissues.[13,20] For example, CCL21 and CCL19 are preferentially expressed by HEVs that are found in the interfollicular areas within a lymph node. They preferentially attract T cells bearing the CCR7 receptor and thus draw T lymphocytes from blood and into these areas. Fractalkine, a CX3CL1 chemokine, can be produced in either a soluble or a membrane-anchored form. It can be found on the HEVs in peripheral lymph nodes and has potent chemoattractant activity for T cells. The major attractants for B cells are CXCL12 and CXCL13.

Although many chemokines are present in different organs in the body, some selectivity in their expression can guide tissue-selective leukocyte trafficking.[20] For example, CCL25 attracts CCR9-positive lymphocytes to the small intestine, and CCL17 and CCL22 attract CCR4-bearing lymphocytes to the skin. Chemokines can form heteromeric complexes to activate chemokine receptors. For example, CXCL13 can enhance triggering of CCR7 by CCL19 and CCL21. Conversely, formation of chemokine complexes may protect a chemokine from degradation.

Integrins and Their Immunoglobulin Superfamily Ligands

Integrins are a large family of heterodimeric molecules consisting of an α and a β chain.[4,21] Traditionally, they are thought to mediate firm adhesion between leukocytes and endothelial cells. However, in specific low-shear conditions, they can also participate in rolling. For leukocyte trafficking, the most important integrins are $\alpha_4\beta_7$, LFA-1, and $\alpha_4\beta_1$.

$\alpha_4\beta_7$ is a principal homing receptor for lymphocyte trafficking to mucosa-associated lymphatic tissues.[21] It binds to MAdCAM-1 on HEVs in organized MALTs, such as Peyer's patch and the appendix, and to flat-walled venules in the lamina propria. α_4-integrin can also pair with a β_1 chain to form $\alpha_4\beta_1$ dimers, which are utilized by lymphocytes primarily in inflammatory conditions. It binds to vascular cell adhesion molecule-1 (VCAM-1) on the endothelium and has been proven central in mediating lymphocyte trafficking into the brain in multiple sclerosis (MS).

LFA-1 (CD11a/CD18) is a member of the group of leukocyte integrins that contain a unique α chain (CD11 a, b, c, or d) but share a common β chain (β_2/CD18).[21] LFA-1 is present on practically all leukocyte subsets. It interacts with its counterreceptors, intercellular adhesion molecules (ICAM-1 and ICAM-2), or junctional adhesion molecule A (JAM-A) on the endothelial cell surface (see Fig. 16.5). ICAM-1 is upregulated at sites of inflammation, whereas ICAM-2 is constitutively present on the vascular endothelium.

To be functional, LFA-1 must be activated. Activation of LFA-1 is thought to be primarily a product of chemokine signaling. Alternative activation pathways include triggering through glycosyl-phosphatidylinositol (GPI)–linked molecules and CD44, as well as through other costimulatory lymphocyte surface molecules.[22] LFA-1–dependent pathways display no significant organ specificity in their function.

Mac-1 (CD11b/CD18) is also involved in leukocyte migration, although its contribution is overshadowed by LFA-1. Like LFA-1, Mac-1 uses ICAM-1 and ICAM-2 as its ligands (see Fig. 16.5). Both VCAM-1 and ICAM-1 also play an important role in initiating transmigration, as they mediate the signals to endothelial cells that are needed to change their shape and other properties in order to allow leukocyte entrance.[22]

Other Homing-Associated Molecules

Several other molecules belonging to various molecular families also participate in the adhesion cascade. CD44 is a multifunctional proteoglycan found on a large variety of different cell types.[23] Using endothelial hyaluronan as its ligand, it mediates lymphocyte rolling. It can form bimolecular complexes with $\alpha_4\beta_1$ that strengthen leukocyte–endothelial cell interaction. In vivo inhibition studies using function-blocking antibodies indicate that CD44 plays an important role in directing lymphocyte trafficking to sites of inflammation (e.g., skin and joints).

CD31, a member of the immunoglobulin superfamily, is found on many subsets of lymphocytes as well as in the continuous endothelium of all vessel types.[13] It is expressed primarily at the intercellular junctions and is involved in a stimulus-specific manner in transmigration, especially through the endothelial basement membrane. Other molecules involved in the transmigration process are CD99 and junctional adhesion molecules (JAMs) A and C, which are expressed on both leukocytes and endothelial cells.[13,18] These molecules interact sequentially in a homotypic fashion during diapedesis. Endothelial JAM-A can also use LFA-1, JAM-C can utilize Mac-1, and JAM-B can use $\alpha_4\beta_1$ as leukocyte ligands.

Also some ectoenzymes contribute to the adhesion cascade.[24] Vascular adhesion protein-1 (VAP-1), CD73, and CD38 have well-established roles in leukocyte trafficking. Because of their enzymatic properties, they can rapidly modify adhesive

interactions and modulate the microenvironment. VAP-1 is a homodimeric sialoglycoprotein that, under conditions of inflammation, is rapidly translocated onto the endothelial cell surface. It mediates early phases of leukocyte interaction with the endothelium, as well as transmigration. Besides its adhesive function, it also possesses an amine oxidase activity that can produce potent immunomodulators, such as H_2O_2 and aldehyde, as end products.

CD73 is present both on a subpopulation of lymphocytes and on the endothelium.[24] It is an ecto-nucleotidase. The main product of its enzymatic activity in dephosphorylation of adenosine monophosphate (AMP) is adenosine, which is highly antiinflammatory in nature and important in maintaining vascular integrity. Endothelial CD73 may also have a counterreceptor on the lymphocyte surface because lymphocyte binding to the endothelium inhibits the enzymatic activity of CD73. This facilitates the extravasation process of the lymphocyte. The importance of CD73 in dampening inflammation is clearly seen in mice deficient in CD73, as they are highly susceptible to inflammatory injuries as a result of leaky vasculature.

CD38, an adenosine diphosphate (ADP)–ribosyl cyclase, is expressed on most lymphoid cells and can use CD31 as its endothelial cell ligand.[24] It regulates calcium fluxes and the sensitivity of leukocytes to chemokine signals via its enzymatic activity.

INTRAORGAN LYMPHOCYTE LOCALIZATION

Following its extravasation from the blood vessels, a lymphocyte needs to interact with several matrix molecules, such as fibronectin, laminin, and collagens. Adhesive interactions between a lymphocyte and the extracellular matrix molecules are largely mediated by β_1 integrins, although lymphocytes can also use CD44 to interact with fibronectin and collagens. The directional movement and the final localization of a lymphocyte within the tissues are controlled by chemokines. Modern two-photon imaging has provided detailed information about the kinetics and directionality of lymphocyte movement in living tissues.[9]

Besides directing the entry of T cells into tissues, CCL21 and CCL19 also determine the final destination of the T lymphocyte within lymph nodes, the spleen, and Peyer patches.[20] CCL19 and CCL21 produced by stromal cells in the T-cell areas within lymphoid tissues guide the T lymphocyte into the interfollicular space. In an analogous manner, CXCL13, the B cell–attracting chemokine-1, is produced by a subset of follicular DCs found in the secondary lymphoid organs. It attracts B cells possessing CXCR5 to the light zone of the follicles. CXCL12, in contrast, guides CXCR4-positive B cells to the dark zone (Fig. 16.6).

The correct localization of a lymphocyte and an APC within the lymph node is a prerequisite for an optimal immune response. For example, B-cell collaboration with T cells is ensured by the upregulation of CXCR5 expression on a subpopulation of T cells and the upregulation of CCR7 on certain B cells. This promotes the movement of these cells to the B- and T-cell zone boundary.

The importance of CCL21 and CCL19 in lymphocyte trafficking is demonstrated by a spontaneous mutant mouse strain, plt, which has reduced expression of these chemokines.[20] In these mice, both lymphocyte entry via HEVs and the organization of T-cell areas within lymph nodes are defective. This phenotype is recapitulated in CCR7-knockout mice. CCL21/CCL19 and CXCL12/CXCL13 are currently the best-known determinants of lymphocyte localization within lymphoid tissues, although several other chemokines are needed for optimal encounters among various cell populations to create a crisp immune response. In addition to chemokines, other attractants (e.g., oxysterols) guide lymphocytes within the nodes. For example, Epstein-Barr virus–induced genes in B cells (EBI2) have a strong migratory response to 7α,25-dihydroxycholesterol, promoting B-cell positioning to the lymphoid follicles.[25]

CELL TRAFFICKING WITHIN LYMPHATICS

Although leukocyte trafficking within the lymphatics is an essential part of the recirculation process and the immune response in general, the molecular mechanisms that regulate this tightly controlled and cell type–selective migration remain poorly understood.[26] It is known that CCL21 secreted by the lymphatic endothelium generates haptotactic gradients in the skin and attracts CCR7-positive lymphocytes (and activated DCs) into the afferent lymphatics. Most leukocytes enter the afferent lymphatics at the blind-ended terminal lymphatic capillaries through button-like interendothelial junctions. They are then carried together with the lymph fluid via the collecting lymphatics into the draining lymph nodes. The afferent lymphatics open into the subcapsular sinus of the lymph nodes (see Fig. 16.6). At this location CCR7 on DCs and lymphocytes again play critical role in directing leukocyte migration through the floor lymphatic endothelial cells of the subcapsular sinus.[8] Leukocyte entry into the lymph node may also take place at the medullary sinusoids. The transmigration of leukocytes from the sinus into the parenchyma through lymphatic endothelial cells in lymph nodes is notoriously independent of classical adhesion molecules.

Lymphocytes, but not DCs, exit from the lymph node via efferent lymphatics at the cortical sinuses and medulla.[4,8] Lymphatic endothelial cells at the exit sites produce and secrete high levels of a multifunctional lipid messenger sphingosine-1-phosphate (S1P). S1P receptor 1 (S1PR1), which is expressed on the exiting T and B lymphocytes, guides their entry into the efferent lymphatics.[27] The role of adhesion molecules at the exit step remains largely unknown, although a few reports have implied a role for ICAM, macrophage mannose receptor, and Clever-1/stabilin-1 in this process.[8]

CLINICAL IMPLICATIONS

Leukocyte trafficking plays a pivotal role in the pathogenesis of all infectious and inflammatory diseases. Trafficking is essential for mounting a proper immune response against an invading microbe. However, in many other cases, inappropriate leukocyte migration also causes tissue destruction. Here, we have chosen a few representative examples to illustrate some of the general principles.

Immunodeficiencies

Various genetic defects in leukocyte trafficking have been identified during the past two decades among a multitude of other immunodeficiencies.[28] Although they often primarily affect neutrophil functions, the defective proteins are usually also present in lymphocytes, and the diseases very faithfully reproduce the leukocyte trafficking defects observed in experimental models.

Leukocytes from patients with Wiskott-Aldrich syndrome (WAS) (Chapter 34) show reduced migration to the chemokines CCL2, CCL3, and CXCL12 as a result of a mutation in the

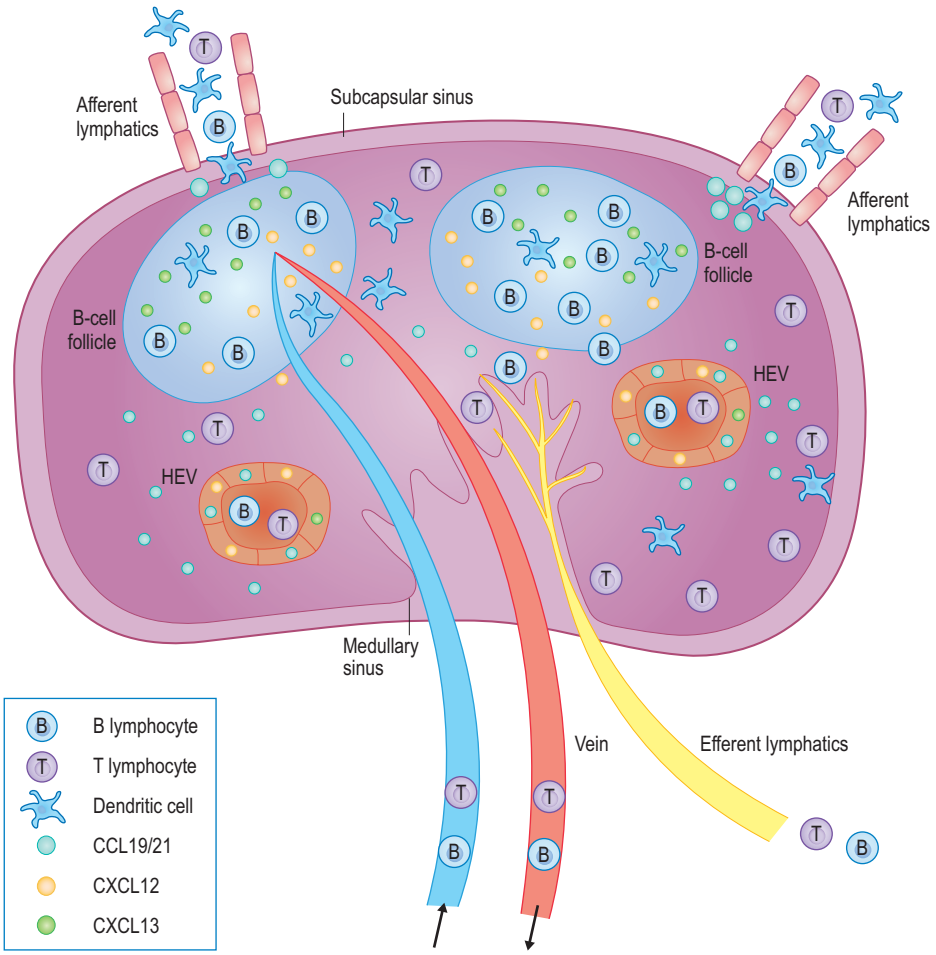

FIG. 16.6 The Role of Chemokines in Entrance and Intraorgan Localization of Lymphocytes. CCL19 and CCL21 are involved in lymphocyte entrance into the lymph node via the high endothelial venules *(HEVs)* and CCL21 also in entry of lymph-borne lymphocytes through the lymphatic sinuses. They also guide migration of T cells to the interfollicular areas within the node. In contrast, CXCL12 and CXCL13 attract B lymphocytes on the vessel wall and direct their movement to the follicles.

gene encoding an intracellular WAS protein that is responsible for proper cytoskeletal organization of the hematopoietic cells. Mutations of CXCR4 in patients with WHIM (warts, hypogammaglobulinemia, infections, and myelokathexis) lead to an enhanced chemotactic response to CXCL12 expressed on the bone marrow endothelium and leukocyte accumulation in bone marrow. A single case of inherited dysfunction of E-selectin has also been reported. The patient had recurrent infections but did not demonstrate neutrophilia. She could not synthesize E-selectin on the endothelium, although her serum level of soluble E-selectin had increased.[29]

Four different forms of leukocyte adhesion deficiency (LAD) syndromes have been described (Chapter 39).[30,31]

LADI: Patients with LADI have defects in the synthesis, pairing, or expression of β_2 integrins. The severe form leads to a drastic reduction or absence of CD11a/CD18 (LFA-1), CD11b/CD18 (Mac-1), CD11c/CD18, and CD11d/CD18. The patients manifest with defects in neutrophil arrest on endothelial cells. Patients suffering from a milder form of LADI (<10% of normal β_2 integrins) demonstrate impairment in leukocyte migration and suffer from frequent infections as well. In these patients, lymphocyte migration to inflammatory sites is close to normal, probably because lymphocytes can utilize the VLA-4–VCAM-1 pathway to compensate for the lack of β_2 integrins.

LADII: The cause of LADII is impaired transport of guanosine diphosphate (GDP)–fucose from the cytoplasm to the Golgi lumen as a result of mutations in a GDP–fucose transporter. The defect leads to impaired fucose modification of selectin ligands, most notably that of PSGL-1. Consequently, these patents demonstrate a marked decrease in leukocyte rolling under flow conditions, and, consequently, neutrophilia, recurrent infections, and impaired pus formation are typical in this disease.

LADIII: The third LAD syndrome involves defective inside-out signaling of β_1, β_2, and β_3 integrins due to mutations in FERMT3 (encoding Kindlin3), which is a major cytoplasmic activator of integrins. This results in impaired activation of multiple leukocyte integrins, including LFA-1 and VLA-4, by chemokine-triggered, G protein–coupled signals.

LADIV: The most recently identified LAD type is caused by defects in cystic fibrosis transmembrane conductance regulator (*CFTR*) gene. These relatively common mutations lead to defective activation of β_2 and $\alpha_4\beta_1$ integrins, and it appears to manifest especially with abnormal adhesion of monocytes to ICAM-1 and VCAM-1.

Autoimmune or Inflammatory Diseases

Multiple Sclerosis

Migration of T and B lymphocytes through the blood–brain barrier into the central nervous system (CNS) is a key pathogenic event that occurs during the development of MS and its widely used animal model, experimental allergic encephalomyelitis (EAE) (Chapter 66). Under normal conditions, lymphocytes only patrol outside of the CNS parenchyma in the leptomeningeal and perivascular compartments.[32] Naïve lymphocytes inefficiently bind to endothelial cells in meningeal microvessels (without a rolling step) using α_4 integrin and then extravasate through the fenestrated choroid vessels using mainly P-selectin and CCR6. Upon inflammation, meningeal and choroid vessels become more adhesive, and the endothelial cells within the CNS parenchyma start to express ICAM-1 and VCAM-1. These alterations allow effector lymphocytes, which have primarily been activated in the cervical lymph nodes that ultimately drain the CNS-derived antigens, to penetrate the blood–brain barrier and enter the CNS parenchyma.

In vivo animal studies have shown that the disease course can be dramatically altered by blocking the function of leukocyte α_4 integrin.[33] This treatment is able to prevent the disease, and even reverse the paralytic disease and lymphocytic infiltrations in the brain. Antibodies against $\alpha_4\beta_1$ integrin show this remarkable efficacy even if started a month after the onset of the clinical disease. Certain EAE models can also be blocked by targeting the α_4 integrin ligand VCAM-1 or by blocking the function of CD44. In contrast, inhibition of many other adhesion molecules, such as L-selectin, PSGL-1, and E- and P-selectins, fails to yield a consistent effect on EAE. It should also be noted that although $\alpha_4\beta_1$ integrin is very important for lymphocyte homing to brain, it is not a brain-specific homing molecule. It is also involved in leukocyte trafficking to other organs, such as the pancreas and the gut.

ON THE HORIZON

Adhesion Molecules as Targets for Novel Diagnostic and Therapeutic Agents

- Use of adhesion molecules as targets for the diagnosis of immune deficiencies, inflammatory disorders, and cancers.
- Use of adhesion molecules as targets for imaging inflammatory responses.
- Use of adhesion modulating therapies and other manipulations of lymphocyte trafficking, including small molecules, to treat infections, immune deficiencies, autoimmune disorders, transplant rejection, ischemia-reperfusion injuries, and cancers.

Inflammatory Bowel Diseases

As described above, effector lymphocytes activated in the inductive sites (Peyer patches and mesenteric lymph node) of the intestine selectively migrate to the effector sites of the gut (mainly the lamina propria) (Chapter 24).[34,35] The key tissue-specific adhesion code for the intestinal entry is $\alpha_4\beta_7$ integrin on lymphocytes and its endothelial counterreceptor MAdCAM-1. Although the canonical CCR9-CCL25 interaction is important for attracting T and B lymphocytes to the small intestine, the critical chemotactic receptors for the entry into the large intestine are GPR15 (on T cells except for Treg cells) and CCR10 (on plasmablasts).

In humans, the homing of regulatory T cells to the colon is GPR15 independent. This creates pathways by which the trafficking of proinflammatory versus antiinflammatory lymphocyte subtypes in the large bowel can be altered. In inflammatory bowel disease (IBD) (Chapter 75), the expression of MAdCAM-1 is upregulated in the vessels of the lamina propria, together with other vascular adhesins, such as VCAM-1 and ICAM-1. Increased expression of CCL20 in the IBD mucosa enhances the recruitment of both T and B cells to the inflamed gut through ligation of CCR6. Successful pharmacological and genetic targeting of these key gut-selective lymphocyte trafficking pathways alleviates inflammation in multiple animal models of IBD.

Cancer

Immunoevasion is one of the main hallmarks of cancer, and insufficient lymphocyte trafficking to solid tumors contributes to tumor progression. In the neoangiogenic vessels of tumors, immature and disorganized endothelial cells often express insufficient amounts of adhesion and attraction molecules.[36] Moreover, tumor-derived factors often render the local endothelial cells unresponsive to inflammatory cytokines. Nevertheless, chronic inflammation in tumors can induce the formation of HEV-like vessels, which show augmented expression of trafficking molecules. The homing patterns of leukocytes and those of cytotoxic T cells in particular, into the tumors (inflamed, excluded, or deserted), often associates with the outcome of the disease.[37]

Lymphocyte migration can be harnessed to improve the outcome of cellular immunotherapy for cancer.[38] Infusion of activated or genetically modified effector T cells, and cytotoxic CD8 T cells in particular, would benefit from a more effective targeting of the cells into the tumor. Homing of CAR-T cells to the tumors could be enhanced by transduction with adhesion molecules and chemokine receptors, possibly with simultaneous induction of tumor vessel normalization. Similarly, antiadhesive therapies targeting inappropriate accumulation of Treg in the tumor would also enhance anticancer immune responses.

THERAPEUTIC PRINCIPLES

- Proadhesive strategies have been mainly developed using gene therapy.
- Inappropriate inflammation associated with many diseases can be dampened by antiadhesive therapeutics.
- Function-blocking monoclonal antibodies (mAbs) are effective antiadhesive molecules.
- Cell migration can also be blocked by ligand and receptor analogues, small-molecule inhibitors, and genetic means (e.g., RNA interference).

ADHESION MOLECULES AS DIAGNOSTIC TARGETS

Immunodeficiency Disorders

Analyses of CD18 integrin expression, presence of fucosylated adhesion molecules (e.g., sLeX epitope), and the activation state of integrins are useful in diagnosis of different forms of LAD (Chapter 39).

Soluble Adhesion Molecules

Most adhesion molecules are found in soluble forms in body fluids. They can be generated by alternative splicing of messenger RNA (mRNA) with deletion of transmembrane anchors, by

proteolytic cleavage of cell-bound proteins by various sheddases (proteases), or by cleavage of the GPI linkage. Either of the soluble forms can function as molecular sinks, competing for their specific ligand(s) with the membrane-bound forms. Alternatively, they can trigger biological responses by interacting with their ligand-bearing cells.

The availability of commercial kits for measuring the levels of soluble adhesion molecules has led to numerous reports describing an increase or a decrease of certain adhesion molecules in different diseases. They may provide additional diagnostic or predictive value derived from the use of these tests compared with more traditional parameters of inflammatory activity. However, at present, the indications for routine measurements of soluble adhesion molecules, or chemokines, in inflammatory diseases and cancers remain to be defined.

Imaging

The use of neutrophil scans or radioactively labeled nonspecific molecules to localize inflammatory foci is not satisfactory in terms of timing, expense, biohazards, specificity, or sensitivity. Hence, there have been trials to radioactively or nonradioactively label monoclonal antibodies (mAbs) or peptides that recognize endothelial adhesion molecules, infuse them intravenously, and monitor their accumulation by appropriate imaging devices. Inflammation-inducible molecules, such as E-selectin, MAdCAM-1, and VAP-1, have been used as target antigens. In the case of radioactively labeled E-selectin antibodies and a VAP-1 binding peptide, the utility of this approach has been verified in patients.

CLINICAL PEARLS

- Blocking of α_4 integrin with natalizumab ameliorates disease activity in multiple sclerosis (MS) and in Crohn disease.
- Blocking of α_4/β_7 with vedolizumab is an effective treatment for inflammatory bowel disease (IBD).

THERAPEUTIC APPLICATIONS OF ADHESION-MODULATING THERAPIES

Pro- and antiadhesive therapies have long been an obvious pharmaceutical goal in the field of leukocyte trafficking. Inflammation-promoting strategies would be beneficial for treating many immune deficiencies, persistent infections, or cancers. Proadhesive control of lymphocyte traffic would benefit specific areas, such as vaccine development (Chapter 87) and bone marrow cell transplantation (Chapters 90 and 92). In practice, lymphocyte recirculation routes are already being empirically exploited, for example, by varying the anatomical site (skin vs. intestine) of vaccination to optimize the immunization response. Antiadhesive therapy, on the other hand, can be seen as a form of treatment applicable to all disease categories that involve an inflammatory component. In addition, it could provide novel precision drugs individually tailored for treating organ-specific inflammatory disorders, which would be predicted to diminish the problems of generalized immunosuppression.

Antibodies and Small-Molecular Drugs

A number of specific antagonists of adhesion molecules have been developed.[21,34,35] Function-blocking mAbs against adhesion molecules and chemokines have often been the drug candidates used for proof-of-principle experiments. In parallel, recombinant ligand or receptor analogs have been developed. Ultimately, knowledge of the structure of the adhesion molecules has allowed the design of rational, small-molecular drugs, such as those affecting the conformational state of leukocyte integrins. Possibilities to modulate mRNA expression of adhesion molecules through antisense oligonucleotides and RNA interference have added another potential tool to the pharmaceutical armamentarium.

Adhesion-Modulating Drugs in Clinical Use

Although several forms of antiadhesive therapy have been enormously successful in a panoply of animal models, transfer to the clinic has been slow. However, a small number of very potent drugs targeting adhesion molecules have already been approved.

The first selective adhesion molecule (SAM) inhibitor was natalizumab. The way for natalizumab, a humanized anti-α_4 integrin antibody, was paved by the excellent results of α_4 blocking in EAE (see above). In patients with relapsing MS, a monthly intravenous injection of natalizumab leads to a significant reduction in the numbers of new lesions, numbers of relapses, and the risk of sustained disability.[33] The beneficial effects of natalizumab treatment are evident also in patients who do not respond to interferon-β (IFN-β) therapy. Because natalizumab also inhibits $\alpha_4\beta_7$, the gut homing receptor, natalizumab also alleviates inflammation in the gut, and it has been shown to be effective in patients with Crohn disease.[34]

Another clinically approved selective modulator of an adhesion molecule is vedolizumab.[34,35] It is a humanized mAb that binds to a combinatorial epitope in α_4/β_7 integrin but does not interact with α_4/β_1 and α_E/β_7 integrins. This makes vedolizumab a remarkably selective inhibitor of lymphocyte homing to the intestine. It has been approved for the treatment of both ulcerative colitis and Crohn disease (Chapter 75). An mAb, etrolizumab, which targets the β_7 integrin (thus blocking both α_4/β_7 and α_E/β_7, but not α_4/β_1), which can induce remission in ulcerative colitis, and an anti-MAdCAM-1 antibody (ontamalimab) that appears to be effective in ulcerative colitis, but not in Crohn disease, are in phase III clinical trials.

These therapies also have adverse effects. The most feared adverse effect of natalizumab treatment is the possible reactivation of polyoma John Cunningham (JC) virus, which leads to the development of potentially fatal progressive multifocal leukoencephalopathy (PML).[39] Up to 1% of natalizumab-treated patients develop PML in the high-risk groups. However, the benefits of this therapy in MS still outweigh the risks (Chapter 66). With good risk stratification and vigilance, the drug has maintained its status as a very effective biological treatment option for MS. Theoretically, α_4/β_7 blocking should not interfere with lymphocyte surveillance functions in the CNS, and in line with this, no PML cases have been reported among vedolizumab-treated patients. Mild adverse effects with SAM therapy include an expected increase in susceptibility to infections and injection site reactions. However, apart from the risk of PML with natalizumab, both natalizumab and vedolizumab seem to have good overall safety profiles.

Lymphocyte migration can also be targeted therapeutically by modulating lymphocyte exit from the lymph nodes.[27] Fingolimod/FTY720 causes S1P receptor internalization and degradation. Consequently, it is a functional antagonist of SIP

receptors 1, 3, 4, and 5. It inhibits lymphocyte egress from the lymphoid organs. It may selectively retain CCR7-positive T cells, including central memory T cells, which may be particularly important for the pathogenesis of brain inflammation, while sparing CCR7-negative effector memory cells. It is used as the first-line treatment for relapsing MS, and it is the first orally active disease-modifying drug for this immunological disease. However, a more specific S1PR modulator, siponimod, targeting S1PR1 and S1PR5, was approved in 2019 by the FDA for the treatment of relapsing MS, including active secondary progressive MS.[40] Another selective S1PR1 antagonist, ozanimod, has shown preliminary efficacy, also in IBD. Although used in certain clinical indications, targeting of chemokine/chemokine receptors for manipulating lymphocyte migration has not yet proceeded to clinical use.

Death Pathways and Immunogenicity

Wulf Tonnus, Alexia Belavgeni, and Andreas Linkermann

For more than a century and a half, we have known that the process of regulated cell death (RCD) is an integral part of life. In 1972, the first insights into the mechanisms underlying RCD came from the identification of apoptotic pathways.[1] For almost 40 years, the apoptotic process of RCD was viewed as the opposite of necrosis, which was considered accidental (and therefore unregulated). In 2008, however, it was realized that necrosis could be antagonized under certain conditions. This led to the appreciation that necrosis could also be a genetically determined, regulated process.

The current challenge is to elucidate the various genes and pathways that take part in regulated physiological and pathophysiological cell death and to better understand why there are multiple pathways. It has become clear from these studies that the various pathways create differences in the immunogenicity of the byproducts of necrosis. This is especially the case when cellular necrosis is not limited to a single cell but affects a functional unit (*e.g.*, ferroptosis). As tissue injury and inflammation are tightly linked, these discoveries fuel the need to better understand how necrosis influences pathologies, including autoimmune diseases, transplant rejection, ischemic injury, and cancer. This chapter focuses on the most clearly identified regulated necrosis (RN) pathways. Our "selection" of the RN pathways discussed is based on the current appreciation of the importance of these pathways, either physiologically or pathophysiologically, to differences in the immunogenicity of these RN pathways and their role in diseases (Fig. 17.1).

CELL DEATH AND DAMAGE-ASSOCIATED MOLECULAR PATTERNS—THE CONCEPT OF NECROINFLAMMATION

Pattern recognition receptors (PRRs) bind a wide range of damage-associated molecular patterns (DAMPs) (Chapter 3). These include exogenous stimuli such as lipopolysaccharides (LPS) as well as an array of intracellular content.[2]

It is now understood that necrosis triggers inflammation and that inflammation can, in turn, lead to further RN. This observation gave rise to the concept of necroinflammation.[3] Necroinflammation can create an autoamplificatory feedback loop that results in DAMP release between organs. For example, ischemic or traumatic tissue in the lung can initiate a positive feedback loop that leads to acute respiratory distress syndrome (ARDS).[4,5] Recent observations indicate that the DAMPs released by this type of feedback after renal transplantation can lead to RN in the lung as well.[6]

KEY CONCEPTS

Necroinflammation—An Autoamplificatory Feed-Forward Loop

- Induced by cells dying by necrosis (*e.g.*, in hypoxia)
- Associated proinflammatory damage-associated molecular pattern (DAMP) release
- Immune cell infiltration
- Regulated necrosis (RN) in parenchymal and endothelial cells induced by immune cells
- RN in inflammatory cells (*e.g.*, macrophages undergoing pyroptosis)
- Surrounding cells die of necrosis
- DAMP transfer to remote organs
- Remote organ injury

For years, immunology focused on the issue of self versus non-self recognition. However, within the past two decades, the danger/injury model has become more and more prominent. Briefly, this model proposes that cellular stress activates the innate immune system, thus leading to an inflammatory response that can, under certain circumstances, then induce a specific adaptive response.

Key to this is the concept are DAMPs (Chapter 3). DAMPs include a wide array of different stimuli, including exogenous stimuli (*e.g.*, LPS) and intracellular contents (*e.g.*, uremic acid and high-mobility group box-1 [HMGB1]).[7,8] These are sensed by either "classic" PRRs or "nonclassic" receptors found on the surface or within cells of innate immunity. When cells die by RN, these DAMPs become accessible to the immune system in the extracellular space. They are sensed especially by cells of the innate immune system. Dendritic cells (DCs) (Chapter 6) are activated by directly sensing DAMPs via surface receptors (*e.g.*, calreticulin [CALR]–CD91, adenosine triphosphate [ATP]–P2X7R, or HMGB1–Toll-like receptor 4 [TLR4]). Sensing of DAMPs by monocytes leads to activation of inflammasomes, which then promote expression of mature inflammatory cytokines (*e.g.*, interleukin-1β [IL-1β] and IL-18) (Chapter 14). Natural killer (NK) cells (Chapter 12) also directly interact with injured cells. However, both monocytes and NK cells give rise to inflammation and thus support the maturation of immature DCs.

The infiltration of innate immune cells into the inflamed tissues and their subsequent inflammatory response is thought to account for a significant part of the overall damage to the organ, above and beyond initial necrosis itself. Mechanisms that mediate this deterioration may include the edema that arises following capillary leakage, induction of cell death by innate immune cells with the effect of decreased organ

function, and dysregulated partial oxygen pressure within the area of inflammation/necrosis. Also, mature DCs interact with CD8 T cells (Chapter 12) via major histocompatibility complex (MHC) class I interaction and CD4 T cells via MHC class II interaction (Chapter 5). This shifts the immune response to an antigen-specific response as cytotoxic T cells and active B cells now specifically attack stressed cells (Fig. 17.2).

In addition to these DAMPs, other intracellular content also has the potential to be sensed as a target, which could lead to the development of autoimmunity. A prominent example is the breaking of intracellular organelle membranes into pieces with exposed neoepitopes. These larger particles are removed by a process referred to as LC3-associated phagocytosis (LAP). Failure to remove these neoepitopes may result in the generation of antinuclear antibodies (ANAs) or antibodies against double-stranded DNA (dsDNA).

In mouse models, genetically induced breakdown of LAP drives a lupus-like phenotype.[9] ATG16L is required for both autophagy and LAP. In humans, ATG16L mutations are markedly associated with the development of autoimmunity.[10]

Usually, IL-10 is secreted by monocytes engulfing dying cells to dampen the immune response. However, LAP-deficient monocytes actively produce proinflammatory IL-1β and IL-6 instead. Orchestrated with other elevated proinflammatory cytokines (IL-17, IL-18, IL-23), a low immunogenic stimulus can thus induce a strong immune response. In the presence of this stimulus, common self-epitopes are classified as DAMPs by the immune system, which explains why mice deficient in LAP develop a lupus-like autoinflammatory disease. As a result, functional LAP may also be required for prevention of memory B-cell priming during solid-organ transplantation.

When challenged with injurious conditions, such as ischemia–reperfusion in solid-organ transplantations, options for cellular fate include directly succumbing via accidental cell death (ACD), restoring cellular homeostasis, or dying by RCD. ACD happens passively under certain conditions, such as extreme heat or mechanical trauma, and occurs nearly immediately in an uncontrolled fashion. Because of the direct loss of membrane integrity, huge amounts of DAMPs are released. This leads to massive recruitment of innate immunity and local

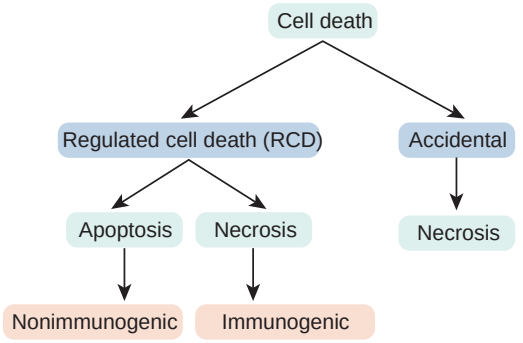

FIG. 17.1 Regulated Cell Death. When apoptosis was first identified, two models of regulated cell death were recognized: apoptosis and necrosis. More recently, however, cell death has been divided into regulated cell death (including apoptosis and regulated necrosis) and accidental cell death (instant necrosis). A second parameter classifies cell death as either immunogenic or nonimmunogenic.

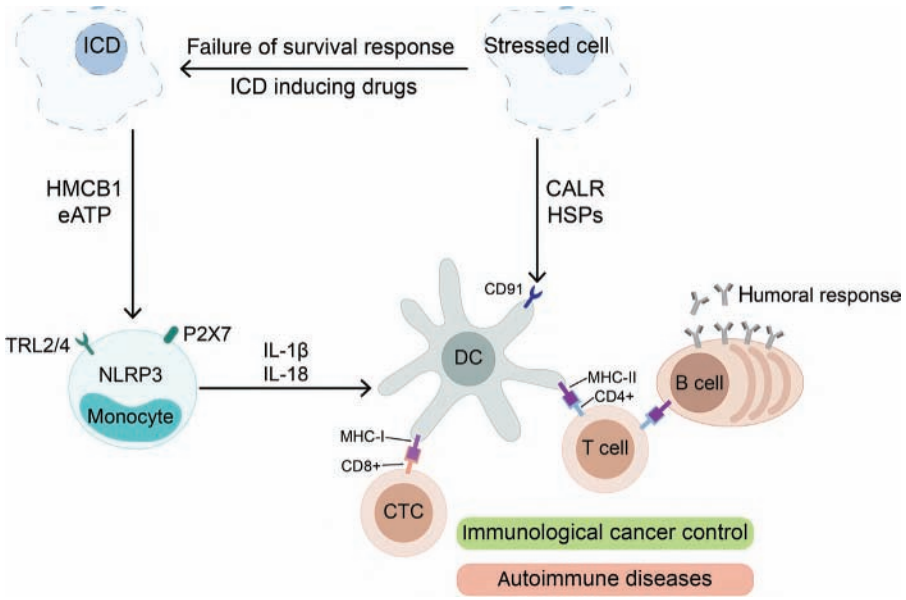

FIG. 17.2 Role of Dendritic Cells *(DCs)* in Necroinflammation. Innate immunity plays a crucial role in necroinflammation. When cells are stressed, they release damage-associated molecular patterns (DAMPs), such as calreticulin *(CALR)* and heat shock proteins *(HSPs)*. These DAMPs are sensed by scavenger receptors, such as CD91. This leads to partial activation of inactive DCs. If those cells fail to restore metabolic balance, they succumb to immunogenic cell death *(ICD)* and release additional DAMPs, which activate inflammasomes, such as LRR and PYD domains–containing protein 3 *(NLRP3)* in monocytes. Activation of the inflammasomes leads to the release of interleukins, which help DCs to gain full activation. These fully activated DCs use major histocompatibility complex *(MHC)* class I and class II antigen presentation to stimulate cytotoxic CD8 T cells *(CTC)* and CD4 T cells, which interact with B cells to trigger a humoral response. Activation of the immune response by necroinflammation can thus promote the control of cancer by immunogenic means. However, the same mechanisms can promote the development of autoimmune diseases.

inflammation. However, if these cells do not explode directly, they balance on the edge. On the one side is restoration to a normal state (*e.g.*, by means of autophagy or the unfolded protein response following endoplasmic reticulum [ER] stress) or, if the damage is too severe, loss of balance and the induction of RCD.

Within the cells that succumb to cell death, the necroinflammatory loop starts with perturbation of intracellular homeostasis (class V DAMPs). This triggers the heat shock response, a system of critical importance for correct protein folding. Secreted or surface-exposed heat shock proteins (HSPs) can be sensed by either classic (*e.g.*, TLR2/4) or nonclassic (*e.g.*, CD91) receptors on DCs. In parallel, ER stress, which is often the result of reactive oxygen species [ROS] generation, leads to secretion of calreticulin (an ER chaperone referred to as *CALR*). CALR then acts extracellularly as a class I DAMP by binding to CD91. This causes inactive dendritic cells (iDCs) to be activated. For full activation, however, an inflammatory milieu is required.

An inflammatory milieu is primarily generated by monocytes. These become active as the survival response fails and the formerly stressed cell succumbs to RN. Necroptosis and ferroptosis are typical modes of RN within this process. The ferroptotic cell can "leech" redox equivalents, such as nicotinamide adenine dinucleotide phosphate (NADP), from neighboring cells (see below), which subsequently undergo necrosis in a wave-of-death-like manner. This noncell autonomous induction of necrosis may involve necroptosis, although in this case the mechanism of necroptosis induction has not yet been elucidated. RN releases high amounts of DAMPs; thus in this context it can also be named *immunogenic cell death* (ICD).

As a DAMP, ATP can reach the extracellular space (eATP). When the plasma membrane is intact, the autophagy machinery seems to be necessary for ATP export. However, upon RN the membrane ruptures, eliminating the need to export ATP. eATP represents a class II DAMP as it activates the purinergic-receptor, ligand-gated ion channel P2X7R. Activation of P2X7R leads to potassium influx, which is sensed by the NACHT, LRR, and PYD domains-containing protein 3 (NLRP3) inflammasome and leads to IL-1β and IL-18 maturation. eATP is thus extremely immunogenic.

Upon membrane rupture, HMGB1 also reaches the extracellular space and is therefore the prototype of a RN-DAMP. iHMGB1 acts via binding to TLR4 of monocytes and also activates the NLRP3 inflammasome.

The DAMPs from the stressed cells and the inflammatory cytokines fully activate iDC, which then create a per-se cytotoxic inflammatory environment. They also prime naïve CD4 and CD8 T cells, thereby inducing an antigen-specific response. This response is the basis for certain conditions, such as chemotherapy in cancer. To stably control (or wipe out) a cancer, a specific response against tumor epitopes is required. Thus, induction of RN can be beneficial. In contrast, in some settings, such as solid-organ transplantation (Chapter 89), an antigen-specific response induced by DAMPs can give rise to antibody-mediated rejection (ABMR), which typically starts after cortisone tapering. In this setting, RN is detrimental.

The activation of an antigen-specific response results in additional cells being attacked. As they succumb, these dying cells replenish the DAMP pool, further attracting cells of innate immunity and further promoting DC maturation and T-cell priming. Thus, tissue injury amplifies while the loop closes (Fig. 17.3).

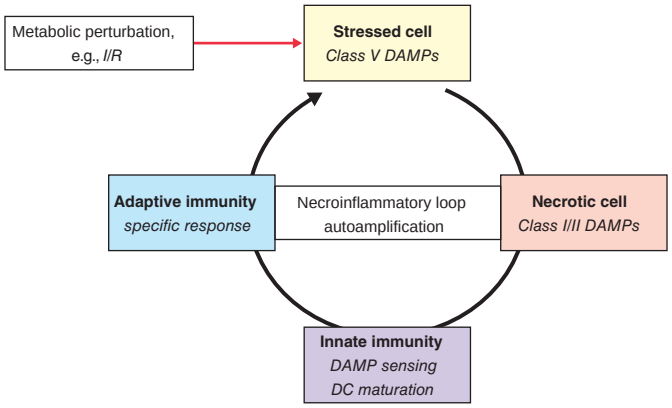

FIG. 17.3 The Autoinflammatory Loop. The necroinflammatory loop is triggered by metabolic perturbations (*e.g.*, ischemia–reperfusion *[I/R]*). The so-stressed cells release class V danger-associated molecular patterns *(DAMPs)*. In the next step, now-necrotic cells release class I/II DAMPs, which can be sensed by cells of innate immunity, such as dendritic cells *(DCs)*, which are then stimulated to mature. Via mechanisms described in *Fig. 17.2*, adaptive immunity is empowered to unleash a specific response to (neo)antigens. This leads to further stressed and dying cells, which, in turn, can themselves then release DAMPs and thus create an autoinflammatory loop.

REGULATED CELL DEATH REGULATES ITS IMMUNOGENICITY IN AN ACTIVE MANNER

Apoptosis is the prototype of non-ICD. Avoidance of immunogenicity is achieved by active processing and covering of DAMPs during the apoptosis program. For example, DNA is fragmented, cell organelles are consumed, and proteins degraded. Moreover, everything is packed in blebbing membranes. It is a matter of debate, however, whether apoptosis should be also considered somehow immunogenic, as some DAMPs (*e.g.*, HMGB1) are still released and phosphatidylserines, which are usually located in the inner leaflet of the plasma membrane, are flipped to the outer leaflet.

Phosphatidylserine surface expression serves as an "eat me" signal for macrophages and other phagocytes, which can then act to remove these cells in an immunologically silent manner. Thus, apoptotic cells recruit cells of innate immunity, but in a manner that is programmed to not induce further inflammation. Therefore, the debate about the inflammatory potential of apoptosis might be more or less of an academic nature. The sophisticated program of apoptosis appears to have evolved to prevent necroinflammation and is therefore favored in physiological settings that result in regular cell turnover.

Under metabolic pressure, such as ischemia–reperfusion injury, tissue damage occurs primarily by RN, and thus, the necroinflammatory loop *per se* tends to refuel itself. Therefore, mechanisms are required to keep this in check. One such mechanism is the active production of IL-33 by cells undergoing necroptosis (see below), which acts to limit the immunogenicity to a certain microenvironment,[11] as IL-33 stabilizes regulatory T cells (Treg) through ST2 receptors.[12] Cells undergoing pyroptosis (see below) actively produce and secrete IL-1β and IL-18 upon their demise. Both of these ILs

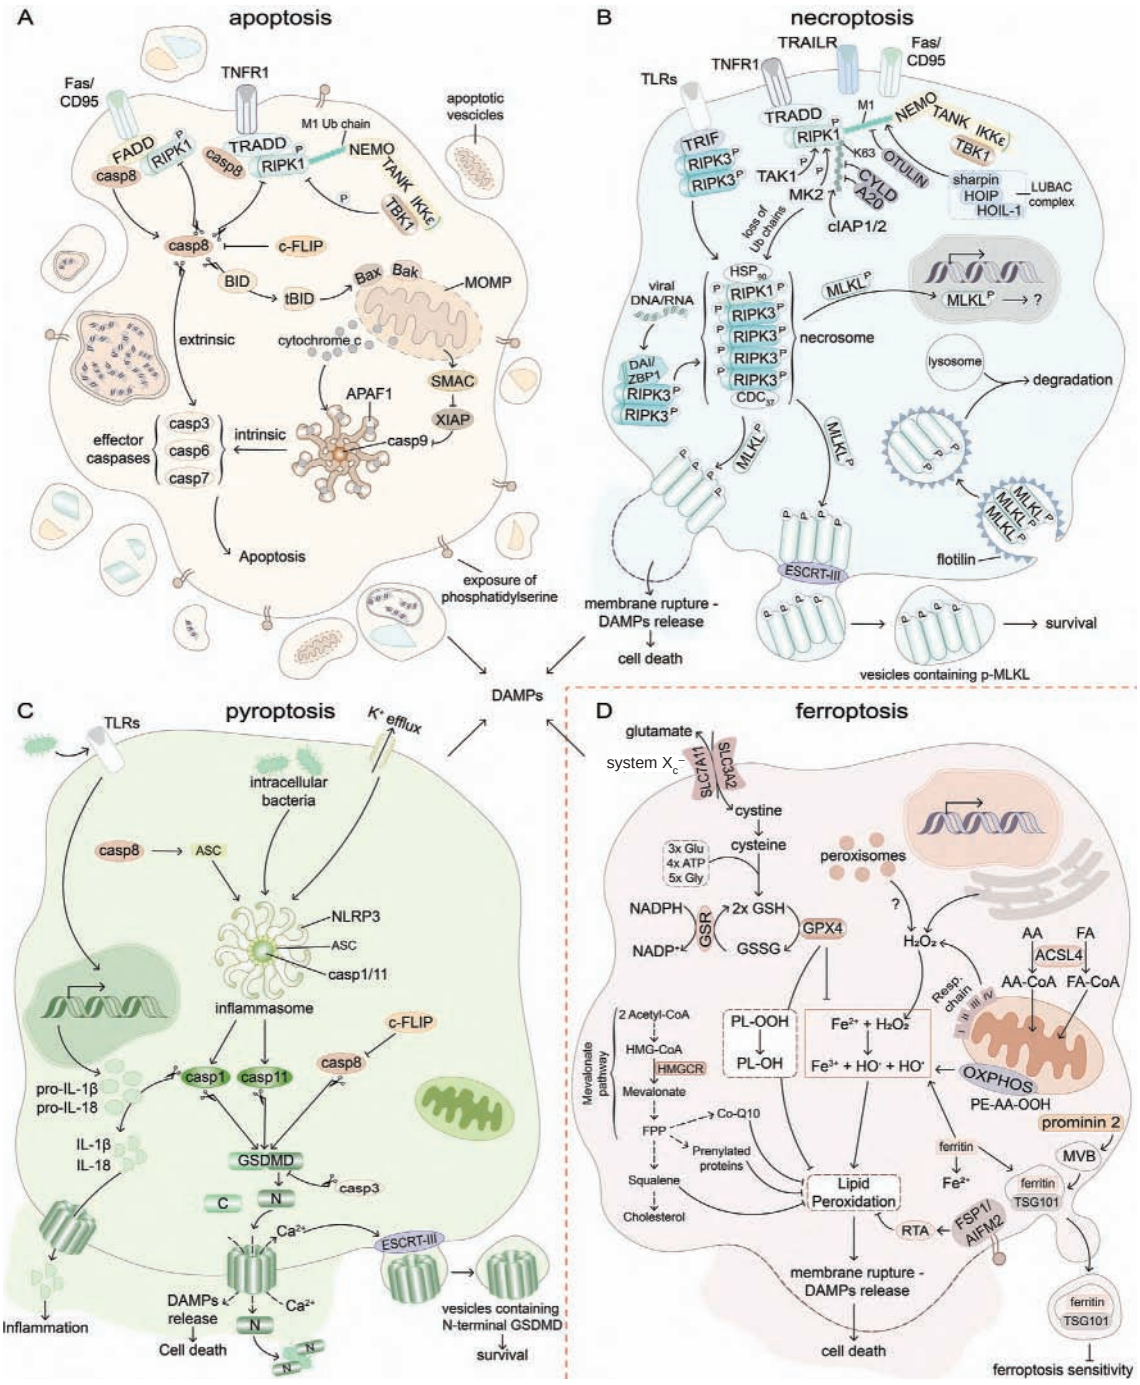

FIG. 17.4 Pathways of Regulated Cell Death *(RCD).* Apoptosis (A) represents a noninflammatory pathway that is mediated by caspases. Two distinct signaling pathways of apoptosis, extrinsic and intrinsic apoptosis, have been characterized. In extrinsic apoptosis, death receptors such as *TNF-R1*, *CD95* (Fas) and *TRAIL-R*, through the engagement of various intracellular adaptor proteins (*FADD, TRADD*) lead to the activation of the master regulator caspase-8. Upon homodimerization, caspase-8 cleaves the effector caspases-3/-6/-7 to propagate the apoptosis program. Upon loss of mitochondrial outer membrane potential *(MOMP)* and the *BAX-BAK*-mediated release of cytochrome c from the mitochondria into the cytosol, the intrinsic apoptotic pathway is triggered. Within the cytosol, cytochrome c, *APAF1*, and caspase-9 form the apoptosome, which activates the *effector caspases-3/-6/-7*. The typical morphology includes nuclear condensation, early loss of cellular volume (shrinking), subsequent membrane blebbing, and exposure of phosphatidylserine *(PS)*. Importantly, PS exposure represents an eat mesignal to macrophages that eliminate apoptotic cells. Importantly, the plasma membrane does not lose its integrity during this process. While apoptosis depends on the activation of caspases, necroptosis (B) is mediated by kinases. Dependent on its RHIM domain, *RIPK3* forms an amyloid-like structure referred to as the *necrosome*, the central relay of necroptosis. Therein, RIPK3 phosphorylates the pseudokinase mixed lineage kinase domain-like protein *(MLKL)*. By unknown mechanisms, the phosphorylated form of *MLKL* (*p-MLKL*) triggers plasma membrane rupture, a process that was demonstrated to be counteracted by the membrane repair *ESCRT-III* complex. The necrosome can be engaged by death receptor signaling in condition, in which caspases are absent or inhibited (*e.g.*, by viral proteins), and *RIPK1* no longer intercalates with RIPK3. Other ways

are highly proinflammatory. As pyroptosis is typical for cells of innate immunity, this might be an alert function of this first-line defense.

In conclusion, even in RN, cells regulate their inflammatory potential in both proinflammatory and antiinflammatory ways. When balanced, this generates a beneficial environment for both defense and regeneration. The exception to this rule is ferroptosis, where lipid peroxides recruit neutrophils (see below), and it is still unclear whether this response can be considered beneficial.[13]

SIGNALING PATHWAYS OF REGULATED CELL DEATH

RCD is an umbrella term for any genetically determined signaling pathway that results in cellular demise.[14] RCD thus includes both nonimmunogenic apoptosis and immunogenic RN. Fig. 17.4 provides an overview of the four most important pathways of RCD, comprising apoptosis, pyroptosis, necroptosis, and ferroptosis. Whereas the first three of these pathways are controlled by an intertwined caspase/kinase system, ferroptosis appears to be somewhat different in nature.

Apoptosis

Apoptosis is a complex program for nonimmunogenic cellular demise that is regulated by caspases. During the first hours of apoptosis, cells maintain their plasma membrane integrity and therefore, by definition, are not necrotic. The apoptotic program may be activated via the intrinsic (mitochondrial) or the extrinsic (death receptor) pathways.

The intrinsic pathway is controlled by different members of the Bcl-2 protein family, such as Bcl-2 or BAX, and therefore reacts to intracellular changes (*e.g.*, DNA damage) by forming transient pores, a process referred to as mitochondrial outer membrane permeabilization (MOMP). The intrinsic pathway reacts to internal stimuli, whereas the default activation of the extrinsic pathway occurs following an outside-in signaling. The latter is typically mediated by death receptors, such as Fas (also known as CD95 or Apo1) or tumor necrosis factor receptor 1 (TNFR1). Upon trimerization/hexamerization, these death receptors recruit downstream molecules via death domains (DDs), such as TRADD or FADD, to form a receptor-associated platform, the death-inducing signaling complex (DISC).

Nuclear factor-κB (NF-κB) signaling is the canonical response to TNFR1 activation. If NF-κB is inhibited and/or receptor-interacting protein kinase 1 (RIPK1) polyubiquitination is lost, the DISC complex is capable of activating initiator caspases (*e.g.*, caspase-8 [CASP-8] or caspase-10 [CASP-10]). Together with RIPK1, RIPK3, and FADD, a CASP-8–cFLIP heterodimer forms a cellular signaling platform, termed a ripoptosome, which usually prevents necroptotic signaling (see below) by cleaving RIPK1, RIPK3, and cylindromatosis (CYLD) while not proteolytically activating downstream effector caspases such as CASP-3, CASP-6, and CASP-7. However, should CASP-8 be activated, it will form homodimers to activate downstream caspases, which induce apoptosis.

RIPK1 polyubiquitination represents a major checkpoint for a cellular decision to either survival or to undergo RCD. For this reason, polyubiquitination is tightly regulated. Inhibitors of apoptosis 1 and 2 (cIAP1/2) and the linear ubiquitination complex (LUBAC) attach ubiquitin chains, whereas OTULIN, CYLD, and A20 remove them. Polyubiquitination is required for NEMO-dependent canonical NF-κB signaling and mitogen-activated protein kinase (MAPK) activation. Both provide a survival signal. In contrast, on loss of polyubiquitination RCD is licensed. Remarkably, both pro-survival NF-κB signaling and necroptosis lead to local inflammation, whereas apoptosis is noninflammatory.

Following the observation that CASP-8-deficient mice (which die in utero) can be rescued on a RIPK3-deficient background to become viable and fertile, the physiological role of apoptosis has been questioned. However, CASP-8 is of critical importance only for the extrinsic pathway of apoptosis. Mice deficient for both BAX and BAK, which cannot undergo intrinsic apoptosis, are not viable. Thus, apoptosis appears to be important for normal development and, particularly in the case of CASP-8, for the inhibition of necroptosis.

Other than hereditary autoimmune syndromes (*e.g.*, autoimmune lymphoproliferative syndrome [ALPS]), no clear role for apoptosis in diseases has been unequivocally reported. To date, inhibition of caspases in certain diseases has either worsened or failed to provide benefits to disease outcomes.

Pyroptosis

Pyroptosis (from "pyro" = fever/inflammation and "ptosis" = to fall) is a form of RCD induced by inflammatory stimuli, transduced via inflammatory caspases and (probably) executed by gasdermins. Inflammatory caspases include CASP-1, CASP-4/-5 (human), and CASP-11 (murine). Unlike apoptosis, caspase activation in this context leads to a necrotic phenotype that is mediated by members of the gasdermin family. In the prototype pyroptosis pathway, CASP-1/-11 cleave gasdermin D (GSDMD). Proteins of the gasdermin family are composed of a self-inhibitory C-terminal and a death-inducing

of engaging the necrosome are through Toll-like receptors (*TLRs*) via the RHIM-containing adaptor molecule *TRIF*, or by activation of the protein *ZBP1/DAI* in response to sensing intracellular oligonucleotides. Finally, and without any clear connection to apoptosis and necroptosis, ferroptosis (C) is a failsafe rather than a typical cell death pathway. In cellular homeostasis, H_2O_2 concentrations iron catalyzed and fenton reactions are limited by diverse cellular antiredox systems. The best-studied system relies on glutathione *(GSH)*, which is generated intracellularly and depends on supply via system X_{c-}, a cys/glu antiporter in the plasma membrane, or products of the mevalonate pathway. Upon sufficient GSH concentrations, glutathione peroxidase 4 (GPX4) prevents lipid peroxidation that otherwise leads to plasma membrane rupture by unknown mechanisms. In contrast, the oxidoreductase *FSP1* (also known as *AIF-M2*) prevents lipid peroxidation upon myristoylation-dependent recruitment to the plasma membrane in a GSH-independent manner. Finally, the targeted release of ferritin from multivesicular bodies into the extracellular space might represent another anti-ferroptosis mechanism that depends on the protein prominin2. Ferroptosis occurs as a non cell-autonomous pathway in a process referred to as synchronized regulated necrosis (SRN).

N-terminal fragment.[15] Upon caspase-mediated cleavage of GSDMD, the N-terminal fragment loses its self-inhibiting C-terminal fragment and therefore becomes active. This, through an as-yet to be defined mechanism, results in the for mation of a plasma membrane pore that allows secretion of active cytokines and necrosis. An exceptionally potent inflam matory stimulus for pyroptosis is LPS, a typical component of bacterial membranes. In pyroptosis, the axis LPS–CASP-11–GSDMD –pyroptosis is also referred to as "noncanonical."

The canonical pathway is initiated by the inflammasomes (Chapter 3). The NLRP3 inflammasome forms upon stimuli that include pathogen-associated molecular patterns (PAMPs), DAMPs, and absent in melanoma-2 (AIM2) as a response to cytosolic DNA. These inflammasomes recruit CASP-1/-11 via adapter molecule ASC (apoptosis-associated speck-like protein containing a C-terminal caspase recruitment domain) and lead to GSDMD cleavage and IL-1β/IL-18 maturation. Indeed, active production of systemically effective inflammatory cytokines during RN has been described for pyroptosis, thus rendering this cell death modality highly inflammatory. Pyroptosis is typically observed in macrophages during gram-negative infection and upon culture with bacterial or viral intracellular pathogens. Thus, pyroptosis is thought to mediate the immunogenic destruction of colonized niches. The other members of the gasdermin family (GSDMA, GSDMB, GSDMC, and GSDME) share structural analogies and potentially represent additional pore-forming molecules. In line with this, it was recently demonstrated that GSDME can be cleaved by Caspase 3 and granzyme B; thus, leading to pyroptosis as well.

Necroptosis

Necroptosis is the best-characterized mode of RN. It was discovered as a type of necrotic cell death in apoptosis-resistant cell lines. Classically, it is induced upon tumor necrosis factor-α (TNF-α) stimulation with concomitant inhibition of apoptosis (*e.g.*, by a virally expressed caspase inhibitor). In this context, TNFR1, Fas, and other death receptors (described at pathways of extrinsic apoptosis, see above) transduce this signal into the cell (see Fig. 17.4).

RIPK1, a key checkpoint of cellular fate, contains a motif next to its DD termed *RIP homotypic interacting motif* (RHIM). This motif is preserved in only four proteins within the mammalian proteome, and all these proteins are associated with the regulation of necroptosis. The necrosome, a higher-order structure with a poly-RIPK3 backbone, is central to necroptosis execution. Importantly, the necrosome can also be engaged downstream of TLR3 and TLR4 signaling through the protein TIR-domain-containing adapter-inducing interferon-β (TRIF) .

Viral recognition is integrated by the protein DNA-dependent activator of interferon regulatory factors (DAIs), also referred to as ZBP1.[16] Recently, DAI has been demonstrated to mediate in utero lethality of RIPK1-deficient mice by forcing RIPK3 oligomerization, which places inactive RIPK1 as an inhibitor of necroptosis. The RIPK1 kinase inhibitor necrostatin-1s (Nec-1s) seems to stabilize this conformation and thereby inhibit RIPK3 oligomerization.

Downstream of the active necrosome, mixed lineage kinase domain-like protein (MLKL) becomes phosphorylated by RIPK3. After phosphorylation of MLKL, this pseudokinase forms oligomers targeting the plasma membrane via its four-helical bundle (4HB) motif to mediate plasma membrane rupture. This process is controlled by the ESCRT-III complex, but the precise mechanisms of necrotic cell death and potential pore formation currently remain undefined. Clearly, phosphorylated MLKL (pMLKL) is required, but it is not sufficient to execute necroptosis. This is of significant interest as pMLKL targets multiple intracellular membranes, translocates to the nucleus to induce CXCL1/IL-33, and is stably expressed in terminally differentiated cells (*e.g.*, podocytes and endothelia) without killing them. Taken together, this might point to a still-unknown physiological role of pMLKL. Mice deficient in RIPK3 or FADD and MLKL die following challenge with influenza A virus. Therefore, RNA viruses, such as influenza A (and potentially also SARS-CoV-2, Chapter 25), drive necroptosis through activation of ZBP1/DAI.[17]

Bacterial infection is sensed via TLR3 and TLR4. This also recruits a RHIM domain–containing adapter protein named TRIF that engages RIPK3 to drive necrosome formation and necroptosis. It is likely that necroptosis exemplifies an evolutionary conserved program to defend the host against viruses and certain bacteria. In keeping with this hypothesis, some virus express caspase inhibitors, such as crmA (*e.g.*, cowpox virus), whereas viral protein M45 (*e.g.*, cytomegalovirus [CMV]) specifically inhibits necroptosis. CMV is a member of the herpesvirus family, which is characterized by its persistence within the host. M45 contains a viral RHIM domain and thereby suppress ZBP1/DAI-induced RIPK3 oligomerization within the necrosome.

Following activation of the necroptosis pathway, chemokines (Chapter 15) and cytokines (Chapter 14) are actively produced to be released in addition to DAMPs. These include CXCL1 and IL-33, a stimulator of ST2 signaling on regulatory T cells. These observations suggest that necroptosis limits the inflammatory response to a certain microenvironment and thereby prevents a systemic inflammatory response syndrome (SIRS) and death. As immunogenic as necroptosis may be on a local scale, on its own it may not induce the release of acute-phase proteins from the liver or with a fever.

CLINICAL RELEVANCE

Selection of Clinically Relevant Conditions Associated With Necroptosis

- Acute kidney injury
- Acute liver failure
- Acute respiratory distress syndrome
- Autoimmune disorders
- Cancer (necrosis in the center of solid tumors)
- Myocardial infarction
- Solid-organ transplantation
- Stroke
- Transplant rejection

Necroptosis critically contributes to diverse pathophysiological settings, including ischemia–reperfusion injury in solid organ transplantations, myocardial infarction, stroke, and SIRS. RIPK3- and MLKL-deficient mice have been demonstrated to be protected from preclinical models of such diseases by several independent groups. As a result, inhibitors of necroptosis (RIPK1 kinase inhibitors, RIPK3 kinase inhibitors, and MLKL inhibitors) have entered phase I and phase II clinical trials. As of the writing of this chapter, no cell death–preventing therapy had been approved by the US Food and Drug Administration (FDA). However, preclinical and first clinical data are very promising. Necroptosis inhibitors may soon become the first-in-class compounds to prevent RN.[18]

Ferroptosis

Ferroptosis is an important RN pathway with respect to ischemic injury of the brain, the heart, and the kidneys. It has been implicated as a mechanism to target cancer. Unlike extrinsic apoptosis and necroptosis, ferroptosis is not initiated by specific receptors. In renal tubules, it mediates an event referred to as *synchronized regulated necrosis* (SRN) of an entire functional unit. Thus, it provides a biochemical basis for the clinical observation of necrotic casts in the urine sediment of patients with acute kidney injury (Chapter 69). Key ferroptosis molecules have been associated with renal clear cell carcinomas.

Ferroptosis is critically mediated by the loss of NADPH (the major cellular redox equivalent) abundance as result of lipid peroxidation. This peroxidation was initially attributed to lipoxygenase ALOX5. However, it has become clear that ferroptosis is predominantly driven by the loss of function of glutathione (GSH) peroxidase 4 (GPX4) and/or ferroptosis-suppressor protein 1 (FSP1, also known as AIFM2), depending on the cell type. Upon GPX4-dysfunction, ferroptosis occurs rapidly in all metabolically active cells by means of ROS that are generated in the mitochondria.[4,19]

GPX4 requires GSH as a redox equivalent to function. Inhibition of the glutamate/cystine-antiporter system X_c^- in the plasma membrane depletes intracellular cysteine required for GSH synthase. Inhibitors of the antiporter system X_c^- are referred to as type 1 ferroptosis inducers (FINs). The default type 1 FIN is the compound "erastin," which was found in a screen for lethal compounds against Ras-transformed tumor cells. Type 2 FIN directly inactivate the active center of the selenoprotein GPX4. Other inhibitors of ferroptosis have also been identified through screens (*e.g.*, the first-in-class compound ferrostatin-1[20] and in cancer cell lines (*e.g.*, diffuse large B-cell lymphomas and clear cell renal carcinomas.[21]

GPX4 catalyzes the reduction of oxidized phospholipids and sphingolipids to the respective alcohols. This is associated with protection from cell death by ferroptosis, indicating that lipid peroxidation drives the loss of plasma membrane integrity. However, precise mechanisms remain to be determined. Defects in enzymes required for generation of polyunsaturated fatty acids (PUFAs), such as acyl-CoA synthetase long-chain family member 4 (ACSL4), prevent cells from undergoing ferroptosis. This further emphasizes the role of lipid peroxidation.

NADPH depletion has been identified as a downstream event of lipid peroxidation. This might explain the nature of cell death propagation during ferroptosis, which is not restricted to a single cell but causes necrosis beyond the plasma membrane limits. This phenomenon has been referred to as a *wave of death*, and was confirmed to occur in cell culture, in fish, and in renal tubules. NADPH may freely diffuse between neighboring cells through intercellular pores, such as gap junctions, leading to RCD in adjacent cells.[22,23]

CLINICAL RELEVANCE

Selection of Clinically Relevant Conditions Associated With Ferroptosis

- Cancer (necrosis in the center of solid tumors)
- Myocardial infarction
- Hemorrhagic stroke
- Acute kidney injury and acute tubular necrosis
- Rhabdomyolysis
- Solid-organ transplantation

At the time of writing this chapter, no immunomodulatory role for cells that die by ferroptosis had been described, and the immunogenicity of ferroptosis is certainly high. It is clear, however, that ferroptosis in ischemic myocardial tissue recruits neutrophils, and that addition of ferrostatins reduces the infarcted area and the scarring.[13] Post-myocardial infarction inflammatory syndromes (Chapter 37), such as Dressler syndrome, may be partially explained by this mechanism. Finally, it remains unclear why some heart attacks are not accompanied by neutrophil infiltration.

The role of mitochondria in ferroptosis has been recently elucidated.[24] Mitochondria are one source of the ROS that drive lipid peroxidation during ferroptosis. These findings, and the identification of FSP1 (see above) also suggested that ferroptosis might substantially overlap with what was previously referred to as "mitochondrial necrosis" or mitochondrial permeability transition-induced regulated necrosis (MPT-RN). The distinction of the RN pathways is of major relevance because of the development of specific small molecule inhibitors. Clear data exist to demonstrate that widespread depletion of mitochondria does not affect necroptosis.[25] Thus, while necroptosis does not require mitochondria and mitochondrial cell death does not require RIPK3, ferroptosis does. Evidence from isolated mitochondria, as well as from immunofluorescence and electron microscopy, suggests a central role of swelling of this organelle and MOMP during MPT-RN, as in apoptosis. To the best of our knowledge, a role of mitochondrial swelling in ferroptosis has not been determined.

Distinction of Other Regulated Necrosis Pathways—Mitochondrial Permeability Transition-Induced Regulated Necrosis and Parthanatos

MPT-RN is the consequence of mitochondrial permeability transition, a highly effective shortcut between the mitochondrial matrix and the cytosol. MPT is mediated through a pore (the MPT pore [MPTP]), the composition of which has been a matter of debate for at least two decades. Currently, a widely accepted model assumes a multiprotein complex physically or functionally involving proteins from the mitochondrial matrix, inner and outer mitochondrial membranes, the transmembrane space, and the cytosol. The pore is controlled by a cyclophilin named *cyclophilin D* (CYPD), a key modulator of MPTP opening and, thus, MPT-RN. Genetic absence of *ppif*, the gene that encodes for CYPD, protects mice from ischemic challenges, including stroke, myocardial infarction, and renal ischemia–reperfusion injury. As with other cyclophilins, the immunosuppressant cyclosporine (CsA) (Chapter 85) inhibits the opening of the MPTP and therefore prevents MPT-RN. This effect may well account for some of the immunosuppressive function of CsA. Other models favor CYPD to interact with the c subunit of F_1F_0–ATPase complex.[26] However, the role CsA in ferroptosis remains unclear, as does the extent to which ferroptosis and MPT-RN express two variations of the same RN pathway.

Parthanatos is defined as cell death that occurs following so-called overactivation of the DNA repair enzyme poly (ADP-ribose) polymerase 1 (PARP1). PAR polymers are formed and translocate to the outer mitochondrial membrane by unknown targeting mechanisms. The default induction of PARP1 overactivation includes a wide array of stimuli, ranging from DNA damage (*e.g.*, through irradiation), over ROS, stress, and induction by toxins, such as methylnitronitrosoguanidine (MNNG). Comparable to MPT-RN, parthanatos results in apoptosis-inducing factor (AIF)

release. It has been suggested that AIF requires active PARP1 to transfer ATP-ribose groups from NAD^+ onto its targets.

Most of our knowledge of PARP1 derives from cancer research. Many tumors have been demonstrated to overactivate PARP1. PARP inhibitors are in the FDA approval process for diverse cancers as a result of promising outcomes of phase III clinical trials. For *BRCA1/2* mutated ovarian and breast cancer, PARP-inhibitor olaparib has already been introduced in clinical practice. As with MPT-RN and ferroptosis, it is possible that parthanatos and ferroptosis are variations of the same RN pathway. Future experiments will have to clarify this issue.

KEY CONCEPTS

Prototype Inhibitors of Regulated Necrosis

- Inhibitors of necroptosis
  - Necrostatin-1 (Nec-1)
  - Nec-1s (Nec-1 stable)
  - Ponatinib
- Inhibitors of ferroptosis
  - Necrostatin-1 (Nec-1)
  - Ferrostatin-1 (Fer-1)

CONCLUDING REMARKS AND IMPLICATIONS FOR SOLID-ORGAN TRANSPLANTATIONS

Understanding the pathways of RN will allow screening for and/or design of specific inhibitors of the enzymes involved. Two major effects are anticipated from inhibiting RN. First, in clinically relevant conditions in which necrosis is the main determinant, such as stroke, myocardial infarction, sepsis, transplantation, acute liver failure, pancreatitis, and the center of solid tumors, it remains to be investigated how beneficial an antinecrosis therapy might be. Second, and probably of at least equal importance in solid-organ transplantation, necroinflammation deteriorates and amplifies the primary organ damage.

In transplantation, standard immunosuppression is carefully individualized to prevent proliferation of immune cells, but it does not avoid the priming of memory B cells. To transplant an organ that contains DAMPs and necrotic debris—a frequent scenario following a period of organ transfer—creates a strong stimulus for memory B cells. Expansion of these cells following the engagement of the BCR is a target for immunosuppression. The memory phenotype may be favored upon these special conditions. This scenario is comparable to a vaccination against intracellular components of the graft. When immunosuppression is tapered, ABMR becomes a major factor, lasting for years.[27] Under these circumstances, ABMR may be triggered by necroptosis of transplanted cells that have been virally infected. Finally, transplantation of necrotic debris hardly happens in living donor transplantation despite HLA mismatch and blood group mismatch and blood group incompatibilities. The upcoming years of RN and transplantation research should clarify how an anti-RN therapy may improve the outcome of transplants, with a particular focus on ABMR (Table 17.1).

TABLE 17.1 Classification of Damage-Associated Molecular Patterns

Classes of DAMPs[a]		Categories of Cognate Recognition Receptors/Sensors (Cell Bound, Humoral)
Class Ia DAMPs	DAMPs such as HMGB1, HSPs, nucleic acids including mitochondrial and cytosolic DNA	Sensed via binding to "classical" recognition receptors (*e.g.*, PRRs such as TLRs, RLRs, ALRs) on/in innate immune cells (*e.g.*, phagocytes and DCs), thereby triggering signaling pathways
Class Ib DAMPs	DAMPs such as CALR and eATP	Recognized by "nonclassical" recognition receptors (*e.g.*, the purinergic receptors P2X7.) thereby contributing to phagocytes including DCs activation
Class II DAMPs	DAMPs (*e.g.*, eATP, uric acid) operating as second signals to activate the NLRP3 inflammasome	Sensed by NLRP3 receptor to form assembly of the NLRP3 inflammasome contributing to phagocytes including DC activation
Class III DAMPs	DAMPs exposed on stressed cells such as MICs and ULBPs	Recognized by the activating NKG2D receptor (*e.g.*, on NK cells, thereby contributing to NK cell activation)
Class IV DAMPs	DAMPs in terms of neoantigens/neoepitopes (*e.g.*, NMHC-II, oxidized phospholipids, and the actin cytoskeleton.)	Recognized by binding to preexisting natural IgM antibodies to activate the complement cascade, thereby contributing to inflammation
Class V DAMPs	Dyshomeostasis-associated molecular patterns (*e.g.*, accumulation of unfolded proteins in the ER; intracellular ion perturbations, hypoxia, and redox imbalance)	Sensed by sensors of the UPR (*e.g.*, PERK) or sensed by NLRP3 receptor, thereby contributing to inflammation and DC activation
Class VI DAMPs	Metabolic DAMPs (*e.g.*, succinate)	Recognized by the "nonclassical" recognition receptor GPR91. Thereby promoting inflammation
Class VII[b] DAMPs	Nociceptor-activating DAMPs (*e.g.*, osmotic challenges, low and high temperature, capsaicin)	Sensed by nociceptors (*e.g.*, TRPA1 channels and TRPV1)

[a]The attempt to classify DAMPs as depicted in this table is restricted for this chapter only and with focus on their crucial role in allograft rejection.
[b]Class VII DAMPs sensed by nociceptors have been tentatively included in this table to show that DAMP-induced responses of the innate immune defense system may exceed the traditional phenomena of inflammation and adaptive immunity. Of course, this approach is debatable and we freely admit that there are still some deficits in our classification waiting for a final resolution.

CD, Cluster of differentiation; *DAMPs*, damage-associated molecular patterns; *DC*, dendritic cells; *eATP*, extracellular ATP; ER, *endoplasmic reticulum*; *GPR91*, G protein-coupled receptor 91; *HMGB1*, high mobility group box 1; *HSPs*, heat shock proteins; *IgM*, immunoglobulin M; *MICs*, MHC class I chain-related proteins; *NK*, natural killer; *NKG2D*, natural killer group 2 member D; *NLRP3*, NLR family, pyrin domain-containing protein 3; *NMHC-II*, nonmuscle myosin II-A heavy chain; *PERK*, the protein kinase R (PKR)-like endoplasmic reticulum kinase; *PRRs*, pattern recognition receptors; *P2X7*, purinergic receptor P2X7; *RLRs*, retinoic acid-inducible gene (RIG)-I-like receptors; *TLR*, Toll-like receptor; TRPA1, transient receptor potential cation channel subfamily A member 1; *TRPV1*, transient receptor potential vanilloid subtype 1; *ULBPs*, UL16 binding proteins.

ON THE HORIZON

In Vivo Interference With Regulated Necrosis

- RIPK1 inhibitors have shown promising results in animal studies/human phase I and II studies. They are the most likely first-in-class cell death inhibitors.
- Ferroptosis inhibitors may be useful for protection against the wave-of-death phenomenon seen in myocardial infarction and acute kidney injury. Perfusion of transplantable organs with ferrostatins may be a clinical application that could soon be tested.
- Immunogenicity of necrosis may boost cancer immunotherapy. Examples for this are approaches of gasdermin-mediated necrosis of tumor cells that are combined with checkpoint inhibitors.

ACKNOWLEDGMENTS AND CONFLICT OF INTEREST STATEMENT

This manuscript was supported by funding of the German Research Foundation, and the Heisenberg-Professorship to W.T., A.B., and A.L. and also supported by the TRR205 Adrenal of the DFG. A.L. was issued a patent for a combined inhibitor of necroptosis and ferroptosis, Nec-1F (patent # 20160943.5). Apart from this, all authors declare no competing interests.

Human Genomics in Immunology

Jennifer M. Puck and Robert L. Nussbaum

The completion of the Human Genome Project in 2003, 50 years after the landmark 1953 publication of the double-helical structure of DNA by James Watson and Francis Crick, was a major milestone in modern biology. The sequence provided a comprehensive and accurate view of the genetic makeup of humans, with an error rate of <0.001% and only a few hundred gaps.[1,2] This detailed picture of a composite human genome is for human genetics what Vesalius's publication of the structure of the human body, *De humani corporis fabrica*, was for anatomy. Like Vesalius's work, it continues to serve as a foundation for further discovery in such areas as genetic variation, gene function, human physiology, and the genetic basis for disease.

The human genome has about 21,000 protein-coding genes distributed on 23 pairs of chromosomes.[3] The total length of the haploid genome is ~3 billion nucleotide base pairs (bp). The protein-coding segments, called exons, are interspersed with noncoding DNA sequences, called introns. The aggregate protein-coding sequences, referred to as the "exome," account for ~1% to 1.5% of the genome, with exons plus introns ~20% and the remainder is DNA located between genes. Some of the noncoding DNA contains regulatory elements that direct gene expression, act as origins for DNA replication, signal where exons start and end so that introns can be spliced out of messenger RNA, control chromatin conformation, encode small regulatory RNA molecules, and participate in three-dimensional looping to produce the large-scale structure of chromosomes. About 40% of the total DNA consists of families of repeated sequences. These repeat elements are generally silent, but they may be involved in some types of gene regulation and can participate in mutations by facilitating deletion, duplication, and insertion. Each cell expresses only a subset of the entire gene repertoire at a given point in time. "Housekeeping" genes are expressed in almost all tissues and cell types, where they perform basic metabolic and structural functions. Other genes are under very specific control, with their expression restricted to one or a few cell types. Differential gene expression specifies the unique composition and functions of cells (e.g., immunoglobulin [Ig] in B cells, and T-cell receptors [TCRs] in T cells). Some genes encode transcription factors, which translocate to the cell nucleus to coordinate the expression of groups of tissue-specific target genes. A few of these apparently act as "master" genes during particular developmental processes or in specific cell lineages. Over 450 genes are known that when mutated result in immune system defects, affecting either innate or adaptive immune cells by altering processes governing cell growth, differentiation, effector functions, or cell death such as by apoptosis.[4,5]

KEY CONCEPTS

- The sequence of the human genome and catalogue of genome variation among humans has revolutionized our approach to heritable immune disorders.
- Genomic DNA sequence is the finest scale physical map of the genome, describing the exact locations of each gene on each of the 22 paired autosomes and the X and Y sex chromosomes.
- The human genome encompasses ~3 billion nucleotide base pairs of DNA with approximately 21,000 protein-coding genes, with each cell expressing only a subset of the genes.
- Coding sequences of genes, referred to as the exome, comprise only 1%–1.5% of the genome.
- Areas of the genome that are critical for normal function of gene products have been conserved through evolution; thus, species conservation suggests functional significance.
- A variety of types of DNA variation are recognized, including single nucleotide changes, insertions or deletions of a few to many nucleotides, copy-number variants consisting of deletions or duplications or triplication of many hundreds to thousands of nucleotides, and structural variants such as inversions or translocations.
- Interpretation of the significance of an observed variant in DNA sequence may require consideration of its location, frequency in the population, inheritance in a family, and specific effect on the resulting gene product.

GENOME ANNOTATION

Each individual inherits genomic material from both parents. The maternal and paternal copies of the genome are nonidentical, and the difference in sequence (a *variant*) at any one location (*locus*) is called an *allele*. The two alleles at a single locus on the two copies of a chromosome (except for the X chromosome in males, when there is only one allele) constitute the *genotype*. Genotype should not be confused with *haplotype*, which is the set of alleles present at a series of loci on a single chromosome. The individual's genotype interacts with the environment throughout life to create the *phenotype*. Some phenotypes, such as body weight, are simple to measure, whereas others are based on complex laboratory evaluation (e.g., T-cell proliferation). Phenotypes may be discrete traits (normal vs. abnormal) or quantitative traits that have a continuous range of values. Relatively common variants, or polymorphisms, account for some of the phenotypic variation between healthy individuals or between populations, and the cumulative percentage of phenotypic variation explained by genetic variation is called *heritability*. In monogenic diseases (also called *mendelian* or single-gene disorders), the presence of variant(s) is usually considered necessary and sufficient to cause disease; when an abnormal genotype does not cause disease in everyone who has that

genotype, the phenomenon is referred to as *reduced penetrance*. The landscape of genetic variation in each individual includes a continuum of gene effects ranging from weak (common single-nucleotide polymorphisms [SNPs] detected in disease-association studies) to strong (rare, damaging variants detected in single-gene disorders).

The consensus sequence of the human genome has been only the first step in exploring normal biological functions and how variants cause disease. The Human Genome Project has matured into a number of basic and applied research areas: (i) acquiring a comprehensive catalogue of human variation and the impact of individual variants on phenotype, including disorders of human development; (ii) comparing human genomes with those of other organisms and human ancestors; and (iii) learning how to interpret all the sequence elements within the genome, not just the codons that determine the amino acid makeup of proteins. Almost two decades after initial "completion" of the human genome sequence a fully complete and accurate single, contiguous reference haploid genome is still being constructed, and updated versions continue to be released. The greatest challenges to completing the human genome sequence are posed by regions that contain segmental duplications of nearly the same sequence.

HUMAN VARIATION

The first publicly available human genome sequence was constructed from a small number of individuals, a composite haploid sequence rather than an actual sequence of a single individual. It was neither a "normal" nor a "control" genome; instead, it was a reference, providing a universally available sequence against which the genomes of individual humans, as well as other species, could be compared and any differences, or variants, determined. Even before the human genome sequence was completed, the need to discover as broad a range of human variations as possible in populations from around the world was recognized to be essential for understanding how genetic variations lead to differences in phenotypic traits and disease susceptibilities. The first effort to catalogue human genetic diversity was the dbSNP (database of single nucleotide polymorphisms) project, followed by the 1000 Genomes project. These catalogues have been supplemented enormously by more comprehensive efforts, including the NHLBI GO Exome Sequencing Project (ESP), and the Exome and Genome Aggregation Consortium databases (EXaC and gNOMAD), which have made publicly available a vast number of variants and their frequencies from hundreds of thousands of individuals.

Variants are classified as rare or common. Most variants (85%) have allele frequencies substantially below the 1% cutoff for being a called a polymorphism and are, instead, considered rare, sometimes restricted to a single ethnic group or even a single kindred.[6]

DNA variation is also classified according to the *type* of DNA change (Table 18.1). Single nucleotide variants (SNVs), insertion/deletion variants (indels), copy number variants (CNVs), and structural variants (SVs) can have different consequences, depending on their location and the number and identity of nucleotides affected. The simplest and most common of all variants are SNVs, in which one nucleotide in the reference sequence is substituted by another. A locus characterized by an SNV usually has only two alleles, corresponding to the more common (major allele) and less common (minor allele) base found at that particular location, although, theoretically, four alleles at any base position are possible (either an adenine [A], cytosine [C], guanine [G], or thymidine [T] nucleotide). SNVs are observed on average once every 1000 bp in the genome but are not distributed evenly and have different frequencies in different populations. Most SNVs are not located within exons or other known functional elements; moreover, over half of coding SNVs do not alter the predicted amino acid sequence of the encoded protein and are thus termed *synonymous*, whereas the remainder that do alter the amino acid sequence are *nonsynonymous*. Other SNVs introduce or change a stop codon, and still others alter a known splice site; such SNVs are likely to have significant impact on the expression of the gene containing the SNV as well as possible phenotypic consequences.

A second general class of variation is the result of insertion and/or deletion compared to the reference sequence, ranging from 1 up to an arbitrary cutoff of ~300 to 1000 bp. When reference nucleotides are simply deleted or duplicated, the variant is referred to as a "del/dup." When the reference sequence has some nucleotides deleted and replaced by another inserted

TABLE 18.1 Types of DNA Variation

Type	Description	Methods for Detection
Single nucleotide variant (SNV)	Sequence change in which, compared with a reference sequence, one nucleotide is substituted for another	Readily found by Sanger or massively parallel sequencing with short or long reads
Deletion or duplication variant (del/dup)	Sequence change involving 2 to ~1000 base pairs (bp) in which reference nucleotides are either missing (deleted) or duplicated and inserted directly 3′ to the reference nucleotides	Small del/dup detected by short-read sequencing, but long reads may be required
Insertion/deletion variant (indel)	Sequence change involving between 2 and ~1000 bp in which one or more reference nucleotides are replaced by one or more other nucleotides and is not an SNV or SV	Most often found by short-read sequencing, but may require long reads
Copy number variant (CNV)	The del/dup or indel is arbitrarily set as larger than ~1000 bp	Difficult to find by short-read sequencing without specialized CNV detection software; long reads or other specialized tools may be required
Structural variant (SV)	Inversion, translocation	May be difficult to find by any sequencing method other than whole-genome sequencing, depending on where the inversion or translocation occurs; karyotype analysis required for large-scale cytogenetic changes

From Human Variome Society, Sequence Variant Nomenclature, version 20.05. Available at: http://varnomen.hgvs.org (accessed January 25, 2021).

sequence, the variant is referred to as an "indel." Each individual carries many hundreds of thousands of indels.

Some del/dup variants are multiallelic because of variable numbers of the identical segment of DNA inserted in tandem at a particular location, thereby constituting what is referred to as a *microsatellite*, or *short tandem repeat* (STR). Microsatellites are segments of DNA composed of units of 2, 3, or more nucleotides, such as $(TG)_n$, or $(CAA)_n$, with n between 2 and several dozen. Many tens of thousands of polymorphic microsatellites are known to exist throughout the human genome, making them useful for tracking inheritance of DNA blocks within kindreds (linkage analysis) as well as for forensic identification of an individual's DNA identity or fingerprint. STR DNA segments within or adjacent to coding exons rarely, but famously, can expand to become hundreds or thousands of nucleotides long, thereby causing such human disorders as fragile X syndrome or Huntington disease. Even without expansion, STRs within exons, some of which may be as small as 9 to 25 bp, have an outsized impact on the frequency of human disease, since they confer a five- to sixfold increase in the frequency of rare disease-causing indel mutations compared with neighboring exon sequences that do not contain an STR.[7]

One subclass of indel variants arises from mobile elements. Nearly half of the human genome consists of widely dispersed families of repetitive elements, of which the two most common are *Alu* (a ~300 bp short interspersed nuclear element) and LINE (long interspersed nuclear element). Although most of the copies of these repeats are stationary, some of them contribute to human genetic diversity through *retrotransposition*, or insertion of a DNA segment generated through transcription of an *Alu* or LINE element into an RNA that is then reverse-transcribed back into DNA. Each mobile element indel consists of two alleles, one with and one without the inserted element. Mobile element polymorphisms are found on all human chromosomes; some have been implicated in gene disruptions underlying human disease.

Another important type of human variation includes CNVs, variations in the number of copies of DNA segments >1000 bp to many hundreds of kilobase pairs (kb). CNVs >500 kb occur in 5% to 10% of the general population, whereas those >1 million bp (1 Mb) occur in 1% to 2%. Not only are CNVs a significant contributor to human variation and disease but also the areas of the genome where they are found are often sites of segmental duplications, some of the most difficult regions in which to develop an accurate reference sequence because the most widely used sequencing technologies generate only short reads of a few hundred bp.[8,9] Many CNVs include genes; thus, CNVs are frequently implicated in diseases that result from altered gene dosage. One well-known human immunological and multisystem disorder, DiGeorge syndrome, is caused by heterozygous deletion CNVs between four sets of repeated DNA elements on chromosome 22q11.2.[10] The deletion occurs de novo in about 1 in 5000 individuals and encompasses dozens of genes, the most important of which for the DiGeorge phenotype is the transcription factor gene *TBX1*.

The most common SVs in the human genome are inversions, which range from a few bp to up to several Mb. Inversions are present in either of two orientations in the genomes of different individuals.[11] Most do not involve gain or loss of DNA, allowing each opposite-oriented allele to achieve a substantial frequency in the general population. Inversions can, however, cause significant gains or losses of DNA in the offspring of inversion carriers because of aberrant recombination during meiosis, leading to serious syndromes brought about by chromosomal imbalance. Furthermore, if inversions interfere with normal gene expression by disrupting a gene or altering the physical relationship between a gene and its regulatory elements, disease may ensue.

CLINICAL IMPACT OF HUMAN VARIATION

One of the greatest challenges facing human geneticists is linking variation to phenotype.[12] The significance for the health of the vast majority of variants of any type is unknown, and yet this knowledge is essential if we are to apply genomics to clinical care. The impact of variants ranges from completely benign to highly pathogenic, the latter causing devastating disorders of the immune system that may occur as new mutation dominants or as autosomal recessively inherited syndromes. Even common polymorphic variants may affect health or longevity, although their being common means that they are likely to produce a relatively subtle alteration of disease susceptibility rather than directly cause a serious illness.[13] Working out the functional impact of human variation will occupy genomics researchers for many years to come. An essential component of this work is to make databases of genetic variants and their impact on human health available to the research and clinical communities, as is being done with the ClinVar database hosted by the National Library of Medicine in the United States and the Leiden Open-source Variation Database (LOVD).[14–16]

COMPARATIVE GENOMICS

Evolution at work is nowhere better illustrated than in the field of comparative genomics, which deals with similarities in the sequence, structure, and chromosomal location of genes between different species whose evolutionary paths diverged up to hundreds of millions of years ago. Direct sequence comparison has revealed that an enormous number of human proteins have orthologues (genes derived from a common ancestor) in other organisms, ranging from 87% in chimps to 79% in mice, 63% in zebrafish, 39% in the fruit fly (*Drosophila melanogaster*), and 31% in the nematode (*Caenorhabditis elegans*). The study of the human genome and the genomic basis for human disease has benefited from studies in other organisms, particularly multiple strains of mice, in which many decades of inbreeding and gene manipulation have permitted characterization of the roles of many gene products and phenotypic consequences of variation. Mouse models of immunity have been highly relevant and informative for humans.

However, orthologous genes may serve different functions in different species; therefore, one cannot assume that a disease-causing variant in humans will cause a similar defect when its orthologue is similarly mutated in mice, and vice versa. For example, the V(D)J recombination activating genes *RAG1* and *RAG2* in humans and *Rag1* and *Rag2* in mice appear to have identical functions, with knockout mice showing the same inability to recombine T- and B-lymphocyte antigen-receptor genes as humans with RAG1 or RAG2 deficient severe combined immunodeficiency (SCID; Chapter 34).[17] As a result, the phenotype of RAG1/2 deficiency in both species is absent T and B cells with normal natural killer (NK) cells, referred to as $T^-B^-NK^+$ SCID. A contrasting situation occurs in other SCID genotypes. For example, humans lacking the common γ chain

(γc) of receptors for interleukin-2 (IL-2) and other cytokines, caused by mutations in the X-linked gene *IL2RG* have SCID in which T and NK cells are absent but nonfunctional B cells are present in normal to high numbers, $T^-B^+NK^-$ SCID. Mice with the orthologous gene *Il2rg* mutated or removed can make T cells but have no B cells, which gives them a $T^+B^-NK^-$ phenotype.[18]

Genes other than *IL2RG* alone must be responsible for this difference between species. Such genes, known as *modifiers*, have not yet been identified. Notably, different strains of mice can also have important phenotypic differences in the presence of a single gene mutation under study; for example, some strains such as nonobese diabetic (NOD) and Murphy Roths Large (MRL) mice are highly prone to developing autoimmunity, while others such as C57BL/6 (B6) are resistant.[19]

FUNCTIONAL GENOMICS

Immediately after the Human Genome Project was declared to have been complete in 2003, an important follow-on project was launched to identify the functional segments of DNA, particularly portions in the 98% to 99% lying outside of the coding exons of genes, for which there was no simple sequence code that could be understood the way the triplet codon code can be read. This project, termed ENCODE (for "encyclopedia of DNA elements") set out to address the problem by studying functional DNA elements in genomes of humans and model organisms.[20] Before ENCODE, estimates were that 3% to 8% of the human genome had some role in function, given that this fraction of the genome appeared to be highly conserved among species with only very limited variation. This estimate was far too low, as it did not take into account rapidly evolving functional elements or those restricted to particular evolutionary lineages, nor did it include segments of DNA too small to show conservation with statistical significance, or functional elements in repetitive DNA not reliably scored as being evolutionarily conserved.

Since the same genome is present but functions differently in different cells of an individual, ENCODE used a number of different tissues for its studies. A comprehensive catalogue of every segment of DNA that is transcribed into RNA in any tissue was required. A second project, GTEx (Genotype-Tissue Expression) was launched to catalogue tissue-specific gene expression and regulation from 54 non-diseased tissue sites across nearly 1000 individuals.[21] ENCODE has analyzed not only total whole-cell RNAs but also those located in the nucleus or cytosol, because subcellular localization of RNAs is important in understanding their functions. Assays for functionality of segments of DNA are to a large extent circumstantial and include biochemical evidence, such as identifying (i) segments of DNA located in chromatin loops that allow chromatin-chromatin interaction; (ii) regions of open chromatin, which are accessible to transcription; (iii) motifs that transcription factors recognize and bind to; (iv) regions associated with histones that have been modified to either promote or suppress transcription; and (v) regions with differential methylation of cytosine residues in different tissues, with methylation being associated with inactivity.

The circumstantial nature of the evidence developed by ENCODE assays associating DNA elements and chromatin changes with gene expression means that not all elements so implicated will turn out to have functional significance. A stringent threshold for ascribing a functional role to DNA segments (i.e., direct effect on gene expression and phenotype of at least one human cell type) suggests that 10% to 20% of human noncoding DNA functions in gene regulation. As of 2020, the ENCODE database contained 1 million functional human elements comprising 7.9% of the human genome and about half that many in mouse.[22] More research will be needed before the ENCODE project delivers its final assessment of the fraction of the human genome that plays a role in gene regulation—that is, in how different cells use their genomes.

APPLYING HUMAN GENOMICS TO DISCOVERY OF DISORDERS OF THE HUMAN IMMUNE SYSTEM

Scientists and clinicians dealing with rare, single-gene disorders must cope with both locus and allele heterogeneity. *Locus heterogeneity* means that the same or a similar phenotype results from mutation in one of several different genes. For example, SCID can result from mutation in the adenosine deaminase, *IL2RG*, *JAK3*, and so on. *Allelic heterogeneity* means that the disease is caused by different mutations in the same gene. In X-linked disorders, allelic heterogeneity is typically high because affected individuals have reduced reproduction (negative evolutionary selection), and most mutations are lost in the population after a few generations. At autosomal loci some mutations have reached appreciable frequency as a result of demographic processes (e.g., *founder effect*).[23] In the heterozygous state, recessive mutations can be weakly deleterious, neutral, or actually confer a small advantage.

If the mutant alleles are common in a population, one can test affected individuals and potential carriers directly for those mutations. However, none of the immune deficiencies result from common mutations that would lend themselves to screening of the general population, except for special instances when one particular variant is responsible for the vast majority of cases of a disease in a particular population (e.g., the particular *DCLRE1C* variant in the Artemis gene causing SCID among Navajo Native Americans). One DNA-based population screening test that has proven highly effective does not identify a specific gene variant, but rather detects T-cell receptor excision circles (TRECs), DNA byproducts of successful T-cell receptor gene recombination in developing thymocytes (Chapter 9).[24] Because TRECs are a biomarker for normal T-cell production, their absence in infant dried blood spots constitutes a newborn screen to identify essentially all cases of SCID as well as other conditions with very low T-cell numbers, regardless of genotype.

Genome research has provided geneticists with a catalogue of essentially all known human genes, knowledge of their location and structure, and an ever-growing list of variants in DNA sequences found among individuals in different populations. In the past, geneticists followed two approaches to identifying the genetic basis for human disorders. The first, linkage analysis, is *family based* (Fig. 18.1). Linkage analysis takes advantage of family pedigrees to follow the inheritance of a disease among family members and test a few hundred DNA variants distributed throughout the genome for consistent, repeated coinheritance, or *segregation*, with the disease. A demonstration of significant coinheritance with a *variant* or *variants* located in a particular region of the genome indicates that the disease-causing mutation is also located in a gene nearby. The marker

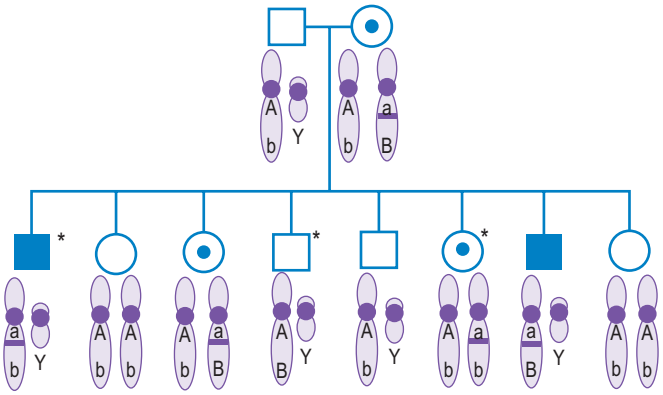

FIG 18.1 An Example of Family-Based Linkage Analysis as a Means to Identify a Disease Gene. The pedigree of a family with X-linked severe combined immunodeficiency (SCID) caused by an *IL2RG* mutation in the proximal long arm of the X chromosome *(marked with dark bar)* is shown. Affected males have *filled in square*; female carriers are designated by *dot in the center* of their symbols. Two loci, one with alleles A and a, and the other with alleles B and b, are shown in the proximal and distal long arm of the X (Xq). There are no recombinations during female meiosis between allele a and the *IL2RG* mutation in any of the eight children, while three children *(marked with asterisk)* show a recombination with the locus on the distal Xq. The father's X chromosome is passed on without any recombinations to each of his daughters and is shown on the left of each pair of X chromosomes in the daughters.

variants segregating with the disease are usually not the variants responsible for the disorder, but are close enough that recombination during meiosis between the marker and the gene mutation responsible for the disease is uncommon.

The second approach, genome-wide association analysis (GWAS), is *population based*. A sample of affected individuals, or "cases," taken from the population, is chosen along with a matched set of unaffected "control" individuals from the same population. Then, a large number of variants throughout the genome are analyzed for an increased or decreased frequency in cases versus controls. The alleles used to test for association need not be the actual variants functionally responsible for the disease association—in fact, this would be highly unlikely. Instead, GWAS, like linkage, depends on one or a few of the vast number of marker alleles tested for association to be located close enough to the functionally responsible alleles for association to have been carried along, on the same chromosome in a haplotype block, through many generations (Fig. 18.2). Association analysis does not require pedigrees and is useful for complex diseases that do not show strict mendelian inheritance.

Linkage analysis and association studies have limitations in investigating the genetic basis for human immune disorders. Linkage analysis is problematic if the disorder is a rare autosomal recessive condition, with a consequence that there are not enough families with two carrier parents to enable such a study; nonetheless, the increased frequency of consanguineous matings in some populations has been utilized to overcome this limitation.[23] Another challenge with linkage analysis is if the disorder is genetically lethal so that it is never inherited and always occurs sporadically as a result of a new mutation. Detecting an association in a case-control study is also a problem when the frequency of any particular allele associated with the disease is too low among the cases to give a detectable association. For example, if the disorder arises from different, independent mutations and if these mutations are found on many different haplotypes in affected individuals, it may be very difficult to establish a significant association with any one variant marker.

Genomic sequencing has become an important alternative to linkage analysis and GWAS. Vastly improved methods of DNA sequencing have opened up new possibilities to discover the genes and mutations responsible for rare mendelian disorders. One can generate a whole-genome sequence (WGS) or, in what has often proven a cost-effective compromise, a sequence of only about 2% of the genome, the part containing the exons of genes, referred to as a whole-exome sequence (WES).

FINDING DISEASE-CAUSING VARIANTS BY ANALYZING DEEP SEQUENCE DATA

Given the high background diversity of genome sequences between individuals, how can pathogenic variants be distinguished from benign polymorphisms? Variant assessments require extensive use of public genomic databases and software tools, including the human genome reference sequence, databases of variants with their allelic frequencies, software that assesses how an amino acid substitution might alter gene function, collections of known disease-causing mutations, and databases of functional networks and biological pathways.[5]

In a recent report of the clinical use of WES in rare disorders, 2000 individuals with a variety of disorders that had escaped diagnosis despite thorough conventional clinical evaluations underwent WES.[25] A likely causative mutation or pair of mutations was found in 504 persons (25.2%). Of these mutations (of which many were severe developmental defects), half were de novo, not present in either parent. Also of interest was that 23 (4.6%) of these 504 patients in whom a diagnosis was made through WES had two different genetic disorders, resulting in a combined phenotype, most likely obscuring the diagnosis of either of the individual disorders had they been present alone.

As an example of what is now possible, suppose that there is a family "trio" consisting of a child affected with a rare immunodeficiency and the child's parents. WES is carried out, yielding typically over 4 million SNVs, indel, and CNV differences in the child compared with the human genome reference sequence. Which of these variants would be responsible for the disease? The extraction of useful information from such a massive amount of data relies on creating a variant filtering scheme based on a variety of reasonable assumptions about likely responsible explanations for the disease; application of filtering in one instance is shown in Fig. 18.3.[26]

1. *Location with respect to protein-coding genes*. Keep variants that are within or near exons of protein-coding genes and discard variants deep within introns or intergenic regions. It is possible, of course, that the responsible mutation might lie in a noncoding RNA gene (e.g., *RMRP*, the gene mutated in the immunodeficiency and dwarfing syndrome cartilage hair hypoplasia). However, these are currently more difficult to assess, and thus, as a simplifying assumption, it is reasonable to focus initially on protein-coding genes.

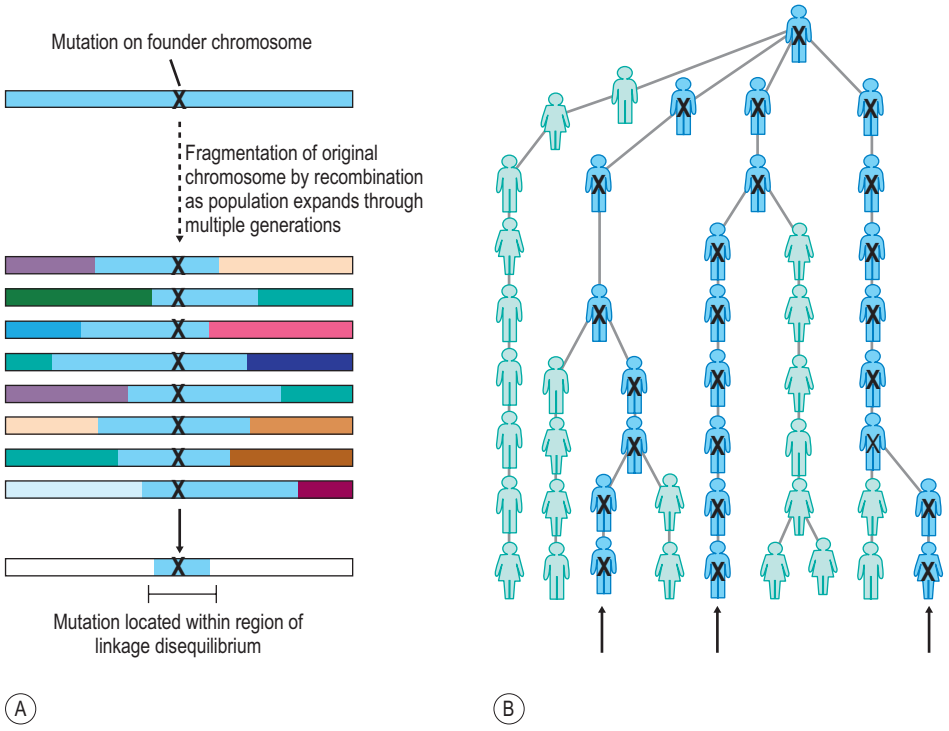

FIG 18.2 An Example of a Population-Based Genome-Wide Association Analysis As a Means to Identify a Disease Gene. (A) A mutation (X) that predisposes to a disease first occurs on a chromosome with a certain set of alleles at polymorphic loci along that chromosome *(symbolized by the blue color)*. With each generation, meiotic recombination exchanges the alleles that were initially present at polymorphic loci on the "blue chromosome" for other alleles present on homologous chromosomes *(symbolized by other colors)*. Over many generations, the only alleles that remain associated with the mutation are those at loci so close to the mutant locus that recombination between them has not occurred. These alleles constitute a disease-associated haplotype. (B) Affected individuals in most recent generation (*arrows*) carry the mutation (**X**) and are enriched for the disease-associated haplotype (*individuals in blue*) compared with unaffected individuals. Depending on the age of the mutation and other population genetic factors, a disease-associated haplotype ordinarily spans a region of DNA of a few kilobases to a few hundred kilobases. (From Nussbaum R, McInnes RR, Willard HF. *Thompson and Thompson Genetics in Medicine*. 8th ed. Toronto, Canada: Elsevier Canada; 2016: 177, Fig. 10.8, with permission.)

2. *Population frequency*. Keep rare variants from Step 1 and discard common variants with allele frequencies <0.05 (or some other arbitrary number between 0.01 and 0.1) because common variants are highly unlikely to be responsible for a disease whose population prevalence is much less than the q^2 predicted by the Hardy-Weinberg equilibrium.
3. *Deleterious nature of the mutation*. Keep variants from Step 2 that cause nonsense or nonsynonymous changes in codons within exons, cause frame-shift mutations, or alter highly conserved splice sites. Discard synonymous changes that have no predicted effect on protein function (unless there is reason to suspect that they influence splicing or expression, such as the last nucleotide of an exon, which is typically "G").
4. *Consistency with likely inheritance pattern*. If the disorder is considered most likely to be autosomal recessive, keep any variants from Step 3 for which an affected child has two variants in the same gene and each parent has one of the variants. The child need not be homozygous for the same deleterious variant but could be a compound heterozygote for two different deleterious mutations in the same gene.

If there were consanguinity in the parents, the candidate genes and variants might be further filtered by requiring that the child be a true homozygote for the same mutation derived from a single common ancestor. If the autosomal recessive mode of inheritance is correct, then the parents should both be heterozygous for the variants. The disease-causing variant in a male could also be X-linked, in which case any variant found in an X-linked gene for which the mother is a heterozygote would be a candidate. For either the autosomal or X-linked case, the disorder could be the result of a new dominant mutation; in this case, keep variants from Step 3 that are de novo changes in the child and are not present in either parent.

In the end, millions of variants can often be filtered down to a handful of SNVs, indels, or CNVs affecting a reasonable number of genes. Once the filtering reduces the number of genes and alleles to a manageable number, they can be assessed individually for other characteristics. Do any of the genes have a known function or tissue expression pattern that would be expected if it were the potential disease gene? Is the gene already implicated in other disease phenotypes, or does it have a role in pathways in which mutations are known to cause similar or different phenotypes? Finally, is the same gene mutated in other patients or in an animal model with a similar phenotype? Finding mutations in one of the candidate genes in additional patients would support that gene's role in the disease of the patient under study. In some cases, one gene remaining on the list in Step 4 may become a leading candidate because its involvement makes biological or genetic sense or it is known to be mutated in other affected individuals. In other cases, however, the gene

responsible may turn out to be entirely unanticipated on biological grounds or may not be mutated in other affected individuals because of locus heterogeneity.

In some cases, the difficulty in making a diagnosis was the result of there being a variant in a gene, previously unknown to cause human disease, but implicated by finding variants that fit the inheritance pattern (de novo dominant or autosomal recessive), and then later confirmed by finding other variants in phenotypically similar patients. In others, the gene involved had been previously described, but not in association with the phenotype for which the patient was undergoing diagnostic exome analysis. For example, in the kindred depicted in Fig. 18.3, two children had an undiagnosed autoimmune syndrome consisting of early-onset bullous pemphigoid, nephritis, autoimmune anti-factor-VIII hemophilia, and inflammatory bowel disease. WES was performed for both children, their unaffected sister, and both unaffected parents.[26] Eighty-eight genes were found in which the two affected children were compound heterozygotes for two different rare mutations, whereas the unaffected sister and both parents were carriers for only one of the two mutations found in the children. Of these, only one gene was known to have any immunological function: *ZAP-70*, previously known to be mutated in combined immunodeficiency but not with strictly autoimmune disease of this type (see Fig. 18.3). Both affected children were compound heterozygotes for two missense mutations, p.R192W and p.R360P, in *ZAP-70*. The mother carried the R192W allele, whereas the father and unaffected sister carried the R360P allele. Neither mutation had been reported previously, nor were they near mutations in the same gene that had been previously associated with human disease. Functional studies revealed the p.R192W had reduced activity, whereas the R360P encoded a modestly hyperactive protein because of disruption of an autoinhibitory mechanism. The combination of these alleles, as proven in laboratory studies, fully explained the autoimmune phenotype.

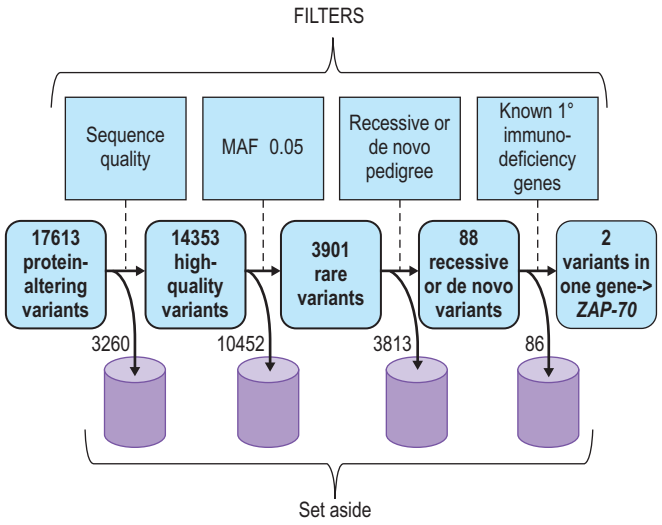

FIG 18.3 Variant Filtering Used to Sort Through Whole-Exome Sequence to Analyze a Familial Disease. Protein-altering variants detected in the affected children, their unaffected sibling, and parents were first filtered by sequencing quality and allele frequency to yield a set of 88 rare, damaging or non-synonymous variants that fit an autosomal recessive inheritance pattern and were then candidates for causing the autoimmune disorder. This group was then further analyzed for genes involved in immune function, which brought two variants in *ZAP-70*, for which the affected children were both compound heterozygotes, to the top of the list as possible causative mutations. (Adapted from Chan A, Punwani D, Kadlecek T, et al. A novel human autoimmune syndrome caused by combined hypomorphic and activating mutations in ZAP-70. *J Exp Med*. 2016;213:155–165, with permission.)

INTERPRETING VARIANTS DISCOVERED THROUGH GENE SEQUENCING

Once a gene and certain variants within it are implicated in causing a particular disease, how is the information applied in clinical diagnostics when the next patient presents with a similar clinical picture and a different, novel variant in that gene? Variation is common and not all variants cause disease. In 2015, much-needed rules were promulgated to measure and standardize the evidence needed to assert that a previously unknown variant is responsible for a disease.[27] The rules stipulated that, by combining five kinds of evidence (Table 18.2), all

TABLE 18.2 Interpreting Variants Found During Clinical Diagnostic Testing

Data Category	In Favor of Benign Score	In Favor of Pathogenic Score
Frequency in the population	• Too frequent, given disease incidence	• Rare and enriched in affected vs. unaffected individuals
Type of alteration in the DNA sequence	• Synonymous single nucleotide variant (SNV) • Del/Dup or indel without frame shift	• Stop gain (nonsense) • Canonical splice site disruption • Gene deletion or disruption
Functional assays in vitro and in model organisms	• No effect on protein expression, enzymatic activity, cellular function, or animal phenotype	• Deleterious effect on protein expression, enzymatic activity, cellular function, or animal phenotype
Segregation pattern in one or more families	• Not present in everyone affected • Absent from some affected individuals	• Co-inherited with disease in all affected individuals and usually not present in unaffected (unless there is incomplete penetrance)
De novo vs. inherited		• Present in affected child but not in either parent (and paternity/maternity confirmed)
Other kinds of data	• In silico predictors • Labelled as B (benign) in other databases	• In silico predictors • Labelled as P (pathogenic) in other databases • Highly suggestive patient phenotype and present with a known pathogenic variant on the other chromosome (for autosomal recessive inheritance)

Adapted from Richards S, Aziz N, Bale S, et al. Standards and guidelines for the interpretation of sequence variants: a joint consensus recommendation of the American College of Medical Genetics and Genomics and the Association for Molecular Pathology. *Genet in Med*. 2015;17:405–424.

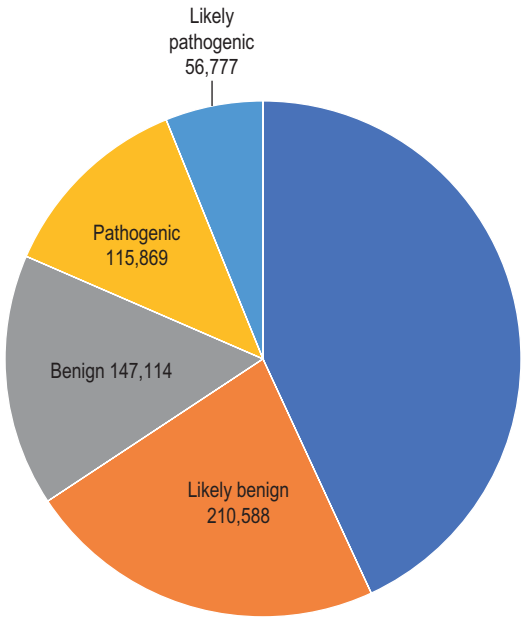

FIG 18.4 Distribution of >930,000 Variant Records in ClinVar by Interpretation. Fully 43% of submitted variants are currently interpreted as variant of uncertain significance (VUS). (According to Richards S, Aziz N, Bale S, et al. Standards and guidelines for the interpretation of sequence variants: a joint consensus recommendation of the American College of Medical Genetics and Genomics and the Association for Molecular Pathology. *Genet in Med*. 2015;17:405–424. Data derived from ClinVar Data Miner at https://clinvarminer.genetics.utah.edu/variants-by-significance, accessed January 25, 2021.)

variants found during clinical testing were to be assessed for pathogenicity and reported as belonging to one of five categories: pathogenic (P), likely pathogenic (LP), likely benign (LB), benign (B), or of uncertain significance. The term "likely" is used to indicate a lack of certainty but with odds of the variant being pathogenic or benign, for LP or LB, respectively, being at least 10:1. Clinical laboratories assess each available piece of evidence and weigh its strength; they then combine all of the levels of evidence to come to an interpretation. Unfortunately, many rare variants are too infrequent to reach B or LB status, while for other variants information is lacking or is contradictory. Any such variant is reported as a variant of uncertain significance (VUS), which under current guidelines is considered non-diagnostic and not to be used in most cases to make a diagnosis or to direct medical management. In ClinVar, for example, there are 1.3 million variants submitted by hundreds of laboratories from around the world, discovered primarily in the course of clinical diagnostic testing.[28] Fully 43% of unique variants currently in ClinVar were called a VUS by at least one submitter. However, many variants initially interpreted as VUSs have over time accumulated enough evidence to allow them to be reinterpreted to be concordant in ClinVar. When reinterpretation becomes possible, ~75% of VUSs are reinterpreted as B or LB, while ~25% are upgraded to P or LP, depending on clinical area and the nature of the VUS (i.e., missense, splice site)[29] (Fig. 18.4).

ON THE HORIZON

- With falling costs and rapid turnaround times, whole-genome sequencing will allow detection of mutations in noncoding regulatory regions as well as exons.
- Data storage and computer speed will need to be improved to handle 50-fold more data from each individual.
- New analytical paradigms for the analysis of variation in noncoding DNA and the interpretation of DNA variants that are not clearly associated with deleterious effects will be required.
- Better catalogues of sequences from diverse racial/ethnic backgrounds will be necessary to distinguish pathogenic changes from natural, non-disease-causing variants in individuals other than Northern Europeans.
- Proving causality of new gene variants causing immune disorders will depend on future cataloguing of deleterious mutations in each gene and on molecular studies of the direct effects of the variants.

FUTURE DIRECTIONS

The application of WES and WGS to rare mendelian disorders, begun in 2009, has greatly accelerated disease gene discovery. As of 2019, over 3500 parings of genotypes with disease phenotypes had been found, including several hundred single-gene immune disorders.[5,30] New discoveries will continue, and we can anticipate that the number of known mendelian disorders, including those characterized by primary immunodeficiency and/or autoimmunity, will continue to grow. While WES has been a useful strategy, future diagnostic sequencing for immune disorders may start with rapid, low-cost, optimized panels of genes, followed by WGS if a pathogenic genotype is not readily identified.

Genetic and genomic analysis will not only continue to potentiate discovery of inborn errors of immunity and, in turn, deepen our knowledge of immune system networks but also the knowledge gained will directly lead to new treatments, using gene addition, gene editing, and epigenetic modifiers therapeutically.

However, the genetic basis for complex disorders that show increased familial occurrence, and yet are not single-gene disorders and do not follow mendelian inheritance, will require further technological and analytical tools to be fully unraveled. Increased genomic data from humans and model organisms will help elucidate these more challenging human immune disorders.

Regulatory RNA in Immunologic Diseases

Thomas M. Aune

Most would agree that the biologic complexity of humans far exceeds the biologic complexity of worms, as exemplified by intellectual, physical, and behavioral capacities: the numbers of discrete organ systems and cell lineages, each with unique biologic functions (Fig. 19.1). A corollary is that humans also develop many more diseases of greater diversity and complexity than worms. However, both humans and worms have about the same number of protein-coding genes (~20,000) in their genomes and the proteins they encode largely carry out similar biologic functions. This has led to the question: where does the information that programs the greater biologic complexity of humans reside? Protein-coding genes in humans take up approximately 2% of the human genome. Thus, one possibility is that this information is encoded in the non-protein-encoding portion of the genome, which is 30-fold larger in humans than in the worm. More than 75% of the human genome is transcribed into RNA, in some human cell lineage at some stage of human development. This led to the hypothesis that these additional transcribed noncoding RNAs (ncRNAs) contribute to the differences in biologic complexity between humans and other species.[1–4] A corollary is that this vast array of transcribed ncRNAs might also contribute to the greater diversity and complexity of human disease.

KEY CONCEPTS

- Only ~2% of the human genome is used to transcribe protein-coding genes,
- >70% of the human genome is transcribed into noncoding RNA (ncRNA), with regulatory functions,
- Newly discovered classes of ncRNA include long noncoding RNAs (lncRNAs), microRNAs (miRNAs), and enhancer RNAs (eRNAs).
- ncRNAs impact critical aspects of mRNA and protein biology via multiple mechanisms.
- ncRNAs are new "master regulators of gene expression and cell fate," and help confer biologic complexity into the human genome.

CLASSES OF REGULATORY RNAS

Classes of regulatory RNAs include long noncoding RNAs (lncRNAs), enhancer RNAs (eRNAs), and microRNAs (mi RNAs).[5–11] lncRNA genes look like protein-coding genes and many, but not all, have exon-intron structures. By definition, lncRNAs are more than 200 nucleotides in length. This definition by length distinguishes lncRNAs from miRNAs and other small RNAs. Most lncRNAs are 5′ capped and polyadenylated, similar to most mRNAs. In contrast to the similarity in numbers of protein-coding genes, human genomes contain 20 times more lncRNA genes than do worm genomes. However, lncRNAs are not transcribed into proteins. They carry out their biologic functions as RNAs (although there are exceptions to this rule). Current classification or naming of lncRNAs largely draws from locations and orientations of lncRNA genes in the genome relative to neighboring protein-coding genes. These include intergenic lncRNAs if located between two protein-coding genes, intronic if located largely in a single intron of one protein-coding gene, and antisense if transcribed from the opposite DNA strand as the neighboring protein-coding gene. This latter category also includes divergent lncRNA:mRNA pairs that are transcribed from opposite DNA strands but have transcriptional start sites that are typically within 1000 bp. Proximity suggests shared promoters and enhancers. It is worth noting that while these classifications provide information regarding their position in the genome relative to protein-coding genes, they do not necessarily provide information regarding lncRNA function or mechanism of action.

Several general classifications can also be made regarding functions of lncRNAs.[5,8,12] First, some lncRNAs can rewrite the histone code at target protein-coding gene loci by recruiting epigenetic machinery to a locus. This often occurs *in cis* with the lncRNA gene and an adjacent protein-coding gene. The lncRNA rewrites the histone code at promoters and enhancers of the adjacent protein-coding gene by producing either activating or inhibitory histone marks to either stimulate or reduce mRNA expression, respectively (Fig. 19.2A). Many lncRNAs target only one protein-coding gene, but others can target multiple protein-coding gene loci. Multitargeting oftentimes involves gene families, such as the globin gene locus, the Hox gene locus, or the interleukin (IL)4-IL5-IL13 Th2 cytokine gene locus. LncRNAs can also regulate expression of genes on different chromosomes. Although these genes may not share a chromosome, they may encode proteins that are involved in common biologic processes.[5,12,13]

Second, certain lncRNAs bind and thus inhibit miRNA or mRNA function. Binding of miRNAs can lead to increased expression of protein-coding genes targeted by a given miRNA. LncRNAs can act on mRNAs to modulate pre-mRNA splicing, interfere with translation or alter mRNA degradation rates (see Fig. 19.2B).

Third, lncRNAs can bind transcription factors to either aid or prevent the recruitment of transcription factors to promoters and enhancers, thereby either increasing or reducing mRNA transcription (see Fig. 19.2C).

Last, lncRNAs also tether individual proteins that work together in common biologic pathways to affect their function or prevent protein-protein interactions (see Fig. 19.2D). Undoubtedly, additional mechanisms by which lncRNAs function will be added to this list as we continue study of this diverse class of RNAs.

Differences between human and worm genomes

	humans	worms	fold difference
genome size (bp)	3,000,000,000	100,000,000	30X
# protein-coding genes	20,000	20,000	1X
# long noncoding RNA genes	60,000	3,000	20X
# enhancer RNAs	400,000	5,000	80X
# microRNAs	2,000	200	10X

FIG. 19.1 Biologic Complexity and Genome Size. Illustration of humans *(upper left)* and roundworms (*Caenorhabditis elegans*, *upper right*). Differences in genome size, number of protein-coding genes, long noncoding RNAs (lncRNAs), enhancer RNAs (eRNAs), and microRNAs (miRNAs) between humans and worms *(lower)*.

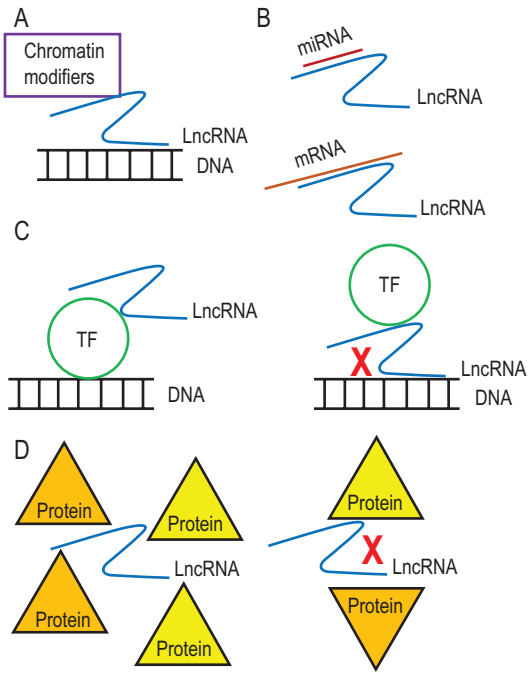

FIG. 19.2 Common Functions of Long Noncoding RNAs *(lncRNAs)*. LncRNAs (A) recruit chromatin modifiers to target DNA, (B) act as sponges and bind *microRNAs (miRNAs)* or mRNAs, (C) bind to transcription factors *(TFs)* to tether them to DNA or block transcription factor binding to DNA, and (D) facilitate or prevent protein-protein interactions.

LNCRNAS AND THE DEVELOPMENT AND FUNCTION OF THE IMMUNE SYSTEM

Individual lncRNAs regulate many key immune processes. This includes the development and function of both innate and adaptive immunity.[12,14] Some examples include lncHSC-1, lncHSC-2, H19, and others that regulate the differentiation of hematopoietic stem cells and progenitor cells into mature hematopoietic cell lineages, as well as the self-renewal of both short- and long-term hematopoietic stem cells. These processes are necessary to maintain numbers of all the mature hematopoietic cell lineages in the periphery. They are also required to sustain both the innate and adaptive arms of the immune system. These functions are achieved by regulation of both protein-coding genes critical for establishing and maintaining these developmental programs and the activity of key transcription factors that guide hematopoietic differentiation programs.

LncRNAs also regulate critical aspects of the innate immune system (Chapter 3). This includes the development of macrophages and dendritic cells from common myeloid progenitor cells (lnc-DC); the lifespan of short-lived myeloid cells, eosinophils, and neutrophils (Morrbid); and the expression of proinflammatory mediators, such as cytokines. Deletion of these regulatory lncRNAs seriously disrupts the function of the innate immune response in a variety of animal models.

LncRNAs also regulate key functions of the adaptive immune response. Many of these studies have focused on the process of differentiation of naïve CD4 T cells to the different T helper lineages, Th1, Th2, and Th17, which are defined by the cytokines they express (Chapter 11). LncRNAs have been identified that regulate expression of GATA3, the key transcriptional regulator required for Th2 lineage commitment. The interferon-gamma-antisense 1 (IFNG-AS1) lncRNA regulates expression of interferon-γ (IFN-γ) in Th1 cells and TH2LCRR regulates IL-4, IL-5, and IL-13 in Th2 cells.[13,15,16] Conversely, other lncRNAs (e.g., linc-MAF-4 and lncRNA-CD244) can negatively regulate T helper lineage commitment by inhibiting expression of transcription factors or stimulating development of opposing lineages.[5,17] By these opposing functions, lncRNAs may guide creation of the proper balance of these critical T helper cell lineages whose primary functions are to orchestrate the adaptive immune response, which is critical for establishing and maintaining lifelong immunity

to pathogens. Studies such as these in the field of immunology as well as other fields have led to the labeling lncRNAs as the "emerging master regulators of gene expression and cell fate."[18]

LNCRNAS AND IMMUNE-MEDIATED DISEASE

Studies have also emerged that associate lncRNA expression and, in some cases, downstream function, to human immune-mediated diseases.[19–21] Following completion of the Human Genome Project and identification and annotation of lncRNA genes, it became possible to use high-throughput methods, such as microarrays or whole-genome RNA sequencing (RNA-seq), to ascertain the expression levels of many, if not all, annotated lncRNAs using fairly standard computational approaches. These same RNA-seq methods could also be used to identify novel or not previously identified lncRNAs. These methods enabled examination of the contribution of lncRNAs to the increased genomic and biologic complexity of humans and the immune-mediated diseases they manifest. In order to illustrate how lncRNA dysregulation may contribute to immune-mediated disease, specific examples are provided below (Table 19.1).

CLINICAL RELEVANCE

- The magnitude of dysregulation of noncoding RNAs (ncRNAs) in immune-mediated disease is vast.
- NcRNA dysregulation disrupts cell phenotypes through the loss of negative regulators and the gain of positive regulators.
- Genetic variants linked to immune-mediated disease preferentially target ncRNA coding regions of the genome.
- It is likely that many immune-mediated diseases reflect as yet undefined dysregulation of ncRNA.

LINKS BETWEEN IFNG-AS1 AND BRUCELLOSIS, INFLAMMATORY BOWEL DISEASE, AND SYSTEMIC LUPUS ERYTHEMATOSUS

IFN-γ is produced by effector and memory CD4 and CD8 T cells and by natural killer (NK) and natural killer T (NKT) cells (Chapter 12), but not by naïve CD4 and CD8 T cells (Chapter 9). This cytokine plays a critical role in regulating the immune response to intracellular infections. It is a major activator of macrophage functions (e.g., phagocytosis and antigen presentation) (Chapter 2), it plays a critical role in stimulating antiviral responses by CD8 cytotoxic T cells (Chapter 12), and it possesses antiviral properties (Chapter 25). Given its proinflammatory nature and results from various immune models, IFN-γ can play critical roles in human immune-mediated diseases (Chapter 14). Induction of the lncRNA IFNG-AS1 (Tmevpg1, NeST) plays a key role during the development of these immune response programs by guiding the writing of the epigenetic code at the IFNG locus. It acts to create a positive transcriptional environment, which is required for efficient production of IFN-γ by these diverse cell types during their response to external stimuli.[5,18]

Levels of IFNG-AS1 have been shown to be elevated in a number of human immune-mediated diseases. For example, in brucellosis, which is the most common zoonotic infection in humans, elevated IFNG-AS1 levels during infection correlate with increased IFN-γ expression.

TABLE 19.1 Examples of lncRNAs Dysregulated in Immune-Mediated Disease

lncRNA	Disease	Level in Disease	Normal Function
lincRNA-p21	RA	Decreased, restored by MTX	Inhibits NF-κB activity
H19	RA	Increased	Increases NF-κB, IL-6, TNF
HOTAIR	RA	Decreased in synoviocytes	Increases MMP-2, MMP-13
HOTAIR	RA	Increased in monocytes	Macrophage activation/migration
MALAT1	RA	Increased in synoviocyte	Apoptosis
C5T1lncRNA	RA	Increased	Increases C5
GATA3-AS1	Allergy	Increased	Induces GATA3/Th2 responses
IFNG-AS1	Brucellosis	Increased	Induces IFN-γ
	IBD	Increased	Induces
	UC	Increased	Induces
	SLE	Increased	Induces
Lnc13	CeD	Decreased	Represses CeD-related genes
LINC00305	CAD	Increased	Increases NF-κB activity
ANRIL	CAD/T2D	Increased	Induction of IL-6 and IL-8 by TNF
Linc00513	SLE	Increased	Increases IFN pathway
RP11-2B6.2	SLE	Decreased	Inhibits SOCS1, neg. regulator of IFN pathway
NEAT1	SLE	Increased	Positive regulator TLR-mediated pathways

CAD, Coronary artery disease; *CeD*, Celiac disease; *IBD*, inflammatory bowel disease; *IFN*, interferon; *IL*, interleukin; *MMP*, matrix metalloproteinase; *MTX*, methotrexate; *NF-κB*, nuclear factor kappa B; *RA*, rheumatoid arthritis; *SLE*, systemic lupus erythematosus; *T2D*, type 2 diabetes; *TNF*, tumor necrosis factor. *TLR*, Toll-like receptor; *UC*, ulcerative colitis.

In Crohn's disease and ulcerative colitis, which are the most common forms of inflammatory bowel disease (IBD) (Chapter 75), colon biopsy samples exhibit increased expression of IFNG-AS1. This suggests that the IFNG-AS1/IFNG axis may also play an important role in this organ-specific immune-mediated disease. In support of this hypothesis, genome-wide association studies (GWAS) have identified genetic variants in the IFNG-AS1/IFNG locus that are linked to increased risk for developing IBS. These genetic risk factors are linked to altered expression of lncRNA and of cytokine genes within this region.[20]

A similar case is seen in systemic lupus erythematosus (SLE) (Chapter 52). GWAS studies have identified genetic risk factors localized to the IFNG-AS1/IFNG genomic region. Studies have shown that the expression of genes within this locus, as well as the lncRNA IFNG-AS1, are dysregulated in SLE.

GATA3-AS1 AND ALLERGY

Widespread dysregulation of lncRNAs has also been observed in allergy and asthma (Chapter 43). One example is the lncRNA GATA3-AS1. GATA3-AS1 is critical for effector T helper cell differentiation programs (Chapter 11).[16] The GATA3 gene and GATA3-AS1 transcriptional start sites are positioned about

1000 bp apart in the human genome. GATA3-AS1 is transcribed from the 3′ DNA strand and the GATA3 mRNA is transcribed from the 5′ strand, thus meeting the definition of a divergent lncRNA/mRNA gene pair. GATA3-AS1 acts as a guide to rewrite the epigenetic code at the GATA3 gene promoter and enhancer loci, thus creating a positive transcriptional environment to induce expression of GATA3. As a transcription factor, GATA3 is considered to be the master regulator of Th2 differentiation and the expression of Th2 cytokines. Not only is GATA3-AS1 required for expression of GATA3 but also it is required for downstream expression of Th2 cytokines.

In general terms, allergy and asthma are considered to be Th2-mediated diseases. In allergic individuals, GATA3-AS1 levels are elevated and GATA3-AS1 is also specifically induced by allergen exposure. Taken together, this suggests a model where GATA3-AS1 contributes to early stages of allergy by promoting Th2 differentiation and function. Responses by differentiated Th2 effector cells are thought to play important roles in the induction of allergic and asthmatic responses and associated pathologies.

LNCRNAS, NUCLEAR FACTOR KAPPA B (NF-KB), AND THE PATHOGENESIS OF RHEUMATOID ARTHRITIS

Three unique biologic functions have been ascribed to LincRNA-p21.[5,21] LincRNA-p21 was originally identified because it plays a critical role in executing the cellular response to DNA damage. This lncRNA also regulates the Warburg effect, which refers to how, in order to generate energy, cancer cells seem to prefer glycolysis rather than the more efficient oxidative phosphorylation pathway, even under aerobic conditions. By regulating levels of a transcription factor that is key to governing cellular responses to hypoxia, hypoxia inducing factor 1-α (HIF-1α) the balance is shifted away from oxidative phosphorylation to glycolysis. A third function of lincRNA-p21 is to bind to certain mRNAs via a base-pairing mechanism and thus interfere with translation of these mRNAs into proteins. Specific examples include blocking translation of RELA and JUN mRNA. RelA protein is a necessary component of the key proinflammatory transcription factor NF-κB, whereas Jun protein is a key component of the AP-1 transcription factor. AP1 also provides critical functions in a variety of cellular responses, including responses to stress.

Levels of lincRNA-p21 are severely depressed in rheumatoid arthritis (RA) (Chapter 53). Basal and induced activities of NF-κB are elevated in RA, suggesting an inverse relationship between lincRNA-p21 levels and NF-κB activity, which has been demonstrated experimentally. In support of this idea, lincRNA-p21 and NF-κB activity normalize in RA patients on methotrexate, which is one of the most common therapies for RA. Further studies support a model where methotrexate therapy directly induces increased expression of lincRNA-p21. LincRNA-p21 is able to bind to RELA mRNA and inhibit its translation, thus reducing basal and stimulus-induced levels of NF-κB activity. In this regard, lincRNA-p21 plays a critical antiinflammatory function. Loss of lncRNA-p21 appears to be an important contributor to proinflammatory responses mediated by NF-κB. In addition to RA pathogenesis, this suggests that lncRNA-p21 may also contribute to the pathogenesis of other autoimmune disorders, especially those in which elevated NF-κB activity plays a central role.

In addition to lncRNA-p21, levels of the lncRNA H19, originally described for its function in hematopoiesis, are also markedly elevated in RA synovium. Elevation of H19 results in increased NF-κB activity and induction of the proinflammatory cytokines IL-6 and tumor necrosis factor (TNF), both of which are NF-κB inducible. H19 controls expression of an imprinted network of genes via epigenetic modifications. H19 lncRNA also contains miRNA members of the miR-675 family. Thus, H19 may directly or indirectly influence NF-κB proinflammatory activity via either alterations in imprinting networks or expression of the miRNAs embedded within it.[21]

Other lncRNAs impact overall NF-κB activity by different mechanisms. NKILAe inhibits IKB phosphorylation, and thus dampens both basal levels and stimulus-induced NF-κB activity. Lethe inhibits binding of the NFκB transcription factor complex to target DNA transcriptional elements, thus inhibiting induction of NF-κB transcriptional response genes. Although these lncRNAs have not been shown to exhibit different expression levels in RA, age-related loss of Lethe expression has been described in mice. Thus, Lethe may be a natural negative regulator of proinflammatory NF-κB function. It is possible that its loss could contribute to age-related increases in NF-κB proinflammatory activity in the immune system.[21]

The lncRNA HOTAIR was originally described to play a critical role in the epigenetic silencing of the HOXD gene locus during early development. HOXD plays an important role in the epigenetic regulation of morphogenesis—for example, how the skin develops over the surface of the body. HOTAIR is also expressed in fully differentiated cells, although its function in these cells is less well understood. Importantly, HOTAIR is expressed at elevated levels in certain cancers and appears to play an important role in cancer and cancer metastasis. This is an active area of investigation. In RA synovium, HOTAIR is expressed at reduced levels and is associated with increased expression of the matrix metalloproteinases (MMP)-2 and MMP-13, which may contribute to tissue destruction. Conversely, HOTAIR is expressed at elevated levels in monocytes/macrophages isolated from RA patients. Elevated HOTAIR levels appear to increase macrophage activation and migration, also potentially contributing to RA inflammation.[21]

In summary, many of the lncRNAs that exhibit dysregulation in RA have been shown to impact the activity of the critical proinflammatory transcription factor complex NF-κB and to influence the expression levels of known NF-κB target genes that are recognized to play important roles in RA pathogenesis.

LNCRNAS AND SYSTEMIC LUPUS ERYTHEMATOSUS

Many autoimmune diseases exhibit increased expression of genes known to be induced by the type 1 interferons IFN-α and IFN-β, which is referred to as the *IFN signature*. This is most notable in SLE but is also seen in other autoimmune diseases, especially at times of increased disease activity. The major stimuli leading to induction of interferons and downstream interferon-stimulated genes are viral infections. Origins of this IFN signature in autoimmune disease in the apparent absence of viral infection are incompletely understood. Positive regulators of the type 1 interferon signaling pathway are among the lncRNAs whose levels are elevated in SLE. One lncRNA, named linc00513, has been shown to increase the phosphorylation of Stat1 and Stat3, two critical positive transcriptional regulators of the interferon signaling pathway. Expression levels of this lncRNA are linked to genetic variants that are themselves linked to SLE disease risk.

A second lncRNA, named RP11-2B6.2, inhibits the activity of SOCS1, a natural negative regulator of the interferon signaling pathway. Given that a cardinal feature of presence of SLE as well as disease activity and severity is increased interferon signaling, dysregulation of interferon-regulating lncRNAs may play an even greater role in SLE than has yet been demonstrated.[22] Further studies will be required to determine whether these and other lncRNAs that control the interferon signaling pathway influence other autoimmune diseases that also exhibit an excessive IFN signature.

MIRNAS

MicroRNAs (abbreviated *miRNAs*) are another important class of ncRNAs.[10] They are transcribed from genes into a long precursor miRNA that is less than 200 nucleotides long. A specific enzyme complex, the Drosha-Dgcr8 micoprocessor complex, digests the precursor miRNA to produce a hairpin intermediate. This miRNA intermediate is exported to the cytoplasm where Drosha, a RNase III—like nuclease, processes the miRNA intermediate into its mature form. Mature miRNAs are bound by argonaute (Ago) proteins and act as guide sequences that bind to typically short 6 to 8 complementary nucleotide sequences on target mRNAs, usually located in the 3′ untranslated region (3′ UTR). If complementarity is perfect between the miRNA and the target mRNA sequences, this triggers what is termed *RNA interference*, resulting in digestion of the mRNA by the RNase H-like activity present in one of the Ago domains. However, this appears to occur only rarely in mammals. The current general view is that miRNAs predominantly cause deadenylation and decay of mRNA.

Initiation and elongation of translation of proteins may also be inhibited by miRNAs. Approximately 2000 distinct miRNA genes have been identified in the human genome. However, individual miRNAs can target multiple protein-coding or lncRNA genes, so their impacts on cell identity and phenotype are quite large. Studies have demonstrated important roles for miRNAs in multiple aspects of development, differentiation, and function of both the innate and adaptive arms of the immune system.

In addition to the intracellular function of miRNAs, recent studies have found the presence of miRNAs in many different extracellular fluids. Originally it was thought that these extracellular miRNAs were simply released from dying or dead cells and tissues. Thus presence of mRNAs in extracellular fluids were considered to lack any real biologic significance. However, more recently it has been found that these extracellular miRNAs are actually packaged in small lipid bilayer vesicles termed *exosomes*. This has led to the view that miRNAs are packaged into exosomes inside cells, released into the extracellular space, and then transported to and taken up by distant recipient cells. As such, these exosomal miRNAs may play a kind of messenger role enabling cell-to-cell communication.

As with lncRNA investigations, implementation of high- dimensional techniques such as RNA-seq or miRNA-specific microarrays to identify expression levels of miRNAs in case/control studies has demonstrated substantial dysregulation of multiple miRNAs in immune-mediated disease.[23] What is notable regarding these studies is that miRNAs dysregulated in a given autoimmune disease are known important regulators of critical molecular and cellular pathways that are thought to contribute to pathology associated with a given autoimmune disease. For example, as with lncRNAs described above, miRNAs that stimulate the type 1 interferon signaling pathway are upregulated in SLE, and miRNAs that inhibit the type 1 interferon signaling pathway are downregulated in SLE. A similar case is observed in RA. Expression levels of specific miRNAs whose natural function is to inhibit cell cycle progression and reduce expression of inflammatory cytokines are depressed in RA, and this might contribute to the hyperproliferation and increased levels of activation exhibited by synovial cells in RA. Expression levels of other miRNAs whose normal functions are to promote activity of the proinflammatory transcription factor NF-κB and stimulate expression of proinflammatory cytokines, are elevated in RA and this is also likely to contribute to elevated inflammatory processes that drive RA pathogenesis. Similar observations have been made in other autoimmune diseases including psoriasis, multiple sclerosis, and systemic sclerosis. Thus, miRNAs play critical roles in determining expression levels of protein-coding genes and, as with lncRNAs, contribute to development of the many diverse cell lineages present in humans. A cost may be that dysregulation of miRNA expression may make significant contributions to the many complex diseases found in humans, including immune-mediated diseases.

Enhancer RNAs

Enhancers are conserved DNA elements whose function is to serve as binding sites for transcription factors and enhance transcription of target genes.[11] In the genome, enhancers can be near to their target genes, many kilobases away, or even on separate chromosomes. They can influence transcription of one or multiple genes. Transcriptional enhancers have conserved DNA motifs that recruit transcription factors, which in turn recruit the epigenetic machinery to enhancer loci to write the epigenetic code culminating in recruitment of RNA polymerase II to the enhancer locus. The general view is that enhancers function by changing the conformation of the chromosome and recruiting bound RNA polymerase II to their target gene loci. This recruitment will enhance transcription. RNA polymerase II can also use enhancer DNA as the template to produce eRNAs.

One class of eRNAs, termed unidirectional eRNAs, are greater than 200 nt in length, transcribed from one DNA strand, polyadenylated and fairly stable, making them, by definition, lncRNAs. Functions of unidirectional eRNAs are incompletely understood. However, these unidirectional eRNAs seem to re-enforce enhancer function by promoting recruitment of transcription factors to enhancers, recruiting histone acetyltransferases to enhancers to write the epigenetic code, increasing enhancer chromatin accessibility, and looping distal enhancers to promoters. All of these effects can serve to stimulate transcription of target genes.

Expression of unidirectional eRNAs may be inferred from RNA-seq experiments using such criteria as (1) the RNA transcript is greater than 200 nt in length and nonspliced, (2) the transcript does not map to a known lncRNA or mRNA gene, and (3) the transcript maps to a known transcriptional enhancer. Studies examining unidirectional eRNAs in immune-mediated diseases are quite limited, but they have shown that the level of dysregulation of unidirectional eRNAs in multiple autoimmune diseases far exceeds the level of dysregulation of either annotated lncRNAs or mRNAs, both in terms of degree of differences in expression as well as the numbers of this class of ncRNA that are dysregulated.[19] This raises the possibility that this dysregulation may contribute to the origins and pathogenesis of multiple

immune-mediated diseases. However, interpreting the significance of these results is difficult. It is not yet known if the differential expression of a given unidirectional eRNA may directly contribute to disease pathogenesis or if differences in eRNA expression simply reflect differences in underlying enhancer function at a different level. These factors could include the sequence of the enhancer DNA, differences in the binding of one or more transcription factors, or reading and writing the epigenetic code. It must be recognized that our lack of knowledge is due in part to the fact that we do not fully understand the contribution of unidirectional eRNAs to enhancer function and to the stimulation of target gene transcription.

GENOME-WIDE ASSOCIATION STUDIES

With the goal of identifying genetic variants, single nucleotide polymorphisms (SNPs) and GWAS have been performed for almost all immune-mediated diseases (Chapter 18). Several unexpected results have emerged from these studies.[9,24] First, many SNPs (100 s), rather than a single monogenic variant, are associated with risk for developing any given immune-mediated disease. Second, less than 10% of GWAS-identified SNPs are found in protein-coding genes in the genome, which suggests that altered protein amino acid sequence and protein function is not a major contributor to genetic risk for developing immune-mediated diseases. Instead, many of these genetic variants have been found to reside in noncoding regions of the genome. This has hindered progress in understanding how these genetic variants confer disease risk. Studies are now emerging that demonstrate that many of these genetic variants are located in lncRNA genes. Expression differences of many of these encoded lncRNAs have been implicated in the pathogenesis of immune-mediated diseases.[20–24]

One example is IFNG-AS1. The IFNG-AS1 gene is located in a region that is rich with genetic variants linked to IBD risk. Expression of IFNG-AS1 is elevated in this disease at sites of inflammation, and this seems to be associated with increased expression of IFN-γ. These and other studies suggest a general rule that genetic variants identified by GWAS that confer disease risk for developing immune-mediated diseases influence expression levels of lncRNAs in the genome, and altered expression of these lncRNAs contributes to disease risk and disease pathogenesis.

A second group of genetic variants identified by GWAS include those that influence functions of miRNAs.[25] One area of attention has been to examine how genetic variants located in the 3′ untranslated regions (3′ UTR) of protein-coding genes alter miRNA target sites. In this regard, genetic variants in 3′ UTRs may produce new miRNA target sites, resulting in increased binding of miRNAs to the 3′ UTR in question and reduced expression of target protein-coding genes. The alternative is also seen; genetic variants in the 3′ UTR of certain protein-coding genes results in loss of miRNA binding sites, leading to increased expression of these target protein-coding genes. Besides genetic variants in 3′ UTRs of protein-coding genes, SNPs linked to immune-mediated diseases have also been found in miRNA genes that change the ability of the encoded and processed miRNA to bind to its target protein-coding gene 3′ UTR and guide mRNA degradation. In summary, these variants produce altered expression levels of proteins that can alter cell traits and confer disease risk.

A third group of immune-mediated diseases' susceptibility to genetic variants includes transcriptional enhancer regions and associated transcribed eRNAs.[9,11,19] Variants in these genomic regions potentially impact expression of target protein-coding genes by altering enhancer functions. Transcriptional enhancers probably represent the most common site of genetic variation linked to immune-mediated diseases as well as other complex traits. Enhancer function is a very complex process and the roles of eRNAs in transcriptional activation and silencing are incompletely understood. Thus, it is not possible to conclude with certainty that altered enhancer function endowed by these genetic variants actually results from loss or gain of eRNA expression or by other mechanisms. However, it has been clearly demonstrated that the presence or absence of disease-associated SNPs at target enhancer loci is associated with differences in eRNA expression and expression of their target protein-coding genes.

One goal of GWAS has been to identify genetic variants that confer risk of developing a given disease, including immune-mediated diseases. Several common themes emerge.[24] One is that multiple genetic variants confer disease risk and effects of a single genetic variant are relatively small so there is no "smoking gun." Perhaps more importantly, the majority of the genetic variants thus far identified by GWAS function primarily by regulating expression levels of target protein-coding genes, rather than by producing proteins with altered amino acid sequence and functions. Most genetic variants identified by GWAS are localized in the noncoding region of the genome responsible for producing the known array of ncRNAs.

The general view is that immune-mediated diseases arise from a combination of genetics, or family traits, and the environment (Fig. 19.3). Genetic variants thus far identified that contribute to immune-mediated disease are predominantly localized in the enhancer elements that give rise to eRNAs and in genes that are transcribed into lncRNAs and miRNAs. Many of these ncRNAs may be stably expressed in certain cell lineages. Therefore the ncRNA transcriptome determines cellular phenotypes by impacting critical mRNA and protein biology. In this way, the ncRNA transcriptome will define how a given cell lineage responds to environmental cues, causing these responses to be predetermined. If this is considered in the context of immune-mediated disease, one might propose that the ncRNA transcriptome shifts the balance toward heightened immune activity by both loss of ncRNAs that inhibit, and gain

FIG. 19.3 Model describing contributions of regulatory RNAs to immune-mediated disease. *eRNA*, Enhancer RNA; *lncRNA*, long noncoding RNA; *miRNA*, microRNA.

of ncRNAs that stimulate, immune activity, thereby shifting the balance to a proinflammatory state. As such, this would lower the threshold at which an individual responds to both external and internal environmental cues. Since these altered responses are predetermined by the ncRNA transcriptome, they may become permanently imprinted in the host and produce lifelong idiopathic disease.

An added consideration is that certain lncRNAs act *in cis* to regulate neighboring target protein-coding genes, while others act *in trans* to regulate expression of large gene sets that seem able to define the inflammatory state. Similarly, activity of critical immune pathways can be positively or negatively regulated by multiple lncRNAs at multiple levels, including the level of gene transcription, mRNA translation, and protein function. Dysregulation of any of these lncRNAs may significantly impact overall immune function. By extension, lncRNAs may represent targets for therapeutic intervention. As discussed earlier, these targets may include lncRNAs that promote the IFN signature in SLE, NF-κB activity in RA, or heightened Th2 responses in allergy. Currently, use of antisense oligonucleotides to silence overexpressed or restore underexpressed lncRNAs via nanoparticle technologies represents a possible therapeutic approach. Undoubtedly, a better and more complete understanding of how lncRNAs regulate key aspects of both innate and adaptive arms of the immune system, mechanisms of dysregulation in immune-mediated disease, and general principles of how lncRNAs interact with their DNA, RNA, and protein binding partners will offer new therapeutic insights that may be applied to this constellation of disease processes.

ON THE HORIZON

- The search for a unifying logical explanation for the role of noncoding RNA (ncRNA) dysregulation in immune-mediated diseases, i.e., identification of a "smoking gun,"
- Elucidation of the contribution of genetic or familial traits and environment to ncRNA dysregulation.
- The development of ncRNAs as therapeutic targets.

Immunometabolism

Michihito Kono, Amir Sharabi, and George C. Tsokos

Cell metabolism (Fig. 20.1) is crucial for cell survival, proliferation, and differentiation, and aberrations are involved in the pathophysiology in many diseases.[1] In recent years it has become clear that cell metabolism not only provides energy but also regulates cell phenotype, fate, and function. During the last 5 years, evidence has demonstrated that modulation of immune cell metabolism can be exploited as a therapeutic target for autoimmune diseases. In this chapter, we describe current insights into the immune cell metabolism in autoimmune diseases by focusing on systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), and multiple sclerosis (MS).

GLYCOLYSIS AND PENTOSE PHOSPHATE PATHWAY

Glycolysis is the metabolic pathway that converts glucose into pyruvate. Ten enzymes (including hexokinase, glyceraldehyde 3-phosphate dehydrogenase [GAPDH], and pyruvate kinase) are involved in this pathway. Execution of the pathway generates two pyruvate, two adenosine triphosphate (ATP), and two reduced nicotinamide adenine dinucleotide (NADH) molecules from each glucose molecule. The generated pyruvate has two options: either to form acetylcoenzyme A (acetyl-CoA) by pyruvate dehydrogenase (PDH) and enter the tricarboxylic acid (TCA) cycle in the mitochondria for further energy production, or to be converted into lactate by lactate dehydrogenase (LDH). The pentose phosphate pathway (PPP) is a metabolic pathway parallel to glycolysis. PPP generates nicotinamide adenine dinucleotide phosphate (NADPH), pentose, and ribose 5-phosphate, a precursor for the synthesis of nucleotides.[2,3]

GLUTAMINOLYSIS

Glutaminolysis is crucial in the production of energy in proliferating cells, including lymphocytes and cancer cells. Glutamine is transported in the cells by specialized transporters and is converted to glutamate by glutaminase. Glutaminase has two isoforms: glutaminase 1 (kidney isoform) and glutaminase 2 (liver isoform). Glutaminase 1 has more and faster enzymatic activity than glutaminase 2. Glutamate is sequentially converted to α-ketoglutarate through the action of glutamate dehydrogenase and enters the TCA cycle.[2,3]

FATTY ACID OXIDATION AND FATTY ACID SYNTHESIS

Fatty acid oxidation (FAO) is a mitochondrial process that generates acetyl-CoA from fatty acids. It involves a repeated action of four enzymes that generate NADH and flavin adenine dinucleotide ($FADH_2$), which are used by the electron transport chain (ETC) to produce ATP. In contrast, fatty acid synthesis is a metabolic process whereby end products of glucose catabolism are converted to fatty acids.[2,3]

TRICARBOXYLIC ACID CYCLE AND ELECTRON TRANSPORT CHAIN

The TCA cycle utilizes acetyl-CoA from glycolysis and FAO, and α-ketoglutarate from glutaminolysis. To generate ATP, NADH produced by the TCA cycle is used in the oxidative phosphorylation (OXPHOS) complexes, which are present in the inner membrane of mitochondria. These complexes are known as NADH: ubiquinone oxidoreductase (complex I), succinate dehydrogenase (complex II), cytochrome bc1 complex (complex III), cytochrome c oxidase (complex IV), and ATP synthase (complex V).[2,3] Metformin, which is widely used for treating patients with type 2 diabetes, inhibits the mitochondrial complex I.[4]

KEY CONCEPTS

Main Cell Metabolic Pathways

Glycolysis
- Used by many proliferating cells (e.g., cancer cells and lymphocytes)
- Converts glucose to pyruvate
- Ten enzymes (including hexokinase and pyruvate kinase) are involved
- Pyruvate is converted to acetylcoenzyme A (acetyl-CoA) to enter the TCA cycle or to lactate

Glutaminolysis
- Used by proliferating cells
- Glutamine is converted to glutamate and then α-ketoglutarate and enters the TCA cycle

Fatty Acid Oxidation (FAO)
- Mitochondrial process
- Generates acetyl-CoA from fatty acids

TCA Cycle
- TCA cycle utilizes acetyl-CoA from glycolysis and FAO, and α-ketoglutarate from glutaminolysis
- To generate ATP, NADH produced by the TCA cycle is used in the oxidative phosphorylation complexes

Immune Cell Metabolism

Adaptive Immune Cell Metabolism

The adaptive immune system, also known as the acquired immune system, is highly involved in eliminating infectious pathogens and cancer cells. This immune response generates

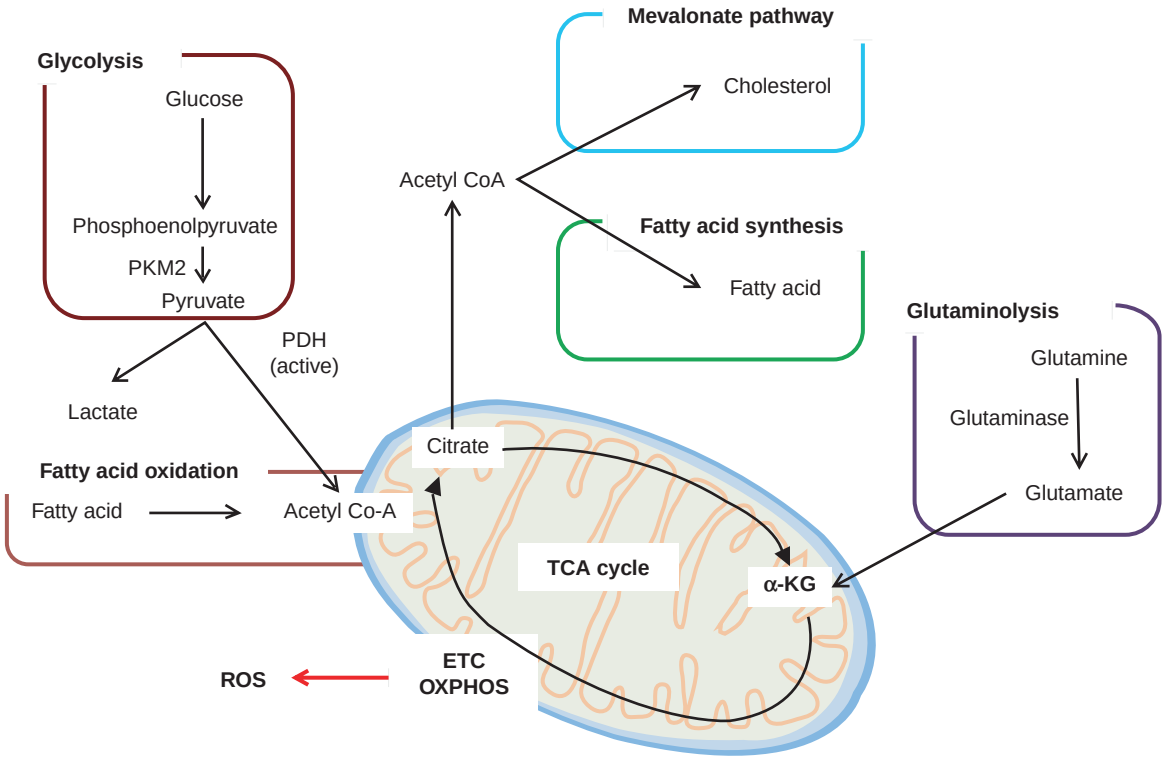

FIG. 20.1 Main Cell Metabolic Pathways. α-*KG*, α-Ketoglutarate; *Acetyl Co-A*, acetyl coenzyme A; *ETC*, electron transport chain; *OXPHOS*, oxidative phosphorylation; *PDH*, pyruvate dehydrogenase; *PKM2*, pyruvate kinase muscle isozyme 2; *ROS*, reactive oxygen species; *TCA*, tricarboxylic acid.

immunological memory which enables a prompt response upon repeat exposure to the same pathogen. Both T cells and B cells are essential components of the adaptive immune system.

T-Cell Metabolism

1. T-cell activation
   Following T-cell receptor (TCR) engagement, naïve T cells undergo a rapid shifting from quiescence to activation and differentiation. Phosphoinositide 3-kinase (PI3K)–AKT–mammalian target of rapamycin (mTOR) pathway is a central signaling pathway in this process that enables a shift from FAO and pyruvate oxidation towards glycolysis and glutaminolysis.[5] Myc is a transcription factor downstream of mammalian target of rapamycin complex 1 (mTORC1), which regulates enzymes involved in glycolysis and glutaminolysis, wherein the levels of Myc, elevated or low, dictate cell differentiation into effector T cells or memory-like T cells, respectively.[5]
2. Effector T-cell metabolism
   Naive CD4 T cells can differentiate into various effector T-cell subsets, and each cell subset utilizes metabolic pathways downstream of the TCR in a differential manner. mTORC1 activity is essential for Th1, IL-17 producing CD4 T (Th17), and CD8 T-cell differentiation, whereas combined mTORC1–mTORC2 activity is required for Th2 and T follicular helper (Tfh) cell differentiation.[1]
   a. Glucose metabolism in effector T cells
      Th1, Th17, and Tfh cells, as well as in CD8 T cells, require glycolysis for cell differentiation, whereas glycolysis deprivation promotes regulatory T (Treg)-cell differentiation (Fig. 20.2).[1] Hypoxia-inducible factor 1α (Hif-1α) and PDH control the differentiation of Th1 and Th17 cells,[2,6] and the Ras homologue gene family member A (RhoA) controls glycolysis during Th2 cell differentiation.[1] The last step of glycolysis results in the generation of pyruvate, which can be converted to lactate in the cytoplasm or to acetyl-CoA in the mitochondria. Th17 cells also express increased levels of pyruvate dehydrogenase kinase 1 (PDHK1) and its inhibition prevents Th17 cell development and promotes Th1 cell differentiation.[6] The transcriptional-factor-inducible cAMP early repressor (ICER), which is present in Th17 cells, suppresses pyruvate dehydrogenase phosphatase catalytic subunit 2 (PDP2) and promotes glutaminolysis.[2,3] Such findings indicate that cell function determination is defined through the control of distinct metabolic processes.
   b. Amino acid metabolism in effector T cells
      The most abundant amino acid in the circulation is the nonessential amino acid glutamine. Following T-cell activation, glutamine consumption is increased.[1,5] Glutamine is hydrolyzed in a process called glutaminolysis into metabolites that support the TCA cycle, as well as the metabolic pathways affecting the synthesis of polyamine, glutathione, and serine.[1,5] Glutaminase is the first enzyme in the glutaminolysis pathway, which is induced by ICER, and glutaminase 1 inhibition impairs mTORC1-dependent Th17 differentiation.[2,3] Glutamine restriction enables Th2 polarization; however, under Th1-polarizing conditions T cells differentiate into Treg cells.[1] Notably, glutamine deprivation promotes Treg cell induction.[1] Leucine is an essential amino acid that stimulates mTOR signaling, and leucine deficiency limits T-cell activation and differentiation into effector T cells.[5] Serine, a nonessential amino acid synthesized from a glycolysis intermediate, is

FIG. 20.2 Main Metabolic Pathway in CD4 T-cell Subsets. *AMPK*, AMP-activated protein kinase; *FAO*, fatty acid oxidation; *HIF-1α*, hypoxia-inducible factor 1α; *mTORC*, mammalian target of rapamycin complex; *OXPHOS*, oxidative phosphorylation; *PPP*, pentose phosphate pathway.

essential for the purine synthesis pathway as well as CD4 and CD8 effector T-cell proliferation.[5]

c. Lipid metabolism in effector T cells
Upon T-cell activation, β-oxidation that catabolizes fatty acids towards the TCA cycle is replaced with glycolysis and glutaminolysis. De novo fatty acid synthesis is important for Th17 cell differentiation. Catalysis of acetyl-CoA is carried out by acetyl-CoA carboxylase 1 (ACC1), and ACC1 deficiency in T cells suppresses Th17 cell differentiation and promotes Treg-cell generation.[5]

3. Memory T-cell metabolism
There are three types of memory CD4 and CD8 T cells: central, effector, and tissue-resident memory T cells. Central memory T cells depend on endogenous lipids and exogenous glycerol for lipid biosynthesis.[1] Upon re-stimulation, a switch to glycolysis takes place to enable the maturation of memory T cells into effector T cells.[5] Tissue-resident memory T cells depend on the presence of exogenous fatty acids for their survival and maintenance within tissues.[1]

4. Treg-cell metabolism
Treg cells utilize mainly fatty acid and pyruvate oxidation (mitochondrial oxidative metabolism) to generate energy. In Treg cells, restraint of mTORC1 signaling is achieved by the high levels of AMP-activated protein kinase (AMPK) and the capacity of forkhead box P3 (FOXP3) to increase ceramide that activates serine/threonine protein phosphatase 2 A (PP2A).[1] Liver kinase B1 (LKB1) is the upstream kinase of AMPK, which is considered to serve as a metabolic sensor in Treg cells that stabilizes FOXP3 expression.[1]

a. Glucose metabolism in Treg cells
During Treg-cell activation and proliferation, glycolysis becomes prominent[4]; however, because mTORC1 prevents

FOXP3 expression, Treg-cell function is interrupted.[1] In contrast, when FOXP3 is increased, the cell preferentially metabolizes lipids over glucose as FOXP3 represses the promoter activity of *MYC*.[1]

b. Lipid metabolism in Treg cells
Peripheral Treg cells use both the mevalonate pathway and end products of glycolysis for the synthesis of fatty acids for their proliferation and function.[1] Tissue-resident Treg cells utilize exogenous fatty acids for their induction and maintenance.[1]

c. Amino acid metabolism in Treg cells
Generally, Treg cells do not require amino acids to exert their suppressive function.[1] However, the induction of peripheral Treg cells is promoted by metabolic intermediates of tryptophan such as kynurenine.[1] Furthermore, Treg cells express amino acid–consuming enzymes, such as indoleamine 2, 3-dioxygenase (IDO) and arginase 1, that reduce the availability of tryptophan and arginine to surrounding T cells, which in turn inhibit mTOR signaling and effector T-cell proliferation and promote Treg-cell induction.[1]

B Cell Metabolism. B cells play a pivotal role in the adaptive immune system by presenting antigens to T cells and by producing pathogen-specific antibodies, as well as cytokines. On the other side, autoreactive B cells are involved in the development of autoimmune diseases. Compared with naïve B cells, activated B cells use more glycolysis and OXPHOS.[7] Activated B cells show an increase in glucose uptake and lactate production, while resting B cells maintain metabolic quiescence through signaling molecules, including TNF-receptor-associated factor 3 (TRAF3) and glycogen synthase kinase 3 (GSK3). Inhibition of glycolysis and mitochondrial respiration or cytosolic acetyl-CoA synthesis reduce activated B-cell proliferation and survival. Several factors (including mTORC1, c-myc, and protein kinase Cβ) are requisite for B-cell activation.[7] After antigen exposure, B cells initiate the formation of germinal centers (GCs) using the help of Tfh cells. During this process, random mutations are introduced into the B-cell antigen receptor (BCR) to increase diversity. GC B cells also consume more glucose than naïve B cells. GC B cells express more genes associated with glycolysis. The expression of HIF-1α, a transcription factor which drives glycolysis, is also enhanced in GC B cells.[7] The serine/threonine phosphatase PP2A is required for GC formation and purine/pyrimidine metabolism.[8] B cells exit GC and differentiate to memory B cells or plasma cells. Since plasma cells produce large amounts of antibodies, they need more glucose and amino acid than naïve B cells. Glucose is also used not only for energy generation but also antibody glycosylation, while OXPHOS is requisite for antibody secretion in plasma cells.[7]

KEY CONCEPTS

B-Cell Metabolism

- Activated B cells use more glycolysis and OXPHOS.
- Germinal center B cells favor glycolysis.
- Plasma cells utilize glucose for not only energy generation but also antibody glycosylation.
- OXPHOS is also requisite for antibody secretion in plasma cells.

Innate Immune Cell Metabolism

The innate immune system (Chapter 3) represents the first response to infections and consists of several primitive components that are recruited and activated before the adaptive immune system. The innate leukocytes include natural killer (NK) cells, mast cells, eosinophils, basophils, macrophages, neutrophils, and dendritic cells (DCs).

Natural Killer Cell Metabolism. NK cells are essential lymphocytes that have antiviral and antitumor activities (Chapter 12). They can produce interferon-gamma (IFN-γ) and directly kill target cells through various cytotoxic mechanisms. Resting NK cells have low levels of glycolysis and OXPHOS.[9] Overnight stimulation of NK cells with cytokines results in substantial increases in both glycolysis and OXPHOS. Activated NK cells metabolize glucose to pyruvate and then lactate through aerobic glycolysis. Inhibition of glycolysis by 2-deoxyglucose (2-DG) or OXPHOS by oligomycin impairs IFN-γ production, while inhibition of glutaminase, the first enzyme in glutaminolysis, or inhibition of FAO by etomoxir does not inhibit NK-cell functions. NK-cell metabolism is impaired in the tumor microenvironment due to the restriction of glucose and amino acids such as arginine.[10] This represents an attractive target to improve NK-cell-based immunotherapy for cancer.

Mast Cell Metabolism. Mast cells are tissue-resident myeloid cells characterized by their effector function in Th2 immunity and are essential in allergic diseases and host defense responses to parasitic diseases (Chapter 44). IgE primes mast cells to release granules and chemical mediators such as histamine and cytokines. IgE-mediated activation of mast cells rapidly increases glycolysis. OXPHOS is also increased after the activation within 2 hours. IL-33 is a cytokine mediator released by endothelial, epithelial, fibroblast cells, and mast cells. IL-33 also activates mast cells and is linked to allergic diseases. IL-33 increases glycolysis and OXPHOS.[11] Inhibition of glycolysis by 2-DG suppresses antigen-induced histamine and inflammatory cytokine release.[11] Suppression of glycolysis with dichloroacetate and inhibition of complex I of the ETC with rotenone results in suppression of cytokine production and degranulation, while inhibiting FAO with etomoxir has no effect.

Eosinophil Metabolism. Eosinophils are important in host defense against parasites and in promoting allergic inflammation (Chapter 45). Eosinophils release their granule proteins, leukotrienes, chemokines, and cytokines. Eosinophils have similar levels of glycolysis and more OXPHOS compared to neutrophils.[12] IL-3, IL-5, or granulocyte–macrophage colony-stimulating factor (GM-CSF) increase glycolysis, lactate production, and OXPHOS.[13] Polyunsaturated fatty acid (PUFA)-derived bioactive metabolites are formed in vivo by enzymatic oxidation through the activation of cyclooxygenases (COX), lipoxygenases (LOX), and cytochrome P450 monooxygenases (CYP). COX-derived prostaglandins and 5-LOX-derived leukotriene play a vital role in the initiation of inflammatory responses. Eosinophil PUVA metabolism represents a target to control allergic diseases.

Basophil Metabolism. Basophils have multiple functions and migrate into organs affected by allergic inflammation and parasitic diseases. Although basophil numbers are low compared with mast cells, the sensitivity to IgE-mediated activation is higher than that of mast cells. IgE-mediated activation of basophils enhances HIF-1α expression, which is essential for glycolysis.[14]

Neutrophil Metabolism. Neutrophils are the most abundant of terminally differentiated leukocytes. During acute inflammation, neutrophils are the first responders to migrate to the sites of inflammation. During differentiation, neutrophils use mainly FAO and OXPHOS while glycolysis is limited.[15] On the other hand,

glycolysis is essential for phagocytosis. PPP potentiates reactive oxygen species (ROS) by providing NADPH, while mitochondrial complex I and III inhibition leads to increased production of mitochondrial ROS. Neutrophil extracellular traps (NETs) are complex extracellular structures composed of DNA from neutrophils and specific proteins from neutrophilic granules. NETs support neutrophil killing of extracellular pathogens but also contribute to the pathogenesis in autoimmune diseases, including ANCA-associated vasculitis and SLE. NETosis increases glucose uptake and glycolysis inhibition by 2-DG, while PPP inhibition by 6-amino-nicotinamide reduces NETs formation.[15]

Macrophage Metabolism. Macrophages are phagocytes that detect, engulf, and destroy pathogens and apoptotic cells. In addition, macrophages are important in tissue homeostasis, repair, pathology, and development. Although several activated forms of macrophages have been reported, there are two main groups: LPS (+IFN-γ)-activated inflammatory macrophages (M1) and IL-4-induced alternatively activated macrophages (M2). Glycolysis is strongly induced in M1 macrophages.[16] The glycolytic enzyme pyruvate kinase M2 (PKM2) is vital to induce IL-1β expression through the activity of HIF-1α. PKM2 also promotes macrophage activation by the inflammasome through the activation of eukaryotic translation initiation factor 2 alpha kinase 2 (EIF2AK2). The glycolytic activator 6-phosphofructo-2-kinase/fructose-2,6-biphosphatase 3 (PFKFB3) promotes the antiviral capacity of macrophages. GAPDH, another enzyme in the glycolytic pathway, regulates TNF secretion in macrophages. Glycolysis is also induced in M2 macrophages and is crucial for IL-4-induced macrophage activation. In M1 macrophages, arginine is used to produce nitric oxide (NO). In contrast, arginine is metabolized by arginase-1 in M2 macrophages. OXPHOS is impaired by NO in M1 macrophages, while in M2 macrophages OXPHOS is induced and supports M2 macrophage development. M1 macrophages also utilize PPP, while M2 macrophages utilize FAO.

Dendritic Cell Metabolism. DCs are professional antigen-presenting cells, which can recognize pathogens and induce naïve T-cell activation and effector differentiation. There are two types of DCs: conventional DCs (cDCs) and plasmacytoid DCs (pDCs). The ETC inhibitor rotenone inhibits the differentiation of human monocytes into DCs by GM-CSF and IL-4.[17] Immature DCs use mainly FAO, and activation of DCs by Toll-like receptor (TLR) agonists increases glycolysis, PPP, and fatty acid synthesis.

Aberrations in Immunometabolism in Immune-Mediated Diseases

a. SLE (Chapter 52).

Patients with SLE exhibit oxidative stress, as reflected by the low levels of glutathione and cysteine in their serum and peripheral blood mononuclear cells.[18] T cells from mice with lupus and patients with SLE are chronically active as a result of TCR signaling hyperactivity and mitochondrial hyperpolarization, which culminate in increased production of ROS.[1] TCR rewiring in SLE favors hyperactivation because the native CD3ζ is replaced with the FcεRIγ chain that increases both the sensitivity and the downstream signaling of the receptor.[1] Increased TCR signaling in SLE can also be due to aberrant lipid raft formation. Lipid rafts are the domains on the plasma membrane where signaling-related molecules accumulate to enable cell activation, and the composition of lipid rafts in resting T cells from patients with SLE resembles that of activated cells.[19] Furthermore, patients with active SLE have a higher synthesis of lipid rafts in CD4 T cells.[19] This can be explained in part by the higher expression of a nuclear receptor: for example, liver X receptor β (LXRβ), which regulates cellular lipid metabolism (including glycosphingolipid synthesis), and the recycling of surface receptors.[1] The transcription factor Friend leukemia integration 1 (FLI1) has been associated with glycosphingolipid synthesis and T-cell activation, and disease severity in lupus-prone mice.[1] FLI1 may also promote lupus nephritis as it increases the expression of chemokines in the kidneys wherein CXCR3-expressing T cells migrate.[1] Passer-by T cells in the kidneys of patients with lupus nephritis are also prone to activation and cell differentiation.[1] Oxidative stress and the increase in PP2A levels in T cells of SLE patients lead to hypomethylation of genes that are involved in SLE pathogenesis.[1] In lupus-prone mice, targeting DNA methylation in CD4 T cells expands Treg cells and in CD8 T cells promotes cytotoxicity.[1] mTOR signaling is increased in T cells from patients with SLE via several pathways. ROS can promote mTOR signaling and CD4 CD8 T-cell differentiation.[1] mTORC1 activity is the highest in CD^{4-} $CD8^{-}$ double-negative T cells from patients with SLE.[18] In SLE, the activity of the T-cell-restricted, serine/threonine protein phosphatase calcium/calmodulin-dependent protein kinase IV (CaMKIV) is upregulated, which promotes mTOR activity.[1] Additionally, the PPP (branches out from glycolysis), which is upregulated in T cells in SLE, as well as amino acid breakdown products, such as kynurenine (a metabolite of tryptophan), can promote mTORC1 activity in these cells.[18] Increase in mTORC1 activity in SLE can also be determined genetically as reported in patients with tuberous sclerosis, who carry mutations of the *TSC1* or *TSC2* genes, resulting in uncontrolled activation of mTORC1 and the development of fulminant

KEY CONCEPTS

Innate Immune Cell Metabolism

Natural Killer (NK) Cells
- Resting NK cells have low levels of glycolysis and OXPHOS.
- Stimulation with cytokines increases glycolysis and OXPHOS.
- Glycolysis and OXPHOS are requisite for NK cell functions.

Mast Cells
- IgE-mediated activation increase glycolysis and OXPHOS.
- IL-33 also increases glycolysis and OXPHOS.

Eosinophils
- Use same levels of glycolysis and more OXPHOS than neutrophils.
- IL-3, IL-5, and GM-CSF increase glycolysis and OXPHOS.

Neutrophils
- Use fatty acid oxidation (FAO) and OXPHOS for differentiation.
- Use glycolysis for phagocytosis.
- Use glycolysis and PPP for neutrophil extracellular trap formation.

Macrophages
- M1 macrophages favor glycolysis, PPP, and use of arginine.
- M2 macrophages also use glycolysis and OXPHOS.

Dendritic Cells (DC)
- Immature DC mainly use FAO.
- Toll-like receptor (TLR) agonists increase glycolysis PPP, and fatty acid synthesis.

manifestations of SLE.[1] The chronic activation of T cells in murine and human SLE is associated with increased rates of glycolysis.[1] Studies in lupus-prone mice have shown that increased glycolysis predisposes to SLE. For example, overexpression of Glut1 in mice leads to lupus-like manifestations, including the production of autoantibodies and deposition of immune complexes in glomeruli.[1] Indeed, patients with active SLE display high levels of GLUT1 in their T cells.[1] The rate of glutaminolysis in SLE is undetermined. Yet, decreasing the rate of glutaminolysis in lupus-prone MRL/*lpr* mice has led to reduced Th17 cell differentiation and lowered disease activity in a mechanism that included HIF-1α and glycolysis downregulation.[2] Th17 cells in comparison with other T-cell subsets in patients with SLE display increased glycolysis and decreased glucose-mediated OXPHOS.[1] These lupus-derived Th17 cells have increased ICER activity, which in turn decreases the levels of PDP2 and diverts pyruvate to lactate.[2,3] In agreement, the ICER/CREMα-suppressive splice variants of CREM are also highly expressed in CD4 T cells from patients with SLE and function as transcriptional enhancers of glutaminase, which promotes glutaminolysis and Th17 cell differentiation.[2,3]

b. RA (Chapter 53).
Many studies have shown the importance of T cells in the pathogenesis of RA.[20] The strong association of RA with the human leukocyte antigen (HLA)-DRB1 locus points to the significance of T-cell selection and antigen presentation in the pathogenesis of RA.[20] Other genetic risk alleles, including variants of the genes *CD28*, *PTPN22*, *IL2RA*, *CD40*, *CCL21*, and *CCR6*, also suggest a role for T cells in the development of RA.[20] Although RA pathogenesis was previously considered to be Th1-dependent, recent evidence indicates the importance of Th17 cells. Th17/Treg balance is also involved in RA pathogenesis.[21] Th1 and Th17 cells use mainly glycolysis, which is initiated within minutes following TCR activation.[22] Glut1, a glucose transporter, is highly expressed in the surface of Th1 and Th17 cells, while Treg cells express low levels of this transporter.[6] A glucose transporter inhibitor CG-5 reduces Th1 and Th17 cell differentiation and promotes Treg cell induction.[4] Inhibition of hexokinase, the enzyme catalyzing the first step in glycolysis, by 2-DG reduces Th1[4] and Th17 cell differentiation.[22] Pyruvate, the end product of glycolysis, is converted to lactate by LDH or converted to acetyl-CoA by PDH to fuel the TCA cycle. In the absence of oxygen and even under normoxic conditions in Th17 cells, pyruvate tends to be converted to lactate by LDH.[22] Lactate itself has an important role in autoimmune diseases and is one of the most enriched products of cellular metabolism in inflamed tissues, including synovial tissue.[23] Lactate induces expression of its transporter, SLCA12, on human CD4 T cells in the inflamed tissue and promotes IL-17 production via PKM2/signal transducer and activator of transcription 3 (STAT3) signaling. Furthermore, SLCA12 blockade ameliorates the disease severity in mice induced to develop arthritis.[23] Sirolimus, an mTOR inhibitor, reduces disease activity in RA.[24]

PPP enables cells to generate products that are crucial for T-cell function and expansion, as they fuel biomass generation.[21] Naïve T cells from patients with RA have a defect in glycolytic flux due to the upregulation of glucose-6-phosphate dehydrogenase (G6PD) and downregulation of 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase 3 (PFKFB3) after stimulation.[21] Excess G6PD shunts glucose into the PPP, resulting in NADPH accumulation and ROS consumption (see Fig. 20.1). T cells from patients with RA do not sufficiently activate the redox-sensitive kinase ataxia telangiectasia mutated (ATM), which in turn shifts naïve CD4 T-cell differentiation towards Th1 and Th17 cell lineages.[21]

c. MS (Chapter 66).
MS is a demyelinating disease characterized by a chronic inflammatory process in the brain and spine. Loss of myelinating oligodendrocytes is considered the beginning of MS pathogenesis, and both Th1 and Th17 cells are involved. Inhibition of glycolysis by 2-DG ameliorates murine MS (e.g., experimental autoimmune encephalomyelitis [EAE]).[22] PKM2 inhibitor, which inhibits the last enzyme of the glycolysis pathway, also ameliorates EAE.[2] Lack of HIF-1α, which mediates glycolysis, diminished Th17 cell development and enhanced Treg cell differentiation in mice, thus protecting them from autoimmune neuroinflammation.[22] Inhibition of glutaminase 1, glutamate oxaloacetate transaminase (GOT) 1, or amino acid transporter ASCT2 reduces Th17 cell differentiation and improves disease activity in EAE.[2] The inhibition of ACC1, the rate-limiting enzyme for fatty acid synthesis, attenuates EAE[5]; C75, which is another inhibitor of this synthesis, also ameliorates EAE.[25]

Immunometabolism-Based Targeted Treatment

Disease-modifying anti-rheumatic drugs (DMARDs) can affect several metabolic pathways. Glucocorticosteroids promote gluconeogenesis and inhibit glycolysis. Methotrexate inhibits folate metabolism, thereby inhibiting the one-carbon metabolism pathway, and it can also increase the adenosine pool and AMP production, which in turn activates AMPK, which inhibits mTOR signaling.[1] Mycophenolate mofetil (MMF) interferes with DNA synthesis and limits T-cell expansion, inhibiting the expression of *MYC* and *HIF1A* and the signaling via the PI3K–AKT–mTOR pathway; MMF also reduces glycolysis and oxidative stress in CD4 T cells in vitro.[1] In a phase I–II clinical trial in patients with SLE, sirolimus, an mTORC1 inhibitor, reduced disease activity and restored the balance of T-cell lineages.[18] Inhibition of mTORC1 signaling suppressed T-cell hyperactivation, the development of Th17, and double-negative T cells, and promoted Treg cell differentiation and function in patients with SLE.[18] Metformin, an antidiabetic medication, when coadministered with 2-DG (an inhibitor of glucose metabolism), normalized T-cell metabolism, decreased the numbers of Tfh cells, and reversed kidney disease in lupus-prone mice.[4] In a proof-of-concept trial studying patients with mild-to-moderate SLE, the addition of metformin to standard-of-care treatment decreased the frequency of clinical flares and permitted prednisone dose reduction.[1]

Pioglitazone, an insulin-sensitizing drug that can rapidly activate AMPK, also inhibits mTORC1 and promotes the expansion of Treg cells from patients with SLE in vitro.[1] Bz-423 is a benzodiazepine compound that can inhibit an ATP synthase, which is increased in autoreactive lymphocytes from mice with lupus; and treatment of the mice with Bz-423 led to autoreactive lymphocyte apoptosis and clinical improvement.[1] Cysteine is depleted in T cells from patients with SLE. *N*-acetyl cysteine is a cysteine analogue that, in patients with SLE, led to inhibition of mTORC1 activity in double-negative T cells and decreased disease activity.[18] NB-DNJ (*N*-butyldeoxynojirimycin) inhibits the synthesis of glycosphingolipids, and it is used to treat type

TABLE 20.1 Drug Treatments Affecting Immunometabolic Targets

Drug	Therapeutic Target	Effects on Disease Model
2-Deoxy-D glucose and metformin	Hexokinase and mitochondrial complex I	Reduces disease activity, and improves kidney disease in lupus model
BPTES, CB-839, and 968	Glutaminase 1	Reduces disease activity in EAE and arthritis model, and improves kidney disease in lupus model
Bz-423	Mitochondrial metabolism	Reduces disease activity in lupus model
NB-DNJ	Glucosylceramide synthetase	Reduces disease activity in lupus model
N-acetyl cysteine	Cysteine metabolism	Reduces disease activity in arthritis model, and improves kidney disease in lupus model
Sirolimus	mTOR signaling	Reduces disease activity in EAE and lupus model, and rheumatoid arthritis
Pioglitazone (agonist)	PPARγ	Improves disease activity in EAE and arthritis model, and nephritis in lupus model

BPTES, Bis-2-(5-phenylacetamido-1, 3, 4-thiadiazol-2-yl)ethyl sulfide; *mTOR,* mammalian target of rapamycin; *NB-DNJ, N*-butyldeoxynojirimycin; *PPARγ,* peroxisome proliferator-activated receptor γ.

I Gaucher disease. In patients with SLE it had beneficial effects on T cells in vitro, and in lupus-prone mice it restored lipid metabolism in T cells and B- and T-cell associated antigen (BTLA) function (Table 20.1).[1]

CONCLUSIONS AND FUTURE DIRECTIONS

Immune cell metabolism changes dramatically during the immune response. It is now evident that cell survival, fate, and differentiation can be determined by the predominance and dynamics of metabolic pathways within the responding cell. Therefore, manipulation of metabolic pathways can be utilized to modulate and rebalance specific subsets of cells within the immune system as a novel approach in the treatment of autoimmune diseases. Future studies will decipher further the pathogenic role of immunometabolism in the development of autoimmune diseases and ways to readjust these metabolic pathways to advance treatment of autoimmune diseases.

Immune Deficiencies at the Extremes of Age

Claire E. Gustafson, Cornelia M. Weyand, and Jörg J. Goronzy

Age is a major factor determining the quality and quantity of an immune response, with alterations most obvious at the extremes of age. Both infants and older adults exhibit impaired immune responses to infection and vaccination. However, the underlying mechanisms for immune dysfunction are distinct. Infants are born with limited antigen exposure and a tolerogenic-inclined immune system, which progressively develops throughout infancy and childhood. In older age, the mechanisms underlying immune decline are broadly termed *immunosenescence*. The term is reminiscent of *cellular senescence*, which is defined as an irreversible cell cycle arrest. However, it is misleading to interpret immune aging only as the accumulation of senescent cells, and, similar to aging in general, numerous pathways are involved.[1] The age-related decline in immune competence is not linear. As early as age 40 years, immune responses to selected vaccines (e.g., hepatitis B) start to decline. The incidence rate of herpes zoster, a reactivation of latent varicella-zoster virus (VZV), starts to increase at age 50 years, as does morbidity and mortality from influenza infection. A more abrupt immunological decline appears to occur in the eighth decade of life.

In terms of public health, infections are major causes of morbidity in the very young and the very old. Although child mortality rates have dropped by almost 50% between 1990 and 2013, pathogenic infections are still one of the largest causes of infant mortality worldwide, accounting for more than 1.6 million deaths per year. Vaccinations have helped change the infectious landscape in children and young adults, but certain vaccines, such as those against *Streptococcus pneumoniae*, still have limited protective capacity. Susceptibility to pathogenic infection and ineffectiveness of vaccination is even greater in older adults than in young infants. Moreover, during aging, a functional immune system is important for tissue repair, such as in degenerative diseases, and it is vital for cancer surveillance.

INFANCY AND THE GENERATION OF AN IMMUNE SYSTEM

Infants start to develop their immune system before birth, maintaining a fine balance between immunological tolerance that helps prevent pro-inflammatory responses in utero while preserving the ability to respond to foreign antigen exposure upon birth. Regulatory pathways utilized by the fetus for protection against possible infections and maternal–fetal rejection in utero are still reflected in the newborn infant immune system, characterized by immune-suppressive and anti-inflammatory cellular responses to foreign antigens. Although newborns and young infants lack the ability to mount effective immune responses against many pathogens, they acquire initial immune protection through the passive transfer of maternal immunoglobulin G (IgG) in utero via the placenta (termed "passive immunity") and from secretory IgA and antimicrobial factors present in maternal breast milk.[2] Alterations in passive immunity (e.g., preterm birth) can lead to increased susceptibility to infections and breakdown of immune tolerance in the infant. Passive immunity can be enhanced by vaccination of pregnant mothers to promote the transfer of vaccine-specific IgG. However, within the first months of life, as maternal IgG wanes and breastfeeding is discontinued, infants must actively develop their own immune responses for protection.

INNATE IMMUNE DEVELOPMENT

The innate immune system is typically considered the first line of defense against infection. The development of the innate immune system begins in utero, with all the classic innate cell types present by the end of the first trimester; monocytes and dendritic cells (DCs) are the earliest cells observed at 4 weeks' gestation (WG) followed by granulocytes and natural killer (NK) cells at 8 WG.[3] These innate immune cells expand in number and mature in utero; however, at birth the functionality of innate immune cells is still diminished compared with later in life.

During early infancy, all cell types of the innate immune system demonstrate some impairment of function, ranging from reduced mobility to skewed cytokine production in response to stimulation.[4] The most significant functional limitation of neonatal innate immune cells is their collective inability to kill pathogens. Limited chemotaxis in neutrophils is accompanied by a reduced ability to effectively kill pathogens as a consequence of poor phagocytosis and decreased secretion of neutrophil extracellular traps. Moreover, NK cells and plasmacytoid DCs have reduced capacity to prevent infection through reduced cytotoxic function and lower secretion of interferon-α (IFN-α), respectively. In addition, antigen-presenting cells (APCs) are unable to provide effective help to T cells because of reduced expression of costimulatory molecules and production

KEY CONCEPTS

Characteristics of the Developing Innate Immune System

- Reduced antibacterial responses (i.e., phagocytosis, secretion of neutrophil extracellular traps [NETs]) by neutrophils and monocytes
- Impaired neutrophil chemokinesis ("directed movement")
- Diminished capacity of antigen-presenting cells (APCs; e.g., dendritic cells [DCs]) to provide proper costimulatory help to T cells
- Reduced antiviral responses (i.e., interferon [IFN]-α secretion) by plasmacytoid dendritic cells (pDCs)

of more anti-inflammatory cytokines. These combined limitations during early infancy lead to increased susceptibility to viral and bacterial infections and also contribute to the reduced functionality of adaptive immune cells.

ADAPTIVE IMMUNE DEVELOPMENT

Adaptive immune cells (T and B cells) begin to develop in utero around the start of the second trimester. It is important to note that although lymphocytes initially develop within the fetal liver (~7 WG) and then in the bone marrow (~12 WG), T-cell maturation occurs in the thymus, whereas B cells continue maturation in bone marrow. Over the course of gestation, both naïve T- and B-cell compartments expand, reaching absolute cell concentrations at birth greater than that of adults. Thus, a defect in cellular generation cannot account for the immune limitations observed in infants. However, the composition of lymphocyte populations within young infants is distinct from that of adults (Fig. 21.1). At birth, the infant T- and B-cell compartments consist mainly of naïve and transitional cells recently migrated out of the thymus or bone marrow (>90% of the population). Infant T- and B-cell repertoires have less diversity within their receptors' antigen-binding regions compared with those of adults. T-cell receptors (TCRs) display reduced V-J complexity and fewer amino acid additions. B cells have decreased B-cell receptor diversity because of less affinity maturation (i.e., somatic hypermutation; Chapter 7) compared with adult populations.

The increased levels of recent thymic emigrants and naïve T cells are maintained both in the periphery and in tissues during early infancy. Effector memory T cells can be found selectively in the lungs and gastrointestinal tract of infants, likely because these mucosal tissues are the earliest sites of antigen exposure. Class-switch antibodies produced by B cells are required for mucosal protection (primarily IgA) and systemic protection (primarily IgG) through opsonization, neutralization, or antibody-dependent cellular cytotoxicity. However, infants demonstrate significantly lower levels of IgG and IgA compared with adults throughout the first year of life, in both the periphery and mucosal tissues.

INFANCY AND FUNCTIONAL DIFFERENTIATION OF ADAPTIVE IMMUNE CELLS

The main feature of a "mature" adaptive immune system is the development of memory T and B cells that recognize specific foreign (or in some context, self) antigens. Not only are infants born with limited antigen exposure and thus little memory, infant responses to antigenic stimulation in the T- and B-cell compartments display altered functionality compared to adults. Some of the most striking alterations are seen within the CD4 T-cell compartment, characterized by significantly increased frequency of immunosuppressive T regulatory cells (Tregs; 30 to 40% in infants vs. 1 to 10% in adults).[5] These changes are accompanied by increased T-helper 2 (Th2) frequencies. This bias is due to preferential dif-

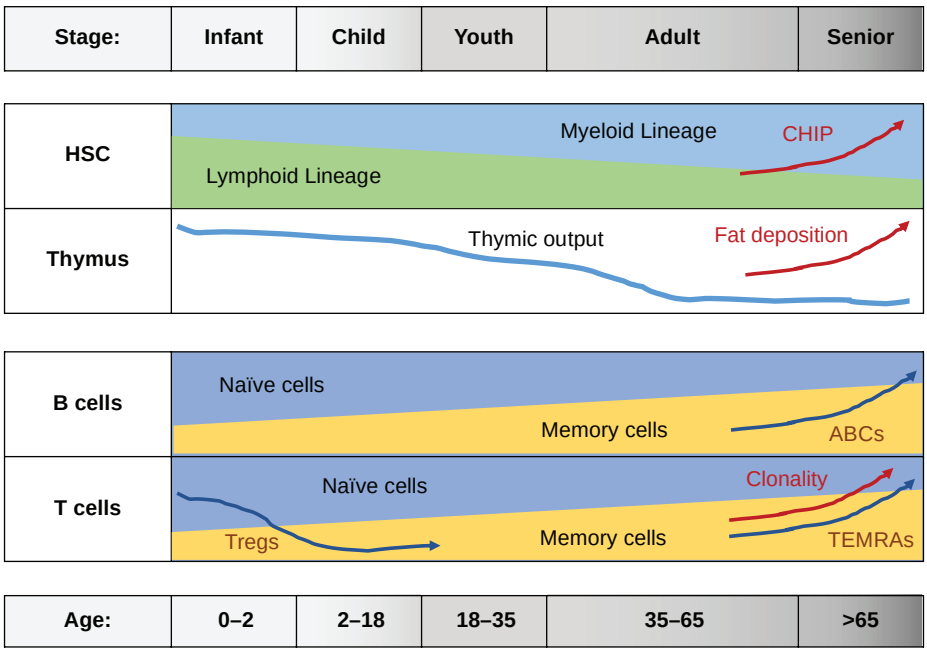

FIG. 21.1 Distinct Changes in Human Immune Cells Across Age. From infancy to old age, the immune system undergoes numerous changes. Hematopoietic stem cells *(HSCs)* progressively become biased towards development into the myeloid lineage, in conjunction with DNA mutations, causing increased clonal hematopoiesis of indeterminate potential *(CHIP)* in old age. Thymic output decreases with time, diminished to almost negligible levels during adulthood. Adipose tissue also accumulates in the thymus with age. In the adaptive immune system, B cells remain relatively constant in absolute numbers, whereas T cells decline. However, B and T cells exhibit alternations in subset composition, highlighted by a decrease in naïve cell frequencies, with a relative gradual increase in memory cells and significant expansion of pro-inflammatory memory subsets (i.e., age-associated B cells *[ABCs]* and terminally differentiated effector memory T cells re-expressing CD45RA *[TEMRA]* that combine features of the innate and the adaptive immune system) with old age. This expansion is in tandem with clonal expansion in the T-cell compartment. Conversely, infants have high levels of the anti-inflammatory regulatory T-cell subset that dramatically decreases with age.

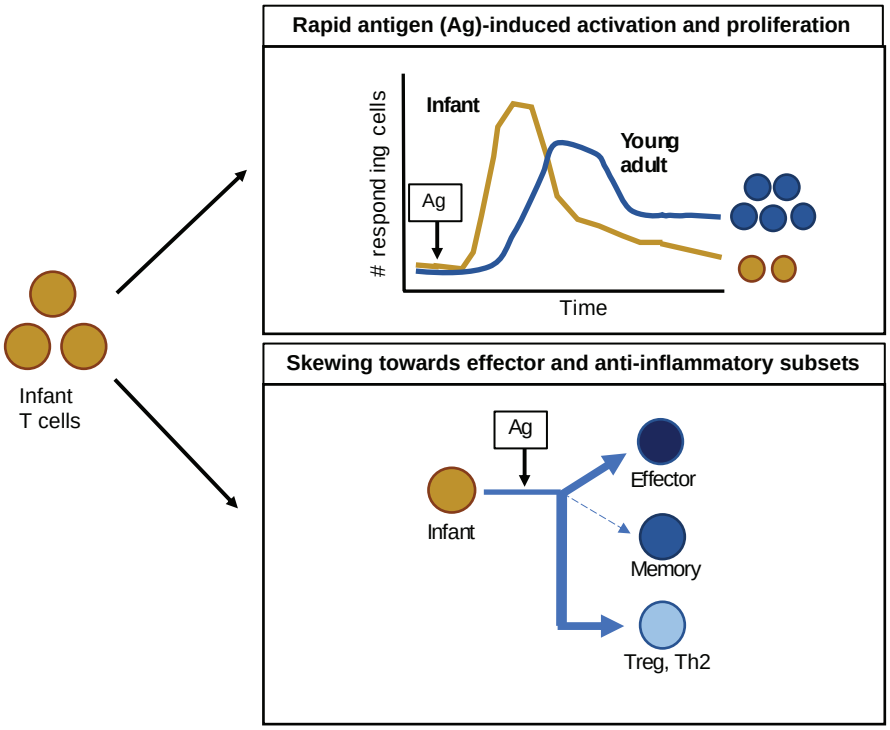

FIG. 21.2 T-Cell Functionality During Infancy. Infant T cells display unique properties compared with those in adults, highlighted by more rapid antigen *(Ag)*-driven effector responses. Additionally, infant T cells show a propensity to differentiate into effector cells, regulatory T cells, or Th2 subsets, instead of memory cells.

ferentiation of neonatal CD4 T cells into Treg or Th2 cells, instead of Th1, Th17, or T follicular helper (Tfh) cells. Altered differentiation of CD4 Th subsets promotes a tolerance-inducing environment good for controlling unnecessary responses to foreign antigen exposure after birth. However, it also leads to inhibition of effector T cells and limits B-cell antibody responses against infectious pathogens and to vaccination (Fig. 21.2).

Until very recently, neonatal T cells were considered "immature" versions of adult cells; however, new studies have elegantly demonstrated that neonatal T cells are actually a functionally distinct population of cells specifically tailored to respond to the needs of the neonatal environment.[6] Neonatal T cells, particularly $CD8^+$ cells, are epigenetically poised to develop into effector over memory T cells and display enhanced ability to respond to danger signals (e.g., pathogen-associated molecular patterns [PAMPs]) and inflammation (e.g., complement) (see Fig. 21.2). microRNA regulation of transcriptional networks contributes to a preferential effector-like state of neonatal T cells, which includes lower TCR activation thresholds caused indirectly via increased miR-181a. The innate-like features of neonatal T cells allow for a more rapid effector response to environmental cues and increase the protective capacity of the infant, albeit at the expense of the development of memory cells. In addition, the more broadly reactive (promiscuous) TCR repertoires, from utilization of more germ-line encoded sequences, may permit a wider responsiveness to multiple types of antigens (i.e., self, commensals, and pathogens).

Similar to T-cell responses, B cells also display less effective immune responses during infancy, with preferential development of short-lived effector cells. Neonatal B cells are less able to undergo class-switching from IgM to IgA or IgG upon antigen stimulation and differentiated antibody-secreting plasma cells within the infant bone marrow have poor survival.[7] Moreover, infant B cells have lower rates of somatic hypermutation compared with those of adults, which is important for the generation of high-affinity antibodies. Although these defects can be partially attributed to extrinsic T-cell defects, such as poor Tfh cell generation, intrinsic defects in infant B cells (e.g., lack of costimulatory molecules) also prevent effective antibody responses. Collectively, these neonatal B-cell defects lead to less effective and shorter-lived antibody responses against infectious pathogens and vaccines during infancy.

KEY CONCEPTS

Characteristics of the Developing Adaptive Immune System

- High frequencies of antigen-naïve T and B cells
- Skewing of naïve CD4 T-cell differentiation toward immunosuppressive regulatory T cells (Tregs) and T-helper 2 (Th2) cells, but not Th1 or Tfh cells
- Skewing of naïve CD8 T cells toward effector cell, but not memory cell, development
- Limited ability of B cells to produce high-affinity, class-switched antibodies in response to both T-cell–dependent and T-cell–independent antigens

INFANT IMMUNE DEVELOPMENT AND THE MICROBIOME

One of the first environmental exposures that infants experience is with colonizing bacteria. Within hours after birth, the

infant intestinal tract is colonized by nonpathogenic bacteria (termed "microbiome"; Chapter 22). The microbiome can reach concentrations of 10^{10} bacteria per gram of stool within 7 days but mirrors an adult-like composition only after 2 years of age. Early animal studies demonstrated that microbial colonization is essential for the normal development of the immune system during early infancy and throughout life.[8] In particular, IgA production requires the presence of a microbiome for its development and long-term maintenance. Moreover, the specific composition of the microbiome influences the generation of innate lymphoid cells and CD4 T-cell subsets (e.g., Treg, Th17, Tfh). Perturbations in the infant microbiome caused by such factors as mode of delivery and antibiotic treatment may significantly alter developing immune responses. For example, babies delivered via cesarean section (C-section) have a microbiome composition distinct from that of babies delivered vaginally, with C-section delivered babies having an intestinal microbiome more dominated by skin bacteria. These differences are correlated with an increased incidence of allergy and asthma during childhood in infants delivered by C-section. Recent work has now demonstrated microbiome-derived metabolites influence Treg development in early infancy, providing a causal link between the microbiome and infant immune tolerance.

CLINICAL CONSEQUENCES FOR CHILDHOOD VACCINATION

Infants are highly susceptible to pathogenic infection during the first year of life. Indeed, infections are one of the major causes of mortality, accounting for more than 24% of global infant mortality. More than 1 million deaths per year are caused by respiratory tract infections (e.g., *S. pneumoniae*, respiratory syncytial virus [RSV]) and almost the same number by intestinal infections (e.g., rotavirus, *Escherichia coli*). The development and distribution of vaccines targeting these pathogens has significantly reduced infant infection rates and consequent mortality; however, vaccine efficacy can vary depending on the infant's gestational age at birth, mode of vaccine delivery (oral vs. intramuscular), interference by maternal antibodies, and tolerogenic immune responses, as described above. Additionally, infants require multiple vaccine boosters to elicit and maintain robust protective immunological memory against infectious pathogens (*Chapter 87*). Better understanding of the mechanisms of these limitations of the infant immune responses, particularly at mucosal sites where these pathogens initially infect, would facilitate the generation of better vaccines designed to induce more effective and long-term immune protection during infancy.

CLINICAL RELEVANCE

Consequences of "Immaturity" of the Neonatal Immune System

- Increased morbidity and mortality from bacterial infections (e.g., pneumococci)
- Increased morbidity and mortality from viral infection (e.g., influenza virus, respiratory syncytial virus, rotavirus)
- Ineffective primary vaccinations; multiple boosters required for most vaccines to elicit effective protection
- Susceptibility to allergy and asthma when microbiome colonization is disrupted during early infancy

OLDER AGE AND IMMUNE CELL GENERATION

The immune system is in constant demand for cellular replenishment to compensate for peripheral losses and cell death. For neutrophils, which have a short half-life, the body needs to produce ~10^{10} cells/kg/day; for lymphocytes, which are more long-lived but are also more numerous because of their wider tissue distribution, the daily need is in the order of several billion cells. Studies in the 1960s showed that the hematopoietic tissue in bone marrow decreases with age. A similar numerical decline is seen for peripheral hematopoietic stem cells (HSCs). Telomerase expression in peripheral HSCs is not fully protective, and telomeric length shortens with age, similar to differentiated mononuclear cells. The functionality of HSCs also changes with age, exhibiting reduced regenerative capacity and a differentiation bias towards myeloid versus lymphoid precursors (see Fig. 21.1).[9] This bias is driven by DNA damage and epigenetic changes and may contribute to the clinical observation that HSC-derived leukemia preferentially has a lymphoid phenotype in the young and a myeloid one in older adults. Additionally, DNA damage causing mutation in genes mediating epigenetic regulation (e.g., TET2, *DNMT3A*) can give certain HCSs fitness advantages, which in turn propagates to all of their descents, in particular the myeloid lineage. This expansion, termed clonal hematopoiesis of indeterminate potential (CHIP), is highly age-dependent and is closely associated with the development of hematological malignancies and cardiovascular disease.[10] CHIP may also contribute to the low-grade inflammation that is characteristic of the aging host.

Collectively, lymphocyte replenishment is more affected by age than that of myeloid lineages. Peripheral neutrophil numbers do not decline and are able to recover after therapy-induced depletion (e.g., chemotherapy). Furthermore, there is no loss in the ability to generate robust neutrophilia in response to infection or other stressors.

KEY CONCEPTS

Aging Influences Immune Cell Generation and Population Homeostasis

- Hematopoietic stem cells (HSCs) are reduced in frequency and biased toward myeloid lineages over lymphoid lineages.
- HSC mutations cause HSC clonality predisposing to hematological malignancies and cardiovascular disease.
- Myeloid cell generation is largely intact.
- B-cell generation is relatively maintained but B-cell repertoire diversity is disturbed.
- As a result of thymic involution, naïve T cells are generated from homeostatic proliferation of peripheral T cells.
- Ability to rebuild a T-cell repertoire after lymphocyte-depleting interventions is compromised after mid-adulthood.
- Naïve T cells acquire memory-like features, and preferentially differentiate into effector, but not memory cell populations. $CD4^+$ cells favor Th1, but not Tfh development.
- Virus-specific terminally differentiated effector T-cell populations accumulate.

Although HSC-intrinsic alterations skew lineage commitments away from lymphoid cell generation, the peripheral B-cell population is relatively maintained across aging, as is the development of effector and memory B cells.[11] However, an expansion of nonclassical memory B cells termed "age-associated

B cells" is observed. These cells are pro-inflammatory, more autoreactive, and secrete antibody in response to innate (i.e., Toll-like receptor [TLR]) but not antigen-specific stimulation.[12] In addition, aged B cells display a reduced ability to undergo class switch recombination and somatic hypermutation, which likely accounts for lower antibody affinities and reduced antibody functionality observed in older individuals. Age-associated differences in B-cell selection and expansion may also contribute to monoclonal gammopathies (in >5% of individuals older than 70 years; Chapter 79) and the presence of autoantibodies in the absence of disease with increasing age.

T-cell generation is more affected by age than any other myeloid or lymphoid lineage because of the involution of the thymus. The thymus undergoes dramatic structural changes that begin during childhood.[13] Thymopoietin niches disappear, and the numbers of thymic epithelial cells and thymocytes decline in what appears to be a developmentally regulated process. Thymic resection in children undergoing cardiac surgery reproduces many of the T-cell repertoire changes in 20-year-old individuals that are otherwise seen in 70 to 80 year olds, documenting the importance of thymic production during the human growth period. In contrast, throughout adulthood, homeostatic proliferation of T cells accounts for the bulk of T-cell generation.[14] This process is more robust for naïve CD4 compared to naïve CD8 T cells, the latter of which are clearly lost with age. Overall repertoire diversity (i.e., the number of different TCRs) contracts with age but still remains highly diverse for both naïve CD4 and CD8 T-cell subsets, suggesting that thymic activity is not necessary to maintain repertoire diversity once a repertoire has formed.

T-CELL POPULATION HOMEOSTASIS

The adaptive system responds to antigenic challenges with clonal expansion and differentiation of naïve cells into effector cells, followed by clonal downsizing and persistence of long-lived memory T cells (i.e., immunological memory). Infections therefore leave a permanent imprint on the immune system, a mechanism on which vaccinations capitalize. Similar to neonatal responses, naïve CD8 T cells in older individuals preferentially differentiate into effector cells and fail to establish memory cells (Fig. 21.3). Naïve CD4 T cells display a similar bias, preferentially developing into short-lived effector T cells at the expense of Tfh and memory cell development. These changes are in tandem with the loss of vaccine-specific memory T cells over time, and likely account, in part, for reduced vaccine efficacy as well as increased susceptibility to infections in older individuals.[15]

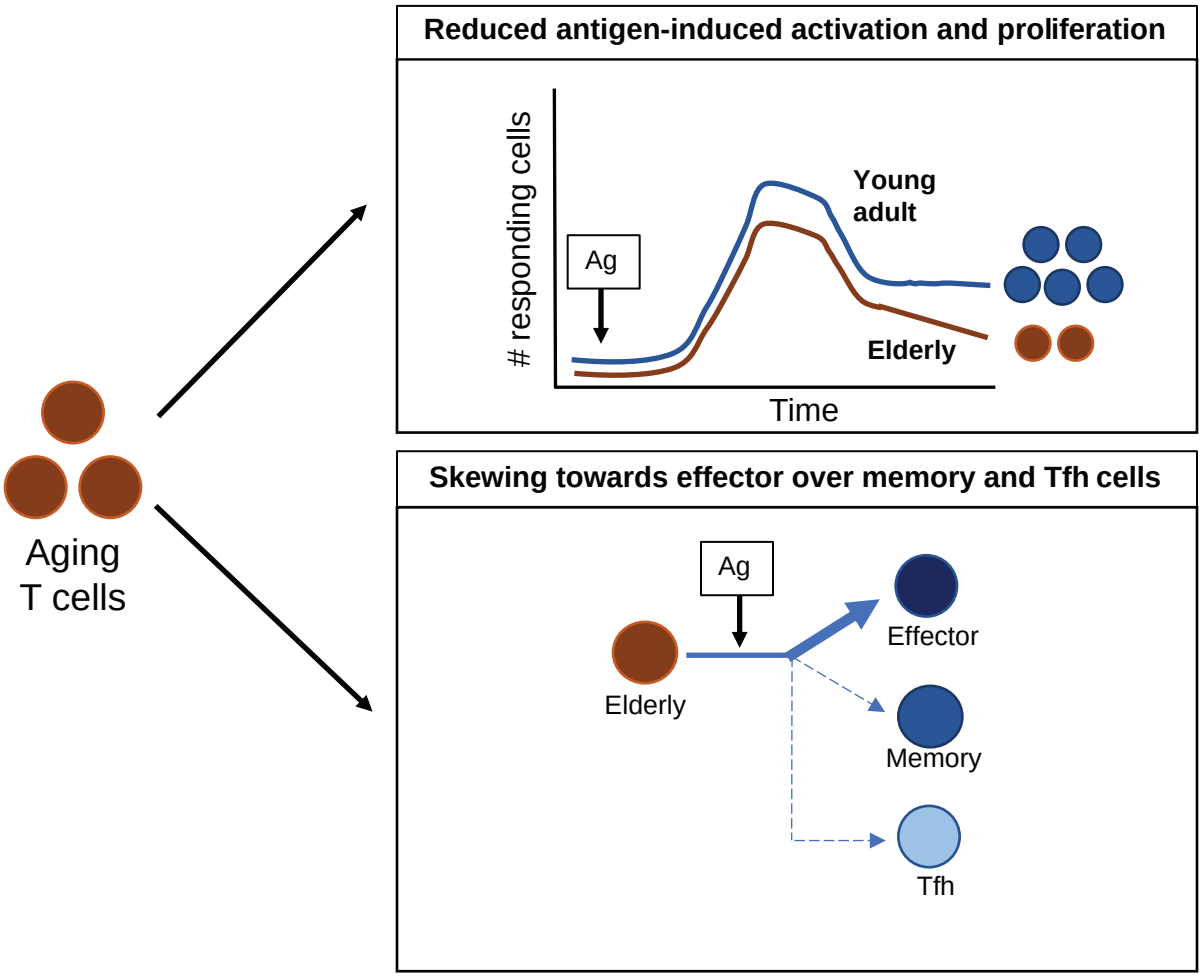

FIG. 21.3 T-Cell Functionality During Advanced Age. In older individuals, T cells show a diminished ability to respond to antigen. This reduction has been linked with preferential development into effector cells over memory or Tfh subsets, which are two subsets essential for long-term immune protection.

Pathogen-induced clonal expansion represents a challenge to homeostatic mechanisms that are supposed to maintain a balance among naïve, memory, and effector cells.[16] This is particularly evident in persistent infections where the offending pathogen cannot be cleared (e.g., herpes viruses). Herpes viruses establish latency following infection, making them highly prevalent in apparently healthy populations without causing active disease. Classic examples VZV, Epstein-Barr virus (EBV), and cytomegalovirus (CMV). The effects of these herpes viruses with immune aging differ greatly. VZV tends to reactivate with age, presenting as shingles. A decrease in the frequency of VZV-specific CD4 memory T cells has been postulated to explain this lack in viral control mechanisms. In contrast, EBV and CMV infections relapse only in severely immunocompromised individuals, not during normal immune aging. The immune system commits extraordinary resources to controlling CMV, and CMV-specific CD8 T cells can make up a large fraction of the entire T-cell repertoire. Whether this memory inflation has broader implications for immune health remains a matter of controversy. Expansion of the CMV-specific T cells may compromise the size of naïve and central memory T-cell repertoires; however, many of the CMV-specific CD8 T cells have the phenotype of end-differentiated effector T cells and are unlikely to compete for the same space as naïve cells.

End-differentiated T cells also express negative regulatory receptors of the killer lectin-like receptor (KLR), killer immunoglobulin-like receptor (KIR), and immunoglobulin-like transcript (ILT) families that appear to constrain their otherwise unopposed expansion. In spite of these inhibitory receptors, these cells are competent effector T cells capable of producing inflammatory cytokines and therefore may contribute to inflammation in older adults. Fig. 21.4 provides a comparison of these cells with age-associated B cells. End-differentiated T cells should be distinguished from exhausted CD8 T cells. T-cell exhaustion is seen with chronic stimulation by highly replicating viruses or tumor cells and is characterized by the expression of inhibitory receptors programmed death 1 (PD-1), T-cell immunoglobulin and mucin-domain containing-3 (TIM-3), and lymphocyte activation gene 3 (LAG3).[17] T-cell exhaustion is not a general feature per se of T-cell aging.

INFLAMMATION, AGING, AND THE AGING HOST ENVIRONMENT

The aging host environment is characterized by the continuous presence of inflammatory mediators (Fig. 21.5).[18] Low-level systemic inflammation plays an important role in the progression of several age-related diseases, including Alzheimer disease, atherosclerosis, and cancer. Moreover, inflammatory markers are associated with several conditions that are characteristic of older adults. IL-6 serum concentrations have been correlated with loss of mobility and advent of disability; increased mortality of older individuals has been shown among those who have higher levels of tumor necrosis factor-α (TNF-α). Increased IL-6 and cross-reactive protein (CRP) serum levels predispose to, and are associated with, frailty. A causative relationship may exist between the increased production of IL-6 or TNF-α and the age-associated loss in muscle mass, eventually presenting as sarcopenia. Moreover, long-lived individuals, such as centenarians, tend to have lower levels of pro-inflammatory cytokines and increased levels of anti-inflammatory mediators, such as cortisol and IL-10.

Production of inflammatory cytokines is driven by several mechanisms. Failure of the adaptive immune system leads to a less effective control of chronic viral infections as well as incomplete response to exogenous challenges, resulting in increased and prolonged innate immune activation. Defective epithelial barrier function, as well as decline in the mucosa-associated lymphoreticular tissue, results in increased leakage, increased systemic levels of lipopolysaccharide, and innate immune activation. Failure in maintaining T-cell population homeostasis and accumulation of effector T cells also favor an inflammatory response.

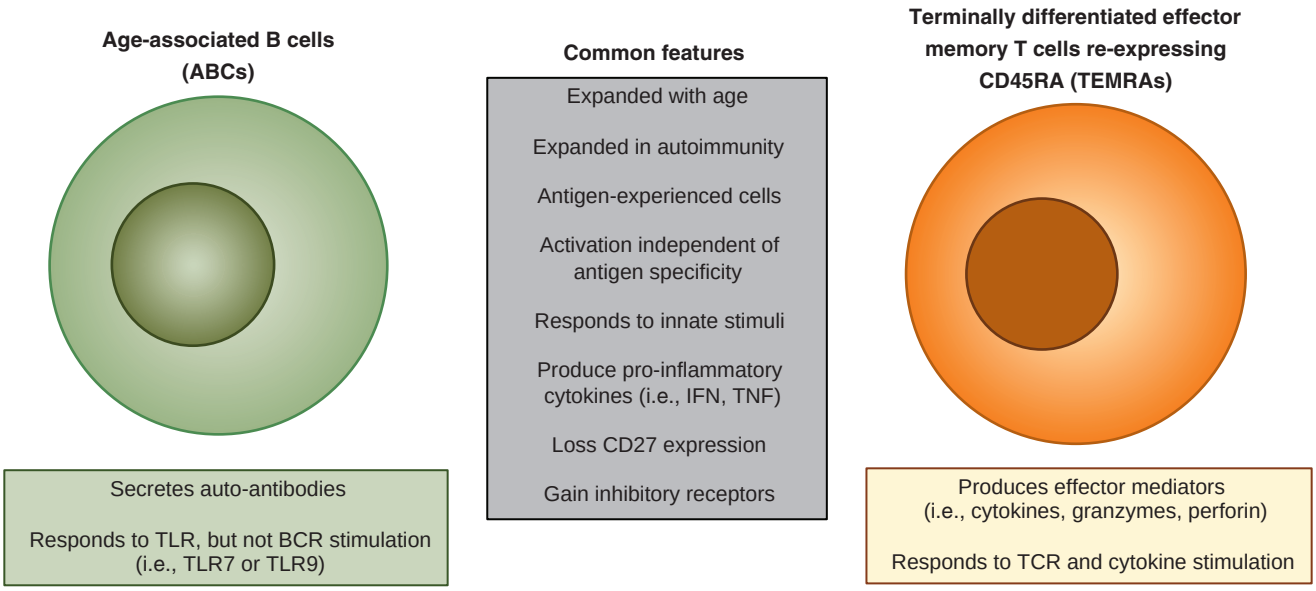

FIG. 21.4 Comparison of B- and T-Cell Subsets Expanded with Age. During aging, both the T- and B-cell compartments demonstrate expansion of pro-inflammatory memory populations with many shared features. These features include the ability to become active independent of antigen, the production of inflammatory cytokines, and alteration in stimulatory and inhibitory receptor profiles. *BCR*, B-cell receptors; *IFN*, interferon; *TNF*, tumor necrosis factor; *TCR*, T-cell receptors; *TLR*, Toll-like receptor.

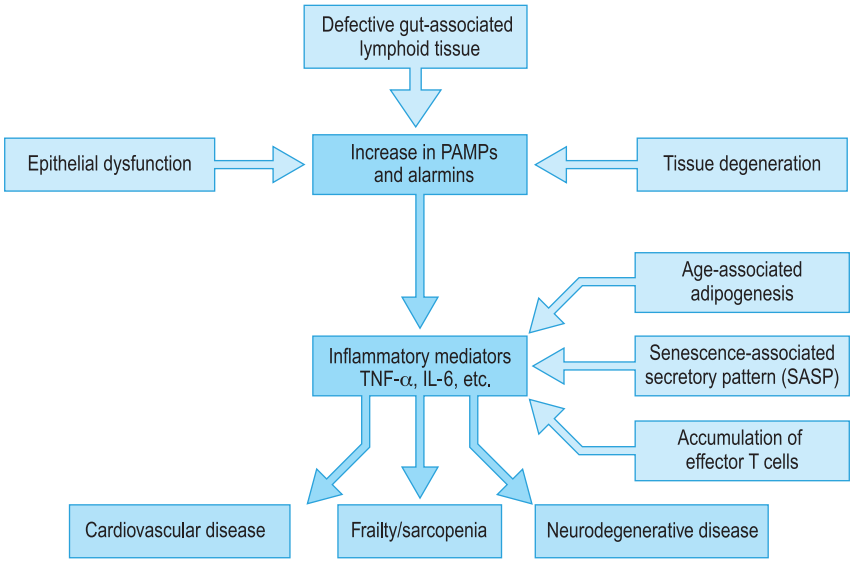

FIG. 21.5 Inflammation in Older Adults. The schematic diagram depicts possible mechanisms that account for the increased production of inflammatory mediators with age. These mediators contribute to many of the age-associated diseases. *IL-6*, Interleukin-6; *PAMPs*, pathogen-associated molecular patterns; *TNF-α*, tumor necrosis factor-α.

KEY CONCEPTS

Causes for Increased Constitutive Production of Inflammatory Mediators With Age (Inflammation in Older Adults)

- Activation of the innate immune system as a result of defective epithelial barrier function
- Activation of the innate immune system as a result of defective adaptive immunity
- Accumulation of adipocytes producing inflammatory mediators
- Accumulation and activation of effector T-cell populations
- DNA damage-induced transcription of inflammatory cytokine genes in senescent cells

The immune system, however, is not the only source of inflammatory cytokines. Adipocytes, in part replacing muscle cells in older adults, produce inflammatory mediators. Additionally, cellular senescence is associated with increased production of pro-inflammatory cytokines, where persistent DNA damage response signaling not only induces an irreversible cell cycle block that is characteristic of cellular senescence but also initiates a transcriptional program to secrete numerous growth factors, proteases, and inflammatory cytokines, termed the *senescence-associated secretory phenotype* (SASP).[19]

CELLULAR DEFECTS IN IMMUNE AGING

As described so far, immune aging occurs at the system level with organizational restructuring. Equally important are changes at the single-cell level, which are partly cell-intrinsic and partly caused by the host environment. The increased cytokine concentrations in older adults not only activate but also attenuate signaling pathways. Low responsiveness to cytokine stimuli is frequently seen in those cells that have increased baseline activation of a signaling pathway (e.g., cells that constitutively have increased signal transducer and activator of transcription 3 [STAT3] or STAT1 phosphorylation respond less to IL-6/granulocyte macrophage–colony-stimulating factor [GM-CSF] or type I/II interferons). Attenuation of signaling pathways by induction of negative feedback loops explains, in part, the reduced responsiveness and functionality of innate immune cells.

Although neutrophil and monocyte/macrophage numbers remain normal, many of their functions decline with age.[20] Decreased chemotaxis in neutrophils delays tissue infiltration; reduced phagocytosis and respiratory burst compromise the ability to control bacterial infections; and TLR-induced monocyte/macrophage activation is dampened in older adults. Declines in responsiveness, for example, to TLR stimulation, are partly reversible *in vitro*, suggesting that they are not intrinsic. Adaptive immune cells are also directly affected by the pro-inflammatory environment in the aging host.

Equally important are cell-intrinsic changes that appear to be a consequence of the replicative history and failures in cellular processes, such as DNA repair and autophagy. The program most obviously influenced by age is cellular senescence. In all hematopoietic cell lineages, including stem cells, telomeric lengths decline with age. Telomeric erosion results not only from cumulative replicative history and DNA damage but also from a decline in the ability to express telomerase and repair

KEY CONCEPTS

Cellular Dysfunction With Advanced Age

- Exposure to aging host environment (e.g., inflammatory cytokines) activates negative regulatory signaling loops.
- Telomeric erosion impairs proliferative competence and restraints clonal expansion.
- End-differentiation reduces functional plasticity.
- Activation of specific gene programs modifies cell function:
  - Gene programs associated with differentiation (e.g., microRNA [miRNA])
  - Loss of CD28 on T cells
  - Gain in natural killer (NK) cell–associated regulatory receptors on T cells (e.g., killer immunoglobulin-like receptor [(KIR], killer lectin-like receptor [KLR], immunoglobulin-like transcript [ILT])
- Senescence-associated gene activation (e.g., inflammatory mediators).

telomeric ends. This is of particular importance for T cells because much of their response depends on their ability to proliferate and clonally expand.

Lymphocytes in older adults are more differentiated than those in the young. Although most obvious for CD8 T cells, increasing differentiation can also be noted for B cells and CD4 T cells. Differentiation is generally driven by antigen recognition but could also occur in the absence of exogenous antigen under the influence of cytokines. Proliferation alone may be sufficient to drive initial steps of differentiation. A classic example is the acquisition of memory-like and effector phenotypes with lymphopenia-induced homeostatic proliferation. So-called virtual memory cells, which presumably have never seen an exogenous antigen, have been identified in mouse models. Some gene expression changes found in aged naïve T cells may represent partial differentiation, such as declines in miR-181a and changes in the expression of phosphatases and other signaling molecules. The downmodulation of miR-181a leads to reduced TCR-induced activation in these cells. Moreover, naïve CD8 T cells in the elderly display an epigenetic landscape more similar to that of memory T cells and a global upregulation of miR-146a, indicating underlying cellular activation.[14]

Within the memory T-cell compartment, changes in cell surface molecules that are seen with terminal differentiation, such as the gain in CD57 and the loss of CD27 and CD28 expression, are the most striking. Of functional importance, predominantly for CD8 T cells, is the gain in expression of cell surface receptors that are usually only found in NK cells. Most of these receptors have inhibitory function, but some of them also stimulate. Since expression of these receptors on individual cells is stochastic, the consequences can range from immunosuppression to autoreactivity.

CLINICAL CONSEQUENCES OF IMMUNE AGING—IMMUNODEFICIENCY, AUTOIMMUNITY, AND ACCELERATED DEGENERATIVE DISEASES

The most profound and most noted consequence of immune aging is the increased susceptibility to infections. Upper respiratory tract and urinary tract bacterial infections are frequent in the older population. Despite annual vaccination, influenza infections continue to be associated with high morbidity and mortality in older individuals. Pneumonia caused by RSV, usually infecting young children, is also common with advancing age, as is the loss of immune competence to combat chronic infections, as described above. Not surprisingly, the immune system of an older adult is not able to induce a protective response to new antigens to which the individual has not been exposed in the past. Clinically important examples are the COVID-19 pandemic, severe acute respiratory syndrome (SARS) epidemic, and West Nile fever virus infection, all of which severely affected the older population. Moreover, first-time vaccinations with live viruses (e.g., yellow fever virus) are associated with increased morbidity and even mortality in older adults.

Immune aging also predisposes for autoimmune manifestations and a breakdown in self-tolerance.[21] Autoantibodies are a common finding in healthy older adults; many of these autoantibodies are specific for common autoantigens, such as IgG Fc or nuclear components. The risk for several autoimmune diseases, most notably polymyalgia rheumatica and giant cell arteritis, increases with age. Although polymyalgia rheumatica predominantly presents as an activation of innate immunity, giant cell arteritis is clearly a disease of the adaptive immune system with T cell–dependent granulomatous inflammation in the vascular wall of midsized and large arteries.

The low-grade inflammation in the aging host has direct clinical consequences in promoting frailty and sarcopenia as well as accelerating degenerative diseases, such as coronary artery disease, osteopenia, and Alzheimer disease. Accelerated immune aging may be one of the reasons that autoimmune diseases, such as rheumatoid arthritis (RA), are associated with a shorter life span and increased risk for cardiovascular morbidity. Inflammation as a manifestation of accelerated aging has also been implicated in the increased morbidity and mortality of patients with HIV infection in spite of highly active antiretroviral therapy (HAART).[22]

CLINICAL RELEVANCE

Consequences of Immune Aging

- Increased morbidity and mortality from bacterial infections (e.g., pneumococci)
- Increased morbidity and mortality from viral infections (e.g., SARS-CoV-2, influenza, West Nile fever)
- Reactivation of latent virus (e.g., varicella-zoster virus)
- Ineffective primary and booster vaccinations
- Acceleration of degenerative diseases as a result of the production of inflammatory mediators (e.g., atherosclerotic disease, Alzheimer disease, osteoarthritis)
- Increased incidence of autoimmune disease (e.g., polymyalgia rheumatica, giant cell arteritis, rheumatoid arthritis)

STRATEGIES AND INTERVENTIONS ON THE HORIZON

Vaccinations hold the promise for reducing susceptibility to infections in young children and older adults but improving vaccine responses has proven to be a challenge. Current strategies for targeting more elusive pediatric pathogens (e.g., RSV) include maternal vaccination and the development of infant-specific vaccine adjuvants utilizing newer understanding of the developing infant's immune system. Further investigations into the role of microbiome and immune regulation may open novel strategies to influence immune system development to reduce immune deficiencies and prevent inappropriate hyperactivity, such as allergies and asthma. Newly developed high-dimensional techniques, such as mass cytometry and single-cell RNAseq, will provide a more comprehensive and mechanistic understanding of immune system development to improve vaccine design and subsequent efficacy in infants.

In older adults, a proper T-cell response to infectious organisms or to vaccines depends on the availability of a T-cell repertoire that includes antigen-receptor specificities that respond to vaccination. Repertoire contraction resulting from thymic involution or memory inflation appears to be less severe than originally thought, and currently explored interventions to restore thymic activity may be meaningful only for selected populations, such as bone marrow recipients. Deficiency in the antigen-presenting system and in costimulatory signals may be overcome by identifying new adjuvants. Increasing the vaccine dose (by utilizing higher antigen doses for older individuals, for example) is another promising approach. Live vaccines or

self-replicating constructs that also accomplish higher antigen loads may not have a sufficient safety profile in older adults. Direct targeting of signaling defects in older T cells resulting from increased expression of cytoplasmic phosphatases or inhibitory cell surface receptors will be feasible, as shown for checkpoint inhibitors in oncology; however, such approaches need to demonstrate a much better safety profile.

Interventions to influence inflammation in older adults at present needs to be nonspecific, given the multitude of underlying mechanisms. Immunomodulatory therapy is obviously standard practice in patients with autoimmune disease who exhibit accelerated aging and increased all-cause mortality; however, such therapy is associated with infections even in young adults. Calorie restriction to slow immune aging to an extent that it is effective is generally not well accepted. Statins and aspirin are being routinely used to prevent cardiovascular disease; their effect may be mostly anti-inflammatory. Future interventions will require the development of mild and low-toxicity medications to reduce low-grade inflammation while not impairing the ability to prevent immune activation in response to harmful antigens. One interesting concept is to deplete senescent cells that may entertain the low-grade inflammation in the elderly through the (SASP) mechanism. Several such senolytic drugs have entered clinical trials. An alternative approach is to restore the ability of the immune system to clear senescent cells.

ON THE HORIZON

- Improved vaccination strategies specifically tailored to the infant or aged immune system (novel adjuvants, novel vaccine delivery systems)
- New vaccines for pregnant females to confer passive immunity
- Manipulation of the microbiome composition to influence immune system development
- Thymic rejuvenation (*e.g.* with KGF, IL-7 and other mediators)
- Prevention of chronic infection that accelerate immune aging (*e.g.* immunization for CMV)
- Pharmacological approaches to improve T- and B-cell activation, clonal expansion and differentiation
- Treatment of inflamm-aging

The Microbiota in Immunity and Inflammation

Craig L. Maynard

Humans and other species of mammals are hosts to an array of microbial communities collectively referred to as the *microbiota*. The microbiota comprises prokaryotes (bacteria and archaea), viruses (bacteriophages as well as eukaryotic viruses), and eukarya or the meiofauna (mainly fungi and protozoa). As revealed by the Human Microbiome Project, specialized subcommunities colonize barrier surfaces of the digestive, respiratory, and urogenital tracts and skin. Our immune system is viewed as having evolved to ensure peaceful coexistence with these microorganisms that aid in immune homeostasis, pathogen resistance, and digestion in exchange for a nutrient-rich habitat. There is a perpetual crosstalk between the microbiota and the immune system throughout an individual's life. Specific modulation of this microbiota, particularly in infancy, has important long-term health consequences. Addition of specific symbionts to the microbiota can provide tangible health benefits. Reconstitution of a dysbiotic microbiota continues to be utilized or explored as therapy for inflammatory diseases.

OVERVIEW OF OUR NONMAMMALIAN "SELF"

Exposure to the microbiota and its products occurs via a gradual, ordered process. It begins in utero and accelerates during and after birth. The overall composition of an individual's microbiota is impacted by such phenomena as the method of birth delivery, diet, treatment with antibiotics, and environmental exposures. All of these modifying factors can have lasting effects on immune health.

Prokaryotes

The bacterial component of our microbiota is the most widely studied by far. This has been made possible, in part, by a fairly recent explosion of genomic and bioinformatics capabilities that has enabled taxonomic identification, and even enumeration, of the members of microbial communities without the need for bacterial culture. Two phyla—Bacteroidetes and Firmicutes—account for almost 90% of intestinal bacteria. The remainder comprises organisms belonging to the phyla Proteobacteria (the third largest), Cyanobacteria, Proteobacteria, Actinobacteria, Fusobacteria, and Verrucomicrobia.[1] It is estimated that the average human being plays host to approximately 100 trillion bacteria. Most of these cells inhabit the lumen of the gastrointestinal (GI) tract. The density of bacteria increases from $\approx 10^2$ to 10^3 bacterial cells per mL in the stomach to 10^{12} cells/mL in the distal large intestine (Fig. 22.1). The sheer number of bacteria sets the stage for a very complex relationship between the mammalian immune system and the microscopic inhabitants of the various barrier surfaces.

Viruses

The viruses that inhabit mammalian hosts can be subdivided into bacteriophages, which infect prokaryotic cells; eukaryotic viruses, which infect host and other eukaryotic cells; and virus-derived genetic elements, which can incorporate into host chromosomes and result in the generation of infectious virus at a later date. It has been difficult to quantify the exact size of the *virome*. In the case of bacteriophages, it is generally accepted that they can exist in 10-fold greater numbers than prokaryotes. Bacteriophages can have profound effects on the structure and functions of intestinal prokaryotic communities via viral gene transfer of virulence factors and antibiotic-resistant genes between prokaryotic organisms or through predator–prey relationships. Indeed, the infectivity of some enteric viruses requires the microbiota.[2] Eukaryotic viruses include a vast array of viruses that permanently infect the host and can exist for decades in asymptomatic individuals. These viruses can persist locally or systemically. They can directly impact tissue-specific immunity, including in the GI tract.

Fungi

Collectively referred to as the *mycobiota*, fungal communities represent a considerably smaller proportion of the total microbes in the human body. Commensal fungi can be detected in the mouth, lungs, intestines, vagina, and skin (Fig. 22.2). Advances in our knowledge and understanding of the size and functions of the mycobiota have been hampered by relatively limited genomics and bioinformatics capabilities when compared with the study of bacteria or viruses. However, studies utilizing broad-spectrum antifungal agents have begun to highlight the possible roles played by fungi in protecting against disease processes, such as inflammatory bowel disease (IBD) (Chapter 75).

The microbes that inhabit the human body are often acceptably referred to as the *commensal microbiota*, which in the strictest sense refers to organisms that derive benefit from their host without negatively or positively affecting the host. Although this is true of some members of the microbiota, our relationship with other microbes is one of *mutualism*, whereby each organism performs unique and necessary functions that benefit the other. For example, certain bacteria find a home in the anaerobic environment of the cecum and proximal colon, where they receive a rich source of nutrients in the form of insoluble carbohydrates, which our own digestive enzymes are unable to process. By the process of anaerobic fermentation, these carbohydrates are broken down to generate short-chain fatty acids including butyrate, which is utilized preferentially by colonocytes and also impacts host immunity and metabolism.

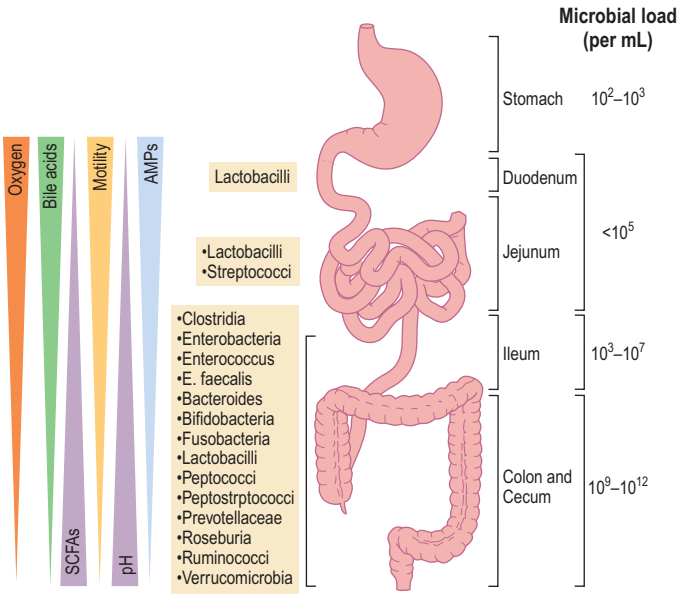

FIG. 22.1 Spatial Organization of Microbial Communities and Physiological Gradients Along the Mammalian Gastrointestinal (GI) Tract. The numbers and types of bacterial communities, as well as physiological factors, vary along the length of the GI tract. It is well-appreciated that the oxygen levels, bile acid concentrations, intestinal motility, antimicrobial peptides *(AMPs)*, and luminal pH in the proximal portion of the GI tract (stomach, duodenum, jejunum) play major roles in restricting the numbers and types of microorganisms. In general, aerobic and facultative anaerobic bacteria are found almost exclusively in the proximal portion of the GI tract. The hypoxic nature and more physiological pH of the distal small intestine (ileum) and colon, coupled with overall reductions of bile acids, AMPs, and gut motility, allows for unfettered growth of large numbers of obligate anaerobic bacteria. These oxygen-sensitive microbes are capable of producing large quantities of short-chain fatty acids (*SCFAs*; acetate, propionate, butyrate) from complex carbohydrates (fiber) to be used for important colonic and immunological processes. (From Reinoso Webb C, Koboziev I, Furr KL, Grisham MB. Protective and pro-inflammatory roles of intestinal bacteria. *Pathophysiology*. 2016;23:67–80, Fig. 2.)

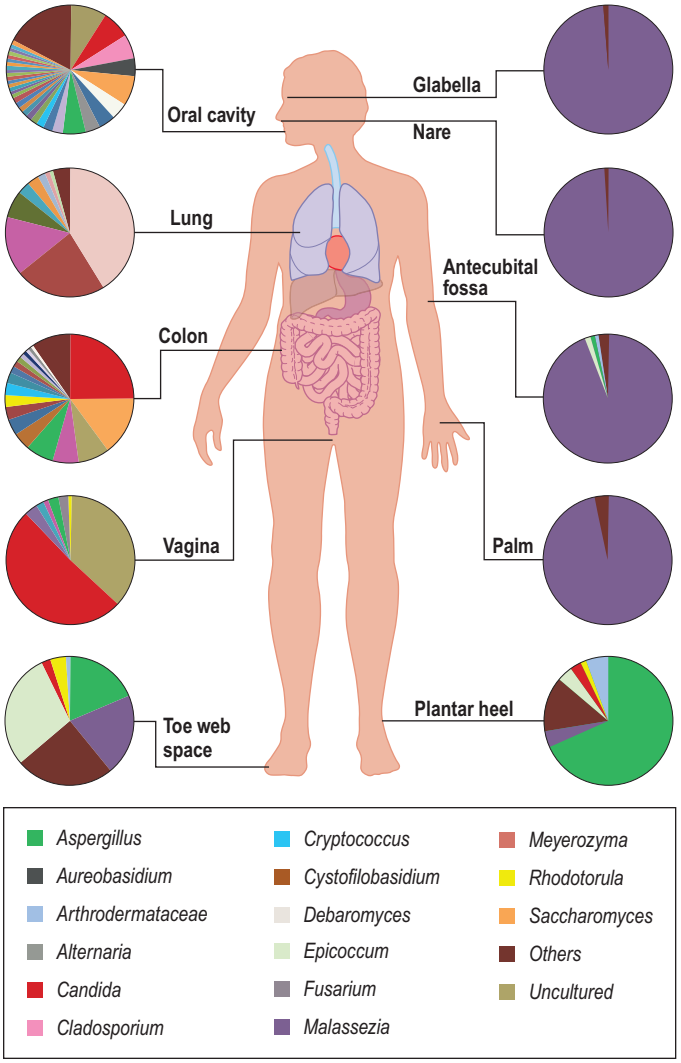

FIG. 22.2 The Human Mycobiota. Complex populations of fungi have been found associated with the skin and all mucosal surfaces of the healthy human body. The *pie charts* indicate the relative proportions of fungal genera that are reported to be associated with the respective sites in representative fungal deep-sequencing studies. The fungal populations that are found on mucosal surfaces tend to be more diverse than those on the skin. The healthy lung probably reflects mostly environmental fungi, which are not included in the key. *Others* refers to sequences that represent <1% of the total recovered sequences at each site. *Uncultured* refers to sequences identified in the National Center for Biotechnology Information (NCBI) GenBank database as fungal, but of uncharacterized, origin. Data for pie charts were derived from studies of the fungal genera that are present in the oral cavity, lungs, colon, vagina, and skin. (From Underhill DM, Iliev ID. The mycobiota: interactions between commensal fungi and the host immune system. *Nat Rev Immunol*. 2014;14:405–416, Fig. 1.)

Obviously, parasitic or harmful microbes are not considered part of the commensal microbiota, although organisms that fit this definition can often coexist with the microbiota without driving overt disease under homeostatic conditions. The term *pathobiont* was previously coined to refer to any microbe that peacefully colonizes its host but can evoke severe inflammatory responses under specific genetic and/or environmental conditions.

THE IMMUNE SYSTEM FACILITATES MICROBIAL COLONIZATION

The developing fetus may be exposed in utero to a microbiota or microbial products acquired via the placenta and/or maternal circulation.[3] The acquisition of microbial communities continues with the passage of the fetus through the birth canal and culminates in the first 2 to 5 years of life in humans. Despite the vast array of microbes that take up residence in the host, colonization is usually an ordered process that—in most cases—is well tolerated. This is because of a robust antimicrobial defense system that is initiated prenatally and fortified postnatally, simultaneous with rapid microbial colonization.

KEY CONCEPTS

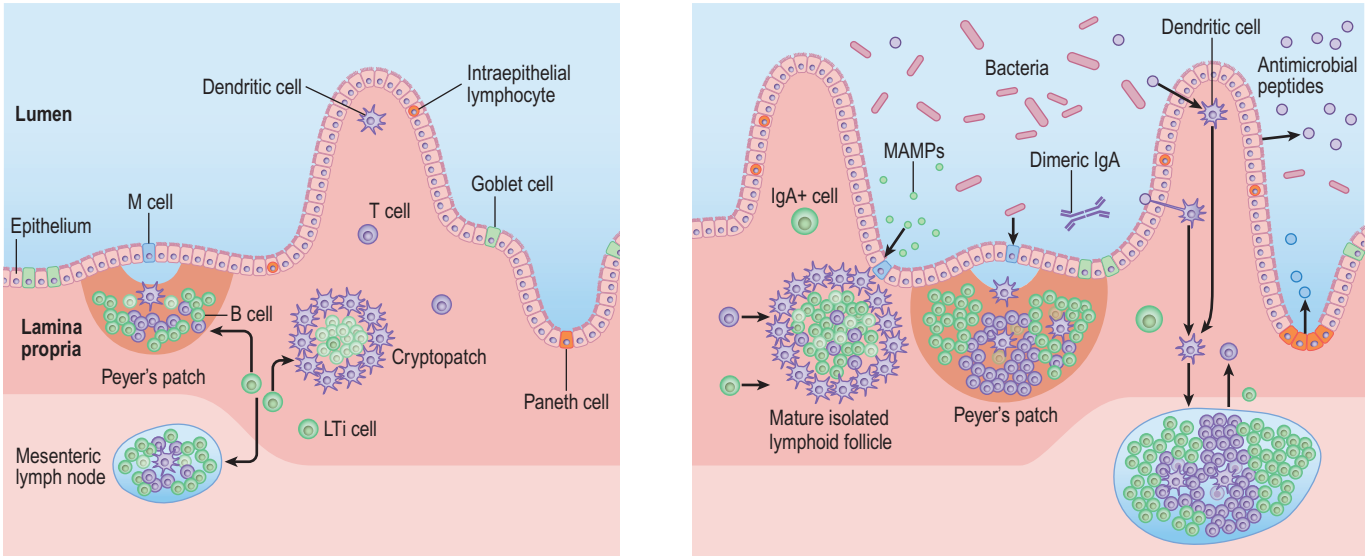
Definitions

- **Microbiota**: A collective term for all the microscopic organisms that reside on or in the human body.
- **Microbiome**: The combined genomes of all the organisms that constitute the microbiota.
- **Mycobiota**: That subset of the microbiota that includes fungi alone.
- **Virome**: The collection of all viruses, including viruses integrated into the human genome, found in or on humans.
- **Dysbiosis**: A condition in which there is disequilibrium of the microbial communities that constitute the microbiota at a given body site.
- **Germ-free**: Experimental animals birthed and raised in a sterile environment, devoid of microbes.
- **Gnotobiotic** ("known life"): Describes animals in which the full complement of colonizing microbes is known.

Prenatal Development of the Immune System

In the fetal liver, some common lymphoid progenitor cells—ancestral to all lymphocytes—develop into a specialized subset of innate lymphoid cells (ILCs) referred to as *lymphoid tissue inducer (LTi) cells*.[4] As their name implies, LTi cells are essential for the development of all secondary lymphoid structures throughout the body. These structures will eventually become the sites for initiation of immune responses to the commensal microbiota, pathogenic invaders, and self-antigens. In the developing fetus, LTi cells promote the development of mesenteric lymph node (MLN) and of the Peyer patches (PPs) (Chapters 2 and 24) in the distal ileum (Fig. 22.3). They also recruit B and T lymphocytes to these tissues and facilitate their organization into distinct B-cell follicles and T-cell zones, respectively. Throughout life, the MLN provides a so-called mucosal firewall that prevents systemic dissemination of gut bacteria.

Other local mechanisms are also initiated to limit host collateral damage to the neonatal intestine by early microbial encroachment. For example, Toll-like receptor 4 (TLR4) (Chapter 3), the receptor for lipopolysaccharide (LPS) that is derived from gram-negative bacteria, is highly expressed by intestinal epithelial cells (IECs) prior to birth, but its expression and signaling are rapidly downregulated following onset of colonization. In addition, a diverse array of lymphocytes



(A) Prenatal (B) Postnatal

FIG. 22.3 The Gut-Associated Lymphoid Tissue (GALT) Establishes Perinatal Host–Microbiota Mutualism in the Intestine. (A) Prenatally, secondary lymphoid tissues (Peyer patches and mesenteric lymph nodes) and cryptopatches develop by the spatiotemporal recruitment of lymphoid tissue inducer *(LTi)* cells to sites of the developing intestine and supporting neurovascular structures. This, in turn, stimulates the recruitment of dendritic cells (DCs), T cells, and B cells in preparation for the immune response to the microbiota. Intraepithelial lymphocytes (IELs) seed the epithelium before birth. (B) Postnatally, bacteria colonize the neonatal intestine immediately, initiating multiple events that affect the development or functional maturation of the mucosa and GALTs. *Shown from left to right:* Microbe-associated molecular patterns *(MAMPs)* sensed by pattern-recognition receptors on intestinal epithelial cells and DCs adjacent to cryptopatches stimulate the further recruitment of B cells and T cells, causing the cryptopatches to develop into mature isolated lymphoid follicles. The isolated lymphoid follicles release immunoglobulin A *(IgA)*–producing plasma cells, which are formed through T-cell–dependent and –independent interactions, into the lamina propria. Microbes also cross the epithelium and enter the Peyer patch through M cells, from which they are endocytosed by the DCs in the subepithelial dome. Antigen-loaded DCs in the Peyer patch interact with local lymphocytes to induce T-cell differentiation and T-cell–dependent B-cell maturation in the germinal center (GC) to induce the development of IgA-producing plasma cells that home to the lamina propria, where they release dimeric IgA for transport into the intestinal lumen. DC-mediated luminal sampling of microbial products or transcytosis of bacteria across the epithelium results in antigen loading of the lamina propria DCs, which then migrate through the afferent lymphatics vessels (not shown) to a draining mesenteric lymph node to induce differentiation of effector T cells that traffic to the lamina propria. *Shown on the far right*: Sensing of MAMPs stimulates the proliferation of intestinal epithelial cells in crypts, resulting in their increased depth and, in the small intestine, increased density of Paneth cells. This sensing also arms the intestinal epithelial cells for release of antimicrobial peptides. (From Maynard CL, Elson CO, Hatton RD, Weaver CT. Reciprocal interactions of the intestinal microbiota and immune system. *Nature*. 2012;489:231–241, Fig. 1.)

collectively referred to as intraepithelial lymphocytes (IELs) can be found intercalated between the IECs. IELs display multiple features of activated cells and participate in the maintenance of epithelial barrier integrity by limiting bacterial translocation and promoting epithelial repair following injury.[5]

Reproductive Tract Microbiota and the Immune System in Perpetuation of the Species

As viviparous organisms, the microbiota of the human genital tract appears to be a critical component of a healthy reproductive system. Dysbiosis in the genital tract is implicated in susceptibility to infection, infertility, and recurrent miscarriage as well as premature delivery and placental malfunction.[6] The human vagina harbors a stable community of microorganisms which, similar to the microbiota at other sites, figures prominently in the maintenance of immune homeostasis and resistance to pathogen colonization.

The vaginal microbiota exists in a state of dynamic equilibrium with minor fluctuations induced by such factors as hormones associated with the menstrual cycle, sexual behavior, and personal hygiene. This community is composed primarily of several species of the genus *Lactobacillus*. In non-pregnant women of reproductive age, the vaginal microbiota is relatively dynamic in comparison to the more stable composition present during pregnancy. The dominance of a few species is believed to be central to the relative stability and colonization resistance of the vaginal microbiota, especially during development of the fetus in the adjacent uterus. Though still dominated by *Lactobacillus*, the dominant species detectable appears to vary with gestational age, history of pregnancy, and ethnicity. For example, *L. crispatus*, *L. iners*, and *L. acidophilus* were the most dominant in Caucasian, African American, and Hispanic cohorts, respectively. Historically, the uterus, and the placenta have been considered sterile. However, due primarily to the emergence of culture-independent methods for microbiota detection, it has been suggested that there exist low biomass microbial communities in both the endometrium and placenta, but this concept remains somewhat controversial. Nevertheless, dysbiosis of the vaginal reproductive tract microbiota is believed to contribute to reproductive difficulties and pregnancy complications that adversely affect the health of the mother, offspring, or both.

Lactobacillus spp. in the upper genital tract are believed to protect this region from infection via the production of lactic acid, maintaining a low pH of less than 4.5, which is prohibitive to the growth of pathogens. The concept of an essential role for *Lactobacillus* reproductive health is supported by an increase in the relative abundance of such species during puberty in response to the hormone estradiol. In general, a beneficial vaginal microbiota promotes robust expression of defensins and specific vaginal antimicrobial peptides (AMPs). In contrast, increased expression of vaginal AMPs such as the secretory leukocyte protease inhibitor and human epididymis protein 4 have been associated with a less beneficial vaginal microbiota. This microbiota must also facilitate the induction of an immune milieu characterized by reduced proinflammatory cytokines and sustained immune regulatory pathways.

Passive Acquisition of Antimicrobial Immunity

The microbiota of the neonate is acquired from his or her mother, who has already established a tolerogenic relationship with the same microbiota. The composition of the transmitted microbiota varies initially with the mode of delivery—vaginal versus cesarean section. The mother's "mucosal memory" also gets transmitted to her offspring. During transvaginal delivery, this mucosal memory is seeded with the mother's native microbiota. Mothers produce antibodies to bacteria-derived antigens. These bacteria-responsive antibodies enter the maternal circulation and ultimately get passed to the offspring in breast milk.

Immunoglobulin A (IgA) is the major antibody isotype (Chapter 8) generated by mammary glands. IgA inhibits bacterial translocation across the neonatal intestinal epithelium, thereby limiting collateral damage by an encroaching microbiota and providing passive immunity to pathogenic infection.[7] The offspring also acquires antibodies of the IgG isotype both in utero and via the breast milk. These antibodies serve to limit enteric infection in the newborn[8] and dampen neonatal mucosal T-cell and germinal center (GC) B-cell responses to commensal antigens.[9]

Maternally acquired anti-commensal antibodies can transfer bound microbial molecules to the offspring during gestation and via the breast milk. This transfer of microbial products contributes to the earliest education of the immune system and limits deleterious postnatal inflammatory responses.[3] Breast milk is also a rich source of immunosuppressive transforming growth factor-β (TGF-β) and interleukin-10 (IL-10) (Chapter 14), which also help promote tolerogenic responses to the microbiota. Recent studies suggest that microbes are also passed to the newborn via the breast milk.

MICROBIOTA-DEPENDENT MATURATION OF THE INTESTINAL IMMUNE SYSTEM

Microbial colonization prompts a rapid organization of immune structures that are quickly seeded with immune cells. This process helps avoid overexuberant responses to the microbiota and sets the stage for continued tolerance of commensals and for defense against pathogens in the future. The intestinal epithelium limits direct encounter between luminal microbes and the immune cells in the underlying lamina propria by forming a physical barrier and by the production and/or transport of immune and antimicrobial factors (Fig. 22.4).

Gut-Associated Lymphoid Tissues

Although MLN and Peyer patches begin to develop before birth, complete maturation does not occur until after birth. Germ-free or "germ-reduced" mice display reduced size and cellularity and altered numbers and distribution of immune cells both in the gut and gut-associated lymphoid tissues (GALTs). Thus, maturation of the mucosal immune system is contingent on the acquisition of microbiota. A third type of secondary lymphoid tissue—isolated lymphoid follicles (ILFs), which are also induced by LTi cells—is also completely dependent on colonization with the microbiota and thus develops postnatally.

LTi cells cluster at the base of the crypts in structures referred to as *cryptopatches*. Stimulation of cryptopatches by peptidoglycan derived from gram-negative bacteria induces recruitment of B cells, thereby forming ILFs. The importance of ILFs in the direct control of bacterial growth is demonstrated by the fact that mice devoid of mature ILFs display an overrepresentation of gram-negative bacteria.[10]

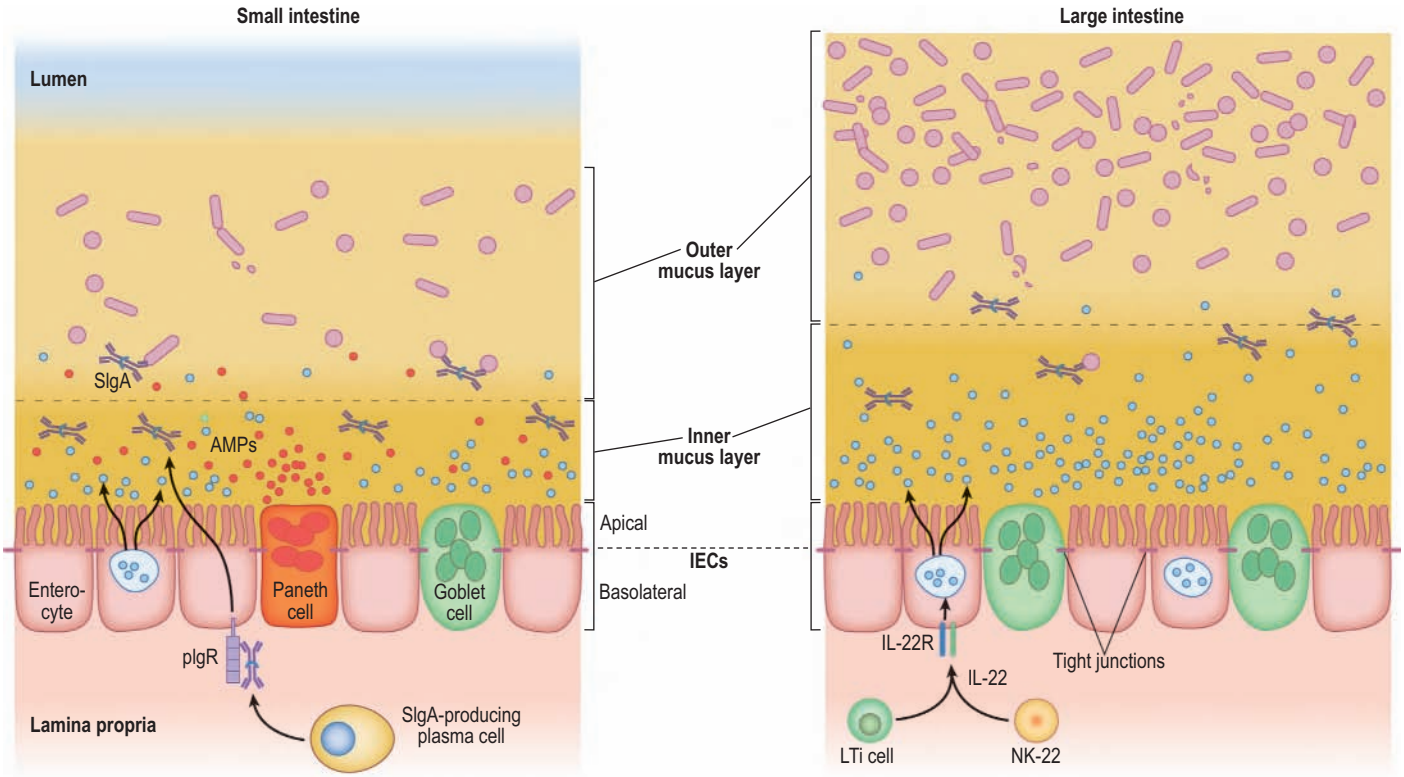


FIG. 22.4 Active Barrier Functions of the Intestinal Epithelium. The intestinal epithelium comprises a single layer of polarized columnar epithelial cells *(IECs)*, which is sealed by tight junctions. Specialized cells known as *goblet cells* secrete mucins that form a bilayered mucus sheath, which maintains separation between the luminal bacteria and the epithelium. The thicker *inner mucus layer* is sparsely populated with bacteria, whereas the *outer mucus layer* is more loosely structured and contains ≈10-fold more bacteria. Paneth cells within the epithelium secrete defensins that, along with epithelial-derived antimicrobial peptides, further help with bacterial containment. Epithelial cells also transport antibodies into the lumen and transmit cytokine signals that help maintain barrier integrity. *AMP*, Antimicrobial peptide; *Ig*, immunoglobulin; *IT*, interleukin; *LTi*, lymphoid tissue inducer; *NK*, natural killer; *SIga*, secretory IgA; *pIgR*, polymeric immunoglobulin receptor.

Innate Lymphoid Cells

ILCs represent an early line of defense at mucosal surfaces. ILCs are classified as LTi or "LTi-like" (described above) cells or as "helper-like" cells. The progenitor of helper-like ILCs is distinct from that of LTi cells or natural killer (NK) cells. "Helper-like" ILCs are classified into three main subcategories based on their expression of particular sets of surface receptors, transcription factors, and secreted proteins. Unlike their adaptive, thymus-derived counterparts, ILCs do not express antigen receptors and are therefore activated by cytokine signals. This enables ILCs to launch an initial rapid response to microbial challenge and facilitate the development of an adaptive lymphocyte-mediated immune response.

ILC1s, such as T-helper type 1 (Th1) cells, express the transcription factor Tbet and secrete interferon-γ (IFN-γ) and tumor necrosis factor-α (TNF-α) in response to intracellular bacteria. Similar to Th2 cells, ILC2s express GATA3 and secrete IL-13 and IL-5. ILC3s are arguably the most complex subset of ILCs and can be subdivided into "LTi-like" ILC3s, which populate the intestinal lymphoid follicles, and the more plastic NKp46$^+$ ILC3s, which are distributed throughout the intestinal lamina propria. Both subsets express retinoic acid–related orphan receptor (ROR)γt and produce IL-22 and IL-17, although NKp46$^+$ ILC3s can also express Tbet and secrete IFN-γ.[11]

The impact of the microbiota on ILC3 accumulation appears to commence in utero, as transient colonization of pregnant germ-free mice with nonpathogenic *Escherichia coli* increases accumulation of NKp46$^+$ ILC3s and F4/80+CD11c+ mononuclear cells in newborn pups.[3] In the normal intestine, ILC3s are the dominant source of IL-22.[11] The microbiota, acting on innate cells, including macrophages and dendritic cells (DCs), induces expression of IL-23, which, in turn, stimulates the production of IL-22 and/or IL-17 by ILC3. IL-22 can induce the secretion of antimicrobial peptides, such as RegIIIγ, by intestinal epithelial cells to limit bacterial invasion and within GALT to prevent systemic dissemination of resident microbes. Throughout life, ILC3 expressing major histocompatibility complex (MHC) class II molecules (Chapter 5) on their cell surface help regulate the pool size and function of commensal-specific CD4 T cells to prevent spontaneous inflammation.[12]

Invariant Natural Killer T Cells

A unique subset of thymus-derived cells, invariant NK T (iNKT) cells (Chapter 12) express an invariant T-cell receptor (TCR) (Chapter 4) that recognizes lipid antigens presented by the nonclassic MHC class I molecule CD1d (Chapter 5). iNKT cells are essential for the ulcerative colitis–like phenotype that develops in experimental mice treated with the chemical compound oxazolone.

The role of the microbiota in iNKT cell expansion and function provides an example of how early postnatal colonization can impact immune maturation and long-term function.

Germ-free mice harbor increased numbers of iNKT cells in both the colon and the lung and correspondingly demonstrate increased severity of experimental colitis and asthma. The disease phenotype can be reduced to that of conventionally raised mice if germ-free mice are colonized with commensals in the neonatal period, but not during adulthood.[13]

Regulatory T Cells

Regulatory T cells (Tregs) (Chapter 13) are crucial to the establishment and maintenance of immune homeostasis. Mice or humans with absent or defective expression of the signature Treg transcription factor Foxp3 (FOXP3 in humans) succumb to spontaneous multiorgan autoimmune disease very early in life. Commencing in the first few days of life, thymic FOXP3$^+$ Tregs seed every lymphoid and nonlymphoid tissue. Most Tregs in the intestine express Foxp3, and most of these coexpress IL-10, TGF-β, and IL-35. However, other FOXP3$^-$ subsets also exist, including IL-10-producing Tr1 cells and human lamina propria CD4CD8αα T cells.[14]

Commensal-specific Foxp3-expressing Tregs in the intestinal lamina propria are viewed as a mixture of thymic-derived Tregs (tTregs) and peripherally induced Tregs (pTregs).[15] The inability to generate pTreg cells results in spontaneously intestinal pathology late in life due to their essential role in tolerizing the host to colonization by epithelial "border-dwelling" organisms.[16] Colonization of germ-free mice with a benign cocktail of eight commensal microbes, collectively referred to as *altered Schaedler flora*, is sufficient to induce expansion and accumulation of Foxp3$^+$ cells in the large intestine, approaching the levels seen in conventionally raised mice. However, a case has been made for the ability of specific bacteria and/or bacterial components to uniquely promote Treg induction. For example, a cocktail of 46 mouse *Clostridium* strains potently induced expansion of colonic Foxp3$^+$ cells.[17] This cocktail, which has since been reduced to 17 strains derived from a single human donor, recapitulates the phenotype in germ-free mice.

Several factors produced or induced by gut microbes have been shown to be essential for microbiota-dependent Treg accumulation, particularly in the colonic lamina propria. The capsular polysaccharide A (PSA) moiety of *Bacteroides fragilis*, which mediates the interaction between the bacterium and the colonic mucosa, can also act via the TLR–MyD88 pathway to promote expansion of IL-10–producing colonic Tregs.[18] Clostridial strains stimulate production of TGF-β by intestinal immune cells and are very effective at limiting pathogen colonization of the GI tract.[19] This, in turn, enhances Foxp3$^+$ Treg induction. Clostridia are also very adept at anaerobic fermentation of indigestible fiber. Their production of butyrate may also enhance accumulation of Foxp3$^+$ Tregs in the colonic lamina propria.[20]

CD4 T-Helper Cells

In the intestines of both mice and humans, both IFN-γ–producing Th1 and T-helper "IL-17–producing" (Th17) cells are present (Chapter 11). These populations, which are reactive to microbial antigens, are largely held in check by the intestinal immunoregulatory system. In some cases, expression of the Th cell signature (transcription factors and cytokines) of distinct lineages can overlap with each other or with the Treg transcription factor Foxp3, denoting either a common progenitor or the dynamic lineage transitions that can ensue in response to competing immune signals. In the absence of regulatory pathways, for example, in IL-10 deficiency, the numbers and frequencies increase gradually, coincident with the onset of chronic inflammation. The same is true during GI infection (see below), where the ability of invasive bacteria or viruses to enter a cell, or the physical interaction of the bacteria with the intestinal epithelium, culminates in induction and expansion of Th1 and Th17 cells, respectively, in the intestinal lamina propria.

Mucosal Antibody-Secreting Cells (ASC)

With increasing colonization comes an increased likelihood of epithelial breach, particularly by bacteria capable of penetrating the inner mucus layer and gain access to the intestinal epithelium. By intercalating dendrites between epithelial cells and into the lumen, DCs in the intestinal lamina propria are able to sample the luminal bacteria. Antigen-loaded DCs migrate to the mesenteric lymph nodes, where they interact with B and T cells to induce production of anti-commensal IgA. These IgA-producing plasma cells migrate to the intestinal lamina propria, where they secrete IgA dimers that migrate across the epithelium and into the lumen. These predominantly polyreactive IgA antibodies bind conserved moieties on the surface of diverse bacterial species, helping to sequester these organisms away from the epithelial layer. Commensal organisms, most notably *Bacteroides fragilis*, can harnesses this anti-commensal IgA to facilitate their own colonization of the GI tract. One study showed that the IgA-bound fraction of commensal bacteria supports the development of more severe disease in an animal model of ulcerative colitis.

In germ-free mice, the absence of the microbiota and resultant absence of IgA production is seemingly replaced by IgE class switching (Chapter 4) in mucosal lymphoid tissues with a corresponding increase in susceptibility to oral antigen-induced systemic anaphylaxis.[21] Therefore, the microbiota itself helps limit hyperreactivity to allergens and parasite challenge throughout an individual's life.

IMMUNE CONSEQUENCES OF EARLY MICROBIAL MANIPULATION

Because the microbiota is so essential to the early postnatal maturation of the immune system, the consequences of manipulation or insufficiency of the microbiota can impact host immunity throughout life. Microbial disruption, particularly during the neonatal–infancy period, is being associated with increased risk of autoimmunity and chronic inflammation later in life.

The increasing incidence of autoimmune disease in industrialized countries has been linked to use of antibiotics,[22] improved sanitation, and consumption of processed foods rich in fat and carbohydrates but negligibly low in fiber.[23] These practices limit microbiota diversity and deplete the bacteria that "educate" the developing immune system, leaving it prone to overreaction to subsequent challenges.

There is a growing body of experimental findings in support of this concept. For example, vancomycin treatment in young mice increases their susceptibility to asthma as well as food allergy, in large part as a result of depletion of clostridial strains known to promote colonic Treg induction and expansion. Antibiotic treatment in early life can limit the success of subsequently administered vaccines. Early life treatment with low-dose antibiotics can also result in increased susceptibility to obesity and corresponding alterations in immune gene expression in

the ileum. Individuals who had limited sanitary amenities during childhood or were raised around livestock are at reduced risk of developing IBD (Chapter 75) during adulthood. This latter phenomenon is commonly attributed to the acquisition of a diverse microbiota in these microbially enriched environments. However, such living conditions also pose an increased risk of parasitic helminth infection. This concept is supported by experimental data showing that treatment with *Trichuris muris* prevents development of experimental colitis in mice deficient for the IBD-related gene *Nod2*.

IMMUNE SYSTEM—MICROBIOTA CROSSTALK IN INTESTINAL INFLAMMATION

The immune system and the microbiota are in constant dialogue at steady state. Throughout an individual's life, the microbiota undergoes transient shifts in response to external influences. These include infections, medications (e.g., antibiotics), and dietary changes. The timing, magnitude, and targets of these perturbations can result in immune responses aimed at resetting this balance or limiting host collateral damage. Furthermore, feces of patients with certain extraintestinal chronic inflammatory diseases also display reduced microbial abundance and diversity relative to their healthy counterparts. This may reflect the role of the intestinal microbiota in the etiology of diseases, the impact of tissue-specific inflammation on the microbiota, or both.

Gastrointestinal Infection

The microbiota helps provide resistance to pathogenic invasion at mucosal sites. This can occur either indirectly by enhancing barrier defenses or directly by competing with harmful microbes. Nevertheless, several organisms still manage to breach these defenses. Such pathogen invasion induces production of proinflammatory cytokines by innate cells that can appropriately expand the magnitude of the immune response by signaling the differentiation of Th cells. The soluble products of these cells recruit other immune cells and collectively aid in pathogen eradication and sometimes in repairing any physical damage to the intestinal barrier. Unimpeded inflammatory responses can be destructive to host tissue, and thus, immunosuppressive mechanisms are induced that help to restore immune homeostasis.

In a healthy host, GI infections are largely self-limiting. However, the temporary disruption of microbial homeostasis (*dysbiosis*) can have lasting effects on host health. In the cases of *Salmonella enterica* serovar typhimurium (*S. typhimurium*) and *E. coli* infection in mice, the associated inflammation can drive production of substances that favor pathogen growth or enable the pathogen to outcompete resident microbes. The inflammatory response to the enteric pathogen *Citrobacter rodentium* promotes a restructuring of the microbiota that can predispose to chronic inflammation. Similarly, *Yersinia pseudotuberculosis* infection results in chronic inflammation and long-term defective lymphatic communication between the gut and mesenteric lymph nodes. These changes are supported by the dysbiotic microbiota.[24]

Infection of mice with the protozoan parasite *Toxoplasma gondii* (*T. gondii*) induces production of IL-12, which, in turn, promotes the differentiation of IFN-γ–secreting Th1 cells. IFN-γ is essential for pathogen control and promotes dysbiosis via targeted destruction of Paneth cells. The production of IL-10 by a subset of the Th1 cells helps overcome the inflammation, whereas IL-10–deficient mice succumb to the infection. However, even when the infection is controlled, the brief disruption in Treg homeostasis enables systemic dissemination of commensal bacteria and a temporary disruption in tolerance to the microbiota.[25]

Certain microbes also induce specific immune responses simply by their physical interaction with host cells. The ability of certain bacteria to bind directly to the intestinal epithelium is central to their ability to provoke a Th17 cell response that culminates in the accumulation of these cells in the underlying lamina propria. In mice, this is vividly displayed following infection with bacterial species, including the *Clostridium* spp., *Candidatus arthromitus* (segmented filamentous bacteria [SFB]), *Citrobacter rodentium*, and enterohemorrhagic *E. coli* (EHEC) O157:H7, which can breach the mucous barrier and adhere directly to intestinal epithelial cells. In the case of *C. rodentium* and EHEC, this results in a temporary effacing of the epithelial cell layer, local inflammation, diarrhea, and weight loss and in robust induction of Th17 cells. The same phenomenon can be reproduced if germ-free mice are colonized with *E. coli*–adherent bacteria derived from patients with ulcerative colitis.[26] Production of IL-17 as a result of the presence of SFB in the terminal ileum provides colonization resistance to *C. rodentium*. Induction of this immune pathway is stimulated by a microbial breach and helps restore epithelial integrity and limit further invasion. This provides an explanation for the therapeutic blockade of IL-17 being ineffective in the treatment of IBD—and even exacerbating the disease—even though it was successful in reversing symptoms of psoriasis (Chapter 64).[27]

Inflammatory Bowel Disease

IBD is a collective term that refers to a group of chronic relapsing–remitting inflammatory disorders that can occur anywhere along the GI tract. The two main forms of IBD, Crohn disease and ulcerative colitis, have similar clinical presentations but can differ in terms of histopathological features, affected sites, and risk of malignancy. Although disease onset can be impacted by a vast array of genetic, environmental, and immune factors, IBD is characterized by dysregulated immune responses to microbial antigens.

Although no single causative microbe or microbial cluster has been identified, there is strong correlative evidence in support of a dominant role for the microbiota in disease development and function. First, antibiotic therapy continues to be very effective in patients with inflammation in the lower bowel.[28] Second, in treatment-naïve patients with IBD, there is increased abundance of mucosa-associated pathobionts, including Enterobacteriaceae, Pasteurellaceae, Veillonellaceae, and Fusobacteriaceae. Conversely, a decrease in "beneficial" microbes, including Erysipelotrichales, Bacteroidales, and Clostridiales, has been observed. Reduced abundance of *Faecalibacterium prausnitzii*, a member of *Clostridium* cluster IV that induces an anti-inflammatory phenotype in immune cells, has also been associated with IBD and risk of relapse. Whether dysbiosis is a cause or consequence of disease is debatable. Dysbiosis can occur in disease-free relatives of patients with IBD,[29] which is consistent with a genetic influence on microbiota composition. However, several inflammatory mediators very effectively promote dysbiosis in experimental systems, supporting the notion that inflammation precedes microbial disruption.

Genome-wide association studies (GWAS; Chapter 18) have identified over 160 genetic loci that segregate with clinical disease. Several genes encode immune-related proteins involved

in detecting and/or responding directly to microbial products, inducing or amplifying the immune response to microbial challenge, or restoring and/or maintaining immune homeostasis with intestinal microbes.[30]

The first gene to be causally linked to IBD is *NOD2*, which encodes the nucleotide-binding oligomerization domain–containing protein 2, a microbial sensor that enables the immune system to recognize and respond to intracellular fragments of bacterial peptidoglycan.[31] Loss-of-function (LOF) mutations in *NOD2* (i.e., defective microbial recognition) predisposes to intestinal inflammation—but only in response to infection or injury. This is consistent with the "multiple hit" model of IBD pathogenesis. *NOD2* deficiency is associated with reduced numbers of intestinal goblet cells and, therefore, reduced mucus production, hyperactive IELs in the small intestine, and increased expansion of the commensal *Bacteroides vulgatus*.[32] All of these abnormalities can be prevented in mice infected with the helminth *Trichuris muris*. However, helminth infection as a therapy for human IBD has been largely unsuccessful.

Another immune-related IBD risk allele identified by GWAS is IL10, which encodes the immunosuppressive cytokine IL-10. In addition, rare LOF mutations in IL-10RA or IL-10RB, which encode the IL-10 receptor α and β chains, respectively, are found in a subset of patients with very-early-onset IBD. Mice with global or even CD4- or Foxp3-specific deletion of *IL-10* develop spontaneous colitis, which is dependent on the presence of the microbiota. The importance of the microbiota is highlighted by the varying kinetics and severity (ranging from complete protection to severe inflammation) of disease in different animal colonies or even in the same colony at different points in time. Disease is more consistent and severe and can even progress to colorectal cancer in mice colonized with *Helicobacter* spp. Thus, IL-10, which can be produced by multiple hematopoietic and nonhematopoietic cells, is critical for maintaining tolerance to the microbiota, particularly in the presence of species that can progressively disrupt the homeostasis of the microbiota.

Experimental studies have suggested a role for the nonprokaryotic inhabitants of the intestines in maintaining the status quo, thus limiting susceptibility to IBD. Fungi interact with the immune system via the receptor dectin-1. A single polymorphism in *CLEC7A*, which encodes dectin-1, has been linked to a severe form of ulcerative colitis. Accordingly, dectin-1 deficiency in mice precipitates increased susceptibility to chemical-induced colitis, and long-term antifungal treatment results in increased severity of acute and chronic experimental colitis.[33]

Members of the virome can either promote or prevent development of IBD-like symptoms via their interactions with intestinal bacteria. Murine norovirus induces inflammation in mice with disruption in the IBD susceptibility gene *Atg16L1*. Antibiotic administration reverses this viral-induced disease.[34] Conversely, antiviral pretreatment of otherwise healthy mice can exacerbate acute experimental colitis by disrupting the production of anti-inflammatory IFN-β.[35]

EXTRAINTESTINAL MANIFESTATIONS OF GUT MICROBIOTA–IMMUNE SYSTEM INTERACTION

Obesity develops when energy intake exceeds expenditure and culminates in deposition of excess adipose tissue. The associated chronic complications, collectively and clinically referred to as *metabolic syndrome*, include hyperglycemia, hypertriglyceridemia, dyslipidemia, and hypertension. Studies in mice and humans have revealed that there are alterations in the gut microbiota in obesity and associated metabolic diseases brought on by increased gut permeability, immune responsiveness, and aberrant bacterial translocation. For example, mice transplanted with human fecal microbiota from obese or lean cotwins displayed increased weight gain and adipose tissue relative to those transplanted with the microbiota of the lean cotwins.[36]

Obesity has been associated with an increased abundance of Firmicutes relative to Bacteroidetes, and differential responses of the lean and obese microbiota to the caloric content of the diet.[37] The altered composition can also lead to a reduction in microbial gene richness, which, in turn, affects the "inflammatory tone" of the microbiota and likely contributes the chronic low-grade inflammation characteristic of obesity. Lipopolysaccharides (LPSs), also known as endotoxins, derived from the outer cell membrane of gram-negative bacteria, are found at low concentrations in the circulation of healthy individuals, but are dramatically increased in obese individuals and even more so in those who develop type 2 diabetes. LPS infiltrates tissues, including the liver and adipose tissues, and the activation of macrophages via TLR4 initiates an innate immune response characterized by secretion of cytokines, including IL-6 and TNF-α. Obesity-related inflammation also contributes to defective insulin signaling or insulin resistance—a major player in the transition from metabolic syndrome to diseases, including type 2 diabetes, hepatic steatosis, and cardiovascular disease.[38]

Although the microbiota (usually fecal) is distinct in certain non-GI diseases, including ankylosing spondylitis (Chapter 58), multiple sclerosis (Chapter 66), and asthma (Chapter 43), whether these changes precede or follow disease development is not clear. One measure might be the effect of microbiota-induced immune mediators on disease pathology in extraintestinal tissues. For example, although gut microbes that can adhere to the epithelial cells induce robust expression of IL-17, their functions in the gut are largely protective. In contrast, microbiota-induced IL-17 can be proinflammatory in extraintestinal tissues. In germ-free mice colonized with SFB and subjected to experimental models of arthritis or multiple sclerosis, severe IL-17–dependent disease develops.[39] Elevated induction of RORγt and IL-17 in the central nervous system is also a hallmark of virus-induced maternal immune activation (MIA), which can lead to autism spectrum disorder (ASD)–like symptoms in a murine model.

CANCER AND THE MICROBIOTA

The tissue-specific immune inflammatory response that is necessary for pathogen eradication or to restore host–microbiota homeostasis can be deleterious to the host if allowed to reach chronicity. In addition to causing permanent tissue damage (scarring), such a chronic inflammatory response predisposes to tumor development and the production of neo-self-antigens that are now recognized as foreign to the host. The antitumor immunity that ensues possesses characteristics similar to those of the antipathogen response and ultimately has the same goal—eradication of a foreign body. Likewise, anti-inflammatory or regulatory mechanisms are deployed to limit the magnitude and duration of the inflammatory response in an effort to restore immune homeostasis (Fig. 22.5). However, continued tumor growth means that the "foreign" antigens have not been eradicated, and/or new ones are continually being generated.

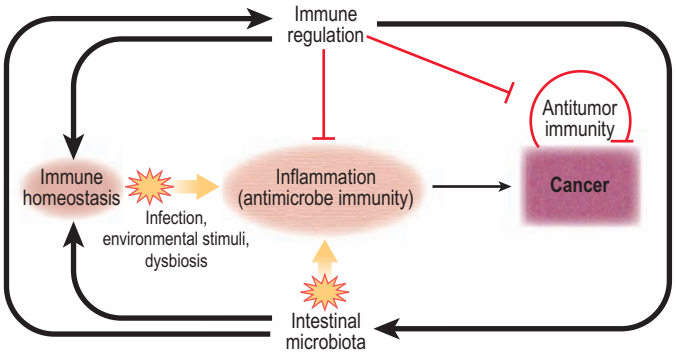

FIG. 22.5 Microbiota–Immunity–Cancer Triad. The reciprocal interaction of intestinal microbiota and the immune system induces default regulatory pathways that help maintain intestinal immune homeostasis. Factors that promote microbial dysbiosis, such as infection and other environmental insults, can disrupt immune homeostasis. This can result in proinflammatory responses targeting the causative agent that accompany immune regulatory responses that aim to reset immune balance. The perpetuation of the inflammatory response enhances the likelihood of progression to cancer. In response to the novel antigens generated in the tumor, an immune response is initiated with the goal of eradicating the tumor. As this response bears similar characteristics to an antipathogen response, it is subject to the same immune suppressive mechanisms.

In response to cancer, the host immune response needs to persist, rather than being opposed by the host's anti-inflammatory arsenal. Thus, similar nondiscriminatory immune regulatory mechanisms that are beneficial in curbing inflammation can impede antitumor immunity, thereby enabling tumor growth and eventual dissemination.[40]

There are several immune-related mechanisms whereby microbes directly impact the inflammation–cancer continuum. Some pathogens can promote an inflammatory milieu that encourages tumor development, whereas others can directly transform the eventual tumor-initiating cells. Oncogenic bacteria, including certain strains of *Enterococcus faecalis*, produce carcinogenic reactive oxygen species (ROS) capable of inducing DNA-damaging compounds or can induce production of carcinogenic compounds by activated immune cells. Inflammation-induced cell turnover directly increases the likelihood of introducing mutations in replicating DNA.

Microbiota–Immune System Interactions in Cancer Susceptibility and Development

Not surprisingly, animal models in which deletions of immune genes favor the emergence of a dysbiotic microbiota tend to develop spontaneous nonremitting intestinal inflammation. These include mice deficient in IL-10, Nod1, Nod2, Tbet, or Rag1. In several cases, microbiota reduction using antibiotics, rederivation in an axenic (germ-free) environment, or colonization with the microbiota derived from a wild-type animal is sufficient to significantly inhibit the development of inflammation, as well as the severity of cancer. Therefore, as a community, the microbiota has the potential to drive both gut inflammation and the eventual progression to cancer.

The gut microbial community has also been implicated in modulating carcinogenesis outside the intestines. Infection with *Helicobacter hepaticus* enhances mammary carcinoma in mice via mechanisms dependent on innate immune activation and TNF production. In addition, TLR5 signaling promotes progression of sarcomas in mice deficient for the tumor suppressor p53 and in which the protooncogene *Kras* has been activated. This disease phenotype can be abrogated by antibiotic-mediated reduction in commensal bacterial load.

In humans, approximately one of every six cancers develop downstream of a pathogenic infection. Notable pathogen–cancer axes include *Helicobacter pylori* and gastric carcinoma, human papillomavirus (HPV) and cervical cancer, and hepatitis B and C viruses and hepatocellular carcinoma.[41] As with intestinal inflammatory diseases, the composition of the fecal and mucosal microbiota in patients with colorectal cancer (CRC) is distinct from that of healthy individuals. The differences between mucosal bacterial populations present "on" and "off" the tumors in the same patient suggest a role for site-specific bacterial community structure in disease development and/or production.[42] More specifically, correlations have been made between CRC and the presence of colonic microbes, including enterotoxigenic *Bacteroides fragilis*, *Fusobacterium nucleatum, Enterococcus faecalis*, and *E. coli*. Animal studies support a role for all these strains in Wnt signaling and myeloid cell activation of nuclear factor-κB (NF-κB)–dependent inflammatory pathways.

The Microbiota in Cancer Immunotherapy

Because of its ability to educate the immune system to be constantly poised to respond to challenge, the microbiota is now also recognized as an important ally in the fight against cancer. Seminal discoveries have been made recently in delineating the pathways whereby the microbiota-primed immune system is essential for the success of common anticancer therapeutic agents and the gut microbiota is being targeted in efforts to enhance cancer immunotherapy.[1,43] Commensal bacteria support the potency of anti–IL-10R/CpG ODN treatment (a form of immunotherapy) as well as oxaliplatin (a form of platinum salt chemotherapy) in treating colon carcinoma by enhancing the production of myeloid-derived proinflammatory cytokines and ROS, respectively. The efficacy of the alkylating drug cyclophosphamide (CTX) is reduced in germ-free mice or mice treated with vancomycin, which depletes gram-positive bacteria, as a result of diminished antitumor adaptive immune responses. The microbiota is also critical for the antitumor effects of immune checkpoint inhibitors anti–programmed death ligand 1 (PD-L1) and anti–cytotoxic T lymphocyte antigen-4 (CTLA-4).[44]

In humans, anti–CTLA-4 treatment induces mucosal damage and microbiota modification, partly as a result of partial depletion of gut Tregs. The modified microbiota and the

consequent Th1-like immune response are critical for anti–CTLA-4 antitumor functions. In this study, the microbiota of patients treated with anti–CTLA-4 was enriched with bacterial species, including *Bacteroides thetaiotaomicron, Bacteroides fragilis*, and *Burkholderia cepacia*. Transplantation of germ-free mice with *B. fragilis* and *B. cepacia* partially rescued the efficacy of anti–CTLA-4 and prevented the mucosal toxicity of the antibody.

THE SKIN MICROBIOTA AND THE IMMUNE SYSTEM

Skin Microbes Maintain Barrier Integrity in the Steady State

With a surface area of approximately 1.8 m^2, skin is the largest organ in the body. Skin functions as a physical barrier against foreign agents (Chapter 23) and also participates in thermoregulation. Unlike the warm, nutrient-rich intestinal tract, skin is cool, desiccates, and is limited in available nutrients for microbial species. Thus, skin is populated by microbial communities capable of tolerating its diverse physiology (Fig. 22.6).[45] The total bacterial content of healthy human skin averages about 1 million/cm^2, for upward of 10^{10} total cells covering a single individual (or ≈1% of the number of bacterial cells per milliliter in the distal colon). The skin microbiota is generally acquired in concert with the colonization of other barrier surfaces in infancy. However, coincident with the individual's sexual maturation during adolescence, his or her skin bacterial communities undergo a major shift.[46]

Unlike the gut microbiota, skin commensals are dispensable for the maturation of the immune compartment of the tissue. However, their involvement in resistance to infection and collateral enhancement of skin disease risk are clear.[47] In response to pathogen challenge, skin-resident microbes mount a robust innate immune response characterized by some of the more primitive and evolutionarily conserved immune system messengers—antimicrobial peptides (AMPs), including cathelicidins and β defensins, components of the complement system (Chapter 40), and IL-1. Epithelial cells constitutively express some AMPs, which can target a vast array of skin pathogens, including bacteria, fungi, viruses, and parasites. Other AMPs are induced in a microbiota-specific manner and are expressed secondary to activation of the complement system.

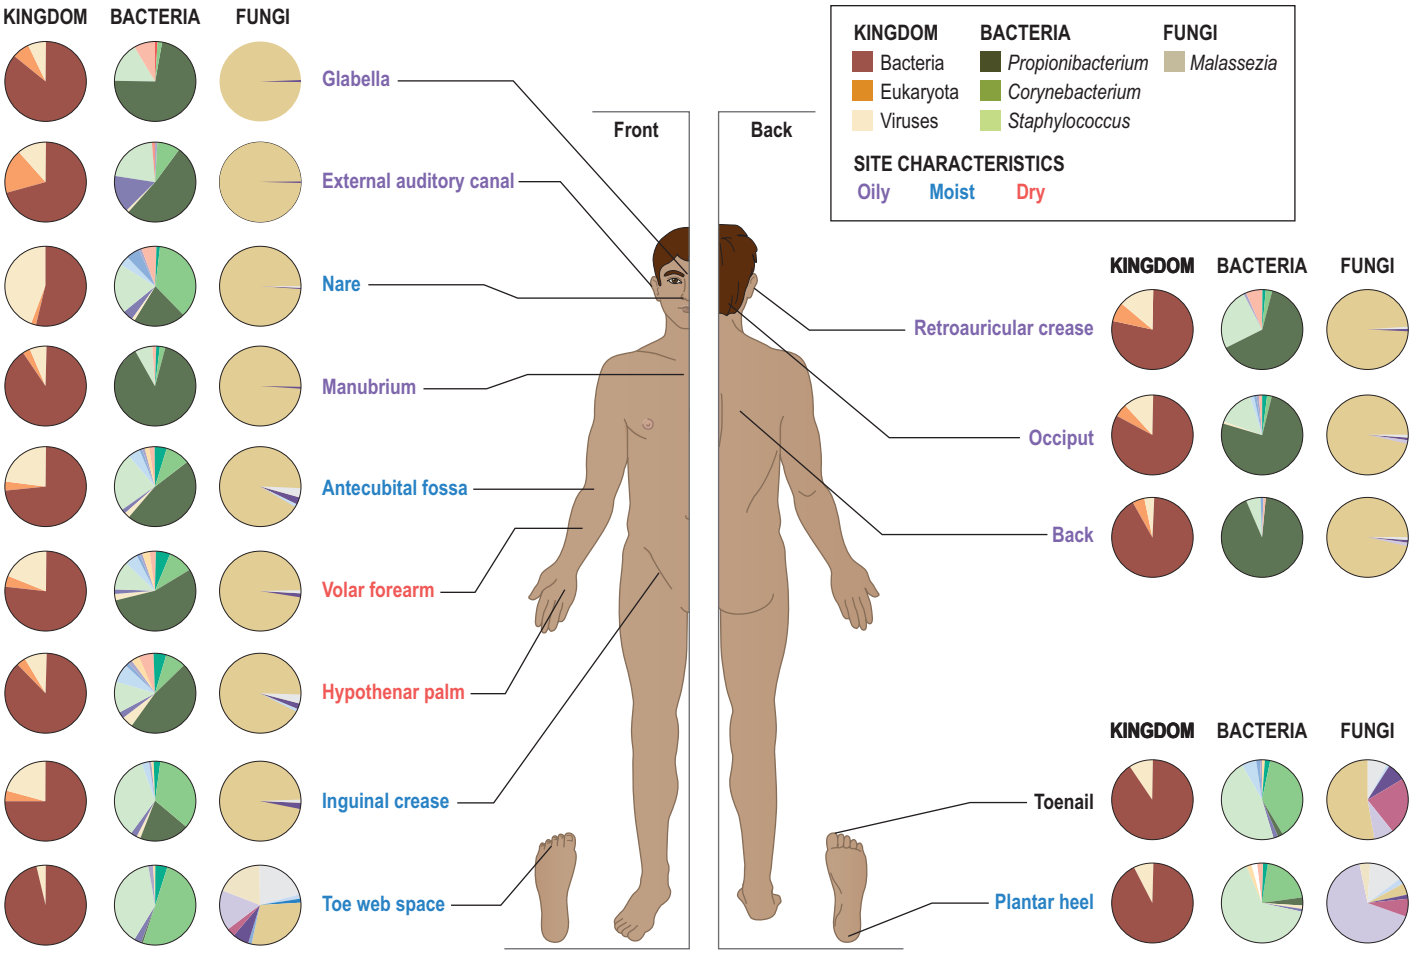

FIG. 22.6 Relative Abundance of Viral, Bacterial, and Fungal Components of The Microbial Community of Skin. Sites represent three microenvironments: sebaceous *(blue)*, dry *(red)*, and moist *(green)*. The toenail *(black)* is a site that does not fall under these major microenvironments and is treated separately. *Pie charts* represent consensus relative abundance of the different categories' kingdom, bacteria, and fungi. For bacteria and fungi, major taxa colors are identified in the legend. The minor taxa are colored to represent their relative proportion. (From Belkaid Y, Segre JA. Dialogue between skin microbiota and immunity. *Science*. 2014;346(6212):954–959, Fig. 1.)

In addition to being part of the innate response to microbial encroachment of skin, IL-1 stimulates robust adaptive immune responses that are essential for containment of both pathogens and commensals. In the skin of germ-free mice, there is reduced expression of IL-1, impaired induction of skin Th1, Th17, and IL-17-producing γδ T cells, and an elevated frequency of Foxp3$^+$ Tregs. Consequently, these mice also mount a suboptimal response to skin infection. Additionally, in germ-free mice, the reduction in adaptive immunity results in impaired containment of skin commensals and their dissemination to the draining lymph nodes. In contrast, in immune-replete mice, introduction of commensal organisms triggers the induction of CD8 T-cell responses, including the production of IL-17—which is further reinforced by DC-derived IL-1—and helps preserve the integrity of the barrier.

Skin Microbes in Chronic Inflammatory Disease

Skin dysbiosis and resultant dysregulated immune responses have been associated with inflammatory disorders, including acne vulgaris, psoriasis (Chapter 64), and atopic dermatitis (AD) (Chapter 48). Modulation of AMP production is critical, although the specific AMP, and whether it is upregulated or downregulated, can vary from one condition to the next.

In acne vulgaris, sebaceous hyperplasia and the release of lipids into the follicular lumen ultimately clogs the follicle and promotes a self-perpetuating outgrowth of *Propionibacterium acnes*. The follicular wall is breached, triggering an influx of inflammatory neutrophils and pustule formation. The expansion of *P. acnes*, as well as *Staphylococcus epidermidis*, leads to dysregulated immune responses, including elevated expression of AMPs and TLR expression by keratinocytes. These factors sustain the inflammatory response.[48]

Psoriatic lesions in human skin have been found to contain a reduced abundance of Actinobacteria, including the genus *Propionibacterium*, but an overrepresentation of Firmicutes. Overexpression of antimicrobial peptides, particularly IL-37 produced by stressed cells, is also detectable in diseased tissue.[49] IL-37 primes the innate immune response that subsequently induces development of Th1 and Th17 cells in the draining lymph nodes. The culpability of IL-17 expression in psoriasis has been confirmed by early clinical trials in which antibody-based targeting of IL-17 or the IL-17 receptor resulted in improvements in Psoriasis Area Severity Index (PASI) in at least 80% of patients after 12 weeks.[49]

Atopic dermatitis is characterized by dry skin (xerosis), which, along with the associated change in skin pH, favors the colonization and expansion of some microbes more than others. Colonization with *Staphylococcus aureus* has been linked to development of AD. *S. aureus* is detectable in the skin lesions of over 90% of patients with AD.[50] *S. aureus* infection induces both innate and adaptive immune activation. The expression of IL-37 transcript is markedly reduced in AD lesions, whereas other AMPs, including psoriasin, human β-defensin-2 and RNase 7, are overexpressed.

THE RESPIRATORY TRACT MICROBIOTA IN HEALTH AND DISEASE

Inhaled air contains bacteria, viruses, and fungi, and the respiratory tract serves as the main entry portal for these airborne microbes. However, for over a century, the healthy lung was considered a sterile environment, free of culturable and/or resident reproducing microbes. The detection of microbes in samples collected using instruments that had to traverse the mouth or nasal cavities was often assumed to have resulted from contamination with microbes from these sites. The emergence of culture-independent techniques for detection of microbial communities has precipitated an appreciation of the presence and diversity of microbial communities along the respiratory tract even in the absence of overt disease.[51] Although the airway and lung microbiota resembles the bacterial populations of the upper respiratory tract, there are differences that point to the existence of a specific lung microbiota.

The concept of a lung microbiota during health is relatively new, but the role of microbial agents in the pathogenesis of chronic lung diseases has been widely examined. In the healthy lung, the immune system eradicates potential pathogens and overcomes environmental disturbances that threaten to impair lung function. Direct impairment or intrinsic failure of the pulmonary defense mechanisms can lead to infection and/or chronic lung diseases, including asthma, chronic obstructive pulmonary disease (COPD), cystic fibrosis, and bronchiectasis.

Although microbial expansion in the lung is a characteristic of many lung diseases, it is not always clear whether the dysbiotic microbiota is the cause, the consequence, or both. Longitudinal studies have established a strong correlation between the early development of the respiratory tract microbiota and respiratory health both in infancy and adulthood. For example, the nasopharyngeal cavity is initially colonized with primarily *S. aureus* in the first few weeks of life. This is rapidly followed by an expansion of *Corynebacterium* and *Dolosigranulum*, with a subsequent transition to predominantly *Moraxella* spp. between 6 and 12 weeks of age. However, a rapid transition from *Staphylococcus* to *Moraxella*, essentially bypassing the *Corynebacterium* phase, occurred in infants who also experienced more frequent respiratory tract infections in the first year of life.

The Shaping of the Healthy Respiratory Microbiota

The bacterial density of inhaled air is approximately 10^4 to 10^6 cells/m^3. Thus, with each breath, mammals are constantly exposing their lungs to airborne bacteria. There are system-intrinsic mechanisms that serve to regulate entry and colonization of the lungs by microbes. The lung, like skin, and in stark contrast to the GI tract, is a very low nutrient resource. The thin mucus layer, which might seem to represent reduced barrier protection relative to the intestine, also means the absence of a valuable source of nutrients for certain mucophilic microbes. Furthermore, the combination of oxygen tension, temperature, regional pH, the diverse architecture of the respiratory tract, and the proximity of inflammatory cells all help keep the bacterial biomass of the lungs extremely low relative to that of the gut.

In a healthy individual, community composition at any given time is largely determined by the relative amount of microbial immigration and elimination. The major routes of immigration are microaspiration, air inhalation, and direct dispersion along the mucosal surface. Elimination is a continuous process mediated by the ciliated epithelial cells, by coughing, and by the actions of the pulmonary immune system. Colonization and growth contribute minimally to microbiota composition during homeostasis but are favored by changes in regional conditions that promote and/or sustain chronic inflammatory diseases of the lung.

Similar to the intestinal microbiota, the microbiota of the upper respiratory tract stabilizes in early childhood and can be

influenced by external factors, including breastfeeding, use of antibiotics, and social interactions as occurs in daycare and in multi-sibling households.[52] In a healthy lung, there is little spatial variation within the same individual. This lack of variation supports the theory that the composition of the lung microbiota is more heavily influenced by immigration and elimination than by local growth.

The most abundant bacterial phyla in the lung are Bacteroidetes and Firmicutes. At the genus level, *Prevotella, Veillonella*, and *Streptococcus* predominate. There are also prominent fungal communities, with dramatic differences in composition observed in different healthy cohorts. The oral cavity is home to several genera of fungi, including *Candida, Cladosporium*, and *Aspergillus;* but the fungal colonization of a healthy lung is unclear. Considering the constant exposure of the lung to oral and inhaled fungi, it is likely that the immune apparatus of the lung does, indeed, encounter fungal antigens in the steady state.

The involvement of the bacterial communities of other body sites, particularly the intestines, in lung immune homeostasis is still being actively explored. This phenomenon is commonly referred to as the "gut–lung axis" and involves the action of soluble mediators produced and/or induced by the gut microbiota that can enter the systemic circulation. By this rationale, this phenomenon is more a reflection of the intestinal microbiota on the organism as a whole and not representative of a unique relationship between these two organs. Nevertheless, there is compelling evidence that modulation of the gut microbiota, particularly during infancy, can have lifelong effects on lung immunity and susceptibility to chronic diseases.

MICROBES AS THERAPY

Certain infections or chronic inflammatory disorders are associated with a severely damaged microbiota. Transplantation of healthy donor microbiota has emerged as a successful therapeutic approach to repair and/or restore microbial communities. Fecal microbiota therapy (FMT), or fecal transplantation, has been safely and effectively utilized as a last resort to treat chronic *Clostridium difficile* infection. FMT presents the risk of adverse effects because the transplanted microbes, which are dormant in the donor, experience propathogenic conditions in the recipient. Because of the successes to date, empirical information regarding the long-term stability and resilience of one individual's microbiota transplanted into another should emerge over time. Other, more focused approaches that employ distinct microbes, groups of microbes, or microbial products known to have immune cell-specific effects to treat inflammatory diseases, such as IBD, are also being considered.

In Western, industrialized societies, there has been a consistent upward trend in the incidence of autoimmune diseases, and this has been linked to improved sanitation and diets low in fiber but rich in unhealthy fats and carbohydrates. These factors have contributed to dramatic shifts in microbial diversity away from that of our ancestral microbiota. Restoration of the richness of the microbiota using *probiotics*—live microorganisms that, when administered in adequate amounts, provide a measurable health benefit to the host—may be helpful in slowing and possibly reversing this trend. Long-term persistence of probiotic organisms within the complex microbiota of the host is essential if these organisms are to induce durable shifts in microbiota dynamics. Complementary *prebiotic* regimens that support the growth and survival of the introduced microbes without detrimental alterations in the distribution of functions of other species will likely be helpful in this regard.

SUMMARY

ON THE HORIZON

- Improved understanding of the structure and function of the microbiota in health and disease:
  - Microbial reconstruction in neonatal life to limit the immediate and long-term effects of cesarean delivery, preterm birth, and oral antibiotics on immune function.
  - Commensal microbes as a rich source of biological agents that can be used to regulate community development and resistance.
  - Improved approaches for the collection and study of organisms that inhabit the mucus layer of the gastrointestinal tract as opposed to just those expelled in the feces.
- Precision medicine and the microbiome:
  - Use of advanced genomic techniques for detailed assessment of microbiota functions in health and specific diseases.
  - Application of host genome and microbiome data to predict disease susceptibility and responses to therapy.
  - Targeting of the microbiota to enhance vaccine efficacy.
  - Assembly of limited "designer microbiotas" to initiate therapeutic reconstruction of dysbiotic patient microbiota.

The peaceful interaction between humans and the microbes that colonize them is essential for a healthy life. As such, the coexistence of the two entities occurs in an organized fashion, and we now know that this commences in utero and is subject to perturbations that can have dire consequences. The involvement of the microbiota as an instigator and/or sustainer of chronic inflammatory diseases and cancer continues to be explored. In the future, these studies may identify novel avenues for targeting certain conditions and restoring the immune balance. Our growing understanding of the essential roles of the microbiota in diverse physiological processes presents new opportunities to harness these capabilities across the clinical spectrum.

Immunology of the Skin

Hui Xu, Nabiha Yusuf, and Craig A. Elmets

Skin, which is the largest organ in the body, is the major interface between an individual and his/her environment. It comprises 12% to 16% of the body's weight and functions chiefly to protect against environmental threats. It also plays an important homeostatic role in maintaining body temperature, water and electrolyte balance, and vitamin D production. It acts as a barrier against invading pathogens, exogenous chemicals, and the destructive effects of physical agents, such as the sun, wind, and heat. To perform these various functions, the epidermis of the skin consists of three specialized compartments—the stratum corneum, the granular layer, and the basal layer—that are layered on top of each other (Fig. 23.1). In turn, the epidermis rests on the dermis, which then rests on the hypodermis. Adnexal tissues, which include hair, nails, sebaceous glands, and eccrine and apocrine sweat glands, are embedded within these tissues to provide specialized protective functions.

KEY CONCEPTS

Primary Functions of Skin

- Body's largest organ (12% to 16% of body weight with a surface area of ≈2 m^2).
- Principal organ for homeostatic thermoregulation and regulation of fluid retention and evaporation.
- Specialized sensory cells create a skin-wide tactile interface with the environment (e.g., fingertips with >2500 sensory cells/cm^2).
- Photosynthetic surface that uses ultraviolet radiation (UVR) to produce cholecalciferol (vitamin D_3).
- Physical barrier to physical stresses, including shear forces, extreme temperatures, wind, water, and solar radiation. Tight junctions between granular layer keratinocytes block entry of small molecules and microbes.
- By virtue of detoxification enzymes, pharmacological barrier to chemicals and other carcinogens (e.g., UVR and ionizing radiation).
- Regenerative organ that continuously replaces older, damaged skin cells, which are eliminated and shed from skin as anucleated squames.
- Immunological barrier using innate and adaptive immune mechanisms against exogenous antigens, microbial pathogens, and endogenous neoplastic cells.

The outermost layer of skin is the epidermis. Blood and lymphatic vessels are absent. However, oxygen and nutrients diffuse to epidermal cells from the microvasculature that is housed in the dermis that lies beneath the epidermis. Approximately 95% of cells within the epidermis are keratinocytes. These form a self-renewing stratified squamous epithelium, which differentiates from bottom to top from a regenerating basal layer containing cuboidal cells to the outer most superficial layer, called the *stratum corneum*, composed of flat, anucleate, compact scales. Keratin intermediate filaments are the major proteins produced by keratinocytes. The type of heterodimers that are made by keratins during differentiation affects the cytoskeletal structure and cell morphology.

Keratinocytes bind to one another through specialized adherence junctions called *desmosomes*. Keratin filaments attach to desmosomal proteins to provide structural, tensile strength. As differentiation proceeds, the composition of the keratin and desmosomal proteins changes. For example, basal layer keratinocytes synthesize keratins 5 and 14, and the desmosomal protein desmoglein 3 is more abundant than desmoglein 1. In the stratum corneum, keratins 1 and 10 and desmoglein 1 are all highly expressed, but keratins 5 and 14 and desmoglein 3 are absent. Finally, the compact tough outer scales (squames) of the stratum corneum are cross-linked with keratin filaments. The differences in protein localization between the epidermal layers have consequences for immunologically mediated skin diseases. Pemphigus vulgaris, a disease in which autoantibodies are formed against desmogleins 1 and 3 (Chapter 63), presents with blisters that originate in the suprabasal layer of the epidermis. Conversely, the closely related disease pemphigus foliaceus, in which autoantibodies recognize only desmoglein 1, results in blisters located exclusively in the upper epidermis.[1]

The remaining cells located in the epidermis are pigment-producing melanocytes, neuroendocrine Merkel cells (important for mechanoreception), and Langerhans cells (LCs) (specialized epidermal antigen-presenting cells [APCs]). Melanocytes are derived from the neural crest, and progenitors seed the epidermis early in development. They synthesize melanin pigment in organelles called *melanosomes*. Melanosomes mature into the melanin-filled granules, which are then transferred and internalized by keratinocytes. Melanin absorbs the damaging effects of ultraviolet radiation (UVR) and protects skin keratinocytes. When stimulated by cytokines, melanocytes express several immunologically relevant proteins, including intracellular adhesion molecule 1 (ICAM-1; CD54), costimulatory receptor CD40, and major histocompatibility complex (MHC) class I and II molecules (Chapter 5).[2]

Malignant melanomas arise from melanocytes. These tumors evade the host immune response, at least in part, through expression of programmed death ligand 1 (PD-L1) (Chapter 17). PD-L1 is an immune checkpoint molecule found on tumor cells and myeloid derived suppressor cells (Chapter 80). The interaction of PD-L1 with PD-1 receptors on T cells inhibits their antitumor activity. The monoclonal antibodies (mAbs),

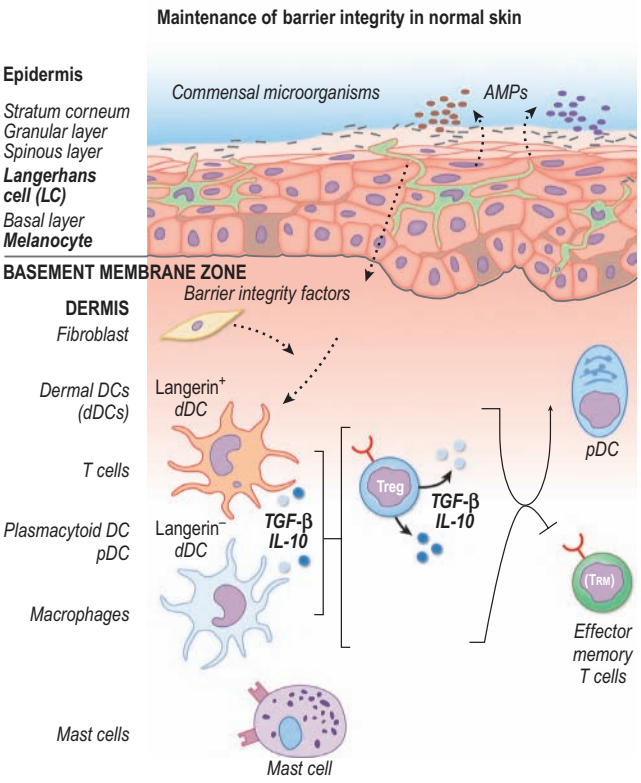

FIG. 23.1 Histological Features of Normal Skin. The epidermis is made up of keratinocytes organized into stratified layers. The most superficial layer is the stratum corneum *(light pink)*. Granular layer cells also secrete antimicrobial peptides *(AMPs)*. The basal layer *(tan)* contains the proliferative cells that give rise to all the differentiated suprabasal keratinocytes. Keratinocytes are connected to each other through tight junctions *(dark grey)*. Basal cells are bound to the basement membrane *(black line)* and share that scaffold with interspersed melanocytes *(brown)*. Langerhans cells *(LCs) (green)* are epidermal antigen-presenting cells (APCs) that reside in the suprabasal layer of the epidermis. The dermis contains a number of dendritic cell (DC) subsets, including langerin$^+$ *(orange)* and langerin$^-$ *(light blue)* dermal DCs (dDCs). Plasmacytoid DCs *(pDCs)* are found in the dermis and secrete type I interferons *(aqua)*. Resident memory T cells (T_{RM}) *(green)* represent previously primed T cells in many lineages (Th1, CTL, Th17, Tc17, Treg) poised to respond when their specific antigens are presented locally. They are quiescent in uninfected skin. Mast cells *(purple)* reside near endothelial venules (not shown). *TGF*, Transforming growth factor. (Drawing by Laura Timares, PhD.)

pembrolizumab and nivolumab, that block the PD-1 interaction with PD-L1 can restore antitumor responses. Tumor immunotherapy with these antibodies results in objective responses and prolonged survival in patients with metastatic melanoma. Ipilimumab, which blocks cytotoxic T lymphocyte antigen-4 (CTLA-4), another immune checkpoint inhibitor, is also effective against melanoma.

The dermis lies beneath the epidermis and serves as a connective tissue layer that provides elasticity and tensile strength to skin. It is filled with a matrix of collagen bundles, elastic fibers, glycoproteins, proteoglycans, and glycosaminoglycans, all of which are produced by dermal fibroblasts. The production of collagen is a dynamic process that involves continual remodeling. Fibroblasts must balance ongoing synthesis of matrix components with the production of matrix metalloproteinases (MMPs) that degrade the matrix. Scleroderma and morphea (also known as localized scleroderma) (Chapter 56) are inflammatory disorders that lead to the overproduction of dermal collagen, thus hardening the skin.

Other cell types normally found in the dermis are mast cells and diverse sets of tissue macrophages (Chapter 44) and dendritic cells (DCs) (Chapter 6).[3] The dermis also supports the microvasculature of skin. Endothelial cells of dermal arterioles, capillaries, and post capillary venules behave differently from those in larger vessels. They express E- and P-selectins, to which circulating skin-homing T cells bind through their homing receptors cutaneous lymphocyte-associated antigen (CLA) and P-selectin glycoprotein ligand (PSGL), respectively. Both homeostatic T-cell trafficking and recruitment of inflammatory leukocytes into skin from the circulation require expression of E- and P-selectins (Chapter 16). The egress of leukocytes from blood occurs primarily through post capillary venules. Egress is regulated, in part, by endothelial responses to cutaneous cytokines and chemokines. New vessels can also develop in skin. They can worsen immunologically mediated dermatological diseases and promote tumor development.

The dermis is separated from the epidermis by the basement membrane. This structure creates a scaffold to which basal keratinocytes and melanocytes are attached. It acts as a selective diffusion barrier that permits passage of necessary small-molecule nutrients while retarding entry of macromolecules and inflammatory cells. In patients with systemic lupus erythematosus (SLE) (Chapter 52), antigen–antibody complexes accumulate at the basement membrane. In addition, skin-specific proteins present in the basement membrane are targets of such autoimmune blistering diseases as bullous pemphigoid and epidermolysis bullosa acquisita (Chapter 63).

The hypodermis lies beneath the dermis and attaches skin to underlying muscle. It is composed mainly of adipose tissue, which cushions skin impacts. Adipose cells produce leptin, which is implicated in a variety of inflammatory skin diseases, including psoriasis (Chapter 64).

The skin protects individuals from exogenous threats through three major barriers: *(i)* physical, *(ii)* pharmacological or detoxifying, and *(iii)* immunological. *The physical barrier* includes the hair and stratum corneum. The stratum corneum provides an impermeable hydrophobic cover of protein-filled squames that hinders the entry of invading microorganisms or toxic chemicals into the body. It also reflects and scatters ultraviolet radiation (UVR), blocking it from reaching the deeper, regenerating layers of skin. *The pharmacological barrier* includes detoxifying and repair enzymes synthesized by epidermal cells. Some metabolize chemicals and xenobiotics, whereas others repair DNA damage resulting from UVR or environmental mutagens.

The immunological barrier includes cells and molecules unique to skin that are historically referred to as "skin-associated lymphoid tissue." They include elements of both innate and acquired immunity. Locally they enhance host defenses that protect affected skin from antigens and pathogens that are present in that site. Systemically, they alert the rest of the body to encourage and expand host defenses. Although these protective measures work exceedingly well, they do not work perfectly. Disturbances in these protective mechanisms can result in increased infections and malignancies when deficient or in immunologically mediated skin diseases when excessive (Table 23.1).

KEY CONCEPTS

Immunological Defenses of Skin

- Innate defenses provide the first line of protection against environmental antigens and pathogens.
- In response to pathogen-associated molecular patterns (PAMPs) and danger-associated molecular patterns (DAMPs), granular layer keratinocytes produce cutaneous microbicidal peptides and proinflammatory mediators.
- At initial skin breach, neighboring keratinocytes and dendritic cells (DCs) initiate and perpetuate a proinflammatory cascade of events.
- Langerhans cells internalize microbes, produce cytokines, migrate from skin to regional lymph nodes, and mature into potent antigen-presenting cells (APCs).
- In lymph nodes, DCs deliver antigens from affected skin to lymph node (LN) resident DCs to initiate and amplify skin-specific immunity.
- Keratinocyte-derived proinflammatory mediators and chemokines act on post endothelial venules to promote extravasation of neutrophils, monocytes/macrophages, natural killer (NK) cells, and memory T cells from the circulation into the dermis.
- In order to clear affected epidermis of invading pathogens and cellular debris, immigrant inflammatory leukocytes attach to activated keratinocytes through interactions with CD54 (intercellular adhesion molecule 1 [ICAM-1]).

MOLECULES PRIMARILY ASSOCIATED WITH INNATE IMMUNITY AND SKIN

Pattern Recognition Receptors

By rapidly sensing and responding to microbial pathogens and environmental toxins, epidermal keratinocytes act as innate first responders (Chapter 3). Keratinocyte pattern recognition receptors (PRRs) recognize highly conserved sequences in macromolecular components of microbial pathogens and host-derived danger indicators. Collectively, PRRs are promising therapeutic targets for cutaneous immune disorders and skin cancer.

Identification of pathogen-associated molecular patterns (PAMPs) and danger-associated molecular patterns (DAMPs) is principally undertaken by an array of PPRs, which include Toll-like receptors (TLRs), NOD-like receptors (NLRs), RIG-I-like receptors (RLRs), and C-type lectin receptors (CLRs).[4] Human keratinocytes express TLRs 1 to 6, and 9. Human melanocytes constitutively express TLRs 2 to 5, and 9.[5]

Human and murine DC subsets show differential TLR expression profiles. For example, conventional DCs (cDCs) express combinations of TLRs 1 to 5 and 8, whereas TLR expression is restricted to virus-detecting endosomal TLRs 7 and 9 in plasmacytoid DCs (pDCs). The latter is consistent with their primary function as major interferon-α (IFN-α) producers.

TLR ligands are derived from conserved microbial products (e.g., lipopolysaccharides, lipoteichoic acid, peptidoglycans, mannans, nucleic acids from viral and bacterial pathogens, and endogenous DNA from stressed host cells). DAMPs are recognized by NLRs. In the clinic, the TLR7 agonist imiquimod is used as an effective topical agent for eliminating human papillomavirus (HPV)–induced genital warts and nonmelanoma skin tumors.

The nucleotide-binding oligomerization domain-like receptors (NLRs) have over 20 members in humans, reflecting the broad spectrum of PAMPs and DAMPs they recognize. Mutations and gene single nucleotide polymorphisms are associated with inflammatory diseases in the skin. Also present are cytosolic NLRs. Although often with partial overlap, TLR and NLR

TABLE 23.1 Immunodermatological Disorders That Affect the Skin

- Papulosquamous disorders
  - Psoriasis
  - Lichen planus
  - Cutaneous graft-versus-host disease
  - Acute, subacute, and discoid lupus erythematosus
- Eczematous disorders
  - Atopic dermatitis
  - Allergic contact dermatitis
- Urticarial disorders
  - Urticaria and angioedema
  - Erythema multiforme
  - Stevens-Johnson syndrome
  - Toxic epidermal necrolysis
  - Autoinflammatory diseases (e.g., cryopyrin-associated periodic syndromes, Muckle-Wells syndrome, familial cold urticarial, neonatal-onset multisystem inflammatory disease [NOMID], deficiency of the interleukin-1–receptor antagonist [DIRA], tumor necrosis factor receptor–associated periodic syndrome [TRAPS])
- Purpuric disorders
  - Leukocytoclastic vasculitis
  - Medium vessel vasculitides (polyarteritis nodosa, granulomatosis with polyangiitis, eosinophilic granulomatosis with polyangiitis (EGPA))
- Vesiculobullous diseases
  - Pemphigus
  - Bullous pemphigoid
  - Paraneoplastic pemphigus
  - Epidermolysis bullosa acquisita
  - Dermatitis herpetiformis
  - Linear immunoglobulin A (IgA) bullous dermatoses
  - Pemphigus gestationis
- Pigmentary disorders
  - Vitiligo
- Hair disorders
  - Alopecia areata
- Autoimmune disorders
  - Acute, subacute, and discoid lupus erythematous
  - Dermatomyositis
  - Mixed connective tissue disease
  - Scleroderma and morphea
- Photodermatoses
  - Polymorphous light eruption
  - Solar urticaria
  - Chronic actinic dermatitis
  - Photoallergic contact dermatitis
- Allergic drug eruptions
- Disorders of subcutaneous tissues
  - Erythema nodosum
  - Erythema induratum
- Immunodeficiencies
  - Ataxia telangiectasia
  - Chronic mucocutaneous candidiasis
  - Chronic granulomatous disease
  - Hyper-immunoglobulin-E (IgE) syndrome (HIES)
  - Leukocyte adhesion molecule deficiency
  - Severe combined immunodeficiency
  - Warts–hypogammaglobulinemia–infections–myelokathexis syndrome (WHIM syndrome)
  - Wiskott-Aldrich syndrome
  - Organ transplant recipients on immunosuppressive medications

expression profiles differ among epidermal and leukocyte cell subsets.

NLRs can be divided into four subfamilies: (i) NLRA, (ii) NLRB, (iii) NLRC, and (iv) NLRC. NLRC is expressed in many tissues, including keratinocytes in the skin. Primary human keratinocytes also express mRNA transcripts for 11 of 14 NLRP family genes.[4] NLR units that recruit and activate the inflammatory protease caspase-1 are known as inflammasomes. NLRs act independently, but in synergy with TLR signals, to trigger fast-acting potent innate immune responses against microbes. They can either promote nuclear factor kappa B (NF-κB) activation or form inflammasomes that generate interleukin-1 (IL-1) and IL-18 family proinflammatory mediators. The set of TLRs and NLRs triggered determines the type and magnitude of the immunomodulatory or inflammatory response that will result.

CLRs are involved in recognition of types of viruses. Several CLRs, including DC-specific ICAM-3 grabbing non-integrin (DC-SIGN), Langerin, mannose receptor, C-type lectin domain family 4 member A (CLEC4A), C-type lectin domain family 5 member A (CLEC5A), and C-type lectin domain family 9 member A (CLEC9A), bind to viruses that invade the skin. Dectin-1 is a membrane-associated glycoprotein that is found on keratinocytes, DCs, and monocytes. It recognizes β-glucan and is involved in the host response to fungal pathogens. Its activation results in production of IL-1β, IL-6, and IL-23 (Chapter 14), which promotes development of Th17 cells, which are important antifungal effector cells (Chapter 11). Patients lacking dectin-1 exhibit Th17-cell deficiency, recurrent vulvovaginal *Candida albicans* infections, and onychomycosis (Chapter 29). Mutations in Card9, a mediator of dectin-1 signal transduction, also lead to Th17 deficiency and chronic mucocutaneous candidiasis.[6]

RLRs, (RIG-I, MDA5, and LGP2) sense viral dsRNA during cutaneous viral infections and DNA released from damaged host cells. RLRs have an important role in type I IFN production.[7] RIG-I signaling can drive IL-23 production and induce psoriasis-like skin disease in mice.[8]

Antimicrobial Peptides

Skin is a production site for antimicrobial peptides, which are important components of the innate immune response.[9] Over 20 antimicrobial peptides have been identified. They function at the earliest stages of infection by microorganisms that breach the stratum corneum. These antimicrobial peptides disrupt bacterial and fungal membranes, and viral envelopes. They have broad effects on innate and adaptive immune responses. The two best characterized skin antimicrobial peptides are the cathelicidins and β-defensins. They are synthesized by keratinocytes, cells of the epidermal sebaceous and eccrine glands, and dermal mast cells. Cathelicidins are secreted as precursor proteins (e.g., hCAP18), which are then processed to an active form (e.g., LL-37). They are detected at low levels in unperturbed skin and are strongly increased following infection or disruption of the epidermal barrier.

Cathelicidins interact with a variety of cell-surface receptors (e.g., TLR-like and endothelial growth factor [EGF] receptors). In skin, they enhance leukocyte migration, stimulate the secretion of cytokines (Chapter 14) and chemokines (Chapter 15), and promote angiogenesis. Vitamin D_3, whose synthesis is initiated in skin by UVR, plays an important role in regulating cathelicidin production through epigenetic mechanisms.[10]

Abnormalities in antimicrobial peptides have been implicated in a variety of immunological and non-immunological skin diseases. Deficiencies in antimicrobial peptides have been found in patients with atopic dermatitis (Chapter 48), which may explain why they are at risk for viral (herpes simplex, vaccinia, HPV-induced warts, poxvirus-induced molluscum contagiosum) and bacterial *(Staphylococcus aureus)* skin infections.

Rosacea manifests as an acneiform eruption with erythema, telangiectasias, and flushing of the face. Excessive amounts of cathelicidins are associated with the characteristic inflammation and angiogenesis in that disease.[11]

In psoriasis (Chapter 64), cathelicidins are postulated to combine with self-DNA from damaged keratinocytes. This stimulates type I IFN production by pDCs, which is a key to the development of pathogenic Th17 cells.[12]

Non-immune mechanisms that cause physical disruption of the skin barrier (e.g., shear forces, chemical, thermal, or UV damage) stimulate "sterile" inflammatory responses that produce similar proinflammatory mediators and antimicrobial peptides to protect vulnerable sites during wound healing.

Cytokines and Chemokines in the Skin

Skin is a rich source of cytokines (Chapter 14) and chemokines (Chapter 15). They are involved in both innate and adaptive immune responses. They influence the magnitude and type of cutaneous immune response generated (Table 23.2).[13] Although many chemokines and cytokines produced in skin are identical to those secreted by non-skin cells, in skin they can have unique effects.

Cutaneous cytokines and chemokines are also important contributors to systemic responses to injury, wound healing, carcinogenesis, and pigmentation. For example, IL-1 can remodel the dermis by inducing matrix metalloproteinases (MMP) production and augmenting collagen production. Production of these mediators in skin involves several different cell types and environmental stimuli (see Table 23.2). Polymorphisms in cytokine genes and their receptors have been associated with a variety of inflammatory diseases. For example, polymorphisms in the tumor necrosis factor (TNF) signaling pathway and in the IL-23 receptor are risk factors for psoriasis.

Two cytokines produced by keratinocytes and epidermal LCs are particularly important for activation of T cells. IL-12 facilitates the generation of Th1 cells; IL-23 has a stimulatory role for the generation of Th17 cells (Chapter 11). Because IL-23 promotes Th17-cell development, antibodies that block the p19 subunit of IL-23 (guselkumab, risankizumab, tildrakizumab, bimekizumab) or the p23 subunit common to both IL-12 and IL-23 (ustekinumab) are effective therapeutic agents for psoriasis.

TABLE 23.2 Cytokines Produced by the Skin

- Keratinocytes
  - Proinflammatory (IL-1, IL-6, IL-33, TNF-α)
  - Immunosuppressive and antiinflammatory (IL-10, TGF-α, TGF-β, IL-1 receptor antagonist [IL-1RA])
  - Colony-stimulating factors (GM-CSF, G-CSF, and M-CSF)
  - Immunomodulatory (IL-7, IL-12, IL-15, IL-18, IL-19, IL-20, IL-23)
  - Chemokines (CXCL8/IL-8, CCL2/MCP-1, CCL20/MIP3α, CCL5/RANTES).
- Langerhans cells
  - Proinflammatory (IL-1α, IL-1β)
  - T-cell maturation (IL-12, IL-23)
  - Chemokines (CCL3/MIP1α, CCL4/MIP1αβ, CCL5/RANTES)
- Melanocytes
  - Proinflammatory (IL-1β, IL-6, TNF-α)
  - Type I interferons (IFN-α, IFN-β)
  - Chemokines (CXCL8/IL-8, CCL2, CCL3, and CCL5)

Chemokines facilitate leukocyte migration and thus skin inflammation and antigen-specific responses (Table 23.3).[13] CXCL12 facilitates DC migration out of skin. CCL17 and CCL27, produced by keratinocytes and dermal cells, facilitate transmigration of circulating skin-homing T cells (expressing the chemokine receptors CCR4 and CCR10). Human skin–resident T cells are retained through the interaction of their chemokine receptor CCR8 and its ligand CCL1 bound to the dermal matrix.[13] Secondary lymphoid chemokine (SLC, CCL21) attracts $CCR7^+$ DCs and T cells from skin to lymph nodes. During inflammation, CXCL1 and CXCL8/IL-8 expedite infiltration of granulocytes and monocytes into skin. Cutaneous T-cell lymphoma (Chapter 78) is a disease in which a malignant population of skin-homing T cells accumulate in skin. The malignant T cells express CCR4 chemokine receptor. Humanized mAbs directed against the CCR4 receptor on T cells (mogamulizumab) are effective at treating this condition.[14]

CYTOKINE SIGNALING

The Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathway is important for downstream signaling of several inflammatory cytokines and multiple growth factors. When cytokines bind to their receptors, it causes phosphorylation of JAK and STAT proteins. The dimerized STATs translocate to the nucleus, and regulate transcription of inflammatory cytokine genes.[15] Numerous inflammatory skin diseases are triggered by soluble inflammatory mediators, which depend on JAK/STAT signaling. Therapeutic intervention can thus simultaneously block the functions of several cytokines. Currently, JAK inhibitors (JAKi) are approved in oral formulations (tofacitinib and baricitinib). They are being tested as therapeutic agents for alopecia areata, atopic dermatitis, dermatomyositis, cutaneous graft-versus-host-disease, hidradenitis suppurativa, lichen planus, lupus erythematosus, psoriasis, and vitiligo.[15] Because of adverse effects associated with JAKi, nanoformulations with greater cutaneous absorption are in development for topical treatment.

Cytokine-Related Autoinflammatory Diseases

Mutations in cytokines are a common feature of autoinflammatory disorders.[16] Examples are familial Mediterranean fever, cryopyrin-associated periodic syndromes, deficiency of the IL-1 receptor antagonist (DIRA), and TNF receptor associated

TABLE 23.3 T-Cell Subsets and Trafficking in Skin

T-Cell Subset	Homing-R[a]	Chemokine-R	From	Homing to	Ligands for Homing and Chemokine Receptors
Naïve T cells	L-selectin (CD62L) Lymph node (LN) homing receptor	$CCR7^+$	Blood	LN	L-selectin ligand: GlyCAM-1 integrin on LN HEV[b]
Central memory T cells (T_{CM}) $CD45RA^+$	L-selectin	$CCR7^+$	LN	LN and the circulation	CCR7 ligand: LN-derived chemokine CCL21 (also called 6Ckine), secondary lymphoid-tissue chemokine (SLC)
Resident memory T cells (T_{RM}) $CD45RO^+$	Cutaneous lymphocyte-associated antigen (CLA^+) (P-selectin glycoprotein ligand-1 [PSGL-1]) Skin-homing receptor	$CCR4^+$	LN	Blood/dermis	CLA ligand: E-selectin on activated post capillary venules CCR4 ligand: skin-derived inflammatory chemokines: MCP-1, MIP-1, RANTES, TARC, CCL22
T_{RM} Subsets Resident in Dermis	**Homing-R**	**Chemokine-R**	**Function**	**Cytokines Produced**	**Notes**
T regulatory (Treg)	CLA^+	$CCR5^+$	Regulatory; resolution phase; inhibit autoreactivity	Interleukin (IL)-10, transforming growth factor (TGF)-β	Tregs are 5%–10% of CLA^+ dermal T cells Treg two-way trafficking–migration from dermis to LN, then recirculate back to dermis CCR5 binds RANTES, MIP-1
T-helper (Th)1, Tc1	CLA^+	$CCR4^+$	Type I antiviral	Interferon (IFN)-γ, tumor necrosis factor (TNF)-α, IL-2	Promotes cellular immunity Development of cytotoxic T cells (CTLs)
Th2, Tc2	CLA^+	$CCR4^+$	Type II parasites cleared	IL-4, IL-5, IL-10, and IL-13	Promotes humoral immunity Recruitment of eosinophils
Th17, Tc17	CLA^+	$CCR4^+$	Inflammatory; antifungal; antibacterial		Activation is dependent on IL-23 derived from keratinocytes/Langerhans cells (LCs)/dendritic cells (DCs)

T-cell distribution density in skin ≈1 million T cells/cm^2.
[a]Homing-R—an adhesion molecule on leukocytes that recognizes and binds site-specific adhesion molecules expressed on high endothelial venules in the lymph node (LN) and activated post capillary venules in the dermis and other organs.
[b]Selectin is the lymph node homing receptor, whereas CLA is the skin-homing receptor.
HEV, High endothelial venules; these are post capillary venous swellings in lymph nodes and most secondary lymphoid organs.

periodic syndrome (TRAPS). These diseases cause fever and arthralgias. Cutaneous manifestations are also particularly common and include atypical urticarial and vasculitic rashes, and other unusual expressions of cutaneous inflammation. For example, DIRA, associated with a mutation in the gene that encodes the IL-1–receptor antagonist, causes severe pustulosis, ichthyosiform lesions, psoriasis-like changes, and nail abnormalities.[16]

KEY CONCEPTS

- Skin-resident and recirculating immunocompetent cells and immune mediators defend against microorganisms, noxious exogenous chemicals, and somatically mutated cells.
- Excessive or dysregulated immune system activity can give rise to autoimmune skin diseases (e.g., production of desmogleins-1 and -3 binding antibodies in pemphigus).
- Underperforming immune system activity can lead to cutaneous immunodeficiency (e.g., skin cancers in patients receiving immunosuppressive medications).
- Skin-specific immune system components provide targets for new therapies (e.g., treatment with neutralizing IL-17 binding antibodies in psoriasis).

CELLULAR COMPONENTS OF THE CUTANEOUS ADAPTIVE IMMUNE RESPONSE

Innate immunity forms the first line of defense against microbial threats in an antigen-nonspecific manner. The host's adaptive immune response provides a second line of protection. In contrast to innate immunity, adaptive immunity is able to distinguish self from nonself to eliminate microbial-infected or mutated cancer cells in an antigen-specific manner without damaging normal cells. The adaptive immune response in skin is carried out primarily by T cells. T-cell mediated immunity is dependent on activation by antigen-presenting DCs.

DENDRITIC CELLS

DCs are a heterogeneous group of leukocytes that, as the name implies, are composed of a central nucleated body from which dendrites emanate. This ensures a large surface area for interaction with T cells and with which to sample the surrounding environment (Fig. 23.2) (Chapter 6). Under resting conditions, two different types of DCs are present in skin: myeloid-derived cDCs and pDCs. cDCs are potent APCs. pDCs are less dendritic and are ineffective APCs, but produce type I IFNs in the skin. pDCs reside in the dermis and are a cellular component of the innate immune response. Unlike conventional DCs, pDCs function primarily to release type I IFN-α and -β. pDCs have also been implicated in the pathogenesis of psoriasis (Chapter 64). In perturbed skin, inflammatory DCs (iDCs) accumulate to produce abundant levels of TNF-α and inducible nitric oxide synthase (iNOS). They are derived from circulating monocytes that differentiate into DCs upon transendothelial migration into inflamed dermis.

To perform antigen-presenting function, LCs and DCs express antigen capture receptors that internalize bound microbes and antigens into processing endosomes, where antigens are cleaved and trimmed into short peptides and then loaded into the peptide-binding groove of MHC (human leukocyte antigen [HLA]) molecules in human) (Chapters 5 and 6). Peptide–MHC molecular complexes are then "presented" at the surface of DCs for recognition by antigen-specific T-cell receptors (TCRs) (Chapter 4) on naïve and/or memory T cells. Through integration of environmental signals, LCs and DCs are able to program naïve T cells into appropriate, functionally distinct subsets of skin-homing effector cells that can respond to a specific pathogen.

Epidermal Langerhans Cells

LCs are specialized epidermal DCs originally discovered by Paul Langerhans in 1868. They are potent APCs for activation of T cells. In normal skin, resting LCs reside in the suprabasal layer of the epidermis. There they cover the entire skin surface in a net-like structure (see Fig. 23.2). LCs represent 1% to 3% of all cells in the epidermis. They are poised to sense and respond to microbial infections or physical breaches of epidermal integrity. LCs are identified by selective expression of the antigen capture receptor langerin (CD207), a C-type lectin. Langerin internalizes to form a definitive "tennis racket–shaped" organelle called the *Birbeck granule*, which is a specialized antigen-processing compartment (see Fig. 23.2). Human LCs are also identified by their expression of CD1a. This protein is structurally similar to MHC/HLA class I molecules but presents lipid and glycolipid microbial antigens, rather than peptides, to specialized populations of T cells. In vivo studies of mouse LCs reveal that they can extrude their dendritic processes across the skintight junction present in the granular layer, through a specialized pore, called *tricellulin*, to sample the microbial environment in the stratum corneum. Langerin receptors concentrate at the tips of the extruded dendrites to aid in the capture of external pathogens.

LCs have long been considered the paradigm-defining cDCs that transfer site-specific antigens to the lymph node, where they inform and activate CD4 and CD8 T cells (Chapter 9) to develop into differentiated skin-homing helper and cytotoxic effector T cells to eliminate the invading threat. Limited studies of primary human LCs indicate they are potent inducers of cytotoxic CD8 T cells and CD4 Th2 cells.[17]

In addition to their potent cross-presenting activity to CD8 T cells (Chapter 12), human LCs also favor development of CD4 regulatory T cells (Tregs) (Chapter 13), antimicrobial Th17 cells, and T follicular helper (Tfh) cells for antibody development (Chapter 11).[17,18] LCs that emigrate from the epidermis leave a hole in the skin surface network. This hole is subsequently replenished for the short term under inflammatory conditions by iDCs and for the long term by resident LC-committed stem cells that seed the epidermis during fetal development.

Dermal Dendritic Cells

Dermal DCs efficiently present to T cells antigens that have reached the dermis. In normal skin, multiple subpopulations of resident dermal DCs can be detected.[19] In mice, langerin-positive and -negative DCs are found in the dermis. Both are developmentally distinct from LCs. In humans, most dermal DCs are langerin negative; only a small number of langerin-low dermal DCs can be detected. Nevertheless, human langerin-negative dermal DCs share functional characteristics with mouse langerin-positive dermal DCs. They are able to cross-present captured intracellular bacterial or viral antigen from infected skin cell debris to activate CD8 T cells without being infected themselves. Thus, they are able to forgo the canonical MHC class I antigen processing pathway, which requires infection for endogenous expression of the pathogen antigens. Mouse

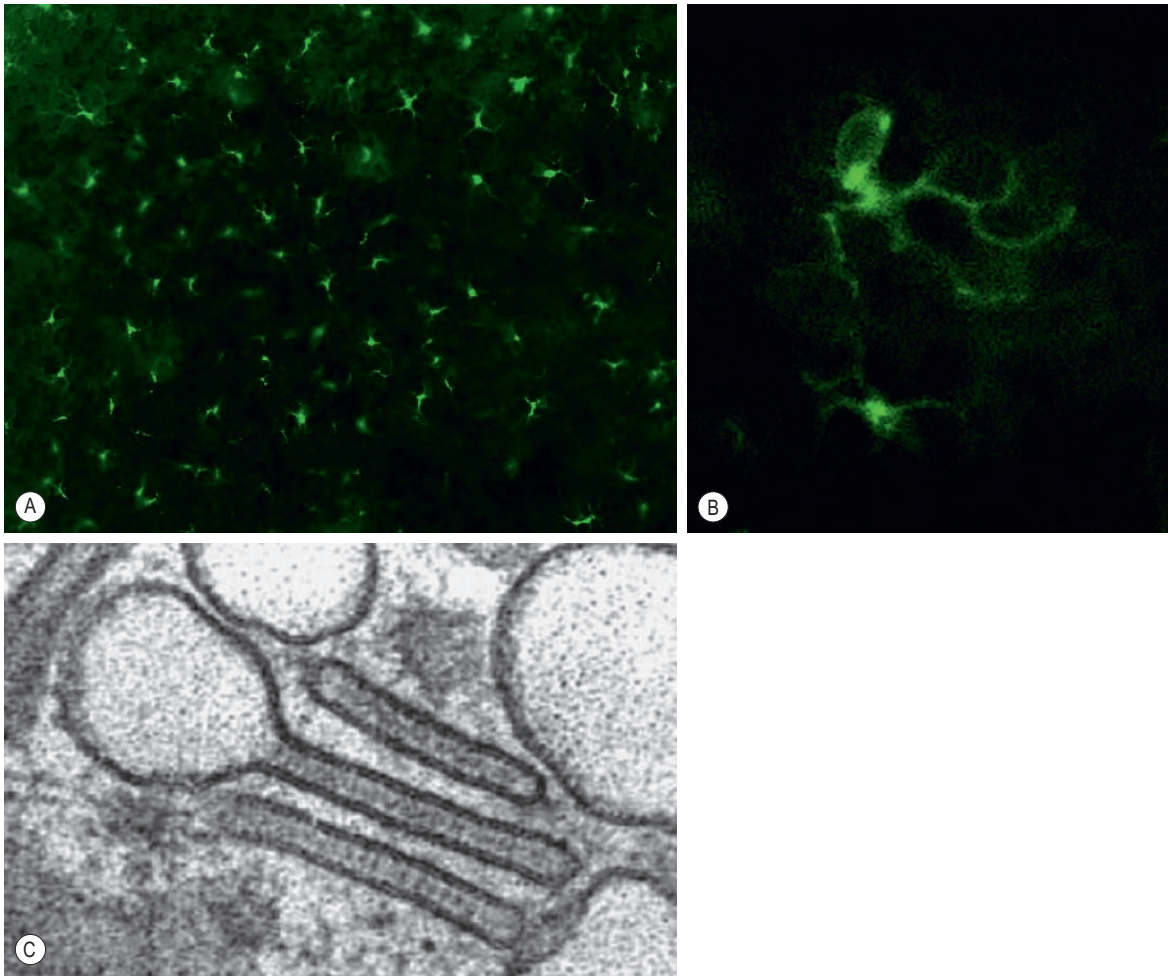

FIG. 23.2 Langerhans Cells (LCs). (A) A horizontal view of epidermis (murine) stained with an antibody to major histocompatibility complex (MHC) class II molecules. Only LCs are positive in unperturbed skin. Dendritic shaped LCs are spaced throughout the epidermis with dendrites stretching out to meet and communicate with neighboring LCs. (B) High-power view of an LC. Note contact between adjacent LCs. (C) Transmission electron microscopy of Birbeck granules in LCs from human epidermis. The Birbeck granule has a "tennis racket" morphology and is formed by internalized langerin molecules. (From Romani N, Clausen BE, Stoitzner P, et al. Langerhans cells and more: langerin-expressing dendritic cell subsets in the skin. *Immunol Rev*. 2010:234[1]:120–141.)

langerin-positive dermal DCs are also critical for activating Tfh cells for IgG2a/c and IgG2b isotype antibody production. In the resting state, all DCs are poor stimulators of T cells. Interaction with so-called immature DCs can generate unresponsive antigen-specific T cells, a key mechanism for maintaining immune tolerance, which is needed to prevent the immune system from attacking self-tissues.

T-CELL SUBPOPULATIONS AND THE SKIN

In response to instructional cues from cutaneous DCs, antigen-specific T cells differentiate into specialized subsets, each with functions that focus on eliminating specific types of pathogens (see Table 23.3). Pre-sensitized, functionally committed T cells that home to skin remain in the dermis as long-lived resident memory T cells (T_{RM}). The skin of a healthy adult contains nearly 20 billion T_{RM} cells, about twice the number present in the entire blood volume.[20] Among the best-characterized differentiated CD4 T-cell subsets are Th1, Th2, Th17, Th22, and Tregs, each of which has a distinct cytokine profile. CD8 T cells primarily function as cytotoxic effector cells, but also express cytokine profiles analogous to CD4 subsets, termed Tc1, Tc2, and Tc17.[21]

Th1 Responses

Th1 cells are the principal mediators of immunity that eradicate intracellular pathogens and tumors. Their major effector cytokine is IFN-γ. IFN-γ from Th1 cells stimulates macrophages to phagocytose and generate oxidative bursts that aid intracellular killing of microbes. IFN-γ also upregulates expression of class I and class II MHC molecules and ICAM-1 (CD54) on keratinocytes, dermal microvascular endothelial cells, and fibroblasts, and induces them to secrete proinflammatory cytokines and chemokines. Deficiencies in Th1 cells increase susceptibility to cutaneous microbial infections and tumors. Th1 cells are responsible for cutaneous delayed-type hypersensitivity responses (e.g., tuberculosis skin test reaction) and allergic contact dermatitis (Chapter 48).

Th2 Responses

Th2 cells are involved in immune responses important for eradication of extracellular parasites and bacterial infections. They produce IL-4, IL-5, IL-10, and IL-13. Th2 cell-mediated inflammation is characterized by the presence of eosinophils (Chapter 45) and basophils as well as extensive mast cell degranulation. In mice, Th2-cell deficiency profoundly increases susceptibility to *Leishmania* infection in skin. In humans, Th2 cells play a critical role in the pathogenesis of atopic dermatitis (Chapter 48). Dupilumab is a monoclonal antibody that inhibits IL-4/IL-13 signaling. It effectively blocks the decrease of skin barrier function, class switch to IgE, and differentiation of Th2 cells. It is approved for the treatment of moderate to severe atopic dermatitis.[22]

Th17 Responses

Th17 cells produce IL-17A, IL-17F, IL-21, and IL-22. Th17 cells protect against extracellular bacterial and fungal infections in skin. Both IL-17A and IL-17F enhance protective immune responses by inducing keratinocytes production of granulocyte colony-stimulating factor (G-CSF), and antimicrobial peptides. Mice deficient in IL-17A are highly susceptible to *S. aureus* infections in skin. IL-17 and IL-22 are important mediators of psoriasis and are implicated in other autoimmune skin disorders. Anti-human IL-17 antibodies (secukinumab and ixekizumab) and an IL-17 receptor antagonist (brodalumab) are effective in over 75% of individuals with moderate to severe psoriasis.[23] Because IL-23 promotes Th17-cell development, antibodies that block p19 subunit of IL-23 (guselkumab, risankizumab, tildrakizumab, bimekizumab) or the p40 subunit common to both IL-12 and IL-23 (ustekinumab) are effective therapeutic agents for psoriasis.[23]

Regulatory T Cells

Tregs diminish immune responses in skin, an important function for dampening inflammatory responses and limiting tissue damage (Chapter 13). Conversely, an increase in Treg suppression can impair host immune surveillance against cutaneous tumors. Natural Tregs (nTregs) develop in the thymus in response to self-antigens, whereas induced Tregs (iTregs) develop in the periphery in response to foreign antigens. Both are commonly characterized as $CD4^+/CD25^+/Foxp3^+$. Both produce immunosuppressive cytokines (IL-10 and/or transforming growth factor [TGF]-β). They can also express immunoregulatory surface molecules, such as CTLA-4, PD-1, glucocorticoid-induced TNFR family–related gene (GITR), and lymphocyte activation gene 3 (LAG-3). They can directly inhibit T-cell activation and function, and suppress the antigen-presenting activity of cDCs. A defect in Treg function will result in autoimmune and inflammatory diseases. About 5% to 10% of the T cells resident in normal human skin are Tregs.[24]

CD8 T-Cell Immunity

CD8 T cells differentiate into cytotoxic T lymphocytes (CTLs), which are essential for the elimination of viral infections and cancerous cells (Chapter 12). CD8 T cells are important effectors of immune surveillance. Their presence in tumor tissues is a good prognostic factor for certain types of cancer.[25] Diminished CD8 T-cell function increases the susceptibility to squamous cell and basal cell carcinomas. Cytotoxic CD8 T cells and CD8 T cells producing IFN-γ or IL-17 (Tc1 and Tc17, respectively) are key mediators in allergic contact dermatitis (Chapter 48).[26]

γδ T Cells

γδ T cells, also known as dendritic epidermal T cells (DETCs), bridge innate and adaptive immunity. In place of conventional αβ chain TCRs, they express a more restricted repertoire of γ and δ chain T-cell receptors (TCRs) (Chapter 4). They reside in epithelial tissues of skin, gut, lungs, and reproductive tract.[27] In humans, γδ T cells account for at least 10% of the T cells in the epithelium. Epithelium-resident γδ T cells differ from circulating γδ T cells with respect to their development, selection, TCR diversity, and effector functions. Epithelial γδ T cells are not restricted by MHC class I or class II molecules (Chapters 5 and 6). Instead, they recognize PAMP and DAMP molecules presented by non-classic MHC molecules, such as CD1. They use alternate sets of costimulatory molecules, such as the junctional adhesion molecule–like protein (JAML) and its ligand, the coxsackievirus and adenovirus receptor (CAR). They are thought to be partially activated under static conditions. This enables them to mount responses to pathogenic stimuli rapidly. γδ T cells are also involved in epidermal wound repair, can influence DC activation, and can directly present antigens.

MAST CELLS

Skin is a rich source of mast cells (Chapter 44).[28] These cells are derived from $CD34^+$ progenitors in bone marrow and migrate into tissues at environmental interfaces. In skin, they are present in the dermis at a density of up to 20,000/mm^2. They are typically concentrated around the dermal microvasculature, appendages, and nerves. Their cytoplasmic granules contain a plethora of preformed mediators that include histamine and heparin; the proteases tryptase, chymase, carboxypeptidase, arylsulfatase A, β-hexosaminidase, and β-glucuronidase; and the cytokines TNF-α, GM-CSF, IL-3, IL-4, IL-5, IL-6, IL-8, and IL-13.

Mast-cell activation plays a prominent role in urticaria and angioedema. Mast-cell activation is also implicated in the pathogenesis of bullous pemphigoid, leukocytoclastic vasculitis, atopic dermatitis, allergic contact dermatitis, and mastocytosis (urticaria pigmentosa).

EVENTS INVOLVED IN THE GENERATION OF A PROTOTYPIC INNATE AND ADAPTIVE IMMUNE RESPONSE IN THE SKIN

Keratinocytes constitutively produce a pool of inactive proinflammatory precursors: pro–IL-1α, pro–IL-1β, pro–IL-18, and others. In response to immunological and inflammatory stimuli, these molecules can be immediately processed into active mediators by inflammasomes, which are rapidly formed in the presence of DAMPs. IL-1β, a potent stimulator of endothelial cell activation, permits rapid infiltration of inflammatory myeloid cells and T cells from blood into the dermis. TNF-α contributes to dermal microvascular endothelial cell activation and augments expression of ICAM-1 (CD54) on keratinocytes and endothelial cells. Infiltrating T cells express the β_2-integrin molecule leukocyte function–associated antigen-1 (LFA-1), which binds to ICAM-1 expressed on affected cells in the dermis and epidermis. IL-6 helps drive the development of IL-17–producing Th17 cells. IL-6 can also perpetuate chronic inflammation.

Activated keratinocytes respond to these proinflammatory mediators by generating a second set of cytokines and chemokines (including GM-CSF, TNF-α, and CXCL8/IL-8) with

autocrine and paracrine effects. They activate unaffected neighboring keratinocytes to amplify proinflammatory signals. These cytokines are a key to triggering adaptive immune responses by activating cutaneous LCs and DCs to become mature potent APCs. APC interaction with antigen-specific, skin-resident memory T cells stimulates proliferation and expansion of differentiated effector T cells at the affected skin site. Keratinocyte-derived IL-8 is a potent chemoattractant for neutrophils. The influx of leukocytes further amplifies local immune responses, inflammation, and associated tissue damage. Stimulation of TLRs 7 and 9 within small numbers of resident dermal pDCs leads to abundant production of type I IFN-α, inducible nitric oxide synthase (iNOS), and arginase, which aid in eradication of viral infection and other invading organisms.

This first-wave innate immune response is followed by a slower, but more specific, second-wave adaptive immune response to control and eliminate antigenic stimuli (FIG. 23.3). Antigens are taken up by epidermal LCs and dermal DCs. They carry antigens from the affected skin site to draining lymph nodes, where they present those antigens to activate and expand T cells specific for the antigens to which the skin was exposed (Chapter 6). To emigrate from the epidermis to regional lymph nodes, LCs downregulate E-cadherin, allowing them to detach from surrounding keratinocytes. During migration to the draining lymph node, LCs and DCs undergo changes that halt antigen capture activity (by downregulation of antigen capture receptors) and increase expression of T-cell interactive molecules: MHC class I and II molecules, costimulatory molecules CD80 and CD86, and ICAM-1 (CD54).

Naïve T cells in lymph nodes that express TCRs for the antigens in skin form APC–T cell conjugates during which T cells are programmed to differentiate into functionally distinct T-cell subsets. These newly activated T cells leave the lymph node by downregulating their lymph node–homing receptors, CCR7, and L-selectin (CD62L) and upregulating the skin-specific homing receptor CLA and chemokine receptors CCR4 and CCR10 to enter the affected skin site.[13] Unless antigen is present in skin for an extended period, the sensitization phase

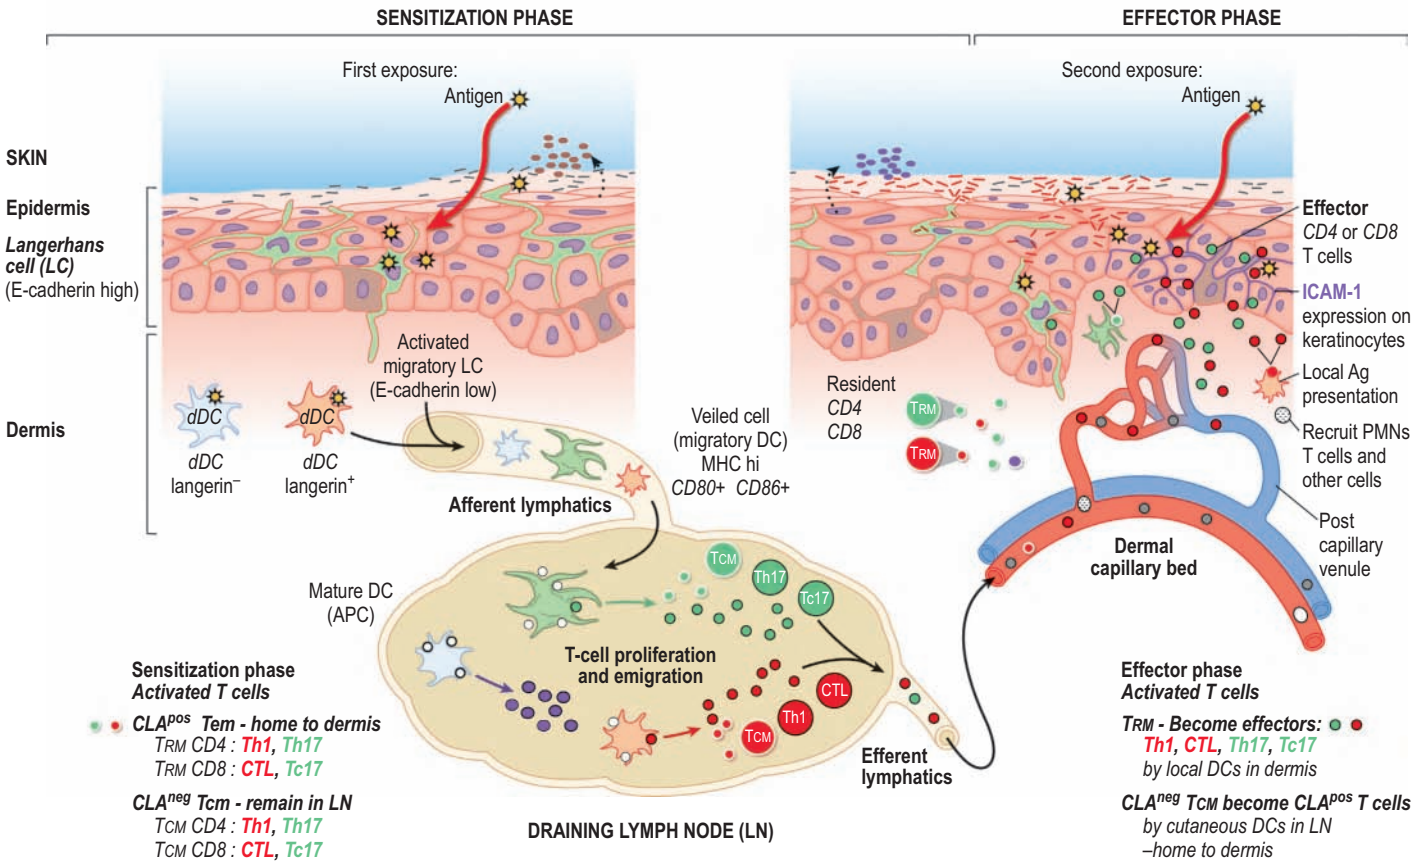

FIG. 23.3 Phases for the Development of Immune Responses in Skin. During the sensitization phase, dendritic cells *(DCs)* capture antigens in skin and migrate through afferent lymphatics to the skin-draining lymph nodes *(LNs)* where they present the antigens to naïve T cells. T-cell differentiation is induced by activated cutaneous DCs, and they develop into resident memory T *(T_{RM})* cells and central memory T *(T_{CM})* cells representing different lineages (Th1, CTL, Th17, Tc17), depending on DC programming. Activated T_{CM} that leave LNs and migrate to skin become skin resident T_{RM}, whereas non-activated T_{CM} remain in lymph nodes. The effector phase occurs in response to subsequent exposures to antigen. DCs become activated, which, in turn, stimulates local T_{RM} to become effector cells in situ. Activated cutaneous DCs that reach the draining LN activate T_{CM} to become skin-homing T effector cells, which are recruited to the inflamed dermal site. These effector cells, in concert with recruited cells, will enter into the epidermal layer by binding intercellular adhesion molecule 1 *(ICAM-1)* molecules present on activated keratinocytes. They act to clear infection, eliminate pathogen-infected cells, remove debris, and repair the skin barrier. (Drawing by Laura Timares, PhD.)

on first exposure to antigen does not cause an inflammatory reaction and often goes unnoticed.

In the dermis of resting skin, resident memory T cells (T_{RM}), previously activated during the sensitization phase, persist in the absence of antigens and are readily available for further encounters with the same antigen. Central memory T cells (T_{CM}) reside in lymph nodes. Unlike T_{RM}, T_{CM} do not express high levels of skin-homing receptors CLA and CCR4 or exhibit immediate robust responses to antigen restimulation. T_{CM} in lymph nodes or spleen can be activated by presentation of antigen by skin-draining LCs or DCs. Activated T_{CM} enter the circulation, express skin-homing receptors, and extravasate into skin sites where antigen is present, thereby further contributing to the immune response. CD4 and CD8 T_{RM} and recruited T_{CM} that interact with antigen-activated LCs and DCs in the dermis are further stimulated to proliferate in situ to *(i)* amplify effector cell numbers, *(ii)* augment cytokine and chemokine production, and *(iii)* recruit additional inflammatory leukocytes, all of which act in concert to eradicate the antigen present in skin. Events are terminated by regulatory T cells and immunosuppressive cytokines such as IL-10, TGF-β, and IL-1 receptor antagonist (IL-1RA). This allows the skin to return to its non-inflamed status. IL-10 is a potent inhibitor of adaptive and inflammatory cellular responses, whereas IL-1RA effectively blocks the activity of IL-1β. In addition, macrophages and certain DC subsets can inhibit ongoing adaptive immune responses through their expression of indoleamine 2,3-dioxygenase (IDO), an enzyme that alters tryptophan metabolism in T cells.

ANTIBODIES AND SKIN

Although the role of IgG, IgA, and IgE antibodies (Chapters 4 and 8) in normal skin homeostasis is not well understood, Igs often play key roles in the pathogenesis of several different dermatological diseases. Pathogenic IgG causes blistering disorders, including pemphigus, bullous pemphigoid, epidermolysis bullosa acquisita, paraneoplastic pemphigus, and leukocytoclastic vasculitis. IgA is key to the pathogenesis of dermatitis herpetiformis, linear IgA bullous dermatosis, and IgA-mediated cutaneous vasculitis. IgE-dependent skin diseases include urticaria and angioedema and bullous pemphigoid.

Urticaria

Urticaria (Chapter 46) is a form of IgE antibody–mediated adaptive immunity in the skin. Mast cells express high-affinity surface receptors for the Fc portion of IgE (FcεRI), which binds and retains IgE for long periods. Antigen-induced cross-linking of IgE bound to FcεRI initiates calcium- and energy-dependent events that culminate in fusion of granules to the plasma membrane and release of granule contents. Degranulation releases potent prostanoids, histamines, and inflammatory cytokines that rapidly recruit inflammatory cells. Non-antigenic stimuli, such as opiates, C5a, anaphylatoxin, stem cell factor, and substance P, can activate degranulation through FcR-independent opioid, adenosine, and β-adrenergic receptors. The products and contents of mast-cell granules are causative agents of acute vasodilatation, edema, pruritus, and rapid influx of leukocytes and eosinophils into skin.

Hyper-Immunoglobulin E Syndrome

Hyper-immunoglobulin E (IgE) syndrome (HIES) is an autosomal dominant disease that develops cutaneous manifestations of severe dermatitis, recurrent infections of staphylococcal abscesses, and, sometimes, cutaneous candidiasis. Dominant negative mutations in the signal transducer and activator of transcription 3 (STAT3) gene are associated with this disease. Deficient STAT3 signaling leads to impaired β-defensin expression, which may explain some of the clinical manifestations.[29]

ENVIRONMENTAL CHALLENGES AND THE SKIN-ASSOCIATED LYMPHOID TISSUE

Chemicals

Environmental chemicals that are able to breach the cutaneous physical barrier are often identified by the host, correctly or incorrectly, as unwelcoming molecules that should be neutralized or eliminated by the immune system. When this occurs to a seemingly innocuous molecule, it causes allergic contact dermatitis. Examples include urushiol, the active moiety in poison ivy, oak, and sumac, and nickel sulfate, responsible for the dermatitis caused by nickel-containing jewelry. Once beyond the stratum corneum, these chemicals bind to epidermal proteins, generating "modified self" proteins as immunogenic complete antigens. Animal models of allergic contact dermatitis have been studied extensively to understand the mechanism of action of T-cell-mediated adaptive immune responses in the skin.

Solar Ultraviolet Radiation

Sunlight is the major environmental agent to which skin is exposed. Injudicious exposure to UV spectrum can lead to sunburn, skin aging, skin cancers, and photosensitivity diseases, many of which have an immunological pathogenesis. Although much of the investigation into the immunological effects of UVR was conducted in animal models, many of the observations have been corroborated in humans.

In mice, as in humans, chronic exposure to UVR results in the development of highly antigenic skin tumors, capable of stimulating a vigorous antitumor response in untreated mice. Despite their antigenic nature, these tumors grow progressively in their original host. This apparent paradox was resolved in studies showing that, in addition to producing mutant neoplastic cells, UVR also impairs cell-mediated immune surveillance, which, under normal circumstances, eliminates mutant cells before they develop into clinically apparent tumors. Thus, mutant cells progress to become tumors only in an environment of immune suppression. For example, organ transplant recipients who are treated with immunosuppressive medications have a greatly increased risk of developing aggressive skin cancers.[30]

UVR mediates its effects on the immune system by perturbing the function of skin APCs. UV-irradiated APCs are poor stimulators of Th1 cells but are able to activate Tregs, which promote antigen-specific immunological tolerance. Enhanced production of the suppressive cytokines IL-10 and TGF-β, as well as by a reduction in the Th1 activation cytokine IL-12 also play a role. It may seem surprising that an environmental carcinogen, such as UVR, suppresses immunological function in skin. One proposed hypothesis is that altered epithelial proteins are constantly generated by UVR exposure, necessitating chronic induction of immune tolerance to UVR-damaged proteins to preserve the integrity of the skin barrier.

The immunosuppressive effect of UVR has been exploited for therapeutic purposes. UVR phototherapy is used to suppress pathological immune responses in such inflammatory skin diseases as psoriasis and atopic dermatitis.[30]

ON THE HORIZON

- Development of small-molecule inhibitors of JAK/STAT signaling that can be given orally or topically for the treatment of psoriasis.
- Elucidation of the mechanisms underlying comorbidities, such as metabolic syndrome and major adverse cardiovascular events in patients with psoriasis.
- Development of new cytokine inhibitors to treat a spectrum of skin diseases (such as IL-17 and IL-23 inhibitors for the management of hidradenitis suppurativa).
- Targeting of dendritic cell subsets (DCs) in order to optimize vaccination.
- Use of cytokines or cytokine inhibitors to manipulate cutaneous immune responses in immunologically mediated skin diseases (such as vitiligo, alopecia areata, cutaneous lupus erythematosus, and dermatomyositis).

Immunology of Mucosal Surfaces

Prosper N. Boyaka and Kohtaro Fujihashi

Mammals have evolved into a sophisticated network of cells and molecules that serves to maintain homeostasis on exposed mucosal surfaces. This system is anatomically and functionally distinct from its bloodborne counterpart and is strategically located at the portals through which most pathogenic microorganisms enter the body. This specific branch of the immune system may have developed in response to the size of the mucosal surfaces, which cover an area of ≈70 m^2 in the airways and ≈400 m^2 in the gut of an adult human, and the large numbers of commensal bacteria and exogenous antigens to which the mucosae are exposed.[1]

THE INNATE MUCOSAL DEFENSE SYSTEM

Cells and molecules that contribute to innate defense of the mucosa include the physical barrier provided by epithelial cells, the movement of the epithelial cilia, the production of mucus by goblet cells, the secretion of molecules with innate antimicrobial activity, and the cytolytic activity of natural killer (NK) cells (Fig. 24.1, A). Innate lymphoid cells (ILCs; Chapter 3) were identified recently as key players in innate mucosal immunity (See Fig. 24.1, B). In concert with the commensal microbiota (Chapter 22), these innate mechanisms provide a first line of defense against exogenous antigens and invading pathogens. Epithelial Cells and Other Effectors of the Mucosal Physical Barrier

KEY CONCEPTS

Innate Defenses of the Mucosal Immune System

The innate defenses of the mucosal immune system provide a first line of protection against the entry of exogenous antigens and microbes, as well as invading pathogens. These defenses include:

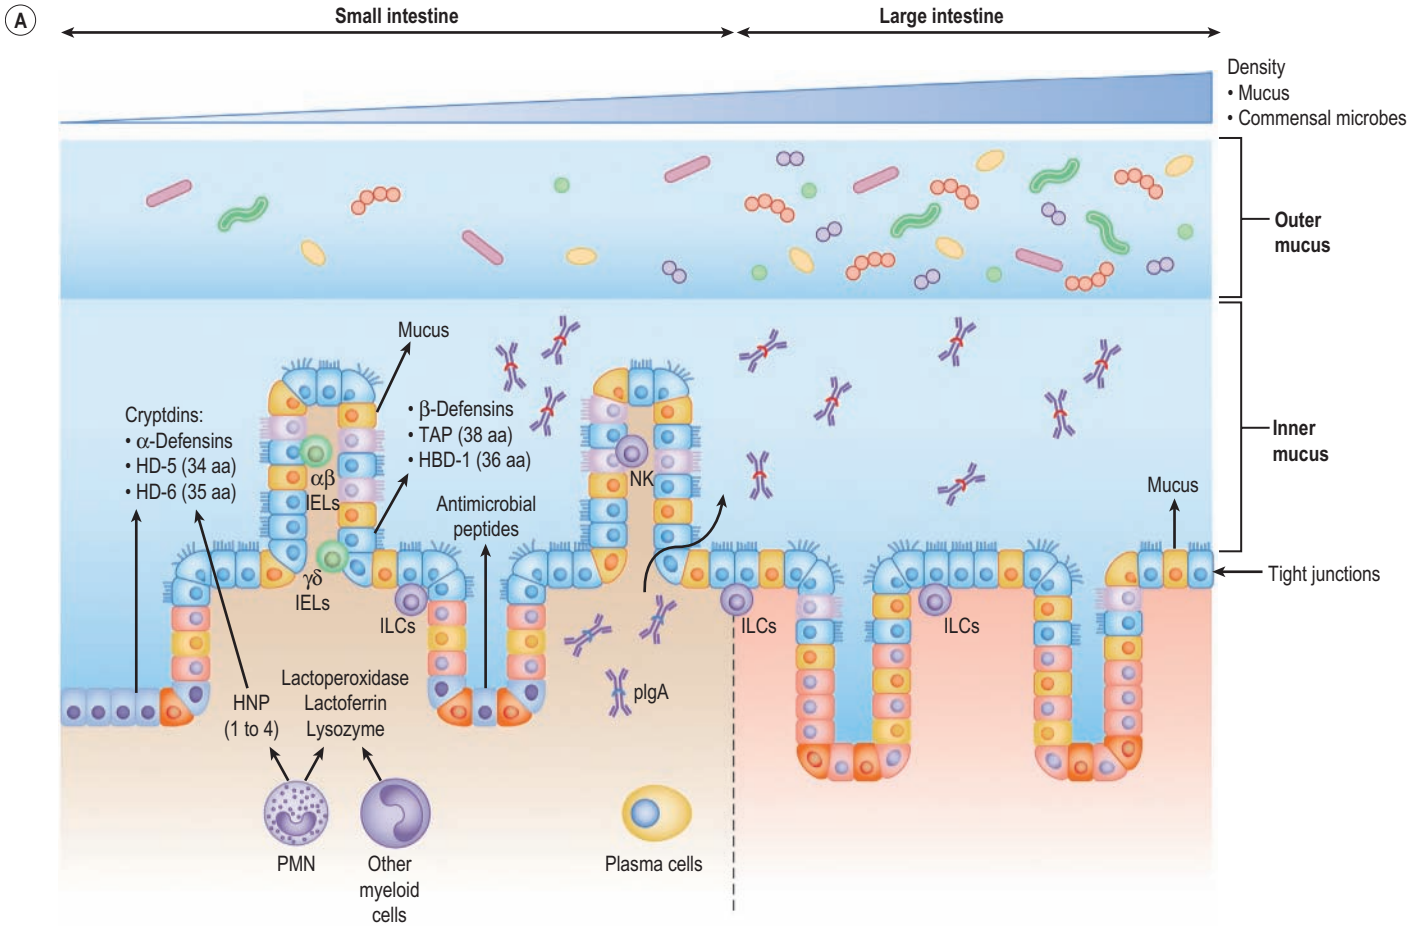
- *Physical and chemical barriers:* the epithelium, epithelial cell cilia, goblet cell mucus production, acid production by the stomach, lipid production by skin.
- *Mucosal antimicrobial molecules:* Paneth cell production of α-defensins in the small intestine; epithelial cell production of β defensins in the oral mucosa, trachea, bronchi, mammary glands, and salivary glands: lactoferrin, lysozyme, lactoperoxidase, and secretory leukocyte protease inhibitor (SLPI).
- *Cellular innate immunity:* mucosal natural killer (NK) cells, innate lymphoid cells (ILCs), dendritic cells (DCs), polymorphonuclear neutrophils (PMNs), mast cells and eosinophils.

All mucosal surfaces are covered by epithelial cells, which contribute to their selective barrier function. In the gastrointestinal (GI) tract, tightly joined enterocytes constitute the cellular component of the physical barrier and are covered by a blanket of mucus. Mucus consists of glycoproteins secreted into the lumen by goblet cells. This layer of glycoproteins interferes with the attachment of microorganisms to the mucosal surface. The replacement of damaged or infected enterocytes by crypt epithelial cells, which differentiate into enterocytes as they migrate toward the desquamation zone at the villus tip, ensures the integrity of this barrier. Multilayered squamous epithelial cells cover other mucosal surfaces, including the oral cavity, pharynx, tonsils, urethra, and vagina. These epithelia lack tight junctions. Instead, mucus coats the intercellular space between the lower stratified epithelial cell layers. Polymeric immunoglobulin A (pIgA) and commensal microbes support the physical barrier function of mucosal tissues. Perturbation of the commensal microbiome, which is present in the mucus ecosystem, facilitates opportunist infections by pathogens such as *Clostridium difficile*.

Defensins and Other Mucosal Antimicrobial Peptides

Selected epithelial cell subsets contribute to innate responses through the production of antimicrobial peptides, iron transporters, and enzymes. Defensins are 30 to 40 amino acid β-sheet peptides with antiviral activity and antimicrobial effects similar to those of antibiotics. Defensins are structurally segregated into α and β categories. α-Defensins are secreted by tracheal epithelial cells and by Paneth cells in intestinal crypts. α-Defensins are homologous to peptide mediators of nonoxidative microbial cell killing in neutrophils (termed *human neutrophil peptides* [HNPs]).[2] Human β-defensin 1 (HBD-1) is expressed in the epithelial cells of the oral mucosa, trachea, bronchi, mammary glands, and salivary glands, whereas HBD-5 is expressed in the gut. Inflammatory cytokines (Chapter 14), including interleukin-1 (IL-1), IL-17, tumor necrosis factor (TNF), and bacterial lipopolysaccharide (LPS), regulate defensin production.

Other antimicrobial products of the epithelium include lactoferrin, lysozyme, peroxidases, secretory phospholipase A2 (S-PLA2), and cathelin-associated peptides. Lactoferrin, a member of the transferrin family, is found in exocrine secretions. S-PLA2 and lysozymes are released by Paneth cells and high concentrations of lysozyme (1209 to 1325 μg/mL) are found in tears, saliva, colostrum, serum, and urine. Human milk contains lysozyme in concentrations ranging from 20 to 245 μg/mL, depending on the lactation period. Milk leukocytes produce myeloperoxidase (MPO), and mammary gland cells produce human lactoperoxidase (hLPO). Both peroxidases display properties similar to those of human salivary peroxidases (hSPO). Secretory leukocyte protease inhibitor (SLPI) is found in human saliva, nasal secretions, tears, cervical mucus, and seminal fluid. It is believed to be responsible for the anti–human immunodeficiency virus (HIV) properties of external secretions.



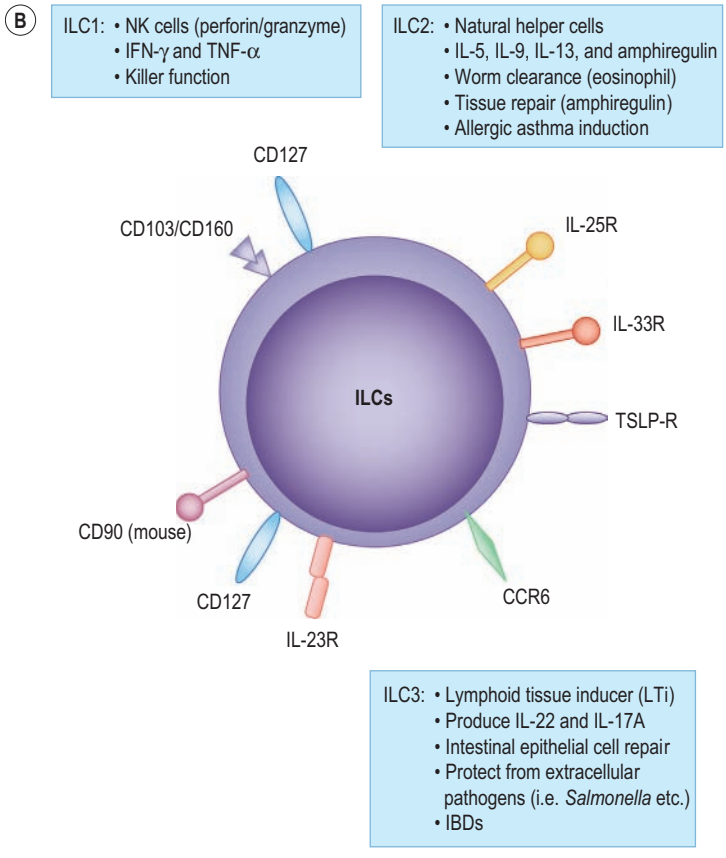


FIG. 24.1 Innate Mucosal Host Defense Factors. (A) A thick coat of mucus prevents penetration of exogenous macromolecules, commensal microbes, and potential pathogens. The epithelial cell barrier is connected via tight junctions and contains both αβ and γδ intraepithelial T lymphocytes (IELs). The crypt regions contain Paneth cells, which produce cryptins (α-defensins). β-Defensins are products of epithelial cells and form a defensin network. Other innate factors such as lysozyme, lactoperoxidase, lactoferrin, and phospholipases, also serve in antimicrobial defense. (B) Three types of innate lymphoid cells are identified based on their cytokine production.

Mucosal Innate Lymphoid Cells

ILCs, recently described, constitute groups of lymphoid cells that are predominantly found in mucosal tissues. ILCs lack T- and B-cell receptors. They contribute to innate regulation of homeostasis through their ability to rapidly produce cytokines. Similar to CD4 T-helper (Th) cells (Chapter 11), ILCs can be divided into three major groups according to the cytokines they produce.[3,4] Group 1 ILCs (ILC1) produce interferon-γ (IFN-γ) and are considered similar to Th1 cells. Cells with ILC1 phenotypes express CD103/CD160 and CD127 and include NK cells, which are large granular lymphocytes found in the lamina propria and the intraepithelial compartment. Group 2 ILCs are similar to Th2 cells and produce IL-5, IL-9, IL-13, and amphiregulin. ILC2 are responsible for innate responses in allergies and asthma. As with Th17 cells, group 3 ILCs (ILC3) secrete IL-17 and/or IL-22. Although lymphoid tissue inducer (LTi) cells are ILC3, functional properties of these cells are distinct from other mucosal ILC3.[3,4]

Two types of ILC1 occur in the tonsils and the mucosa of the GI tract. $CD103^+$, $CD160^+$ ILCs are found in the intraepithelium compartment of the intestines and produce "*perforin*" a granzyme like NK cells. This ILC1 subset requires Nfil3 and T-bet transcription factors for its development. An ILC1 population expressing low levels of RORγt and aryl hydrocarbon receptor (Ahr) similar to ILC3 was identified in humans. These ILCs express IL-7Rα (CD127), but not conventional lymphocyte lineage or NK cell markers. Both subsets of ILC1 may be involved in the induction of inflammatory bowel disease (IBD).[3] ILC2 are seen in the lungs, upper respiratory mucosa, gut, and skin. By producing IL-5, IL-13, and amphiregulin, they play key roles in the clearance of parasites, including *Nippostrongylus brasiliensis* and *Trichuris muris*. ILC2 are also important in the development of asthma and allergies, including atopic dermatitis. Although ILC2 were reported to promote airway hypersensitivity during acute influenza virus infection, the amphiregulin they produce could also help maintain lung epithelial cell homeostasis.[3] A recent study showed that ILC2 also play a key role in the induction of IgA Ab responses. Thus, absence of ILC2 prevented the induction of IgA Abs that protect the stomach by eliminating IgA-coated bacteria, including pathogenic *Helicobacter pylori*.[5]

ILC3 display heterogenic cytokine profiles in both humans and mice. Thus, human ILC3 bearing NKp44 and CCR6 produce IL-22 alone. However, human ILC3 isolated from patients with Crohn disease produce IL-17 and IFN-γ. Mouse LTi and LTi-like ILC3 produce both IL-17 and IL-22. $NKp46^+$ ILC3 secrete IL-22, as well as IFN-γ under certain conditions, but not IL-17. Another subset of mouse ILC3 that produces IFN-γ, IL-17, and IL-22 can be found in the large intestine. ILC3-derived IL-22 induces antimicrobial peptide responses by intestinal epithelial cells (IECs). Furthermore, IL-22 from ILC3 was reported to enhance innate immunity against *Salmonella* and bacterial infection secondary to influenza virus infection.[3,4] Because ILC3 are also involved in the induction of colonic inflammation and colorectal cancer, they may act as a double-edged sword in the mucosal immune system.[3,4]

THE COMMON MUCOSAL IMMUNE SYSTEM

Higher-order mammals have developed an organized secondary lymphoid tissue system in the GI and upper respiratory tracts. Gut-associated lymphoid tissues (GALTs) include Peyer patches (PPs), the appendix, and solitary lymphoid nodules in the GI tract (Chapter 2). Tonsils and adenoids comprise nasopharyngeal-associated lymphoid tissues (NALTs). Experimental animals, such as rabbits, rats, and guinea pigs, exhibit organized bronchus-associated lymphoid tissues (BALTs) that also occur in human airway branches with inflammation.[1] Together, GALTs and NALTs in humans and GALTs, BALTs, and NALTs in experimental species are termed *mucosa-associated lymphoid tissue* (MALT).

The vast areas of the mucosal immune system characterized by diffuse collections of lymphoid cells are termed "*effector tissues*." These include the interstitial tissues of the mammary, lacrimal, salivary, sweat, and all other exocrine glands, as well as the lamina propria and the epithelium of the GI tract. The lamina propria areas of the upper respiratory and genitourinary tracts are also lymphoid effector sites. MALT is connected with effector sites through the migratory patterns of effector cells.

KEY CONCEPTS

The Common Mucosal Immune System

The term *mucosa-associated lymphoid tissue* (MALT) comprises discrete and diffuse collections of lymphoid tissues that share distinctive features, including a unique type of epithelium, a distinct architecture, a unique set of antigen-presenting cells (APC) and B cells, where switching to immunoglobulin A (IgA) predominates. The involved tissues include:

- *Gut-associated lymphoid tissues (GALTs):* Peyer patches (PPs), the appendix, and solitary lymphoid nodules in the gastrointestinal (GI) tract
- *Nasopharyngeal-associated lymphoid tissues (NALTs):* tonsils and adenoids
- *Effector tissues:* the interstitial tissues of the mammary, lacrimal, salivary, sweat, and all other exocrine glands; the lamina propria and the epithelium of the GI tract; and the lamina propria areas of the upper respiratory and genitourinary tracts.

Mucosa-Associated Lymphoid Tissue as an Inductive Site

MALT has a unique type of epithelium for antigen uptake. Its features include a characteristic architecture, antigen-presenting cell (APC), and B-cell areas with germinal centers where switching to IgA predominates. The columnar epithelium that covers MALT is infiltrated with lymphocytes and APCs, leading to the term follicle-associated epithelium (FAE). Lacking goblet cells, the FAE is covered with far less mucus than normal enterocytes. Soluble and particulate luminal antigens are taken up by microfold (M) cells and are delivered to adjacent APCs. M cells have been described in PPs, the appendix, and tonsils, and represent 10% to 15% of cells within the FAE.[5] M cells are also found in isolated lymphoid follicles (ILFs) and at the tips of the villus, where they are termed "*villous M cells*."[5] The microvilli of these cells, which are less dense than those of adjacent enterocytes, offer a portal of entry into MALT (Fig. 24.2). The M cell is often identified by an invagination of the basolateral membrane into a "pocket" normally occupied by lymphocytes and APCs (Fig. 24.3).

M cells appear ideal for antigen uptake owing to a well-developed microvesicle system that includes endosomes. However, it remains unclear whether M cells act as classic APCs. M cells also provide a portal of entry for some pathogens, such as invasive strains of *Salmonella typhimurium*, but not for noninvasive strains of *S. typhimurium* and reoviruses.

FIG. 24.2 The Microfold (M) Cell. A scanning electron micrograph of an M cell with adjacent enterocytes. The M cell has selectively bound *Escherichia coli* 0157. Note that a thick brush border is lacking, facilitating the binding and uptake of microparticles. (Courtesy of Dr. Tatsuo Yamamoto, Niigata University.)

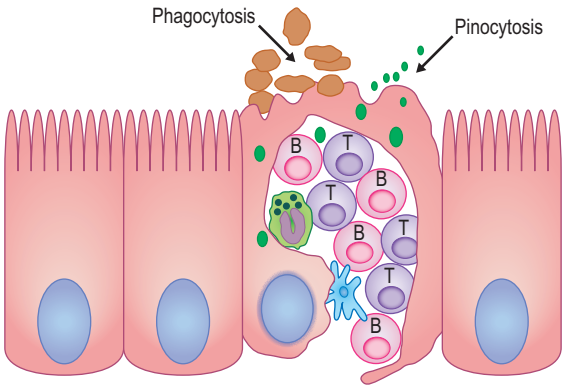

FIG. 24.3 Microanatomic Features of Microfold (M) Cells. The M cell forms a "pocket" containing memory lymphocytes. It actively pinocytoses soluble antigens and phagocytoses particulates such as viruses, bacteria, and microspheres. (Courtesy of Dr. Svein Steinsvoll, University of Oslo.)

Gut-Associated Lymphoid Tissues

Each PP contains a dome region that is positioned under the FAE. This dome region is populated by T cells, B cells, macrophages (MØs), and dendritic cells (DCs). It includes follicles that contain germinal centers. The presence of all three major APC types in the dome (i.e., memory B cells, MØs, and DCs) makes it likely that antigen uptake occurs immediately following release from M cells (Fig. 24.4, A). M cell pockets in PPs contain approximately equal numbers of T and B cells, but fewer MØs. Approximately 75% of the T cells are Th cells.

GALT B-cell follicles are enriched in IgA-bearing B cells, suggesting that they are major sites for B-cell μ to α switching (Chapters 4 and 7). The interfollicular regions of PPs contain high endothelial venules (HEVs) (Chapters 2 and 16). Both CD4 and CD8 TCRαβ T cells are found in these interfollicular regions, with CD4 T cells representing the predominant phenotype. Both naïve and memory T cells are present in PPs, with one-third in cell cycle (see Fig. 24.4; Table 24.1). Lymphotoxin-α (LT-α), lymphotoxin-β (LT-β), and TNF (Chapter 14) are critical for lymphoid tissue organogenesis (Chapter 2). LT-$\alpha^{-/-}$ mice are deficient in secondary lymph nodes, whereas LT-$\beta^{-/-}$ mice have mesenteric and cervical lymph nodes but lack peripheral lymph nodes and PPs. Tumor necrosis factor–receptor I (TNF-RI)$^{-/-}$ mice lack or display abnormal PP structures, whereas TNF$^{-/-}$ mice exhibit normal PPs.

Nasopharyngeal-Associated Lymphoid Tissues (NALTs)

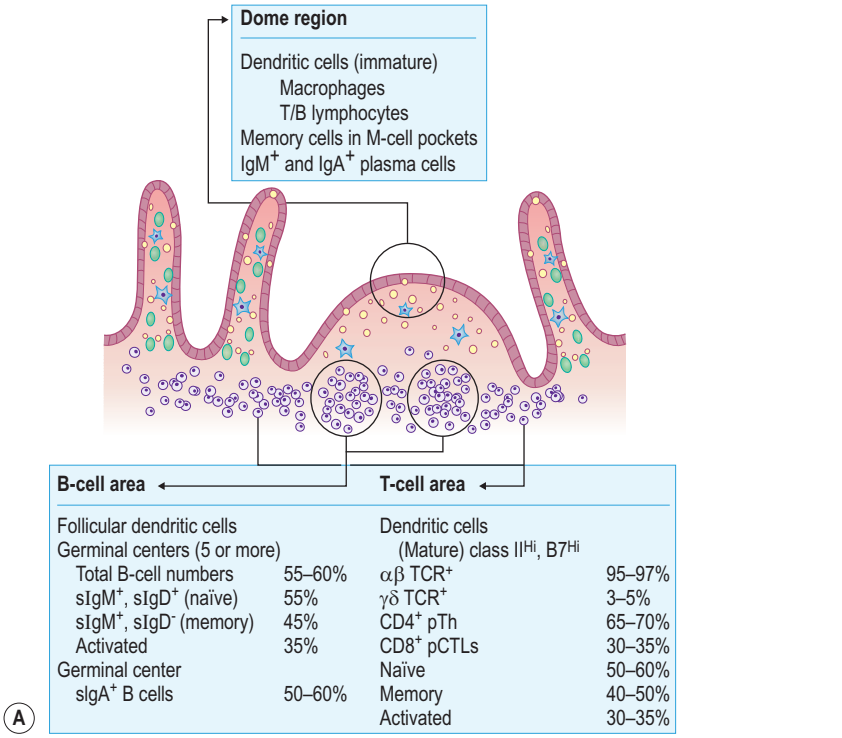
Strategically positioned at the entry of the respiratory and the digestive tracts are the accumulations of lymphoid tissues that comprise the palatine, lingual, and nasopharyngeal tonsils, which collectively form the *Waldeyer ring*. These tissues resemble both lymph nodes and PPs, including a FAE with M cells in the tonsillar crypts that is essential for selective antigen uptake (see Fig. 24.3). Germinal centers containing B and T cells, plasma cells, and APCs are also present. Tonsillar tissues can serve as a source of precursors of IgA plasma cells found in the upper aerodigestive tracts, as well as inductive sites for systemic and mucosal immune responses.[6] The LTα1β2 – LT-β receptor signaling pathway is essential for the maintenance, but not the initiation of NALT organogenesis.[7] Signaling via the IL-7/IL-7R and the L-selectin/peripheral lymph node addressin (PNAd) adhesion molecules both play important roles in the organization of NALTs.[8]

Other Sites for Mucosal Induction of an Immune Response

The follicular structures analogous to PPs in the large intestine are known as rectal-associated lymphoid tissues (RALTs). Unlike most other mucosal tissues in humans, the large intestine lamina propria is home to more IgA2- than IgA1-producing cells.[8] Eye drop administration of antigen elicits secretory immunoglobulin A (SIgA) antibody responses in ocular and nasal mucosae. Thus, both tear-duct associated lymphoid tissue (TALT) and conjunctiva-associated lymphoid tissue (CALT) take up antigens for the initiation of mucosal immune responses as a component of MALT.[9] Immunization via the epicutaneous and sublingual routes is emerging as a potential method for induction of mucosal immunity, and structures facilitating these responses are being investigated.

LYMPHOCYTE HOMING INTO MUCOSAL COMPARTMENTS

Mesenteric lymph node cells of orally immunized animals can repopulate the lamina propria of the gut, mammary glands, lacrimal glands, and salivary glands with antigen-specific IgA plasma cells (see Fig. 24.4, B),[1] pointing to the existence of a "common" mucosal immune system. This concept has undergone further refinement, with evidence that migration of cells into and from NALTs follows rules different from those for GALTs and the GI tract.



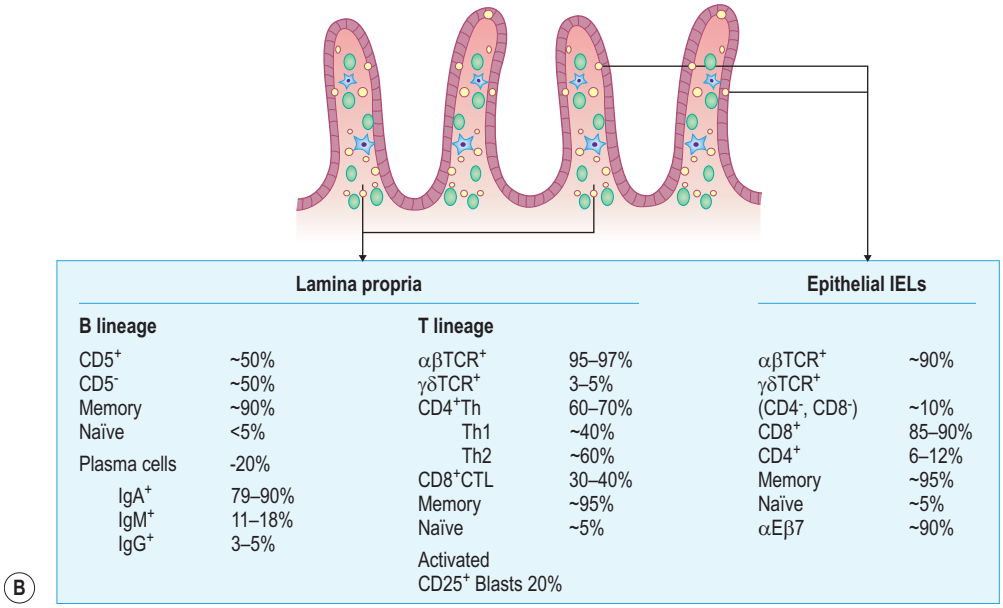


FIG. 24.4 Structural Features and Cellular Components of Gut-Associated Lymphoreticular Tissues (GALTs). (A) The dome region is covered by the follicle-associated epithelium (FAE) with its characteristic microfold (*M*) cells. Major features of the dome include M cells with lymphocyte pockets, scattered plasma cells, and immature dendritic cells (DCs). The B-cell area contains five or more germinal centers with high frequencies of surface immunoglobulin (Ig)A+ B cells. The adjacent T-cell area contains mature interdigitating DCs and precursors of CD4 Th and CD8 CTL. (B) Structural features and cellular characteristics of mucosal effector sites. The lamina propria is equally populated by B1 and B2 cells, both of which differentiate into IgA+ plasma cells. Note that memory B and T lymphocytes are also both present in this compartment. Although intraepithelial lymphocytes (*IELs*) in humans are mainly T-cell receptor (*TCR*) αβ+, significant numbers of TCRγδ+ T cells are also found in this compartment.

TABLE 24.1 Major T-Cell Subpopulations Associated With Murine Peyer Patches

T-Cell Phenotype	Percentage of Total T Cells
$CD3^+\alpha\beta$ T-cell receptor $(TCR)^+$	95–97
$CD3^+\gamma\delta$ TCR^+	3–5
$CD3^+$, $CD4^+$ (precursors of T-helper [Th] cells)	65–70
$CD3^+$, $CD8^+$ (precursors of cytotoxic T lymphocytes [CTLs])	30–35
Naïve ($CD45RB^{Hi}$)	50–60
Memory ($CD45RB^{Lo}$, $CD45RO^{Hi}$)	40–50
Blasts (in cell cycle)	30–35

Lymphocyte Homing in the Gastrointestinal Tract

Naïve lymphocytes enter mucosal or systemic lymphoid tissues from blood through specialized HEVs (Fig. 24.5, A) (Chapter 16). In GALTs, HEVs are present in the interfollicular T-cell zones.[10] In effector sites such as the lamina propria of the gut, the HEVs tend to occur near villi crypts (see Fig. 24.5, B). Mucosal addressin cell adhesion molecule-1 (MAdCAM-1) is the most important addressin expressed by PP HEVs or lamina propria venules (LPVs). PNAd and vascular cell adhesion molecule 1 (VCAM-1) are the principal addressins expressed by peripheral lymph node and skin HEVs, respectively (Chapter 16).

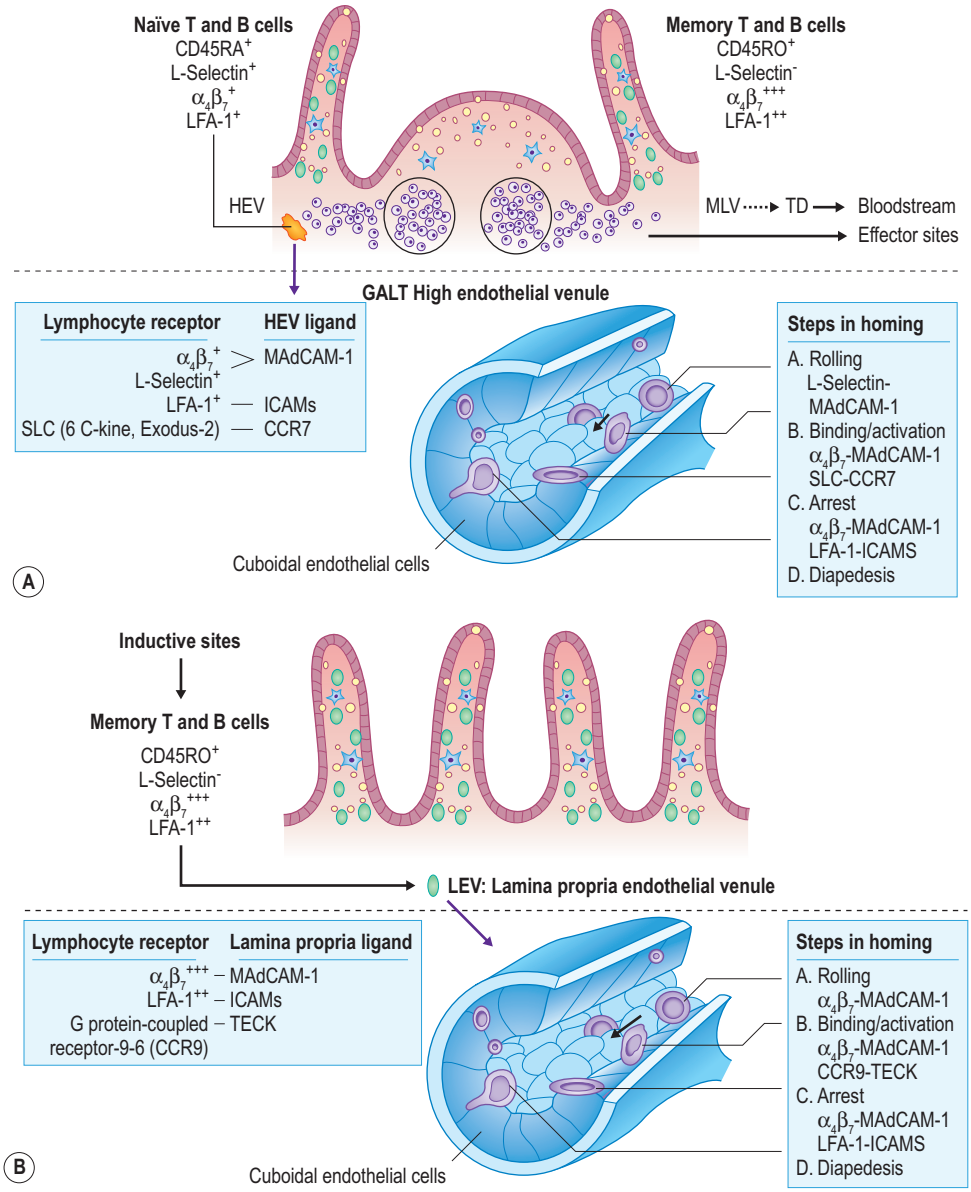

FIG. 24.5 Structural Features and Lymphocyte Homing to Gut-Associated Lymphoreticular Tissues (*GALTs*). (A) High endothelial venules (*HEVs*) occur in T-cell areas and express the ligands mucosal addressin cell adhesion molecule-1 (*MAdCAM-1*), intercellular adhesion molecule 1 (*ICAM-1*), and *CCR7*. Naïve T and B cells, which are L-selectin$^+$, $\alpha_4\beta_{7^+}$, and leukocyte function–associated antigen-1 (*LFA-1*)$^+$, all participate in rolling, binding activation, arrest, and diapedesis in the HEV. Memory B and T cells express $\alpha_4\beta_7$ and LFA-1 at a higher level. (B) Lymphocyte receptors and addressin ligands involved in homing to mucosal effector sites of the gastrointestinal (GI) tract. The majority of B and T cells exhibit a memory phenotype with co-expression of high levels of $\alpha_4\beta_7$ and LFA-1. The expression of the G-protein–coupled receptor *CCR9* allows the homing steps that occur on lamina propria venules.

Integrins are a large class of homing receptors characterized by heterodimeric α and β chains (Chapter 16). In general, the β1 integrin characterizes the homing receptor for skin, whereas the β_7 integrin characterizes the receptor for the gut. The pairing of α_4 with β_7 is thus responsible for lymphocyte binding to MAdCAM-1, which is expressed on HEVs in PPs and gut LPVs (see Fig. 24.5).[10] The C-type lectins—L-, E-, and P-selectins (Chapter 16)—also serve as homing receptors. For example, L-selectin can bind to carbohydrate-decorated MAdCAM-1 and is an important initial receptor for homing into GALT HEVs.

Chemokines (Chapter 15) are also involved in immune-cell homing in mucosal tissues. For example, loss of secondary lymphoid tissue chemokine (SLC) results in lack of naïve T-cell or DC migration into the spleen or PPs. Conversely, memory $\alpha_4\beta_{7^{hi}}$ T cells that express the receptor for thymus-expressed chemokine (TECK), CCR9, migrate into the lamina propria of the GI tract. Both human $\alpha_E\beta_{7^+}$ and $\alpha_4\beta_{7^{hi}}$ CD8 T cells express CCR9, suggesting that TECK-CCR9 is also involved in lymphocyte homing and the arrest of intraepithelial lymphocytes (IELs) in the GI tract epithelium (see Fig. 24.4) (Chapters 15 and 16).

PPs and GALTs contain both naïve and memory T- and B-cell subsets, whereas the lamina propria consists of memory T and B cells and terminally differentiated plasma cells (see Table 24.1 and see Fig. 24.4). Naïve lymphocytes destined for GALTs express L-selectin, moderate levels of $\alpha_4\beta_7$ ($\alpha_4\beta_{7^+}$) and lymphocyte function–associated antigen-1 (LFA-1). Memory lymphocytes destined for lamina propria express higher levels of $\alpha_4\beta_7$ ($\alpha_4\beta_{7^{hi}}$) and lack L-selectin. Initial rolling is dependent on $\alpha_4\beta_7$ interactions with LPV MAdCAM-1. Activation-dependent binding and extravasation require LFA-1–ICAM binding. $\alpha_4\beta_7$ also mediates binding to E-cadherin, and CCR9 expression can result in activation-dependent entry into the epithelial cell compartment.

Cryosections of human tissues have revealed naïve lymphocytes in HEVs that express both L-selectin and $\alpha_4\beta_7$, whereas memory lymphocytes in efferent lymphatics express $\alpha_4\beta_7$, but not L-selectin. The majority of cells in mesenteric lymph nodes, including B-cell blasts, tend to be of the memory phenotype and are $\alpha_4\beta_{7^{hi}}$, L-selectin^{lo}. Ig-containing B-cell blasts also express high levels of $\alpha_4\beta_7$. This separation of naïve and memory T and B cells for entry into GALT HEVs or LPVs has important implications in vaccine development (Chapter 87).

An oral cholera vaccine was reported to elicit transient IgA antibody-forming cells (AFCs) in blood and subsequent IgA anticholera toxin AFCs in duodenal tissues.[11] In a separate study, peripheral blood AFCs induced after parenteral immunization were L-selectin$^+$, whereas those induced after oral and rectal immunization were predominantly $\alpha_4\beta_{7^+}$ AFCs.[11] In the latter study, most of the AFCs produced IgA, but some also expressed IgG. After nasal immunization, AFCs expressed both L-selectin and $\alpha_4\beta_7$ homing receptors. The APCs in GALTs were shown to produce high levels of retinoic acid, which promotes expression of $\alpha_4\beta_7$. Thus, enteric immunization of GALTs more effectively triggers $\alpha_4\beta_7$ memory IgA and IgG B cells, which can then migrate into the bloodstream.

Lymphocyte Homing in Nasopharyngeal-Associated Lymphoid Tissues and Lung-Associated Tissues

Unlike PP HEVs, which are found in T-cell zones, murine NALT HEVs are found in B-cell zones and express PNAd, either alone or associated with MAdCAM-1. Moreover, anti–L-selectin antibodies—but not anti–MAdCAM-1 antibodies—block the binding of naïve lymphocytes to NALT HEVs, suggesting a role for L-selectin and PNAd in the binding of naïve lymphocytes to these HEVs.[12]

During pulmonary immune responses, induction of VCAM-1, E-selectin, and P-selectin in the pulmonary vasculature is matched by increased expression of P-selectin ligand on peripheral blood CD4 and CD8 T cells.[13] As the cells accumulate in the bronchoalveolar lavage (BAL) fluid, the number of cells that express P-selectin ligand in blood declines. Very late antigen-4 (VLA-4) appears to be involved, as migration of VLA-4$^+$ T cells into BAL fluid is impaired following treatment with anti-α_4 antibody. Following systemic immunization, most NALT effector B cells express L-selectin, with only a few cells expressing $\alpha_4\beta_7$.[14] Effector B cells induced by nasal immunization display a more promiscuous pattern of adhesion molecules, with a large majority expressing both L-selectin and $\alpha_4\beta_7$.

The Common Mucosal Immune System Revisited

The homing pattern that has been elucidated in the GI tract after immunization of GALTs has been the model for all mucosal immune sites. As summarized above, the specific set of homing receptors and ligand addressins expressed in the GI tract are absent in NALTs and associated lymph nodes. It remains possible, and even likely, that memory lymphocytes from the gut may enter NALTs for additional priming and reprogramming of homing receptors. Likewise, memory lymphocytes induced in NALTs may traffic to lung and genitourinary tract tissues as well as to the GI tract. Thus, the rules for the homing of naïve lymphocyte precursors to NALTs need to be more clearly defined.

INDUCTION OF MUCOSAL IMMUNITY

Mucosal immune responses are typified by SIgA antibodies, the predominant Ig isotype in external secretions. The resistance of SIgA to endogenous proteases makes them uniquely suited to protect mucosal surfaces. The development of mucosal adaptive immunity requires cytokine signals from CD4, as well as from CD8, T cells, DCs, MØs, B cells, and nonclassic APCs (e.g., epithelial cells). B-cell commitment (Cμ to Cα switching) and the interactions of B and T cells are of central importance for induction of pIgA-producing cells.

Mucosal Antigen-Presenting Cells

Large macromolecules are taken up by M cells in the GI tract. Just beneath the follicle epithelium, N418$^+$, 2A1$^+$, NLDC-145$^-$, and M342$^-$ DCs, form a dense layer of cells in the subepithelial dome (SED) where CD4 T cells can be found.[15] Another subset of DCs, N418$^+$, 2A1$^+$, NLDC-145$^+$, and M342$^+$ DCs populate the interfollicular T-cell regions, where both CD4 and CD8 T cells reside. DCs in the dome region are immature, highly endocytic, and express low levels of major histocompatibility complex (MHC) (Chapter 5) and B7 molecules. DCs in the T-cell area are mature, with low endocytic activity, high levels of MHC class I and II molecules, and B7 molecule expression (see Fig. 24.4, A). DCs are also found in NALTs, where they play essentially the same role as in GALTs.

IECs express MHC class II and class I molecules and present peptides to primed CD4 and CD8 T cells. Human and murine IECs also express CD1d, a nonclassic MHC class I molecule involved in the presentation of lipid and glycolipid antigens (Chapter 5).

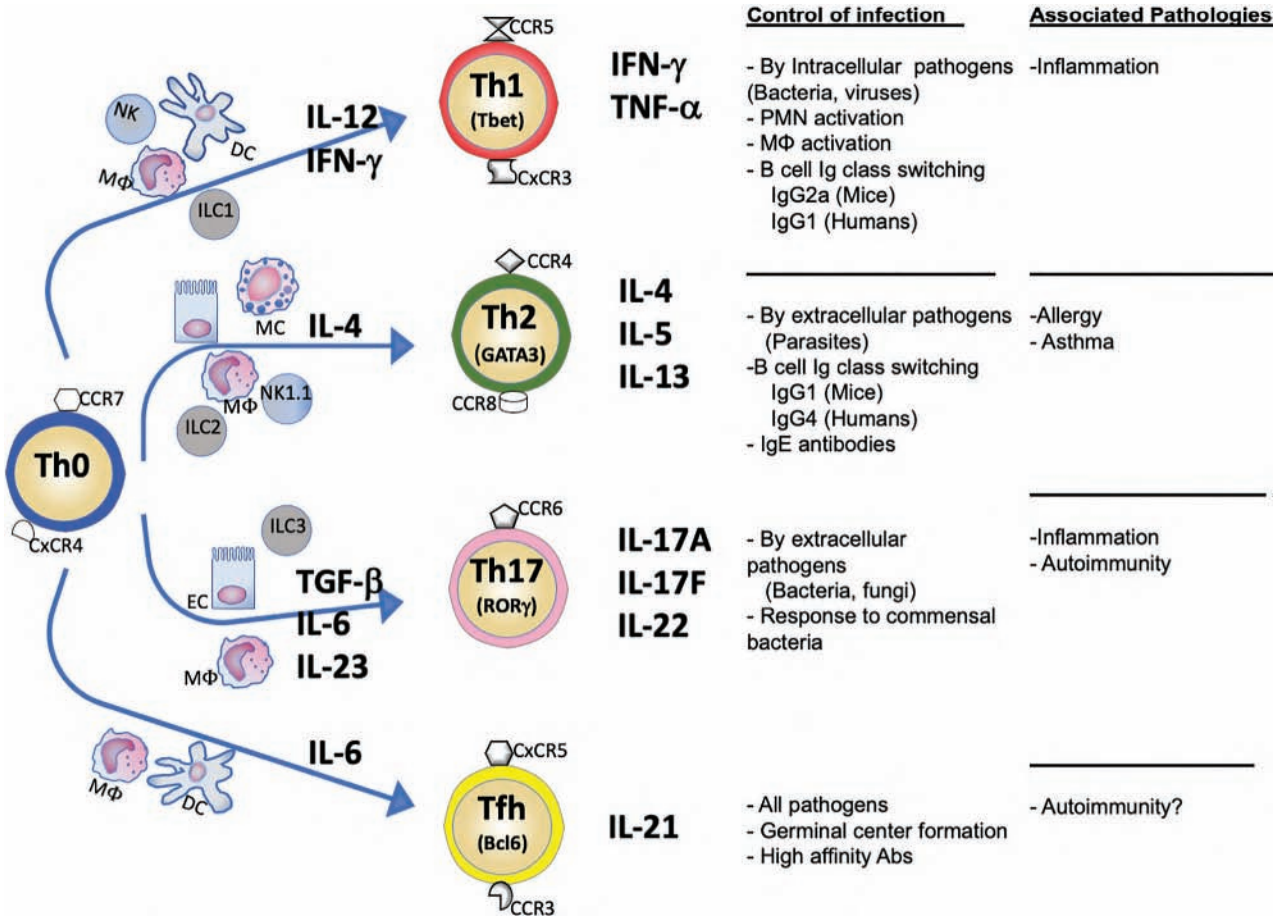

FIG. 24.6 T-Helper (*Th*) Cell Subset Development in Mucosal Tissues. The cellular and cytokine environment induces Th0 cells to develop into Th1, Th2, or Th17 subsets that can be discriminated, based upon their cytokine production. Antigen-presenting cells (APCs) produce IL-12 in response to microbial assault and, together with interferon (*IFN*)-γ produced by natural killer (*NK*) cells and group 1 innate lymphoid cells (*ILC1*), induce mature Th1 cells. Th1 cells express select chemokine receptors and through IFN-γ synthesis, activate macrophages (*MØs*), and induce B cells to produce opsonizing antibodies. Other cells, such as NK1.1, mast cells, and ILC2, respond to parasite/antigen/allergen with interleukin (*IL*)-4 production. IL-4 induces Th0 to Th2 differentiation. Epithelial cells (*ECs*) also produce cytokines that facilitate Th2 cell differentiation. Th2 cells produce IL-4, -5, -6, -9, -10, and -13, which help regulate mucosal secretory immunoglobulin A (*SIgA*) antibody responses. Transforming growth factor (*TGF*)-β, IL-6, and IL-23 produced by epithelial cells, MØs and other cells, help promote the differentiation of Th17 cells. The cytokines produced by Th17 cells contribute to several functions for the host response to commensal bacteria and protection against fungal infections. Follicular T-helper cells (*Tfh*) are a subset of Th cells that help the germinal center formation and the development of high-affinity antibodies (*Abs*).

CD4 T-Helper Cell Subsets in Mucosal Immunity

Th cells are classified as Th1, Th2, Th17, regulatory T cells (Treg), or follicular Th (Tfh) cells, according to the cytokines they produce (Chapter 11). Th1 cells produce IFN-γ, LT-α, LT-β, and TNF, whereas Th2 cells produce IL-4, IL-5, IL-6, IL-9, IL-10, and IL-13 (Fig. 24.6). In mice, mucosal Th1-type responses are associated with cell-mediated immunity and B-cell responses with characteristic IgG2a antibodies. Th2 cells support the production of IgA, as well as IgG1, IgG2b, and IgE. In humans and mice, Th1 and Th2 cells regulate the development of the opposite subset reciprocally through IFN-γ and IL-4 secretion, respectively (see Fig. 24.6). Human Th1 cells and IFN-γ responses are associated with IgG1, IgG3c-fixing antibodies with low IgG2, and undetectable IgG4 antibody levels,[16] suggesting that in humans IL-4 promotes IgG4 and IFN-γ promotes IgG1 (see Fig. 24.6).

Treg and Th17 cells play a role in mucosal homeostasis and inflammatory responses (Chapter 13). Human tonsil CD4 T cells expressing the B-cell follicle homing receptor CXCR5 are identified as Tfh cells that help B-cell differentiation.[17] Foxp3$^+$ Treg in PPs can apparently differentiate into Tfh cells, which express the chemokine CXCR5, the transcription factor Bcl-6, and the cytokine IL-21, to promote germinal center formation and IgA synthesis in the gut.[18]

B-Cell Isotype Switching and Immunoglobulin A Plasma Cell Differentiation

Isotype switching is preceded by transcriptional activation of the isotype in question (Chapter 4). IL-4 and TGF-β induce surface IgM-positive (sIgM$^+$) B cells to switch to IgE and IgA. TGF-β1 can induce sIgM$^+$ to sIgA$^+$ B-cell switches, and addition

of TGF-β1 to LPS-triggered mouse B-cell cultures increases IgA synthesis. In humans, anti-CD40 stimulation of tonsillar B cells, together with TGF-β1 in the presence of IL-10, stimulates IgA synthesis[1]Cα1 transcripts can also be induced by B-cell mitogen plus TGF-β, and Cα2 transcripts can be induced by TGF-β together with IL-10.

DCs can also induce surface IgA$^+$ B cells via direct stimulation of B cells with B-cell activation factor of the TNF family (BAFF) and a proliferation-inducing ligand (APRIL).[19] APRIL–transmembrane activator and CAML interactor (TACI) signaling play a key role in CD40-independent IgA class switching in mice.[19] In humans, functional mutations in TACI can result in IgA deficiency (IgAD; Chapter 33). Differentiation of sIgA$^+$ B cells into IgA-producing plasma cells is dependent on IL-5 and IL-6.[20]

VACCINE DEVELOPMENT AND MUCOSAL IMMUNE RESPONSES

Mucosal SIgA antibodies, as well as Th cell and cytotoxic T lymphocyte (CTL) responses, can be induced by pathogens triggering organized mucosal inductive sites. Effective protection against virulent mucosal pathogens requires prophylactic immune responses that can be achieved through mucosal vaccines. In contrast to conventional injected vaccines, those administered via mucosal routes can stimulate organized mucosal inductive sites and trigger both mucosal immune responses as a first line of defense at the portal of pathogen entry, and systemic immune responses that neutralize pathogens that have penetrated that barrier. Thus, safe adjuvants and delivery systems boosting SIgA antibodies and mucosal immunity are being developed for immunization by needle-free vaccines. These efforts are in large part as a result of knowledge gained from studies of bacterial enterotoxins and nontoxic derivatives (Fig. 24.7).

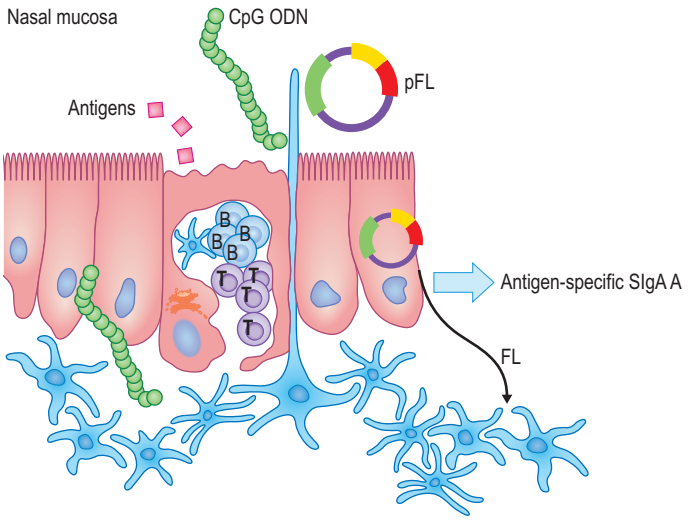

FIG. 24.7 Dendritic cell (DC) targeting with a nasal adjuvant. Nasal administration of CpG oligodeoxynucleotide (*ODN*) and plasmid expressing FLT3 ligand cDNA (*pFL*) specifically target DCs in nasopharyngeal-associated lymphoid tissues (NALTs). These nasal DC-targeting vaccines successfully elicit protective antigen-specific secretory immunoglobulin A antibody (*SIgA Ab*) responses in older adults.

Lessons From Studies of Bacterial Enterotoxins

Earlier studies of cholera toxin (CT) and heat-labile toxin I (LT-I) from *Escherichia coli* helped establish that mucosal (i.e., oral or nasal) administration of vaccines was an effective approach for the induction of both mucosal and systemic immunity, to co-administered vaccine antigens (Chapter 87). These closely related molecules are AB-type toxins consisting of two structurally and functionally separate enzymatic A subunits and binding B subunits (see Fig. 24.7). The B subunit of cholera toxin (CT-B) binds to GM1 gangliosides, whereas the B subunit of heat-labile toxin I (LT-B) binds to GM1 as well as GM2 asialo-GM1 gangliosides. The A subunits of these toxins are adenosine diphosphate (ADP)–ribosyl transferases. Binding of the B subunits to ganglioside receptors on target cells allows the A subunits to reach the cytosol where they elevate cyclic adenosine monophosphate (cAMP) levels.

Cellular Targets of Vaccine Adjuvants Can Shape the Immune Response

Studies with CT and LT-I revealed the importance of the cellular targets for shaping the profile of immune responses induced by mucosal adjuvants. In fact, CT promotes CD4 Th2 and Th17 responses, whereas LT-I also induces a CD4 Th1 (i.e., IFN-γ) response.[21] As discussed below, studies with mutants of these enterotoxins and other toxins (e.g., *Bacillus anthracis* edema toxin[22]) have shown that their enzymatic activities are dispensable for vaccination.

Potential Central Nervous System Targeting Is a Safety Concern with Nasal Vaccines

Cholera induces diarrhea as a result of its ability to elevate cAMP in epithelial cells, thereby promoting secretion of water and chloride ions into the intestinal lumen. Diarrhea is thus the primary limiting factor for the use of oral enterotoxin as an adjuvant in humans. The olfactory neuroepithelium in the nasopharynx constitutes approximately 50% of the nasal surface and has direct neuronal connection to the olfactory bulbs (OBs) in the central nervous system (CNS). Nasally delivered enterotoxins can enter and/or target olfactory neurons and therefore gain access to OBs and deeper structures in the brain parenchyma. These adverse effects are, in large part, mediated by the ADP–ribosyl transferase activity and the nature of the cellular receptors targeted. Both CT and LT-I bind to GM1 on epithelial cells and require endocytosis followed by transport across the epithelial cell to reach the basolateral membrane. GM1 gangliosides are also abundantly expressed by the neuronal and microglial cells of the CNS.[23] CT or CT-B, when administered nasally to mice, enters the olfactory nerves and epithelium (ON/E) and OBs by mechanisms that are selectively dependent on GM1.[24] The targeting of CNS tissues by nasally administered bacterial enterotoxins is clearly related to a higher incidence of Bell palsy (facial paresis) among volunteers of a nasal vaccination trial given LT-I as a mucosal adjuvant. Bell palsy occurring among study subjects who received a non-living nasal influenza vaccine (Nasalflu) led to its withdrawal from the market in the year 2000.

CLINICAL RELEVANCE

Examples of Mucosal Adjuvants and Delivery Systems for the Induction of Targeted Immunity

Genetically Engineered Bacterial Toxins
- Examples are derivatives of the enterotoxin cholera toxin (CT) and heat-labile toxin (LT-I) from *Escherichia coli*.

Nucleic Acid Toll-Like Receptor Ligands
- These sequences typically contain a transcription unit designed to express the antigen in question that is coupled to an adjuvant/mitogen unit, such as CpG motifs.

Mucosal Cytokines and Innate Factors as Adjuvants
- Mucosal delivery of specific cytokines or innate factors can reduce the risk of adverse systemic effects while targeting the immune response to the mucosa.

Transgenic Plants
- Plants, such as potatoes, bananas, lettuce, and rice, can be engineered to express both B- and T-cell antigen epitopes, providing a simple delivery system for oral vaccination or oral tolerance induction.

New Mucosal Adjuvants and Delivery Systems

Nontoxic Derivatives of Bacterial Enterotoxins

To circumvent the toxicity of enterotoxins, mutants of CT (mCT) and LT (mLT) molecules were generated by site-directed mutagenesis in the active site of the A subunit of CT or LT, or in the protease-sensitive loop of LT. These mutants induced comparable levels of antigen-specific serum IgG and IgA antibodies as wild-type CT and significantly higher levels than those induced by recombinant CT-B.[25] One of the mutants also induces Th2-type responses through a preferential inhibition of Th1-type CD4 T cells. mLT molecules, whether possessing a residual ADP–ribosyltransferase activity (e.g., LT-72R) or totally devoid of it (e.g., LT-7 K and LT-6 K3), can also function as mucosal adjuvants for nasal vaccine antigens in mice.[26] As LT induces a mixed CD4 Th1- and Th2-type response,[21] one might envisage the use of mLTs when both Th1- and Th2-type responses are desired.

The use of GM1-receptor binding holotoxins as nasal mucosal adjuvants is currently not recommended because of the risk for their accumulation in the CNS. However, nontoxic mCT could overcome these potential problems. To this end, a model adjuvant has been developed by combining the ADP-ribosylating ability of native CT (nCT) with a dimer of an Ig-binding fragment, D, of *Staphylococcus aureus* protein A.[27] This CTA1-DD molecule directly binds to B cells of all isotypes, but not to MØs or DCs. Despite the lack of a mucosal binding element, the B-cell–targeted CTA1-DD molecule is as strong an adjuvant as nCT. Notably, CTA1-DD promoted a balanced Th1/Th2 response with little effect on IgE antibody production. CTA1-DD did not induce inflammatory changes in the nasal mucosa and, most importantly, did not bind to or accumulate in the OBs or the CNS.[27] CTA1-DD is an example of the use of nonganglioside targeting adjuvants and delivery systems as new tools for the development of safe and effective nasal vaccines.

Nucleic Acid Toll-Like Receptor Ligands

Toll-like receptor 3 (TLR3) and TLR9 recognize the pathogen-associated microbial pattern double-stranded RNA (dsRNA) and unmethylated DNA, respectively (Chapter 3). The latter contains immunostimulatory sequences consisting of short palindromic nucleotides located around a CpG dinucleotide core (e.g., CpG motifs). CpG motifs bind to intracellular TLR9 and induce cytokine secretion (i.e., IL-6, IFN-α, IFN-β, IFN-γ, IL-12, and IL-18) by a variety of immune cells. CpG motifs can enhance both systemic and mucosal immune responses when given nasally to mice.[28] An injection of bacterial DNA or CpG motifs with a DNA vaccine or with a protein antigen promotes Th1-type responses even in mice with preexisting Th2-type immunity. Stimulation of TLR3 by dsRNA results in the production of type I IFNs (i.e., IFN-α/β), which stimulate antibody responses to injected vaccines.[29] The synthetic TLR3 ligand polyinosinic–polycytidylic acid (poly I:C) has been shown to enhance responses of CD8 T cells to an experimental nasal influenza vaccine in mice and promote heterosubtypic protection via stimulation of TLR3 signaling by nonhematopoietic radioresistant cells.[30]

Cyclic dinucleotides that bind stimulator of interferon gamma genes (STING) were recently shown to be potential alternatives to cAMP-inducing bacterial toxins, and derivatives as vaccine adjuvants for induction of mucosal immunity. For example, STING ligands of bacterial origin, including 3′3′-cGAMP, c-di-AMP, and c-di-GMP, have been shown to effectively elicit mucosal and systemic immune responses following nasal or sublingual immunization. Like the enterotoxins CT and LT, the STING ligands stimulate Th17 responses, an important observation since Th17 cells are believed to be crucial for production of high-affinity T-dependent IgA.[31]

Mucosal Cytokines and Innate Factors as Adjuvants

Mucosal delivery of cytokines offers a means to prevent the adverse effects associated with the large and repeated parenteral doses often required for the effective targeting of tissues and organs. For example, nasal delivery permits acquisition of significant serum levels of IL-12 at one-tenth the dose required for inhibition of serum IFN-γ by parenteral administration.[1] Earlier studies have shown that nasal administration of tetanus toxoid with IL-12 as adjuvant induced high titers of SIgA antibody responses in the GI tract, vaginal washes, and saliva.[32] Similar results were reported when mice were nasally immunized with soluble influenza H1 and N1 proteins and IL-12. Related studies showed that mucosally administered IL-12 can redirect antigen-specific Th2-type responses toward the Th1 type or promote mixed Th1- and Th2-type responses, depending on the mucosal route and timing of delivery.[1]

FMS-like tyrosine kinase 3 ligand (FL) binds to the FMS-like tyrosine kinase receptor Flt3/Flk2. FL mobilizes and stimulates myeloid and lymphoid progenitor cells, DCs, and NK cells. Although FL dramatically augments numbers of DCs in vivo, it fails to induce their activation. Treatment of mice by systemic FL injection can induce marked increases in the numbers of DCs in both systemic (i.e., spleen) and mucosal lymphoid tissues (i.e., iLP, PPs, and mesenteric lymph nodes). Although this increase in mucosal DCs can, in some cases, initially enhance induction of oral tolerance, it favors the induction of immune responses by mucosal or systemic vaccines. Nasal administration of plasmid or adenovirus encoding FL cDNA (pFL or Ad-FL) with protein antigens was shown to induce antigen-specific secretory IgA (SIgA) and protective immunity.[28] Thus FL cDNA may be an alternative to costly treatments with FL protein.

Transgenic Plants

Edible plants have been engineered to synthesize and assemble one or more antigens that retain both T- and B-cell epitopes, thereby inducing systemic and mucosal immune responses in both mice and humans.[33,34] To circumvent potential denaturation of the plant antigen during cooking, recombinant bananas that can accumulate up to 1 mg of vaccine antigen per 10 g of banana were developed. Most recently, the CT-B subunit has been expressed under the control of the rice seed storage protein glutelin promoter (MucoRice-CT-B). Oral feeding of powdered MucoRice-CT-B to mice and nonhuman primates resulted in the induction of both systemic and mucosal antibody responses for protection against CT.[35] Unlike plant vaccines expressed in banana, tomato, or lettuce, MucoRice vaccines were shown to be stable for years at room temperature.

ON THE HORIZON

Development of Transgenic Plants as Vehicle for Vaccine Administration

- The MucoRice system is a novel strategy for vaccine development.
- The MucoRice system may also be used as a passive neutralizing antibody delivery system.

SYNTHESIS AND FUNCTIONS OF SECRETORY ANTIBODIES

Mucosal SIgA differs from serum IgA in both molecular composition and specific antibody activity. Humans possess two Cα gene segments, Cα1 and Cα2 (Chapter 4), the use of which defines the two IgA subclasses, IgA1 and IgA2.[8] These IgA subtypes differ primarily in their hinge regions (Chapter 8). IgA1 antibodies contain an additional 13 amino acids in the hinge region, and this renders them more flexible and susceptible to IgA1-specific proteases produced by certain bacteria. IgA1-secreting cells are prevalent in most human mucosal tissues, especially the small intestine and the respiratory tract, whereas the human colon and genital tract are enriched by IgA2-secreting cells. SIgA is mostly viewed as a barrier at mucosal surfaces to regulate interactions with commensals and prevent adhesion and colonization of pathogens, as well as an effective means to neutralize viruses and toxins. Nonetheless, these antibodies confer the additional advantage of having anti-inflammatory properties.[8]

In external secretions, adult levels of SIgA are reached considerably earlier (1 month to 2 years) than in the serum (adolescence). Approximately 98% of SIgA antibodies are produced locally in mucosal tissues, with only a minor fraction deriving from the circulation.Polymeric Immunoglobulin Receptor and plgA Transport

The polymeric Ig receptor (pIgR) is synthesized as a transmembrane protein by epithelial cells and is found on the basolateral surface of epithelial cells. It acts as a receptor for the endocytosis of pIgA(dimeric) and pentameric IgM, both of which contain a J-chain. The pIgR is produced by bronchial epithelial cells, renal tubules, glands, and the epithelia of the small and large intestines.[1] The pIgR is not expressed by the FAE (including M cells) of PPs, but only by the adjacent columnar epithelial cells. Furthermore, pIgR is expressed in the upper respiratory tract, which includes the nasal cavity, tonsils, trachea, bronchi, and tracheobronchial glands. Expression in the lower lungs is restricted to the pulmonary alveolar cells.

In female reproductive tissues, the expression of pIgR is influenced by the sex hormones. It is low in the vagina, absent in the ovary and myometrium, and very high in the fallopian tubes and uterus. Normal kidneys do not express pIgR, whereas epithelial cells in the lower urinary tract may normally express pIgR and transport pIgA into urine. The expression of pIgR can be upregulated by several cytokines, such as IFN-γ, TNF, IL-1α, IL-1β, and TGF-β.

KEY CONCEPTS

Secretory Immunoglobulin A

- Unlike serum immunoglobulin A (IgA), mucosal secretion of IgA reaches adult levels early in life (1 month to 2 years after birth).
- The polymeric Ig receptor (pIgR) is expressed on the basolateral surface of epithelial cells and facilitates the active transport of polymeric (mainly dimeric) IgA, as well as pentameric IgM into mucosal secretions.
- SIgA protects the host by inhibiting microbial adherence, neutralizing viruses, enzymes, and toxins, and engaging in anti-inflammatory activities by means of inhibiting IgM and IgG complement activation.
- Although selective IgA deficiency could occur, the most common is primary immune deficiency; normally, it is clinically inconsequential. Some affected subjects develop recurrent mucosal infections, including sinusitis, otitis media, bronchitis, and pneumonias of viral or bacterial origin, as well as acute diarrhea caused by viruses, bacteria, or parasites such as *Giardia lamblia*.

IgA-Mediated Inhibition of Microbial Adherence

The inhibition of microbial adherence plays a critical initial role in the protection of the host. This inhibition is mediated by both specific and nonspecific mechanisms. The surface of microorganisms interacting with SIgA becomes less hydrophobic and thus more likely to be entrapped in mucus. A series of recent studies have revealed that binding of SIgA to intestinal microbes is more sophisticated than originally envisioned. Thus, individual SIgA can specifically bind to a broad, but well-defined subset of bacteria.[36] Furthermore, while most commensals are dually targeted by SIgA1 and SIgA2 in the small intestine of humans, the situation appears to be different in the large intestine where some bacteria are either preferentially or exclusively recognized by IgA2. Finally, SIgA antibodies are more effective at agglutinating microorganisms than membrane-bound IgA, and the agglutinating ability of SIgA specific for capsular polysaccharides of *Haemophilus influenzae* appears to be crucial to preventing colonization by *H. influenzae*.

Neutralization by SIgA of Viruses, Enzymes, and Toxins

SIgA antibodies have been shown to be effective at neutralizing viruses in several experimental systems (e.g., influenza virus, Epstein-Barr virus [EBV], HIV) and at different steps in the infectious process. SIgA specific for influenza hemagglutinin can interfere with the initial binding of influenza virus to target cells or with the internalization and the intracellular replication of the virus. In vitro experiments employing polarized murine epithelial cells have demonstrated that antibodies specific to rotavirus and hepatitis virus can neutralize the viruses inside epithelial cells. Finally, SIgA can neutralize the catalytic activity of many enzymes of microbial origin.

Anti-Inflammatory Actions Mediated by SIgA Antibodies

IgA antibodies are unable to activate complement by either the classical or the alternative pathway (Chapter 40). Nevertheless, they can interfere with IgM- and IgG-mediated complement activation.[8] SIgA can inhibit phagocytosis, bactericidal activity, and chemotaxis by polymorphonuclear neutrophils (PMNs), monocytes, and MØs. IgA can downregulate the synthesis of TNF and IL-6, as well as enhancing the production of IL-1R antagonists by LPS-activated human monocytes. Thus, the anti-inflammatory properties of IgA are of significant importance for the integrity of the mucosa in that IgA can limit bystander tissue damage that may result from the continuous interactions of the mucosa with myriad dietary and environmental antigens. Systemically, circulating IgA also appears to help limit inflammatory reactions that result from complement fixation and phagocyte activation, and it contributes to the inhibition of IgE-dependent anaphylactic responses.

IgA Deficiency

Selective IgAD is the most common primary immune deficiency (PID) in individuals of European descent (Chapter 33). The clinical diagnosis of IgAD depends on the relative absence of IgA in the serum. However, the most important manifestations of the disorder primarily reflect the absence of both SIgA1 and SIgA2 in the external secretions. Thus IgAD affects both the mucosal and systemic immune compartments, with only rare individuals exhibiting a superselective loss of either IgA1 or IgA2 alone.

MUCOSAL CYTOTOXIC T LYMPHOCYTES

M cells have specific receptors for mucosal virus that allow certain viruses, such as reoviruses, to enter the cells in both NALTs and GALTs. It is likely that enteric viruses, such as rotavirus, and respiratory pathogens, such as influenza virus and respiratory syncytial virus (RSV), also enter the mucosal inductive pathway via M cells.[37] After enteric infection or immunization, antigen-stimulated CTLs are disseminated from PPs into mesenteric lymph nodes via the lymphatic drainage. Oral immunization with live virus can thus induce antigen-specific CTLs in both mucosal and systemic lymphoid tissues.

KEY CONCEPTS

Mucosal Cytotoxic T Lymphocytes

- After enteric infection or immunization, antigen-stimulated cytotoxic T lymphocytes (CTLs) are disseminated from Peyer patches into mesenteric lymph nodes via the lymphatic drainage.
- Oral immunization with a live virus can induce antigen-specific CTLs in both mucosal inductive and effector tissues for mucosal immune responses, as well as in systemic lymphoid tissues for serum immune responses.

Enteric Viruses and Mucosal Cytotoxic T Lymphocytes

CD8 CTLs (Chapter 12) play a central role in rotavirus and reovirus immunity. Reovirus-induced CTL precursors (pCTLs) in GALTs migrate to the systemic compartment. Reovirus-specific CD8 CTLs associated with the αβ T-cell population are also observed in intraepithelial T lymphocytes. Oral delivery of rotavirus increases pCTLs in GALTs and results in their dissemination throughout the murine lymphoid system within 3 weeks. Moreover, adoptively transferred CD8 T cells mediate the clearance of rotavirus infection in severe combined immunodeficiency mice.

Respiratory Viruses and Mucosal Cytotoxic T Lymphocytes

Studies of immune responses after nasal infection with influenza virus in CD4-coreceptor knockouts, or other mice in which this subset had been depleted, have shown that CD4 T cells do not affect the induction of pCTLs or significantly alter clearance of infection. Clearance of influenza is unaltered by the use of β2-microglobulin knockout mice, which lack CD8 T cells, or of mice that have been treated with monoclonal anti-CD8. γδ T cells with several Vδ chain specificities increase in the infected site as clearance occurs, which suggests a regulatory role for γδ T cells in antiviral immunity.

Mucosal AIDS Models for Cytotoxic T-Lymphocyte Responses

Approximately 80% of new HIV-1 infections result from sexual transmission (Chapter 41). Studies using the rhesus macaque and the simian immunodeficiency virus (SIV) vaginal infection model have provided evidence that pCTLs occur in female macaque reproductive tissues and that infection with SIV induces CTL responses. This important finding was extended to vaginal infection with an SIV/HIV-1 chimeric virus (SHIV) containing the HIV-1 89.6 *env* gene. Other studies have shown that nasal immunization with SIV/HIV components induces antibody responses in vaginal secretions.

Other Mucosal Cytotoxic T-Lymphocyte Systems

Salmonella can elicit CD8 T-cell responses, including CTLs, to expressed proteins, and CD8 T cells induced by the parasite *Toxoplasma gondii* have been shown to be protective. Thus, mucosal CD8 CTLs can also be induced in nonviral situations. Significant questions remain as to the mechanism by which naïve CD8 T cells can be triggered to expand into pCTLs and to the rules for expression of effector CTLs and memory in the actual mucosal compartment that manifests the infection. pCTLs accumulate in immunologically privileged sites, but they do not develop a cytotoxic function until they encounter infected class I MHC-presenting target cells. It is possible that this mechanism protects the common mucosal immune system network from inadvertent cytotoxic inflammatory events.

MUCOSAL IMMUNE RESPONSES IN EARLY LIFE AND AGING

Although most of its structures are present at birth, the mucosal immune system requires further postnatal development and maturation before becoming fully functional (Chapter 21). GALTs, NALTs, and tonsils are present in humans at birth. The bacterial colonization after birth increases the number of immune cells and germinal centers in these sites and the number of secondary lymph nodes (e.g., mesenteric lymph nodes and cervical lymph nodes; Chapter 2) and generates innate lymphoid follicles (ILFs). Significant changes that occur after bacterial colonization include an increase in SIgA levels and in the numbers of IgA-secreting cells, Treg, and Th17 cells. BALT

only develops after birth. It is clear that the immature mucosal immune system in early life cannot protect against infectious pathogens entering mucosal surfaces. This gap is filled by maternal antibodies, which are acquired either before birth through the placenta or after birth via ingestion of milk.

KEY CONCEPTS

Mucosal Immunosenescence

- Early mucosal aging is evident in the gastrointestinal (GI) tract immune system.
- Nasal immunization is an effective route for the induction of mucosal and systemic immune responses in aging mice.
- Dendritic cell (DC)–targeting mucosal adjuvants are able to elicit protective pathogen-specific secretory immunoglobulin A (SIgA) antibody responses in aged mice.

Immune functions are known to deteriorate as a result of aging in several species (Chapter 21). The risk and severity of infections are higher, and the susceptibility to certain types of autoimmune diseases and cancer are greater in older adults, and responses to vaccination are diminished. Aging-associated alterations of the systemic immune compartments have been studied extensively. Dysfunctions occur in both B and T cells, although the latter are considered more susceptible to immunosenescence.[38]

In humans, older subjects were reported to have significantly higher concentrations of salivary SIgA antibodies compared with younger subjects, whereas whole gut lavages of aged and young subjects contain similar amounts of antibodies.[28] Analogous results have also been obtained for total IgA antibody responses in the serum of aged animals and humans. These results indicate an absence of aging-associated impairment in total IgA antibody levels in external secretions.

The GI tract in older adults is particularly susceptible to infectious diseases. Antigen-specific mucosal IgA antibody responses are diminished in aged animals, especially those in GALTs.[28] In older humans, pathogens that invade through mucosal surfaces of the airways, such as influenza virus, SARS-Cov-2, and the bacterial pathogen *Streptococcus pneumoniae*, cause more severe and more frequently lethal infections. The development of effective vaccines for older adults remains a largely unmet goal. To provide effective protection against influenza, *S. pneumoniae* and COVID-19 for this population, one should strongly consider developing a new generation of vaccines that could induce pathogen-specific immunity in the respiratory tract.[28] Although it has been shown that effective protection can be provided by pathogen-specific systemic IgG without mucosal IgA responses, pathogen-specific SIgA responses are a necessary component for providing a first line of effective immunity against these respiratory pathogens at their entry site.

Host Defenses to Viruses

Scott N. Mueller and Barry T. Rouse

Viruses as obligate intracellular parasites require their host to replicate them and to facilitate their spread to others. In humans, most clinically relevant infections were derived from other animals, and this process continues. Recent examples include human immunodeficiency virus (HIV), Ebola virus, Zika virus, and severe acute respiratory syndrome (SARS) virus, including the novel coronavirus (CoV), SARS-CoV-2, that is responsible for the ongoing COVID-19 pandemic. In contrast to these examples, viral infections are rarely lethal, even if they are highly cytolytic to individual cells. Mortality commonly occurs when viruses jump species (SARS-related coronaviruses are believed to have originated in horseshoe bats in China), when the virus undergoes a major antigenic change (i.e., influenza viruses), or when host immunity is compromised. HIV (see Chapter 41) represents one of the more dramatic human examples of an exotic virus that kills its host. However, HIV kills slowly, providing ample time to spread to new hosts and an effective strategy for persistence in the species. Death or dire consequences following virus infection in mammals with inadequate immunity are well illustrated by observations that fetuses or neonates, especially if deprived of passive immunity, succumb to many agents well tolerated by healthy adults. The science of viral immunology seeks to understand mechanisms of virus-host interactions with a view to applying this knowledge to the design of effective vaccines and immunomodulators that control virus infections. These objectives are facilitated by an increasing wealth of immunological techniques, an expanding array of genetically manipulated animal models, and an abundance of high-throughput technologies, which generate data that can be subjected to complex computational analysis. Such analyses can yield signatures indicative of optimal immunogenicity and vaccine efficacy or failure and can explain the variable outcome of infections in individual hosts. In most situations, defense against viruses involves multiple immune components, and the impact of a single mechanism varies greatly according to the method by which individual viruses enter, replicate, and spread within the host. In this chapter, we highlight the principal means by which the host achieves immunity after infection by viruses. Table 25.1 presents an overview.

VIRAL ENTRY AND INFECTION

Access to target tissues presents numerous obstacles for entry and infection by most human viruses. Most effective of these are the mechanical barriers provided by skin and the mucosal surfaces, as well as the chemically hostile environment of the gut (Fig. 25.1). A number of common human viral pathogens enter through the gastrointestinal tract, including rotavirus, enteric adenoviruses, and hepatitis A virus (HAV). These are usually spread via person-to-person contact or contaminated food and water. Respiratory infections caused by influenza viruses, rhinoviruses, coronaviruses (including the SARS coronaviruses), measles virus, varicella-zoster virus (VZV), and respiratory syncytial virus (RSV) are often spread by aerosol transmission, as well as person-to-person contact. Many of the herpes viruses target the skin or the mucosae, such as herpes simplex virus (HSV) and VZV. HSV, in particular, can infect the oral and genital mucosae, the eye, and skin through small cuts and abrasions. Other herpes viruses, such as Epstein-Barr virus (EBV) and cytomegalovirus (CMV), target mucosae. CMV can also spread vertically from mother to baby or rarely via blood transfusions. Human papillomavirus (HPV) targets skin and mucosae and causes warts and may transform cells, inducing cancers, such as cervical cancer. Some viruses, such as West Nile virus, sengue virus, Semliki Forest virus, and Zika virus, can enter through the skin via insect vectors. HIV and hepatitis B virus (HBV) are commonly spread via sexual contact. HIV, HBV, and hepatitis C virus (HCV) can also infect humans by direct entry into the bloodstream via transfusions or contaminated needles.

Most human viruses replicate only in certain target tissues, this being mainly the consequence of viral receptor distribution. Many viruses use two receptors, such as the use of the CD4 coreceptor and the chemokine receptor CCR5 on T cells by HIV. After attachment to a cellular receptor, viruses may fuse with the cell membrane or be endocytosed and then gain entry into the cytoplasm or nucleus by fusing with the vesicular membrane (enveloped viruses, such as HSV and HIV), or translocate across the cell membrane or induce lysis of the endocytic vesicle once in the cytoplasm (nonenveloped viruses, such as Norwalk virus and poliovirus).[1] Viruses then utilize host cell machinery and specialized virally encoded proteins to replicate rapidly within the cell. Once they have multiplied within the cell, many viruses induce cytolysis to facilitate the release of new infectious virions (e.g., poxviruses, poliovirus, and herpes viruses). Other viruses are released from infected cells by budding through the cell membrane in the absence of cell death (e.g., HIV and influenza virus). Having entered the body, however, viruses encounter numerous innate defenses and activate the components of adaptive immunity. The latter usually assures that clinical disease, if not infection, will not become evident. Successful exploitation of these defenses through the use of vaccines (see Chapter 87) remains a central challenge for many human viruses, particularly those that cause chronic infections, such as HIV and HCV.[2]

TABLE 25.1 Viral Infections and Immunity

Viral Event	Obstacles	Time Course
Transmission	Mechanical and chemical barriers	0
Infection and replication	Innate immunity	0 →
Infection stopped or spreads	Viral antigens transported to lymphoid tissues	Within 24 h
Infection controlled	Specific antibodies and cell-mediated immunity	4–10 days
Sterile immunity	Immune memory	14 days to years
Viral persistence if infection not controlled	Immune disruption or evasion	Weeks to years

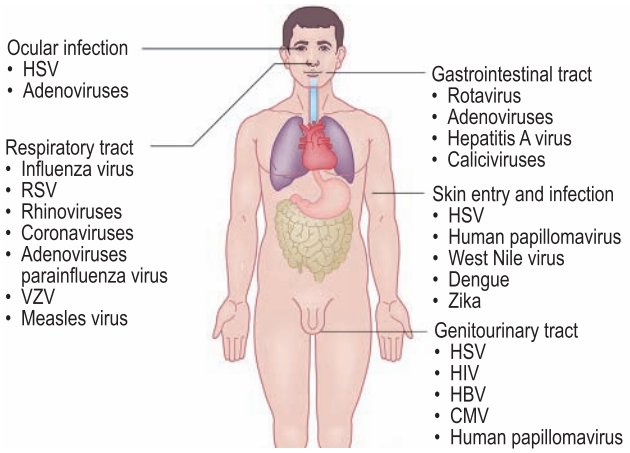

FIG. 25.1 Common Routes of Entry and Infection for Human Viral Pathogens. *CMV*, Cytomegalovirus; *HBV*, hepatitis B virus; *HIV*, human immunodeficiency virus; *HSV*, herpes simplex virus; *RSV*, respiratory syncytial virus; *VZV*, varicella-zoster virus.

TABLE 25.2 Sensors of Viral Infection

Toll-Like Receptors (TLRs)	
TLR3	dsRNA, MCMV, VSV, LCMV, HSV, EBV
TLR7 and TLR8	ssRNA, influenza virus, HIV, VSV
TLR9	dsDNA, HSV, MCMV
TLR2	MV hemagglutinin protein, HSV, HCMV
TLR4	MMTV envelope protein, RSV
RIG-I–Like Helicases (RLHs)	
RIG-I	Influenza virus, VSV, HCV, JEV, MV, RSV, Sendai virus, EBV
MDA-5	Poly(I:C), MV, Sendai virus, VSV, MCMV, picornaviruses
NOD-Like Receptors (NLRs)	
NLRP3	Influenza virus, Sendai virus, adenovirus, vaccinia virus
NOD2	Influenza virus, VSV, RSV
Other Sensors	
AIM2	Vaccinia virus, MCMV
ZBP1 (DAI)	Cytosolic dsDNA, HSV
IFI16	Cytosolic dsDNA, HSV
cGAS	Cytosolic dsDNA, HSV

AIM2, Absent in melanoma-2; *cGAS*, cyclic GMP-AMP synthase; *DAI*, DNA-dependent activator of IFN; *dsRNA*, double-stranded RNA; *EBV*, Epstein-Barr virus; *HCMV*, human cytomegalovirus; *HCV*, hepatitis C virus; *HIV*, human immunodeficiency virus; *HSV*, herpes simplex virus 1/2; *IFI16*, Gamma-interferon-inducible protein Ifi-16; *JEV*, Japanese encephalitis virus; *LCMV*, lymphocytic choriomeningitis virus; *MCMV*, murine cytomegalovirus; *MDA-5*, melanoma differentiation-associated gene; *MMTV*, mouse mammary tumor virus; *MV*, measles virus; *RSV*, respiratory syncytial virus; *ssRNA*, single-stranded RNA; *VSV*, vesicular stomatitis virus; *ZBP1*, Z-DNA–binding protein 1.

INNATE IMMUNITY TO VIRUSES

Viral infection induces an extensive array of defense mechanisms in the host. Innate defenses come into play to block or inhibit initial infection, protect cells from infection, or eliminate virus-infected cells. Innate mechanisms occur well before the effectors of adaptive immunity become active, but they are critical for the initiation of adaptive immunity via the elicitation of inflammation that promotes immune cell activation. The innate immune defenses are initiated via pattern recognition receptors (PRRs), which recognize pathogen-associated molecular patterns (PAMPs)[3] (see Chapter 3). These include transmembrane receptors of the Toll-like receptor (TLR) family, two families of intracellular receptors including the NOD-like receptors (NLRs) and the RIG-I–like helicases (RLHs), as well as the sensor molecule absent in melanoma-2 (AIM2). Additionally, the molecules cyclic guanosine monophosphate–adenosine monophosphate (GMP-AMP) synthase (cGAS), DDX41, IFI16, and Z-DNA–binding protein 1 (ZBP1) can sense cytosolic DNA (Table 25.2). These cellular sensors promote the expression of interleukin-1 (IL-1) and IL-18, type I (α/β) interferon (IFN-I), and a variety of IFN-stimulated genes and inflammatory cytokines, and chemokines. TLRs are cell surface or endosomal membrane-bound proteins expressed by numerous cells, including dendritic cells (DCs), macrophages, lymphocytes, and parenchymal cells. Expression of TLRs is largely inducible in most cell types, although some (TLR7/8/9) are constitutively expressed at high levels by specialized plasmacytoid DCs for rapid IFN production. Different TLR molecules recognize specific viral products, such as single- and double-stranded RNA (TLR 3 and TLR7/8, respectively) or double-stranded DNA (TLR9).

The RLHs retinoic acid-inducible gene I (RIG-I) and melanoma differentiation-associated gene (MDA-5) mediate cytoplasmic recognition of viral nucleic acids. These activate mitochondrial antiviral signaling (MAVS) proteins to stimulate IFN-I production and activate inflammasomes, which are molecular complexes that facilitate the activation of caspases and induce the production of proinflammatory IL-1β and IL-18. NLRs are a second class of cytosolic sensors of PAMPs that activate inflammasomes via the adapter protein ASC. These include the NLRP (or NALP), NOD, and IPAF/NAIP receptors. Three major inflammasomes have been shown to be involved in antiviral immunity: the NLRP3 inflammasome, the RIG-I inflammasome, and the AIM2 inflammasome.[3]

The innate defense system consists of multiple cellular components and many specialized proteins. The longest known and best-studied antiviral proteins are the α/β IFNs, which act by binding to the type I IFN receptor and result in the transcription of more than 100 IFN-stimulated genes. One consequence of this "antiviral state" is the inhibition of cell protein synthesis and the prevention of viral replication. Multiple leukocyte subsets are involved in innate defense, including macrophages,

KEY CONCEPTS

Major Antiviral Innate Defense Mechanisms

Acting to block infection:
- Natural antibodies
- Complement components
- Some cytokines and chemokines

Acting to protect cells from infection:
- Interferon-α/β (IFN-I)
- Interferon-γ (IFN-γ)
- Interleukin-1 (IL-1),18

Acting to destroy or inhibit virus-infected cells:
- Natural killer (NK) cells
- Natural killer T cells (NKT cells)
- Macrophages
- Neutrophils
- γδ T cells
- Nitric oxide

Involved in regulating antiviral inflammatory response:
- ILs-1, 6, 10, 12, 18, 23, 33
- Transforming growth factor (TGF)-β
- Chemokines (CCL2, 3, 4, 5)

DCs, neutrophils, natural killer (NK) cells, natural killer T cells (NKT cells), and γδ T cells. Furthermore, tissue cells, including fibroblasts, epithelial cells, and endothelial cells, express PRRs and respond to viral infection via the production of innate cytokines, including IFN-I and IL-1. IFN-I is a critical link between the innate and adaptive immune systems via activation of DCs and T cells, as well as protecting T cells from NK cell–mediated attack.[4] IFN-Is can also activate NK cells and induce other cytokines that promote NK responses, such as IFN-γ and IL-12. NK cells produce proinflammatory cytokines; they can kill infected cells and interact with DCs and are an important component of innate defense against viruses. NK cells can protect against some herpes viruses, which downregulate major histocompatibility complex (MHC) expression in the cells they infect. NK cells are also important in resistance to mouse and human CMV and possibly to HIV, influenza virus, and Ebola virus.[5] NK cells have also recently been shown to possess traits of adaptive immunity and, like T and B cells, can form populations of memory cells.[6] NK cells are regulated by an array of activating and inhibitory receptors, whose expression and function are just beginning to be understood. Uninfected cells are usually protected from NK cell cytolysis as they deliver negative signals, such as high expression of MHC molecules. In contrast, virus-infected cells are killed either because they deliver positive signals or because they lack adequate MHC-negative signals. NK cells may also control excessive immune responses to viruses by killing $CD4^+$ T cells and indirectly regulating cytotoxic T lymphocyte (CTL) responses. NKT cells may provide some antigen-specific innate immune protection against certain viruses, such as influenza virus.

Several classes of innate host proteins function in antiviral defense. These include natural antibodies, which may play a role in defense against some viral infections, as well as pentraxins and complement proteins. Some viruses may be directly inactivated by complement activation or be destroyed by phagocytic cells that bind and ingest complement-bound virions. Several proinflammatory cytokines and chemokines induced by virus infection also play key roles in defense. Foremost among these are IL-1 and other members of the IL-1 family, including IL-18 and IL-33. These cytokines influence both innate and adaptive immune cells and play critical roles in antiviral defense. Other antiviral cytokines are produced early, following infection, such as tumor necrosis factor (TNF), IFN-γ, IL-12, IL-6, and chemokines, such as MIP-1α. In particular, IL-12 is a potent inducer of IFN-γ from NK cells. Inflammatory chemokines also play an important role in innate antiviral defense by orchestrating macrophage, neutrophil, DC, and NK cell responses at the site of infection. Not only are these components of innate immunity involved in mediating initial protection against viruses but also several components (e.g., the PRRs; the cytokines IFN-I, IL-I, IL-33, and IL-12; and phagocytes, including macrophages, monocytes, and DCs) serve to shape the nature and effectiveness of the subsequent adaptive response to viral pathogens. For instance, DCs require innate signals, such as IFN-I and IL-12, for maturation and optimal T-cell activation. Furthermore, $CD8^+$ T cells responding to viruses need IFN-I and IL-33 signals for expansion and memory formation. Thus, both the magnitude and the type of innate response induced by virus infection have a marked influence on the generation of adaptive immune responses.

ADAPTIVE IMMUNITY TO VIRUSES

Innate immunity generally only slows, rather than stops, viral infection, allowing time for the adaptive immune response to begin. The two major divisions of adaptive immunity, antibody-mediated and T-cell–mediated, are mainly directed at different targets. Antibodies usually function by binding to free viral particles and, in so doing, block infection of the host cell (see Chapter 8). In contrast, T cells act principally by recognizing and destroying virus-infected cells or by orchestrating an inflammatory response that includes several antiviral components (see Chapter 12). As all viruses replicate within cells and many can spread directly between cells without reentering the extracellular environment, resolution of infection is reliant more on T-cell function than on antibody function. However, broadly neutralizing antiviral antibodies have the potential to be effective therapies against many different human infections, including HIV, influenza viruses, and Ebola virus. Recent advances have allowed researchers to isolate and identify human monoclonal antibodies (mAbs) against these and other pathogens,[7] offering promise of new therapies as well as significant insight for vaccine design. Antiviral antibodies are also very important as an immunoprotective barrier against reinfection. It is the presence of antibodies at portals of entry—most often mucosal surfaces—that is of particular relevance to influenza, HSV, and HIV infections. Yet, how to generate vaccines that induce optimal antibody responses, including broadly neutralizing antibodies, remains an important unsolved problem.

In some individuals, highly potent or highly cross-reactive antibodies are generated naturally in response to viral infection. Such broadly neutralizing antibodies, sometimes called super-antibodies, offer many potential advantages for therapy, especially if engineered to have a long half-life in vivo.[8] Current single-cell approaches to identify and isolate B cells for human monoclonal antibody generation will be decisive for the use of broadly cross-reactive human monoclonal antibodies for therapy, including against emerging and pandemic viruses, such as SARS-CoV-2, the causative virus of the recent COVID-19 pandemic.

Initiation of adaptive immunity is closely dependent on early innate mechanisms that activate antigen-presenting cells (APCs), principally subsets of DCs. APCs and lymphocytes are drawn into lymphoid tissues by chemokine and cytokine signals and are retained there for a few days to facilitate effective

intercellular interactions. The architecture of the secondary lymphoid tissues supports the coordinated interactions among the cells of the adaptive immune system through a network of supportive stromal cells and local chemokine gradients (see Chapter 2). The induction events occur in lymph nodes draining an infection site or in the spleen if the virus enters the bloodstream. The passage of viral antigens to lymph nodes usually occurs in DCs. Some viruses are able to compromise the function of APCs, such as HSV and measles virus, which can inhibit DC maturation.

B-cell activation occurs following antigen encounter in the B-cell follicles, and possibly the T-cell zones, in the spleen or lymph nodes. Some activated B cells become short-lived plasma cells, whereas others move to the edges of the B-cell follicles and interact with antigen-specific helper CD4 T cells via the presentation of antigenic peptides on B-cell MHC class II molecules. These Bcl6-dependent CD4 T follicular helper (Tfh) cells are specialized for providing help for B-cell responses and are needed to promote and regulate B-cell responses.[9] Activated B cells initiate germinal center (GC) reactions with the help of CD4 Tfh cells, ensuring somatic hypermutation and affinity maturation for the selection of high-affinity, antibody-producing, long-lived plasma cells, as well as memory B cells.[10] At the molecular level, upregulation of the transcription factors Blimp-1, XBP-1, and IRF-4 dictates plasma cell formation, whereas Pax-5 expression delineates B cells destined for GC reactions and the memory B-cell lineage.

Antibody binding to epitopes expressed by native proteins at the surface of free virions usually blocks viral attachment or penetration of target cells. Sometimes the consequence is viral lysis (with complement proteins also involved), opsonization, or sensitization for destruction by Fc receptor-bearing cells that mediate antibody-dependent cellular cytotoxicity (ADCC). Occasionally, however, Fc receptor binding of antibody-bound virus may facilitate infection and result in more severe tissue damage. This occurs in dengue fever and may happen in some instances in HIV infection. This antibody-dependent enhancement (ADE) effect occurs in dengue fever, some vaccines against dengue, and possibly in some instances in HIV infection.[11] Although ADE was a concern with the development of coronavirus vaccines because animal models challenged with SARS-CoV were found to develop ADE, this has not proven to be a problem following SARS-CoV-2 vaccination with current approved vaccines.

The antibody involved in the protection of mucosal surfaces in humans is predominantly secretory immunoglobulin A (IgA), but serum-derived IgG may also be protective, particularly in such sites as the vaginal mucosa. Both antibody isotypes act mainly to block infection of epithelial cells, although, in some instances, the antibody may transport antigen from within the body across epithelial cells to the outside. Mucosal antibody persists for a much shorter period compared with serum antibody, which explains, in part, why immunity to mucosal pathogens is usually of much shorter duration compared with immunity to systemic viral infections.

Like B-cell responses, T-cell responses to viral infections also begin within lymphoid tissues. Specific CD8 CTL precursors recognize antigen in the context of major histocompatibility complex (MHC) class I–peptide antigen complexes on DCs. The CD8 T cells become activated, proliferate, and differentiate into effectors. Expansion of these naïve antigen-specific precursors is considerable, often exceeding 10,000-fold, and results in an effector population that can account for 40% or more of a host's total CD8 T-cell population (Fig. 25.2). Various factors, including antigen and APCs, costimulatory molecules (e.g., CD28 and 4–1BB), and inflammatory cytokines (e.g., IFN-I and IL-12), are required to program the development of functional effector lymphocytes.[12] In some infections, CD4 T-cell help is also important to prime robust CTL responses via signals, including CD40 that are delivered to DCs. Activated CTL effectors then exit lymphoid organs and access almost all body locations via the bloodstream. However, effectors do not stay activated for long once the virus is cleared, and approximately 95% die by a process termed *activation-induced cell death*. Following this contraction phase, the remaining cells differentiate into memory cells, which remain as a more or less stable population in the host for many years. They represent an expanded pool of CTL precursors that can be activated upon secondary encounter with antigen and provide enhanced protection upon reinfection with the same virus (see next section). Although much of our knowledge of T-cell responses to viruses has been obtained from murine studies, it is increasingly clear that the fundamental principles are the same or similar in humans.

T-cell immunity against a particular virus involves both CD4 and CD8 T-cell subsets that recognize peptides derived from viral antigens bound to surface MHC proteins (class II and class I, respectively) (see Chapters 5 and 6). Complexes of viral peptides bound to MHC class II proteins are generated by APCs from scavenged and processed virus-infected cells or viral particles. Antigen–MHC class I complexes are expressed on the surface of infected cells, and antigen can also be transferred to

KEY CONCEPTS

Antiviral T- and B-Cell Immunity

Effector Systems	Recognized Molecules	Control Mechanisms
Antibody	Surface proteins or virions	Neutralization of virus, opsonization, or destruction of infected cells by ADCC
Antibody + complement	Surface proteins expressed on infected cells	Infected cell destruction by ADCC or complement-mediated lysis
Mucosal antibody (IgA)	Surface proteins or virions	Viral neutralization, opsonization, and transcytosis
CD4 T cells	Viral peptides (10–20 mers) presented on MHC class II surface, internal or nonstructural proteins presented by APCs	Antiviral cytokine and chemokine production; help for CD8 T-cell and B-cell responses; killing infected cells; regulatory functions to reduce immunopathology
CD8 T cells	Viral peptides (8–10 mers) presented on MHC class I surface, internal, or nonstructural proteins presented on infected cells or by cross-presentation	Killing infected cells or purging virus without cell death; antiviral cytokine and chemokine production

ADCC, Antibody-dependent cellular cytotoxicity; *APC*, antigen-presenting cell; *IgA*, immunoglobulin A; *MHC*, major histocompatibility complex.

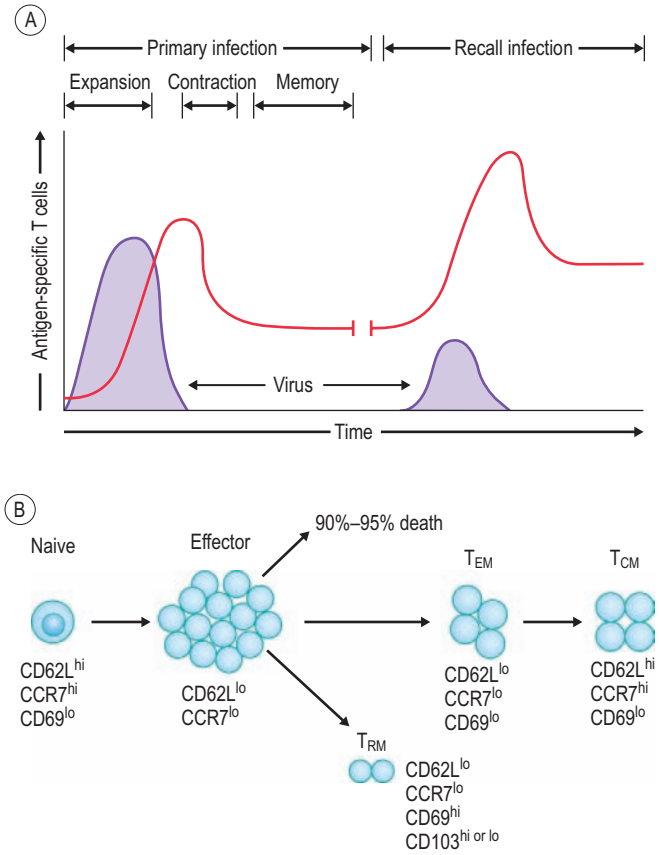

FIG. 25.2 Expansion/Contraction/Memory Phases of Adaptive Immunity and Memory Cell Subsets. (A) Dynamics of primary and secondary (recall) T-cell responses to viral infection *(red line)*. Both primary and recall T-cell responses undergo expansion and contraction phases, followed by stable immune memory. Recall responses induce a larger effector pool and reduced contraction, further boosting the memory pool. (B) Effector and memory T-cell differentiation. Antigen stimulation expands effector cells, most of which die during the contraction phase. Effector memory T cells (T_{EM}) that are formed gradually convert to central memory T cells (T_{CM}) over time, with corresponding changes in surface marker expression. Some effector T cells develop into resident memory T cells (T_{RM}) that persist in the tissues and do not reenter the circulation.

APCs from infected cells by a process known as *cross-presentation*. Recent experiments in mice have also demonstrated a role for the transfer of antigen between DCs as they migrate from infected tissues to the lymphoid tissues. Multiple subsets of DCs exist and specialize somewhat in antigen presentation on MHC-I or MHC-II.[13] During the process of activation, T cells can receive signals from multiple DC types in a temporally controlled sequence that coordinates CD4 and CD8 T-cell interactions.[12] Use of MHC class I and class II tetramers to directly visualize antigen-specific CD8 and CD4 T-cell responses, respectively, has demonstrated the significant size of T-cell responses to viruses, such that the majority of the activated T cells seen at the peak of the response are virus-specific.

CTLs function by recognizing virus-infected cells and killing them; this often involves perforins and cytotoxic granules containing granzymes. Effector CTLs can also induce death in target cells following engagement of the Fas ligand on the CTL with Fas on target cells. Both pathways lead to apoptosis of the target cell, involving the degradation of nucleic acids, including those of the virus. Alternatively, CD8 T cells also mediate defense through the release of various cytokines after antigen recognition. Some of the cytokines and chemokines most highly produced by CTLs include IFN-γ, TNF, lymphotoxin-α, and RANTES (CCL5) (see Chapters 14 and 15). These cytokines can have multiple antiviral effects on infected cells and on the cells around them, including the purging of virus from infected cells without killing the cells. This is particularly important for such viruses as HSV, which infects non-rejuvenating cells, such as nerve cells.

CD4 T cells are involved in antiviral defense as well as being modulators of inflammatory reactions to viruses. Multiple functional subsets of CD4 T cells are recognized based largely on the types of cytokines produced when they recognize antigen. CD4 T cells are more broadly reactive than CD8 T cells; they recognize larger peptides processed from viral proteins and are restricted by MHC class II. These CD4 T cells participate in antiviral immunity in several ways. They can act as helper cells for the development of high-affinity antibody responses and for more functional CD8 T-cell responses.[9,14] Additionally, CD4 T cells act as effectors and orchestrate inflammatory reactions, which either serve a protective function or, in some cases, become prolonged, causing chronic tissue damage (see Chapter 11). The latter can happen in HCV-mediated hepatitis and HSV-mediated stromal keratitis. Occasionally, CD4 T cells can mediate direct cytotoxicity, but they are less effective than CD8 T cells. The principal subsets of CD4 T cells involved in inflammatory reactions are T helper-1 (Th1) cells (producing mainly IFN-γ, TNF, IL-2) and Th17-producing cells (IL-17 and IL-22). A third effector subset, Th2 cells producing (IL-4, IL-5, and IL-13), also participates in inflammatory reactions, although in the case of viruses, these are usually more tissue-damaging than protective. This situation can occur in response to RSV infection. Regulatory T cells (Tregs) are a further subset of CD4 T cells of particular importance since these cells largely act to regulate the function of effector subsets and, in so doing, influence the severity and duration of inflammatory reactions (see Chapter 13).[15] Tregs produce antiinflammatory cytokines, such as IL-10 and transforming growth factor-β (TGF-β), and can be distinguished from other CD4 subsets by their expression of a unique transcription factor, FoxP3. The balance of CD4 T-cell subset representation in response to a viral infection is critical. In situations where responses become overtly tissue-damaging and chronic, the balance favors effector subsets. In such situations, changing the balance to favor Tregs can result in diminished lesions. How to achieve this objective by acceptable therapeutic approaches represents an active area of research.

IMMUNOLOGICAL MEMORY

Immunological memory is a cardinal feature of adaptive immunity. The goal of vaccinology is to induce long-lived immunological memory to protect against reinfection (see Chapter 87). Following infection with certain viruses, memory can be exceptionally long-lived, potentially for the life of the host (e.g., yellow fever and smallpox viruses).[16,17] Memory is defined by the persistence of specific lymphocytes and antibody-producing plasma cells rather than that of antigen to induce continuous lymphocyte activation. Humoral memory to viruses involves

long-lived plasma cells in bone marrow, which provide a continuous, low-level source of serum antibodies. This maintenance of humoral immunity also involves a population of homeostatically maintained memory B cells, which may be required to maintain stable numbers of long-lived plasma cells over time. The pool of memory T cells is regulated by low-level homeostatic division controlled by the cytokines IL-7 and IL-15. For memory CD8 T cells, IL-7 is primarily important for survival, whereas IL-15 is crucial for low-level proliferation to maintain the size of the memory T-cell pool.

KEY CONCEPTS

Principles of Antiviral Immunity

- Many human viral infections are successfully controlled by the immune system.
- Certain emerging viruses may overwhelm the immune system and cause severe morbidity and mortality.
- Other viruses have developed mechanisms to overwhelm or evade the immune system and persist.
- Individuals with defects in innate or adaptive immunity demonstrate more severe viral infections.
- T-cell immunity is more important for control than are antibodies in many viral infections.
- Antibodies are important to minimize reinfection, particularly at mucosal sites.
- Immune memory is often sufficient to prevent secondary disease, although not in all viral infections.
- Tissue-specific immune memory may be important to rapidly protect against reinfection at peripheral sites (e.g., skin and mucosae).

Immunological memory is defined by a pool of antigen-specific cells whose increased frequency enables rapid control of viral reinfection (see Fig. 25.2). IL-7Rα-expressing effector T cells are the precursors of this memory pool. This population of cells, which constitutes about 5% to 10% of the effector pool, preferentially survives the contraction phase and gradually differentiates into a stable memory population.[18] Upon reinfection, these memory cells can be rapidly activated and, by virtue of their increased frequency, mediate more rapid clearance of the viral pathogen. Moreover, repeated stimulation of memory cells via multiple infections with the same virus, or prime-boost vaccine regimes, further increases the size of the antigen-specific memory T-cell pool.[19] Restimulation also affects the activation status and tissue distribution of memory T cells, which may enhance protection from viral infection in mucosal and other tissues.

Experiments in humans and mice have demonstrated that memory T cells are heterogeneous. Memory T cells were divided into effector memory (T_{EM}) and central memory (T_{CM}) subsets, defined by the expression of two surface molecules involved in T-cell migration: CD62L and CCR7.[18] The $CD62L^{lo}CCR7^{lo}$ T_{EM} subset is found primarily in nonlymphoid tissues and the spleen, whereas the $CD62L^{hi}CCR7^{hi}$ T_{CM} subset is largely present in lymph nodes and the spleen. The current model predicts that effector T cells form the T_{EM} subset and that these cells gradually convert to a T_{CM} phenotype over time (Fig. 25.2, B). Although the conditions that control the rate of this conversion are unknown, it is likely that the amounts of antigen and inflammatory signals received during the effector phase greatly influence this by programming the epigenetic regulation of gene expression[20]. It has also been shown that CD4 T-cell help is required for the generation of long-lived memory CD8 T cells via interactions with DCs.

Studies suggest that T_{CM} are capable of mounting stronger proliferative responses following reinfection. Tissue-specific homing of T_{EM} cells permits them to enter sites of potential viral infection, such as skin and mucosae. However, we now know that many memory T cells found at sites of previous viral infections take up long-term residence in tissues.[21] This includes skin, intestines, lungs, the liver, and the brain (Fig. 25.3, A). These tissue-resident memory T cells (T_{RM} cells) are sequestered from the circulation and provide rapid protection against viruses, such as HSV in the skin, where they localize with a unique dendritic morphology and undergo slow surveillance of the tissue (Fig. 25.3, B). T_{RM} cells can produce various cytokines, including IFN-γ and IL-17. Notably, activation of T_{RM} cells can trigger enhanced early inflammation to drive local immunity. This is in contrast to T_{CM}, which migrate largely through lymphoid organs (spleen and lymph nodes), and T_{EM} cells, which can migrate through nonlymphoid tissues. These differences may define the physiological *raison d'être* for these memory T-cell subsets, highlighting that measurement of memory T cells in human peripheral blood is a poor representation of the total-body memory T-cell pool.

T_{RM} cells can be detected in tissues by using markers, such as CD69 and CD103, although these are imperfect identifiers and may not identify T_{RM} in all human tissues. T_{RM} cells in different anatomic locations share a common genetic signature and require common transcription factors for their formation, including T-bet, Eomes, Blimp1, and Hobit, as well as cytokines including TGF-β and IL-15. Yet, these cells also adopt a unique gene expression that is imprinted by the tissue environment and presumably imparts specialized functions on T_{RM} cells in each location. However, memory in certain peripheral tissues, such as lungs, appears to wane over time, suggesting that memory T cells may not persist in sufficient numbers in this site. This rationalizes a need for vaccines that induce optimal numbers of memory T cells in tissues as well as blood. For vaccines to be effective against many virus infections, they need to induce optimal T_{RM} responses at sites of viral entry. Using appropriate signals to "pull" memory cell precursors to specific sites could be one way of achieving this objective.[22]

IMMUNE EVASION AND IMMUNITY TO CHRONIC VIRAL INFECTIONS

Many, if not all, viruses employ immune blunting or delay tactics to circumvent aspects of the immune system, allowing them time to replicate further or escape detection (Table 25.3). One such mechanism may involve killing or infecting APCs. Viruses may also delay or prevent apoptosis induced by CTLs within infected cells. Other viral evasion measures aimed at the CD8 T cell–mediated antiviral defense system inhibit antigen processing, thereby minimizing effector CTL induction. To escape CTL killing, many viruses also downregulate the MHC molecules on the surface of infected cells. In addition, viruses may produce various mimics or modulators/inhibitors of cytokines, chemokines, or other components of the immune system or their receptors. Viruses also resort to antigenic hypervariability to escape antibody or T-cell recognition. This can occur during transmission from host to host (e.g., influenza virus) or within hosts during chronic infection through the generation of viral escape mutants. The latter is particularly important for HIV and HCV infections.

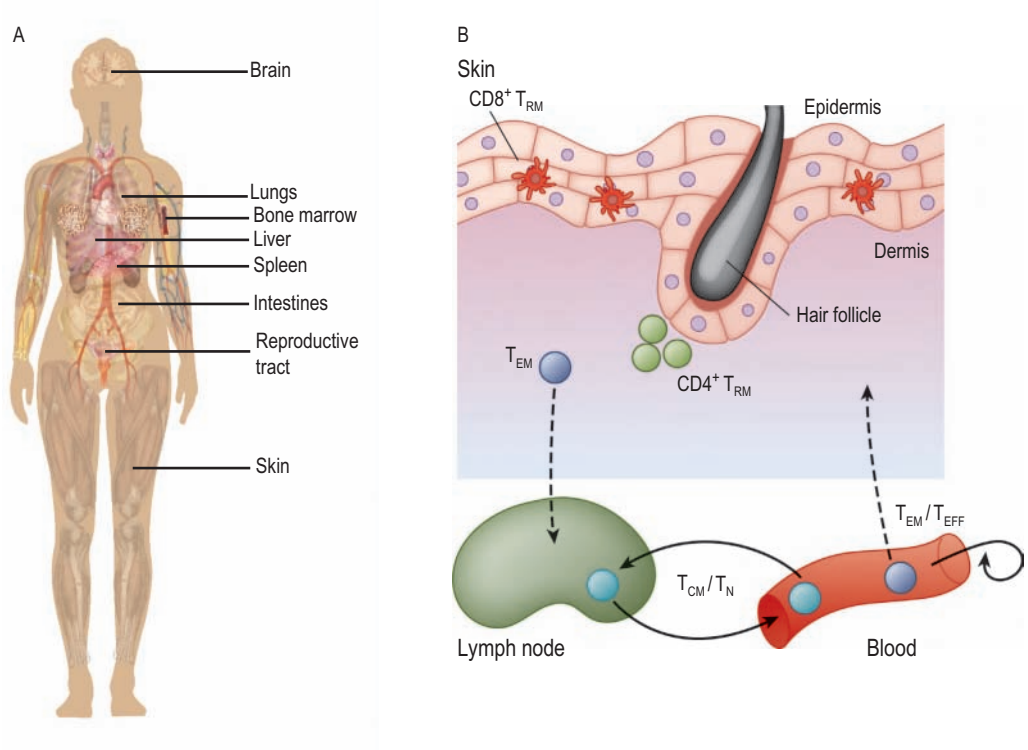

FIG. 25.3 Tissue-Resident Memory T Cells T_{rm} Reside Within Tissues and Sites of Previous Viral Infection and Provide Rapid Protection Against Reinfection. (A) T_{RM} cells have been found in most locations in the body. (B) Subsets of memory T cells in the skin. CD8 T_{RM} cells remain localized in the epidermis of the skin after herpes simplex virus (HSV) infection. Resident memory $CD4^+$ T_{RM} cells cluster in the dermis. Effector memory T cells ($CD4^+$ T_{EM}) continue to migrate through the dermal layers of skin with access to blood and lymphoid tissues. Central memory T cells (T_{CM}) and naïve T cells (T_N) circulate through lymphoid tissues via the blood.

TABLE 25.3 Mechanisms and Examples of Viral Immune Evasion

Mechanism	Example
Interference with viral antigen processing and presentation	HSV (ICP47), EBV (EBNA-1), HIV (Nef, Tat), HPV (E5), CMV (UL6)
Evasion of NK cell function	HIV (Nef), EBV (EBNA-1), CMV (UL40, UL18)
Inhibition of cell apoptosis	Adenovirus (RID complex and E1B), HIV (Nef), EBV (BHRF-1)
Destruction of T cells	HIV
Interference with antiviral cytokines and chemokines	EBV (IL-10 homolog), CMV(US28 chemokine receptor homolog), vaccinia virus (IL-18-binding protein), HIV (Tat chemokine activity)
Inhibition of complement action	HSV, pox viruses
Inhibition of DC maturation	HSV, vaccinia virus
Frequent antigenic variation	Influenza virus, HIV
Infection of immune-privileged site	Measles virus, VZV, and HSV (neurons)
Immune exhaustion	HIV, HCV, HBV

CMV, Cytomegalovirus; *DC*, dendritic cell; *EBV*, Epstein–Barr virus; *HBV*, hepatitis B virus; *HCV*, hepatitis C virus; *HIV*, human immunodeficiency virus; *HPV*, human papillomavirus; HSV, herpes simplex virus; *IL-18*, interleukin-18; *NK*, natural killer; *RID*, receptor internalization and degradation; *VZV*, varicella-zoster virus.

The success of many viral pathogens rests in their ability to subvert the host immune response. The most successful human viruses can escape the immune system and persist for the life of the host. Two well-studied examples of this are CMV and EBV. T-cell responses to these viruses are prominent and readily detectable in humans, and yet the immune system is unable to clear either pathogen completely. However, these viruses generally remain undetectable in immunocompetent individuals. Other viral infections, such as those caused by the herpes viruses HSV and VZV, are marked by periods of latency when no virus can be detected. Yet, periods of viral reactivation, often triggered by stress, can lead to episodes of disease. These are controlled by the immune response, which plays a central role in controlling herpes virus latency.

Many of the most medically important human viruses are associated with persistent viremia. These include those causing chronic infections, such as HIV, HCV, HBV, and human T-lymphotropic virus (HTLV), among others. Such chronic viral infections are marked by high levels of persisting antigen and can result in skewed T-cell immunodominance hierarchies, altered tissue localization of immune cells, and severely impaired T-cell function.[23] This altered T-cell function is hierarchical and results in functional T-cell defects ranging from reduced cytokine production and altered proliferative capacity (exhaustion) to death (deletion) of the responding T cells (Fig. 25.4, A).

Sustained viral antigen levels and inflammation are responsible for this immune dysfunction. This is in stark contrast to normal memory T-cell development, which occurs in the absence of persisting antigen (see previous section). Studies have demonstrated that signaling through multiple inhibitory receptors expressed on the cell surface contributes to exhaustion during chronic infections.[23] This includes the receptor programmed death (PD)-1, expression of which may be essential for preventing excessive

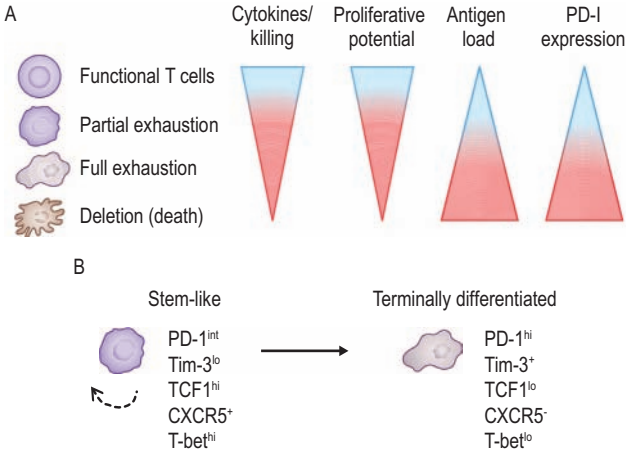

FIG. 25.4 Hierarchical Model of T-Cell Exhaustion During Persistent Viral Infection. (A) T-cell function (cytokine production, killing, and proliferative potential) is negatively influenced by increasing levels of antigen. Low levels of persistent antigen may lead to partial loss of function and intermediate levels of programmed death *(PD)*-1 expression. High, sustained levels of antigen over time can lead to full loss of function, high levels of PD-1, and eventually cell death (deletion). (B) A subset of stem-like exhausted T cells forms during chronic infection that can give rise to more terminally differentiated effector-like T cells.

immunopathology by effector T cells and yet appears to contribute directly to failed immunity to HIV infection and other chronic human viral infections. Although the molecular mechanisms of exhaustion remain incomplete, differential involvement of transcription factors (including Tbet, Blimp1, and Tox) and altered gene expression define exhausted T cells. Studies have implicated multiple inhibitory receptors as potential therapeutic targets, and although combinations of these checkpoint inhibitor blockade therapies are proving highly beneficial to the treatment of certain cancers,[24] similarly efficacious responses have yet to be fully demonstrated during chronic virus infection. Yet, the discovery of a stem-like subset of exhausted T cells that express Tcf1 and Tim3 and display enhanced proliferative capacity provides considerable promise for enhancing immunity against chronic viral infections (Fig. 25.4, B).

It is also important to note that the activation of immune cells involves considerable changes in their metabolic demands, in particular T cells that undergo phases of rapid expansion and production of antiviral cytokines. During chronic viral infection, exhausted T cells demonstrate marked changes in cellular metabolism, shifting from glycolysis to fatty acid oxidation, as well as impaired mitochondrial function.[23,25] Immune cells that are targets of viral infection, such as HIV-infected T cells or macrophages, also show marked metabolic changes. The complex interplay between immune cell functions and metabolic reprogramming in response to viral infections is yet to be fully appreciated but could reveal important new avenues for therapy and treatment of viral diseases.[26]

OUTCOMES OF VIRUS INFECTION: IMMUNITY OR IMMUNOPATHOLOGY

Typically, individual humans respond to a viral infection in different ways. When the common cold or even pandemic influenza infection occurs, only a small percentage of exposed persons may develop overt clinical disease. In the pre-vaccine days, poliomyelitis was a much-feared consequence of poliovirus infection, but only a very small percentage of infected persons developed paralyzing complications. Similarly, only an unfortunate few develop life-threatening meningoencephalitis following infection with the insect-transmitted West Nile virus. It is particularly characteristic of chronic viral infections that clinical expression is highly variable. With HCV, for example, in 70% to 80% of patients, some form of chronic liver disease develops, and the virus is not cleared. However, in up to 30%, the infection is controlled, the virus is cleared, and immunity to reinfection develops. The latter group of individuals make a type of immune response that includes protective antibodies along with an appropriate pattern of T-cell responsiveness.[27] This issue is particularly relevant during the recent SARS-COV-2 pandemic, where it seems that age and the presence of comorbidities, such as diabetes and hypertension, are variables that could greatly affect the outcome of infection.

We do not fully understand the reasons for the varying outcomes of virus infections in different persons, and almost certainly, multiple factors are involved. Many of these factors impact the response pattern made by the innate immune system, which, in turn, affects the magnitude and type of adaptive immune response that occurs. Some of the circumstances that do influence the outcome of infection include genetic susceptibility of the host, the age of the host when infected, the dose and route of infection, the variable induction in the host of anti-inflammatory cells and proteins, and the presence of concurrent infections and past exposure to cross-reactive antigens.

IMMUNOPATHOLOGY AND AUTOIMMUNITY

Immune responses against virus-infected cells often result in tissue damage, especially if cell killing is involved or if there is extensive recruitment and activation of inflammatory cell types, such as macrophages and sometimes neutrophils. If the response is brief and is quickly repaired, it is usually deemed an immunoprotective event. A prolonged tissue-damaging effect resulting from an immune reaction against viruses is considered immunopathology (Fig. 25.5). Such situations most commonly involve persistent viruses, which are themselves often mildly cytodestructive in the absence of an immune reaction. Chronic tissue damage initiated by viruses can also result in the development of an autoreactive and occasionally oncogenic response. For example, some autoimmune diseases may be initiated or exacerbated by viral infections, but no named virus has been regularly incriminated as a cause of human autoimmune disease.[28]

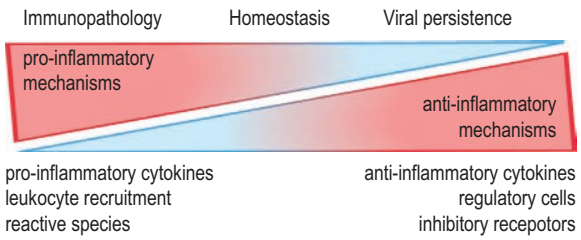

FIG. 25.5 A Balance of Signals is Required to Protect Against Viral Infection and Prevent Immunopathology. Multiple pro- and antiinflammatory mechanisms together decide the outcome of viral infection and the degree of tissue damage.

TABLE 25.4 Lesions Resulting From Immunopathology

Primarily involving CD8 T cells acting as cytotoxic T lymphocytes or sources of proinflammatory cytokines	Murine lymphocytic choriomeningitis virus
	Hepatitis B virus (HBV)–induced chronic hepatitis
	Coxsackie B virus-induced diabetes
	Coxsackie B virus-induced myocarditis
	Demyelination caused by some strains of mouse coronavirus and Theiler virus
Primarily involving CD4 T cells that produce Th1 cytokines	Demyelination caused by some strains of mouse coronavirus and Theiler virus
	Herpes simplex virus (HSV)–induced stromal keratitis
Involvement of CD4 T cells that produce Th2 cytokines	Respiratory syncytial virus (RSV)–induced pulmonary lesions
Involvement of antibody	Glomerulonephritis in chronic hepatitis B
	Dengue hemorrhagic fever

Circumstantial evidence exists for a virus link in multiple sclerosis (MS), insulin-dependent diabetes, and possibly systemic lupus erythematosus (SLE). In MS, many viruses have been isolated from patients, although no specific one has been tied to the disease etiology. The current hypothesis is that viral infections set up an inflammatory environment that may exacerbate or tip the balance toward disease in genetically susceptible individuals.

Immunopathological reactions involving viruses have several mechanisms, but T cells are usually involved as orchestrators of inflammatory events (Table 25.4). A clear example of immunopathology involving a virus is lymphocytic choriomeningitis virus (LCMV) in the mouse. This model has dominated ideas and has set several paradigms in viral immunology in general.[29] The first virus-induced immunopathological lesions recognized were glomerulonephritis and arteritis, noted in mice persistently infected with LCMV. The lesions were assumed to represent inflammatory reactions to tissue-entrapped immune complexes that activate complement. Similar immune complex–mediated lesions occur in other infections, including lung lesions found in severe influenza, RSV infection, viral hepatitis, and arthritis. However, only rarely have viral antigens been shown to contribute to the antigen component of the complex. An example where the inclusion of viral antigen in immune complexes has been demonstrated is chronic HBV infection of humans. Autoimmune diseases, such as SLE, also result from immune complex–mediated tissue damage. However, evidence linking viruses to the etiology or pathogenesis of SLE is scarce since the immune complexes in SLE do not appear to include viral antigens at any stage.

Thanks largely to the LCMV model, it is clear that CD8 T-cell recognition of viral antigens can result in tissue damage. In LCMV infection, damage occurs in the leptomeninges of immunocompetent mice, infected intracerebrally. Hepatitis can also occur in mice infected intravenously. Neither lesion becomes evident if the CD8 T-cell response is suppressed. CD8 T cell–mediated immunopathology can be a causative mechanism of chronic hepatitis associated with HCV and HBV infection, although the tissue damage also involves inflammatory CD4 T cells. Additional viral immunopathology models where lesions result primarily from CD8 T-cell involvement include myocarditis and insulin-dependent diabetes associated with coxsackie B virus infection. In both instances, CD8 T cells mainly orchestrate events, but tissue damage may result from the bystander effects of cytokines and other molecules, such as lipid mediators, metalloproteinases, and components of the oxygen burst. Although coxsackie virus can be a cause of diabetes in the mouse, attempts to relate viral infection directly to the etiology of human diabetes have so far failed.

CLINICAL RELEVANCE

Hypothesized Role of Viruses in Autoimmunity

Molecular mimicry: similar epitopes shared by virus and host

Bystander activation: chronic release of cytokines and host antigens activates local autoreactive lymphocytes

Viral persistence: chronic viral antigen presentation on host cells leads to prolonged immunopathology

Immunopathological reactions against viruses can also involve subsets of CD4 T cells, which can be either Th1 or Th17 or both. One well-studied example involves persistent infection with Theiler virus in mice.[30] This infection causes a demyelinating syndrome that resembles the autoimmune disease experimental allergic encephalomyelitis. In both situations, CD4 T cells that produce Th1 cytokines appear to serve as pathological mediators. Furthermore, in both models, an increase in the involvement of myelin-derived autoantigens occurs as the disease progresses. Once again, such observations indicate the possible role of a virus in autoimmune disease. With the Theiler virus model, the virus persists in the nervous system and chronically stimulates CD4 T cells to secrete an array of cytokines. The demyelinating events appear to result from cytokine action on oligodendrocytes. Myelin components, such as myelin basic protein, proteolipid protein, and myelin oligodendroglial glycoprotein, may be released and can participate as additional antigen in immunoinflammatory events. This scenario is referred to as *epitope spreading*.

Another model of virus-induced immunopathology that mainly involves the Th1 subset of CD4 T cells is stromal keratitis caused by HSV infection (Fig. 25.6).[31] The pathogenesis of this immunopathological lesion is unusual in that it occurs and progresses when viral antigens can no longer be demonstrated. The chronic immunoinflammatory lesions are mainly orchestrated by CD4 T cells, but multiple early events induce the subsequent pathology. Viral replication, the production of certain cytokines and chemokines (IL-1, IL-6, IL-12, and CXCL8), recruitment of inflammatory cells (e.g., neutrophils), and neovascularization of the avascular cornea all precede immunopathology. Recently, it has become evident that Th17 T cells participate in stromal keratitis lesions. The role of Th17 T cells as orchestrators of inflammatory reactions has been a major research focus, especially in lesions of autoimmune diseases.[32] When Th17 T cells are the principal mediators of tissue damage, abundant neutrophils are recruited to inflammatory sites, with such cells being mainly responsible for tissue damage.

A further mechanism of viral-induced immunopathology and autoimmunity is molecular mimicry. Molecular mimicry represents shared antigenic epitopes, either B- or T-cell antigen, between the host and virus. This concept originated with streptococci and their association with rheumatic fever. With human

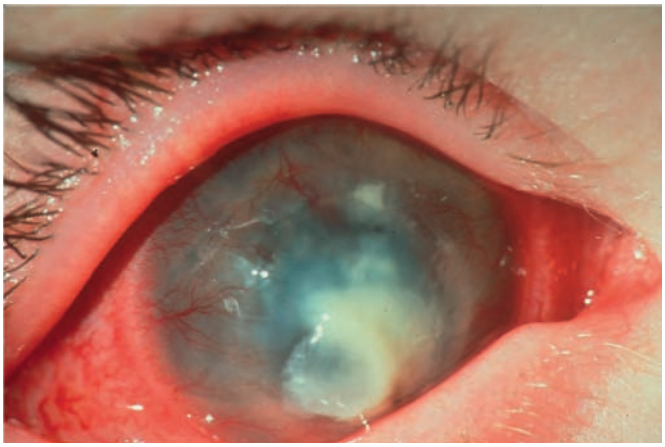

FIG. 25.6 Example of Herpetic Stromal Keratitis (Hsk) in the Human Eye After Herpes Simplex Virus-1 (HSV-1) Infection. Inflammation of the eye and eyelid can be observed, as well as neovascularization and substantial necrosis, ulceration, and opacity of the cornea.

autoimmune disease, there is little direct support for viral molecular mimicry; however, some animal models have been used to prove the theoretical case, where a viral antigen is expressed as a self-protein in the islet cells of the pancreas. In this model, subsequent infection with the virus induces diabetes. However, this is not true mimicry and may be more closely related to viral antigen persistence in a model such as Theiler disease.

As discussed previously, the outcome of a T-cell response to a virus may be critically dependent on the balance of the T-cell-type response. Thus, tissue damage is likely to be more severe and prolonged if CD8 or Th1 and Th17 CD4 T cells are predominant. Lesions become milder and may resolve when the balance favors Tregs. Accordingly, therapeutic approaches that can shift the balance of T cells are under trial.

KEY CONCEPTS

Phases of Immunity Affected by Regulatory T Cells

- Interference with antigen presentation by dendritic cells
- Inhibition of T-cell proliferation
- Inhibition of molecules involved in tissue-specific migration of effector cells
- Inhibition of T-cell effector functions in lymphoid and nonlymphoid tissues

TRANSLATIONAL RESEARCH OPPORTUNITIES

Reversing T-cell exhaustion in patients suffering from chronic infections or cancer will be a key clinical target in the near future. The discovery of multiple inhibitory receptors on exhausted T cells (e.g., PD-1, LAG-3, 2B4, TIM-3), as well as a stem-like subset of cells, has provided the opportunity to selectively improve T-cell function through blockade of these inhibitory receptors. This may be combined with a blockade of immunosuppressive cytokines (e.g., IL-10) or enhancement of signals stimulatory to the response (e.g., IL-7 therapy), as well as with more traditional antiviral therapies and vaccination. The challenge that lies ahead will be in determining which combination of inhibitory and stimulatory signals will need to be manipulated in different diseases and in different groups of patients.

The design of a new generation of vaccines to target diseases, such as HIV and influenza, may require tailor-made solutions for patients who respond poorly to vaccination or respond improperly, as with adverse effects, such as autoimmune reactions. High-throughput approaches now allow for the generation of a molecular signature of vaccination or infection.[33] Such systems biology approaches are expected to result in novel screening for immune protection parameters after vaccination. In the near future, this should also assist in the formulation of new vaccines containing key immune activators, such as those that stimulate certain subsets of T cells or induce appropriate homing molecule expression on these cells to direct them to tissues where they are required to mediate protection (e.g., mucosal sites, or skin).

ON THE HORIZON

Pressing Issues in Need of Solutions

- Design of new vaccines that induce broadly neutralizing antibodies
- Design of new vaccines that induce tissue-resident and circulating memory T-cell subsets
- Overcoming immune dysfunction during chronic viral infections for successful viral clearance
- Improving the efficacy of vaccines to viruses using systems biology approaches
- Therapies for reducing immunopathology during viral infections

In some individuals, viral infections cause mild, or sometimes debilitating, tissue damage. Factors that influence whether a viral infection results in immunopathology vary from individual to individual. These factors include age, the route of infection, preexisting immunity, host genetics, and the host's viral burden (or virome). The SARS coronaviruses, including the causative virus of the recent COVID-19 pandemic, SARS-CoV-2, are an excellent and timely example of viruses that can cause significant immunopathology. Pneumonia and pulmonary edema occur in patients with SARS due to excessive inflammatory cell recruitment to the lungs. Many patients also have multi-organ damage and vascular pathology due to a systemic cytokine storm.[34] Such responses usually involve strong stimulation of inflammatory cells and T cells which generate excessive amounts of cytokines, chemokines, and other damaging mediators. Patients with more severe COVID-19 disease are also typically lymphopenic, possibly due to substantial recruitment of lymphocytes into inflamed tissues. This presentation of severe disease is absent in most patients, and it remains unclear what factors govern the unrestrained inflammatory response in COVID-19. The many lessons learned from viruses provide a strong basis for understanding the immunopathogenesis of SARS-CoV-2 infection and future emerging diseases.

CONCLUSIONS

Humans are infected by many pathogenic viruses. In most cases, these infections are controlled by the immune system with limited damage to the host. However, certain viruses, particularly in cases where the host's immune system is impaired, can cause significant damage to the host's tissues. As our understanding of the mechanisms underlying innate immune defenses, antigen presentation, T- and B-cell responses, and Tregs continues to improve, so too does the ability to design better vaccines and

therapies to boost the immune control of viral infections. Although this remains a challenging goal, particularly for viruses such as HIV, and for novel viruses that can emerge swiftly, such as SARS-CoV-2, rapid scientific advances continue to provide many new avenues for novel therapies and vaccines.

Host Defenses to Intracellular Bacteria

Stephen T. Reece and Stefan H.E. Kaufmann

The evolutionary relationship between humans and bacteria is so intimate that it is impossible to imagine the development of one without the other. Evolution of human immunity to bacteria has been accompanied by evolution of ingenious bacterial mechanisms to not only survive its onslaught but also to manipulate it for enhanced survival. These concepts are reflected in the lifestyle of intracellular bacteria. These pathogens actively seek out an environment inside human cells in which to flourish; yet, this is not an easy environment in which to survive. Human cells have developed an ability to differentiate bacterial from host components and to direct host cells to clear the invader. The most successful intracellular pathogens have adapted to the intracellular environment of a particular host cell, proliferate only slowly, and can live for long periods of time completely undetected by the immune system, as we see in the case of tuberculosis (TB). In other instances—for example, during listeriosis—intracellular infection is more explosive with the rich intracellular environment harnessed to rapidly amplify bacterial growth. More recently, bacteria that are not considered to typically adopt an intracellular lifestyle, but do so opportunistically, are being appreciated. *Staphylococcus aureus* can survive the intracellular environment of neutrophils and mononuclear phagocytes (MPs), and in doing so, spread infection around the human body, causing sepsis. In most cases, intracellular bacteria are long-lived in the human body, sometimes for the entire human lifetime. A wide spectrum of pathologies ensues from intracellular infection, making most intracellular bacteria highly clinically relevant. Moreover, new concepts on the influence of intracellular bacteria on host cell differentiation point to an ability to change infected cell phenotype to enhance survival.

This chapter dissects the current interpretation of this fascinating interplay between human and microbe, sheds light on how our immune system functions, and how cellular phenotype can be molded in cells whose fates were previously believed to be strictly predetermined. Finally, such insights can inform new therapeutic and prophylactic approaches to keep intracellular bacterial infections under control.

CLINICAL PEARLS

Distinguishing Clinical Characteristics of Infections With Intracellular Bacteria

- Nonsterilizing immunity
- Persistent bacteria, sometimes latent infection
- Formation of long-lasting tissue granulomas containing low numbers of viable bacteria
- Critical role of T cells in protection, role of antibodies less well established but likely to play an as-yet unappreciated role
- Critical role of immune response in pathology
- Lack of effective vaccines
- Host-directed therapies toward enhancing antimicrobial mechanisms while limiting host pathology

BALANCE OF PROTECTION AND PATHOLOGY DEFINES THE CHRONIC NATURE OF INTRACELLULAR BACTERIAL INFECTION

Some bacteria, such as *Listeria monocytogenes*, are fully eradicated once the host immune response has reached its peak activity. More often, the intracellular habitat provides a protective niche that promotes persistent infection in the face of an ongoing immune response. Here the bacteria can persist for long periods of time without causing clinical signs of illness, but bacterial growth can be reactivated and cause disease if the immune response becomes compromised. This occurs in *Mycobacterium tuberculosis* infection, resulting in disease years or even decades after primary infection. In fact, disease need not arise from infection at all; in many regions, for example, the vast majority of adults harbor *M. tuberculosis* without suffering from clinical disease. Alternatively, disease can develop directly after primary infection, during maturation of the immune response, or with regression once the immune response is sufficiently strong. Yet sterile eradication of the pathogen is rarely achieved; bacteria persist in a latent form, and illness may re-emerge at a later time. For example, *Rickettsia prowazekii* may persist for decades after convalescence from typhus to later cause Brill–Zinsser disease.

Several intracellular bacteria possess components that can profoundly influence the course of disease (such as the lipopolysaccharides [LPSs] of brucellae and salmonellae). Chronic persistence inside host cells, however, depends on the target cell remaining intact and physiologically active. Accordingly, many intracellular bacteria are of low toxicity and do not have dramatic direct effects on their host. Instead, pathogenesis is largely determined by the immune response. Classic examples of this concept include granuloma liquefaction in acute TB, which severely affects lung function, and eye scarring due to chronic or recurring *Chlamydia trachomatis* infection that ultimately leads to trachoma.

Intracellular bacterial survival and persistence have major consequences for pathology. Although many intracellular bacteria show some organ tropism, dissemination to other organs frequently occurs, resulting in different disease forms. For example, TB is generally manifested in the lung with 80% of cases, yet many other organs can be affected. In contrast to other *Salmonella enterica* serovars, the serovars Typhi and Paratyphi are not restricted to the gastrointestinal tract but are disseminated

to internal organs, primarily the liver and spleen. In these cases, the type of clinical disease depends markedly on the infected tissue type.

KEY CONCEPTS

Characteristic Features of Intracellular Bacterial Infections

- Persistence of bacteria inside mononuclear phagocytes (i.e., macrophages)
- Low to absent bacterial-mediated toxicity to the host
- Protection requires cytokine-mediated activation of infected phagocytes
- Interferon-gamma (IFN-γ) and tumor necrosis factor (TNF) produced by antigen-specific T cells are key cytokines for protection

INTRACELLULAR BACTERIAL INFECTIONS OF CLINICAL RELEVANCE

Granulomatous Infections

Tuberculosis

The major entry of tubercle bacilli into the human body is via inhalation into the lung (Table 26.1). These inhaled bacteria are then engulfed by alveolar macrophages (AMs), which transport the pathogens to the lung interstitia. Their exact fate after these events is enigmatic. Moreover, most infections in humans result in an asymptomatic carrier state referred to as latent TB infection (LTBI). Infection with *M. tuberculosis* starts with the so-called Ghon complex, characterized by a caseous lesion in the mid-lung as well as in the draining lymph nodes. These primary lesions can progress but their development rarely causes disease directly. Moreover, bacteria from these sites can disseminate to other regions of the lung and systemically, causing disease of the kidneys, liver, and central nervous system. Containment of the primary lesions, which leads to LTBI, is a function of an effective, predominately cellular anti-tubercular immune response. Infection of immunocompromised patients, notably newborns or those with acquired immunodeficiency syndrome (AIDS), frequently results in systemic disease (miliary TB). TB represents a major health problem worldwide, including an increasing incidence in many industrialized countries. In 2020, WHO estimated that 10 million active TB cases were diagnosed worldwide, with 1.5 million people dying of the disease. The much larger estimated number of 1.7 billion healthy individuals infected with *M. tuberculosis* well illustrates the dissociation of infection from disease. The emergence of multidrug-resistant strains and extremely drug-resistant strains has complicated treatment with currently available antibiotic therapy, and even when treatment is successful, recurrence of disease can occur. The currently available live whole cell vaccine BCG (bacille Calmette–Guérin), an attenuated strain derived from the etiological agent of bovine TB, *Mycobacterium bovis*, shows only low and variable protection against pulmonary TB; see (Table 26.1).

TABLE 26.1 Major Infectious Diseases Caused by Intracellular Bacteria

Disease	Pathogen	Prevalence	Incubation Time	Route of Infection	Target Cell
Granulomatous Intracellular Bacteria					
Tuberculosis	*Mycobacterium tuberculosis*	Worldwide	Years (latency after primary infection and disease reactivation) Weeks (miliary TB)	Inhalation of bacteria-containing microdroplets	Macrophage
Leprosy	*Mycobacterium leprae*	South America Africa India Southeast Asia	Years	Smear infection through mucosa/inhalation	Macrophage Schwann cell
Typhoid fever	*Salmonella enterica* serovars Typhi and Paratyphi	Worldwide	7–10 days	Fecal-oral	Macrophage
Brucellosis	*Brucella* spp.	Worldwide	Weeks to months	Zoonosis; cows, goats, pigs; inhalation, gut, skin abrasion	Macrophage
Listeriosis	*Listeria monocytogenes*	Worldwide	Days to months	Fecal-oral	Macrophage Hepatocyte
Nongranulomatous Intracellular Bacteria					
Legionnaires' disease	*Legionella pneumophila*	Worldwide	2–10 days	Inhalation	Macrophage
Rocky Mountain spotted fever	*Rickettsia rickettsia*	Western hemisphere	1 week	Tick bite	Vascular endothelial cell Smooth muscle cell
Urogenital infection	*Chlamydia trachomatis* serovars D–K	Worldwide	1–3 weeks	Sexual intercourse	Epithelial cell
Conjunctivitis, trachoma	*C. trachomatis serovars D–K*	Africa	Conjunctivitis: 1–3 weeks Trachoma: years	Eye	Epithelial cell
Cat-scratch disease	*Bartonella henselae* *B. quintana* *B. bacilliformis*	Worldwide	Bacillary angiomatosis Peliosis hepatis Endocarditis Bacteremia with fever Neuroretinitis: 1–3 weeks	Flea, sandfly or mosquito bite; animal scratch or bite	Erythrocyte Endothelial cell

Leprosy

Mycobacterium leprae is most likely transmitted by contact with patients who shed microorganisms in nasal secretions and lesion exudates. It primarily affects the nerves and the skin, frequently leading to stigmatizing deformities. In the skin, bacilli target keratinocytes and histiocytes as well as macrophages, whereas in the peripheral nerves, Schwann cells are the major target for entry. Leprosy is a spectral disease. The tuberculoid pole is characterized by rigorous T-cell responses, which succeed in restricting microbial growth in well-defined lesions containing few bacilli. In contrast, at the lepromatous pole, bacterial growth is unrestricted, and lesions contain abundant bacilli within macrophages lacking signs of activation. Several types of immunosuppression have been implicated in this latter type of disease. Infection of Schwann cells promotes nerve damage and anesthesia, which results in injuries and secondary infections that significantly exaggerate the disease. Despite the success of multidrug therapy in reducing the number of registered leprosy cases worldwide, there were some 200,000 new cases reported in 2018. This suggests that active transmission of *M. leprae* is still occurring and more effective interventions are required to prevent it.[1]

Nontuberculous Mycobacteria

Mycobacterial species present in the environment are typically unable to persist within activated macrophages, so rarely cause disease in individuals with competent immune status. Because of human immunodeficiency virus (HIV) infection, however, nontuberculous mycobacteria (NTM), primarily *M. avium/M. intracellulare*, have gained clinical importance, and these infections are recognized as one of the most common complications of AIDS in industrialized nations.

Mycobacterium scrofulaceum occasionally causes lymphadenitis in children, and *Mycobacterium kansasii* primarily causes infections in elderly individuals with pre-existing lung disease. Incidences of atypical mycobacteria, notably *Mycobacterium abscessus* in cystic fibrosis patients, have increased markedly over the last decades.[2] *Mycobacterium ulcerans* causes a severe subcutaneous infection characterized by chronic skin ulcerations known as Buruli ulcer. This pathology is caused—at least in part—by elaboration of a mycolactone toxin by the bacillus that exhibits highly cytopathic effects. Buruli ulcer is most predominant in West African countries, which accounted for most of the 2251 cases reported globally in 2014.[3]

Typhoid or Enteric Fever

S. enterica serovars Typhi and Paratyphi A, Paratyphi B, and Paratyphi C are leading causes of community-acquired bloodstream infections in low- and middle-income countries. The route of transmission is fecal-oral, and largely occurs via contaminated water sources. Bacteria are disseminated within MPs from the gastrointestinal tract to macrophage-rich organs, particularly the liver, spleen, and lymph nodes. Accordingly, typhoid is characterized by systemic symptoms such as prolonged fever and malaise with sustained bacteremia, although diarrhea or constipation may also be present. In some cases, an asymptomatic carrier state can persist as a result of chronic infection of the gallbladder, which maintains the environmental reservoir of infection in endemic areas. Typhoid fever remains a major cause of morbidity and mortality, with an estimated 11 million new cases and 117, 000 deaths per year worldwide.[4]

Gastroenteritis

S. enterica serovars Typhimurium and Enteritidis, often referred to as nontyphoidal salmonellae (NTS), are the major causes of salmonella gastroenteritis in humans, which occurs mainly as a result of the ingestion of contaminated food or water. The bacteria rapidly cross the intestinal epithelia and replicate in the lamina propria, inducing an influx of polymorphonuclear neutrophils (PMNs), which is generally sufficient to resolve the infection within a week. In rare cases, the bacteria enter the bloodstream and cause systemic bacteremia, most notably in AIDS patients, where death can occur as a result of septic shock.

Listeriosis

L. monocytogenes causes food-borne gastroenteritis. Clinical listeriosis affects mainly pregnant women, the elderly, unborn babies, and neonates. Disease manifestations are most severe in patients with a compromised immune system where the central nervous system becomes involved and fatal bacteremia can result. Additionally, as these bacteria can cross the placenta, listeriosis is a major cause of perinatal and neonatal disease, typically resulting in abortion. Listeria outbreaks are sporadic with low incidence but high fatality and affect high-income countries such as the United States. Outbreaks of *L. monocytogenes* due to contamination of meat products have increased over the last decades.[5]

Brucellosis

Brucellosis is the most common global zoonosis of humans, with approximately 500,000 cases per year.[6] It is caused by *Brucella abortus*, *Brucella melitensis* or *Brucella suis*, which primarily infect cows, goats and pigs, respectively. The bacteria are transmitted to humans via inhalation, abraded skin, or the gastrointestinal tract. Lesions are primarily found within macrophage-rich tissues, especially the spleen and bone marrow. Human brucellosis is characterized by systemic symptoms, particularly undulant fever. Although the disease often remains subclinical, in some patients it becomes chronic, and relapses and remissions may occur. Interest in brucellosis has increased in the last 5 years due to elevated levels of detection resulting from better surveillance.

Lymphogranuloma Venerum

Lymphogranuloma venereum (LGV), a sexually transmitted disease, is highly prevalent in Africa, Southeast Asia, and Latin America. LGV has recently emerged as an infection of sexually active homosexual men in Europe and the United States. It is caused by the L1, L2, and L3 serotypes of *C. trachomatis*, which are disseminated from the urogenital tract to local lymph nodes and to the skin. Accordingly, LGV is characterized by lymph node swelling and skin lesions.[7]

Melioidosis

Burkholderia pseudomallei is a gram-negative bacillus and the causative agent of melioidosis, endemic in Southeast Asia and northern Australia. The disease can be acquired through inhalation, ingestion, or through cuts in the skin. Susceptible hosts can suffer from abscess formation in multiple organs and, in some cases, disseminated infection resulting in septic shock accompanied by pneumonia. There are an estimated 165,000

cases of melioidosis per year globally, resulting in approximately 89,000 deaths.[8]

Tularemia

This rare zoonosis in humans caused by *Francisella tularensis* is mainly found in rabbits and has recently gained wider recognition due to its potential for dual use. Infection can be spread to humans via contaminated animals or tick bites. This gram-negative bacterium survives in macrophages and primarily causes acute pneumonia as well as sores of the skin, with subsequent involvement of the lymph nodes.[9]

Nongranulomatous Infections

Legionnaires' Disease or Legionellosis

Legionnaires' disease is caused by *Legionella pneumophila*, an environmental bacterium that persists within amoeba living in water reservoirs (e.g., air-cooling systems), from where it is spread aerogenically. Infection is exacerbated by a compromised immune status. Characteristically, legionnaires' disease presents as atypical pneumonia associated with general symptoms and is complicated by extrapulmonary infection, renal failure, and lung abscesses. Cases of legionnaires' disease in the United States increased from 0.39 to 1.36 per 100, 000 people from 2000 to 2011.[10]

Chlamydial Urethritis, Cervicitis, and Conjunctivitis

C. trachomatis serovars D–K enter and persist in epithelial cells of the urogenital tract, causing cervicitis and urethritis. In women, infertility can develop as a result of chronic or recurrent infection. In neonates, congenital infection during birth may result in conjunctivitis and pneumonia. Urogenital infections by chlamydiae occur worldwide and are now considered to be the most common bacterial sexually transmitted disease, with an estimated 100 million new infections occurring annually.

Trachoma

Smear infections of the eye with *C. trachomatis* serovars A, B, and C cause inclusion conjunctivitis. As a consequence of multiple chronic infections and of the resulting immune response, scars develop that eventually injure the cornea, leading to trachoma. *C. trachomatis* has been responsible for 1.9 million cases of visual loss worldwide; mass administration of azithromycin as part of a WHO public health strategy aims to eliminate trachoma by 2020.

Chlamydia pneumoniae

C. pneumoniae (formerly known as *C. trachomatis* TWAR strain) is the cause of mild respiratory disease in young adults and may cause serious infections in older, more debilitated patients. Atypical pneumonia may also be caused by *C. psittaci*, although this zoonosis, transmitted by birds, is relatively rare.[11]

Typhus

Rickettsia prowazekii, R. typhi, and *Orientia tsutsugamushi* cause diseases of varying severity. They are transmitted by arthropods and infect vascular endothelial cells at the site of an insect bite or scratch, causing skin reactions.[12] Subsequently, pathogens are disseminated to the central organs and more general symptoms develop. Globally, typhus is of minor importance.

Rocky Mountain Spotted Fever, Ehrlichiosis

Rocky Mountain spotted fever is caused by *Rickettsia rickettsii*. Infection of the vascular endothelium leads to systemic symptoms and skin manifestations that may be followed by shock and neurological complications. Worldwide, this disease, as well as Mediterranean spotted fever caused by *Rickettsia conorii*, is of minor importance, as is ehrlichiosis, a newly emerging zoonosis transmitted by ticks and caused by various *Ehrlichia* spp., mainly *E. chaffeensis*.[13] Disease manifestations include generalized symptoms such as fever and muscle pain.

Bartonella

Bartonella spp. represent gram-negative facultative intracellular pathogens transmitted by insect vectors such as fleas, sandflies, and mosquitoes. The most clinically relevant species are *B. henselae*, *B. quintana*, and *B. bacilliformis. B. henselae* causes cat-scratch disease (CSD), resulting in local lymphadenopathy in the lymph node draining the scratch site accompanied by fever, headache, and splenomegaly. Oculoglandular involvement (Parinaud syndrome), encephalopathy, neuroretinitis, or osteomyelitis can occur, albeit in rare cases. In immunosuppressed patients, bacillary angiomatosis and peliosis can occur, characterized by pseudotumoral proliferation of endothelial cells. Bacteria persist within erythrocytes with the intracellular location providing a protective niche.[14]

Sepsis, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*

Sepsis is a life-threatening condition caused by a dysregulated response to infection. Bacteremia, or presence of bacteria in the blood, is a common trigger for sepsis. *S. aureus*, a gram-positive bacterium, often presents asymptomatically in the human nasal pharynx and on the skin. Yet, it causes up to 23% of healthcare-associated bacteremia infections in the United States.[15] Infection in hospital settings is likely via soft tissue lesions during surgical intervention or introduction of catheters and other medical prosthetic devices. Although *S. aureus* is considered a facultative intracellular pathogen, intracellular survival in a subset of neutrophils that are rendered defective in intracellular bacterial killing contributes to systemic dissemination of infection. Furthermore, reduced intracellular penetrance of the antibiotic treatment of choice for methicillin-resistant *S. aureus* (MRSA), namely vancomycin, requires extended treatment durations of up to 6 weeks, reflecting the clinical importance of clearing this intracellular niche.

Pseudomonas aeruginosa is an opportunistic gram-negative bacterial pathogen and prominent cause of ventilator-acquired pneumonia in immunosuppressed individuals in healthcare settings. In addition, chronic *P. aeruginosa* infection is associated with greater than 80% of adult cystic fibrosis sufferers and significantly shortens the life span of these individuals due to destructive bronchitis and bronchiolitis. Although, *P. aeruginosa* primarily forms extracellular biofilms during infection in the lung, persistence of *P. aeruginosa* in neutrophils and epithelial cells occurs via manipulation of intracellular killing mechanisms and could contribute to the chronic nature of infection and dissemination in the lung.

GRANULOMA PATHOLOGY AS HALLMARK OF INTRACELLULAR BACTERIAL INFECTION

KEY CONCEPTS

Balance of Protection and Host Pathology in Granulomas

- Macrophage activation results in bacterial death (protective)
- Intracellular bacterial killing by "killer molecules" from T cells (protective)
- Lysis of infected macrophages by T cells results in release of bacteria and killing by more effective effector cells (protective) or bacterial dissemination (pathogenic)
- Development of central necrosis in granulomas results in death of tissue and bacteria (protective/pathogenic)
- Fibrotic encapsulation of granuloma results in containment of infection (protective)
- Over-exuberant tissue fibrosis and necrosis (pathogenic)
- Liquefaction of central necrotic tissue in granulomas results in bacterial replication, cavity formation, and transmission of bacteria (pathogenic and contagious)

A characteristic feature of many infections caused by intracellular bacteria is the eventual need for tissue remodeling by the host at the site of infection. Granulomas are the result of an inability to rapidly clear host tissue of intracellular bacteria and are a striking locus of the host–pathogen interface (Fig. 26.1). The longevity of a granuloma depends directly on the continuous presence of the microbial pathogen, and the lesion generally disappears after its sterile eradication. Granulomas form the focus of the coordinated crosstalk between different types of T and B lymphocytes and infected and uninfected MPs and dendritic cells (DCs). Even if the immune system fails to eliminate bacteria inside the granuloma, the latter performs a protective function by containing microbes within distinct foci and preventing their dissemination. At the same time, the granuloma can be detrimental to the host because it can interfere with physiological organ functions.[16] More detailed study of cellular phenotype within granulomas is starting to establish how cellular differentiation is orchestrated and how the granuloma develops.

Granulomatous lesions are generally initiated by nonspecific inflammatory signals mediated by bacterial products, chemokines, and proinflammatory cytokines that are produced by endothelial cells and MPs at the site of infection. Inflammatory phagocytes (of both monocytic and granulocytic origin) are attracted to the site of microbial replication and an infiltrative, sometimes exudative, lesion develops. Following the accumulation and activation of increasing numbers of MPs and DCs, this lesion takes an increasingly structured granulomatous form. A significant number of B cells are also found, which seem to influence granuloma morphology. Once specific T cells have been attracted to the lesion, it transforms into a solid granuloma that provides the most appropriate tissue site for antibacterial protection. Here, activation of MPs by interferon-gamma (IFN-γ) and tumor necrosis factor (TNF) inhibits microbial growth. However, unbridled macrophage activation can have tissue-damaging effects and mechanisms within the granuloma tightly regulate these effects. Eventually, the granuloma is encapsulated by a fibrotic wall and its center becomes necrotic. Both tissue reactions are primarily protective, the former by promoting bacterial containment and the latter by reducing the nutrient and oxygen supply to the pathogen. The combined effects of chronic macrophage activation, persistence of intracellular bacteria, and hypoxia likely lead to enhanced cell death in the center of granulomas, resulting in the formation of a caseum. Caseation may also favor the local replication of normally facultative intracellular bacteria in the cellular detritus, as well as microbial dissemination to distant tissue sites and the environment to transmit infection. Hypoxia also has pronounced effects on enzyme functions that can dictate macrophage phenotype.

In direct contrast to the localized containment of bacterial intracellular infection mediated by granuloma formation in the host, more disseminated forms of TB also occur, particularly in children or those with HIV.[17] Multiple organs can be involved in extrapulmonary TB, including the spleen, liver, and kidney. Dissemination of infection to the brain tissue leads to TB meningitis, which is fatal if left untreated. Dissemination of bacteria typically occurs via the lymphatic system and is likely to involve intracellular carriage.

ROLE OF THE FACULTATIVE INTRACELLULAR NICHE IN SEPSIS AND PNEUMONIA

Dissemination of *S. aureus* and *P. aeruginosa*, triggering sepsis and causing pneumonia, is increasingly appreciated as involving intracellular carriage of bacteria. *S. aureus* infection is typically cleared by neutrophils, and neutropenia in both humans and mice causes high susceptibility to infection. Despite this, neutrophils that are defective for intracellular bacterial killing also allow dissemination of bacteria to other organs, thereby seeding new sites of infection. Recent studies indicate that *S. aureus* surviving within Kupffer cells in the liver also leads to dissemination to the peritoneal cavity, where in turn bacteria are taken up by tissue-resident macrophages able to disseminate infection further. Targeting these infected cells with novel therapies could stem dissemination of infection and safeguard against sepsis in high-risk patients.

Neutrophils are similarly vital for protection against *P. aeruginosa*. Intracellular survival can be enhanced by a type III secretion system (T3SS) encoded by *P. aeruginosa* that secretes bacterial proteins via a specific needle structure that projects from the bacterial surface. These secreted proteins then interfere with intracellular killing of bacteria by neutrophils. Antibodies that inhibit T3SS by *P. aeruginosa* could prove useful in treating lung infections in susceptible patients, such as those with cystic fibrosis.[18]

THE INTERDEPENDENCE OF INNATE AND ADAPTIVE IMMUNITY IN PROTECTION AGAINST INTRACELLULAR BACTERIA

Innate Immune Mechanisms as First-Line Defense

The interaction between host cell and pathogen that defines the intracellular fate is represented by multiple layers. The first layer that differentiates intracellular bacteria from other bacteria, notably commensal bacteria that colonize the host but do not cause infection, is that of host cell entry. Extracellular bacteria are typically engulfed by professional phagocytes, which include tissue macrophages, DCs, and PMNs. This uptake is enhanced by host components of the complement system and antibodies, which bind to complement receptors (CRs) and Fc receptors, respectively, on professional phagocytes.[19] *M. tuberculosis* actively

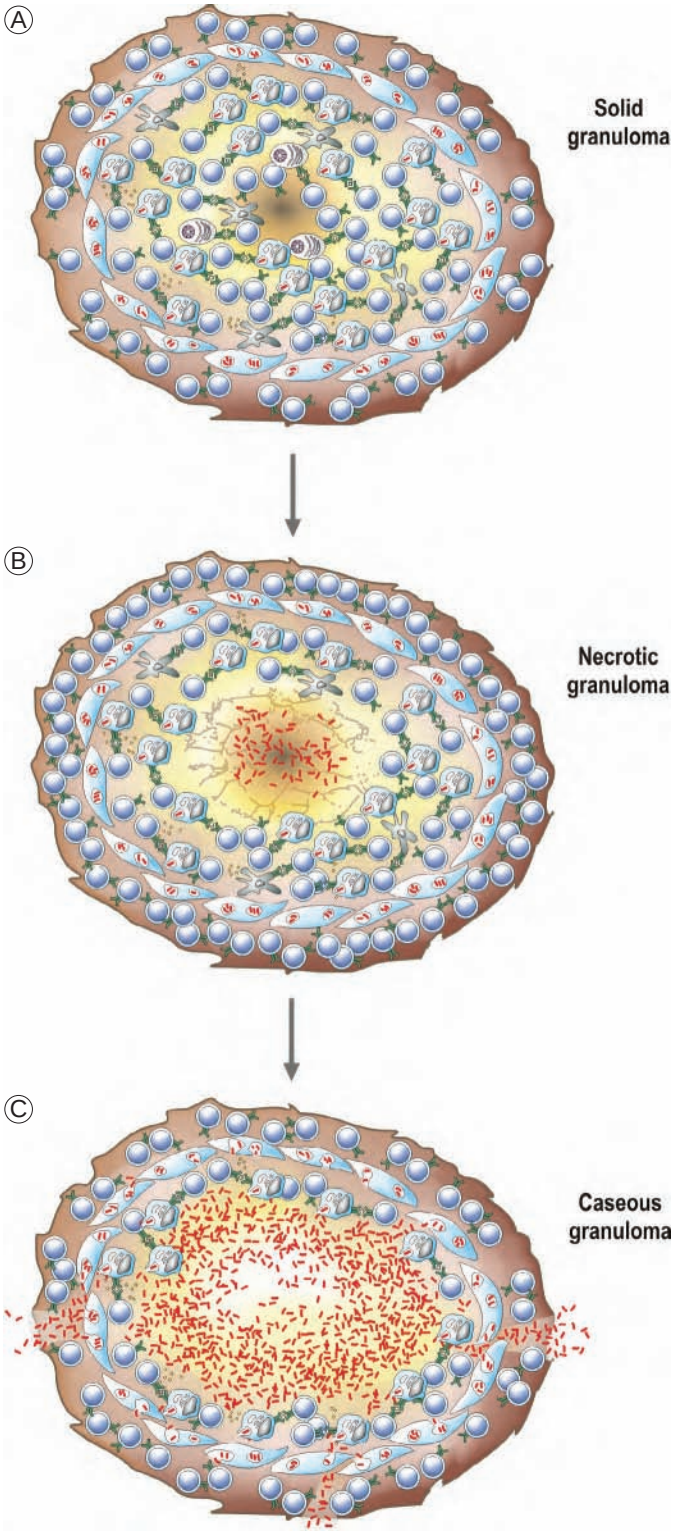

FIG. 26.1 Development of granuloma pathology and implications for tuberculosis (TB). This figure depicts three distinct yet continuous stages of granuloma pathology in the lung due to *Mycobacterium tuberculosis* infection. (A) Solid granuloma: composed largely of T cells and infected and uninfected macrophages (MPs). These granulomas are defined by a lack of central necrosis and are likely representative of an ability to control *M. tuberculosis* replication. (B) Caseous/necrotic granulomas: these structures contain a central region of demarcated necrotic cell death. Bacteria are often detected within the caseous necrotic region and in proximal cells, notably MPs. Since calcified caseous granulomas containing few bacteria have been observed, development of central necrosis may be a consequence of antibacterial mechanisms resulting in sacrifice of host cells to contain infection. (C) Cavity formation: these structures result from inability of caseous granulomas to contain bacterial replication. The acellular necrotic region, containing a large number of extracellular bacteria, increases in size and can liquefy and empty into the lung airways, resulting in transmission of viable bacteria via cough. Therefore, granuloma formation is central to human-to-human spread of TB. Dissemination of bacteria through the bloodstream results in disease manifestation in other organs, such as meninges and urinary bladder.

targets macrophages where it must counteract numerous antimicrobial mechanisms operative in these cells (see below). Intracellular bacteria also use elaborate mechanisms to enter nonprofessional phagocytes by which they must subvert host endocytic processes that are normally engaged in traffic of cellular cargoes. In some cases, this provides a less hostile environment owing to their inability to efficiently mobilize antibacterial effector mechanisms. *Bartonella* spp., unique among intracellular bacteria, can enter red blood cells, allowing transmission via blood-sucking insect vectors. This represents a particularly advantageous niche, as red blood cells lack the machinery to drive the adaptive immune responses required for protection. Entry into nonphagocytic host cells requires bacteria to induce their own internalization. Bacteria that colonize the gastrointestinal tract (i.e., *L. monocytogenes* or salmonellae) or mucosal membranes of the urogenital tract (i.e., *C. trachomatis*) must mediate tight adhesion to the host cell membrane and be capable of mediating the uptake process. Broadly, two processes are utilized by bacteria to induce uptake into a nonphagocytic cell. The "zipper" mechanism is mediated by binding of a bacterial cell surface protein to a cognate receptor on the host cell membrane. *L. monocytogenes* entry into intestinal epithelial cells depends on engagement of InIA to E-cadherin to mediate uptake.

Salmonellae and *C. trachomatis* use a "trigger" mechanism to induce internalization and inject multiple factors into the host cell cytoplasm to mediate uptake. These proteins are delivered by the needle-like structures that form part of bacterial T3SSs. These injected proteins target host proteins involved in host cell signaling and actin remodeling to induce bacterial entry. The *C. trachomatis*–secreted proteins Tarp, CT166, and CT694 reversibly stimulate the Rho-family GTPase Rac1 to trigger internalization. Similarly, salmonellae inject T3SS factors to stimulate Rho-family GTPases Cdc42 as well as Rac1. The success of these mechanisms of induced uptake enables intracellular bacteria to persist inside diverse cell types. *Rickettsia* spp., *C. trachomatis, M. leprae*, and *L. monocytogenes* ultimately target

vascular endothelial cells, epithelial cells, Schwann cells, and hepatocytes, respectively, as their preferred intracellular habitats.

To prevent intracellular infection, the host depends on its ability to discriminate between host and bacterial molecules. As already mentioned, bacteria targeting the intracellular environment often do so via mucosal surfaces already populated by commensal organisms (the microbiome) that do not alert host defenses. The host must therefore discriminate between commensal and pathogenic bacteria via recognition of conserved molecular motifs of bacteria, namely pathogen-associated molecular patterns (PAMPs). This occurs via host receptors broadly defined as pattern recognition receptors (PRRs, Table 26.2 Chapter 3).

The best-characterized group of PRRs are the so-called Toll-like receptors (TLRs). The TLR system constitutes an innate scanning mechanism of microbial pattern recognition to distinguish between a wide spectrum of bacteria and viruses. TLRs are present as homo- or heterodimers on the plasma membrane or within the intracellular endosome/phagosome compartment. PAMPs of bacterial origin comprise di- and tri-acylic lipoproteins, LPSs, and flagellin, which are recognized by TLR2/6, TLR2/1, TLR4/4, or TLR5/5, respectively. The vast array of mycobacterial cell wall lipids such as lipoarabinomannan (LAM), trehalose dimycolate (TDM), and phosphatidyl inositol mannosides (PIMs) bind either TLR2 or TLR4. Lipoteichoic acid (LTA) of gram-positive bacteria is recognized by TLR2. TLR9 binds low-methylated bacterial DNA containing CpG motifs within endosomes.

Scavenger receptors and C-type lectins are also PRRs and function at the cell membrane. Scavenger receptors were first defined by their ability to transport modified forms of low-density lipoproteins inside cells, indicating their ability to also interact with host molecules. However, receptors such as SR-A, MARCO, CD36, LOX-1, and SREC can bind a wide array of bacterial molecules such as lipids, CpG DNA, and proteins (see Table 26.2 for binding specificities). SR-A is important for clearance of extracellular bacteria from the spleen and liver. MARCO expressed on AMs is implicated in clearance of pneumococcal bacteria, preventing pneumonia. C-type lectins are similarly membrane-expressed and include DC-specific intercellular adhesion molecule-3-grabbing nonintegrin (DC-SIGN), mannose receptor, dectin-1, dectin-2, which chiefly recognize fungal components and MINCLE, which recognizes TDM, the cord factor of *M. tuberculosis*.

It has been suggested that whereas scavenger receptors and C-type lectins are required to bind and internalize the bacillus, it is primarily the TLRs that discriminate between the pathogens and initiate the necessary intracellular signaling events. It should, however, be noted that intracellular signaling events can also be triggered by other interactions, such as ligand binding to macrophage mannose receptor (MMR), dectin 1, or DC-SIGN. Far from a one-ligand, one-receptor binary mechanism of sensing and signaling, PRRs often collaborate to produce multiprotein complexes. CD14, MD2, and TLR4 collaborate for LPS sensing and signaling. Similarly, MARCO and TLR2 synergize to recognize TDM. To allow signaling, these complexes interact with adaptor proteins containing immunoreceptor tyrosine-based activation motif (ITAM)-like or Toll/interleukin-1 receptor (TIR) domain motifs. TLR signaling occurs via the adaptor proteins MyD88, TIRAP/Mal, and Trif. These molecules then orchestrate a downstream signaling cascade culminating in induced patterns of gene transcription that mediate innate and, ultimately, adaptive immune mechanisms that aim at combating the intracellular bacteria.

TABLE 26.2 Major Pattern Recognition Receptors Involved in Sensing of Intracellular Bacteria

PRR	Location	Ligand
Toll-like Receptors		
TLR1	Plasma membrane	Triacyl lipoprotein
TLR2	Plasma membrane	PGA, porins, LAM
TLR4	Plasma membrane	LPS
TLR5	Plasma membrane	Flagellin
TLR6	Plasma membrane	Diacyl lipoprotein
TLR7(human TLR8)	Endosome	ssRNA
TLR9	Endosome	CpG DNA
Scavenger Receptors		
SR-A	Plasma membrane	LPS, LTA, CpG DNA, proteins
MARCO	Plasma membrane	LPS, proteins
CD36	Plasma membrane	Diacyl lipoprotein
LOX-1	Plasma membrane	Protein
SREC	Plasma membrane	Protein
C-type Lectins		
DC-SIGN	Plasma membrane	LPS, ManLAM, capsular polysaccharide
MINCLE	Plasma membrane	Mycobacterial cord factor: TDM
NOD-like receptors		
NOD1	Cytoplasm	D-glutamyl-meso-diaminopimelic acid
NOD2	Cytoplasm	MDP
NLRP1	Cytoplasm	MDP
NLRP3	Cytoplasm	RNA, LPS, LTA, MDP
NLRC4	Cytoplasm	Flagellin
Naip5	Cytoplasm	Flagellin
AIM2-like Receptors		
AIM2	Cytoplasm	dsDNA
IFI16	Cytoplasm	dsDNA
STING/cGAS Pathway		
cGAS	Cytoplasm	dsDNA

We omit PRRs (e.g., TLR3, which binds viral-produced double-stranded RNA) not classically associated with intracellular bacteria.
AIM2, absent in melanoma 2; *CD36*, cluster of differentiation 36; *CpGDNA*, cytosine-phosphatidyl-guanine DNA; *DC-SIGN*, dendritic cell-specific intercellular adhesion molecule-3-grabbing nonintegrin; *dsDNA*, double-stranded DNA; *LAM*, lipoarabinomannan; *LOX-1*, lipoxygenase1; *LPS*, lipopolysaccharide; *LTA*, lipoteichoic acid; *ManLAM*, mannose lipoarabinomannan; *MARCO*, macrophage receptor with collagenous structure; *MDP*, muramyl dipeptide; *MINCLE*, macrophage-inducible C-type lectin; *NLR*, NOD-like receptor; *NOD*, nucleotide-binding oligomerization domain; *PGA*, peptidoglycans; *PRR*, pattern recognition receptor; *SR*, scavenger receptor; *SREC*, scavenger receptor expressed by endothelial cell-I; *ssRNA*, single-stranded RNA; *TDM*, trehalose dimycolate; *TLR*, Toll-like receptors.

The cellular cytoplasm is monitored for the presence of molecules of bacterial origin by a further group of PRRs, the nucleotide oligomerization domain protein-like receptors (NLRs). These molecules are characterized by a nucleotide-binding domain and leucine-rich repeat motifs. Molecules from this group recognizing bacterial components are nucleotide-binding oligomerization domain (NOD)-containing proteins NOD1 and NOD2, NOD-like receptors (NLR)P1, NLRP3, and Naip5. Other cytosolic PRRs include the absent-in-melanoma-2-like (AIM2) receptor family (ALR), cGMP-AMP synthase (cGAS), and stimulator of IFN genes (STING), all of which can be activated by bacterial DNA (see Table 26.2).

Engagement of NLRs and ALRs leads to activation of the multiprotein complex called the inflammasome, leading to cleavage of pro-IL-1β and pro-IL-18 to their active forms. In addition, activation of the NLRs NOD1 and NOD2 results in inflammatory cytokine secretion.[20] Certain PRRs are also receptive to certain endogenous "danger" signals produced by tissues undergoing stress, damage, or cell death. These signals are triggered by self-proteins, named danger-associated molecular patterns (DAMPs), and include endogenous heat shock proteins, host nucleotides, and the chromatin component HMGB1. Therefore, PRRs mediate signals not only emanating from intracellular bacteria but also from host cells damaged by the infection process. Understanding how PAMP and DAMP PRR signaling meshes to produce a coherent disease-specific output remains an exciting challenge for future research.

As already noted, the culmination of PRR collaborative sensing and signaling is the induction of inflammatory genes that induce innate immune mechanisms and, subsequently, the mobilization of the adaptive immune response. These include cytokines that act both locally and systemically and are important mediators of protection against intracellular bacteria via specific signaling through engagement of host cell surface receptors. Such engagement mobilizes both critical mechanisms of host protection and orchestration of adaptive immune responses.

Cytokines as Mediators of Defense Against Intracellular Bacteria

We have already mentioned that a range of cytokines are induced by the signaling mechanisms that result from engagement of PRRs. These serve by both enhancing intracellular mechanisms of bacterial killing and mobilizing adaptive immune responses, representing the next layer of host defense.[21] Because these responses allow an amplification of the initial innate immune responses, they must be carefully regulated by the host to prevent extensive tissue pathology. In fact, we might view the development of a granuloma as the sequela of a balance between bacterial killing mechanisms and the need to restrict tissue pathology orchestrated by adaptive immunity. At the onset of infection, initial cytokine secretion occurs in the cell type that first encounters intracellular bacteria and on initiation of signaling cascades by PRRs. These molecules can act locally and systemically to directly instruct cells, to produce antibacterial molecules, to combat intracellular infection, and both to increase numbers of immune cells and to direct the composition of the cellular infiltrate that will ultimately attempt to resolve intracellular bacterial infection.[22] Cytokines are ultimately produced by multiple cell types, including adaptive T cells, B cells, unconventional T cells, MPs, DCs, PMNs, and even epithelial and endothelial cells. We will first consider the hierarchy by which these cytokines act in the control of intracellular bacterial infection and the antibacterial mechanisms they regulate. We will then return to the generation and regulation of the cells that produce them.

KEY CONCEPTS

T-Cell-Mediated Mechanisms Underlying Protection

Interferon-gamma (IFN-γ)- and tumor necrosis factor (TNF)-mediated activation of phagocytes to kill bacteria by means of:

- Reactive oxygen intermediate (ROI) and reactive nitrogen intermediate (RNI)
- Delivery of lysosomal hydrolytic enzymes and antimicrobial peptides to the bacteria-containing phagosome
- Xenophagy
- Formation and maintenance of granulomas
- T-cell-mediated response controls, but does not eradicate, the pathogen

IFN-γ, TNF, IL-12, and IL-18

The cytokine with the clearest demonstrable potency against intracellular bacteria is IFN-γ. Extensive studies on the activation of antibacterial effector functions in macrophages have revealed a central role for IFN-γ. Accordingly, IFN-γ neutralization with antibodies or deletion of the IFN-γ gene by homologous recombination markedly exacerbates infectious diseases such as listeriosis, TB, or typhoid in experimental animals. For macrophages harboring intracellular bacteria, namely *M. tuberculosis*, signaling with IFN-γ is a game-changer, summoning infected macrophages to escalate an mechanisms. The action of TNF appears to augment IFN-γ and is also important in control of intracellular infection. This has been demonstrated in humans through use of blocking of TNF by antibodies as anti-inflammatory therapy. Such treatments can activate TB in individuals with LTBI. Despite this, these potent protective effects of IFN-γ and TNF come at a price. The need to kill intracellular bacteria often leads to death of the host cell as collateral damage. In part, the host manages this by controlling how the cell dies; excessive TNF leads to less-regulated necrotic cell death, benefiting *M. tuberculosis*. For this reason, elaborate host mechanisms have evolved to maintain TNF at optimum levels to control infection. The host enzyme leukotriene A4 hydrolase (LT4H) catalyzes synthesis of a highly proinflammatory lipid leukotriene B4. In the event of enzyme deficiency, an anti-inflammatory lipid lipotoxin A4 accumulates, which counteracts effects of TNF. Two common variant promoters control expression of *LT4H* in humans, and homozygotes are associated with either high or low inflammation. In contrast, the heterozygotes show a balanced response to TNF associated with resistance against TB. Such a finding strongly hints that genetic mechanisms can maintain an optimum level of TNF responsiveness of cells harboring intracellular bacteria, namely *M. tuberculosis*.

A central antimicrobial mechanism stimulated by IFN-γ and TNF is production of reactive nitrogen intermediates (RNIs) via the induction of nitric oxide synthase (NOS)2 and reactive oxygen intermediates (ROIs) via activation of reduced nicotinamide adenine dinucleotide phosphate (NADPH)-dependent oxidative burst. IFN-γ also promotes antimicrobial effects associated with vitamin D and induces autophagy, a mechanism that plays an important role in host defense. It is now clear that the production of IFN-γ depends on prior activation by IL-12 and/or IL-18. IL-12 in concert with TNF induces a cytokine loop resulting in the production of IFN-γ, which sustains the production of IL-12 and IL-18. These observations have been extended to humans where mutations that effect IFN-γ signaling cause susceptibility to *M. tuberculosis* and salmonellae, as well as BCG and commonly nonpathogenic mycobacteria termed Mendelian susceptibility to mycobacterial disease (MSMD). These mutations are in genes that include *IL12B* and *IL12RB*, which encode subunit β of IL-12 cytokine and its receptor respectively, and *IFNGR1* and *IFNGR2*, which encode the IFN-γ receptor.[23] Further unraveling of the molecular basis of human genetic susceptibility to intracellular bacterial infection will continue to illuminate our understanding of how immunity is similarly orchestrated across multiple infectious diseases.

Proinflammatory Cytokines and Phagocyte Attraction

The recruitment of more phagocytes to the site of infection represents a vital process in the resolution of infection. Phagocyte recruitment is achieved via the secretion by MPs and endothelial cells of cytokines of the IL-1 family, TNF-α, IL-6, and chemokines. Signaling via IL-1 cognates is considered closely related to that of the TLRs due to close homology of the cytoplasmic domains of TLRs and IL-1 family receptors. The most studied member is IL-1β, which in synergy with chemokines and TNF increases the expression of adhesion molecules on the vascular epithelium, thereby promoting extravasation of the inflammatory cell infiltrate into infected tissues. Chemokines are a family of structurally related proteins (Chapter 15). The positions of the first two cysteine residues in the protein sequence have been used to divide chemokines into four subfamilies: CC (MIP-1β, MCP-1, -2, -3), CXC (MIP-2, IL-8), C (lymphotactin), and CX3C chemokines (fractalkine), where C represents cysteine and X represents any amino acid other than cysteine. These molecules are critical in controlling the migration of PMNs (IL-8) and monocytes (MCP-1, also known as CCL2) from the bloodstream to infected tissue. Recently, the role of chemokines in intracellular infections has been increasingly appreciated, e.g., with mice lacking the receptor for CCL2 being deficient in their ability to clear listeria infection. It has been suggested that in the early stages of infection, *M. tuberculosis* exploits a delay in the mobilization of T-cell immunity to recruit MPs to the site of infection, which preferentially serve as habitat due to a lack of local IFN-γ from T cells. Moreover, *M. tuberculosis* is thought to infect the lower airways with a limited microbiome. This scarcity could mean that *M. tuberculosis* uses cell surface phenolic glycolipid (PGL) to signal epithelial cells to produce the chemokine CCL2 in the absence of signaling via other PAMPs. Phthiocol of *M. tuberculosis* is sensed by the aryl hydrocarbon receptor (AhR) to produce CCL2 and other chemokines for attraction of blood-derived phagocytes.[24] This mechanism then recruits MPs that are more permissive for bacterial growth than those recruited by a more "global" MyD88-dependent signaling of TLRs, requiring co-engagement of PAMPs on commensal bacteria that are more abundant in the upper airways. The initial MP infiltrates could play an important role in early granuloma development.

Cytokine-Induced Host-Protective Mechanisms

Effector Molecules

Activation of a membrane-bound NADPH oxidase by stimulation with IFN-γ or IgG initiates an oxidative burst that generates the ROI, O_2^-, H_2O_2, OH^-, $^1O_2$, and •OH radical (Table 26.3). In human PMNs and blood monocytes that possess myeloperoxidase, ROI activity is further augmented by the formation of hypochlorous acid. Oxidation and/or chlorination of bacterial lipids and proteins results in their inactivation and subsequent bacterial killing. The importance of ROIs in antibacterial defense is underlined by recurrent infections in patients whose phagocytes fail to generate an oxidative burst (Chapter 39). NOS2 is an inducible cytosolic enzyme in professional phagocytes that delivers NO to the phagolysosome-harboring bacteria while consuming O_2 and L-arginine. NO is further oxidized to NO_2^- and NO_3^-. Nitrification and/or oxidation then inactivates bacterial molecules needed for bacterial growth.[25] The formation of NO is catalyzed by NOS2, which is promoted by both immunological stimuli such as IFN-γ and TNF, and microbial products such as LPS, LTA, and mycobacterial lipids. RNIs exert their bactericidal activity by destroying iron-/sulfur-containing reactive centers of bacterial enzymes and by synergizing with ROIs to form highly reactive peroxynitrite ($ONOO^-$). Despite being highly effective in killing intracellular bacteria, NO production relies on a continuous supply of L-arginine, which becomes limited due to competition with another macrophage enzyme, Arginase-1 (Arg-1). Arg-1 metabolizes L-arginine to produce urea and ornithine and demonstrates anti-inflammatory activity. The competitive function of Arg-1 likely regulates collateral tissue damage caused by over-exuberant RNIs. The final downstream product of NOS2 activity is citrulline, which is recycled to L-arginine by the enzymes argininosuccinate synthase (Ass1) and argininosuccinate lyase (Asl). A mouse deficient in macrophage Asl activity is unable to control mycobacterial infection, highlighting the importance of this recycling pathway. The central role of NOS2 in protection against intracellular bacteria is well established in murine models of infection. Whether NOS2 plays a similarly central role in humans is still unclear. Defensins are small lysosomal polypeptides that are microbicidal at basic pH and are particularly abundant in phagocytes. These include granulysin, present in granules of human natural killer (NK) and cytolytic T lymphocytes (CTLs), and cathelicidin, which is regulated by vitamin D in a TLR-dependent manner and is converted by cleavage to the antimicrobial peptide LL-37.

Apoptosis and Autophagy

Apoptosis is a highly regulated form of cell death that is critical for control of cell turnover, which is a vital process for tissue homeostasis.[26] Macrophage apoptosis also constitutes a defense

TABLE 26.3 Antibacterial Effector Mechanisms of Activated Macrophages and Corresponding Microbial Evasion Strategies

Macrophage Effector Mechanism	Microbial Evasion Strategy
Production of ROIs	Uptake via complement receptors; production of ROI detoxifying molecules (superoxide dismutase, catalase); bacterial ROI scavengers (phenolic glycolipids, sulfatides, lipoarabinomannans)
Production of RNIs	Inhibition of phagosome maturation via blockage of H^+ATP pump; indirect effect of ROI-detoxifying molecules
Autophagy, intraphagolysosomal killing	Egression into cytoplasm; resistant cell wall
Phagosomal acidification, phagosome–lysosome fusion	Inhibition of phagosome maturation
Defensins	Modification of cell wall lipid A to resist defensins
Reduced iron supply (transferrin receptor downregulation, lipocalins)	Expression of microbial siderophores to increase iron uptake
Tryptophan degradation	Upregulation of bacterial tryptophan synthesis

RNI, Reactive nitrogen intermediate; ROI, reactive oxygen intermediate.

mechanism, allowing removal of phagocytes containing intracellular bacteria without the need to generate significant inflammation. Apoptosis, in contrast to cellular necrosis, results in cell death without permeabilization of the host cell membrane (Chapter 17). The process can be triggered by TNF signaling and augmented by IFN-γ, resulting in activation of cellular caspases, mitochondrial membrane permeability, and cytochrome *c* release. These processes result in cellular disintegration and generation of apoptotic bodies that are engulfed and digested by neighboring phagocytic cells. Apoptosis is protective against *L. monocyogenes* and *Salmonella* spp. and is inhibited by *M. tuberculosis*, which promotes necrotic cell death of infected cells to its benefit via mitochondrial membrane damage and by caspase-independent mechanisms during conditions of high bacterial burden in macrophages. Noninfected cells engulf bacterial antigens associated with vesicles produced by apoptotic cells. Apoptosis as a prerequisite for this pathway is induced by many intracellular bacteria, such as salmonellae, mycobacteria, and listeriae. This cross-presentation pathway in infections with intracellular bacteria adds an essential function to the physiological role of apoptosis in maintenance of tissue integrity and growth.

Upon signaling via IFN-γ, autophagy (a process common to all cells for removal of dysfunctional or damaged cellular organelles) can be harnessed to dispose of intracellular *L. monocytogenes* and *M. tuberculosis* in a process termed xenophagy. Signaling via members of the immunity-related GTPase family (IRG family) and the guanylate-binding protein family, TLR2 and 4 engagement and the active form of vitamin D_3 all act to augment xenophagy. This process is also triggered via the cGAS-STING (cyclic GMP-AMP sythase-stimulator of interferon genes). STING senses cyclic GMP-AMP generated by cGAS on binding bacterial DNA and leading to engagement of the autophagic machinery. Formation of double-membrane autophagosomes that mature analogously to the phagosomal pathway fuse with lysosomes that degrade bacteria contained within. The importance of this process is highlighted by polymorphisms in one of the three IRG family genes in humans, *IRGM*, being associated with susceptibility to TB. Recently, a host-encoded microRNA, miRNA-155 was shown to potentiate xenophagy during intracellular mycobacterial infection by targeting an endogenous inhibitor of autophagy, Ras homologue enriched in brain (Rheb).

Nutrient Deprivation

Deprivation of required nutrients to intracellular bacteria is also a strategy employed by the host, markedly so within infected macrophages. Tryptophan degradation is achieved by the enzyme indolamine 2, 3-deoxygenase (IDO), which degrades tryptophan to kynurenine (see Table 26.3). This reaction is induced by IFN-γ in both MPs and IFN-γ-responsive nonprofessional phagocytes and inhibits the growth of *C. psittaci* and *C. trachomatis* inside human macrophages and epithelial cells. Similarly, augmentation of NOS2 by IFN-γ and TNF depletes intracellular L-arginine, also required for growth of intracellular bacteria.[19]

Evasion From, Interference With, and Resistance to Microbial Killing

Strategies Against Toxic Effector Molecules

Many intracellular bacteria have exploited successful strategies against macrophage effector mechanisms (see Table 26.3). One mechanism of evasion is determined by the receptor that is used for pathogen entry into the host cell. Internalization via complement receptors (CRs) inhibits the production of IL-12, a cytokine critical in facilitating macrophage activation. Engulfment by this receptor also bypasses activation of the oxidative burst, thereby avoiding ROI production. Similarly, engaging MMR and DC-SIGN for uptake triggers secretion of the suppressive cytokines IL-10 and TGF-β. Several intracellular bacteria also produce ROI detoxifiers, including superoxide dismutase and catalase, which nullify O_2 and H_2O_2, respectively. Finally, a number of small bacterial products, such as phenolic glycolipid, phthiocol, and LAM of mycobacteria or phenazines of *P. aeruginosa*, scavenge ROIs. Many of the strategies used to counteract the effects of ROIs also overlap in their effects on RNIs. A modification of lipid A renders gram-negative bacteria, including salmonellae, resistant to the effects of host antimicrobial peptides.

Intraphagosomal Survival

Inhibition of phagolysosome fusion represents a major intracellular survival strategy for a number of intracellular bacteria, including *M. tuberculosis*, *Francisella* spp., *Brucella* spp., and *L. monocytogenes* (Fig. 26.2). After engulfment, these pathogens manipulate the endocytic fate of the phagosome that contains them. This is achieved in part by manipulation of Rab GTPases (proteins required for normal endocytic trafficking) positioned in the phagosome membrane. Rab GTPases associated with phagosome maturation of the pathogen-containing phagosome are Rab 3, 4, 5, 9, 7, 11, and 14. These proteins are associated with different maturation stages of the phagosome and chiefly orchestrate membrane fusion events to allow delivery of vesicular protein cargo to the phagosomal compartment. The mycobacteria-containing phagosome acquires Rab5a, but not the late endosomal marker Rab7a, which ultimately mediates fusion of the bacterial-containing phagosome with lysosomes that contain proteolytic enzymes active at low pH. By enabling arrest of this maturation, *M. tuberculosis* maintains its compartment at an early endosomal stage. This compartment does not acidify, due in part to a paucity of vacuolar H^+ ATPase; at the same time, it exchanges molecules with the plasma membrane such as the transferrin receptor to access iron. Activation of macrophages with IFN-γ restores the normal maturation of the mycobacterial phagosome, resulting in a drop in mycobacterial viability. Francisellae and brucellae are engulfed by phagosomes that acquire the early endosomal markers EEA1 and Rab5a. The Francisella-containing vacuole acquires late endosomal markers, but the pathogen escapes into the cytosol by perforating the late endosomal membrane. After a transient phagosomal stage, brucellae enter compartments enclosed by endoplasmic reticulum (ER) membranes to escape delivery to phagolysosomes.

Phenotypic Plasticity of the Infected Cell

The ability of intracellular bacteria to influence the phenotypic fate of both the cell in which it dwells and cells within lesions that form due to unresolved infection is becoming increasingly appreciated. This has already been highlighted by the tendency of *M. tuberculosis* to use its own membrane lipids to exploit host chemotactic pathways to recruit bacterial growth-permissive macrophages to the site of infection, subsequently allowing a proliferative head start before adaptive immunity kicks in, and amplifies intracellular defense by the action of cytokines such as

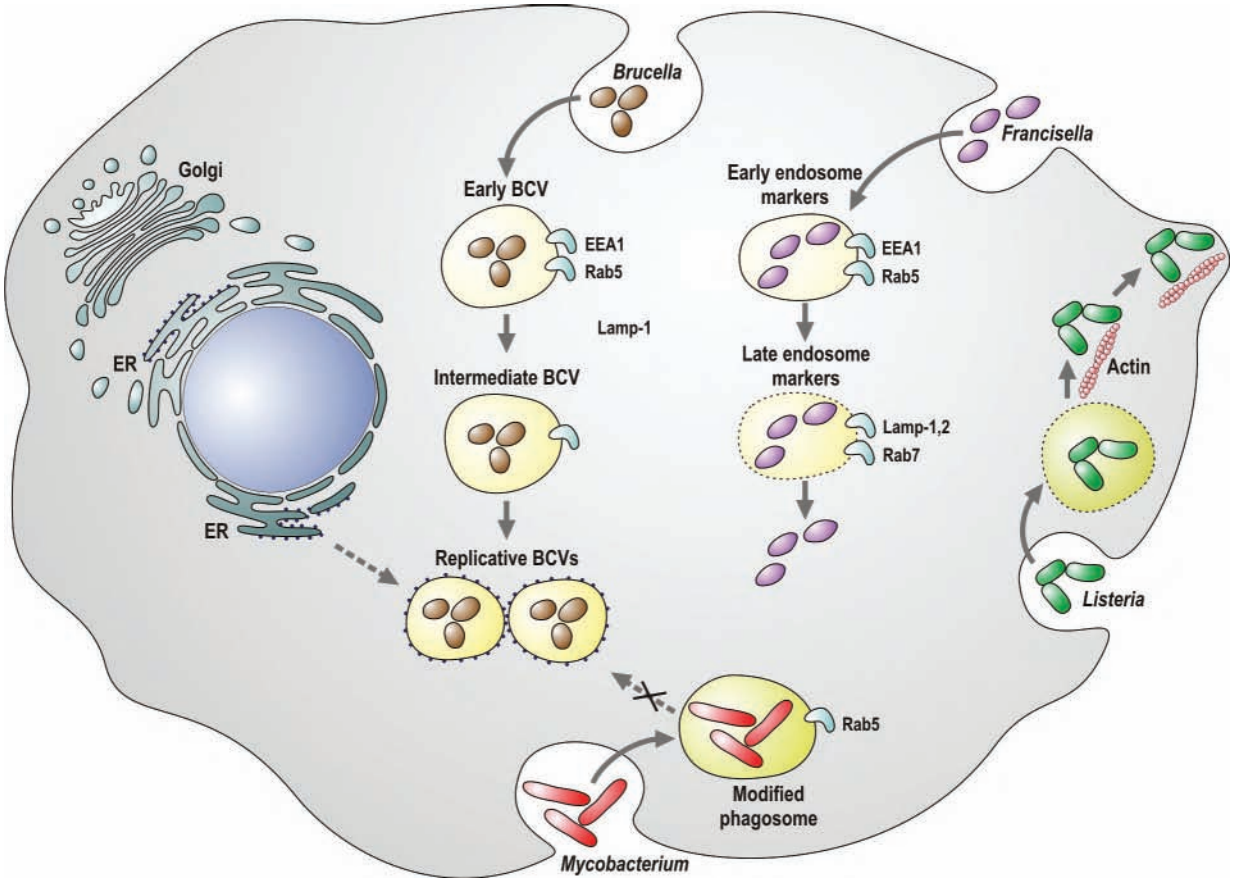

FIG. 26.2 Inhibition of Phagolysosome Fusion Represents a Major Survival strategy for a number of Intracellular Bacteria, Including *Mycobacterium tuberculosis*, *Francisella* spp., *Brucella* spp., and *Listeria monocytogenes*. The mycobacteria-containing phagosome acquires Rab5, but not the late endosomal markers Lamp-1 and 2, enabling arrest of maturation of this compartment at an early endosomal stage. *Francisella* spp. and *Brucella* spp. are engulfed by phagosomes that acquire the early endosomal markers EEA1 and Rab5. The *Francisella*-containing vacuole acquires late endosomal markers, but escapes into the cytosol by perforating the late endosomal membrane. A similar strategy is adopted by *L. monocytogenes*. After a transient phagosomal stage, brucellae enter compartments enclosed by endoplasmic reticulum (*ER*) membranes to escape delivery to phagolysosomes. Brucella-containing vacuole (*BCV*).

IFN-γ and TNF. Moreover, bacterial killing must be tempered inside the granuloma to prevent destruction of host tissue. This is achieved by balancing the macrophage phenotype ranging from highly bactericidal, termed "classically" activated (also termed M1 macrophages), to a phenotype that is more suppressive of inflammation and associated with wound healing, tissue remodeling, and fibrosis, termed "alternatively" activated (also called M2 macrophages). Tipping the balance one way or the other is detrimental for the host in terms of disease.[27]

Myeloid-derived suppressor cells (MDSCs) represent a certain stage of development of myeloid cells (both of monocytic and granulocytic lineage). Although most of our knowledge stems from their suppressive role in cancer, recent evidence suggests that they play a role in control of chronic infection such as TB. They can be distinguished from canonical MPs and granulocytes by means of distinct surface markers. The granulocytic MDSCs are $CD11b^{+}$ $LY6G^{hi}$ $Gr1^{int}$, whereas the monocytic MDSCs are $CD11b^{+}$ $LY6G^{neg}$ $LY6C^{+}$ $Gr1^{hi}$.

During intracellular infection of Schwann cells, *M. leprae* downregulates genes active for the Schwann cell phenotype and upregulates genes that orchestrate differentiation to a "stem-cell-like" phenotype. This stem-cell-like property allows the infected cell to differentiate further to multiple mesenchymal cell states, such as skeletal cells or smooth muscle cells.[28] This ability to regress and then re-program infected cell phenotype could play a role in spreading infection throughout the host during leprosy.

Recently, both mesenteric stem cells (MSCs) and hematopoietic stem cells (HSCs) have been identified as intracellular niches of *M. tuberculosis* in mice and humans. Because these cells predominantly reside in hypoxic niches in the bone marrow and most antimycobacterial therapies are inactive in these conditions, it is possible that MSCs and HSCs maintain intracellular bacteria during long-term infection and represent a protective niche from drug therapy. *M. tuberculosis* was also detected in long-term repopulating pluripotent HSCs, and these cells could also be capable of resuscitating active disease.

Training of Innate Immunity

Vaccination with BCG induces IFN-γ-dependent effects on HSCs and their more immediate progeny, multipotent progenitors (MPPs), leading to production of myeloid cells that contain epigenetic changes and that are more resistant to intracellular infection by *M. tuberculosis*.[29] Moreover, BCG vaccination

was shown to induce changes in patterns of methylation of the NOD2 gene in humans, and these epigenetic changes led to increased production of proinflammatory cytokines. Furthermore, this enhanced innate immunity caused increased resistance not only against *M. tuberculosis* but also against other bacterial pathogens. Indeed, it has been speculated that epigenetic alterations in MPs following vaccination are responsible for the nonspecific reduction of mortality in BCG-vaccinated infants in resource-poor regions.

Effects of bacterial infection on myelopoiesis can also mediate resistance to sepsis in neonates. Neonates produce high systemic levels of the alarmins S100/A8 and S100/A9. In model systems, these alarmins effect myelopoiesis by inducing a more tolerogenic monocyte phenotype that attenuates hyperresponsiveness to bacterial colonization while not affecting intracellular bacterial killing mechanisms. Therefore, alarmins in neonates could reduce the risk of sepsis in the first year of life by generation of monocytes less likely to trigger a hyperinflammatory response to a bacterial infection.

Escape into Cytoplasm

A successful strategy for survival inside activated macrophages is egression from the phagosome into the cytoplasm, which has been exploited by *L. monocytogenes* and the various pathogenic *Rickettsia* spp. (see Fig. 26.2). This has the advantage of both avoiding the cellular defense mechanisms within the phagosome and providing the bacteria with a nutrient-rich environment. *L. monocytogenes* possesses several virulence factors to facilitate its escape from the phagolysosome, a pore-forming hemolysin (listeriolysin, LLO) that acts together with a metalloproteinase, a lecithinase, and two phospholipases to efficiently promote the rupture of the phagosomal membrane, as well as spreading to other cells. To avoid collateral damage, LLO contains an amino acid sequence that initiates its own destruction soon after it has entered the cytosol. *M. tuberculosis* and *M. leprae* can also egress from the phagosome into the cytoplasm of macrophages and DCs, a behavior that is mediated by mycobacterial protein secretion system ESX-1. Bacterial virulence factors secreted by ESX-1 may also contribute to increased cell death and are not expressed by the vaccine BCG, which does not escape from the phagosome.

T Lymphocytes as Specific Mediators of Acquired Resistance

Whereas activated macrophages act as the nonspecific executors, T lymphocytes are the specific mediators of acquired resistance against intracellular bacteria. The dramatic increase in the incidence of TB and other intracellular bacterial infections in AIDS patients illustrate the central role of T lymphocytes in protection. For instance, 15 million individuals are co-infected with HIV and *M. tuberculosis*, and HIV increases the risk of developing TB by several orders of magnitude, resulting in one million TB cases annually. At the site of microbial growth, T lymphocytes not only initiate the most potent defense mechanisms available but also focus this response to the site of encounter, thus minimizing collateral damage to the host. Although protective T-cell responses are multifactorial, they can be reduced to a few principal mechanisms (Fig. 26.3).

As previously mentioned, T cells inevitably also produce pathology through cytotoxic antimicrobial defense mechanisms. Moreover, pathogenesis of intracellular bacterial infection is highly influenced by T cells. It is therefore important that the T-cell response be tightly controlled and downregulated when necessary. Regulatory mechanisms, including regulatory T (Treg) cells, are in place to limit immunopathology.[16]

Protective immunity involves so-called conventional T-cell sets, CD4 αβ T cells, and CD8 αβ T cells, as well as unconventional T cells, such as γδ T cells, CD1-restricted αβ T cells, and T cells that recognize antigen in the context of other nonclassical MHC class I molecules, such as mucosal-associated invariant T (MAIT) cells (see Fig. 26.3). Although these T-cell sets perform different tasks, substantial redundancy exists. Furthermore, these T-cell populations act in a coordinated way in close interaction with other leukocytes. Depending on the etiological agent and the stage of disease, the relative contribution of the different T-cell subsets to acquired resistance may vary. The conventional αβ T cells make up more than 90% and γδ T cells less than 10% of all lymphocytes in the blood and peripheral organs of humans and mice. However, γδ T cells represent a significant proportion of the intraepithelial lymphocytes in mucosal tissues, suggesting a particular role at this important port of microbial entry.[30]

CD4 T Cells

The CD4 T-cell population can be further subdivided into distinct subsets, according to their pattern of cytokine production and expression of unique transcription factors that control patterns of gene expression. At least four major subsets exist: Th1, Th2, Th17, and Treg. The first two subsets were discovered several decades ago and are identified in both mice and humans; Th1 cells overwhelmingly produce IFN-γ and IL-2, and Th2 cells produce IL-4, -5, and -13. The Th1 subset can also be defined based on the T-bet transcription factor and the signal transducer STAT4, while Th2 classification is consistent with expression of the transcription factor GATA-3 and signal transducer STAT5.

Th17 cells express the retinoid orphan receptor γT (RORγT) transcription factor and the signal transducer STAT3. They produce the cytokines IL-17, IL-22, and GM-CSF. Cytokines of the IL-17 family are strong inducers of granulopoiesis, proinflammatory mediators such as IL-6, and the chemokines CXCL1, CXCL8, and CXCL6, which attract neutrophilic and eosinophilic granulocytes and prolong their survival.[31] Th17 cells have limited importance for protection in murine models against primary infection with mycobacteria, salmonellae, and listeriae. However, Th17 cells can drive more rapid Th1 responses against pulmonary TB in mice after vaccination, resulting in enhanced protection. IL-17 is also required for optimally protective Th1 responses during murine *F. tularensis* infection.[31]

Despite the convenience of defining T-cell populations in terms of subsets, recent evidence suggests considerable plasticity in cytokine production by T cells. This was first suggested by demonstration that all subsets could produce IL-10, which regulates potency of T-cell responses to limit host collateral damage during immune responses. IL-10 expression might be an intrinsic control mechanism common to all T cells. However, reduction in T-cell potency also favors chronic intracellular bacterial infection. T-cell subsets may acquire the ability to produce additional cytokines by expression of additional transcription factors or by remodeling chromatin structure.

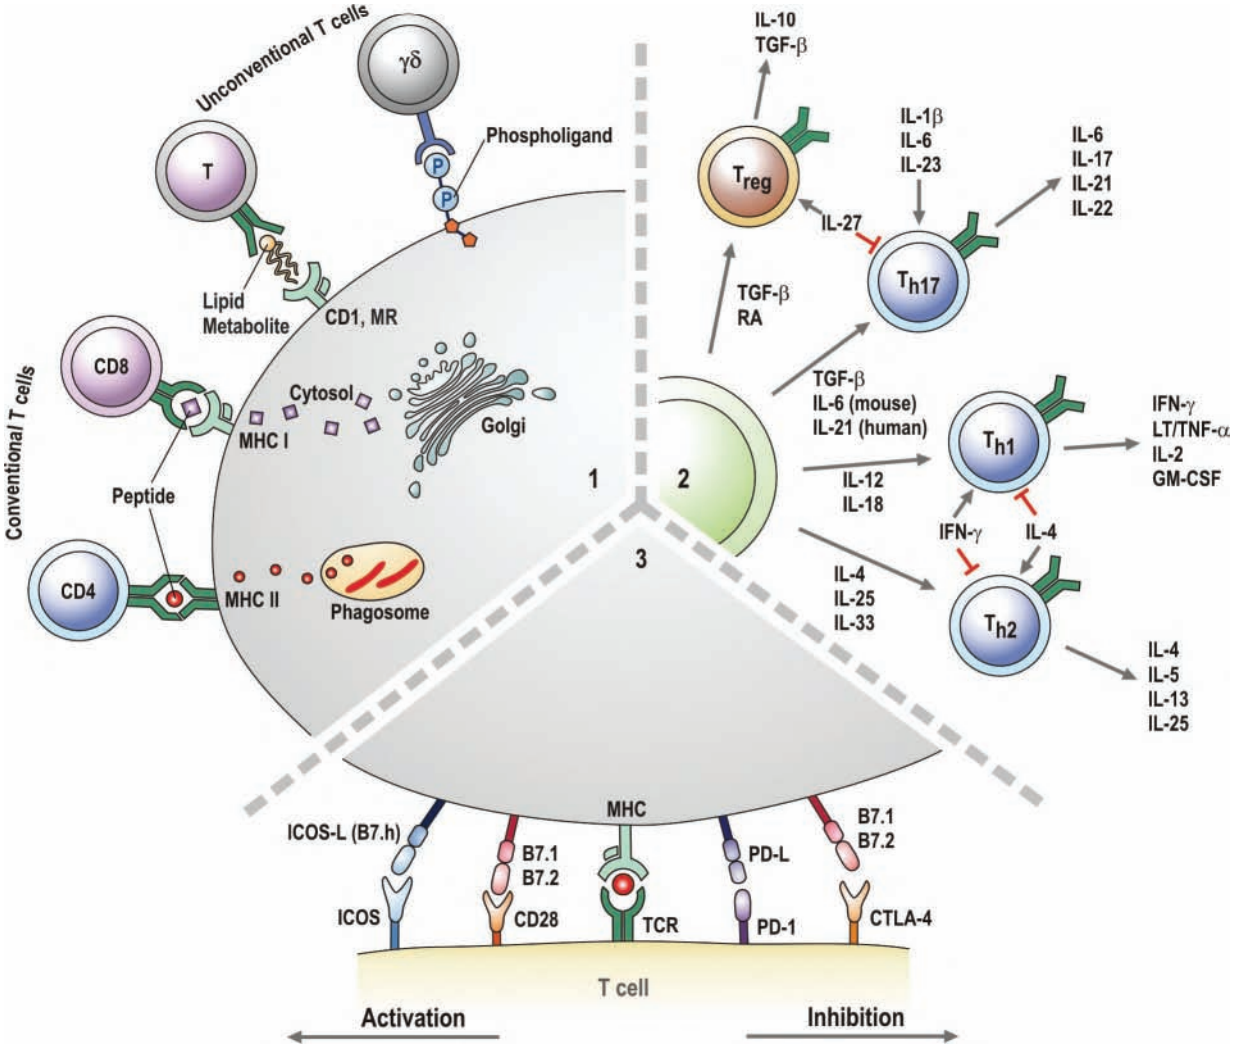

FIG. 26.3 T-Cell Stimulation During Infection. Recognition of bacterial antigen by T cells (A). Antigen originating from intracellular bacteria is presented to conventional CD4 and CD8 T cells. Unconventional T cells including gamma-delta (*γδ*) T cells, mucosal-associated invariant T (MAIT) cells, and CD1-restricted T cells are also activated. Human γδ T cells recognize small molecules containing pyrophosphate residues; MAIT cells recognize bacterial metabolites such as vitamin B_2 derivatives in the context of major histocompatibility complex (*MHC*)-related (*MR*) gene products; CD1-restricted T cells recognize glycolipids in the context of CD1 molecules. (B) CD4 T cells can be subdivided into different T helper (*Th*) cells according to their cytokine expression pattern. Th1 cells are critical for protection against intracellular bacteria; they typically produce interferon-gamma (*IFN-γ*), tumor necrosis factor-alpha (*TNF-α*), lymphotoxin (*LT*), interleukin (*IL*)-2, and granulocyte–macrophage colony-stimulating factor (*GM-CSF*). Th2 cells stimulate humoral immune responses via secretion of IL-4 and IL-5. Other cytokines produced by Th2 cells include IL-13 and IL-25. Th17 cells produce IL-6, IL-17, IL-21, and IL-22, which probably contribute to early protection. Regulatory T cells (*Treg*) produce transforming growth factor beta (*TGF-β*) and IL-10, which suppress immune responses. Additional abbreviations: inducible co-stimulatory molecule (*ICOS*); programmed death 1 (*PD-1*); program death ligand (*PD-L*); retinoic acid (*RA*); T-cell receptor (*TCR*). See Chapters 6, 10, and 14 for details. (Modified from Kaufmann SHE, Parida SK. Tuberculosis in Africa: learning from pathogenesis for biomarker identification. *Cell Host Microbe*. 2008;4[3]:219–228, with permission of Elsevier.)

CD8 T Cells

Infection of mice deficient in specific T-cell subsets has conclusively demonstrated a role for CD8 T cells during listeriosis and TB. Furthermore, CD8 effector T cells have been identified in granulomas of tuberculoid leprosy patients that contain low numbers of bacteria. The cytolytic potential of these T cells can serve two roles in infection with intracellular bacteria: namely, target cell killing or lysis of cells that are unable to control the infection, thus releasing the bacteria for phagocytosis by more efficient cells. In humans, CD8 T-cell-mediated killing is cell-contact-dependent and based on production of perforin, granzymes, and granulysin (Chapter 12).[32] Finally, CD8 T cells are also a potent source of IFN-γ and TNF, thus contributing to direct activation of infected macrophages to enhance protective mechanisms (see Fig. 26.3).

CD8 T cells recognize antigenic peptides in the context of MHC class I gene products, which are responsible for presentation of antigens residing in the cytosol (Chapter 9).

Initially, therefore, it was mysterious how CD8 T cells were stimulated by intracellular bacteria, which were thought to have a uniquely restricted phagosomal residence. However, with the knowledge that many intracellular bacteria egress into the cytoplasm, one major mechanism for MHC class I processing became obvious: proteins secreted by bacteria in the cytoplasm undergo antigen processing and presentation similar to newly synthesized proteins of viral or host origin.[33] Yet, alternative contact points for MHC class I molecules and bacterial peptides exist. Cross-presentation by noninfected antigen-presenting cells (APCs) of antigens engulfed within apoptotic blebs from infected cells represents a critical pathway to induce CD8 T cells by phagosomal bacteria (see below). One major advantage of CD8 T cells over CD4 T cells is their recognition of antigen bound by MHC class I gene products, which are expressed by almost all host cells. Thus, CD8 T cells recognize professional and nonprofessional phagocytes equally well.

Unconventional T Cells

The relevance of the γδ T cells to antibacterial immunity is not fully understood. Several studies indicate that γδ T cells are rapid producers of IL-17 at sites of bacterial implantation. Transient participation of γδ T cells in protection and a unique requirement for γδ T cells in granuloma formation have been described for murine listeriosis and TB. While murine γδ T cells appear to recognize peptides presented by nonpolymorphic MHC class I molecules, human γδ T cells respond to nonpeptidic phosphorylated metabolites, notably from the isoprenoid pathway of bacterial and host origin.

MAIT cells are primarily localized at mucosal sites and current evidence suggests that they play a role in control of bacterial infections in mucosal tissues such as lung (*M. tuberculosis*) and gut (gram-negative bacteria). Antigenic ligands include derivatives of vitamin B_2 (riboflavin), produced by many intracellular bacteria, including salmonellae and mycobacteria.[34]

CD1 comprises a group of nonpolymorphic MHC-related molecules that can present glycolipid antigens to unconventional T cells. In humans, group 1 CD1-restricted T cells respond to a variety of microbial glycolipids, including LAM, PIMs, mycolic acids, sulfatides, sulfoglycolipids, and lipopeptides. Group I CD1 molecules are absent in mice. The group II CD1 molecule CD1d is present in both humans and mice and controls development of NKT cells that express the NK cell marker NK1.1 and an invariant T-cell receptor. Upon antigen activation, these T cells rapidly produce cytokines and are capable of producing both IL-4 and IFN-γ. Bacterial antigens recognized by NKT cells, PIMs from mycobacteria, and glycosphingolipids from *Ehrlichia* and *Sphingomonas* spp. have been identified. NKT cells also respond to host endogenous lysosomal lipids loaded onto CD1d.[35]

In sum, unconventional T cells often recognize nonpeptidic ligands of bacterial origin, emphasizing that they play a particular role in immunity against bacteria, including intracellular bacteria. Because of the highly skewed T-cell receptor, these T cells are specific for a limited variety of bacterial ligands. As a consequence of their less-demanding antigen recognition and activation requirements, unconventional T cells may fill a gap between prompt innate resistance and the delayed conventional T-cell response.

T-Cell Memory and Regulation of Immune Responses

Long-term protective immunity against infectious agents relies on immune memory, which principally forms the basis for the success of vaccines (Chapter 87). Memory T cells can be divided into central memory T cells (TCM) and effector memory T cells (TEM), based on differential surface phenotypic and tissue migration patterns.[36] TEM accumulate in peripheral tissues where they express effector functions, while TCM persist in lymph nodes where they rapidly develop into TEM after secondary antigen encounter. The tissue-resident memory T cells (TRM) are localized to mucosal sites where they provide efficient protection against invading pathogens. Although it is generally accepted that memory T cells can survive in the absence of persistent antigen, little is known about the induction and maintenance of long-lasting T-cell memory in chronic infections with intracellular bacteria.

B Cells

Historically, antibody is presumed to be protective largely when the bacillus is extracellular and, as such, has been perceived unlikely to play a central role in intracellular bacterial infection. However, recent evidence is beginning to challenge this assumption and suggests a role in protection against TB. Antibodies from healthcare workers exposed to *M. tuberculosis* have been shown to be protective, and this protection was abrogated in the absence of CD4 cells.[37] Furthermore, the Fc portion of *M. tuberculosis*-specific antibodies from individuals with latent TB showed a specific pattern of glycosylation, resulting in enhanced binding of FcγRIIIa. This receptor mediates antibody-dependent cell cytotoxicity by NK cells and indicates that this mechanism may play a role in preventing development of active TB. Moreover, individuals that are exposed but do not become infected show IgA and class-switched IgG to major antigens of *M. tuberculosis* with characteristic patterns of Fc glycosylation. This indicates that these antibodies may prevent infection completely, leading to a so-called "resistor" immune status.[38] Aside from antibody production, B cells are potent APCs for soluble antigens (including lipids presented by CD1c) and secrete many cytokines otherwise associated with T cells, DCs, and macrophages. B-cell signaling via MyD88 during *S. typhimurium* infection has been associated with B-cell production of IL-10, and mice with B-cell-specific deficiency in MyD88 were more resistant to infection demonstrating that, like T cells, a subset of B cells can perform regulatory functions. These B cells, termed regulatory B cells (Breg), function via production of IL-10, IL-35, and TGF-β, and have been shown to suppress immunity to intracellular bacteria through cognate interactions between Breg and CD4 T cells via MHC-II.[39]

From the therapeutic perspective, there is increasing interest in using antibody therapies as checkpoint inhibitors to potentiate T-cell responses to clear chronic bacterial infection. Inducible T-cell co-stimulation (ICOS) and programmed cell death protein 1/PD ligand 1 (PD-1/PDL-1) are molecular checkpoint targets whose inhibition has been therapeutically useful in cancer settings. In the case of TB, there remains controversy as to whether expression of these targets is associated with protection against or enhancement of disease.

In humans, the proportion of both $PD\text{-}1^+CD4^+$ and $PD\text{-}L1^+CD4^+$ T cells in TB patients are significantly increased compared to healthy controls, and blockade of PD-1 significantly enhances $CD4^+$ T-cell proliferation. Phagocytosis and

intracellular killing activity of macrophages increased significantly with PD-1/PD-L pathway blockade.[40] Despite this, recent case studies on patients enrolled in trials of anti-PD1 therapy for cancer showed exacerbation of latent TB accompanied by increased numbers of TB-specific CD4 T cells in the blood.[41]

KEY CONCEPTS

How Might a Vaccine Work?

- Activation of innate immunity for instruction of appropriate acquired immune response (pattern recognition receptors)
- Activation of the appropriate array of T-cell populations
- T-cell secretion of appropriate cytokine combination
- Efficient development of T-cell memory
- Efficient activation of antibacterial effector mechanisms
- Best-case scenario: sterile pathogen eradication
- Second best-case scenario: driving the infection "deeper" into latency, thus efficiently preventing reactivation of disease
- Alternative scenario: prevention of stable infection by antibodies and T cells

Regulatory T Cells

Intracellular bacteria can cause detrimental inflammation and tissue damage, e.g., due to IFN-γ- and TNF-mediated Th1 responses. Under normal circumstances, control mechanisms are in place to limit immunopathology; such countermeasures are elicited as part of the ongoing immune response during infection. The main cytokines, which limit inflammation and control IFN-γ production, are IL-10 and TGF-β. Although macrophages and DCs produce these cytokines, their main producers are Treg cells, which are the prime cells involved in immune regulation. Natural Treg cells are responsive to IL-2 due to high constitutive CD25 expression and are characterized by expression of the transcription factor FOXP3 (Chapter 13).[42] Expansion of Treg cells appears to be both antigen-dependent and -independent. In addition, Treg cells selectively express TLRs and can be activated, for example, by LPS and possibly other TLR ligands. This makes their immediate activation during bacterial infection a probable scenario. Although Treg cells limit CD8 T-cell responses in experimental listeriosis, their general role in infections with intracellular bacteria has not been fully elucidated. Suppression of T-cell responses and anergy have been clinically documented for TB and leprosy. Although Treg functions can limit detrimental T-cell responses and immunopathology, they can also prevent elimination of bacteria, and hence are likely a key factor in promoting the persistent chronic state of infection with intracellular bacteria.

Innate Lymphoid Cells

Innate lymphoid cells (ILCs) are a family of cell types that share features of both innate and adaptive immune cells. They typically locate to mucosal tissues where they orchestrate early barrier-protective responses to infection.[43] There are three main subsets: ILC1, which produce IFN-γ and include NK cells and non-cytotoxic, non-NK type I ILCs; ILC2, which produce IL-4, IL-5, and IL-13 and are involved in inflammatory-linked airway hyperactivity, tissue repair, and helminth clearance; and ILC3, which produce IL-17 and/or IL-22 and are involved in the structure of ectopic lymphoid tissue. Circulating ILC precursors can differentiate into all ILC types, rapidly developing into a diverse ILC population in response to environmental cues. ILCs are depleted in the blood during TB, but ILC1 and ILC3 rebound in numbers after treatment. In mouse models of TB, ILC3s accumulate in the lung early after infection with TB concomitantly with AMs, which precedes infiltration of monocytes and macrophages. Increased numbers of ILC3 in the lung are associated with early-stage protection against TB via IL-17 and IL-22 production, accumulation of AMs, and orchestration of ectopic lymphoid structures in the lung.[44]

CONCLUDING REMARKS

ON THE HORIZON

- Design of predictive biomarkers to prognose risk of progression to active tuberculosis (TB).
- Development and clinical testing of new drugs for MDR/XDR-TB and dormant *Mycobacterium tuberculosis*.
- Developing host-directed therapy (HDT) in adjunct to conventional drugs, notably for highly drug-resistant pathogens.
- Development and clinical testing of new vaccines that protect against pulmonary TB in adults.
- Reduction of the unequal burden of TB in developing and industrialized countries by public health measures, education, and socioeconomic advances.

Our deepening understanding of the molecular events governing intracellular bacterial infections is allowing development of novel therapeutic and preventive approaches. The need for such interventions is becoming all the more pronounced in the face of increasing levels of antibiotic resistance of bacteria, such as *M. tuberculosis*, rendering canonical drugs that specifically target bacterial molecular processes ineffective. Host-directed therapy (HDT), an approach for which there is accumulating activity, aims to develop new drugs or repurpose previously approved ones directed at host molecular processes.[45] Such approaches include monoclonal antibodies to neutralize cytokines such as TNF or IL-6 to abrogate tissue destructive inflammation, repurposed use of licensed drugs such as ibuprofen and verapamil to modulate inflammation and enhance antibiotic effectiveness, respectively, and use of immunostimulatory molecules such as vitamin D_3 to enhance bacterial killing by xenophagy. Metformin was developed as an oral treatment for type 2 diabetes mellitus and functions as an insulin anti-sensitizer. It can also enhance treatment of TB by augmenting formation of ROS species, and it shows promise as an adjunct to TB chemotherapy. These approaches range from preclinical and early-stage clinical development to late-stage clinical development and offer promise to shorten the traditional duration of therapy.

It is becoming increasingly recognized that the interaction between intracellular bacteria and the immune system is not of the "all or nothing" type but is instead a "continuous struggle." This realization has far-reaching implications for preventive and therapeutic strategies against intracellular bacterial infections. First, vaccination against intracellular bacteria has not yet been effected satisfactorily because of the involvement of several distinct T-cell subsets with different modes of stimulation and activity profiles. Second, chemotherapy has frequently proved suboptimal for the sterile eradication of bacteria hidden in cellular niches. A better understanding of the complex crosstalk between cytokines, T lymphocytes, macrophages, and infected host cells will no doubt directly promote the development of improved control measure.

ACKNOWLEDGMENTS

We are grateful to Souraya Sibaei for excellent assistance and Diane Schad for the figures.

Due to space considerations, we have been unable to include several pertinent references for some of the concepts we have described. We apologize to those researchers whose important work we were unable to cite for this reason.

Host Defenses to Extracellular Bacteria Including Spirochetes

Sarah W. Satola, Marcos C. Schechter, Shyra Wilde, and David S. Stephens

The human host has developed protective mechanisms to interact with the multitude of bacterial species encountered in nature. These host defenses include nonspecific mechanisms of clearance as well as innate and specific adaptive immune responses. Partly because of these mechanisms, most bacterial species do not cause human disease. Many bacterial species have established symbiotic or commensal relationships with the human host and colonize skin and mucosal surfaces. These commensals are generally of low virulence except in individuals whose host defenses are compromised. Despite the diversity of the microbial world, a relatively few pathogenic bacterial species or subpopulations of those species have evolved virulence factors or strategies that can overcome or circumvent intact human host defense mechanisms to cause localized or systemic disease.

Bacterial pathogens of clinical importance reside mostly extracellularly (Table 27.1) and can be transmitted from one individual to another by close contact or transmitted through food, water, animal, or other environmental contact. Acquisition of these pathogenic bacteria may be transient, resulting in intervals of colonization varying from asymptomatic carriage to localized or systemic disease. Extracellular bacterial pathogens can produce acute inflammatory and purulent infectious diseases, such as meningitis, septicemia, pneumonia, urethritis, pharyngitis, inflammatory diarrhea, cellulitis, and abscesses, and/or produce disease by the release of toxins. Disease associated with some extracellular bacteria (e.g., *Helicobacter pylori*) results from chronic colonization. Susceptibility to extracellular bacterial pathogens is enhanced by hereditary, acquired, or age-related defects in innate or adaptive host defenses. Resistance to extracellular bacterial pathogens or their toxins can be accentuated by chemoprophylaxis vaccines, and other immune modulation processes (e.g., passive immune globulin administration). Caution is urged in the interpretation of the term "extracellular." The classification of bacteria as "extracellular" and "intracellular" is primarily based on observations in vitro and has been challenged by some authors, as some "extracellular" bacterial species invade host cells as a part of their normal life cycle and during steps in the disease process (e.g., *Staphylococcus aureus, Streptococcus pneumoniae, Streptococcus pyogenes, Neisseria meningitides*).[1] Conversely, bacteria typically classified as "intracellular" can have an extracellular component to their life cycle (e.g., *Mycobacterium tuberculosis* in cavitary lesions).

Spirochetes constitute a unique group of extracellular bacteria that inhabit many different environments, such as soil, arthropods, and mammals. Spirochetes share a typical spiral shape and a distinctive flat-wave morphology (Fig. 27.1). They are motile organisms with a multilayered outer membrane that encapsulates a peptidoglycan layer surrounding their inner membrane. The viability of the organism is dependent on an intact outer membrane, which can be damaged by variations in osmolarity, antibodies, or complement, resulting in the loss of intracellular components and ultimately death of the bacterium.

CLINICAL PEARLS

Distinguishing Clinical Characteristics of Infections With Extracellular Bacteria

- Sterilizing immunity
- Colonization of mucosal surfaces often precedes disease
- Causes of pyogenic infections
- T-helper (Th)17 response critical in generating a neutrophilic response
- Antibodies are protective for some of the major pathogens
- Effective vaccines available for many of the major pathogens

Several spirochetal species can induce disease (Table 27.2) including syphilis (*Treponema pallidum* subspecies *pallidum*, hereafter *T. pallidum*) and Lyme disease (*Borrelia burgdorferi* sensu stricto, hereafter *B. burgdorferi*). Syphilis is primarily sexually transmitted, whereas Lyme disease is transmitted by *Ixodes* complex ticks and is the most common tickborne disease in the United States.[2] *T. pallidum* cannot be cultured in the laboratory and *B. burgdorferi* culture is not routinely available. Thus, diagnoses for syphilis and Lyme disease are usually based on clinical presentation and serological tests.

Although dark-field microscopy can be used for the identification of *T. pallidum*, infection with *T. pallidum* leads to the production of nonspecific antibodies to cardiolipin-cholesterol-lecithin antigen, which are the basis for nontreponemal serological tests, including the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests. Because these tests are nonspecific, false-positive reactions can occur as a result of pregnancy, autoimmune disorders, or infections. Treponemal-specific tests such as the *T. pallidum* hemagglutination test (TPHA) and fluorescent treponemal antibody-absorption test (FTA-ABS) are more specific and often used as confirmatory tests following a positive nontreponemal test. Of note, some laboratories are now using reverse-screening algorithms that start with a treponemal-specific test.

A two-tiered approach is standard for the serodiagnosis of Lyme disease: serum is first tested for *B. burgdorferi*–specific antibodies by enzyme-linked immunosorbent assay (ELISA) or immunofluorescent assay (IFA), followed by more specific immunoblotting for immunoglobulin M (IgM) and IgG antibodies. However, a positive serological test, particularly IgG, is evidence of exposure to *B. burgdorferi*, but not necessarily an active infection.

Despite similar ancestry and morphological features, these spirochetes have striking differences at the genetic level, which may account for the differences in their life cycles, environmental adaptations, and the diseases they cause. *B. burgdorferi* has one

TABLE 27.1 Examples of Clinically Relevant Pathogenic Extracellular Bacteria

Species	Examples of Human Disease	Selected Mechanisms of Pathogenesis	Special Features Key to Host Infection	Examples of Susceptible Populations/Risk Factors
Staphylococcus aureus	Cellulitis, abscesses, bacteremia, endocarditis, toxic shock syndrome, osteomyelitis, pneumonia, wound infections	Protein A: promotes fibronectin binding PVL: cytotoxic α-toxin: membrane damage eTSST-1: superantigen	Asymptomatic colonization, resistant to dehydration	Injection drug users, patients on hemodialysis, defects on Th17 response (Job syndrome), surgical procedures and skin trauma
Streptococcus pneumoniae (pneumococcus)	Pneumonia, otitis media, meningitis	Capsule: prevents phagocytosis, antigenic variation Pneumolysin: cytotoxic PspA & C: inhibition of complement Neuraminidase, hyaluronidase: spread and colonization IgA_1 protease	Asymptomatic colonization, readily acquires new genes through transformation	Smokers, cerebrospinal fluid leak, asplenia, hypogammaglobulinemia, human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), unvaccinated children
Streptococcus pyogenes (group A *streptococcus*)	Pharyngitis, cellulitis, erysipelas, toxic shock syndrome, necrotizing fasciitis, scarlet fever, rheumatic fever	Hyaluronic acid capsule, M protein: prevents phagocytosis Streptolysin O & S: cytotoxic Streptococcal pyrogenic exotoxins C5a peptidase	High diversity of M-proteins, molecular mimicry of human antigens	School-age children, crowded-conditions (e.g., military barracks), injury to lymphatic system (e.g., surgical harvest of saphenous vein)
Streptococcus agalactiae (group B *streptococcus*)	Neonatal sepsis, pneumonia and meningitis, perinatal infections, bacteremia	FbsA: fibrinogen receptor, promotes adherence Capsule β-Hemolysin C5a peptidase β Protein: downregulates complement	Asymptomatic colonization, acquisition by infants during birth	Neonates and infants (immunity dependent on passive transfer of maternal antibodies), diabetes mellitus
Neisseria meningitidis (meningococcus)	Meningitis, bacteremia (purpura fulminans)	Capsular polysaccharide: promotes adherence and prevents phagocytosis Type IV pili: promote attachment to host cells LOS: analogues to LPS, activates TLR4 pathway IgA_1 protease fHbp: downregulates the host alternative complement pathway	Molecular mimicry of human antigens, phase and antigenic variation, asymptomatic carriage	Terminal complement deficiencies, hypogammaglobulinemia
Neisseria gonorrhoeae (gonococcus)	Urogenital infections, disseminated gonococcal infection, pharyngitis	Type IV pili: promote attachment to host cells Opa protein adhesion IgA_1 protease LOS: analogs to LPS, activates TLR4 pathway	Phase and antigenic variation, molecular mimicry of human antigens	Terminal complement deficiencies, women during menstrual period (increases risk of dissemination)
Escherichia coli	Urinary tract infections, gastroenteritis, sepsis, neonatal meningitis	Capsular polysaccharide Tissue-specific fimbriae Heat-labile enterotoxins: increases intestinal chloride secretion LPS: activation of TLR4	Antigenic heterogeneity of LPS and capsule	Bladder instrumentation, pregnancy
Pseudomonas aeruginosa	Ventilator-associated pneumonia, bronchiectasis	Pili and flagella: attachment to the host and formation of biofilms LPS Exotoxin A Lipases, lecithinases, elastase	Considerable adaptability to changes in environment, large genome size, biofilms	Orotracheal intubation, cystic fibrosis
Clostridium difficile	Colitis	Toxin B: cytotoxic Flagella	Endospore formation, asymptomatic carriage	Antibiotics and other disruptions of the microbiota
Haemophilus influenzae	Otitis media, pneumonia, epiglottitis, bacteremia, meningitis	LPS with phosphorylcholine Pili: adherence Capsule High-molecular-weight adhesins IgA_1 protease	Phase variation of pili, asymptomatic carriage	Unvaccinated children, immunocompromised, sickle cell disease, smoking
Helicobacter pylori	Peptic ulcer disease	Urease: colonization of gastric mucosa Flagella: motile in gastric mucus CagA; bacteria-derived carcinogen	Polymorphism of CagA	Crowded living conditions, unreliable source of clean water, living with someone who has *H. pylori*
Bordetella pertussis	Whopping cough (children), chronic cough (adults)	Pertussis toxin: inhibits neutrophils, macrophages, lymphocytes Pertactin and filamentous hemagglutinin; mediates attachment	Antigenic variation of adhesins	Nonvaccinated adults and children, infants who have not completed vaccine series, adults and adolescents whose immunity has diminished

CapA, Cytotoxin-associated gene A; *fHbp*, factor H–binding protein; *Ig*, immunoglobulin; *LOS*, lipooligosaccharide; *LPS*, lipopolysaccharide; *Psp*, pneumococcal surface protein; *PVL*, Panton-Valentine leukocidin; *TLR*, Toll-like receptor; *TSST-1*, toxic shock syndrome toxin 1.

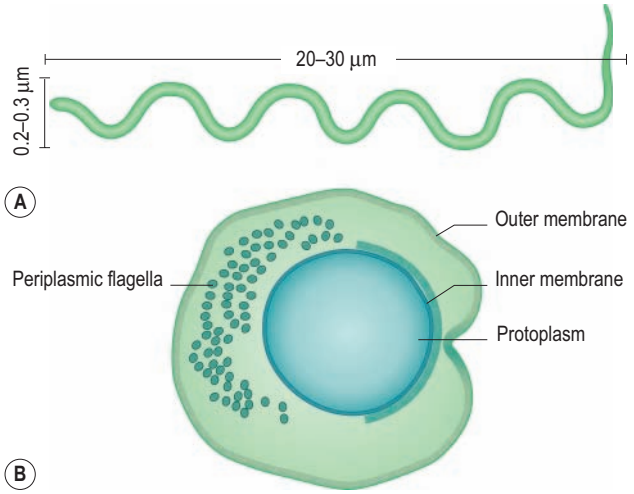

FIG. 27.1 The *Borrelia burgdorferi* structure is characterized by a distinctive flat-wave morphology consisting of approximately 18 bends and a length of 20 to 30 µm (A). A cross-section of this spirochete reveals the endoflagella, which are responsible for the unique morphology and motility of this organism (B).

CLINICAL PEARLS

Lyme Disease

- Erythema migrans at inoculation site (early stage)
- Joint inflammation in untreated individuals (often synovium of the knee)
- Chronic arthritis, neuroborreliosis, or cutaneous lesions (late stage)

Venereal Syphilis

- Hardened and painless ulcer (*chancre*) at initial infection site
- Secondary eruption often accompanied with rash on the palms of hands/soles of the feet. (4–6 weeks post infection); resolution of secondary manifestation weeks to a year
- Long periods of latency, late lesions of skin, bone, and viscera, cardiovascular system and CNS
- Susceptibility to *T. pallidum* universal; only 30% of exposures with lesions result in infection
- Infection results in gradual development of immunity against *T. pallidum* and often against heterologous treponemes as well

of the most complex genomes known among prokaryotes, with a single linear chromosome and 21 plasmids, the largest number of plasmids of any characterized prokaryote, and less than 10% of *B. burgdorferi* plasmid-coding regions are found in other microorganisms, including spirochetes.[3,4] In contrast to

TABLE 27.2 Major Diseases Caused by Spirochetes[a]

Disease	Agents	Distribution	Transmission	Symptoms
Lyme disease	*Borrelia burgdorferi*	North America, Europe	Tick engorgement	Development of a skin rash known as *erythema migrans*, accompanied by other symptoms, such as malaise, myalgia, and/or arthralgia. Symptoms can progress to include carditis and arthritis. Persistent infection can result in chronic arthritis, neuroborreliosis, or cutaneous symptoms (acrodermatitis chronica atrophicans)
	B. garinii	Asia, Europe		
	B. afzelii	Asia, Europe		
	B. andersonii	North America		
	B. japonica	Japan		
	B. lusitaniae	Southern Europe		
	B. valaisiana	Europe, Ireland, UK		
	B. mayonii	North America		
	B. miyamotoi	North America		
Relapsing fever	*B. hermsii*	Western USA	Tick engorgement	Clinical manifestations of infection include high-density spirochetemia, high fever, myalgias, and arthralgias and can even include cerebral hemorrhage and fatality
	B. turicatae	Southwestern USA, Mexico		
	B. parkeri	Western USA		
	B. mazzotti	Central America		
	B. venezuelensis	Central America		
	B. duttonii	Sub-Saharan Africa		
	B. crocidurae	North Africa, Middle East

	B. caucasia	Iraq, Eastern Europe		
Venereal syphilis	*Treponema pallidum pallidum*	Worldwide	Sexual contact	Disease progresses from a primary lesion (chancre) to a secondary eruption and then to a latent period, and if left untreated, tertiary symptoms may appear
Endemic syphilis or Bejel syphilis	*T. pallidum endemicum*	Eastern Mediterranean region, West Africa	Nonsexual skin contact	Symptoms begin with a slimy patch inside the mouth, followed by blisters on the trunk and limbs. Bone infection in the legs soon develops, and in the later stages, lumps may appear in the nose and on the soft palate of the mouth
Yaws	*T. pertenue*	Humid equatorial countries	Nonsexual skin contact	Destructive lesions of the skin and bones, which is rarely fatal but can be debilitating
Pinta	*T. carateum*	Mexico, Central America, South America	Nonsexual skin contact	Dark-colored skin lesions found on those areas of the body that are exposed to sunlight. Eventually, the skin lesions become discolored
Leptospirosis	*Leptospira interrogans*	Worldwide	Urine from an infected animal	Symptoms include fever, headache, chills, nausea and vomiting, eye inflammation, and muscle aches. In more severe cases, the illness can result in liver damage and kidney failure

[a]Spirochetes are the causative agents of many diseases, which can have social as well as lasting health-related consequences.

other spirochetes, *B. burgdorferi* and *T. pallidum* do not contain lipopolysaccharide (LPS). Lipoproteins are the major immunogens of *B. burgdorferi* and most likely *T. pallidum*, and, thus, they are their dominant proinflammatory agonists.

CLEARANCE AND NONSPECIFIC HOST DEFENSES AT MUCOSAL EPITHELIAL SURFACES

Bacteria first encounter a physical barrier, which comprises skin, mucus and mucosal surfaces, and the normal microbiota as well as nonspecific factors, such as nutrient limitation (e.g., iron) and antimicrobial proteins or peptides (AMPs). Intact skin and mucosal surfaces provide complex chemical and biological obstacles to bacteria and are an important line of defense preventing the invasion of these pathogens and their products. As such, the human epithelium has evolved to prevent colonization and invasion.[3] Skin is a relatively dry, acidic (pH 5–6) barrier that contains growth-inhibiting fatty acids and AMPs, characteristics that are detrimental to many bacteria. The constant desquamation of stratified epithelial surface of skin helps in the removal of microorganisms.[4] Disruption of these physical barriers can augment pathogen tissue colonization and invasion. Infections by *S. aureus* and *S. pyogenes*, bacteria that can colonize skin, are often preceded by skin damage. Repeated trauma to skin (e.g., dialysis and intravenous drug use) also enhances skin colonization with pathogens, including that by *S. aureus*.

Mucosal surfaces have additional nonspecific antibacterial defenses. The mucociliary blanket of the respiratory tract and the female urogenital tract (fallopian tube) move bacteria away from epithelial surfaces, as does the flushing of the urinary tract with urine, intestinal peristalsis, and the bathing of the conjunctiva with tears. Lysozyme is found in most mucosal secretions and lyses bacterial cell walls by splitting muramic acid β(1–4)-*N*-acetylglucosamine linkages. The acid pH of the stomach, intestinal peristalsis, and the antibacterial effect of proteolytic enzymes present in intestinal secretions are important gastrointestinal (GI) tract host defenses against many pathogenic bacteria. The GI mucosa has a layer of mucus that acts as a physical shield to bacteria. Mucus is rich in mucin, glycoproteins that limit pathogen binding to other host molecules necessary for mucosal adhesion. Additionally, the mucus layer may function as more than a physical barrier by acting as a diffusion barrier to concentrate antimicrobial proteins at the appropriate epithelial cell surface. The glycocalyx, an extracellular layer of the apical surface of mucosal cells composed of carbohydrates, also protects cells against bacterial attachment.

Bacterial attachment and colonization of mucosal surfaces can be inhibited by bacterial binding to human cellular antigens present in secretions, such as ABO blood group antigens. Cell adhesion and extracellular matrix molecules, such as fibronectin and proteoglycans, can also inhibit or enhance bacterial binding to epithelial surfaces. The Tamm-Horsfall glycoprotein, found in urine, can bind avidly to a variety of bacteria and facilitate clearance. Proteins, such as lactoferrin, present at mucosal surfaces, bind iron, which is an important requirement for bacterial growth. This action may reduce microbial proliferation, but some mucosal pathogens bind lactoferrin and remove iron from the molecule for growth.

To colonize human epithelial and mucosal surfaces, extracellular bacteria must overcome the local host defense mechanisms described above. After navigating these defenses, adhesion to host cells is usually the first important step for extracellular bacterial pathogens (Fig. 27.2). Initial attachment of bacteria to human epithelial cells is, in part, mediated by pili, fimbriae, or other bacteria ligands or adhesins, and close adherence of bacteria to the human cell-surface receptors involves the cell wall, outer membrane proteins, lipopolysaccharide (LPS), and other bacterial surface structures. The attachment of bacteria to human epithelial cells prevents elimination of bacteria from the host. Attachment can also induce host cell pathways leading to cytoskeletal rearrangements, such as elongation and branching of the microvilli, the accumulation of actin, and calcium efflux, which facilitates close adherence and invasion of epithelial cells by normally "extracellular" bacteria, especially at sites with fluid movement. Strains of *Escherichia coli* that successfully colonize the bladder and cause renal infection possess pili that allow adhesion to the renal epithelium.[5,6] Type IV pili are fundamental for attachment of gonococci to the male reproductive tract and play a role in the attachment of meningococci to vascular endothelial cells.[5,7] Meningococcal pili also facilitate twitching motility and microcolony formation, which allows the penetration of mucus and provides initial attachment. The pneumococcal CbpA surface protein promotes mucosal adhesion and dissemination.[6] *B. burgdorferi* produce many adhesive surface proteins that collectively recognize diverse host substrates and cell types and are likely to promote dissemination and chronic infection in a variety of tissues. *B. burgdorferi*-endothelial interactions are mediated by the adhesin BBK32. *T. pallidum* protein Tp0751 (pallilysin) binds to host laminin, fibrinogen, fibronectin, and collagen, important constituents of blood and endothelia.[8]

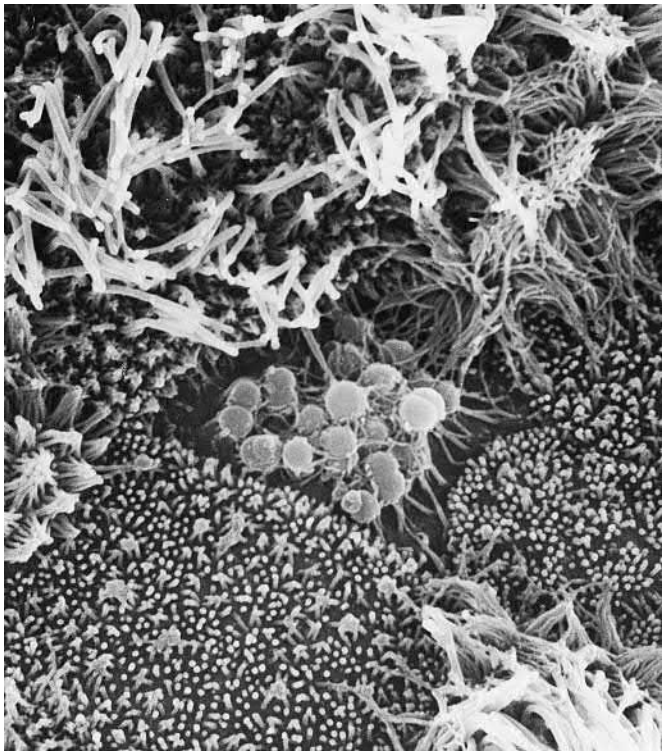

FIG. 27.2 Colonization and Adherence of Extracellular Bacteria at Mucosal Surfaces. Scanning electron micrograph of *Neisseria meningitidis* adherence and microcolony formation of a human upper respiratory mucosa (×16, 250).[46]

Bacteria utilize several mechanisms to avert the host immune response to bacterial surface antigens (see Table 27.1). Phase variation of adhesins is a mechanism of immune evasion common to

pathogenic *Neisseria* spp. Meningococcus, for example, utilizes phase variation of the adhesion protein Opa and type IV pili during the process of colonization of human upper respiratory mucosal surfaces.[9] Sialylation of LPS, a potent inducer of host inflammatory response, is an example of bacterial "hiding" of surface antigens. Sialylation of lipooligosaccharide, a molecule analogous to LPS, in meningococci has been shown to increase resistance to classical pathway (CP) and alternative pathway (AP) complement-mediated killing by decreasing the deposition of C3b and IgM on the cell surface, irrespective of capsular phenotype.

Normal Microbiota as Host Defense

The human microbiome is now recognized as a major host defense against bacterial pathogens by providing "colonization resistance," maintaining a balance of commensals to pathogens, and by priming the immune system.[10] Altering or disrupting the normal microbiota by antibiotics facilitates the expansion of enteric pathogens as *Clostridioides difficile* and *Salmonella typhimurium* or selection of antibiotic-resistant members of the microbiome. Similarly, changes in human physiology—for example, exposure of skin to elevated temperatures and humidity, chronic stress, host immune suppression, or active behavioral changes, such as smoking—can cause a commensal-to-pathogen switch. Recent studies have demonstrated that certain resident microbiota can resist pathogen colonization and infection. For example, matched volunteers were inoculated with *Haemophilus ducreyi* into the arms, and the subsequent infection either resolved or resulted in formation of abscesses; characterization of the skin microbiome before, during, and after the experimental inoculation showed that the microbiomes of those with pustule formation and of those with resolved infection were distinct and influenced the course of the *H. ducreyi* infection.[11]

The interaction of the microbiome with the immune system is also important for defense against extracellular pathogens. Normal microbiota prime the immune system by maintaining high levels of major histocompatibility complex (MHC) class II molecule expression on macrophages and other antigen-presenting cells. Pathogen recognition receptors (PRRs; see below) are traditionally known to recognize microbial molecules during infection; however, ligands for PRRs are abundantly produced by the resident microbiota during normal colonization. The integrity of the intestinal epithelial layer is dependent on activation of Toll-like receptors (TLRs; see below) by normal microbiota.[4] Stimulation of TLR-5 has been shown to increase resistance to *Enterococcus faecium* infection in a murine model. Activation of nucleotide-binding oligomerization domain 1 (NOD1) receptors by gut resident microbiota is necessary for priming of the innate immune system. Additionally, resident microbiota produce such factors as bacteriocins, lantibiotics, and phenol-soluble modulin (PSM), which function in a similar manner to that of host-derived AMPs (see below), suggesting an important host defense strategy against pathogen colonization.[12] Importantly, members of the resident microbiota can cause disease, particularly with loss of epithelial integrity and translocation to a different host tissue.

KEY CONCEPTS

Host Defenses and Immune Response at Epithelial Surfaces to Extracellular Bacteria

- Clearance and nonspecific host defenses at skin and mucosal surfaces:
  - Epithelial barriers
  - Antibacterial factors (fatty acids, antimicrobial peptides, lysozyme, phospholipase A_2)
  - Mucociliary activity
  - Normal microbiota
  - Adherence blocking molecules
- Specific immune defenses at mucosal surfaces:
  - Innate immune mechanism
  - Immunoglobulins
  - Phagocytosis at mucosal surfaces
- Mucosa-associated lymphoid tissue (MALT), gut-associated lymphoreticular tissue (GALT), bronchus-associated lymphoid tissue (BALT)

HOST DEFENSES TO EXTRACELLULAR BACTERIA INCLUDING SPIROCHETES

Early pathogen recognition by the innate immune system is key for rapidly responding to pathogens, allowing for the development of more advanced immunity mediated by T and B cells. Spirochete and extracellular bacterial pathogens' virulence is attributed, in part, to the evolution of their sophisticated tactics to evade killing mechanisms during all stages of the immune response, including serum complement and cellular immunity, as well as pathogen-specific antibodies. Both the innate and adaptive immune responses elicited by spirochetes and other extracellular bacteria are discussed, with the supposition that these responses are required for efficient bacterial clearance, while acknowledging that unnecessarily prolonged or intense responses may contribute to pathology arising from infection. Indeed, predisposition to infection could be the result of one or more monogenic traits that confer primary immunodeficiencies; whether or not this is the case remains to be determined, but human studies have shown that responses to *B. burgdorferi* are diminished in individuals with specific mutations in or diminished expression of innate immune cell receptors (nucleotide-binding oligomerization domain 2 [NOD2] and Toll-like receptor 1 [TLR1]). It has also been observed that individuals on anti-IL-1β immunotherapy experience an increased frequency of invasive infections caused by *S. pyogenes*.[13]

Similarly, *T. pallidum* is known colloquially as the "stealth pathogen" because of its denuded outer membrane, which comprises mostly nonimmunogenic transmembrane proteins, whereas the highly immunogenic lipoproteins are contained within the periplasmic space.[14] This molecular architecture, coupled with the ability to generate antigenic variants, is responsible for the treponeme's remarkable ability to cause persistent infection with relatively few organisms.[15] Consequently, our understanding of the immune responses to this pathogen is not nearly as detailed as our knowledge of those elicited in response to infection with *B. burgdorferi* and other bacterial pathogens. Here, we will discuss both the innate and adaptive immune responses to bacterial pathogens, as well as physical and genetic barriers extracellular bacteria and spirochetes use to evade host killing.

Innate Immune Responses

Early Pathogen Recognition and Antimicrobial Peptides

The initial recognition of pathogens by host cells relies on a complex interplay between PRRs and bacterial constituents, initiating a cascade of responses leading to the upregulation of chemokines and cytokines, adhesion molecules, and other effector

molecules. This response is often initiated by endothelial and/or epithelial cells, resulting in the recruitment and activation of innate immune cells. Each PRR recognizes a specific structure that is present in a group or groups of microorganisms. The recognition of patterns instead of specific antigens provides the innate immune system with a rapid way to respond to infecting organisms until the more specific response mediated by T and B cells develops. Immune pattern recognition molecules are a major arm of the innate immune system and are released or expressed by a range of host cells, including lymphocytes, macrophages, dendritic cells (DCs), polymorphonuclear leukocytes (PMNs), and epithelial cells. The discovery and characterization of specific pattern recognition molecules (see below) has revolutionized our understanding of the initial specific events occurring between microbes and human cells.

Innate immune recognition relies on the detection of unique molecular structures found on microorganisms by host PRRs.[16,17] Toll-like receptors (TLRs) and NOD-like receptors (NLRs) are the best studied PRRs (Table 27.3). TLRs (TLR1–11) are found on macrophages, PMNs, and other host cells. These receptors recognize a variety of microbial ligands or pathogen-associated molecular patterns (PAMPs), including lipoproteins, lipopolysaccharide (LPS), flagellin, and nucleic acids produced by gram-negative and/or gram-positive bacteria. For instance, the interaction of *B. burgdorferi* lipoproteins with complexes formed by TLRs 1 and 2 initiates a series of signaling cascades that results in the production of proinflammatory cytokines (IL-1β, tumor necrosis factor [TNF], IL-12, and IL-18, among others), chemokines (IL-8, monocyte chemoattractant protein [MCP]-1, keratinocyte chemoattractant [KC]), metalloproteinases, adhesion molecules (E-selectin, vascular cell adhesion molecule-1 [VCAM-1] and intercellular adhesion molecule-1 [ICAM-1]),[17] and type I interferons (IFNs). Extracellular bacterial pathogens such as *S. pyogenes* signal through an unknown TLR but—like spirochetes—elicit the production of proinflammatory cytokines and chemokines.

TABLE 27.3 Pattern Recognition Receptors Recognize Pathogen-Associated Molecular Patterns From Various Bacteria

PRRs	PAMPs	Microbes
Toll-like receptor (TLR)2/1	Triacyl lipoproteins lipoprotein	Bacteria *B. burgdorferi, T. pallidum*
TLR2/6	Diacyl lipoproteins	Mycoplasma
	Lipoteichoic acid	Gram-positive bacteria
TLR2	Peptidoglycan	Gram-positive bacteria
	Porins lipoprotein	Bacteria (*Neisseria, Treponema denticola*)
TLR4	Lipopolysaccharide (LPS)	Gram-negative bacteria
TLR5	Flagellin	Flagellated bacteria (*Helicobacter pylori, Salmonella*)
TLR7/8	RNA	Group B *streptococcus*
TLR9	CpG-DNA	Bacteria (*Salmonella*)
	DNA	Bacteria (*Staphylococcus* at low MOI)
TLR11	Not determined	Uropathogenic bacteria
Nucleotide-binding oligomerization domain (NOD)1	Meso-diaminopimelic acid	*H. pylori, Bacillus* spp., *Campylobacter jejuni, Pseudomonas aeruginosa*
NOD2	Muramyl dipeptide (MDP)	*Streptococcus pneumoniae, Staphylococcus aureus, Salmonella typhimurium*
NOD-like receptor (NLR)P3	Whole pathogens	*Staphylococcus aureus*
	Toxins, LPS, MDP, and RNA	Bacteria
NLRP1	MDP	Bacteria
NLRP1b	Microbial toxin	*Bacillus anthracis*
NLRC4	Flagellin	*P. aeruginosa*

MOI, Multiplicity of infection; *PAMP*, pathogen-associated molecular pattern; *PRR*, pattern recognition receptor.

Both spirochetes and *S. pyogenes* use MyD88-dependent mechanisms to stimulate cytokine induction. Mice deficient in TLR1, TLR2, or MyD88—an adaptor molecule—have significant increases in *B. burgdorferi* burdens after infection, underlining the importance of TLRs in early pathogen detection; similar to *B. burgdorferi* lipoproteins, treponemal lipoproteins appear to be the major proinflammatory agonists during treponemal infection through engagement with their cognate receptors, TLR1/2, and CD14. The inflammatory milieu established by treponemal lipoproteins is a principal driving force for immune cell recruitment to *T. pallidum*-infected tissues. The importance of this immune system compartment during the response to *T. pallidum* is further supported by the systemic upregulation of innate immune cells during treponemal dissemination and by demonstration that macrophages are principal effectors of treponemal clearance during infection.[18] Other extracellular pathogens such as *S. pyogenes* lack LPS but do contain surface proteins such as M protein that elicit a highly inflammatory immune response largely mediated by macrophages, dendritic cells, and PMNs.

The NLRs are a family of intracellular receptors, some of which also function as PRRs.[16] NOD1 and NOD2 are well characterized as PRRs to extracellular pathogens, such as *S. pyogenes*. Importantly, in concert with TLR signaling, NLR can respond to a variety of PAMPs by forming the inflammasome complex. Inflammasome activation generates interleukin (IL)-18 and activates IL-1 through caspase-1, an important step in the immune response to many bacteria. Inflammasome activation is critical to the restriction of many pathogens. Interestingly, *S. pyogenes* can directly activate IL-1β independently of the NLRP3 inflammasome, leading to a highly inflammatory and often detrimental host immune response.[13] Similarly, *B. burgdorferi* stimulates the production of IL-17 and IFN-γ by a caspase-1-dependent mechanism leading to a highly inflammatory immune response critical to Lyme disease progression and pathology, but unlike *S. pyogenes*, does not rely on the NLRP3 inflammasome.

Upon recognition of bacterial pathogens by PRRs, immune cells produce antimicrobial peptides (AMPs) in addition to cytokines and chemokines that either kill invading microbes or modulate and dampen host inflammatory responses (Table 27.4).[12] Cells that are present on skin and mucosal surfaces constitutively express AMPs as a first line defense against invading pathogens, but AMPs can also be induced by infection or injury.[12] Electrostatic interactions between AMPs and negatively charged cell membranes result in either membrane disruption or entry into the cell, consequently inhibiting critical cell functions. Humans produce two main classes of AMPs: defensins and cathelicidins. Defensins, for example, are expressed in skin, intestines, and the respiratory tract and have activity against gram-positive and gram-negative bacteria. Cathelicidins such as LL37 are produced by macrophages and PMNs and are important for rapid bactericidal activity against both spirochetes and extracellular bacteria. Keratinocytes of inflamed psoriatic lesions produce increased levels of certain AMPs, and

TABLE 27.4 Antimicrobial Proteins Against Extracellular Bacteria and Spirochetes

AMP	Tissue/Cell Sources	Mechanism of Action	Target Organisms
α-Defensins	Small intestines, Paneth cells	Membrane disruption; inhibits complement activation; chemoattracts dendritic cells	Gram-positive bacteria Gram-negative bacteria
β-Defensins	Large intestines, skin, respiratory tract epithelial cells	Membrane disruption; lipid II binding	Gram-positive bacteria Gram-negative bacteria
Cathelicidin (LL37)	Large intestine, skin, lung, urogenital tract	Membrane disruption	Gram-positive bacteria Gram-negative bacteria
RNases	Skin, intestine, respiratory epithelia, placenta	Unknown	Gram-positive bacteria Gram-negative bacteria
Psoriasin (S100A7)	Skin, urogenital tract	Unknown	*Escherichia coli*
Calprotectin (S100A8-A9)	Abscesses/neutrophils	Metal chelation	*Staphylococcus aureus*
C-type lectins	Small intestines	Peptidoglycan recognition	Gram-positive bacteria
Bactericidal/permeability-increasing protein (BPI)	Neutrophils, epithelial cells	Neutralizes lipopolysaccharide	Gram-negative bacteria
Lysozyme	Skin, body fluids, tears, intestinal Paneth cells	Degrades peptidoglycan	Gram-positive bacteria Some gram-negative bacteria activity
Dermcidin	Sweat glands	Membrane disruption	Gram-positive bacteria Gram-negative bacteria
Peptidoglycan recognition proteins	Liver, intestines, skin, neutrophils	Activates bacterial two-component systems; targets peptidoglycan	Especially active against gram-positive bacteria Gram-negative bacteria
Phospholipase A_2	Tears, intestines	Hydrolysis of bacterial phospholipids	Gram-positive bacteria

AMP, Antimicrobial proteins.

patients with such lesions rarely have secondary bacterial infections. Not surprisingly, successful pathogens have developed several mechanisms to counteract AMPs; invasive clones of *S. pyogenes*, for example, uses the M surface protein to sequester the human cathelicidin LL37 to evade killing by AMPs and cause diseases such as necrotizing fasciitis.[19]

The interaction of several cell types with spirochetes and other extracellular bacteria also involves several integrins. Integrins are involved in the adhesion of cells to a variety of ligands and mediate essential cellular processes, including attachment and cell migration. Some integrins have also been associated with the phagocytosis of microorganisms. For the most part, studies of the interaction between the spirochete and integrins have focused on their role in aiding the adhesion of *B. burgdorferi* to host cells and the colonization of tissues and as receptors that contribute to signals that induce the production of proinflammatory factors (Fig. 27.3). Integrins are also important for restricting extracellular bacteria. Some serotypes of *S. pyogenes* encode a CD11b homologue that is able to modulate host immune responses and prevent phagocytosis; conversely, *S. pyogenes* can also encode collagen-like surface proteins that bind to $\alpha_2\beta_1$ integrins to promote phagocytosis, which allows for the bacterium to later re-emerge as an extracellular pathogen.

Complement

Destruction of microorganisms via complement involves the formation of a pore in the microbial cell membrane by the membrane attack complex (MAC), which results in the lysis of the organism and leads to the release of opsonins and chemoattractant molecules for phagocytic cells.[20] There are three different pathways that elicit complement activation: the classical (antigen/antibody–mediated) pathway (CP), the lectin pathway, and the alternative (pathogen surface) pathway (AP). These pathways converge at the level of C3 convertase, a protease that cleaves complement component C3 into C3a and C3b. As a

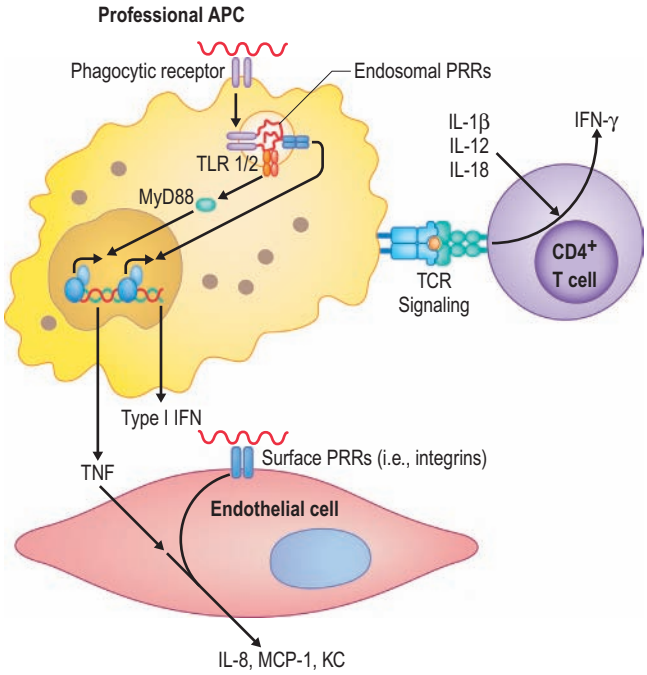

FIG. 27.3 The Interaction of Borrelia burgdorferi With Pattern Recognition Receptors (PRRs) in Innate Immune Cells and endothelial Cells Mediates the Inflammatory Response to the Spirochete. Phagocytosis induces Toll-like receptor (*TLR*)–driven proinflammatory cytokine production as well as antigen presentation by professional antigen-presenting cells (*APCs*), which leads to the activation of CD4 effector T cells, marked by the production of interferon-gamma (*IFN-γ*). Likewise, PRR- and tumor necrosis factor (*TNF*)–receptor signaling lead to the upregulation of chemokines by endothelial cells. Overall, these responses lead to increased activation and recruitment of innate immune cells in sites of infection.

result, C3b can (1) bind to the surface of the bacteria and facilitate internalization of the bacterium via opsonization; or (2) it can bind C3 convertase and facilitate the deposition of downstream components onto the surface of the bacterium resulting in the formation of MAC and lysis of the cell. Spirochetes such as *B. burgdorferi* and *T. pallidum* activate the CP and AP of the complement cascade. Moreover, the activation of complement has been associated with dramatic decreases in spirochetal numbers in different tissues of infected mice, indicating the importance of the complement system in early infection, particularly for *B. burgdorferi*. The immune protection afforded by human syphilitic serum is, in large part, a result of the activation of the complement cascade by bactericidal antibodies and spontaneous hydrolysis of C3, and there is a considerable amount of evidence for an important role of these pathways in syphilitic lesion resolution during human infection with treponemes.

Bacteria have evolved several ways to evade complement-mediated killing. Gram-positive extracellular pathogens resist the bacteriolytic action of the MAC as a result of a thick peptidoglycan layer, which impedes the insertion of the MAC C5b-9 complex; similarly, bacteria such as *Streptococcus pyogenes* and *Staphylococcus aureus* can evade host immune detection by producing a thick capsule that precludes opsonization. *S. pyogenes* M protein can also directly bind C4b and fibrinogen, thus inhibiting complement-mediated opsonization. Gram-negative bacteria can resist the MAC through structural alterations in their LPS (the possession of O antigen keeps the MAC at a distance from the bacterial surface) or by masking or deleting the epitope(s) responsible for binding bactericidal antibodies. Binding of human factor H (hfH) by meningococci factor H-binding protein (fHbp) downregulates the host AP and helps the organism to evade host innate immunity and is now included in the new serogroup B vaccines.[21] Spirochetes like *B. burgdorferi* have evolved a variety of mechanisms enabling them to escape complement-mediated lysis, including the expression of complement regulator-acquiring surface proteins (CRASPs).[22] Of these CRASPs, the Erp (OspEF-related protein) family of outer membrane proteins serve as binding sites for the complement inhibitor factor H and factor H–like protein 1 (FHL-1).[23] The interaction of factor H with these proteins recruits a protease (factor I) that cleaves and inactivates the complement serum proteins C3b and C4b. Cleavage of these two complement proteins prevents the deposition of downstream components onto the surface of the spirochete, thereby halting the formation of MAC. *B. burgdorferi* also express a CD59-like molecule on the outer membrane that can inactivate MAC and prevent complement-mediated lysis.[24] In contrast to *B. burgdorferi*, there is no evidence indicating that *T. pallidum* has evolved mechanisms to evade complement-dependent killing, suggesting that these complement pathways have a larger role in controlling treponemal infection than in the case of *B. burgdorferi*. During experimental syphilis, immunization with purified outer membrane vesicles (OMVs) isolated from *T. pallidum* results in complement-dependent bactericidal activity.[25] More recently, immunization with OMVs led to the isolation of a bactericidal monoclonal antibody (mAb) M131 that provides partial protection to experimental syphilis.

Phagocytic Cell Recruitment and Pathogen Clearance

The recruitment of phagocytic cells and other cell types into sites of infection is mediated by the production of chemokines, increased vascular permeability, and upregulated expression of cell adhesion molecules in endothelial cells. Macrophages, PMNs, and other phagocytic cells are also present at mucosal surfaces. These cells express PRRs and migrate to mucosal surfaces by chemotaxis and diapedesis between epithelial cells. Macrophages are also encountered after crossing the epithelial barrier. Specialized epithelial M cells of mucosal surfaces are key sites for antigen sampling, including viruses, and bacteria and macrophages surround these sites.[26] Dendritic cells (DCs; Langerhans cells) sample live bacteria at the mucosal surface, traffic to mucosal lymphoid tissue, and induce B cells to produce bacteria-specific immunoglobulins.[4] In most tissues, DCs are at a low level of activation and are immature, but upon activation, they take up and process antigens. DCs are rich in PRRs (e.g., TLRs), and microbe–PRR interactions have a key role in shaping the T-cell response.[27] DCs play a central role in controlling *S. pyogenes* infection by the production of TNF, and mice deficient in CD11c+ DCs fail to control infections caused by *S. pyogenes*. Skin contains a major supply of tissue DCs, and their involvement in combating skin and soft tissue infections must be considered along with their function and contribution to stimulating immunity during vaccination.

Chemokine production at sites of pathology in disease-susceptible C3H/HeJ mice and disease-resistant C57BL/6J mice shows that inflammation is related to increased production of neutrophil and monocyte–macrophage chemokines, KC and MCP-1, respectively. In humans, the production of chemokines, especially IL-8, during the initial response to *B. burgdorferi* correlates well with the onset of symptoms associated with the early stages of infection. This suggests cytokine production is increased during the early stages of infection to recruit phagocytic cells, which are involved in the initial clearance of the spirochete.

In areas of epithelial inflammation, PMNs can be recruited to mucosal and skin surfaces. PMNs are more effective in the presence of other immune defenses, such as antibody and complement components. PMNs express PRRs and have both oxygen-dependent and oxygen-independent mechanisms of killing (Fig. 27.4). Activated neutrophils can release granule proteins with direct antibacterial action (e.g., bactericidal/

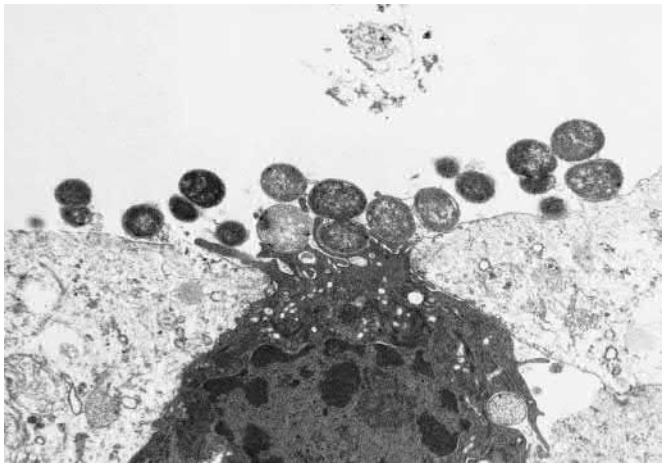

FIG. 27.4 Bacterial Phagocytosis at Mucosal Surfaces. Transmission electron micrograph of phagocyte engulfing *Neisseria meningitidis* at a human respiratory epithelial mucosal surface (×19,000).

permeability-increasing [BPI]) or degradative activity (e.g., elastase) and chromatin containing the antibacterial histone H2A.[28] These released compounds work together to form extracellular fibers, termed *neutrophil extracellular traps* (NETs), which can trap and kill gram-positive and gram-negative bacteria and degrade their virulence factors as well. NETs have been observed in instances of acute inflammation (experimental dysentery and spontaneous appendicitis) and provide a mechanism for reducing bacterial spread at sites of acute infection. Strains of *S. pyogenes* that encode the DNase Sda1 that degrades NETs are significantly more virulent, highlighting the importance of NETs in restricting extracellular bacterial pathogens. PMNs are important to restricting infection by both spirochetes and other extracellular bacteria due to their production of reactive oxygen species (ROS) including superoxides; consequently, neutrophil influx may also contribute to the onset of arthritis observed during Lyme disease. The importance of PMNs in host defense against extracellular pathogens can best be highlighted by the increased frequency of bacteremia and other life-threatening infections in patients with neutropenia or those individuals with neutrophil deficits (e.g., chronic granulomatous disease, Chediak-Higashi syndrome, or specific granule deficiency, to name a few).

Phagocytosis plays a major role in the pathogenesis of spirochetes and other bacteria not only through the control of bacterial numbers but also through modulation of the potency and quality of proinflammatory cytokine induction. However, little is known about the molecular events or receptors that mediate *B. burgdorferi* phagocytosis despite the importance of this cardinal mechanism of pathogen clearance. MyD88-mediated signals substantially mediate the phagocytosis of *B. burgdorferi* and *T. pallidum;* however, MyD88-mediated phagocytosis occurs independently of any known *B. burgdorferi*-recognizing TLRs. Similarly, it is unclear which TLRs are required for phagocytosis of *S. pyogenes*, but MyD88 deficiency leads to impairment of phagocyte recruitment and significantly decreased production of cytokines and chemokines. The analysis of MyD88-deficient macrophages shows that although reduced, phagocytosis of *B. burgdorferi* is not absent, indicating that uptake seems to be mediated by more than one receptor. Indeed, as opposed to MyD88-mediated phagocytosis—which is proinflammatory—the internalization of *B. burgdorferi* by CR3 tempers the inflammatory response of macrophages; therefore the presence of alternative phagocytic mechanisms has nonredundant physiological consequences during infection with the spirochete. Similarly, activated macrophages readily phagocytose antibody-opsonized *T. pallidum* and other treponemes through Fc receptor–mediated uptake. These results revealed a previously unsuspected link between MyD88 signaling and FcR-mediated phagocytosis.

Once bacteria are taken up by phagocytic cells, they must endure the intracellular phagolysosome. Phagolysosomes form after bacteria are taken up by professional phagocytes, forming small vacuoles that fuse with lysosomes containing ROS and other hydrolases used to kill bacteria. The acidification of the phagolysosome is a critical step in the clearance of bacterial pathogens. The presence of the phagolysosome initiates a cascade of intracellular signaling, leading to the increased production of proinflammatory cytokines; for example, spirochetes like *B. burgdorferi* induce interferon production from within the phagolysosome through a MyD88-TLR8-dependent pathway, resulting in killing of the spirochete. Very little is known about killing of *T. pallidum* through phagolysosomes, but it has been shown that both spirochetes are able to induce production of IFN-γ.[29,30] Bacteria have developed a variety of ways to evade both phagocytosis and phagolysosome-mediated killing. These can involve physical barriers such as the hyaluronic acid capsule and M protein of *S. pyogenes* that bind the Fc region of antibodies, or the denuded outer membrane of *T. pallidum* that results in diminished phagocytosis; other mechanisms include the degradation of phagolysosomes through pore-forming toxins such as streptolysin O produced by *S. pyogenes*.

Several extracellular bacteria possess polysaccharide-rich capsules that resist phagocytosis. A number of pyogenic bacteria (e.g., *S. aureus*) secrete leukocidins, which lyse phagocytes. Other pathogens (e.g., group A streptococci) inhibit chemotaxis of neutrophils through the elaboration of enzymes (e.g., C5a peptidase) that proteolytically cleave chemotactic signals. Some bacteria possess mechanisms to prevent opsonization by changing surface antigens.[7] Many bacteria form biofilms, which shield these microorganisms from host defense molecules and antibiotics.[31] Leukocytes that invade *S. aureus* biofilms exhibit impaired phagocytosis and decreased ability to kill bacteria. In addition, biofilm matrices can protect bacteria from antibody-mediated phagocytosis.

Adaptive Immune Responses to Extracellular Bacteria and Spirochetes

T Cell–Mediated Responses

Upon antigen presentation by macrophages, dendritic cells (DCs), or B cells, naïve CD4 T cells are activated and differentiate into effector T cells. Effector CD4 T cells are classified on the basis of their cytokine production profile, which determines their mode of action and downstream effects, and include T-helper [Th]1 (IFN-γ-producing), Th2 (IL-4, IL-5, IL-13), Th17 (IL-6, IL-17), or regulatory T cells (Tregs; IL-10). Interaction of *B. burgdorferi* antigen with TLRs induces the production of IL-12, which drives the differentiation of CD4 T cells into Th1 effector cells. Th1 cells are regulators of the cell-mediated inflammatory reactions, which are characterized by macrophage activation, including phagocytosis, or the induction of opsonizing IgG antibodies. In the case of *T. pallidum*, the infiltration of T cells and macrophages into the primary and secondary syphilitic lesion facilitates local clearance of the majority of treponemes via a vigorous cell-mediated immune response characteristic of a delayed-type hypersensitivity or Th1 response.[32,33] CD4 T cells are the principal T-cell subset found in the lesions and are believed to promote macrophage activation and subsequent treponeme clearance through IFN-γ secretion.

Although IFN-γ and Th1 CD4 T cells have been shown to be protective during cardiac inflammation with *B. burgdorferi*, joint inflammation is independent of this effector cell type in mice. However, in patients with Lyme disease, Th1 cells dominate in the synovial fluid, and the severity of arthritis directly correlates with increased levels of Th1 cells in the synovium.[34] Whether neutrophilic infiltration during joint infection with the spirochete is influenced by Th effector cells that more directly affect this cell type, such as Th17 cells (through the production of IL-17), remains to be elucidated.

Th1 cells are characterized by IFN-γ production and function to activate macrophages to phagocytize and kill pathogens. While this mechanism of pathogen elimination is primarily directed against pathogens with a predominant intracellular life

cycle, Th1 cells are relevant for typical extracellular bacteria such as *Streptococcus pyogenes* and *pneumoniae*.[35] The neutrophilic response to extracellular bacteria is primarily coordinated by Th17 cells.[36] Animal models have suggested that the Th17 response is central for protection against a wide variety of gram-positive and gram-negative bacteria. For example, Th17 response has been shown to induce nasopharyngeal clearance of Pneumococcus in both animal models and in children. Differentiation toward the Th17 subtype appears to be favored by strong antigenic signals and broad activation of PRRs. IL-17 and IL-22, the signature ILs of the Th17 response, promote AMP secretion by epithelial cells, neutrophil migration, and epithelial integrity. *S. pyogenes* induces a strong inflammatory response, leading to the activation of Th1 and Th17 cells, which is largely mediated by IFN-γ and IL-6 production. Invasive infections by *S. pyogenes*, particularly toxic shock syndrome, are a result of aberrant activation of large populations of T cells that produce fatal levels of inflammatory cytokines.

B Cell–Mediated Responses

Antibodies are specific and powerful effector molecules of the adaptive immune response. Once antibodies bind to their specific foreign antigen, they confer protection to the host by using a variety of effector mechanisms. However, in response to *B. burgdorferi*, T cell–independent humoral responses also confer protection to the host. This is supported by studies that indicate unusually large numbers of B cells residing in lymph nodes with minimal activation of CD4 T cells; follicular helper T cells that are commonly associated with germinal center B-cell responses, were also present.[37] Mice that are deficient in CD4 T cells were still able to resolve infection, but mice that lack both B and T cells developed severe arthritis and carditis in response to infection with *B. burgdorferi*, indicating that B cells are also important for clearance of spirochetes. In addition, mice deficient in CD40L and MHC class II infected with *B. burgdorferi* mount a protective antibody response, which, upon passive serum transfer, affords protection to severe combined immunodeficient (SCID) mice from homologous challenge.

The role of antibodies in controlling *B. burgdorferi* infection may be more important during the hematogenous dissemination phase, when they are easily accessible, than after the spirochetes have colonized tissues. Once the spirochete is in the joints and the heart, its clearance may be more dependent on cellular responses (e.g., macrophages in the heart) than on antibodies. In fact, the lack of IFN-γ–mediated activation of macrophages has profound consequences on murine cardiac inflammation, even in the presence of strong antibody responses. Furthermore, the bacterial clearance potential of infected mouse sera administered in newly infected mice is lost when administered 4 to 8 days after infection, potentially the result of the colonization of tissues into which antibodies are less able to penetrate. Like *B. burgdorferi*, many functional activities of human syphilitic serum originate from B-cell responses to *T. pallidum*. Infection with *T. pallidum* invokes a humoral immune response early in the course of infection, which strengthens as the number of recognizable antigens increases during the progression of infection.

Both *B. burgdorferi* and *T. pallidum* can avoid clearance by antibodies through antigenic diversity. *B. burgdorferi* differentially expresses outer membrane antigens under pressure from the immune response, which might contribute to the ability of the spirochetes to persist in the host. A mechanism that is potentially essential for spirochetal immune escape is the recombination that takes place at the *vls* locus,[38] located near the right telomere of the linear plasmid lp28-1. TprK, an immunogen found in *T. pallidum* has seven discrete variable regions differing among isolates of the spirochete.[39] In fact, the antibody response to *T. pallidum* is directed against these variable regions, which leads to immune selection of new TprK variants; thus, antigenic variation is involved in the reinfection of hosts by spirochetes despite robust immune responses.[39]
