Table 1 Drugs that inhibit mitochondrial respiration and/or β-oxidation

Drug	*Inhibition of respiration*	*Inhibition of β-oxidation*	*Drug*	*Inhibition of respiration*	*Inhibition of β-oxidation*
Amineptine	–	Yes	Ibuprofen	–	Yes
Amiodarone	–	Yes	Lovastatin	Yes	–
Aspirin/salicylic acid	Yes	Yes	Nefazodone	Yes	–
			Panadiplon	–	Yes
Benzarone	–	Yes	Paroxetine	Yes	–
Benzbromarone	Yes	Yes	Perhexiline	Yes	Yes
Buprenorphine	Yes	Yes	Phenformin	Yes	–
Carvedilol	Yes	–	Pirprofen	–	Yes
Cerivastatin	Yes	–	Pivampicillin	–	Yes
Chloroquine	Yes	–	Primaquine	Yes	–
Ciglitazone	Yes	–	Propofol	Yes	–
Darglitazone	Yes	–	Quinine	Yes	–
Diethylamino-ethoxyhexesterol	Yes	Yes	Simvastatin	Yes	–
			Tamoxifen	Yes	Yes
Efavirenz	Yes	–	Tetracyclines	–	Yes
Fenofibrate	Yes	–	Tianeptine	–	Yes
Flurbiprofen	–	Yes	Troglitazone	Yes	Yes
Glucocorticoids	–	Yes	Tiaprofenic acid	–	Yes
Hopantentate	–	Yes	Valproate	Yes	Yes

drugs into more toxic metabolites via the arsenal of drug-metabolizing enzymes which are highly expressed in the liver and (ii) that a major part of the mitochondrial impairment caused by different drugs is directly or indirectly linked to hepatic lipid metabolism. Thus, a majority of all drugs causing DILI do so through formation of reactive metabolites. Furthermore, direct or indirect inhibition of fatty acid oxidation or, in some cases, lipid transport causes steatohepatitis and decreased acetyl-CoA, inhibits gluconeogenesis and impaired glucose homeostasis, and also causes energy deficiency in extrahepatic tissues.[47] Also, the accumulation of drug cations (e.g. from amiodarone) in the intermembrane space causes the inhibition of mitochondrial respiration and subsequent inhibition of fatty acid oxidation. Eventually, these processes lead to secondary cellular impairment and cell death and result in the potentially catastrophic effect of uncoupling the mitochondrial respiratory chain.

4.13.3.5 Structural Aspects of Drugs Eliciting Mitochondrial Damage

Drug structure plays an important role in the propensity to cause mitochondrial dysfunction. Amphiphilic drugs such as amiodarone, perhexiline, buprenorphine, and tamoxifen harbor protonatable amine groups, thereby favoring their accumulation inside the mitochondrial matrix under the influence of the membrane potential.[8,47,55] Valproic acid (dipropylacetic acid) is activated by CoA and therefore reduces the intracellular levels of CoA.[47,56] Also the CYP2C9-mediated transformation of valproic acid to D4-valproic acid and subsequently to D2,4-VPA-CoA inactivates fatty acid oxidase enzymes. Furthermore, antiviral drugs inhibit mtDNA replication because they undergo phosphorylation to cognate endogenous nucleosides incorporated into mtDNA by DNA polymerase γ.[57] Apart from these examples, the structural aspects of drugs causing mitochondrial dysfunction are not well understood. In particular, there is a lack of identification of the fatty acid oxidases that are inhibited by these drugs, and such site identification will be necessary in order to improve predictive models that recapitulate drug-induced mitochondrial dysfunction.

4.13.3.6 Mitochondrial Adaptation to Drugs

DILI occurs when liver cells do not adapt to drug exposure. Adaptation may involve upregulation of defense systems such as Nrf2 and the unleashing of antioxidant defenses, upregulation of drug transport, development of immune tolerance through the adaptive immune system, and adaptation of the mitochondria to stress induced by drugs.[46] Mitochondrial adaptation to drugs include: activation of mitophagy, remodeling of the mitochondria to increase respiratory capacity, increased mitochondrial biogenesis, altered fusion–fission exchange of mtDNA, changes to respiratory chain complexes, and other constituents that alter mitochondrial morphology, for example, elongated mitochondria that are more resistant to mitophagy.[46,58] Examples of drugs known to cause mitochondrial pertubation leading to DILI include chloramphenicol and troglitazone which have been shown to cause the formation of megamitochondria[59,60] and trovafloxacin that alters mitochondrial gene expression, indicative of morphological changes.[61] However, as yet, a causative role for the increased size of the mitochondria and adaptation or failure to adapt to drug exposure has not been unequivocally proved.[46]

4.13.4 Lysosomal Perturbation and DILI

4.13.4.1 Introduction

There is clear evidence for a role of lysosomal perturbation in DILI. For example, DILI is clearly associated with the development of phospholipidosis, that is, the accumulation of lipids in the lysosomes as a consequence of disturbed phospholipid breakdown of lysosomes, for example, by phospholipases.[59] Phospholipidosis is related to the physicochemical characteristics of DILI compounds, in close association with the cellular function of lysosomes in critical liver functions during normal and adverse cell physiology.

The lysosomes are acidic organelles that play key roles in endolysosomal catabolism in (receptor-mediated) endocytosis, followed by fusion of late endosomes with lysosomes for degradation of their cargo. This degradation is mediated by around 50 hydrolases including proteases and phospholipases that are catalytically active at low pH. In addition, lysosomes are central to the macroautophagy program, which has been implicated in cellular stress responses triggered by drugs known to cause DILI.[60] Furthermore, lysosomal activity (and thereby correct cellular function) may be severely perturbed at the onset of hepatocyte death, through the release of proteolytic enzymes from injured lysosomes.[61] Each of these issues is discussed in more details in the succeeding text.

4.13.4.2 Physicochemical Properties of Drugs and Lysosomes

The physicochemical properties of a drug are a critical component in the development of phospholipidosis. In particular, compounds that are highly lipophilic ($\log P > 1$) or amphiphilic (cationic amphiphilic drugs) with ionizable amines ($pK_a > 6$) accumulate in the acidic lumen of lysosomes. Several chemoinformatics tools have been established that can predict relatively well the hazard for lysosomal accumulation.[62–64] Recently, such an in silico quantitative structure–activity relationship (QSAR) analysis of phospholipidosis showed around 80% concordance and $>80\%$ predictivity,[65] but discussions are ongoing what database is most

reliable for in silico modeling-based prediction of phospholipidosis.[66] In DILI, the dosing regimen is likely to be an important component for actual phospholipidosis development in vivo. Therefore, drugs that require high doses and fit the QSAR criteria for accumulation in the lysosomes are at risk of provoking drug-induced phospholipidosis, whereas patient-specific confounding factors may also be involved. In preclinical safety studies, phospholipidosis can easily be assessed in various cell types by the accumulation of phospholipid in the lysosomal compartment, using special fluorescently labeled lipids (i.e., LipidTOX Red or NBD-PE), followed by high-content imaging analysis of the lysosomal localization of these dyes and the comparison with electron microscopy techniques.[67–69] However, systematic comparisons between in silico QSAR approaches and cell-based assays for phospholipidosis prediction are still needed.

4.13.4.3 Autophagy, Lysosomes, and DILI

Lysosomal perturbations are related to different programs involved in the control of cell survival, namely, autophagy, apoptosis, and necrosis.[61] Autophagy is a rescue program that mediates intracellular degradation of injured macromolecules and organelles and can serve as an internal energy source during nutrient deprivation as well.[70] Autophagosomes are formed when macroautophagy is initiated, and this involves various ATG protein family members such as ATG5 and ATG7. These autophagosomes fuse the lysosomal compartment; this process is then followed by degradation of the lysosomal content. The onset of increased autophagy can be determined by the accumulation of LC3-phosphatidylethanolamine on the surface of these autophagosomes,[71] which is also easy to access in living cells using GFP-tagged LC3 (see Fig. 3). So far, there is little hard evidence of the effect of DILI-causing drugs on autophagy. Compounds that affect lysosomal acidification, such as chloroquine, readily induce the accumulation of autophagosomes in the cytosol, since these can no longer be engulfed by the lysosomes, which is represented by the accumulation of GFP-LC3 in the lysosomal compartment (see Fig. 3). The relationship between phospholipidosis and perturbations of autophagy remains unclear. Nevertheless, a perturbation of the lysosomes is likely to affect the autophagy flux; therefore, compounds that cause phospholipidosis are likely to disturb the endogenous autophagy process.

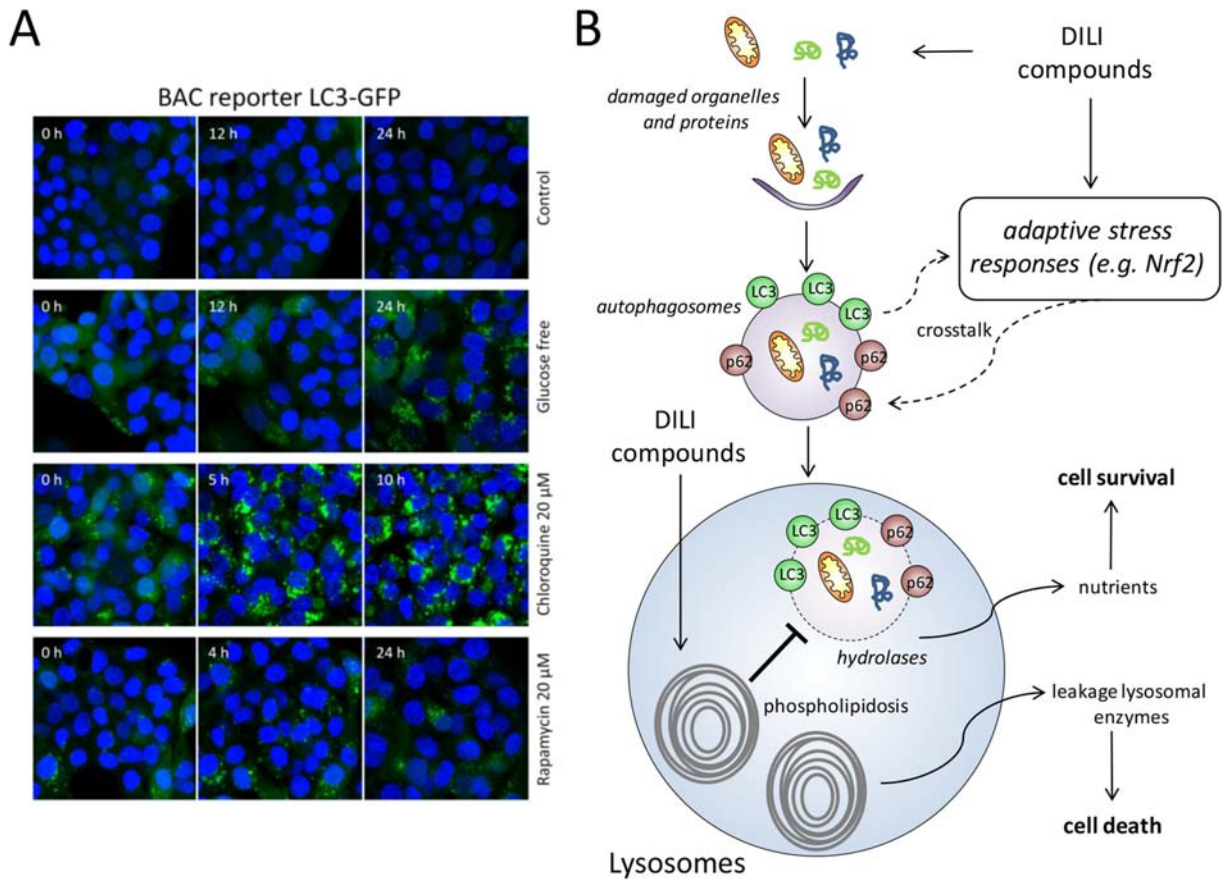

Fig. 3 Potential roles of autophagy and phospholipidosis in determining the sensitivity of the liver to drug exposure. (A) GFP-LC3 HepG2 reporter cell line for determining the effect of autophagy modulation, whereby rapamycin and glucose deprivation stimulate the rate of autophagy and whereby chloroquine prevents the turnover of autophagosomes. (B) Schematic overview how DILI compounds may affect the autophagy process and lysosomal function and likely consequences for cell survival.

4.13.4.4 Would Perturbation of Autophagy Trigger a Concern for DILI in Compound Assessment?

There is little published information on this topic. Intriguingly, carbamazepine, a well-established DILI compound, can induce an increase in autophagy.[72] Carbamazepine-induced autophagy can also protect against liver injury associated with fatty liver disease or fibrinogen storage disease.[73,74] Conversely, inhibition of autophagy by chloroquine exacerbated the liver injury caused by these diseases. Acetaminophen induces autophagy in vitro and in the liver in vivo, which seems to form part of a survival response. Thus, inhibition of autophagy, using ATG7 knockout mice, enhances the onset of acetaminophen-induced acute liver injury,[75] whereas stimulation of autophagy protects against APAP liver injury.[76] But, intriguingly, the ATG5 knockout is protective, and this appears to be linked to enhanced cytoprotection through the Nrf2 pathway.[77] Possibly, this is related to the induction of the expression of autophagy receptor p62/SQSTM1, which is involved in Nrf2 activation but is also a direct target of Nrf2.[78] Some putative roles of autophagy in DILI are illustrated in Fig. 3.

Clearly, autophagy plays a role in the cytoprotection of the liver. Hence, any drug that has the potential to interfere with the autophagy flux is likely to increase the susceptibility of liver injury. Such a perturbation of autophagy could also sensitize against the contribution of TNFα proapoptotic signalling in liver cells.[79] As yet, there is a limitation to a systematic analysis of the relationship between phospholipidosis, autophagy regulation, and susceptibility to liver cell injury. Simultaneous high-content imaging analysis of these processes, making use of the previously mentioned marker for phospholipidosis, and markers for autophagy such as GFP-LC3 could solve these issues.

4.13.4.5 Lysosomal Perturbations and Cytotoxicity

More than 50 hydrolases are present in the lumen of lysosomes; this creates a hazard for overall cellular maintenance: when these lysosomes break open, their content may evoke a serious problem in the cytosolic compartment. Cathepsins are proteases that can cleave critical target proteins and are released from the lysosomes and are involved in the onset of cytotoxicity.[61] Interestingly, cathepsins can directly target apoptotic machinery components that will sensitize cells to the onset of apoptosis. Thus, the proteolytic activation of Bid by cathepsins to truncated Bid may serve as a complementary trigger to speed up the onset of cell death.[80] In addition, the antiapoptotic Bcl2 protein is also cleaved. Cathepsins, in fact, play a critical role in liver injury in vivo.[81] An additional factor involved in cell death is both the presence and release of Fe(II) from lysosomes. Fe(II) accumulates in these organelles after the breakdown of iron-containing enzymes. Here, increased levels of Fe(II) may promote the onset of oxidative stress and the formation of hydroxyl radicals through the Fenton reaction,[82] causing membrane damage of lysosomes and further release of Fe(II) and the hydrolases into the cytosol. In cases where cells have an attenuated antioxidant potential, this may sensitize the cells toward lipid peroxidation and membrane damage and eventually cell death by necrosis. While these relationships have been demonstrated for individual cases of chemically induced cytotoxicity, it remains unclear if these programs are also relevant to DILI and to what extent sustained phospholipidosis actually contributes to DILI.

4.13.5 Assessment and Prediction of the Role of Transporters in Drug- and Bile Acid-Induced Liver Injury

4.13.5.1 Introduction and Classification of Drug and Bile Acid Transporters

Membrane transporters play an important part in drug absorption and disposition, therapeutic efficacy, and ADRs. They are grouped in two major families: ATP-binding cassette (ABC) and soluble carrier (SLC) proteins.[83] In the hepatocyte, transporters for drugs and endogenous substances are distributed among the basolateral (sinusoidal) and canalicular (apical) membranes, as illustrated in Fig. 4.

4.13.5.2 Bile Acid Uptake and Excretion

Synthesis of bile acids (BAs) and the biliary secretion of endogenous and exogenous substances, including drugs and metabolites, are the main functions of the liver. Vectorial transport of BA across hepatocytes is a major driving force for bile flow. Bile formation is a complex sequence of cellular events, which involves uptake of bile constituents and xenobiotics at the basolateral plasma membrane of hepatocytes and secretion of cholephilic compounds across the apical membrane. The transcellular transport of BA is mediated by transporter proteins located on the basolateral and canalicular membranes of hepatocytes. The sodium/taurocholate cotransporting peptide (NTCP) enables sodium-dependent uptake of BAs and some drugs from the space of Disse into hepatocytes (Box 2). Human NTCP accepts most physiological BAs and some organic anions. Sodium-independent uptake of BA is mediated by members of the OATP family. Although there are several carrier proteins capable of transporting BA, NTCP-mediated transport accounts for the bulk of BA uptake (about 90%).

Excretion of the individual bile constituents such as bile salts, phospholipids, and cholesterol mainly involves highly specialized canalicular proteins. BSEP is the major canalicular BA efflux system. However, the affinity and capacity of BSEP for individual BA conjugates differ between species. MRP2 mainly excretes bilirubin glucuronides and glutathione conjugates but also exports divalent sulfo-conjugated BAs into the bile. Other canalicular transporters include members of the family of P-glycoproteins such as MDR1 (ABCB1) and MDR3 (ABCB4) that mediate excretion of biliary phospholipids and cholesterol, respectively. Both MDR1 and BCRP have also been implicated in BA transport under cholestatic conditions. However, MDR1/P-glycoprotein is not thought

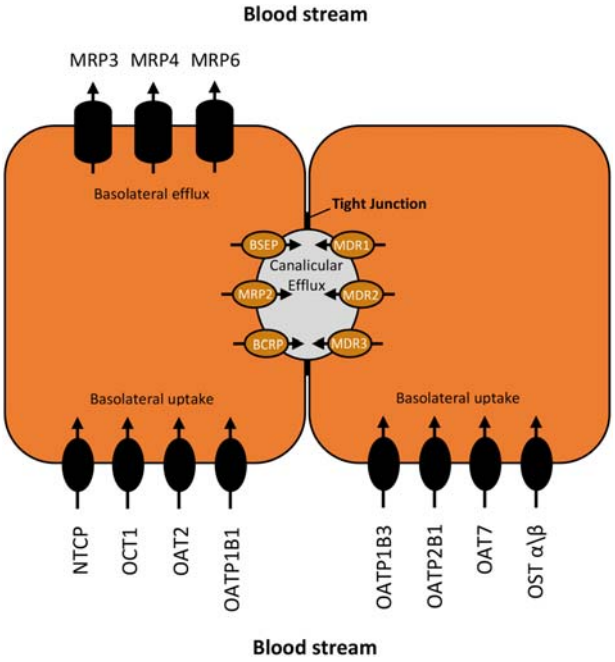

Fig. 4 Two major superfamilies of transporters exist in hepatocytes: ATP-binding cassette (ABC) and soluble carrier (SLC).

Box 2

Key basolateral transporter proteins include the sodium/taurocholate cotransporting peptide (NTCP; SLC10A1), three members of the organic anion transporting polypeptides (OATP) family (OATP1B1 (SLCO1B1), OATP1B3 (SLCO1B3), and OATP2B1 (SLCO2B1)), organic anion transporter 2 (OAT2; SLC22A7) and organic anion transporter 7 (OAT7; SLC22A9), and organic cation transporter 1 (OCT1). Efflux pumps include the multidrug resistance-associated proteins MRP3 (ABCC3), MRP4 (ABCC4), and MRP6 (ABCC6). Key canalicular (apical) efflux transporter proteins include P-glycoprotein (MDR1; ABCB1), bile-salt export pump (BSEP; ABCB11), multidrug resistance-associated protein 2 (MRP2; ABCC2), and breast cancer resistance protein (BCRP; ABCG2). In addition, the multidrug and toxin extrusion protein 1 (MATE1; SLC47A1) is also located in the apical membrane.

to have a primary role in the biliary excretion of drug conjugates, but it is one of the major determinants of cation excretion into bile. The basolateral membrane localizes members of the alternative basolateral BA efflux system, mainly, MRP3, MRP4, and the heterodimeric organic solute transporter OSTα/OSTβ. Any functional disturbance of the bile secretory process can lead to cholestatic liver disease, which is associated with intracellular accumulation of toxic bile constituents and consecutive cholestatic liver cell damage. Additionally, MATE1 has emerged as a transporter with an important role in the biliary excretion of cations.

4.13.5.3 The Cellular and Hepatic Features of Cholestasis

Since canalicular transporter proteins play a major role in hepatic drug clearance, changes in their expression or activity in acquired cholestasis have been reported to occur at the transcriptional, post-transcriptional, or post-translational levels within days, hours, or minutes/seconds, respectively. Cholestatic liver disorders are among the most severe clinical manifestations of DILI[84] and account for up to half of the cases of drug hepatotoxicity with high mortality rates.[85] They include a spectrum of acute or chronic hepatobiliary diseases of diverse etiologies that are characterized by impaired hepatocellular secretion of bile, resulting in accumulation of BAs, bilirubin, and cholesterol. Intrahepatic cholestasis represents a frequent manifestation of DILI in humans. In many cases, this results from changes in the hepatobiliary transporter system, in particular BSEP, which is the most physiologically important canalicular bile transporter. However, the mechanisms by which drugs induce cholestasis are diverse and remain poorly understood. Indeed, in addition to hepatobiliary transporter changes, other mechanisms, such as altered cell polarity, disruption of cell-to-cell junctions, and cytoskeletal modifications, can participate in cholestasis. A role for oxidative stress as a primary causal agent and/or as an aggravating factor has been shown in extrahepatic cholestasis induced by bile duct ligation, but it remains poorly documented in intrahepatic cholestasis. In addition, genetic mutations in genes encoding transporters may also result in the onset of cholestatic disorders and may increase the susceptibility to DILI. For instance, defects in BSEP, MDR3, and ATP8B1 cause progressive familial intrahepatic cholestasis. Defects in MRP2 cause the autosomal recessive liver disorder known as Dubin–Johnson syndrome, characterized by an elevated concentration of bilirubin glucuronides in blood.

Numerous drugs inhibit the biliary excretion of conjugated bile salts mediated by BSEP, which can result in DILI.[86] Noticeably, trafficking of hepatic efflux transporters is also an important concept: intracellular pools exist from which membrane transporters can be swiftly recruited and inserted into membranes as a result of xenobiotic treatment or physiological demand. Endocytic retrieval also occurs for BSEP and MRP2. As a result, substrates of efflux transporters are constantly accumulating within these vesicles.

Not all cholestatic drugs are BSEP inhibitors, and their detection can depend on the method and/or the model used. As examples, captopril and cimetidine caused cholestasis without interaction with BA transporters.[87] In a study using inverted membrane vesicles from cells overexpressing the human transporter and sandwich-cultured human hepatocytes, the BSEP-expressing inverted membrane vesicles were found to be suitable to evaluate the risk of DILI (according to FDA labeling) associated with BSEP inhibition. However, it resulted in many false positives. By contrast, the sandwich-cultured human hepatocytes allowed to separate BSEP inhibitors associated with severe DILI (e.g., cyclosporine, ritonavir, and troglitazone) from those with no or mild DILI (e.g., rifampicin).[88] In another study, 16 of the 42 drugs that were reported to cause cholestatic/mixed DILI (e.g., carbamazepine, dapsone, iproniazide, and ranitine) did not inhibit hBSEP using transfected inverted membrane vesicles.[89] Many BSEP inhibitors are also NTCP inhibitors, while some others, such as rifampicin, appear to be ineffective on NTCP activity.[90] Further investigations based on several methods and models could however be advisable.

As a result of BSEP inhibition or another mechanism, BAs can accumulate in the cytosol of the hepatocytes or in bile canaliculi and induce cellular damage. However, hepatocytes are able to counteract their intracellular accumulation; their uptake and synthesis decrease, while basolateral excretion and detoxification are enhanced.[91,92] Recent observations suggest that in vitro hepatocytes exhibit a rapid adaptive response to early cholestatic features induced by cholestatic drugs such as chlorpromazine (CPZ) and cyclosporine A, which are characterized by generation of an oxidative stress, inhibition of BSEP, and alteration of the pericanalicular cytoskeleton. This response is typified by rapid inhibition of NTCP activity, constriction of bile canaliculi with discharge of BAs, enhanced basolateral excretion, and downregulation of genes related to bile synthesis and detoxification.[93,94]

4.13.5.4 Model Systems for Transport Evaluation

Various in vivo and in vitro biological approaches are currently used for studying transporters. Whole tissues and whole animal models can be used in single-pass configuration and in a recirculating configuration. A number of knockout and mutant animal models have also been developed to analyze the role of transporters, but species differences and compensatory mechanisms can make interpretation of data from these models difficult. In vitro systems are mainly based on membrane and cell assays. Inverted vesicles derived from various nontransfected or transfected cell lines are used to analyze interactions between substrates and inhibitors with target transporters. A number of probe substrates and inhibitors are recommended for evaluation of human ATP-dependent transport into membrane vesicles.[95]

Polarized cell lines are standard models for evaluating drug transport. Primary hepatocytes should be the most appropriate cell model to mimic the hepatic uptake function. However, freshly isolated or cryopreserved hepatocytes are not polarized. In standard culture conditions, they rapidly lose their functional activities and functional bile canaliculi.[96] Rat hepatocyte couplets and primary rat and human hepatocytes in a sandwich configuration have been the most widely used in vitro cell models to analyze hepatic transport processes. In a sandwich configuration, hepatocytes recapitulate polarized architecture.[97] An alternative to sandwich-cultured primary hepatocytes is the human HepaRG cell line, a new liver cell line that expresses features of mature hepatocytes and exhibits typical functional bile canaliculi.[96] Recent studies have shown that cholestasis can be induced by CPZ and cyclosporine A in these cells.[93,94]

It is now recognized that compounds known to interfere with BSEP function are often not associated with significant liver cell injury in these preclinical models although they have been related to liver damage when administered in humans.[89,98] Moreover, since species-dependent differences have been reported, studies with human liver cells are preferable. For instance, taurocholic acid elimination through the basolateral membrane is much higher in rat hepatocytes than in their human counterparts.[99]

It is also important to note that in addition to biological models, computational modeling algorithms are used to evaluate drug–transporter interactions.

4.13.5.5 Bile Acid Toxicity

About 0.2–0.6 g of BAs are synthesized daily in humans, and serum (BA) concentrations of about 3–7 μM are considered physiological. However, in the μM range of supraphysiological BA concentrations, BA-induced apoptosis is believed to be the predominant mechanism. At higher concentrations, in the mM range, necrosis appears to be predominant.

Species differences in BA composition, synthesis, and regulation between humans and rodents exist.[100] The human liver synthesizes the two primary BAs cholic acid (CA) and chenodeoxycholic acid (CDCA), which are mostly conjugated to taurine and glycine. In the intestine, CA and CDCA conjugates are deconjugated and converted to the secondary BAs deoxycholic acid (DCA) and lithocholic acid (LCA), respectively. Sulfation is the major pathway for detoxification of extremely hydrophobic BA in humans such as LCA.[101] Conversely, in mice, the BA pool consists mostly of hydrophilic BA; it is predominantly composed of hydrophobic BAs. Only these latter are efficacious ligands of the nuclear receptors farnesoid X receptor (FXR), pregnane X receptor (PXR), and vitamin D receptor, which play a role not only in the regulation of BA synthesis and metabolism but also in the metabolism of chemicals and other endogenous compounds.[100] In humans, the five most important BAs present in plasma are glycochenodeoxycholic acid,

CDCA, glycodeoxycholic acid (GDCA), DCA, and glycocholic acid. The primary BAs CA and CDCA and the secondary BA DCA are present for 95% as conjugates of taurine and glycine. Sulfate and glucuronate forms are also present.

BA-mediated toxicity has been investigated in various in vitro systems, including isolated rat liver mitochondria, cell lines, isolated hepatocytes in suspension, and cryopreserved hepatocytes in conventional primary cultures. However, contrary to hepatocytes in a sandwich configuration and HepaRG cells, these in vitro systems do not reflect the polarity of hepatocytes.

The toxicity of BAs can be estimated by various assays of cell necrosis and apoptosis, oxidative stress (ROS generation), measurements of mRNA and activity levels of transporters, and other genes related to bile synthesis, detoxification, etc. It is important to note that the expression of BA-related genes is tightly controlled by nuclear receptors. Thus, the nuclear receptor FXR, activated by BAs, is a central player in the network while the nuclear receptors constitutive androstane receptor (CAR) and PXR facilitate adaptation to increased BA concentrations through the upregulation of alternative hepatic routes (MRP3 and MRP4) and induction of detoxifying enzymes (particularly CYP3A4).

Other endpoints of BA-induced toxicity are also used, that is, urea formation and the drug-induced cholestatic index (DICI):

$$\mathrm{DICI} = \frac{\text{Urea formation} - \text{test compound} + \text{BAs}}{\text{Urea formation} - \text{test compound alone}}$$

This reflects the residual urea formation by hepatocytes coincubated with the test drug and BAs.

4.13.5.6 Transporters and Bile Acid Toxicity: Comments and Future Challenges

The biology of liver transporters is a rapidly moving field. If major progress has been made in their knowledge, regulation, and interactions with drugs and substrates, further work is still required to better define their role in DILI, in particular in drug-induced cholestasis. Furthermore, BSEP inhibition alone is not sufficient to accurately predict drug-induced cholestasis for compounds exerting hepatotoxicity via multiple/or complex mechanisms.

New models such as humanized transporter animal models, hepatocytes derived from stem cells, and 3-D cultures of hepatocytes alone or with nonparenchymal cells (NPCs) could be useful to better understand drug-induced alterations of BA influx and efflux in the liver and related liver lesions and to evaluate which factors (inflammation, immune response, oxidative stress, viral infection, etc.) may contribute to aggravate such lesions. The use of new methodologies, for example, cell imaging to follow time-dependent cellular alterations, including induced by drugs and/or BAs, and sensitive methods to measure BAs, will also be of critical importance. Preliminary data have shown that by using HepaRG hepatocytes, two types of bile canaliculi alterations resulting in either constriction or dilatation associated with induction or inhibition of the Rho kinase pathway, respectively, could be observed with cholestatic drugs.[174]

In summary, more information is particularly needed on the following:

- BA profiles in liver cell models, the influence of culture time on these profiles, the capacity of the cell models to synthesize BAs from precursors, and their ability to form conjugates. Importantly, the composition of the culture medium must be considered; indeed, serum itself contains BAs.
- Early events induced by drugs and/or BAs and identification of the mechanisms involved should lead to the development of new predictive tests.
- Drug-induced alterations in BA profiles and the resulting toxicity, the mechanisms of short-term and long-term cell adaptation, and protection against intracellular accumulation of toxic BA. This should allow us to better understand DILI and hopefully even idiosyncratic DILI.

4.13.6 Evidence for the Role of the Innate Immune System in DILI in Man

4.13.6.1 Introduction

Involvement of the innate or the adaptive immune system in DILI in man is based on circumstantial evidence, and it remains to be established in man, whether immune alterations (inflamed tissue, changes in inflammatory cells (eosinophils or neutrophils)) found in DILI cases are causally related or if they are the consequence of inflammatory responses in the liver or elsewhere.

4.13.6.2 HLA Associations With DILI

A strong indication for a role of the adaptive immune system (i.e., T-cell sensitization) is based on genetic studies showing associations between DILI and certain HLA polymorphisms, but this is only reported for a limited number of drugs. HLA associations to DILI have been demonstrated for some drugs (HLA-A*33:03 for ticlopidine, HLA-B*57:01 for flucloxacillin, HLA-DQA1*02:01 for lapatinib, HLA-DRB1*15:01 for amoxicillin clavulanate, HLA-DRB1*15:01 for lumiracoxib, HLA-DRB1*07 for ximelagatran, and HLA-DRB1*01:01 for nevirapine (reviewed by Kaniwa and Saito,[102]) but not (yet) established for others (diclofenac are trovafloxacin). Associations between HLA and hypersensitivity syndromes have also been established for other drugs, for example, carbamazepine and abacavir.

The occurrence of HLA associations points to an important role of the adaptive immune system, in particular T-cell sensitization, which can only take place via HLA–TcR interactions combined with proper costimulatory help. In some cases (flucloxacillin),[103,104] drug-specific T cells have been found using IFNγ ELISpot, but again for most DILI-inducing drugs, this has not been tested.

4.13.6.3 Role of Cytokines and Chemokines

Cytokines are regulatory molecules serving as stimulators, regulators, or inhibitors of cells. Immune cells are among the most well known but certainly not unique cytokine-producing and cytokine-responding cells. For diclofenac-induced DILI, genetic associations have been found with IL4 and IL10, and for acetaminophen and other DILI associations, these have been found with blood (plasma or serum) levels of IL1a, IL6, IL8, IL10, IP-10, IL15, IL17, IL21, and monocyte chemoattractant protein 1 (MCP1) (reviewed in Laverty et al.[105] and Li et al.[106]) One of the key cytokines implicated here is TNFα, the role of which is outlined further in the succeeding text.

4.13.6.4 The Role of TNFα

It is evident that the hepatotoxicity of many drugs is dependent on activation of NPCs of the innate immune system, such as Kupffer cells, and consequent release of TNFα. TNFα binding to the hepatocyte will activate both a cytotoxic pathway involving JNK signaling and caspase 8 activation and a survival pathway involving NF-kB. ROS generation sensitizes hepatocytes to TNFα-induced apoptosis mainly through mitochondrial release of cytochrome *c*.[107,108] Many idiosyncratic drugs have been shown to induce redox perturbation and oxidative stress that may activate JNK and/or inhibit the NF-kB activity important in sensitization to TNFα. An example of this is shown by the action of the antipsychotic agent CPZ.[109]

4.13.6.5 Autoantibodies and DILI

Autoantibodies have been found in several cases,[106] that is, antinuclear antibodies (ANA) and anti-MPO in the case of diclofenac, including in a recent study in children, suffering from DILI.[110] In that study, ANA and anti-smooth muscle antibodies were found in 46% and 42% of the investigated population of children, respectively. Autoimmune responses may also point to an important role of the immune system, but one should be aware of the fact that autoimmune responses may occur due to mere adjuvant-mediated bystander activation (e.g., strong inflammatory responses) as well. It can by no means as yet be concluded that these autoimmune responses are causally related based on the occurrence of autoantibodies or autoreactive T cells. However, immune-mediated DILI may occur in patients with an autoimmune history. This was recently shown in a case report in which a patient with a history of systemic lupus erythematosus (SLE) was presented with autoimmune hepatitis to ibrandonates. The 61-year-old female patient showed elevated levels of IgG, and histology of liver biopsies showed the presence of portal and centrilobular hepatitis with lymphocytes, plasma cells, and eosinophils.[111]

4.13.6.6 The Role of the Innate Immune System in DILI

Despite the fact that the link with the immune system and DILI has not been formally proved in man, indications for at least part of the cases seem supportive. Studies in animals, showing liver injury with various drugs that are known to cause DILI in man, however clearly demonstrate that in particular the innate immune system is activated. The best studied drug in this case is trovafloxacin (TVX), at least in mice. Trovafloxacin but not the structurally related drug levofloxacin induced acute and profound liver pathology but only in combination with LPS, peptidoglycan-lipoteichoic acid (PGN-LTA), or TNFα.[112] The liver effects were accompanied by changes in various factors, including TNF-a, IL6, IL18, IL1b, MCP1, IFN-g, and MIP-2. In addition, liver effects were absent in $SOD^{-/-}$ mice, which is indicative of a role of mitochondrial stress, in neutrophil elastase-deficient mice[112] and in mice that lacked TNF-a receptor,[112] and in case CD18 was blocked. These findings together indicate a crucial role of the innate immune system in TVX-induced DILI, but the fast kinetics (effects occur within 4–24 h) also indicate that adaptive immune cells are not involved. Few other drugs (apart from APAP and TVX) have been demonstrated to induce liver pathology in mice, that is, CPZ, diclofenac (DF), and carbamazepine (CAR). CPZ-induced effects were also shown to be dependent on coexposure to LPS or LTA and in addition shown to be mediated by TIRAP-JNK-mediated cell death.

Diclofenac-induced liver effects (liver enzymes and pathology), at relatively high intraperitoneal dosing levels, and in addition a time-dependent increase in gene expression in the liver of STAT3, RORγT and of IL1b, TNF-a, MIP-2, FASL, MCP1, and IL17 have also been demonstrated.[113] Depletion of IL1b strongly reduced diclofenac-induced liver pathology, whereas depletion of IL17 had minor protective effects. Depletion of Kupffer cells with GdCl3 did not prevent liver damage.

CAR requires very high doses to induce a liver toxic effect in mice and also a high repeat dose.[114] In this situation, increases in similar innate immune system-related factors were observed, that is, IL6, IL17, IL13, MIP-2, and FASL. In addition, a role for oxidative stress and metabolism was demonstrated.

In summary, data that are available on DILI not only in mouse but also in rat suggest a triggering role of innate immune factors, but the effects are so rapid that one may conclude that adaptive immunity is not required to cause liver effects.

4.13.6.7 In Vitro Liver Models to Capture the Innate Immune System

Only a few in vitro studies have been performed with regard to the immune system in DILI. Mostly, they are done with hepatocyte cell lines and some with cocultures of hepatocytes and macrophages. In the latter combination, the role of interaction of both cell types can be evaluated, but macrophage activation by, for instance, LPS can also be mimicked by TNFα or other cytokines. This has, for instance, been done with CPZ.

4.13.7 Evidence for a Role of the Adaptive Immune System in Humans

4.13.7.1 Introduction

The adaptive immune system is often implicated in DILI. This is largely because a delayed onset is a common clinical characteristic. Many people develop reactions several months after drug exposure. For example, the median time to the onset of hepatic adverse events following exposure to the tyrosine kinase inhibitor lapatinib is 110 days.[115,116]This time course is very different to a classical drug hypersensitivity reaction (e.g., maculopapular eruption or SJS/TEN), which develops 1–4 weeks after initial drug exposure.[117] Thus, if the adaptive immune system is involved in DILI, additional yet to be elucidated factors trigger the immune response and subsequent tissue injury.

4.13.7.2 Evidence From Studies Using PBMC From Patients With DILI

A case report describing a patient with drug rash with eosinophilia and systemic symptoms has shown that a hypersensitivity reaction can develop into fulminant liver failure.[118] Histological investigations revealed infiltration of granzyme B-secreting CD3+ lymphocytes in close proximity to apoptotic hepatocytes suggesting that T-lymphocytes participate in the liver reaction. Isolation of drug-specific T-cells from DILI patients, but not drug-exposed controls, provides direct evidence that they participate in the disease pathogenesis. Early studies using the lymphocyte transformation test—a simple in vitro assay based on assessment of lymphocyte proliferative responses in drug-treated and vehicle control cultures—detected drug-specific lymphocyte responses in approximately 50% of patients with DILI.[119] Drugs to which T-cell reactivity was detected in more than one patient included co-trimoxazole, allopurinol, fentiazac, captopril, phenytoin, and carbamazepine. More recently, similar data has been reported in Chinese patients with DILI. The lymphocyte transformation test was reported to have a sensitivity (% of DILI patients with a positive lymphocyte transformation test) and specificity (% of control patients with a negative lymphocyte transformation test) of 47.5% and 95.9%, respectively.[120] The phenotype and function of the T-cells were not defined in either manuscript, and additional studies have not been forthcoming.

Liver dysfunction occurs in approximately 20% of patients exposed to isoniazid. As such, its ability to activate drug-specific T-lymphocytes has been studied in detail. Warrington reported that the lymphocyte transformation test was positive in 95% of DILI cases, whereas lymphocyte responses were not detected in patients receiving isoniazid without evidence of liver damage.[121] Interestingly, the patients T-lymphocytes were activated with the parent compound and/or an isonicotinic acid–human serum albumin conjugate. The predictive value of the lymphocyte transformation test in isoniazid-induced hepatitis was studied in a cohort of 61 patients receiving isoniazid for chemotherapy. Liver injury was detectable in not only 58% of the lymphocyte transformation test positive group but also 23% of the lymphocyte transformation test negative group.[122] Metushi et al.[123] have characterized a range of antidrug and autoantibodies in patients with isoniazid hepatotoxicity. Antibodies were not detected in tolerant patients. Although this study does not define the role antibodies play in the disease pathogenesis, the data provides strong evidence that isoniazid induces an immune response only in patients with DILI.

Most recently, the usefulness of the lymphocyte transformation test for diagnosing hepatic reactions to antituberculosis drugs has been studied.[124,125] The sensitivity of the lymphocyte transformation test for all four drugs studied was low (14% for isoniazid, 14% for rifampicin, 14% for ethambutol, and 0% for pyrazinamide[124]). We are conducting a similar study and finding similar data. The lymphocyte transformation test yields largely negative data. However, by cloning T-cells from DILI patients, it has been possible to isolate CD4+ T-cells that secrete an array of cytokines following isoniazid stimulation. Hence, the negative lymphocyte transformation test data likely relates to a low frequency of drug-specific T-cells in patient blood.

Therefore, it is clear that there is still much to learn regarding the role of T-lymphocytes in DILI. With this in mind, flucloxacillin-responsive T-cells have been isolated and fully characterized from patients with DILI. CD8+ clones expressing CCR4 and CCR9 migrated toward CCL17 and CCL25 and secreted IFN-γ, perforin, granzyme B, and FasL following drug stimulation.[104] These studies define the immune basis for flucloxacillin-induced liver injury; however, additional studies are needed to explore the drug-specific T-lymphocyte response in other forms of DILI.

For an increasing number of hepatotoxic drugs (e.g., flucloxacillin,[126] augmentin,[127] lumiracoxib,[128] lapatinib,[116] ximelagatran,[129] and isoniazid[130]), genome-wide association studies have identified specific HLA alleles as important susceptibility factors. These data suggest that a highly restricted drug-derived antigen interacts with the protein encoded by HLA risk allele to activate T-cells in susceptible patients. For flucloxacillin, the CD8+ T-lymphocyte response was shown to be HLA-B*57:01 restricted, which effectively links the genetic association to the tissue injury. Furthermore, naive CD45RA+CD8+ T-cells from volunteers expressing HLA-B*57:01 were activated with flucloxacillin when dendritic cells presented the drug antigen.[104] Similarly, Wuillemin et al. found that it was possible to isolate flucloxacillin-responsive T-cells directly from healthy donor blood lymphocytes using extended

3–8 week culture protocols that involved weekly stimulation with drug and autologous antigen-presenting cells.[131] One must emphasize that flucloxacillin is the only example to date where it has been possible to define the immunogenetic basis of the reaction.

One should also note the following:

- The majority of individuals who carry known HLA risk alleles do not develop clinically relevant reactions when exposed to the culprit drug.
- For most HLA-associated DILI drugs, many patients that develop DILI will not carry the risk allele.

Thus, with a small number of exceptions (e.g., abacavir hypersensitivity), HLA associations are not absolute indicators of risk. Therefore, there is an urgent need to characterize the immunologic parameters that are superimposed onto the HLA association and indeed HLA-restricted T-cell activation to determine why particular individuals develop DILI. One hypothesis that should be tested is that DILI drugs activate innate signaling and hence provide the wave of costimulatory signaling and a cytokine environment rich in inflammatory mediators, to drive the drug-specific T-lymphocyte response.

Finally, the hapten hypothesis states that a drug or a reactive metabolite must bind irreversibly to a protein to initiate an adaptive immune response. For reactions targeting liver, it is widely believed that drugs must modify hepatic protein. To activate T-cells through their T-cell receptor, peptides liberated from the modified proteins must associate with and be presented in the context of specific MHC molecules. In contrast, B-cells can be activated to produce antibodies through a direct interaction of the modified protein with the B-cell receptor. The majority of hepatotoxic drugs have been shown to form reactive metabolites in humans that subsequently modify protein.[8] However, as drugs modify multiple proteins and the drug protein binding interaction is incredibly heterogeneous, it is difficult to define which modifications are involved in the activation of the adaptive immune system.

4.13.8 Signaling Pathways and Mathematical Models: Toward Prediction of DILI

4.13.8.1 Introduction: What Experimental In Vitro and In Silico Models Are Available for the Detection of DILI?

This section should illustrate how the complexities of intracellular signaling pathways and intercellular communication can be addressed in a rational and mathematical approach in order to leverage the knowledge and data gained through mapping the mechanisms and processes.

DILI is a complex process resulting from intricate interactions at multiple levels that despite much effort is still poorly understood. In vitro assays and preclinical models are regularly updated, but increasingly in silico approaches are being considered in parallel with these efforts in order to assist the decision-making process during drug development and unravel underlying mechanisms.

To support selection of the most promising chemical structures at the earliest time point in the drug development, pipeline classification models, such as QSAR models, have been developed that link physicochemical properties of compounds to therapeutic categories like hepatotoxicity.[132–136] For example, Liu et al.[134] developed a drug-induced liver injury prediction system (DILIps) that is based on the identification of 13 types of hepatotoxic side effects. It utilizes information from clinical trials and postmarketing surveillance and the SIDER database[137] to relate drugs with associated side effects. To computationally screen compounds for each of the hepatotoxic side effects, a QSAR model was established. This showed that the combination of three hepatotoxic side effect models ("rule of three" criterion) was sufficient to identify compounds with a high potential of causing DILI.[134] The success of all these approaches depends on a reliable annotation of compounds that cause DILI.

Physiologically based pharmacokinetic (PBPK) modeling can be applied to appropriately simulate the distribution and action of pharmacologically active substances. This, in combination with other methods, will contribute to an improved understanding of DILI. PBPK are multicompartment models that consist of ordinary differential equations (ODEs) following the principles of mass transport, fluid dynamics, and biochemistry and attempt to predict ADME of compounds. ADME properties of a compound are estimated using the octanol-to-water partitioning coefficient and the acid dissociation constant, and from these values for oral absorption characteristics, metabolites binding to proteins (adduct formation), renal clearance, and organ partitioning are calculated. Key parameters related to drug metabolism are estimated using in vitro studies with primary hepatocytes or microsomes.[138] A prime example for the in silico representation of physiological processes involved in DILI is the DILIsym software that encompasses models that span from the organ to the cell and so far focuses on reactive metabolite-induced DILI.[139] The multiscale model is organized in multiple submodels that comprise compound distribution and metabolism, descriptions of glutathione depletion and recovery, mitochondrial dysfunction, hepatocyte life cycle with a focus on cell death, and clinically relevant endpoints such as alanine aminotransferase (ALT) levels. The submodels are integrated to simulate an organism level response. The model uses publicly available data and is highly simplified in several aspects but nevertheless has already supported the formulation of new hypotheses and the optimization of protocols.

Increasing effort is currently directed toward the development of improved in vitro assays, such as cell-based high-content screening[140] and expression profiling,[141] which will provide further insights into mechanisms contributing to hepatotoxicity and will help to significantly improve the accuracy of in silico approaches. So far, studies have primarily used endpoint measurements and focused on metabolic conversion of compounds in hepatocytes and correlating this with hepatotoxicity. However, hepatocyte damage also triggers regenerative processes in the liver, which are coordinated by multiple growth factors and cytokines that are secreted by hepatocytes and NPCs.

4.13.8.2 How to Use In Silico Models to Detect Hepatocyte and NPC Perturbation?

Usually, compounds are metabolized in hepatocytes and then conjugated with hydrophilic substances and excreted. However, during this process, reactive metabolites may be generated that result in protein adducts and stress responses that can lead to hepatocyte apoptosis and/or necrosis; this is considered to be an adverse outcome pathway (AOP).[142] The chemical reaction network of drug metabolism and clearance, for example, via GSH conjugation, has already been successfully modeled by ODEs[143] in an iterative way: clearance and production rates on a tissue level are estimated based on the kinetic rate laws of a PBPK model.

Based on these rates, a flux distribution of cellular exchange rates is computed by flux balance analysis based on stoichiometric models. Detailed mechanistic models of the intracellular events in hepatocytes will be required to specifically address the contribution of inflammatory signaling, reactive metabolite effects, and impaired transporters to hepatotoxicity of compounds. Apoptosis has been extensively investigated using mathematical models, mostly based on ODEs,[144,145] describing the dynamics of caspase 8, 9, and 3 activation. Additionally, apoptosis is highly regulated by feedback mechanisms, for example, via Bid/cytC or via IAP. A key aspect of apoptosis is its switch-like behavior that was theoretically approached by bifurcation analysis.[146] When apoptosis is initiated and ATP levels fall below the value needed for caspase activity, cells can switch to a necrotic state that has been shown to be regulated by signaling pathways.[147] To gain a more comprehensive understanding of the interlinked processes, it is necessary to couple the existing ODE models for redox signalling,[148,149] apoptosis pathways,[144] and drug metabolism.

Upon liver damage, inflammatory and proliferative ligands are excreted by NPCs, such as Kupffer cells, hepatic stellate cells, and liver sinusoidal endothelial cells. The impact of TNFα, primarily secreted by Kupffer cells, and transforming growth factor (TGF)β, secreted by hepatic stellate cells, on hepatocytes has been examined by ODE-based dynamic pathway models.[150,151] To capture the impact of NPC, realistic concentrations of these factors and cocultivation studies would be required to advance the existing models. Furthermore, examination of the impact of the NPC-secreted factors on cell death decisions and specific model adaptations would be important. Thereby, the systematic development of integrative in silico models, considering pro- and anti-inflammatory signaling pathways, offers a powerful tool to simulate and predict the occurrence of idiosyncratic liver injury.

4.13.8.3 What Can Be Learned From Modeling Signaling Pathways for Better Prediction?

DILI triggers regenerative processes comprising the secretion of inflammatory stimuli such as TNFα and TGFβ by NPCs. Infection of the liver elicits antiviral response that are initiated by interferon (IFN) secretion. These inflammatory stimuli activate multiple signaling pathways in hepatocytes and thereby can influence drug-induced hepatotoxicity. By integration of dynamic pathway models of the respective signaling pathways into the mathematical models of cell death, it is possible to simulate and integrate critical mechanisms of signaling effects on toxicity.

A prime example that shows the impact of inflammatory responses on the toxicity of compounds is the toxicity enhancing effect of TNFα on Diclofenac.[152] In general, upon liver injury or infection, Kupffer cells secrete TNFα, which either leads to an activation of NF-κB signaling, which promotes cell survival, or induces the TNFα death receptor complex formation leading to apoptosis. One of the key properties of this pathway is the oscillation of NF-κB translocation, as it shuttles between nucleus and cytoplasm upon TNFα stimulation.[153,154] Several mathematical NF-κB pathway models were designed in order to investigate and increase the understanding of the regulation and function of this oscillation.[150,153,155–157] In a computational analysis of the mathematical NF-κB model by Ashall et al.,[153] different TNFα levels in healthy individuals and patients with chronic inflammation are compared. Their model exhibits a bifurcation point, showing sustained NF-κB oscillations above a certain TNFα concentration and a dampened NF-κB oscillation below.[157] This is of interest for the prediction of DILI, especially in the context of known TNFα-induced compound-dependent hepatotoxicity.[158,159] By interfering with the oscillation, compounds could shift network outputs and thereby might increase the sensitivity to DILI. To unravel the underlying mechanisms, mathematical models need to be applied to predict the contribution to DILI.

During the late stages of liver regeneration, hepatic stellate cells secrete TGFβ, a member of a superfamily of proteins regulating cell proliferation, differentiation, and apoptosis. The formation of an activated ligand–receptor complex on the cell surface results in the activation of the Smad proteins, which translocate to the nucleus and regulate the transcription of target genes, for example, p53 or Bax.[160] Multiple dynamic pathway models of TGFβ signaling have been established.[160–163] The models focus on different aspects of the TGFβ signaling capturing receptor trafficking or nuclear-cytoplasmic shuttling of Smads. Since it was shown that TGFβ signaling is affected by other cytokines, for example, IFNγ,[164] and redox-sensitive reactions,[157] and that it is a key regulator of hepatic fibrosis, it is of particular interest in the context DILI.

In response to infection of the liver, IFN are secreted as important mediators of antiviral responses.[165] It was reported that the occurrence of DILI as an adverse effect of antiretroviral therapy in HIV/HCV coinfected patients was reduced by IFN therapy.[166] This suggests that IFN may affect different AOPs and thereby inhibit the onset of DILI. To date, several modeling approaches have been carried out to study perturbations in IFNα signaling. It was demonstrated that the positive feedback regulator IRF9 is crucial for the amplification of the early dynamics of IFNα-mediated signal transduction.[167–170] This suggests that if compounds or their metabolites affect IRF9, this could influence antiviral responses of an infected liver and consequently may have an impact on the threshold for hepatotoxic effects.

4.13.8.4 How Can the Physiological Response and Toxicological Perturbation of Signaling Pathways for the Prediction of DILI Be Quantified?

Measurements required for the calibration of a mathematical model depend on the modeling approach and the question that needs to be addressed. For example, classification models that link physicochemical properties of compounds to an effect are widely used, for example, the DILIps approach, which is based on databases of physicochemical properties of compounds, patient information, and side effects.[134]

Molecular-scale classification models predict the hepatotoxicity of a compound based on its chemical and physical features and in vitro endpoint measurements using, for example, high-content imaging.

PBPK models quantitatively describe the absorption, distribution, metabolism, and excretion of compounds and consist of compartmental representations of all relevant tissues and the vascular system. PBPK models use in vivo determinations such as measurements in biofluids (e.g., serum, plasma, and urine) and in vitro-derived physicochemical properties of compounds.

At the intracellular scale, stoichiometric models describe metabolic conversion of compounds. These models are constructed based on extensive biochemical knowledge on metabolic enzymes to establish the reaction network and use enzyme kinetics. The exchange rates determined by the stoichiometric models provide integration points into PBPK models, which quantitatively represent time–concentration profiles at higher scales.

Dynamic pathway models are calibrated using quantitative measurements of pathway activation. At the protein level, pathway activation is determined by quantitative immunoblotting, protein arrays mass spectrometry,[150] and various imaging techniques, whereas the dynamics of target gene expression is monitored by qRT-PCR.[171,172]

In conclusion, high-quality, quantitative, time-resolved data are required to establish reliable mathematical models that enable the understanding of mechanisms causing DILI and to facilitate quantitative predictions. Accurately calibrated models will allow the simulation of interindividual differences in enzyme kinetics and protein concentrations. From this, it may be possible to identify targets that positively or negatively affect compound toxicity and thresholds. Ultimately, it is clear that mathematical models capturing DILI mechanisms must be validated with patient-derived material.

4.13.8.5 How Mathematical Modeling Can Improve, for Example, the Human Relevance of Our In Vitro Models

As previously described, DILI results from the complex interplay of multiple biological processes. However, these underlying processes are likely to be clearly defined for every individual occurrence of DILI. Thus, one must identify which combination of inputs leads to detrimental reactions. This in turn allows the exact reproduction of these conditions in our in vitro systems. The difficulty here lies within the complexity of biological systems, making it extremely unlikely to identify and define each condition in which DILI or detrimental reactions occur experimentally. Given that the biological interactions are well defined, mathematical modeling provides the tools to simulate and assess all imaginable input combination and predicts the outcome that can then be validated in vitro.

Fig. 5 exemplifies the process how mathematical modeling is used to improve the predictability of DILI. In vitro data, such as from HepG2 and primary human hepatocytes, are used to define the possible interactions and the stoichiometry within the biological system. Then, PBPK modeling is applied to identify the conditions and concentration of active molecules at the cell surface. These are then used as input parameters for the dynamic pathway model, which in turn predicts the phenotype and reaction of cells, thereby providing crucial information as to whether DILI is likely to occur under these conditions.

4.13.8.6 Conclusions and Future Perspectives

From a general perspective, it is unlikely in the short-term that any single model system is able to incorporate physiologically relevant aspects of all of these mechanisms and thereby demonstrate predictivity for all types of human DILI. The uncracked nut is still the model of idiosyncratic DILI, in which there is real scientific progress being made, but we do not know how this understanding can help to develop predictive models in the laboratory. A particular case in point is our new understanding of the association of several forms of DILI with particular HLA variants. While this is certainly a step forward, it is unclear how this understanding can help us predict ab initio the DILI risk of new chemical entities.

Nevertheless, this review should provide sufficient knowledge to guide the field in its attempts to address the status quo through the development of models of improved physiological relevance. Currently used models that are unable to emulate all of the mechanisms described here but can address selected ones are likely to become part of a new testing paradigm, to be deployed at different points and on different scales, in the drug development process.

There are genuine signs that we are learning the lessons of past failures in safety assessment approaches. Beyond the new realization that prediction needs to be intelligent and mechanistically driven, as spelled out in this review, it is also important to note that several novel (bio)markers have recently been identified, which may be useful for early assessment of hepatotoxicity. For example, microRNAs (e.g., miR-122), HMGB1, and other intracellular proteins, which are passively or actively released by hepatocytes as they exist in the liver and in cell-based in vitro systems, may be helpful in our understanding of the physiological and mechanistic response to chemical stress and could provide an analytic bridge to help us assess the physiological relevance of in vitro models. In addition, high-content screening methods and cellular imaging techniques may provide important information on the physiological pathways that are perturbed by drugs causing DILI.

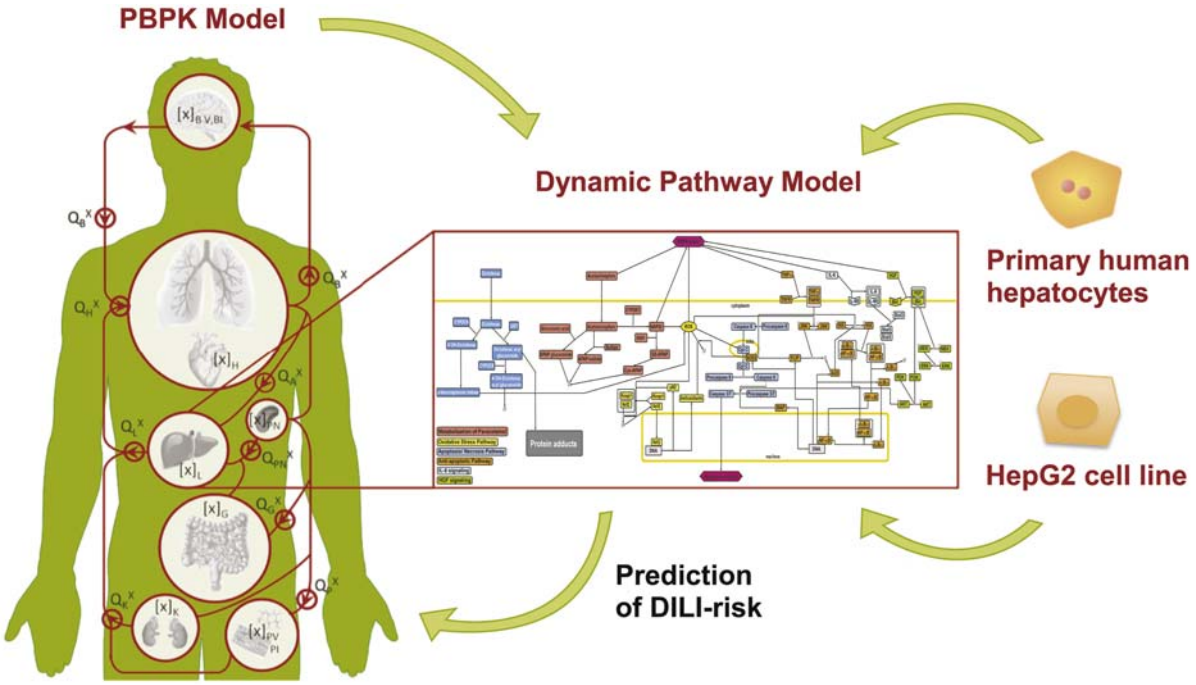

Fig. 5 Dynamics of signalling components from either primary human hepatocytes or the HepG2 cell line are integrated into dynamic pathway models. These models are then connected to the physiologically based pharmacokinetic (PBPK) model to improve the prediction of DILI. Information about compound absorption, distribution, metabolism, and excretion gained from the PBPK model is used for the refinement of dynamic pathway models.

4.14.1 Introduction

The advent of the modern age has provided several material comforts and luxuries. This may be directly correlated with the development of new chemicals, compounds, and materials. One of the main problems with several of these chemicals is the lack of complete safety data regarding their effects on human health as well as some deficiencies in the modern testing paradigm. There are several thousand (>75,000) legacy compounds in commerce that do not have definitive safety data regarding their potential to cause cancer in humans. Based on some estimates, 5–10% of these compounds might be reasonably anticipated to be carcinogenic to humans.[1] Unfortunately, in some instances we learn of the carcinogenicity hazard of compounds only after a cohort of the human population has been exposed to those chemicals and have suffered negative health effects. Due to obvious ethical reasons, humans should not serve as models for carcinogenicity testing, and hence a bioassay system that can confidently identify the carcinogenic hazards posed by these chemicals is needed. Bioassays using rodents have served as a surrogate for the human population and any chemical that is positive for carcinogenicity is deemed to be a human carcinogen unless mechanistic data suggest otherwise. However, continuous improvements are needed because of the recognized occurrences of false negatives and false positives in animal testing, though substantive improved understanding exists today as to the reasons for discrepancies.

Various national and international agencies have done a commendable job in identifying and classifying potential carcinogens using data from rodent carcinogenicity bioassays as well as human epidemiology. In addition, chemical and pharmaceutical companies also conduct rodent bioassays and provide other safety data for product registration and licensing. To date, the gold standard for identifying carcinogenicity hazard is the rodent chronic 2-year bioassay. There is no question regarding the pivotal role played by rodent bioassays in identifying chemicals that pose a carcinogenic hazard to people. Several chemical carcinogens were first identified by rodent bioassays before any epidemiological studies implicated them in causing cancer in the human population.[2] However, due to the substantive backlog of chemicals without safety data and the long time and high cost it takes to complete the rodent bioassays, alternative approaches that are fast and yet provide reliable data are urgently needed.[3] In addition, with increasing interest in the 3Rs (replace, reduce, refine) principal there is also a focus to reduce the number of rodents used in the bioassay while obtaining an answer in a shorter period of time at reduced expense. In order to gain an appreciation of this topic, the past, present, and future of carcinogenicity testing will be discussed. Discussions will be focused on small-molecule pharmaceuticals and environmental and occupational chemical exposures.

4.14.2 History of Carcinogenicity Testing

Before the advent of the rodent regulatory bioassays for cancer hazard identification in the late 1960s, the cancer hazards were usually identified from observational and epidemiological studies. Examples include breast cancer in nuns;[4] nasal cancer in tobacco snuff users;[5] scrotal and nasal cancers due to chimney soot;[6] skin cancer due to sunlight;[3] lung cancer in uranium miners;[7] bladder cancer in aniline dye workers;[8] skin and bladder cancers due to 2-napthylamine and benzidine in dye workers;[9] and lung cancers

due to chromium,[10] nickel,[11] asbestos, beryllium, and arsenicals.[12] Based on these epidemiological data, scientists established that certain chemicals and lifestyles cause cancers in people. In the early 20th century, scientists began experiments using animal models to study cancer hazards of novel chemicals that were being increasingly developed during and after both the world wars. Yamagiwa and Ichikawa[13] painted coal tar derivatives on rabbit ears and demonstrated skin cancer from those exposures. Subsequent studies purified several compounds from the coal tar mixture and demonstrated the carcinogenic hazard associated with the individual constituent compounds in rodents upon repeated exposures.[14]

The use of animals for testing the carcinogenic potential of agents continues to this day and will likely continue in the future. The major assumption of all these animal bioassays is that the changes observed in animals due to chemical exposures also would occur in humans unless proven otherwise. Though several long-term bioassays were conducted during the first half of the 20th century, the guidelines for the bioassays aimed to detect carcinogenic effects of chemicals were only first established in the FDA black book in 1949. Within the National Cancer Institute (NCI) in 1961, a Carcinogenesis Studies Branch was established under the leadership of Michael Shimkin for research on chemical carcinogenesis and also to monitor a contract program on the design and conduct of carcinogenicity studies.[15] One of the first studies included examination of 30 alkylating compounds in Strain A mice for a pulmonary carcinogenic response.[16] Following this study, 35 compounds plus 10 mixtures were examined for carcinogenicity in F344 rats. In 1962, Hans Falk,[17] the head of the bioassay section of the branch, set up a comparative study of 120 pesticides and industrial intermediates in two hybrid mice, including the B6C3F1 mouse, that became the standard National Toxicology Program (NTP) mouse model in later years. As newer environmental carcinogens were identified, more sensitive models such as infant mice and virgin female Sprague–Dawley rats (for mammary tumors) were explored. Due to the high background tumor incidence and the large size, the Sprague–Dawley rat was abandoned and the smaller, easy to maintain F344 that was sensitive to various chemical carcinogens became the preferred rat model in the NCI.[15] The guidelines for the cancer bioassay were published based on a workshop in 1973 and the study design remains essentially the same today.[18] By 1978, the carcinogenicity bioassay program expanded substantially and more than 400 chemicals comprising pharmaceuticals, pesticides, industrial chemicals, food, and tobacco ingredients were evaluated for carcinogenicity by rodent bioassays. In 1978, all the NCI carcinogenicity testing programs were merged with similar efforts at other agencies to form the NTP, housed at the National Institute of Environmental Health Sciences (NIEHS). The bioassay testing methods from the NCI after its various iterations were incorporated into the NTP bioassay.[19] Similar long-term carcinogenicity testing guidelines were published by the FDA,[20] the Environmental Protection Agency (EPA),[21] and the Organisation for Economic Co-operation and Development (OECD).[22] These standardized bioassay protocols increased the scientific validity and acceptance by various regulatory agencies worldwide.

For drug development, by the mid-1980s, carcinogenicity studies conducted by a drug sponsor for the FDA included 3 dose groups of at least 50 animals for rats and mice. In 1987, Center for Drug Evaluation and Research (CDER) was established within the FDA (from the Center for Drugs and Biologics), and soon after, the Carcinogenicity Assessment Committee (CAC) was created to review carcinogenicity protocols and results to promote consistency across the divisions. Although the quality assurance procedures for pathology assessment were outlined by the NTP, CDER/FDA relies on the sponsor for the pathology assessment, only occasionally requesting an external review.[23] Pharmaceutical cancer bioassays typically were conducted in the Sprague–Dawley or Wistar rat and the CD-1 mouse. The standards and system of quality control in the bioassay pathology process, developed at the NTP in the 1970s, are generally recognized and practiced by pharmaceutical companies and contractors conducting rodent cancer studies.

Several organizations have been established to identify and classify carcinogens. Among the data used by these agencies, relevant human epidemiological data followed by the animal (primarily rodent) carcinogenicity data carries the greatest weight in terms of evidence of human carcinogenic potential. Among these agencies, the International Agency for Research on Cancer (IARC), part of the World Health Organization, was established as an intergovernmental agency in 1965. Since 1971, IARC evaluated more than 900 agents, of which more than 400 have been identified as carcinogenic (Group 1), probably carcinogenic (Group 2A), or possibly carcinogenic (Group 2B) to humans, and this information is published in the monographs on the evaluation of carcinogenic risks to humans. In the United States, the National Institute for Occupational Safety and Health (NIOSH) and Occupational Safety and Health Administration (OSHA) were created in 1970 to ensure worker safety from occupational exposures by providing research, education, and training in occupational health and safety. In 1978, the Department of Health and Human Services established the NTP, an interagency initiative, to coordinate, test, and report on various carcinogenic hazards from environmental exposures. In addition, the NTP also publishes the Annual Report on Carcinogens (RoCs) by examining epidemiological, in vitro, and animal data associated with various exposures that a significant US population is exposed to and classifies these potential human carcinogens as known to be human carcinogen or reasonably anticipated to be human carcinogen in the advent of positive data. To date, the RoC has published 13 documents classifying more than 240 substances and exposures. Unlike the IARC, the RoC does not list agents that have been studied and found not to be carcinogens. Similar classifications of potential human carcinogens are provided by various other agencies such as the US Environmental Protection Agency (USEPA); (**Table 1**).

4.14.3 Current Approaches to Carcinogenicity Testing

The objective of the carcinogenicity bioassays for environmental and pharmaceutical chemicals as well as food additives and cosmetics is to examine the carcinogenic hazard associated with 2 years or lifetime exposure of the rodent to the agent in question. These bioassays will determine if there is an increase in the tumor incidence in exposed animals compared to the concurrent and historical controls, target organs of carcinogenicity, tumor latency, preneoplastic lesions, tumor progression, benign and malignant

Table 1 Classification of carcinogens by various agencies

Organization	*Classification*				
IARC (International Agency for Research on Cancer), World Health Organization	*Group 1*: Carcinogenic to humans (118 agents)	*Group 2A*: Probably carcinogenic to humans (79 agents)	*Group 2B*: Possibly carcinogenic to humans (290 agents)	*Group 3*: Not classifiable as to its carcinogenicity to humans (501 agents)	*Group 4*: Probably not carcinogenic to humans (1 agent)
RoC (Report on Carcinogens) National Toxicology Program	Known to be human carcinogen (56)	Reasonably anticipated to be a human carcinogen (187)			
EPA (Environmental Protection Agency)	*Group A*: Carcinogenic to humans	*Group B*: Likely to be carcinogenic to humans	*Group C*: Suggestive evidence of carcinogenic potential	*Group D*: Inadequate information to assess carcinogenic potential	*Group E*: Not likely to be carcinogenic to humans

tumors, tumor multiplicity, and tumor–dose response. This information will be used to determine the no-observed-adverse-effect level (NOAEL) or the benchmark dose (BMD) for establishing point of departure, extrapolation of carcinogenic effects to human exposure levels, and finally examination of potential mode of action (MOA) of carcinogenicity. The BMD is the dose at which a specific adverse response occurs compared to unexposed controls, and the lower 95% confidence limit is termed the benchmark dose level (BMDL). In addition to the lifetime animal bioassays, several in vitro and short-term in vivo tests have also been incorporated into carcinogenicity testing by various testing agencies and industry. These include testing for mutagenicity and clastogenicity using bacteria and other genotoxicity assays[24] (**Table 2**).

As discussed in the previous section, the current guidelines for carcinogenicity testing are the result of an iterative process over the past 65 years. These guidelines provide consistency to the cancer hazard identification process, as well as data for worldwide regulatory assessments and applications, while also optimizing the use of animals for these bioassays. The current guidance documents for carcinogenicity testing have been revised and published by various agencies.[20,25] Most of the details of the bioassay design are very similar across agencies and a brief summary of these guidelines are described here (**Table 3**).

The need for long-term testing of pharmaceutical chemicals and biologics is defined in the International Council for Harmonization (ICH) S1A and S6(R1) documents, respectively. In this article, the focus is only on the chemicals and not biologics. According to the ICH S1 guidelines, pharmaceuticals used clinically for 3 months or more generally require carcinogenicity studies, whereas, in Japan and Europe, carcinogenicity studies on pharmaceuticals are necessary if they are clinically administered continuously for at least 6 months or administered in an intermittent manner that equals 6 months of continuous administration in the clinic. Other pharmaceuticals that are used infrequently do not generally need carcinogenicity testing unless there is a cause for concern, such as radiolabeled imaging agents. Several other considerations for conducting a carcinogenicity bioassay include if there is a cause for concern of carcinogenicity of the pharmaceutical if the product class has carcinogenic potential, structural activity relationship alerts, preneoplastic lesions in repeated-dose toxicity studies, and long half-lives of the parent or its metabolites. In addition, the route of exposure, extent of systemic exposure, pharmacodynamics in animals and in humans (guidelines ICH S1C), genotoxicity of the compounds (guidelines ICH S2A and S2B), and finally the recommended indication and target patient populations are also considered (guidelines ICH S1A).

Table 2 Genotoxicity assays

Gene mutations
- Ames assay (*Salmonella typhimurium*, (*TA 98*, *100*, *1535*, *1537*, *97*, *97a*) *or E. coli* (WP2 *uvrA*)), with/without microsomes
- Tests in rodent somatic cells or transgenic animals
- *Drosophila* sex-linked recessive lethal assay

Chromosome aberrations
- Micronucleus assay in rodent bone marrow or peripheral blood
- Metaphase analysis in rodent bone marrow
- Human lymphocyte metaphase chromosome aberration assay
- Cytogenetic analysis of cultured Chinese hamster cells or human cells
- Mouse lymphoma L5178Y cell Tk (thymidine kinase) gene mutation assay

DNA damage
- Mitotic recombination assay in yeast or Drosophila
- Unscheduled DNA synthesis (UDS) test mostly in rodent hepatocytes
- Comet assay (single cell gel electrophoresis for DNA strand breakage)
- P^{32}-post labeling test (DNA adducts)

Table 3 Study parameters and general guidelines for rodent carcinogenicity studies[a]

Protocol parameter	*Guidelines*
Purpose of study	Identify oncogenic effects in a major proportion of rodents during a normal lifespan
Study design	
Study duration	24–30 months; in ERF bioassays, animals are allowed to live out their natural life spans after the 2 year repeat dose exposures
Animals	
Age at initiation	Male and female, rat and mouse; F344 rat, Sprague-Dawley, B6C3F1, or other strains
Sample size	$\leq$6–8 weeks old
No. of treatment groups	50/sex/group; 100–150/sex/group for "mega" experiment in ERF procedures
Dose selection	$\geq$3 dose groups; 1 concurrent control group/sex Maximum tolerated dose (MTD) is the highest dose based upon minimal toxic clinical and pathological effects in subchronic study; mid and lower doses are based on a variety of factors and purpose
Frequency of dosing	5–7 days/week for 24 months
In life	
Individual body weights	At initiation; 1 $\times$/week for 13 weeks and 4 week intervals to termination
Clinical pathology	Y—10 animals/sex all groups at 2 weeks, multiple time points during entire of study duration
Study termination	
Gross pathology (Y/N)	Y—Detailed necropsy and gross evaluation
Organ weights (Y/N)	Y—Variable number of organs included
Time to tumor (Y/N)	Y
Histopathology	
No. of tissues/organs	30–43
Pathology peer review (Y/N)	Y—Multistage review
GLP protocol (Y/N)	Y—Required by GLP
Statistical analysis of tumor incidence	Survival adjusted quantal-response by poly K testing

[a]These guidelines are compiled from OECD guidelines 451, FDA Redbook (Section IV.C.6 Rev. January 2006), US EPA (OPPTS Guideline 870.4200), National Toxicology Program (Bucher, 2002),[19] European Ramazzini Foundation (ERF) (Soffritti et al., 2002).[26b]

The guidelines on the need for long-term rodent carcinogenicity studies for environmental chemicals or agents (such as nonionizing radiation) are different since they can potentially affect all the human and animal populations in various environmental niches. For high production volume (HPV) chemicals ($>$1 million pounds in the United States or in the OECD $>$1000 tons) and compounds/agents for which widespread environmental exposures are suspected, the long-term rodent carcinogenicity bioassays are needed to assess the carcinogenic hazard associated with these exposures. Of course, not every HPV chemical is a carcinogen, so epidemiological studies, and exposure data (occupational and lifestyle) usually provide a justification for testing for carcinogenicity.

Guidelines on the selection of animal species in the long-term carcinogenicity bioassay suggesting use of the rat and mouse animal models are provided by the ICH S1B and OECD TG 451. The ICH guidelines suggest a number of criteria in selecting a species for long-term carcinogenicity studies. These include pharmacologic responsiveness, repeated-dose toxicologic response, comparative metabolic and toxicokinetic attributes, and intended route of administration. In the absence of clear evidence favoring one species, the rat is usually the recommended species. Additional in vivo tests for carcinogenicity that contributes to the weight of evidence (WOE) may involve short- or medium-term studies using transgenic mice or a long-term mouse study. The testing paradigm is different for the NTP bioassays where 2-year studies are required in both rat and mouse species. The carcinogenicity studies conducted by the European Foundation of Oncology and Environmental Sciences (Ramazzini foundation) consist of full natural lifespan studies in rats, where the repeat dose exposures are stopped at the 2-year time point and the rodents are allowed to live out their natural lifespan.[26] Though the goals of the bioassays conducted by the NTP and Ramazzini foundation are the same, the approaches are similar in some ways and different in others. For more details, please refer to the article by Bucher.[19]

Guidelines for dose selection are provided in ICH S1C, and OECD TG 451 documents, reports from the two International Life Sciences Institute (ILSI) workshops[27] and also other papers.[28] Please refer to these documents for detailed information. In brief, dose levels in the carcinogenicity bioassay are generally based on shorter-term repeated-dose range-finding studies (28-day or a 3-month repeat dose study). Ideally, the doses in the short-term repeat dose studies should be spaced in such a way that a NOAEL, the minimally toxic dose (MTD, also known as maximum tolerated dose), and the dose response curves may be generated. The animals are exposed by the most appropriate route of exposure (feed, drinking water, gavage, intravenous, inhalation, and dermal) that is relevant to the human exposure scenario. Effects specific to certain routes of exposures, such as gavage versus dietary or

drinking water exposures, should also be taken into consideration. The repeat dose exposure usually starts after weaning and continues until the end of the study. The study design should control for various confounding factors such as cage location, time of dose administration, and volume and frequency of handling or manipulation, feed, and litter effects. All the studies should be conducted according to the FDA's good laboratory practices.

Multiple dose groups (up to 5 treated for environmental molecules and 1 control) that capture the range of potential toxicities are included in the 3-month study and the group size is limited to 10 animals/sex/dose. For the 2-year study, groups of at least 50 male and female rats and mice are randomly assigned to 3 treated groups at high, medium, and low doses with 1 vehicle control group. The repeat dose exposure usually starts at weaning and continues till 2 years of age when the animals are euthanized, necropsied, sampled for a complete and systematic gross and microscopic evaluation. For any pharmaceutical compound requiring a cancer study, a 6-month rat chronic toxicity study is also conducted. On some occasions in NTP studies, interim sacrifices (at 6 months, 1 year) are scheduled to allow for tissue burden studies, toxicokinetics, and mechanistic studies. For some NTP studies where maternal exposure and transplacental exposure is suspected, exposure of pregnant rats begins in utero at 6 days of gestation and the resulting F1 pups are continuously exposed for 2 years as a regular chronic bioassay. Additional cohorts of animals are usually added to all dose groups to allow for toxicokinetic and metabolism studies to characterize quantitative dose–response relationships for any anticipated toxic effects.

The selection of the doses for the 2-year bioassay is one of the most critical decisions for the success of the bioassay, thus allowing for meaningful interpretation in terms of human health risk. If the doses are too low, the animals might not be challenged sufficiently resulting in a false negative response and if the doses are too high, it might lead to overwhelming of the metabolic or homeostatic mechanisms resulting in a false positive response. The lowest dose should also receive considerable attention since it should attempt to reflect environmental exposure levels or clinically relevant exposures and aid in the determination of NOAELs. Due to the inherent limitations of the statistical power of a bioassay that employs only 50 animals/dose group due to practical considerations, it is essential to maximize the sensitivity of the bioassay and make sure that the animals are challenged to the maximum extent without causing overt toxicity that impacts the natural lifespan of the animal on the study. It is also important that the animals be challenged at the MTD to give confidence in case of a negative study. This maximum challenge is accomplished by administering the chemicals at the MTD and is defined as a dose that causes no more than a 10% body weight decrement as compared with controls; and does not produce mortality, clinical signs of toxicity, or lesions that would be predicted to shorten the animal's natural lifespan.[18,28b] In addition, the MTD is also limited by physical criteria of the test agent such as solubility, suspendability, stability, aerosol generation limit, and also physiological limits of the animal such $\leq$5% in diet, 5 mL kg^{-1} (rats) and 10 mL kg^{-1} (mice) by gavage, 0.3 mL (rats) and 0.1 mL (mice) for dermal exposure; and lung burden (overload) levels.[29] Further information on the chemicals including the physicochemical characteristics, toxicokinetic data absorption, distribution, metabolism, and excretion (ADME), physiologically based toxicokinetic modeling, and any available literature on the proposed (MOA, especially for nongenotoxic carcinogens) should be taken into consideration during dose setting for the carcinogenicity bioassay. Comprehensive clinical examination and pathology data should capture qualitative and quantitative adverse and adaptive effects in subchronic studies. All this information will also aid in dose level spacing to allow for generation of meaningful dose response curves and determining NOAEL and BMDL as well as identifying threshold effects. Usually, it is very difficult to generate all this information (hazard identification/characterization and dose response data; NOAEL/BMDL-seeking threshold effects; safety assessment of human exposure levels) in one experiment but optimal study design approaches can assist in generation of the maximum relevant information for risk assessment purposes.

4.14.3.1 Experience With Transgenic Carcinogenicity Assays

Two-species rodent lifetime cancer bioassays have traditionally been the primary in vivo testing paradigm to identify cancer-causing agents for environmental agent cancer hazard identification.[30] However, it is not feasible to conduct the standard two-species/two-sex lifetime (2-year) carcinogenicity bioassays to assess the possible carcinogenicity of the many thousands of legacy chemicals in commerce. Also, it was determined that a second rodent cancer bioassay especially, the mouse does not add much value for pharmaceutical safety assessment when compared with alternative models.[31] With gain of significant insights into structure and nature of the human and rodent genomes and with recognition of the common alterations in cancer genes in many human and rodent tumors, genetically modified (GM) animals have been developed and utilized to provide insights into normal and disease-related processes.[32] GM mice have been proposed as adjuncts or replacements for the conventional mouse 2-year carcinogenicity bioassays.[33] Cancer bioassays involving genetically altered mice are shorter in time and less expensive than the traditional 2-year mouse cancer bioassay. Two major types of genetically altered mice have been developed; one type involves creation of GM animals by inserting one or more genes from the same or another species randomly into the host genome. The second type involves targeted insertion by homologous recombination in embryonic stem cells at the gene locus by either partial deletion or mutation at specific amino acid positions for loss or gain of function.[34]

Some of the desirable characteristics of GM animals include phenotypically normal physiology and health prior to chemical exposure, low level of spontaneous tumor incidence, intact genetic stability, increased sensitivity, decreased tumor latency, and expression of the genetic modification in a wide range of tissues to ensure assessment of nonneoplastic and neoplastic effects in all potential target organs.[35] Four mouse models, specifically the heterozygous *Trp53*$^{+/-}$ (B6.129-*Trp*^{tm1Brd}, Trp53$^{+/-}$, or *Trp53*^{def}),[36] FVB/N-Tg.AC (carrying the mouse mutant v-Ha-*Ras* oncogene under the control of the zeta-globin promoter),[37] *ras*H2 (carrying multiple copies of human *HRAS* proto-oncogene),[38] and the xeroderma pigmentosum group A (*Xpa*$^{-/-}$)[39] have been extensively

Table 4 Comparison of the NTP 2-year bioassay with the genetically altered mouse assays[a]

Assay characteristics	*2-year bioassay*	*Tg.AC*	Trpp53^{+-}	rasH2	Xpa$^{-/-}$
Mouse strain	B6C3F1	FCB/N-Tg.AC	B6.129-*Trp53*^{tm1brd*}	CB6F1-Tg-H*ras2*	B6.129-*Xpa*^{tm1Hvs}
Genetic background	C3HeN and C57B/6N	FVB/N	C57BL/6NTac	BALB/cByJJic and C57BL/6J	C57BL/6J
Zygosity/genotype	Heterozygous	Hemizygous for a mutant v-Hras1 transgene	Heterozygous	Hemizygous for human *HRAS* transgene	Homozygous
Recommended chemicals for testing	Wide range of agents	Genotoxic, nongenotoxic	Genotoxic	Genotoxic Nongenotoxic	Genotoxic Nongenotoxic
Age at start of the expt.	6–8 weeks	7–9 weeks	6–8 weeks	7–9 weeks	6–8 weeks
No. of mice/cage	10	1	5	5	1 (male), >1 (female)
Treatment duration	104 weeks	26 or 36 weeks	26 or 36 weeks	≤26 weeks	39 weeks
Route of exposure	Feed, gavage, inhalation, topical, drinking water, i.p.	Topical, feed, gavage	Topical, gavage	Gavage, feed, i.p., drinking water	Topical, gavage
No. of mice/dose	50	15–20	15–20	25	15
Basis for dose selection	MTD[b]	MTD from previous cancer bioassay	MTD from previous cancer bioassay or dose range finding	MTD from previous cancer bioassay	4-week dose range finding study with genetically modified mice
No. of tissues for necropsy and histopathology	>40 tissues	12 tissues	>40 (nongenotoxic) and 12 (genotoxic)	>40 tissues	>40 tissues
Common spontaneous tumor	Hepatocellular adenomas/ carcinomas Alveolar bronchiolar (A/B) carcinomas	Odontogenic tumors, forestomach and cutaneous papillomas, A/B adenomas	Lymphomas, osteosarcoma, hemangiosarcoma	Hemangiosarcoma, A/B carcinoma, cutaneous papilloma, Harderian gland carcinoma, lymphoma	Lymphoma, A/B adenoma, adrenal tumors

investigated by researchers as suitable models for accelerated cancer bioassays.[32,40] The characteristics of each of these models are summarized and compared to that of inbred mice used in the conventional 2-year bioassay, in **Table 4**. The *Trp53*$^{+/-}$ model has been reported to detect primarily genotoxic carcinogens, whereas the Tg.AC and the *ras*H2 models were able to include a broader range detecting both genotoxic and nongenotoxic carcinogens.[40c,41] The standard study design for a rasH2 mouse study includes 3 treatment groups and a vehicle control group composed of 25 animals/sex/group. A positive control group (usually N-Nitroso-N-methylurea (MNU) or urethane) composed of at least 10 animals/sex is required. Note that it is acceptable to only examine microscopically the thymus in the positive control (MNU-treated) group to conserve the pathology resources.[42]

There are several advantages of using GM mice in hazard identifications; use of fewer animals, a more rapid completion of the study (within 26 weeks), a significant reduction in the cost to test a chemical, a larger number of chemicals can be tested, and more translatability, relevant to humans (human cancer genes in the mouse). However, a number of potential problems and concerns have been recognized with the use of GM animals as a primary method to identify carcinogenic agents.[40a,b,43] There are significant genetic background differences, route and type of exposure, degree of organ specificity, between the animals used in conventional and short-term cancer assays. The mechanisms underlying the chemically induced cancers in the GM animals may differ fundamentally from those occurring in non-GM mice due to copy number variation in the transgene and altered global gene expression pattern as both *RAS* and *TP53* are master regulatory genes that control and/or influence many other genes and pathways within the cells.[44,45] Hence, there is a concern that the tumors in the genetically altered animals may arise from different mechanisms or be unique to specific genetic modifications that differ from those occurring in wild-type animal models. Further, the use of the current GM animal data in dose–response assessment (such as NOAEL or BMDL) and for quantitative risk estimation is more problematic due to small sample size typically used in the accelerated bioassay.

The predictivity of transgenic mouse models has been chronicled by workers in the NTP. The transgenic alternatives, specifically the combined predictivity data of *Tp53*$^{+/-}$ (for genotoxic molecules) and *ras*H2 (for nongenotoxic molecules), provide comparable

predictiveness for human response to known (Group 1) and probable (Group 2A) human carcinogens to the rat and mouse lifetime bioassays, alone or in combination. The Group 2A molecules tested in the NTP survey all tested positive using a combined Tg.AC, *Tp53*$^{+/-}$, and *ras*H2 test system. Similarly, of the 14 Group 1 carcinogens tested in this combined Tg.AC, *Tp53*$^{+/-}$, and *ras*H2 test system, 11 yielded positive responses, 1 yielded a negative response, and 2 were untested. In contrast, when applying the conventional 2-species lifetime rodent test system to this same list of 14 Group 1 carcinogens, 5 positive tests, and 1 negative test were reported, with most (8) untested. These data support the belief that the transgenic alternatives alone provide comparable ability to detect Group 1 and 2A carcinogens as the lifetime combined rat and mouse lifetime bioassays. Of course, the rat and mouse lifetime responses predict for rat and mouse carcinogenicity, thus predicting with precise accuracy for possible (Group 2B) human carcinogens, since all positive rodent responses are automatically classified as Group 2B by IARC, when there is inadequate evidence of carcinogenicity in humans. The *Tp53*$^{+/-}$ and *ras*H2 lifetime models do not predict as well for the rat and mouse lifetime bioassay outcomes; thus these two model systems reduce the generally recognized high false-positive rate, while not compromising the ability to identify known (Group 1) and probable (Group 2A) human carcinogens. That is, these models substantially improve the precision in the identification of human cancer risk for pharmaceutical agents. Numerous drugs that had rodent responses known to be nonpredictive are listed as IARC Group 2B agents, such as phenobarbital and benzoyl peroxide.[40b,46]

A direct evaluation of these models would be to compare the results of carcinogenicity assays conducted in the GM models with the tumor data seen in non-GM mouse bioassays even though the purpose of the bioassay is to predict for human response.[47] The degree of concordance for the bioassays conducted in *Trp53*$^{+/-}$, Tg.AC, and *ras*H2 bioassays with 2-year NTP mouse chronic bioassay was about 57% (17/30), 61% (20/33), and 82% (23/28) of the chemicals tested, respectively.[47b] There were 11 chemicals that induced tumors in the NTP mouse bioassays that were not detected as carcinogens by the bioassays conducted in GM models (tested in one or more but not all GM models). Four of the 11 chemicals were trans-species carcinogens with a positive response in both the rat and mouse NTP bioassays and the remaining 7 were carcinogenic in the NTP mouse only. In another comparison with chemicals independent of their genotoxicity and immunosuppressive ability but are identified as known human carcinogens or reasonably anticipated to be human carcinogens, the concordance was 86% (12/14), 67% (8/14), and 43% (6/14) in the *ras*H2, the Tg.AC, and the *Trp*53$^{+/-}$ model, respectively.[47b] On the other hand, the concordance with the NTP mouse (21/21) and rat (20/20) bioassays was 100%. This finding is a reflection of the ability of the traditional rodent studies to not miss true positives but they probably give rise to some false positives, as well. However, the traditional mouse or rat models have their limitations especially with false negatives when testing well-known human carcinogens such as cigarette smoke and certain immunosuppressive agents.

Even though the genetically altered mouse models have shown some value in identification of carcinogens and noncarcinogens, they cannot completely replace the traditional rodent models. These genetically altered mice seem to be more efficient in correctly identifying noncarcinogenic agents (thus reducing the false positives), but they tend to miss certain carcinogens, thus prone to some false negatives.[47b] Even combining multiple genetically altered mouse models will not likely detect all trans-species and human carcinogens. In summary, the overall accuracy in classifying carcinogens and noncarcinogens was good, but all GM strains failed to detect some chemicals known to be human carcinogens when used as stand-alone assays.[40b] However, when the GM models (especially the *ras*H2 mouse) were combined with a rat bioassay, the overall predictivity was better than the traditional rat and mouse cancer bioassays.[40b,48]

Further validation studies to optimize study designs and protocols can address some of the concerns associated with sample size, study duration, genetic instability, dose response curves, and reproducibility. The small sample size ($n=25$) of the GM mouse protocols compared to the traditional mouse protocol ($n=50$) may result in incongruent conclusions with respect to dose–response curves and detecting threshold effects for certain chemicals.[47b] In general, due to the small sample size and reduced study duration, no effect may be detected in the low dose group, falsely suggesting a threshold effect. This is especially apparent for chemicals such as phenolphthalein (lymphoma) and urethane (hemangiosarcoma, lung tumors).[47b] This is an important consideration for risk assessment purposes of environmental chemicals (probably not so much for pharmaceutical compounds) since the regulatory requirements of the EPA differ for chemicals with and without thresholds for carcinogenic response. Increasing the GM mouse sample size to 50 for studies aimed at detecting thresholds and comparing to the traditional mouse studies may be necessary for generating risk assessment data for environmental chemicals. Of course, there could be erroneous conclusions regarding thresholds even with a sample size of $n=50$ but with a smaller sample size, the error rate is probably high for certain chemicals. The issue of pathway-dependent effects and different mechanisms of chemical carcinogenesis, especially for nongenotoxic carcinogens, operating in these genetically altered models are a concern and further studies are needed to address the translatability of chemical carcinogenesis pathways in the genetically altered mice to humans. As we learn more about the mechanisms of chemical carcinogenesis, newer GM rodent models may be developed to advance the MOA and risk assessment studies. Genetically altered mouse models such as PPAR alpha knockout (KO), aryl hydrocarbon receptor (AhR) KO, CYP2E1 KO, and CYP1B1 KO mouse models have shown value in this regard.

4.14.4 Future Approaches of Carcinogenicity Testing

There has been a call to improve the carcinogenicity hazard identification process as well as to reduce, modify, or even abandon the 2-year bioassays over the past few decades. The often cited reasons are the cost of the 2-year studies, the use of large number of animals, the long duration of these bioassays, uncertainty of the outcomes in terms of equivocal evidence of carcinogenicity,

high background tumor response in the B6C3F1 mouse, and uncertainty in extrapolation of the rodent tumor response to human cancer risk.[49] On the other hand, the cancer bioassay (and other animal studies) has been evolving from a simple "cancer-no cancer" screening assay to one that provides more mechanistic information on toxicity and carcinogenicity over the past decades. In the following section, discussion will be focused on some of the current and future approaches to carcinogenicity testing.

4.14.4.1 New Paradigms in Rodent Bioassays

Most human carcinogens have proven to be rodent carcinogens when they were adequately tested. On the other hand, some of the rodent carcinogens do not necessarily pose a carcinogenic hazard to people due to species-specific mechanisms as well as laboratory testing artifacts, such as high dose exposures that greatly exceed human exposure values.[50] For genotoxic carcinogens, there is a high degree of correlation with tumor response across species. However, for nongenotoxic carcinogens, there are several examples of species-specific mechanisms that result in tumors in only certain species.[50] Historically, the rodent carcinogenicity data served a critical role for identifying carcinogenic hazards and due to historical knowledge and experience with this data, the risk assessors usually find comfort in having and using the rodent carcinogenicity data. When alternative approaches are proposed for replacing the traditional rodent carcinogenicity bioassays, the toxicology/pathology community becomes polarized between groups/individuals that believe that any positive response in rodents is relevant for humans regardless of the mechanism versus those that believe that the rodent lifetime bioassay no longer adds value, precluding toxicology/pathology community alignment for change. As a result, though imperfect, the rodent carcinogenicity bioassays continue to be central but modifications to those bioassays in terms of reduced animal numbers and alternate strategies based on WOE are increasingly being considered for hazard identification and risk assessment. In this next section, some of the current and future approaches that are being considered to optimize the rodent bioassays and in some cases, even obviate the need for the rodent carcinogenicity bioassays for cancer hazard identification are presented.

4.14.4.2 Proposals for Pharmaceutical Carcinogenicity Studies

The small-molecule carcinogenicity assessment guidelines of ICH suggest a 2-year rat bioassay and either a 2-year mouse or an alternative 6-month transgenic mouse carcinogenicity bioassay. There is increasing evidence that in certain cases, the 2-year rat bioassay may potentially be obviated in the absence of certain characteristics.[51] Monro[51a] has proposed that the few pharmaceuticals known to cause cancer in humans operate through at least one of four features: genotoxicity, immunosuppression, hormonal activity, and chronic toxicity. Reddy and colleagues[51b] demonstrated that the absence of histopathologic risk factors (cellular hypertrophy, hyperplasia, and atypical cellular foci) associated with neoplasia in *any* organ within the animal was highly predictive of a negative rat carcinogenicity bioassay. A consortium of pharmaceutical companies examined the various risk factors associated with rat carcinogenicity bioassay data from 182 pharmaceutical compounds and came up with a proposal termed NEGCARC (*N*egative for *E*ndocrine, *G*enotoxicity, and *C*hronic study *A*ssociated histopathologic *R*isk factors for *C*arcinogenicity).[51c] According to this proposal, little value is gained from a 2-year rat carcinogenicity bioassay for compounds that lack (1) treatment-related histopathologic risk factors (hypertrophy, hyperplasia, and atypical cellular foci) of rat neoplasia in *any* tissue within a 6- or 12-month chronic toxicity study, (2) positive response in any of the assays in the ICH S2 genotoxicity battery (bacterial mutation, in vitro mammalian cell mutation or clastogenicity, or in vivo clastogenicity), (3) perturbation of hormonal function by WOE approach, and (4) a positive response in a 6-month transgenic mouse carcinogenicity bioassay. Sistare et al. proposed that in the absence of these four NEGCARC criteria, the 2-year rat study may be waived and only the 6-month transgenic mouse study or a 2-year mouse study needs to be conducted, while in the presence of any one of the four NEGCARC criteria, then a 2-year rat study along with the corresponding mouse study need to be conducted. Their data suggests that the absence of any of these four risk factors is highly predictive of a negative rat carcinogenicity bioassay.[51c] Sistare and colleagues estimated that this decision paradigm has the potential to eliminate over 40% of the rat 2-year bioassays for new pharmaceutical compounds without compromising patient safety.

Based on this proposal, in 2013 the FDA considered a revision to the ICH S1 guidance on rodent carcinogenicity testing and issued a notice for public comments with the goal of introducing a more comprehensive and integrated approach to address the risk of human carcinogenicity associated with small-molecule pharmaceuticals (Federal register 78:52). The FDA applied the NEGCARC criteria on an independent set of 60 additional pharmaceutical compounds and achieved similar results as Sistare et al.(2011)[51c,52] In addition, the Japanese Pharmaceutical Manufacturer's Association (JPMA) also applied the NEGCARC criteria on a set of 64 compounds and attained similar results. The independent replication of the results by various agencies appears to give confidence for the application of NEGCARC criteria for current and future drug development.

There are, however, some reservations in following the NEGCARC criteria in its current form. Any one of three triggers based on histologic risk factors, hormonal perturbation, and genotoxicity can trigger a 2-year rat cancer bioassay. This rule has to be followed in its entirety and no exceptions should be made especially with arguments about the translational relevance of these respective triggers for tumor risk.[52] The NEGCARC proposal assumes that the endpoint of the bioassay is assessing tumor risk in rodent (rat) models and not necessarily of the tumor risk in humans, that is, the false negative cases (positive for 2-year rat carcinogenicity tumor response and negative for all the three risk factors) in their data set have no implications for human cancer risk. If there was positive rat carcinogenicity data, the sponsors and risk assessors would consider this during clinical trials. In the absence of this lifetime rat tumor data, the risk assessors and sponsors would be challenged if there was a tumor response during phase 3 clinical trials or during postmarketing.[52] Of course, demonstration of positive responses in humans in the presence of negative lifetime

mouse and rat studies plagues the current testing paradigm (e.g., cigarettes and tacrolimus), unfortunately there is no perfect testing strategy. While the NEGCARC proposal is reasonably sensitive (79%) in predicting rodent carcinogens based on just three risk factors, it does not consider equally important mechanistic data about the compound's pharmacology. In fact, when the compounds from various agencies (Pharmaceutical Research and Manufacturers of America (PhRMA), FDA, JPMA) were unblinded, the compound's known pharmacologic properties could easily predict the rodent tumor response of the false negatives (14%), where NEGCARC criteria failed to accurately predict rodent tumor response.[52] Immunosuppressive drugs represent a pharmacologic category that pose cancer risk in humans that is not detected in rodent bioassays, a category not included in the NEGCARC paradigm, but a risk factor that could possibly be identified in subchronic toxicology studies.

Based on the earlier observation and analysis of various datasets (by the PhRMA, FDA, JPMA, and European Union, EU), it was concluded that the NEGCARC criteria and the compound's pharmacology (WOE approach) could reasonably predict the outcome of the 2-year rat carcinogenicity bioassay at the two extremes of the spectrum, that is, negative predictions could be made when the predictive signals are absent and positive predictions could be made when the predictive signals are present. However, an in-between category of compounds exists where the outcomes of carcinogenicity outcomes cannot be predicted with certainty (Federal register 78:52). This WOE approach can potentially assess the need for conducting a 2-year rat carcinogenicity bioassay and subsequently classify the pharmaceutical compounds into three categories (1, 2, 3a, 3b): Category 1: product likely to be tumorigenic to humans and a 2-year rat study would not add value; Category 2: uncertain tumorigenic potential in humans and hence a 2-year rat study is likely to add value; Category 3a: likely to be tumorigenic in rats but not in humans based on prior-established and well-recognized carcinogenic mechanisms not relevant to humans and a 2-year rat study would not add value; Category 3b: likely not tumorigenic in either rats or humans and no 2-year rat study is needed. Based on these categories, as discussed earlier, it is easy to categorize compounds into Categories 1 and 3b. Classification of compounds into Category 3a may also be relatively easy provided the sponsor and the regulatory agency agree on the strength of the WOE. In the lack of sufficient or incomplete data for the WOE analysis, a number of compounds will be categorized into Category 2, where a 2-year rat study will provide value for risk assessment.

The ICH expert working group is currently conducting a prospective evaluation (exercise) where sponsors voluntarily submit carcinogenicity assessment documents or WOE assessments to the drug regulatory agencies prior to the initiation of the 2-year rat studies or before the results of the 2-year rat study are known. The sponsors also prospectively categorize (1, 2, 3a, or 3b) their compound regarding the need for a 2-year rat study. The ICH working group independently evaluates the data in a blinded manner and arrives at their own category for that data. The intention of this exercise is to check the predicted outcomes of their respective hypothesized categories against the actual tumor outcomes from the completed prospective 2-year rat studies. The information generated from this exercise will demonstrate the concordance or discrepancies between the WOE assessment by the sponsors and the FDA regulators. These experiences will provide an opportunity to generate more refined, uniform, unbiased approaches for the WOE assessment before it can be incorporated into ICH S1 guidelines.

As the learnings from this exercise result in changes in cancer hazard identification practices with the WOE approaches, it is clear that the rat 2-year studies will not be replaced completely in the near future. For EPA-regulated compounds, specifically the legacy compounds, the necessary subchronic data typically are not available, obviating utility in this circumstance, but this paradigm may have significance for compounds in development.

4.14.4.3 Future Paradigms for Environmental and Other Carcinogens

The paradigms of carcinogenicity testing of environmental chemicals appear to be similar to that of pharmaceuticals. However, there are significant differences between the two especially when it comes to the nature of the compounds. During pharmaceutical development, any compound exhibiting genotoxicity or indicating potential carcinogenicity are typically discarded early in development. The only exceptions are pharmaceutical compounds being developed for cancer (some of them are genotoxic compounds) or other life-threatening conditions or seriously debilitating disease such as lupus (immunosuppressive agents), where benefits may outweigh the risk of cancer. However, most of the environmental chemicals selected for carcinogenicity testing today are suspected carcinogens based on epidemiological data, or are likely widespread in the environment with no cancer hazard data, or are HPV chemicals with a high potential for occupational or environmental exposures. In addition, chemicals such as pesticides, feed additives, and packaging materials in contact with food also have the potential for widespread and indiscriminate exposure to humans and environment. The risk tolerance for environmental chemicals is very low compared to pharmaceutical compounds due to the widespread nature of environmental exposures compared to targeted exposures in patient populations, respectively. Even though false negatives and false positives are inherent in the current testing paradigm, it is very difficult if not impossible to eliminate a regulatory test although it is quite possible to add on new regulatory tests. Nonetheless, it behooves toxicologists/pathologists to periodically challenge the existing testing paradigms and work to improve the testing methods.

The NTP carcinogenicity bioassays are considered the gold standard, however, due to the time, expense (especially considering the large numbers of untested compounds in commerce), and the need to conserve animal resources through the 3Rs principle (*replace* rodents with lower order species or in vitro systems, *reduce* the number of animals, *refine* the endpoints to derive maximum information with minimal pain and improving animal welfare), NTP and other stakeholders are considering alternative approaches for determining toxicity and subsequently carcinogenicity hazard.[53] As discussed in the beginning of this article, there are several thousands of chemicals within the environment and in commerce and newer chemicals being produced every year, it is imperative to come up with newer resource efficient methods of identifying the cancer hazards associated with these chemicals. Of course, it

would be impractical to expect 2-year rodent bioassay data on all these legacy chemicals, though any new chemical must be tested using the contemporary paradigm prior to commercialization.

In developing the future carcinogenicity paradigms, the approaches taken by various investigators and programs fall into two broad categories: top down or bottom up, that is, the top-down approach is a traditional approach and typically starts with the chemical-induced adverse effect and the subsequent studies are focused in evaluating the MOA and mechanisms of action in animals with a focus on human relevance, while the bottom up is a predictive approach and typically consist of several high-throughput in vitro screening assays aimed at understanding the chemical-induced biological perturbations with a focus to elucidate the MOA and then apply quantitative in vitro to in vivo extrapolation (qIVIVE) and subsequently predict an adverse outcome (AO) in animals and humans.[54] None of these two approaches in isolation provide a solution for future carcinogenicity studies. However, the lessons learnt from these two approaches may provide unique approaches to carcinogenicity testing. Cancer is a chronic disease and a certain amount of time should elapse before the earliest cancer signature can be detected, that is, the process of carcinogenesis has initiated and progressed unequivocally (probably within 6–12 months in rodent cancer models). Biomarkers that can confidently detect these earliest cancer signatures will provide a path forward for future carcinogenicity testing. Hence, at least in some cases, the need for the traditional 2-year carcinogenicity studies may be obviated if these biomarkers can be identified. In the end, future cancer bioassays may probably be condensed to <2 years but since cancer is typically a chronic disease, a certain amount of time should elapse before the earliest signature of cancer can be detected.

In the following paragraphs, some of the alternative approaches that are being undertaken by various stakeholders in toxicity testing and regulation are discussed.

4.14.4.4 Toxicology Testing in the 21st Century (Tox21)

Tox21 is a federal collaboration among the EPA, FDA, and NIH (National Center for Advancing Translational Sciences (NCATS) and NTP) to test a collection of 10,000 environmental chemicals and approved drugs (Tox21 10K library) for their potential to disrupt biological pathways and cause toxicity by using several 100s of high-throughput screening (HTS) assays. EPA's Toxicity Forecaster (ToxCast) is a similar initiative that uses HTS screening methods (>700 in vitro assays) and computational toxicology approaches to rank and prioritize chemicals (>2000 chemicals) for further testing. The principal goals of the Tox21 program are to prioritize legacy chemicals for further in-depth toxicological evaluation, identify mechanisms of action for further investigations, and develop models that better predict chemical effects in biological systems.[53] One of the first objectives of the Tox21 program is to develop better methods to quickly and efficiently identify if a chemical has the potential to cause negative health effects in humans by identifying disruption of cellular processes. These data will be used to identify hazards associated with carcinogenicity, endocrine disruption, reproductive toxicity, immunotoxicity, neurotoxicity, genetic toxicity, and other potential toxic effects. These HTS assays together with bioinformatics and systems biology approaches examine the "hits" from the high-throughput assays and help understand the underlying cellular and molecular pathway alterations in biological systems. The chemicals identified in the initial screening assays will be prioritized for testing in more complex biological systems in the increasing order of biological complexity such as cells, organ cultures, *Caenorhabditis elegans*, zebrafish, and rodents. Since disruption of biological processes and toxicity plays a significant role in the process of neoplasia, identification of chemicals by these approaches can be a way to prioritize chemicals for further testing and also identify chemicals that are of not much concern, for regulatory purposes.

The HTS data that is being generated in the Tox21 initiative is providing multiple streams of data on biological perturbations induced by chemicals in various cell lines with and without metabolizing capability. While this information is important in understanding the alterations in molecular pathways, it still does not provide reliable information on the potential phenotypic alterations that could result from these molecular alterations, that is, there is still no convincing way to qualitatively measure the consequence of these molecular alterations on the phenotypic responses that could either result in adaptive or adverse responses in the whole organism. As discussed earlier, prioritizing and testing in higher order biological systems will provide more convincing information on the biological relevance of these molecular alterations. This paradigm of HTS testing and validation in more complex biological systems is an iterative process and a critical body of knowledge needs to be accumulated before these alternative toxicological methods become mainstream. For now, the regulatory agencies cannot rely exclusively on the HTS data to identify and regulate potential carcinogens. In the near term, these data could be operationally used to identify chemicals with few or no "hits," indicating that these legacy chemicals may be a low priority for carcinogenicity testing. These HTS data (and mechanistic data) can also be used to regulate chemicals with no safety data but that are within a class of chemicals with a well-defined MOA.

Some of the IARC Group 1 agents with less than sufficient evidence of carcinogenicity in humans were regulated based on the well-accepted relevant MOA that is conserved across species including humans. 2,3,7,8-Tetrachlorodibenzo-para-dioxin (2,3,7,8-TCDD) binds to AhR and causes similar downstream molecular alterations resulting in cell proliferation and inhibition of apoptosis, mechanisms that are conserved in humans and experimental animals. 2,3,7,8-TCDD was classified as Group I carcinogen based on the conserved MOA and even in the absence of sufficient epidemiological evidence of carcinogenicity. This classification was ratified in subsequent years by concordant human epidemiological data, supporting the cancer risk based on the conserved MOA.[55] Chemicals (such as 2,3,4,7,8 pentachlorodibenzofuran and 12 dioxin-like polychlorinated biphenyl (PCB) congeners) that activate the AhR nuclear receptors and cause subsequent downstream effects at very low concentrations and in a dose-dependent manner are classified in the same class as 2,3,7,8-TCDD (a known class I carcinogen) and can be categorized as IARC Group I carcinogens even without sufficient evidence of carcinogenicity in humans.

4.14.4.5 The Promise of -Omics Approaches

Genomic and epigenomic technologies (-omics) have the potential to alter the practice of traditional toxicology by providing data that describes genome-wide molecular alterations underlying toxicity and carcinogenicity in various organs and in vitro cell culture systems.

Toxicogenomics is the application of genomics (transcriptomics, RNA-Seq, DNA-seq), epigenomics (methylation and histone modifications, miRNA alterations), proteomics, and metabolomics to characterize tissue responses secondary to chemical exposures. Due to the substantial qualitative and quantitative dynamic range of protein alterations in toxicities, it is technically challenging to comprehensively capture these alterations by the currently available technologies.[56] On the other hand, the dynamic range of the transcriptomic responses is more amenable to capture by the oligonucleotide probesets (cDNA arrays) and have been adapted to such a wide extent in the field of toxicology that transcriptomic responses in toxicity are commonly referred to as toxicogenomics.

Toxicogenomics (transcriptomics) provide a genome-wide snapshot of the differential gene expression profiles and subsequently an insight into the molecular pathways associated with various toxicities and carcinogenicities.[57] This technology enables comparison of alterations in molecular pathways of various chemical-induced toxicities and carcinogenicity and thus promises to be a valuable tool for the identification of corresponding hazards related to chemical exposures. Initially and even currently, toxicogenomics are predominantly descriptive in nature, where the molecular pathways altered by various chemical exposures provide a clue to the MOA of a particular phenotype (toxicity or carcinogenicity).

The idea that transcriptomic data can be used for predictive toxicology was based on the demonstration that chemical-specific gene signatures may be derived from hepatic gene expression data from various chemical exposures.[58] Subsequent demonstration that gene signatures derived from training sets containing chemicals with known modes of action could be used to identify previously unknown or blinded chemicals with similar modes of action provided an impetus to use this approach to study carcinogens.[58b,59] With increasing knowledge based on chemically induced carcinogenic mechanisms, toxicogenomics is increasingly being leveraged for prediction of potential carcinogenic effects based on short exposures in which morphological evidence of neoplasia or preneoplasia are not typically present. The premise behind the use of toxicogenomics for the prediction of carcinogenicity using tissues from very early exposures (3 days to 3 months) is that repeat dose chemical exposure initiates unique chemical-specific molecular pathways in the cells early on that ultimately progress to neoplasia. Thus, predictive toxicogenomics aims to examine tissues from very early exposures for the alterations in these molecular pathways in tissues with or without morphologic evidence of preneoplasia or in some cases even without histologic lesions. This approach was successfully exploited in the areas of predictively toxicology and carcinogenicity, where a gene signature is generated based on the transcriptomic responses of known genotoxic and nongenotoxic carcinogens and this gene signature data is compared against unknown compounds for their genotoxic and nongenotoxic hepatocarcinogen phenotypes, respectively.[59b,60] The success of these prediction models depends heavily on the robustness and quality of the training set. In addition, the test tissue samples generated should have similar protocols as the training sets and any departures from the protocols of the training set result in poor signature performance.[60b,61] A metaanalysis of short-term rat studies on over 150 compounds from different laboratories suggested that gene signatures for nongenotoxic carcinogenicity were relatively robust and were deemed worthwhile in the early assessment of the chemicals for prioritizing for further validation studies but not yet for regulatory decision making.[62] An important limitation of these data is that most of the current toxicogenomic approaches are liver-centric and the predictive signatures probably may apply only to cancer hazards where liver is the target organ. In order to make these toxicogenomics approaches widely applicable for safety assessment, chemical-specific toxicogenomic signatures should also be developed for other target organ systems in the body.

These predictive toxicogenomics tools are not necessarily intended to replace the traditional chronic rodent bioassay for carcinogenicity but rather to guide compound prioritization, and provide mechanistic data to understand the MOA. It is generally accepted that the process of chemically induced toxicity or carcinogenicity consists of simultaneous alterations in numerous molecular pathways resulting in disruption of cellular homeostasis that eventually manifest as morphological phenotypes of cellular degeneration, necrosis, hyperplasia, and neoplasia. These changes occur over a period of time that range from hours to weeks to months to years. The time frames of predictive toxicogenomics studies usually range from 3 to 90 days and the odds of detecting an actual molecular alteration reflecting preneoplasia or neoplasia will probably increase with time. Another factor that is not typically considered in these predictive toxicogenomics studies especially for predicting carcinogenicity is the fact that any "gene signature" that is identified reflects a disruption of normal physiological homeostasis, but it does not take into account if that altered physiological state is an adaptive or adverse finding. However, with the generation of large databases with signatures for all known chemical carcinogens and noncarcinogens based on various time points and doses established in a single model system can potentially serve to predict carcinogens with greater accuracy. Until then, predictions that are based on limited training sets leave much to be desired for regulatory purposes.

Toxicogenomics may not accurately predict carcinogenicity from short-term studies but transcriptomic data from those studies could serve as valuable tools in dose response studies for calculating transcriptional BMDs and identifying points of departure (an estimated dose near the lower end of the observed range that serves as a reference point for human health risk assessment) for cancer and non-cancer endpoints.[63b] In the absence of a rodent cancer bioassay data or human epidemiological data, this approach is especially useful to arrive at a dose where there will be no transcriptional alterations and thereby no negative health effects would be expected at exposures below those doses. In a series of studies, Thomas et al.[63] used the BMD approach and has demonstrated a good concordance between the cancer or noncancer apical endpoints (any observable outcome such as a clinical sign, histological

change, or death) and transcriptional changes. These BMD values for the apical and transcriptional changes in the target organs (based on biological processes or signaling pathways) were comparable even with studies of varying duration ranging from 5 days to 13 weeks, suggesting this approach is robust for identifying doses at which there is minimal biological activity of the compounds in question.[63d] This approach could be expanded to other unknown chemicals by including a battery of eight tissues that represent the most common sites of rodent carcinogenicity and establish the lowest transcriptional BMD value across all analyzed tissues that would be used to estimate the point of departure. It should be emphasized here that this approach does not provide definitive evidence of carcinogenicity and cannot substitute a traditional rodent cancer bioassay but these values could serve as the starting point for risk assessment purposes especially for chemicals with limited toxicity or no carcinogenicity data.[64] However, one apparent limitation to this approach is that it may result in some false positives since alteration in transcriptional profiles does not necessarily mean an adverse response. For example, rodents exposed to chemicals such as theophylline or ginseng that were negative for carcinogenicity in rats and mice of both sexes could show transcriptional alterations and transcriptional BMDs could be calculated based on the dose responses. On the other hand, the issue of false negatives has not been sufficiently addressed by these approaches. Some chemicals may have limited transcriptomic alterations at early time points and there could be a latency in eliciting these significant transcriptomic changes and thus could potentially contribute to a false negative prediction. Further research is needed to fill this issue.

It has been demonstrated that cancers resulting from certain chemical exposures induce distinct mutation spectra and preferentially affect certain cancer genes.[65] Examples of chemical-specific mutation spectra in corresponding cancers include C:G>A:T in tobacco smoke induced lung cancers, T:A>A:T in aristolochic acid induced urothelial tumors, C:G>A:T in aflatoxin B1 induced hepatocellular carcinomas, and C:G>T:A in ultra violet (UV) light induced melanomas.[65a] Similarly examples of chemical-specific mutations in cancer genes include *KRAS* in tobacco smoke induced lung cancers, *EGFR* mutations in lung cancers in nonsmokers, *TP53* in aristolochic acid induced urothelial tumors, and *CTNNB1* in hepatocellular carcinomas. Demonstration of distinct genetic mutations in cancer genes and the corresponding mutation spectra in rodent tumors provides a translational context to human cancers.[66] As discussed earlier, the genetic events in the chemical carcinogenesis are initiated early on and their signatures may be identified by examining tissues from those animals at earlier time points before the cancer is presented clinically. Using in vitro approaches, it has been demonstrated that these mutation spectra and gene signatures may be identified in immortalized fibroblasts exposed to various chemicals such as aflatoxin B1, aristolochic acid, benzopyrene, and UV light.[67] These proof of concept studies provide an impetus for future approaches of understanding each of the unique chemical-induced mutation spectra using in vitro and shorter-term animal exposure studies.

Another area in toxicogenomics that could add value for future carcinogenicity testing is the field of epigenetics. Epigenetics comprises of any heritable change in the gene expression mediated by DNA methylation, histone modification (posttranslational modification of histone proteins by methylation, acetylation, phosphorylation, etc.), nucleosome positioning, and alterations in noncoding RNAs (miRNA, long ncRNA) that are not due to DNA sequence alteration. Alterations in global methylation of some cancer genomes is a well-known phenomenon and is responsible for the activation of the tumor promoting genes, loss of imprinting, and elevated mutation rates.[68] Data suggests that epigenetic alterations may be early events in the carcinogenic process and these alterations may be carcinogen specific and tissue specific, suggesting that epigenetic biomarkers could serve as surrogates for carcinogenicity prediction based on short-term animal studies.[69] In addition, just as in genetic mutations that may be either driver or passenger mutations, carcinogen induced epigenetic alterations may also be categorized into driver or passenger epigenetic changes. Monitoring for the driver epigenetic changes from shorter-term exposure studies may have value in carcinogenicity predictions. The volume 100 of the IARC monograph has highlighted the literature on the epigenetic mechanisms of carcinogenic chemicals such as diethylstilbestrol, chromium (IV), nickel chloride, tobacco, alcohol, and smoky coal emissions.[70] These examples demonstrate a promise of epigenetics in carcinogenicity assessment. However, the field of epigenetics in chemical carcinogenesis is still burgeoning and as more datagaps (normal epigenome in various tissues with and without chemical exposures and the corresponding phenotype anchoring) are filled, this information can be leveraged to study chemical carcinogenesis and risk assessment.

4.14.4.6 Adverse Outcome Pathway (AOP)/MOA Framework

The OECD launched the AOP approach to take the mechanistic data into consideration and link the exposures and its related consequences with the eventual phenotype (or AO).[71] The AOPs link the molecular initiating event (MIE) and one or more intervening key events (KEs) through key event relationships (KERs) to the eventual AO (apical endpoint such as toxicity or carcinogenicity).[72] An MIE is the first step in an AOP pathway and represents the initial interaction between a chemical and a protein within an organism that can be causally linked to the apical endpoint. A KE is a critical step(s) necessary for the progression of the MIE to the subsequent steps in the AOP. KER describes the causal relationships between KEs. These AOs may be at the cellular, tissue, organ, organism, or population level. Prior to the AOPs, the WHO/International Programme on Chemical Safety (IPCS) launched the MOA analytical framework for chemical carcinogenesis based on a series of KEs critical in carcinogenesis, identified using a weight-of-evidence approach based on the Bradford Hill criteria.[73] The MOA approaches are similar to the AOPs' but they are more chemical or chemical class specific, whereas the AOPs are pathway specific and not chemical specific. The advantage of these approaches is that when a key observation is made, the upstream or downstream events may be predicted based on the well-established AOPs or MOAs.

These frameworks are constantly being developed and refined for various apical endpoints. Once a comprehensive network of AOPs are developed and a critical toxicological knowledge base is built, in vitro approaches that can measure MIEs or KEs can be used for predicting and prioritizing chemicals for carcinogenicity. For example, detection of a MIE such as alkylating ability of a chemical could suggest an AO of a gene mutation. It is known that alkylation of DNA in male premeiotic germ cells leads to heritable mutations and alkylation of DNA in somatic cells leads to somatic mutations that may subsequently result in neoplastic transformation (initiation). DNA alkylation and adducts may be measured by high-performance liquid chromatography or immunological methods. The alkylation of DNA is the MIE; the failure to repair DNA sufficiently and subsequent mutation formation are KEs; and the inherited mutations in the off-spring or tumor formation are the AOs.[74] Thus, the AOPs may be able to predict AOs for various chemical exposures based on the large amounts of in vitro data generated from the HTS approaches on respective chemicals. This example is relatively linear and straightforward and very few disease processes have such elegantly defined pathways. In reality, disease processes are complex and could include multiple, interacting pathways (AOP networks) with shared KEs, feedback loops, thresholds, life stage, and sex and species specificity.[75] In addition, the quantitative information or magnitude of each of the MIEs and KEs are important variables in AOPs and are vital for differentiating adaptive from adverse effects in organs and organisms. Thus, at the moment, these AOPs and MOAs based on in vitro data may be useful for prioritization of compounds for further testing but do not replace the animal testing for carcinogenicity for the majority of the chemicals. A recent FutureTox II highlighted the need to accelerate the development and refinement of the AOPs in chemical carcinogenesis using short-term animal studies, computational models that integrate in vitro data with advanced literature data mining techniques.[76] Other highlighted future strategies include targeted development of cancer AOP-based assays and complex cell culture models that account for human genetic heterogeneity. Another approach is to conduct systematic literature mining that focus on key characteristics of carcinogens and hallmarks of cancer and develop assays that target these key features and hallmarks[76b,77] (**Table 5**). As implied earlier, it will take decades before a comprehensive database of AOPs are worked out for various chemical carcinogens and it is going to be an iterative refinement process until they can be confidently applied for risk assessment purposes.

4.14.5 Conclusions

The rodent cancer bioassay and genetic toxicity assays have served an important role in protecting public health from environmental and occupational carcinogens and also for developing safer pharmaceuticals. However, these approaches are low throughput, expensive, time consuming, and sometimes have debatable relevance for human health. In view of the lack of safety data for

Table 5 Key characteristics of chemical carcinogens

Characteristic	*Examples of relevant evidence*
1. Electrophilicity or can be metabolically activated	Parent compound or metabolite with an electrophilic structure (e.g., epoxide, quinone, etc.), formation of DNA and protein adducts
2. Genotoxicity	DNA damage (DNA strand breaks, DNA–protein cross-links, unscheduled DNA synthesis), intercalation, gene mutations, cytogenetic changes (e.g., chromosome aberrations, micronuclei)
3. Alters DNA repair or causes genomic instability	Alterations of DNA replication or repair (e.g., topoisomerase II, base-excision or double-strand break repair)
4. Induces epigenetic alterations	DNA methylation, histone modification, microRNA expression
5. Induces oxidative stress	Oxygen radicals, oxidative stress, oxidative damage to macromolecules (e.g., DNA, lipids)
6. Induces chronic inflammation	Elevated white blood cells, myeloperoxidase activity, altered cytokine and/or chemokine production
7. Immunosuppressive ability	Decreased immune-surveillance, immune system dysfunction
8. Modulates receptor-mediated effects	Receptor in/activation (e.g., ER, PPAR, AhR) or modulation of exogenous ligands (including hormones)
9. Causes immortalization	Inhibition of senescence, cell transformation
10. Alters cell proliferation, cell death, or nutrient supply	Increased proliferation, decreased apoptosis, changes in growth factors, energetics and signaling pathways related to cellular replication or cell cycle control, angiogenesis

R.; Stewart, B. W.; Baan, R. A.; Cogliano, V. J.; Straif, K. Key Characteristics of Carcinogens as a Basis for Organizing Data on Mechanisms of Carcinogenesis. *Environ. Health Perspect.* **2016**, *124* (6), 713–721.

1000s of legacy environmental chemicals, there is an urgent need to develop assays and methods targeted for cancer hazard identification that are inexpensive, high throughput, and have a short turnaround time. So far, no single alternative approach can satisfactorily replace the rodent cancer bioassay. However, these newer methods can arguably identify chemicals that may not pose a cancer hazard based on the absence of significant biological perturbations in the in vitro cell culture systems, assays in lower order organisms, qIVIVE models, and short-term animal studies coupled with toxicogenomics approaches. The recent NTP experience with the West Virginia Elk river chemical spill has taken these approaches (toxicogenomics, genotoxicity testing, in vitro approaches, testing in lower order organisms, short-term rodent studies) and provided safety information for risk assessment purposes without conducting a chronic rodent bioassay.[78] The pharmaceutical and chemical industry have been using these strategies for compound prioritization and dropping candidate compounds from the development pipeline for decades.

In the future, the rodent cancer bioassay will continue to provide value but may not be needed in some circumstances. Targeted in vitro assays, advanced literature mining tools, genotoxicity assays, quantitative structural activity relationship studies, cancer AOPs based on HTS data, short-term animal studies with mechanistic assessments (toxicogenomics, immunosuppression, hormonal perturbation, etc.), genetically altered animal models, and cancer biomarkers will inform on the potential carcinogenicity of a compound with sufficient confidence. In cases where these multiple streams of data do not confidently inform on the compound's carcinogenic ability, the traditional rodent bioassays will remain indispensable.

4.15.1 Introduction: Emerging Translatable Safety Biomarkers

Drug safety is an important cause of drug candidate attrition in the biopharmaceutical industry. Rates of attrition due to toxicity are highest in preclinical and Phase I clinical trials, with a failure rate estimated at 50% of drug candidates. Further attrition of drugs at regulatory filing (post a successful Phase III) and postmarketing highlight the need for improved prediction and assessment of safety in drug development.[1,2]

The FDA has recognized that innovation is needed to achieve more expeditious and accurate risk-benefit assessment in the drug development process. To this end, the critical path opportunities report and list of priorities was generated in 2004–06. An era of forward-looking regulatory science has emerged with new regulatory Guidances and instruments from multiple health authorities (FDA, EMA, and PMDA) that encourage the discovery, evaluation, and qualification on new safety biomarkers.[3]

This article will focus on several emerging biomarkers for toxicities that are considered by drug developers and health authorities to be poorly monitorable that is, when there are no existing biomarkers for detection or prediction of toxicity, or where specific performance attributes (i.e., sensitivity and/or specificity for the toxicity) could be improved. These emerging biomarkers denote an expanded toolkit of minimally invasive, stable, and tractable safety biomarkers for translational use that is, biomarker performance in preclinical drug testing is also applicable to clinical contexts of use. The value of these biomarkers lie in individual patient monitoring to detect or predict toxicity, or epidemiological evaluation of a population's risk status for developing drug-related toxicity. Although the emphasis here will be on biomarkers in body fluids, it is important to note that advances in bioimaging technology have resulted in innovative application of this modality in preclinical and clinical safety monitoring, particularly for cardiotoxicity, For toxicities where there are routine biomarkers (often clinical pathology tests) that provide a historic benchmark for safety monitoring, the intent of emerging biomarkers is to complement these existing markers by adding diagnostic accuracy and/or improving predictivity. A point of emphasis in this article, and germane to any new test, is that characterization and understanding of a biomarker is a lengthy and incremental process. Much still remains to be learnt of these emerging biomarkers, however their promise for improvement in drug development and patient care outweighs some information gaps that can be addressed by the greater scientific community generating and sharing new information on the biomarker.

4.15.2 Translational Safety Biomarkers

A toxicity biomarker is an objective measurement of a pathologic response to a therapeutic intervention resulting in a toxicologically important structural or functional change in a tissue or biological system. These biomarkers may signify tissue-specific toxicity that is; leakage of cytosolic enzymes such as ALT from the liver with liver injury, or a mechanistic process that is, elevated serum cytokine concentrations diagnostic of cytokine release syndrome (CRS). Translatable toxicity biomarkers are applicable to both animals and humans. The desired goal for new translatable safety biomarkers is to advance a minimally invasive tool that adds value or outperforms existing biomarkers in the detection or prediction of toxicity. These biomarkers are evaluated preclinically to identify relationships between drug exposure, drug activity, and toxicity to underpin safety assessment in clinical trials. In preclinical toxicity studies, the potential of a biomarker for noninvasive monitoring can be thoroughly evaluated in comparison to histopathology as the gold-standard safety endpoint. Response of the biomarker to the drug in preclinical safety studies can potentially predict biomarker changes in clinical trials.

In preclinical development, biomarkers can be used for internal decision-making to assist in lead drug optimization, candidate drug selection, evaluating the potential monitorability of the toxicity in patients, and to dose selection for first in human trials. Biomarkers in the preclinical setting should always be evaluated together with histopathology to provide an integrated assessment of toxicity and establish the utility and context of use (COU) for the biomarker for a specific drug-related toxicity.

Translatable safety biomarkers can be used to derisk uncertainty of the human translatability of suspected animal-specific drug toxicity. A sensitive and specific safety biomarker can ensure the safe conduct of clinical trials and proof of a hypothesis that toxicity seen in preclinical studies may not be relevant to patient populations under study. In clinical studies, safety biomarkers can predict future toxicity, risk stratify patients based on susceptibility to drug-related toxicity, and monitor for early safety signals. Safety biomarkers are used to profile the safety of a drug to assess the therapeutic index, which is the exposure margin between efficacious and toxic drug concentrations. Enhanced use of emerging safety biomarkers has the potential for improving patient safety by preventing unmanageable adverse drug reactions. In an era of tailored (or precision) medicine, defining the risk-benefit ratio in individual patients is an attractive prospect for improved patient outcomes.

4.15.3 Methodology of Biomarker Qualification and Assay Validation

4.15.3.1 Molecular Classes of Biomarkers

The majority of emerging safety biomarkers are proteins measured in easily accessible biofluids (i.e., blood, urine). Some of these markers are enzymes and are quantified with activity-based assays on clinical chemistry analyzers. Other proteins are quantified by mass with immunoassays, and less commonly, by mass spectrometry. For protein biomarkers, it is essential to characterize the molecular form (i.e., full length or fragment, monomer or higher order complex) of the biomarker that is qualified to diagnose toxicity. Particularly with immunoassays, antibody pairs may differ between assays and therefore various forms of the protein could be measured. Alternative forms of the protein may have widely different release kinetics into the circulation, half-life, and biological interactions. Various "omics approaches" for example, genomics, proteomics, metabolomics have surveyed vast numbers of molecules of a specific class (respectively, RNA, protein, metabolites) for biomarker discovery and are now maturing to evaluate individual or combinations of these candidates as biomarkers of toxicity. Subfields of these approaches have also been explored to search for unique molecules that may more sensitively and specifically relate to the toxicity under investigation, examples include lipid biomarkers and posttranslational modifications of proteins for example, glycomics (glycan modifications).

MicroRNA (miR) is an exciting new subfield of genomics that has emerged recently. MiRs are short noncoding RNA (19–23 nucleotides in length) that bind to complementary sequences within mRNA to destabilize the mRNA and/or repress protein translation. miRs are of interest as safety biomarkers due to the high species conservation and sequence homology for some molecules, stability, reagent availability (probes are easy to design and synthesize), and potential for tissue specificity.[4] There are 1881 annotated human

microRNA loci in the latest miR database (miRBase release 21). Extracellular forms of miRs are largely complexed to RNA-binding proteins such as Argonaute-2 and high density lipoprotein, or encased in exosomes, microparticles, or apoptotic bodies. The release mechanisms of miRs from cells into the circulation are still under active investigation, therefore it is not well understood what could influence the measured levels of a circulating miR species. Additionally, extracellular miRs may be transferred from cell to cell by exosomes. Consensus on optimized methodology for miR detection and assay validation criteria have yet to be established, owing to the novelty of this type of biomarker. There is currently no standardized approach for sample preparation, normalization, and quantification, which will hamper comparability and reproducibility between published reports[5]. The results of studies are best viewed independently, with relative differences (rather than absolute quantification) as a realistic measure for biomarker performance

4.15.3.2 Biological Qualification

The biological qualification of a biomarker is a process that provides adequate evidence that a biomarker quantifiably and accurately measures a toxic effect as compared to an accepted gold standard. In preclinical studies, the gold standard is often histopathological grading of tissue injury*. In clinical studies, less invasive measures, including preexisting monitoring tools, expert opinion of clinicopathologic findings, and ancillary testing may also be enlisted. The approach for biomarker qualification has a corollary with the diagnostic accuracy assessment of clinical laboratory tests for diagnosing disease. Formal regulatory qualification (outlined in the section below) includes specific claims on when and how the biomarker can be used to detect a specific toxicity.

Biomarker qualification is necessarily a step-wise approach that begins with discovery of candidate biomarkers (Fig. 1). The discovery stage may take the form of "omics experiments" where model toxicants are studied and genomics, proteomics, and

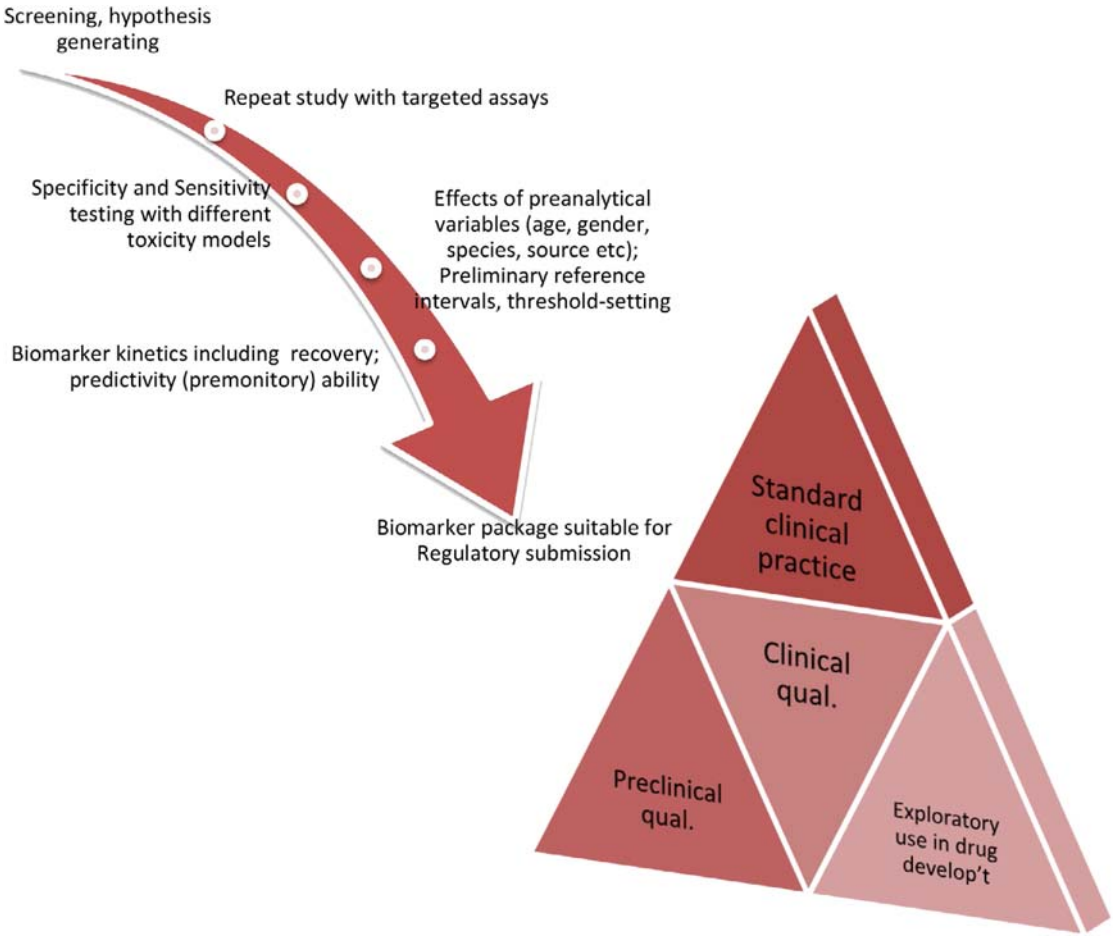

Fig. 1 The process of biomarker qualification from discovery to regulatory qualification. Biomarker discovery begins with studies that generate biomarker candidates that are correlated with a histologic and/or functional endpoint of toxicity. Biomarker candidates are interrogated with repeat studies using different models to determine if the relationship with toxicity is consistent across pharmacologic agents and toxicity mechanisms and to determine the kinetics and biologic behavior of the biomarker. Biomarker performance in preclinical models is followed-up with clinical qualification studies. Preanalytical aspects of sample handling, preliminary reference intervals and thresholds, together with analytical performance of targeted assays, are defined. These data are presented in a biomarker submission for regulatory qualification of the biomarker in defined contexts with an articulated approach to interpretation and application.

metabolomics (to name a few) analysis of biological samples profile the changes in a broad swath of these molecule classes associated with the toxicity. This can be conducted using clinical samples, but is more commonly done in animal studies using model toxicants. Animal models have considerable advantages by controlling multiple variables, adequate power, reduced selection bias (when selecting patients based on traditional/poor monitoring endpoints) and paired comparison to invasive measures of toxicity such as histopathology. In addition, multiple toxicants encompassing distinct mechanisms of toxicity can be evaluated for biomarker response with minimal resource (compared to clinical studies across multiple therapeutics). Results of screening studies must always be repeated in a follow-up study, preferably using targeted assays with higher performance specifications for sensitivity and quantification of the biomarkers of interest. Candidate biomarkers may also be selected based on the similarity of toxicity to spontaneous disease states and the hypothesis that clinical laboratory tests for the disease could potentially be relevant to toxicity monitoring.

The specificity of the biomarker for particular organ toxicity can initially be supported by the tissue expression profile of the biomarker and whether it is confined to a specific organ. The expression of some biomarkers is up- or downregulated with toxic insult and this dynamic expression adds to the understanding of the biomarker response. Tissue microarray experiments to document the expression pattern in multiple species are useful in determining the potential translatability of the biomarker across species, particularly from rodent to dog to human. Classic specificity studies for safety biomarkers test the performance of the biomarker for toxicity in a single organ in a model where multiple other organs are also affected. This will determine if there are other tissue sources for the biomarker and if a change in organ function associated with the drug will alter the clearance of the biomarker. These experiments are usually prioritized after proof that biomarkers have the required sensitivity.[6]

The biologic plausibility of the new biomarker helps substantiate its validity. Broadly, fluid-based biomarkers constitute (1) leakage markers liberated by the injured cell, (2) response markers to injury, and (3) measures of functional change. Determining the mechanism underlying the relationship of the biomarker to toxicity will allow greater understanding of the biomarker response and inference of its utility across different toxicities and drug classes.

The temporal kinetics of the biomarker response are important for ascertaining if the biomarker has suitable sensitivity and appearance (relative to dosing) to monitor early toxicity when tissue damage or functional change is nonadverse. Ideally the biomarker should also reverse with resolution of the toxicity. The onset, maxima, and reversal of the biomarker change should be characterized relative to a gold-standard measure of organ toxicity and in relation to drug exposure concentration. If blood volumes allow, modeling the exposure-biomarker-toxicity relationship can offer insight on the biomarker response and corroboration of the potential utility of the biomarker for the toxicity.

Due consideration must be given to preanalytical variables. These are factors that can influence the levels of the biomarker prior to variables introduced by technical analysis and later data handling and interpretation. Preanalytical variables include potential effects of biological variables of age, sex, strain, environment (to name a few) and impact of sample collection, handling, and storage. The final series of studies could include assessment of prognosis where there is sufficient range of toxicity to include reversible toxicity, adaptation, and persistence of toxicity without progression, progressive injury, and severe adverse injury.

Biomarker qualification is an iterative and progressive process. The current Regulatory strategy is used by private–public consortia to evaluate and qualify several new safety biomarkers with overlapping performance and contexts of use. Potentially these biomarkers may be used individually or as combinatorial measure. Qualification of a seemingly redundant set of biomarkers in the first instance is based on the logic that it is premature to "choose a winner" on what is essentially a limited dataset for emerging biomarkers. To fully understand the diagnostic performance of each biomarker over a multitude of drug classes in different species and different patient populations, they must be upheld and further explored by drug developers to characterize the ultimate utility in a variety of contexts.

4.15.3.3 Statistical Approaches

The statistical assessment of biomarker discovery and evaluation is itself a field of active investigation. Regulatory guidance for the statistical evaluation of clinical diagnostic tests exist,[7] however the statistical approaches to biomarker qualification are often the product of iterative consultation and advice discussion with health authorities. This can detract from the estimated performance of the new biomarker in the clinic. A brief description of common statistical approaches is provided to help familiarize the reader to this aspect of biomarker evaluation.

4.15.3.4 Biomarker Evaluation

Statistical approaches to biomarker selection and evaluation enlist classification, regression, and tree-based methods. The ability of a biomarker to classify or discriminate between the presence or absence of toxicity is most commonly assessed by the receiver operator characteristic curve (ROC). This graphical presentation compares the true positive rate (or sensitivity) on the *y*-axis, to the false positive rate (1-specificity) on the *x*-axis (Fig. 2). A curve is created relating the true positive rate to false positive rate at every biomarker cutpoint (or threshold value). The area under the ROC curve (AROC) provides a measure of accuracy, therefore perfect discrimination would be represented as a curve to the upper left of the graph, with an area of 1 (100% accuracy), and an area of 0.5 represents an equal rate of true positive and false positive detection, or 50% accuracy (curve A in Fig. 2). Desirable performance is considered to be ≥ 0.8 or 80% (curve B in Fig. 2). The 95% confidence intervals should be reported to indicate the precision of the estimate. The use of only one value to describe the whole curve results in a loss of information, therefore a partial AROC within a desirable range of false positive rates (i.e., focusing on the left portion of the curve) or a single measure of sensitivity at a cutpoint

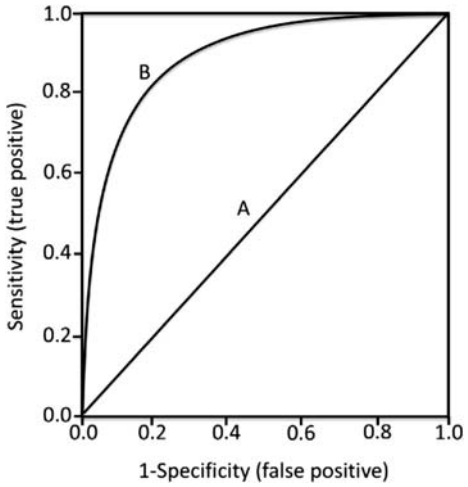

Fig. 2 The receiver operating characteristic (ROC) curve depicts the true-positive and false-positive rates at every cut-point threshold value of a biomarker or test. The area under the ROC curve (AROC) is a measure of the accuracy of a biomarker. As depicted by curve A, a biomarker that has an equal false-positive and false-negative rate (50% sensitivity, 50% specificity, 50% accuracy) has an AROC of 0.5 and is a poor test. A biomarker with good diagnostic performance would have a curve similar to B, with a diagnostic accuracy and AROC of at least 80% and 0.8, respectively.

of 90% specificity, can also be reported. The AROC is very useful during early evaluation of translational biomarkers, however in later stage assessment of clinical outcome testing, the metric lacks clinical meaning.[8]

Biomarker combinations (or panels) for diagnosing or predicting toxicity can be assessed using regression analysis and decision tree analysis. In the latter, various combinations of the biomarkers are evaluated for their ability to predict the outcome (i.e., toxicity) and are particularly useful for nonlinear relationships; random forest is one such method.[9]

To determine if novel biomarkers can improve diagnostic performance of the existing test or risk prediction model, several approaches are used. The delta of the AUC between the existing test with and without the new biomarker/s can be calculated to assess the improvement in discrimination. However, when the existing test performs reasonably well, it is harder to show significance. More importantly, this measure may produce incorrect estimates due to inherent bias when using highly correlated datasets.[8] New measures that describe net improvements in classifying both toxicity positive and toxicity negative states are becoming more popular and continue to be refined.[10] Two such measures are the net reclassification index (NRI) and the integrated discrimination improvement (IDI) index. The NRI evaluates the net proportion of subjects reassigned a diagnosis (i.e., toxicity vs. nontoxicity) or for clinical risk models, a risk categorization (e.g., low vs. high). Usually, the proportion of classifications that are improved or made worse for both toxicity cases and the controls are added to calculate a holistic index. The IDI is calculated by determining the average probability for toxicity minus the average probability for nontoxicity. An improved IDI assigns higher probability (or risk) to toxicity cases than to nontoxicity. There are strengths and limitations to these new measures of improved performance, which do not allow for a consensus approach at this stage.[8]

4.15.3.5 Normal Range and Threshold Setting

Understanding the biological variability of a biomarker is essential to interpreting changes in biomarker values. Characterization should include relevant species, strain, source (for preclinical testing), ethnicity (clinical testing), gender, and age stratification. Usually this data is first generated in healthy individuals, and with time may be expanded to different patient groups, and explore more detailed observations pertaining to circadian differences, diet, body mass index, and other variables. Understanding biological variability can help make rational use of reference intervals and for interpreting single measurements and serial analysis of a biomarker.

Reference intervals are usually constructed prior to clinical evaluation of a novel biomarker. These may be estimates in the first instance, simply to describe biological variability and 95% confidence intervals for a relatively small number of subjects.[11] In preclinical biomarker evaluation and toxicity studies, emphasis is most often placed on baseline data and/or the intervals (i.e., defining the upper and lower limit) determined from the control group within the study. This approach can better account for study variables (source, age, husbandry, dosing, vehicle formulation, blood collection, assay reagent changes, technical variables) than a "one size fits all" reference interval.

Between subject (or interindividual) and within subject (or intraindividual) variation can be derived by serial measurements in subjects representative of the population the biomarker will be used in. By determining these measures of biological variation, one can ascertain whether changes in a biomarker should be assessed compared to previous measurements in the individual or against a reference interval. Generally, if an individual has high variation in the biomarker in comparison to low variation between subjects, then evaluation is improved by use of a reference interval. On the other hand, low within individual compared to high between individual variation would support evaluating each individual based on previous measurements for that subject. The significance

of differences between serial measurements of a biomarker should also be interpreted with regard to expected biological variability. The concept of reference change value (RCV) defines the difference in value for serial measurements to be statistically likely to represent a change beyond that attributable to biologic variability alone at a defined probability (e.g., $p < 0.05$). The RCV can therefore be used to define a pharmacologic or toxicologic effect of a drug on the biomarker. These estimates of biological variability have been calculated for emerging kidney toxicity biomarkers in the rat.[12,13]

4.15.3.6 Assay Validation

Assay validation is the technical performance involving testing of biomarker assays evaluated against preset criteria (or specifications) for acceptance. This testing is designed to demonstrate that the assay is appropriate for its intended use. The analytical variables of the biomarker test are also identified in this stage and the contribution of technical error to the measured biomarker concentration can be estimated. There is an incremental approach to the rigor of assay validation and data quality that couples with the progressive stages of biomarker qualification from exploratory use to decision-making. Common terminology and basic principles related to assay validation are provided in (**Tables 1** and **2**, respectively) with a focus on immunoassays for protein

Table 1 Assay validation terminology

Parameter	*Definition*
Accuracy	Is a measure of the bias of a sample from the true or nominal/expected value. It is usually expressed as the percent of the expected value or percent recovery
Calibrator	A material that represents the biomarker. It may be purified native protein or a recombinant (synthesized) reagent. Also referred to as a standard
Calibration curve	The fitted concentration–response curve of a set of calibrators that define the quantification range of the assay. Also referred to as standard curve
Coefficient of variation	Calculated as the standard deviation of a set of repeated measures divided by the mean
Cross-site validation	Compares test results at different sites using the same assay and same sample aliquots
Dilutional linearity	Demonstration that samples with initial biomarker concentration above the upper limit of quantification can be diluted into the measuring range of the assay and meet acceptance criteria
Interference	Substances that result in physicochemical interference and artifact in the measured value of the biomarker (e.g., hemolysis, lipemia, icterus, pH)
Limit of detection	The limit of detection as defined by a signal greater than background. This is usually calculated as 2 or 3 standard deviations greater than the buffer (or blank matrix without biomarker)
Lower limit of quantification	The lowest measureable value that meets acceptance criteria for accuracy and precision
Minimal required dilution	Minimal dilution of biologic sample that removes matrix interference to meet criteria for accuracy and precision. Manufacturers of commercial kits will usually recommend dilution that optimizes assay performance
Multiplex	Multiple biomarkers tested together in one assay run
Parallelism	The biologic sample (sometimes spiked with a standard within the working range of the assay) is serially diluted with buffer to determine if there is a proportionate response relationship to that of the calibration curve thereby confirming the suitability of the calibration curve for biomarker quantification in the biologic sample
Precision	Precision is the random error assessment of repeated measures. It is calculated as the percent coefficient of variation = (standard deviation/mean) × 100%
Quality control sample	A set of sample pools, consisting of either native matrix with endogenous biomarker, native matrix spiked with calibrator, or calibrator-spiked buffer with a predetermined value that is used to verify the assay is performing to specified criteria. The QC samples should span the working range of the assay (i.e. high, medium, and low)
Recovery	Percent recovery of the measured compared to the nominal or expected value is a measure of accuracy. Recovery = measured value/expected value × 100%
Robustness	Ability of assay to withstand small variations in procedure to produce repeatable results
Selectivity	Detection of a specific protein biomarker in a complex biologic matrix without interference from endogenous substances of exogenous compounds (e.g., drug and metabolites)
Sensitivity	The lowest biomarker concentration measurable in the assay. This can refer to the limit of detection or the lower limit of quantification and should be defined
Singleplex	Single assay for an individual biomarker
Specificity	Ability of assay to detect the intended biomarker with negligible affinity for structurally similar molecules
Stability	The retention of *physicochemical* characteristics of the biomarker over storage conditions to maintain recovery of the biomarker within prespecified acceptable limits
Upper limit of quantification	The highest measureable value that meets acceptance criteria for accuracy and precision (often 20% CV, 80%–120% recovery)
Validation	Validation of an analytical method by assessing a series of performance measures against preset specifications
Working range	Measurement interval of the assay as defined by highest and lowest limit of quantification. Also known as dynamic range

Table 2 Assay validation principles

Assay performance measure	*Test (example)*	*Specification (example)*
Calibration curve	2–3 replicates of calibration curve (6 non-zerostandards) over 2–3 separate runs	CV $\leq$20% and recovery of 80%–120%; CV $\leq$25% and recovery of 75%–125% at LLOQ. 75% of calibrators (including LLOQ) should meet criteria for acceptance of curve
Accuracy	$\geq$3 samples (or QC) at low, medium, and high concentrations spanning the calibration curve range, $\geq$5 replicates of each sample. Calculate percent recovery of observed as a fraction of expected values	Recovery of 80%–120% and 75%–125% at LLOQ
Parallelism	$\geq$3 samples spiked with calibrator and serially diluted	Recovery of 80%–120% (compared to neat OR concentration at minimum recommended dilution)
Dilutional linearity	$\geq$3 samples spiked with calibrator to above the ULLOQ and serially diluted	Mean recovery of 80%–120%
Intraassay precision	$\geq$3 samples (or QC) at low, medium, and high concentrations spanning the calibration curve range, $\geq$5 replicates of each sample	CV $\leq$20% and 25% at LLOQ
Interassay precision	$\geq$3 samples at low, medium, and high concentrations spanning the calibration curve range, $\geq$3 replicates, $\geq$3 analytical runs	CV $\leq$20% and 25% at LLOQ
Lower limit of quantification	Lowest calibrator that meets criteria and verified with 5 biologic samples that surround the putative LLOQ	CV $\leq$25% and recovery of 75%–125% at LLOQ
Minimal recommended dilution	Dilution of sample that obtains best CV and accuracy for samples at different concentrations of biomarker spanning the analytical range	
Quality control	$\geq$3 samples at low, medium, and high concentrations spanning the calibration curve range, 2 replicates	$\leq$20% recovery met by at least 1 replicate at each QC concentration and 4 of 6 QC replicates in total for acceptance of run
Stability—short term	Hold sample at temperatures (i.e., room temp and 4C) and length of time expected for general running of the assay. Use 3 samples at different concentrations. Test 3 freeze–thaw cycles	Mean recovery 85%–115%
Stability—long term	Hold sample frozen at varying lengths of time. Use 3 samples at different concentrations	Mean recovery 85%–115%
Reference interval	At least 40 subjects per sex of a defined age range, strain, ethnicity, BMI/wieght	Estimate with nonparametric statistics (require 40 values/sex)
Upper limit of quantification	Highest calibrator that meets criteria	CV $\leq$20% and recovery of 80%–120%

biomarkers (i.e., ligand binding assays), which is the most common method used for the emerging safety biomarkers. However, these principles are generally applicable to other types of biomarkers using different techniques.

Regularly employed methodologies for analyzing protein biomarkers include immunoassay and mass spectrometry quantification of protein mass and enzyme activity assays. Immunoassays cover a variety of formats and detection methods with both singleplex and multiplex testing. Molecular biomarkers are generally quantified with PCR-based methods. As emerging biomarkers are in the early phase of commercialization and not widely implemented by industry, these assays are almost exclusively so-called "Research Use Only" (RUO) assays and are not approved by health authorities as an in vitro diagnostic assay for clinical diagnosis and patient management. Most often these are commercialized kits, with very few laboratory-developed assays. Reagent characterization and optimization of RUO assays can vary widely, requiring verification of the manufacturer's protocol and assay performance claims by each testing laboratory.

Assay validation for biomarkers is based on "fit for purpose" principles conceived by professional bodies in recognition that biomarkers used in drug development did not fit into published standards for diagnostic tests published by Clinical and Laboratory Standards Institute (CLSI), nor guidances for validation of bioanalytical assays for pharmacokinetic analysis.[14,15] This influential framework recommends that the parameters evaluated for performance testing of an assay fits (or matches) the intended use of the data. For example, if the objectives of the biomarker study are rudimentary, then a simple set of assay performance testing to verify that the assay reliably detects a biomarker, is satisfactory. The assay performance testing becomes more comprehensive, and acceptance criteria more stringent, as the biomarker advances from early stages of evaluation to later qualification. Biomarker measurement differs from the drug bioanalytical context due to the presence of endogenous levels of the biomarker in the biological matrix, lack of standardized reference material, and calibrators that are often synthetic and therefore only approximate the native form of the biomarker. The use of new technology (with limited independent technical characterization) is another difference.[16] The quantification of emerging biomarkers may consequently represent a relative quantification that provides an estimate of true accuracy. Moreover, without standardized reference material, there is often a lack of agreement in the measured value between different assays.

Currently there is no specific Health Authority Guidance for the analytical validation of safety biomarkers. Instead, expert groups and private–public partnerships have recommended approaches and criteria for biomarker assay validation in the spirit of best practice for bioanalaytical assays as recommended by major health authorities.[17–19] In the preclinical context, these assays are usually validated nonGLP but use the foundation of GLP principles.[16] Clinically, biomarker validation packages qualified through the Drug Development Tools mechanism (see section "Regulatory Qualification of New Toxicity Biomarkers") follow an approach consistent with that recommended by bodies such as the College of American Pathology but are generally not compliant with more rigorous CLSI criteria that is the standard for clinical diagnostic laboratories.

The fit for purpose, or progressive, approach to assay validation can be conceived broadly into two stages: assay feasibility and exploratory method validation stage, and then a more comprehensive validation stage incorporating key milestones.[14,16] Selection of assays for feasibility testing occurs at the beginning of the fit for purpose paradigm and constitutes a basic series of testing to demonstrate that the biomarker is quantifiable with the standard curve, and that the assay is selective for the biomarker and precise. Several approaches have been advocated.[19,20] To begin, the precision of the calibration curve and verification of the working range of the assay are conducted. Next, a parallelism study to characterize several key attributes of the assay including selectivity for the biomarker, suitability of the calibration curve to represent the biologic sample, and the minimal recommended dilution. Parallelism is an integral milestone of feasibility testing.[16] In this test, the sample (often spiked with a standard within the working range of the assay) is diluted with buffer to determine if the response in the diluted sample has a proportionate (i.e., linear) relationship to that of the calibration curve. Accordingly, these data evaluate the immunological similarity of the calibrators in buffer or matrix to the endogenous protein in sample matrix, hence the suitability of the calibration curve for biomarker quantification. The selectivity for the biomarker and relative accuracy is demonstrated by the percent recovery of the biomarker in this parallelism test. Basic repeatability of the assay is determined by intraassay precision of calibration curve and samples. The precision performance standards for these experiments are usually between 20% and 25% for the assay with marginally higher (an additional 5%) at the upper and lower limits of quantification. Short-term stability within the time frame of expected sample analysis in addition to freeze–thaw cycle comparisons complete this early assay feasibility evaluation.

When the biomarker is ready for biological qualification, an advanced assay validation is initiated which is more comprehensive. A sequence of key milestones begins with the generation of quality control material in biologic matrix for performance testing across multiple studies. Key performance measures include: intra and interassay precision, dilutional linearity, antibody specificity for the biomarker, interference testing, long-term freezer stability, and detailed evaluation of technical robustness by evaluating the effect of fine differences in assay protocol, lot–lot variability and cross-site validation.[16,20]

The seminal framework of fit for purpose assay validation is both appropriate and expedient for safety biomarker assays. The key performance measures of assay validation, precision, parallelism, selectivity, and stability are emphasized to ensure reliable and reproducible data. The framework rationalizes the time and resource commitment allocated to assay development and validation with the stage of biomarker qualification and COU.

4.15.3.7 Regulatory Qualification of New Toxicity Biomarkers

In order to meet the societal need for new therapies to treat unmet medical needs and to improve human health, there has been a push by regulators to improve assessment of drug benefit and risk. Innovative tools to enhance safety monitoring are an important element in achieving improved risk assessment.[21] A formal process has been instituted by Health Authorities to facilitate regulatory qualification of new drug development tools, which includes safety biomarkers (see referenced websites for the FDA and EMA). The FDA defines regulatory qualification as "a conclusion that within the stated COU, a biomarker can be relied upon to have a specific interpretation and application in drug development and regulatory review."[21] There are two major paths for qualification of safety biomarkers. Drug developers can seek approval for both a drug and a safety biomarker through the investigational new drug application for an individual therapeutic. Alternatively, a stand-alone qualification through the biomarker qualification process (BQP) is disclosed publically and allows broad application of the biomarker across multiple drugs, patient populations, and therapeutic indications (**Fig. 3**). The BQP has been enthusiastically embraced by private–public partnerships comprising pharmaceutical companies, diagnostic companies, academic groups and public organizations, and regulatory advisors to collaborate on the generation and voluntary submission of data packages that support the qualification of new safety biomarkers.

The BQP begins with an initiation stage where a sponsor submits a letter of intent (LOI) to the agency nominating novel safety biomarker/s, identifying the assays for biomarker measurement, and proposes a specific COU that frames the use and interpretation of the biomarker in regulatory decisions regarding the safety of a drug. If the LOI is approved, the agency forms a biomarker qualification review team (BQRT) and the process moves to a consultation and advice stage to help shape the qualification package for submission. The review stage follows submission of the qualification package and evaluation by the BQRT. If the biomarker is approved, draft guidance is issued by the FDA and posted for public comments.[21] A qualification can only set-out a base case for confidant application within a defined context, and therefore the use of emerging safety biomarkers is necessarily an iterative and progressive process that requires continuous review and dialog between the drug development community and Health Authorities. The initial qualification may be for a limited COU, which is later expanded in subsequent submissions (**Fig. 3**). A newer instrument, the letter of support (LOS), is a less rigorous process to bring greater public attention to promising new biomarkers with preliminary evaluation packages.[21] The LOS is a new mechanism provided by the EMA and FDA.

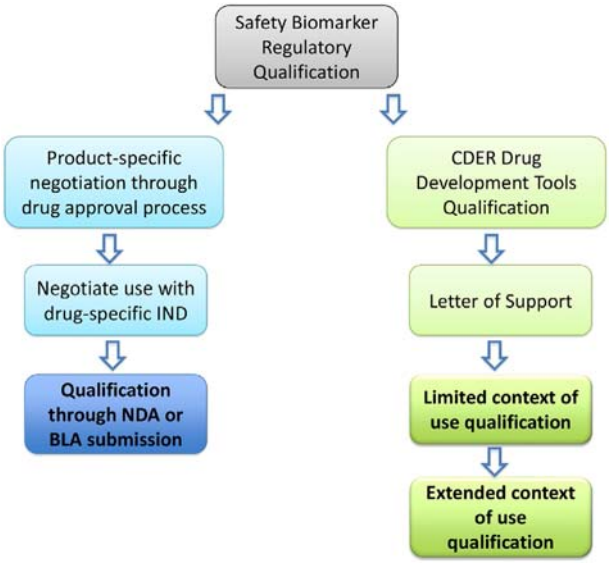

Fig. 3 An overview of the different regulatory paths to formal biomarker qualification for drug development use. The example here is representative of the process used by the U.S. Food and Drug Authority. The drug developer can qualify biomarkers for use with a specific drug through product-specific NDA or BLA submissions. The qualification data and biomarker performance may not be widely shared with the community in this path. Alternatively, sponsors of a biomarker can use a separate path to qualify the biomarker independent of a specific drug product. This is an incremental process, beginning with recognition of the potential of the biomarker by the agency (Letter of Support) and followed by a full qualification for specific contexts of use in various scenarios of drug development.

4.15.4 Emerging Biomarkers of Drug-Induced Liver Injury

Drug-induced liver injury (DILI) accounts for approximately half the cases of acute liver failure in the US and is a leading cause for regulatory actions post drug approval.[22–24] Together with cardiovascular toxicity, DILI (synonymous with hepatotoxicity) is the most common cause for safety-related attrition of drug development candidates from preclinical phases through clinical trials. The clinical epidemiology of DILI includes predictable DILI that is related to drug overdose, and idiosyncratic DILI, a rare category of toxicity. Idiosyncratic DILI is defined as an unpredictable, nondose-related, severe adverse event that can lead to liver failure and death and is the one of the most concerning and baffling risks to patient safety. Although it is recognized that predictive biomarkers for idiosyncratic DILI are a vital medical need, the rarity of idiosyncratic DILI continues to prove an out-sized challenge for biomarker discovery and evaluation. This article will focus on emerging biomarkers for predictable DILI.

The liver is particularly susceptible to drug toxicity as the major organ responsible for first-pass metabolism of orally administered drugs. The portal vein, which drains the gastrointestinal tract and spleen, supplies the liver with approximately 75% of its blood and exposes the liver to high concentrations of drugs absorbed directly from the gastrointestinal system. Portal blood is distributed in the liver via sinusoids, notable for having a discontinuous lining of endothelial cells without a basement membrane, maximizing contact of blood with hepatocytes. Hepatocytes are richly equipped with enzymes that metabolize drugs to active and inactive forms.

The diagnosis and monitoring of liver toxicity in drug development is based on a panel of serum clinical chemistry tests, including the enzyme activities of alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase (ALP), and the concentration of total bilirubin. These enzymes are liberated from the parenchymal cells of the liver upon cell injury and reflect the cellular integrity of the organ. In contrast to the hepatic enzymes, total bilirubin is a marker of hepatocyte and biliary function. Additional (but insensitive) measures of hepatic function include serum levels of major hepatic biosynthetic products such as albumin, prealbumin (transthyretin), urea, glucose, and coagulation factors (indirectly measured as prothrombin time). These biomarkers are readily implemented and form part of the routine clinical pathology assessment of preclinical and clinical studies. Although this panel is remarkably broad, it fails to address some of the key needs for contemporary drug development and patient safety. Both ALT and AST are not liver specific and can increase with skeletal muscle and cardiac injury, and the functional markers are also nonspecific and notably insensitive.[25] Furthermore, the relatively long half-life of ALT and AST in humans (22 and 47 h, respectively) can impede close patient management of DILI for the in-patient setting. Major gaps in the current safety monitoring paradigm for DILI include a desire for biomarkers with improved specificity for liver injury and prediction of patients that will progress to liver failure versus adaptation to transient liver toxicity (i.e., manifest as transient increases in ALT despite continued drug exposure from drugs such as heparin) or nonprogressive DILI.[26] Additionally, mechanistic biomarkers would permit a more sophisticated characterization of DILI and could improve drug-causality assessment and potentially augment patient management and safety assessment. Biomarkers with shorter half-lives and faster appearance in the serum would also improve the ability to detect the onset and reversal of liver injury over current markers.

4.15.4.1 General Characteristics of Emerging Liver Safety Biomarkers

Assays for the emerging DILI biomarkers encompass a noteworthy variety of platforms, levels of standardization, diversity of biomarker type, and biomarker utility. Several promising biomarkers are laboratory-derived tests (acetylation status of high mobility group box 1 protein, HMGB1) and/or there is a lack of assay availability in preclinical species (measuring the different forms of cytokeratin 18, CK18) which has hindered investigation of these biomarkers. The enzyme leakage biomarkers, alpha-glutathione-S-transferase (alpha-GST), arginase-1, and glutamate dehydrogenase (GLDH), have been recognized as potential biomarkers of liver injury for decades. There could be several reasons as to why these liver enzyme leakage biomarkers may have been left on the shelf for so long. At first glance, these have a similar mechanism of release to ALT and may have been initially categorized as redundant. However, with the current desire to formalize and systematize the evaluation and use of emerging and nonroutine biomarkers, a specific COU for the added value of these biomarkers has been articulated, (1) monitoring liver injury with muscle comorbidity and (2) biomarkers with shorter half-life than standard markers (ALT, AST) that permit real-time monitoring and decision-making to improve patient care. Also, the potential for combinatorial biomarker panels to improve on individual biomarker performance is a valid path with new technology that multiplexes biomarkers. A summary of emerging DILI is provided in **Table 3**. A selection of these biomarkers is described in greater depth in this section.

Emerging liver safety biomarkers are intended for use with the standard liver panel (ALT, AST, ALP, total bilirubin) to add information and improve safety assessment and patient management. **Table 4** appraises the comparative performance of the more promising emerging liver safety biomarkers. GLDH, miR-122, arginase-1 have the potential for improved specificity over ALT. GLDH has particularly favorable technical and performance characteristics based on the availability of a standardized test on a clinical chemistry analyzer and data supporting equivalent sensitivity, with improved specificity, compared to ALT.[26] Alpha-GST has the advantage of fast kinetics, rising early with injury. However, the potential for high biological variability may ultimately challenge the performance of alpha-GST. miR-122 has equivalent sensitivity to ALT with the advantage of improved kinetics for close patient management, that is, earlier appearance, higher magnitude of change and faster reversal. CK18 and HMGB1 (and their modified forms) are mechanistic biomarkers, which could improve prediction of severity and outcome of DILI.

4.15.4.2 Arginase-1

Arginase-1 (EC 3.5.3.1) is a highly expressed liver cytosolic enzyme. Arginase-1 is confined to periportal and midzonal regions involved in the final step of the urea cycle converting L-arginine to L-ornithine and urea. The protein has also been demonstrated

Table 3 Emerging safety biomarkers of drug induced liver injury

Biomarker	*Description*	*Assay*	*Injury type*	*Biomarker utility*
Alpha-fetoprotein (AFP)	Protein in hepatocyte progenitors	Immunoassay	Hepatocellular regeneration	Prognosis
Arginase-1	Hepatocellular cytosolic enzyme	Immunoassay	Hepatocellular necrosis	Injury, specificity
Colony-stimulating factor-1 receptor (CSF1R; MCSFR1R)	Kupffer cell membrane receptor	Immunoassay	Inflammation	Mechanism, prognosis
Cytokeratin 18, full length (CK18, K18, M65)	Intermediate filament protein in hepatocytes	Immunoassay (human)	Hepatocellular necrosis	Injury, prognosis
Cytokeratin 18, caspase-cleaved fragments (ccCK18, ccK18, M30)	Caspase cleaved fragment of cytokeratin 18	Immunoassay (human)	Hepatocellular apoptosis	Injury, mechanism
Glutamate dehydrogenase (GLDH)	Hepatocellular mitochondrial enzyme	Clinical chemistry enzyme activity	Hepatocellular necrosis; mitochondrial dysfunction	Injury, specificity
Glutathione-*S*-transferase-alpha (GST-apha)	Hepatocellular enzyme	Immunoassay	Hepatocellular necrosis	Injury, specificity
High mobility group box 1 (HMGB-1), total	Hepatocellular and immune cell protein	Immunoassay	Hepatocellular necrosis	Injury, prognosis
High mobility group box 1 (HMGB-1), hyperacetylated	Activated immune cell protein	LCMS	Inflammation, immune cell activation	Injury, mechanism, prognosis
Leukocyte cell-derived chemotaxin2 (LECT2)	Hepatocellular cytosolic enzyme	Immunoassay	Hepatocellular regeneration	Injury, regeneration, prognosis
miR-122	22 nucleotide microRNA	qPCR	Leakage, hepatocellular injury	Specificity, clearance
Osteopontin	Kupffer cell secreted protein	Immunoassay	Inflammation and fibrosis	Injury, prognosis
Sorbitol dehydrogenase (SDH)	Hepatocellular cytosolic enzyme	Clinical chemistry enzyme activity	Hepatocellular necrosis	Injury, specificity

Table 4 Comparative performance of liver safety biomarkers[a]

	Standard biomarkers				*Emerging biomarkers*			
		Comparative performance				*Comparative performance*		
		Sensitivity	*Specificity*	*Mechanistic*		*Sensitivity*	*Specificity*	*Mechanistic*
Structural injury	ALT	+++	++	−	Arginase-1	+++	++	−
	AST	+++	+	−	CK-18 (full length and caspase cleaved)	++	++	++
	ALP	++	+	−	GLDH	+++	+++	−
	GGT	++	+++	−	GST-a	+++	++	−
					HMGB-1 (hypo and hyperacetylated)	++	−	++
					miR-122	+++	+++	−
					SDH	+++	+++	−
Functional injury	Total bilirubin (conjugated and unconjugated bilirubin)	++	++	+				
	Total bile acids	++	++	+				
	Albumin	+	+	−				
	Urea	+	+	−				
	Prothrombin time	+	++	−				

[a]This is a subjective, comparative performance of biomarkers based on available published data.

in lung (100-fold less than liver), with very low expression in the pancreas and kidney.[27,28] Arginase-1 is expressed in various blood cells including lymphocytes, tissue resident macrophages, and erythrocytes.

Arginase-1 is measured by immunoassay. Various preanalytical factors have been identified that could potentially influence the measured level of arginase-1, although these have not been rigorously assessed. Arginase-1 can be upregulated during Th2-type activation of kupffer cells (resident macrophages in the liver), although it is unknown if inflammatory liver injury would manifest in higher circulating levels of arginase-1. Erythrocytes show remarkable species differences in the level of arginase-1.[29] In rodents, rabbits, and dogs the levels are negligible, but are readily detectable in humans. Cynomolgus monkeys have polymorphisms that result in a range of arginase activity ranging from very low to higher than that of humans. Release of red cell arginase-1 during hemolysis in vivo or from poor sample handling could therefore result in increased arginase-1 measured in blood. There is also evidence in mice that this biomarker decreases with age and liver expression can be increased with dietary restriction.[30]

Serum arginase-1 in the blood has been shown to have good performance over many different hepatotoxicants in rats.[27,31,32] Interestingly, decreased levels of serum arginine have also demonstrated good correlation to ALT activity in rat DILI studies. The low serum arginine in these studies was likely a consequence of elevated arginase activity in the serum.[32] In a comprehensive characterization of biomarker performance using 31 different agents of acute hepatotoxicity in the rat, serum arginase-1 was more sensitive than ALT for detecting minor injury (single cell necrosis), improved specificity for toxicants causing muscle and/or gastrointestinal injury in the absence of liver injury. Additionally, it was shown to be specific for hepatocellular versus biliary toxicity.[27] The short half-life (approximately 20 min) and rapid release of arginase-1 in rat models may potentially provide advantages over ALT in clinical patient management where early detection of DILI is required, that is, following accidental overdose of drugs known to cause DILI.[31] To date, arginase-1 has not been well studied for DILI in patients.

4.15.4.3 Alpha-Gluthathione-S-Transferase

Alpha-GST (EC 2.5.1.18) is one of a family of Phase II metabolizing cytosolic enzymes that conjugate glutathione to substrates to augment water solubility and detoxify xenobiotics. There are eight classes of mammalian cytosolic GSTs and five alpha isoforms (or subunits). The alpha-GST class is the most abundant of liver GSTs and GSTs in general constitute approximately 2% of the liver's protein.[33] Alpha-GST is also abundant in the kidney tubules (equally in the rat, on protein mass/tissue weight), with low expression in the bladder, duodenum, femoral artery, spleen, testis, in addition to small intestine, pancreas, and adrenal in humans.[27,34,35]

GSTs are highly polymorphic in humans. An estimated 14% of the population is homozygous for the alpha-GST1 haplotype that results in lower levels of enzyme expression[36]. There are significant sex differences for the levels of alpha-GST in liver and plasma of human males and females, with higher levels in liver of females, and in contradistinction, higher plasma levels in males, which is also the case for rats.[33,37,38] Plasma levels in females (but not males) increase with age.[33,37] In rats, additional hormonal regulation has been demonstrated for growth hormone and testosterone on liver GST. GST can also be induced by consumption of cruciferous

vegetables (e.g., broccoli, cabbage, and Brussels sprouts), xenobiotics, and oxidative stress.[34,39,40] Alpha-GST may pose various challenges as a biomarker given this biological variability. A large interindividual variation has previously been demonstrated in plasma, with notable differences between genders.[33] Technical variations due to differences in antibody pairs and calibrators used in various immunoassays is another potential source of variation given the presence of multiple alpha-GST isoforms.

Studies in the rat have shown alpha-GST to be an early and sensitive marker in many models of DILI, outperforming ALT and AST including carbon tetrachloride, thioacetamide, bromobenzene, and ANIT.[41,27,35,42] The short half-life of the biomarker (~1 h) likely contributes to these attributes. Alpha-GST showed similar sensitivity to ALT in detecting liver necrosis over many rat hepatotoxicity models and showed additive performance to ALT for detecting hepatocellular vacuolation.[27] It was specific for hepatocellular versus biliary toxicity, however was increased with liver hypertrophy, a nonadverse toxicity.[27,35] A drawback of alpha-GST in these studies was the lower specificity than ALT with concurrent kidney, or gastrointestinal toxicity.[27]

In the clinical setting, alpha-GST outperformed AL/AST in patients with acetaminophen overdose,[43] and has been identified as a tool for monitoring hepatotoxicity with general anesthetics.[44]

4.15.4.4 Cytokeratin 18

CK18 is a cytoskeletal protein and the main intermediate filament family member expressed in the liver. The full-length form is liberated from necrotic cells, whereas a caspase-cleaved fragment is a product of the structural changes that occur during apoptosis. Soluble CK18 fragments can be detected in human serum with immunoassay.[45] The M65 assay detects total CK18 that is, full length and fragments of CK18 representing the necrotic and apoptotic biomarkers. The M30 assay detects a neopepitope created in the caspase-3 cleaved 30 kDa fragment (cc-CK18). CK18 fragments have been proposed as a promising biomarker for the diagnosis of nonalcoholic steatohepatitis by clinical gastroenterology organizations.[45]

Restricted availability of rodent reagents at the time of writing limits the preclinical assessment of these biomarkers. In a mouse acetaminophen model, both full length and cleaved CK18 (measured by immunoprecipitation-LC–MS assay) showed similar diagnostic performance to ALT. The pattern of change, with the apoptotic marker rising early and the necrosis marker progressively increasing with time conforming with morphologic and biochemical evidence of hepatocyte apoptosis and necrosis, indicated value as mechanistic biomarkers.[46]

In patients with suspected acetaminophen overdose, serum levels of CK18 total and cc-CK18 at hospital admission had good correlation with peak ALT and the liver functional marker, prothrombin time.[47,48] Furthermore, CK18 and cc-CK18 predicted patients that progressed to acute liver injury better than ALT in two important settings, when (1) ALT was still within normal range at admission and (2) patients presented to hospital within 8 h of overdose.[48] Conversely, in clinical settings of mild, nonprogressive and/or transient DILI, CK18 has shown concordance with mild changes. This was demonstrated at maximum therapeutic doses of APAP or patients treated with highly active antiretroviral therapy regimen (HAART) where CK18 had a comparable time to peak and magnitude fold change as ALT.[49] Also, generally mild-moderate increases in ALT associated cholestyramine treatment that caused mild DILI was associated with minor increases in CK18 (2.1-fold) and cc-CK18 (1.7-fold).[50] As a stand-alone marker CK18 (either form) has shown modest prognostic accuracy, with cc-CK18 apoptotic marker higher in patients that recovered from acute liver failure (of various etiologies including toxicity) compared to nonsurvivors.[51] However use of these markers in a panel-based approach may augment discrimination as demonstrated by improvement in the model for end-stage liver disease (MELD) score to predict survival in patients with acute liver failure.[52]

Specificity of CK18 for DILI has not been fully addressed in human populations. As cytokeratins are ubiquitously expressed in epithelial tissue, damage to nonhepatic tissues can contribute to increased circulating levels in addition to nondrug-related natural liver disease. Consequently, CK18 are increased in cancer, chronic kidney disease, and nonalcoholic steatohepatitis. A small cohort of humans subjected to exercise-induced muscle damage had no effect on circulating CK18 or cc-CK18.[49]

4.15.4.5 Glutamate Dehydrogenase

GLDH (E.C. 1.4.1.3) is a major liver enzyme. GLDH is predominately mitochondrial but low levels are also found in the endoplasmic reticulum.[53] Although expression in the liver is largely confined to centriblobular zone of the liver, there may be a dynamic aspect to subzonal expression that is influenced by diet, sex, and endocrine factors.[54] GLDH catalyzes the reversible conversion of glutamate to α-ketoglutarate and ammonia. Humans have 2 GLDH genes encoding 2 enzyme isoforms (hGDH1 and hGDH2), whereas preclinical species have only 1 gene (the homolog of GDH1). The major isoform (GDH1) is present in all mammals and is expressed largely in the liver. The human-specific homolog (hGDH2) is expressed in the brain and testis. The two human GLDH isoforms have different basal activity levels, enzyme properties, and are differentially regulated by GTP.[55] GLDH has a housekeeping role in cell metabolism, which explains its abundant levels in tissue. In mouse, tissue enzyme activity in the liver is approximately 5× activity levels of pancreas, small intestine, heart, and cerebellum, with trace activity in other tissues (including kidney). GLDH has been induced in cell culture systems by glucocorticoids and cytokines (TNFα, IL-1).[56,57] GLDH is measured by enzyme activity assay, an approved in vitro diagnostic assay in Europe, Canada, and China. Published reference ranges for GLDH in human populations are comparable as may be expected of a standardized clinical chemistry assays using highly precise testing platforms.

GLDH is released into the circulation following necrosis of the cell and/or mitochondrial injury and dysfunction. In theory, mitochondrial injury can be distinguished from frank cellular necrosis by the release of free GLDH in the former versus intact mitochondria as a consequence of hepatocellular necrosis.[58] Preclinically, GLDH has demonstrated similar or superior sensitivity to

ALT.[59] The half-life of GLDH in the rat is 8 h, similar to ALT and AST in that species. GLDH was highly correlated with ALT over a number of different drugs and liver injuries, with a higher magnitude of change and longer duration of increase in blood compared to ALT.[59] Circulating GLDH was increased with a hepatic mitogen (cyproterone) in the absence of necrosis, and also increased with corticosteroids[59,60] but did not show induction by phenobarbital.[42,59] Generally, GLDH has been demonstrated to be an early marker (3–24 h postdose) across models of acute hepatotoxicity comprising ANIT, acetaminophen,[42] thioacetamide, and bromobenzene.[35] GLDH had similar performance to ALT (but inferior to arginase-1) in acute allyl alcohol, lipopolysaccharide, and concanavalin A toxicity in the rat.[31]

GLDH was highly correlated with ALT over a variety of natural and drug related liver disease in patients and had equivalent diagnostic performance to ALT (AUROC 0.98 vs. 0.99).[26] GLDH measured at hospital admission in patients with normal ALT and/or within 8 h of overdose predicted patients that proceeded to have elevated ALT (>3 ULN).[48] Another group showed an increase in GLDH in lethal acetaminophen-induced acute liver failure compared to survivors however, due to the overlapping values between survivors and nonsurvivors, the sensitivity at 90% specificity for predicting lethality was 37%.[61] Perhaps the greatest advantage of GLDH is the liver specificity of the enzyme in contrast to ALT. In humans with exercise-induced muscle damage, there was no effect on serum GLDH confirming the liver specificity of this biomarker.[49]

4.15.4.6 HMGB1

HMGB1 is a nonhistone chromatin-associated protein that stabilizes the nucleosome and regulates transcription. HMGB1 is ubiquitously expressed, highly conserved (99% amino acid identity between rodents and humans), and abundant in the nucleus. There are six polymorphisms in the gene although it is undetermined whether this may impact the use of HMGB1 as a biomarker.[62] Hypoacetylated HMGB1 is loosely bound to nuclear chromatin and will leak out of necrotic cells. In activated monocytes, macrophages, and natural killer cells, and mature dendritic cells, HMGB1 can be hyperacetylated permitting translocation from the nucleus to the cytosol and active secretion as a cytokine.[63] Secreted HMGB1 binds to receptor for advanced glycation endproducts (RAGE) and Toll-like receptor 2 (TLR2) and 4 to act as a proinflammatory cytokine. In the extracellular environment, both forms of HMGB1 act as damage-associated molecular pattern molecules (DAMPs), orchestrating the immune activity and repair responses associated with tissue injury. HMGB1 was thought to be retained by apoptotic cells, although this notion has recently been challenged with evidence that chemotherapeutics and radiotherapy can release DAMPs such as HMGB1 during apoptosis.[64,65] Thus, circulating hyperacetylated HMGB1 represents an immune response marker and the hypoacetylated form is a marker of hepatocellular necrosis.

Total HMGB1 can be measured by immunoassay, however mass spectrometry is required to detect hyperacetylated forms, in addition to redox modifications. High titer autoantibodies to HMGB1 have been observed in healthy people and patients with autoimmune disease and are a potential interferent in the immunoassay.[66]

HMGB1 has only recently been investigated as a mechanistic biomarker for DILI. In a mouse model of acetaminophen toxicity, total HMGB1 was increased slightly earlier than ALT and showed similar diagnostic performance. The kinetics of the hypoacetylated (necrosis marker) and hyperacetylated HMGB1 (immune response) biomarkers were different and consistent with the pathogenesis of this toxicity. Hypoacetylated HMGB1 had a faster rise and reversal that corresponded to peak necrosis, whereas the hyperacetylated form had a later onset, lower magnitude of change, and sustained increase and was compatible with the phase of liver regeneration and systemic inflammation.[46]

In patients with suspected acetaminophen overdose, admission HMGB1 had good correlation with peak ALT and prothrombin time/international normalized ratio.[47,48] Elevated total HMGB1 on admission also had the best prediction and separation in values (little overlap) for patients with normal ALT and/or within 8 h of overdose that went on to have DILI with elevated ALT.[48] Total HMGB1 had a high positive predictive value and AROC for DILI in this patient population, outperforming other emerging hepatotoxicity biomarkers (CK18, ccCK18, GLDH) for prediction of DILI. Further support that HMGB1 may have prognostic capability was in a clinical study with cholestyramine treatment. This agent causes increased ALT without serious hepatotoxicity and only resulted in minor increases in HMGB1 (1.7-fold).[50]

4.15.4.7 miR-122

miR-122 is a liver-specific miR with expression orders of magnitude higher than any other tissue. miR is highly abundant in the liver, estimated to comprise 70% of hepatic miRs.[4]a,67,[4]b Several functional roles for miR-122 have been identified, such as the maintenance of a differentiated hepatocellular phenotype, tumor suppression, hepatic cholesterol, triglyceride, and iron metabolism. The intracellular half-life has been loosely determined to be longer than 24 h,[68] and the circulating half-life has not been reported.

Most reports on miR-122 to date have been in rodents and human studies, with limited reports in the dog.[69] Rat studies with different liver toxicants have shown a correlation with severity of liver lesions by histopathology.[42] In rodent acetaminophen models, this is an early marker, that is, at 1 h postdose in the mouse.[70] miR-122 was more sensitive than ALT for acetaminophen, CCl4, and CBrCl3 hepatotoxicity in rodents.[4]b,70 The rise in plasma miR-122 levels has been related to a corresponding loss in the liver tissue.[70]

The few clinical studies of miR-122 have revealed a comparable or improved performance to ALT. Investigation of miR-122 in patients with acetaminophen overdose correlated with ALT with an earlier rise and faster reversal to baseline in recovered patients.[49,71,48] The prognostic capability, that is, to predict outcome postadmission, of miR-122 in acetaminophen overdose is not clear from current investigations.[71,48] In states of benign elevations in ALT caused by cholestyramine treatment, miR-122

had similar increases relative to baseline.[50] Specificity studies are scarce for miR-122. Interestingly, miR-122 decreased postrace in a small study ($n=39$) examining effects of muscle injury from endurance exercise on liver biomarkers.[49]

4.15.5 Emerging Biomarkers of Acute Kidney Injury

Drug-induced kidney injury (DIKI) is a prominent cause of acute kidney injury (AKI), accounting for approximately 19–26% of cases over a number of large multicenter studies.[72] Tubular necrosis was the most common DIKI pathology.[72] Drugs frequently implicated in DIKI include aminoglycoside antibiotics (e.g., gentamicin and tobramycin), the immunosuppressive agents cyclosporine and tacrolimus, the antineoplastic drug cisplatin, NSAIDs, and contrast media. During drug development, DIKI is an important cause of safety-related attrition, responsible for termination of approximately 8% and 9% in preclinical and clinical candidates, respectively.[1,73]

Several aspects of kidney physiology influence susceptibility to DIKI. The kidney receives 25% of cardiac output, has the highest flow rate of any organ, and therefore renal clearance can influence small molecule drugs in circulation. Tubule cells are richly decorated with transporters that facilitate the uptake of drugs and contain multiple pathways for the biotransformation of drugs. These metabolic pathways generally detoxify the drug and facilitate excretion, but for some drugs the production of reactive metabolites may lead to renal toxicity.

The standard tests for nephrotoxicity, serum creatinine, and serum urea nitrogen concentration, are markers of kidney function. Creatinine is a byproduct of skeletal muscle metabolism. It is a low molecular weight (LMW) (113 Da) metabolite produced at a constant rate proportional to muscle mass and is freely filtered by the glomerulus. Blood urea nitrogen is also a metabolic waste product that is freely filtered by the glomerulus, therefore is a similar biomarker to creatinine, but less specific due to influences from diet, protein catabolism, and liver function. Both markers serve as indicators of glomerular filtration rate (GFR) and kidney function. Ancillary serum endpoints measured in routine monitoring, through nonspecific and insensitive markers also support detection of functional kidney injury and include serum protein, electrolytes, phosphorus, and calcium concentration. Additional tests for kidney toxicity are mentioned in the ICH S7A guideline for safety pharmacology, comprise urine tests for volume, specific gravity, osmolarity, pH, fluid/electrolyte balance, protein, and cytology.[74] Biomarkers of structural kidney injury were lacking in standard monitoring panels in preclinical and clinical drug development studies.

Standard functional markers for monitoring kidney toxicity are insensitive owing to the large functional reserve of the kidney. For example, serum BUN and creatinine only rise with loss of at least 50% of renal function. Also, serum creatinine has a parabolic response, with the magnitude of increase being low at the lower threshold for injury detection. Specificity of BUN and creatinine for renal injury is also compromised when transient prerenal factors such as reduced renal blood flow (i.e., states of dehydration). Therefore, there is a need for early markers of kidney injury with improved sensitivity and specificity for nephrotoxicity.

Emerging biomarkers for kidney injury conform to three major categories, which are not mutually exclusive. These comprise markers of structural injury that leak from cells, markers upregulated in states of damage and repair, and markers of tubular function (reabsorption and small molecule exchange). **Table 5** lists the emerging safety biomarkers of kidney injury. These markers are expressed in different locations of nephron and have the potential to localize injury and may assist in assigning drug causation to kidney effects in patients. Structural injury markers also offer the opportunity to detect subclinical kidney disease prior to functional impairment detected by standard markers. Furthermore, patients with subclinical kidney injury may be at higher risk for DIKI when exposed to nephrotoxicants.[75] The regional location of the emerging kidney safety biomarkers are depicted in **Fig. 4**.

The qualification of eight renal safety biomarkers by FDA, EMA, and PMDA in 2008–10 recognized that new urine biomarkers outperformed and/or added value to the measurement of serum creatinine and urea nitrogen, and represented an important advance in safety assessment.[76] The new biomarkers comprise: albumin, beta-2-microglobulin, clusterin, cystatin-C, kidney injury molecule-1 (KIM-1), renal papillary antigen 1 (RPA-1), trefoil factor 3 (TFF3), and total protein (**Table 5**). These urine biomarkers were qualified for use in rat studies and voluntary use on a case-by-case in clinical trials for the detection of tubular toxicity. Subsequently, osteopontin and neutrophil gelatinase-associated lipocalin (NGAL) have received a "Letter of Support" recognition from the FDA and EMA to encourage further evaluation of these biomarkers for their utility as kidney injury biomarkers.[77] The comparative performance of these new urine biomarkers is summarized in **Table 6**. The strategy used by the predictive safety testing consortia (PSTC) to qualify kidney biomarker qualification was to focus on renal tubular in the rat and use a thorough and standardized histomorphological assessment across a number of model toxicants with different mechanisms of toxicity as the gold standard for assessing biomarker performance. The translational value of these biomarkers would then be confirmed in human subjects with renal tubular DIKI within a limited COU. Subsequent qualifications for clinical use would be incremental, and extend the claims of biomarker performance in an expanded COU.[6] Glomerular toxicity biomarkers and contexts of use were to be undertaken at a later date by the PSTC.

Although information on the adoption of qualified renal safety biomarkers by drug developers is extremely limited, one survey of big pharma suggests they are used preclinically on a for-cause basis, with few sponsors measuring the entire panel of eight markers.[78] The most commonly evaluated new kidney biomarkers were reported to be total protein, albumin, and KIM-1.[78] In keeping with a phased and incremental approach to Regulatory qualification of biomarkers, consortia (PSTC) are actively investigating clusterin, cystatin-C, KIM-1, *N*-acetyl-beta-D-glucosaminidase (NAG), NGAL, and osteopontin for clinical use.

This section will focus on the new urine biomarkers qualified in the rat, and on the urine biomarkers under current evaluation for qualification in humans. As urine albumin and total protein have an extensive historical use with considerable evidence for their

Table 5 Emerging safety biomarkers of acute kidney injury

Biomarker	*Sample*	*Kidney association*	*Assay*	*Toxicity mechanism*	*Biomarker utility*
BUN	Serum	Filtered serum metabolite	Colorimetric assay	Reduced glomerular filtration	Function
Creatinine	Serum	Byproduct of muscle metabolism	Colorimetric dye-binding or enzymatic assay	Reduced glomerular filtration	Function
Albumin	Urine	Filtered serum protein	Immunoassay	PT transport; compromise of glomerular filtration barrier	Function: tubular and glomerular
alpha-1-microglobulin	Urine	Filtered serum protein	Immunoassay	PT transport; compromise of glomerular filtration barrier	Function: tubular and glomerular
beta-2-microglobulin	Urine	Filtered serum protein	Immunoassay	PT transport; compromise of glomerular filtration barrier	Function: tubular and glomerular
Calbindin D28	Urine	Tubular protein	Immunoassay	Injury, leakage	Distal tubule and collecting duct injury
Clusterin	Urine	Tubular protein, locally secreted protein	Immunoassay	Injury: upregulated, secreted	Proximal and distal tubular injury
Creatinine	Urine	Filtered serum protein and secreted by tubules	Colorimetric dye-binding or enzymatic assay	NA	Corrects biomarkers for dilution and urine flow rate
Cystatin-C	Urine	Filtered serum protein	Immunoassay	PT transport; compromise of glomerular filtration barrier	Function: tubular and glomerular
IL-18	Urine	Secreted tubular protein	Immunoassay	Injury: upregulated, secreted	Injury response
KIM-1	Urine	Transmembrane protein of proximal tubule	Immunoassay	Injury: upregulated and shed with injury	Proximal tubular injury
Liver fatty acid-binding protein	Urine	Proximal tubule cellular protein		Injury: upregulated, leakage	Proximal tubular injury
NAG	Urine	Lysosomal enzyme of proximal tubule	Colorimetric enzymatic activity	Injury, leakage	Proximal tubular injury
NGAL	Urine	Tubular cell and neutrophil protein	Immunoassay	Injury: upregulated, secreted	Tubular injury
Osteopontin	Urine	Secreted tubular protein	Immunoassay	Injury: upregulated, secreted	Proximal and distal tubular injury
Retinol-binding protein	Urine	Filtered serum protein	Immunoassay	PT transport; compromise of glomerular filtration barrier	Function: tubular and glomerular
Renal papillary antigen-1	Urine	Collecting duct cellular protein	Immunoassay	Injury, leakage	Collecting duct injury
Total protein	Urine	Filtered serum protein	Colorimetric binding assay	Compromise of glomerular filtration barrier	Function: glomerular
Trefoil factor 3	Urine	Secreted tubular protein	Immunoassay	Injury: downregulated	Proximal tubular injury (decreases)

diagnostic utility these will not be covered here. Both these biomarkers are readily implemented, particularly in clinical studies where diagnostic laboratories have access to standardized tests for automated platforms. Other new biomarkers not elaborated here due to a paucity of translational data in addition to reasons already stated, include alpha-GST, alpha-1-microglobulin, gamma glutamyltransferase, IL-18, liver fatty acid binding protein, RPA-1, and TFF3 (Table 5). The less attractive prospect of a marker that decreases with toxicity together with limited availability of assays have constrained further investigations of TFF3. Adding to the low appeal of TFF3, is the suggestion that it is a delayed marker of nephrotoxicity.[79] Circulating (i.e., serum) levels of some of these same biomarkers (e.g., osteopontin, albumin, NGAL, KIM-1) have also been evaluated as safety biomarkers for kidney injury, however information is sparse and these often have specificity concerns in the serum. The exception is serum cystatin-C, which has long been investigated as an alternative marker to serum creatinine for estimating GFR, a marker of kidney function. There continues to be conflicting evidence and opinion for the performance of serum cystatin-C compared to serum creatinine for estimating GFR.

4.15.5.1 General Considerations for Preanalytical Factors, Assays, and Biomarker Biology

4.15.5.1.1 Preanalytical factors

Urine presents one of the least invasive of body biofluids to sample with little impact on the health and discomfort of the subject. However, there is added complexity to the collection, analysis, and interpretation of urine biomarkers compared to those in the blood. Proteins may be degraded by bacterial action, the sample compromised by contaminants, and the biomarker bound to factors that interfere with the assay. Ideally, urine samples should be accompanied by a short description of the physical

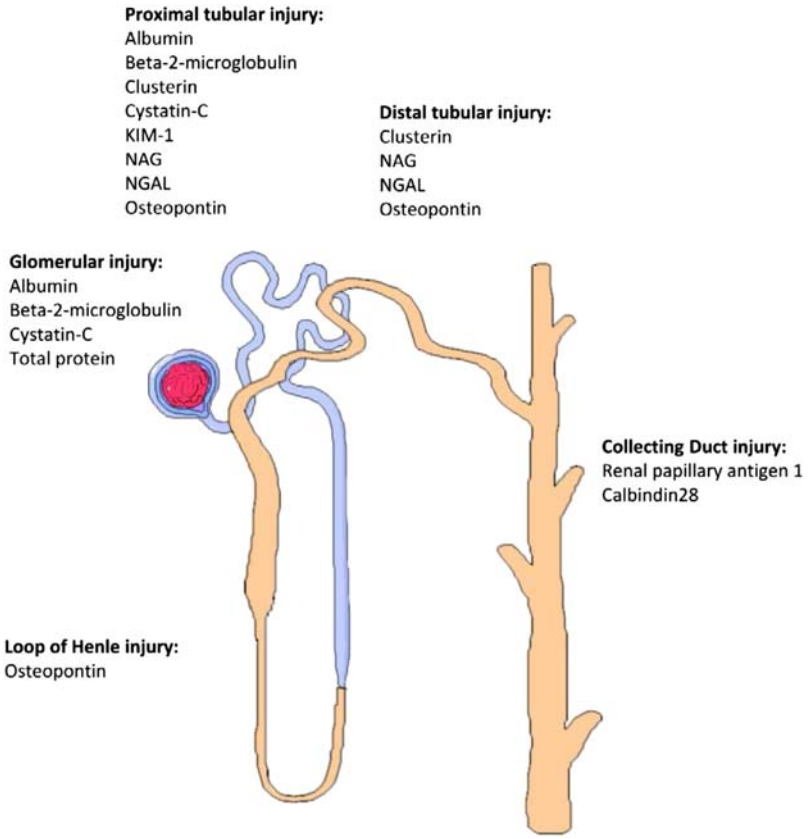

Fig. 4 Kidney toxicity biomarkers correspond to different anatomical regions of the nephron. Shown is a cartoon of the nephron, the structural and functional unit of the kidney. Injury to different segments of the nephron can result in increased excretion of specific biomarkers into the urine assisting in diagnosing the site of injury. Ferguson, M. A.1; Vaidya, V. S.; Bonventre, J. V. Biomarkers of Nephrotoxic Acute Kidney Injury. Toxicol. **2008**, *245*(3), 182–193. http://dx.doi.org/10.1016/j.tox.2007.12.024.

Table 6 Comparative performance of kidney safety biomarkers[a]

	Standard biomarkers			*Emerging biomarkers*		
		Comparative performance			*Comparative performance*	
		Sensitivity	*Specificity*		*Sensitivity*	*Specificity*
Structural injury	Serum protein and albumin	+	+	Urine clusterin	+++	+++
				Urine KIM-1	+++	+++
				Urine NAG	++	+++
				Urine NGAL	++	+++
Functional injury	Serum creatinine	+	++	Urine albumin	++	++
	Serum (blood) urea nitrogen	+	++	Urine beta-2-microglobulin	++	++

Table 7 Select preanalytical variables for urine analysis

	Factor/variable	*Effects*	*Recommendations*
Contamination	Gross external contamination	Interference with assay	Urine should be collected in clean environment and centrifuged postcollection
	Bacterial	Bacteria degrade biomarker; change pH of matrix and interfere with assay conditions	Keep urine at 4°C and minimize time at room temperature; centrifuge urine to remove gross debris and cells; acidivication of urine can be attempted (e.g., sodium azide) if proven not to interfere with biomarker analysis
	Endogenous not directly from the site of kidney injury	Circulating biomarker levels in blood add to measured concentration; blood interferes in assay; contribution of biomarkers in contaminating cells	Centrifuge, measure blood via dipstick, perform urine cytology to verify blood cells; check assays for interference; dilution of samples with visible hemolysis may reduce interference
Lower urinary tract inflammation	Inflammatory cells	Inflammatory cells contribute inflammatory biomarkers, e.g., NGAL	Determine if lower urinary tract information is present and relationship to drug; Inflammatory markers may be confounded if there is upper and lower UTI; spot samples with rapid processing may reduce effects on sample
Collection	Timed collection; spot (single sample collection); time of day for collection vs. random	Differences in biomarker concentration and excretion estimates	Timed collections may reduce variability and account for diurnal variations; suitability of spot collections should be established in relation to timed collections
	Temperature	Urine collected over longer periods at higher temperatures are susceptible to bacterial overgrowth	(see bacterial contamination above)
Processing and handling	Centrifugation	Potential for cellular contamination in whole urine (altering biomarker level; assay interference)	Standardized centrifugation protocols should be in place prior to sample collection
	Protease inhibitors	Potential degradation by endogenous proteases and reduced stability	Not usually of value
	Storage time/stability	Degradation of biomarkers or altered epitopes detected by immunoassay	Short-term, freeze–thaw effects, and long-term stability should be determined. Storage at −80°C is usually acceptable
Food effects		Alters biomarker concentration	Preliminary data indicates there are no food effects on major new kidney biomarkers (human)
Gender and age		Alters biomarker concentration	New biomarkers are likely to show differences between males and females (human)

characteristics (color, clarity) and routine dipstick analysis to provide a preliminary quality control check for the presence of blood contamination and inflammation, which may result in artefactual values when biomarkers are also present in blood. Beta-2-microglobulin has been reported to be unstable unless the pH is >6.5.[80] The long-term frozen stability at −80°C was poor for KIM-1, NAG, and NGAL and should be established for the assay and conditions to be used in a study.[81] **Table 7** provides a summary of major preanalytical factors that should be considered when measuring biomarkers in urine.

Timed collections over a period up to 24 h may be used to account for diurnal variations in biomarker release and can potentially reduce variability in the concentration of the analyte.[82] The convenience of spot samples (from a single collection) may trump timed collections if there is evidence of acceptable agreement to timed samples. Fresh urine has shown to be preferable to prolonged storage for several biomarkers (cystatin-C, KIM-1, NAG, NGAL). Alkalization (adjustment of urine pH to >8 with sodium hydroxide) or use of protease inhibitors did not improve frozen stability.[81,83] Urine biomarkers are generally normalized to creatinine to account for urine flow rate and variable dilution of the urine by water. Although most of the excreted creatinine is contributed by glomerular filtration, a portion is also derived from tubular secretion and this shows species and sex differences. For example, humans have a low proportion, 10–20%, of total urine creatinine that is secreted from the tubules, whereas in mice this may account for 35–50% of excreted creatinine.[84,85] With lower GFR and higher serum creatinine concentrations, the relative proportion of secreted vs filtered creatinine can also change.[84] This ratio may also be invalid when injury to tubules results in variations in the excretion of creatinine that may differ between individuals.[86] An alternate method to account for dilution and urine flow rate is by collecting a timed specimen and expressing values as total mass excreted over the time period that is, dilute urine will presumably have a higher

volume of urine and lower concentration and conversely, concentrated urine will have a lower volume and higher concentration of the analyte in healthy subjects. Despite these caveats, correcting to urine creatinine is usually favored, with studies in the rat demonstrating a stronger correlation between biomarker concentration and urine creatinine and less gender-related differences than urine volume.[12,13] The ratio to creatinine has been used in regulatory qualification of new urine biomarkers in rat and in human.

Biological variability of urine albumin, KIM-1, NAG, NGAL, osteopontin, RPA-1, and total protein has been evaluated in the rat.[12] These markers had intraindividual variation of $\leq$44% and interindividual variation $\leq$46%. Given these data, it is estimated that a twofold increase in any of these biomarkers (corrected for urine creatinine) is likely to indicate toxicity, with KIM-1 having the lowest threshold (at 1.4-fold baseline). Sex-related differences in rats have also been identified, with increased beta-2microglobulin, clusterin, cystatin-C excretion in male rats compared to females.[87,13] Although, still under active investigation, preliminary reference interval data in humans characterized NGAL, beta-2-microglobulin, clusterin, osteopontin as higher in females than males, with no gender effect for cystatin-C and KIM-1.[11,88] These qualification studies, and other studies in the last few years, have demonstrated no difference in biomarker performance in the major rat strains used in drug development (Sprague-Dawley, Han Wistar).[89]

4.15.5.1.2 Pathophysiologic factors

Several of the new biomarkers are freely filtered LMW proteins (beta-2-microglobulin, cystatin-C, L-FABP, NGAL, osteopontin) that are reabsorbed along with albumin by megalin–cubilin endocytic transporters present on the luminal border of proximal tubular epithelium. Consequently, increased excretion of these LMW biomarkers will reflect injury and/or dysfunction to the proximal tubule. However, additional mechanisms may affect these biomarkers. For example, competition for megalin–cubilin may lead to in saturation of active transport. This situation can occur in conditions that lead to increased albumin in the filtrate, as may occur in conditions with high serum protein load.[90] Glomerular injury and disease states accompanied by proteinuria (sepsis, chronic kidney disease) also resulted in increased LMW urine biomarkers. Additionally, a number of agents including nephrotxicants (puromycin), xenobiotics (e.g., the mTOR inhibitors sirolimus and everolimus) endotoxemia, and heavy metals (e.g., cadmium) may also downregulate megalin expression and increase LMW biomarker excretion.[91]

In a rat gentamycin model of nephrotoxicity, gender differences in biomarker response were explored for 16 candidate urinary biomarkers. Intriguingly, biomarker fold increases were generally higher in females equivalent microscopic severity grade of injury compared to males in Sprague-Dawley rats. Only for beta-2-microglobulin and TIMP-1 could that be clearly related to a lower baseline in females compared to males.[92]

4.15.5.1.3 Assays

The majority of these biomarkers are measured with immunoassays. Assays designed for detecting biomarkers in blood may not use buffers and reagents that adequately account for the different physicochemical properties of urine and performance evaluation of the assay in a urine matrix is a necessary feature of assay validation. Urine biomarkers are usually measured with multiplexed assays in the rat, but singleplex assays tend to be favored in human studies. The immunoassays are nonstandardized, and use different reagents (detection and capture antibodies, calibrators, diluent), therefore values for these biomarkers may differ across kits and labs. One study investigating assays for human urine biomarkers found a high correlation between singleplex and multiplex assays across vendors for most of these biomarkers, except for beta-2-microlobulin.[11] In the rat, different platforms have also shown reasonable correlation, similar direction of changes, but differences in the measured values.[13,93] On the other hand, a high level of agreement is expected across platforms and sites for those biomarkers that are measured on the automated clinical chemistry analyzer (urine creatinine, albumin, total protein) often with calibration to similar reference material. Although the enzyme activity of urine NAG is also measured simply and accurately with a colorimetric assay on an automated clinical chemistry analyzer, it did not show good cross-site correlation when evaluated by one group of investigators.[11]

Several assays are approved for measuring human urine NGAL in the European Union on automated clinical chemistry analyzers. These high throughput assays have shown good correlation with research-grade ELISA.[94] Development of new tests that can distinguish the monomeric form from the dimer released by neutrophils is expected to result in a gain of specificity and diagnostic performance.[94]

4.15.5.1.4 Postanalysis, interpretation

In preclinical qualification and published reports, the biomarkers have been evaluated as single biomarkers where the pattern of individual markers is related to toxicity. On the other hand, the clinical qualification strategy for the first stage limited COU is to propose a composite measure of the biomarker panel to detect deviation of human subjects from normal variability as a measure of potential toxicity. As more data is generated on the diagnostic performance of these biomarkers, both individually and in combination in patients exposed to drugs in different contexts, it will become evident how to optimally apply these biomarkers in clinical development.

The emerging kidney toxicity biomarkers have been qualified for nonclinical use in rats, with a submission planned for clinical qualification. These biomarkers have been demonstrated to at least add value to the diagnostic performance of serum BUN and creatinine standard endpoints (Table 6); therefore these biomarkers should be applied as adjunct tests that are interpreted together with changes in the serum markers. Consortia have focused the first round of qualification on acute tubular injury in a staged approach to manage the resource required to generate a data package for regulatory submission. Consequently, only a limited evaluation of these new biomarkers has been conducted by consortia or published by independent researchers in the context of glomerular injury.[95,96]

4.15.5.2 Beta-2-Microglobulin

Beta-2-microglobulin is a LMW (17 kDa) ubiquitously expressed protein and a component of the major histocompatibility class (MHC) I molecule family. It is produced at a constant rate and freely filtered by the kidney. Similar to other LMW proteins, beta 2-microglobulin is completely reabsorbed by megalin-mediated endocytosis on the proximal tubules and then completely catabolized within the tubular cell. The fractional urinary excretion of beta 2-microglobulin has been estimated at 0.03%.[97] Levels are increased in the urine if there is direct functional impairment of the proximal tubular epithelial cells or an indirect compromise to proximal tubular function from protein overload (e.g., states of glomerular injury) and saturation of tubular transporters.

In a gentamycin nephrotoxicity model of proximal tubular injury in the rat, beta-2-microglobuin increased prior to microscopic lesions after a single dose and was robustly increased in a multidose setting.[93,92] In part, this prodromal activity may be related to gentamycin-induced functional changes on transporter activity in the proximal tubules that impair LMW protein uptake. Beta-2-microglobulin outperformed serum BUN and creatinine in detecting glomerular injury in multidose acute studies using puromycin and doxorubicin in the rat.[95] However, in a single-dose puromycin model with low-grade glomerular injury this biomarker did not show a significant difference.[96] Beta-2-microglobulin was not an adequate immunohistochemistry (IHC) marker in kidney tissue for cistplatin nephrotoxicity in the rat.[79]

There is limited clinical data on DIKI with beta-2-microglobulin. Early studies with gentamycin did not reveal a close correlation with serum creatinine values, although stability in the urine was questionable in this study.[80] The diagnostic performance of this biomarker for detecting fumaric acid ester-induced nephrotoxicity was equivocal in one case series.[98]

4.15.5.3 Clusterin

Clusterin is ubiquitously expressed protein, with one isoform located in the nucleus and an 80 kDa secreted glycoprotein. Secreted clusterin is involved in lipid transport and is released in response to cell stress where it protects the cell by reducing oxidative stress and binding to misfolded proteins.[99,100] In mouse models of renal injury secreted clusterin is antifibrotic.[100] On the other hand, nuclear clusterin is upregulated by apoptosis and in-turn promote apoptosis through bax.[100] As a consequence of glomerular size exclusion, clusterin in urine should be locally derived from the urogenital tract. The secreted isoform is induced and released by the proximal and distal tubules, glomeruli, and collecting duct during drug-related kidney injury and is therefore considered a pan-nephron biomarker.[79,101] Clusterin secreted at or proximal to the proximal tubule is a ligand for megalin-facilitated endocytosis, therefore increased urine clusterin could also be influenced by effects on proximal tubular function. Of note, high concentrations are also found in seminal fluid[99] and could potentially contribute to urine samples in males of some species (e.g., rat, dog).

There is ample evidence in rat studies that urine clusterin is superior to serum BUN and creatinine for the detection tubular nephrotoxicity over a wide range of toxicants,[79,95,101,89,102] with limited reports in monkeys,[103] and dogs.[104] In a comprehensive multinephrotoxicant metaanalysis in the rat, clusterin was second only to KIM-1 as the best performing of the new urinary biomarkers of tubular injury.[102] Clusterin correlated with the microscopic severity of proximal tubular injury in the rat including lesions of minimal severity.[95] It also showed slow reversal with injury resolution in rat models, consistent with a role in the repair process.[105] In the monkey, upregulation of clusterin expression by quantitative PCR in kidney tissue correlated to gentamycin and everninomicin proximal tubular nephrotoxicity.[106] Consistent with the expression of clusterin throughout the nephron, a novel compound that selectively injured the distal tubule and/or collecting duct in the monkey was associated with increased urine clusterin.[103]

There are relatively few clinical studies evaluating urine clusterin in DIKI although investigators have begun to examine this biomarker in naturally occurring kidney disease. Clusterin did not perform well in liver transplant patients treated with the nephrotoxin Tacrolimus in one report.[107]

4.15.5.4 Cystatin-C

Urine cystatin-C is a 13 kDa, LMW protein, with similar characteristics to beta-2-microglobulin as a urinary biomarker of reduced proximal tubular function. The protein is ubiquitously expressed and is a cysteine protease inhibitor. Serum cystatin-C has long been evaluated as an endogenous marker of GFR. There is no clear advantage of using serum cystatin-C over estimates using serum creatinine.

Cystatin-C has shown mixed performance in rat models of nephrotoxicity. It did not change in single-dose cisplatin toxicity,[96] although at higher or multiple doses of cisplatin, cystatin-C was an early marker with urine elevations that preceded microscopic changes.[93,105] For other tubular toxicants in the rat, urine cystatin-C was an early marker for gentamycin[93] and correlated with the severity of renal histopathology for paraquat.[108] Cystatin-C outperformed serum BUN and creatinine in a glomerular injury in multidose acute studies using puromycin and doxorubicin in the rat, although not in a single-dose puromycin model.[96,95] In a metaanalysis of 12 rat nephrotoxicity models in cystatin-C did not perform as well as other new urinary biomarkers (KIM-1, clusterin, albumin, NGAL, ostopontin).[102] For gentamycin toxicity in the dog, it outperformed serum creatinine, urine NAG and NGAL, and significantly correlated with measured GFR ($r = -0.89$).[109]

There have been mixed results on the diagnostic and prognostic ability of urine cystatin-C for patients in intensive care units with AKI of various causes.[110,111] In contrast it showed good performance in diagnosis of patients with AKI from renal causes versus prerenal (circulatory) causes and was prognostic for in-hospital mortality.[112]

4.15.5.5 KIM-1

KIM-1 is a cell surface glycoprotein expressed on proximal tubular epithelial cells of the kidney and upregulated during injury. It is also known as T-cell immunoglobulin domain and mucin domain-1 or Hepatitis A virus cellular receptor 1 (HAVcr-1), and is expressed by innate and adaptive immune cells, including Th2 cells, activated B cells, B regulatory cells, dendritic cells, and invariant NKT cells.[113,114] The activity of this protein is highly cell and context-driven. In sum, the protein functions in antiinflammatory activities, scavenging, and self-tolerance.[114] KIM-1 is a receptor for phosphatidylserine (exposed on apoptotic cells), modified low density lipoprotein, and necrotic cell debris to impart the capacity of tubular epithelial cells to scavenge and remove apoptotic and necrotic debris in the lumen and participates in repair.[115]

KIM-1 has a cleavable ectodomain (90 kDa) that is shed into the tubular lumen by the action of metalloproteinases. KIM-1 is measured by immunoassay, however available reagents show limited species cross-reactivity.[116] There are reliable and accurate immunoassays for measuring KIM-1 in humans and rodents, which has allowed the evaluation and further investigation of KIM-1 biomarker in those species. Cross-reactivity and performance of KIM-1 assays for dogs and nonhuman primates have been questionable here-to-date, however new reagents and assays are in development and under validation by independent investigators.

In the rat, KIM-1 has repeatedly been shown to be an early and accurate marker of tubular injury in a variety of models, usually outperforming serum creatinine, and often outperforming other new biomarkers.[96,102,108,105,117–119] KIM-1 has good specificity for proximal tubule injury in the face of collecting duct necrosis and when there is nonkidney toxicity that is, liver.[117,119,105] KIM-1 also correlated with the histopathology severity grade in a rat model of cisplatin or paraquat nephrotoxicity[105,118,108] and showed excellent diagnostic performance across all severity grades (minimal to marked) of tubular injury using a variety of nephrotoxicants.[117] Further, KIM-1 IHC correlated to urinary biomarker levels in cisplatin nephrotoxicity in the rat.[79] KIM-1 reversed with injury resolution,[105,118] although with slow kinetics likely reflecting the activity of this protein in states of repair. In a monkey model of acute tubular injury due to polymyxin B, KIM-1 increased comparably to serum creatinine.[116]

KIM-1 is an early marker of clinical AKI, rising within 24 h of injury and moreover demonstrated good diagnostic performance in a variety of diseases in patients. KIM-1 was elevated in nondiabetic proteinuria and responded to therapy that improved proteinuria.[120] A study of AKI due to DIKI, contrast-nephropathy, and sepsis also showed a high diagnostic accuracy for KIM-1 in comparison to serum creatinine (AROC 0.9 l).[121] In patients with established acute renal failure, urine KIM-1 activity was associated with disease severity (according to standard clinical scoring systems) and had similar prognostic performance to serum creatinine.[122]

4.15.5.6 *N*-Acetyl-β-D-Glucosaminidase

NAG is a 140 kDa lysosomal enzyme that hydrolyzes glucosamine from oligosaccharides. NAG is largely located in the proximal tubule cells and is a leakage marker of epithelial injury.[123] It is a large protein and urine levels are believed to originate exclusively within the kidney. This marker has been noted as a marker of kidney disease for decades and more recently applied to nephrotoxicity.[124] NAG is also a marker of oxidative stress and increased levels have been shown to correlate to other markers of oxidation. There is a prominent sex difference in the dog for urinary NAG, due to contributions of NAG high in seminal fluid.[124]

NAG added value over a series of 17 rat studies using multiple nephrotoxicants.[117] NAG correlated to histopathological lesions in the proximal tubules in cisplatin rat model.[118] This marker has a lower appeal compared to other new urinary biomarkers in the rat owing to a lower fold change in addition to being less reliably increased in rat models of nephrotoxicity.[118,104,119,116] In contrast, NAG shows more value in dog and monkey DIKI. NAG has been evaluated in several models of proximal tubular toxicity in the dog and outperformed a standard renal panel.[124] It was significantly and closely correlated with measured GFR ($r = -0.82$) and showed an early increase that corresponded to lesion severity with a high AROC (0.948) that exceeded serum creatinine.[104,109,124] NAG has lower magnitude of change of NAG compared to other emerging biomarkers (e.g., urinary NGAL and clusterin) in the dog.[104] NAG performed usefully in monkey and dog models of acute tubular injury due to polymyxin B, increasing together with urine protein, and serum BUN.[116]

NAG activity in urine of patients with AKI has been shown by several groups to have prognostic utility for adverse outcomes. In patients with acute tubular necrosis, NAG could predict those who required renal replacement therapy however, the performance of cystatin-C was superior.[111] NAG also showed good performance with serum creatinine as the benchmark, in early detection of acute tubular necrosis in an intensive care unit setting.[125] Urine NAG activity was a prognostic marker for patients with AKI.[122] The specificity of urine NAG activity has been questioned with individual reports that NAG can be elevated in patients with rheumatoid arthritis, glucose intolerance, and hyperthyroidism in the absence of kidney injury.[126]

4.15.5.7 Neutrophil Gelatinase-Associated Lipocalin

NGAL, or lipocalin-2, is a protein covalently bound to gelatinases originally described in neutrophils, but also upregulated during disease in the parenchymal cells of many tissues including kidney, liver, and lung. Kidney NGAL is a 25 kDa monomer whereas neutrophils express the protein as a heterodimer. NGAL binds to siderophores (iron-containing complexes), and has multiple roles including controlling the exposure of the organism to iron, reducing oxidative stress, decreasing apoptosis, and participates in mesenchymal–epithelial transition during kidney development.[94] Epithelial cells upregulate NGAL in response to inflammation, infection, injury, or neoplasia[127] and are induced in the kidney during ischemia-reperfusion injury.[128] Serum NGAL is filtered freely

through the glomerulus and actively reabsorbed in the proximal tubule by megalin. Basal levels of NGAL in urine are thought to be released from epithelial cells of the thick ascending limb of the loop of Henle and the collecting duct.[129]

NGAL is significantly increased in rat models of glomerular injury caused by puromycin and tubular injury caused by cisplatin or gentamycin.[93,105,96] This biomarker showed reversal with recovery in rat nephrotoxicity models.[105] In a head–head study with new biomarkers, NGAL performed moderately well across many tubular toxicants (still improved upon the sensitivity of serum BUN and creatinine) but had issues with poorer specificity with muscle toxicants and endotoxemia related to LPS.[102] In contrast, this biomarker outperformed most of the emerging biomarkers with the exception of KIM-1 in rat studies proximal tubular injury caused by a number of polymyxin analogs.[116] In dog models of gentamycin toxicity, urine NGAL was an early and robust biomarker of toxicity, correlating with GFR and preceding microscopic evidence of toxicity.[104,109] The magnitude of NGAL increase corresponded with the severity grade assessed by histopathology.[130] NGAL performed equivalently to urine NAG and total protein and serum BUN in polymyxin B toxicity in the dog.[116]

A large metaanalysis of 58 studies in over 2000 patients at risk for AKI in the settings of critical care, postoperative cardiac surgery, and postkidney transplant revealed NGAL had good diagnostic accuracy (AUC of 0.79–0.87) and improved risk prediction for AKI compared to standard clinical models.[94] In similar clinical settings, increased urine NGAL in the absence of elevated serum creatinine detected patients with "subclinical AKI."[94] NGAL has also performed well as a diagnostic and predictive marker of DIKI for tacrolimus and contrast-induced nephropathy.[131,107]

4.15.5.8 Osteopontin

Osteopontin is a secreted glycoprotein. Osteopontin binds to integrins and CD44 family of cell–cell and cell–matrix receptors and has a variety of roles including cell adhesion, migration, cell signaling, and cell survival.[132] It is proinflammatory and protects against oxidation and ischemia.[133] Osteopontin is upregulated in the kidney during the processes of injury and repair in response to proinflammatory and profibrotic cytokines. Additionally, osteopontin is upregulated in response to parathyroid hormone (PTH), vitamin D_3, calcium, and phosphate.[132] Osteopontin is also involved in the pathogenesis of calcium-containing urine stone formation and an important organic component of the stone nucleus.[134]

The protein has wide expression in the body, predominately in the bone and epithelia, with lower levels in white blood cells, endothelium, and smooth muscle.[132] Osteopontin shows subtle species differences in the localization within the distal nephron. In the mouse kidney, it is primarily located in the thick ascending limbs of the loop of Henle and distal convoluted tubules, in rat, the descending thin limbs of the loop of Henle, and in human, the thick ascending limbs of the loop of Henle.[132] Osteopontin is readily measureable in the urine of healthy subjects.

Osteopontin correlated with the histopathologic grade of proximal tubular necrosis in a rat cisplatin model and reversed with injury resolution.[118] In this model tissue IHC of osteopontin expression also correlated closely with urinary biomarker measurements.[79] Other nephrotoxicity models have also demonstrated that osteopontin is a sensitive marker and can outperform traditional serum BUN and creatinine.[105,77] Moreover, urine osteopontin levels decreased with recovery in rat gentamycin and carbapenem A-models.[105] Osteopontin improved upon the sensitivity of serum BUN and creatinine for detecting nephrotoxicity over a number of different tubular toxicities, although compared to other new biomarkers, it was inferior to urine KIM-1 and clusterin and showed nonspecific rises in models of muscle toxicity and LPS-induced endotoxemia.[102] In monkey nephrotoxicity models using the tubular toxicants, gentamycin and everninomicin, osteopontin expression by quantitative PCR was increased in kidney tissue.[106]

Urine osteopontin is increased in various human kidney diseases including progressive idiopathic membranous nephropathy, cresentric glomerulonephritis, IgA nephritis, and diffuse proliferative lupus nephritis.[132] Little investigation has been done in DIKI. Osteopontin protein and RNA expression was upregulated in proximal tubules in biopsy samples of renal allografts prior to transplantation following cold ischemia and in patients with cyclosporine toxicity.[135] Osteopontin was not a good biomarker for tacrolimus-related nephrotoxicity.[107]

4.15.6 Blood Cytokines as Safety Biomarkers

4.15.6.1 Biology

Cytokines are small proteins produced by a variety of immune and nonimmune cells and act as messengers between cells. They are essential coordinators of inflammatory and immune responses. Cytokines also act as hematopoietic regulators and have roles in nervous, endocrine, and reproductive system function. These molecules generally have induced production, are short-lived, and act locally to deliver an effect. Cytokine profiles vary over time in response to an inflammatory event, displaying a cascade of cytokine synthesis and release. The cascade originates with production of proinflammatory cytokines TNFα and IL-1β, which then elicit downstream generation of other proinflammatory cytokines (e.g., IFN-γ and IL-6), chemokines, followed by the antiinflammatory cytokines, IL-1Ra and IL-10. The outcome of cytokine activity is contingent on the cell context and environment and reflects diverse receptor expression in different tissues and the potential for pleiotropic activity of cytokines that is, the same cytokine may have different actions depending on receptor and cell type.

4.15.6.2 Cytokine Biomarkers

The advent of multiplex assays for cytokine panels with improved sensitivity has fostered interest in the exploration of blood (serum or plasma) cytokines as general biomarkers for toxicity. Cytokines may provide a discriminating toxicity signal when sampled at time points proximal to the inflammatory event. In the context of monitoring specific organ toxicity that is, detection of lung toxicity that has an inflammatory mechanism, there are several caveats when considering the suitability of cytokines. Cytokines are general inflammatory biomarkers therefore are not specific for site/organ of toxicity, an important challenge for a translatable biomarker when used in a patient population with preexisting disease and multiple comorbidities, some of which may have an inflammatory basis. Circulating levels of biomarkers imply a systemic "spill-over" of cytokines that has overcome the local mechanisms for restricting cytokine diffusion such as proteases to release membrane-bound cytokines, competition with cell-associated receptors, binding by soluble inhibitors and receptors.[136] Local cytokine aberrations associated with organ toxicity may therefore not reach the magnitude or circumstances that permit measurable concentration in the circulation. Importantly, assays need to be sensitive enough to detect elevations that, using traditional cytokine assays (with high pg/mL lower limits of quantification), have a low to negligible baseline. New technologies are exploring the sub-pg/mL concentrations that may be necessary for blood cytokine levels to achieve acceptable diagnostic performance.*

It has been the emergence of immunotherapy, the reactivation of the immune system against cancer, which has bolstered the rationale for exploring systemic cytokine levels as biomarkers for safety assessment. In this case, cytokines may be used to demonstrate a pharmacodynamic effect of therapy-related immunostimulation and also to diagnose adverse immune events.[136] Given that many new molecules are still under development with few drugs licensed for use by health authorities, published biomarker data is also just emerging. Serious adverse systemic immune toxicities (i.e., potentially fatal) have been observed in patients administered both small molecule drugs and biotherapeutics. The exact pathogenesis is not often fully elucidated. Differences in severity may be in part related to the therapeutic agent, dose, duration, and patient factors including target density/distribution, concomitant medications, comorbidities and therefore difficult to predict a priori. Immune toxicities associated with cytokine biomarkers include: CRS, systemic inflammatory response syndrome (SIRS), macrophage activation syndrome (MAS, also referred to as hemophagocytic syndrome, secondary hematophagocytic lymphohistiocytosis), and vascular leak syndrome. A brief description of these toxicities follows, with diagnostic criteria provided in **Table 8**. For several of these conditions, notably, CRS and vascular leak, there is the diagnosis that is not harmonized and there exists an opportunity for evaluating new biomarkers for prognosis and safety monitoring. Cytokines that are currently recognized in association with these immune toxicities are listed in **Table 9**. CRS is the consequence of widespread immune cell stimulation and unregulated systemic release of cytokines. The syndrome can range from mild and transient to life-threatening. The major clinical symptoms include nausea, headache, tachycardia, hypotension, rash, and dyspnoea. It has been noted that agents targeting T or B lymphocytes, and NK cells, include superagonist anti-CD28 mAbs, alemtuzumab (anti-CD52), rituximab (anti-CD20) and muromonab-CD3 (OKT3), and CAR-T cells. SIRS is a state of uncontrolled systemic inflammation that affects multiple organs and may be the outcome of CRS. Ultimately SIRS can progress to multiple organ dysfunction, organ failure, and death.[137] Noninfectious SIRS related to drug administration is very uncommon, and less frequent than sepsis-related SIRS. MAS is characterized by excessive T-cell activation leading to dsyregulation of macrophage function, hemophagocytosis, cytopenias, hepatitis, and neurological symptoms. Vascular (or capillary) leak syndrome is caused by increased permeability of capillaries leading to movement of plasma out of the circulation. Clinicopathologic changes include edema of the face, trunk and extremities, hypotension, hemoconcentration, oliguria. The condition may progress to localized ischemia, renal failure, stroke, deep vein thrombosis, and cardio-pulmonary failure. This is a major dose-limiting toxicity associated with IL2 immunotherapy. It can be appreciated that overlap exists between the various symptoms related to adverse immunostimulation. Interestingly, one group claims that the cytokine profile of CRS associated with T-cell engaging therapies (i.e., chimeric antigen receptor-modified T-cells and bispecific antibodies) is interchangeable with MAS, also sharing common laboratory abnormalities (i.e., hyperferritinemia and hypofibrinogenemia).[138] The excessive IFN-γ produced by T-cell activation is hypothesized to result in pathological activation of the monocyte-macrophage system and MAS. The use of cytokine biomarkers for prediction and diagnosis is thus far not well studied.

Table 8 Select immunotoxicities associated with adverse drug-related immunostimulation

Immunotoxicity	*Diagnosis*
Cytokine release syndrome	Clinical symptoms including nausea, headache, tachycardia, hypotension, rash, and dyspnea. Severe events may have hypoxia and neurological symptoms (e.g., change in mental status, seizures). May have elevations of one or more of IL-2, IL-6, IFN-γ, TNF-α
Macrophage activation syndrome	Diagnosed with at least 5 of fever ($\geq$38.5°C), splenomegaly, cytopenia (2 or more lineages), hypertriglyceridemia and/or hypofibrinogenemia, hyperferritinemia, increased soluble CD25 (IL-2Ra), hemophagocytosis in bone marrow/spleen/lymph nodes, low NK cell activity
Systemic inflammatory response syndrome	Diagnosed with at least 2 of temperature change, ($<$36°C or $>$38°C), tachycardia ($>$90 bpm), tachypnea ($>$20 bpm), and leukocyte abnormality ($<$4.000, $>$12.000 mm^3)
Vascular leak syndrome	Clinical symptoms including edema of face, trunk and extremities, hypotension, hemoconcentration, oliguria, may progress to localized ischemia, renal failure, stroke, deep vein thrombosis, and cardio-pulmonary failure

Table 9 Cytokine biomarkers of drug-related adverse immunostimulation

Category	*Toxicity/response*	*Implicated circulating cytokines*	*Other key circulating biomarkers*
Toxicity	CRS	IL-2, IL-6, IFN-γ, TNF-α	
	Macrophage activation syndrome (also hemophagocytic syndrome, hemophagocytic lymphohistiocytosis)	IL-6, IL-10, IFN-γ, sIL2Ra	Ferritin
	Systemic inflammatory response syndrome	IL-1β, IL-6, IL-8, (IL-17), MCP-1, TNF-α	
	Vascular leak (capillary leak)	IL-2, IL-3, IL-6, CXCL8, G-CSF, GM-CSF, IFN-α, IFN-β, TNFα	
Mechanistic immune response	Acute phase response	IL-1β, IL-6, TNF-α	CRP, fibrinogen, α1-acid glycoprotein 1, α2-macroglobulin
	Innate immune response	IL-1β, IL-6, IL-8, MIP1a, MIP1b, MCPC-1, TNF-α	CRP
	Th1 response	IL-1, IL-2, IL-12, IFN-γ	
	Th2 response	IL-4, IL-5, IL-10, IL-13	

Cytokines are potentially translatable biomarkers; however there may be differences in the pattern of response (i.e., magnitude, cytokine type) observed in preclinical studies in animals compared to patients. There could be several factors underpinning differences between preclinical and clinical studies, most fundamentally species differences in biology and pharmacologic target expression, altered immune contexture in patients that have preexisting disease, altered populations of leukocyte subsets, and high baseline levels of cytokines that modify the cytokine profile.[136,139,140] Additionally, the cytokine response observed in young, healthy animals is not representative of patients with various diseases. Differences in assay performance such as specificity for the biomarker, sensitivity, and study-related factors including time points of assessment are also important factors that contribute to species disparities. Consequently, in vivo cytokine profiling in preclinical toxicity studies may in some cases (drug, therapeutic indications, intended patient populations, etc.) be more akin to hazard identification for toxicity, as proposed by professional groups for use and interpretation of in vitro cytokine release assays.[141] Despite these concerns, cytokines are potentially translatable biomarkers and fundamental in profiling the immune response, therefore investigation and ultimately, application, of these biomarkers for immunotoxicity assessment is warranted. It should be noted that measurement of blood cytokines is not covered by current regulatory guidances for general toxicity or immunotoxicity assessment in drug development, however the current ICH S8 Immunotoxicity Guidance predates the severe adverse CRS that occurred in the TGN1412 clinical trial in 2006.[142] Notably, CRS is included in the National Cancer Institute Common Terminology Criteria for Adverse Events (CTCAEs) Version 4.0 and routinely applied to clinical trials for cancer.[143]

4.15.7 Bis(monoacylglycero)phosphate (BMP) a New Biomarker of Drug-induced Phospholipidosis

4.15.7.1 Phospholipidosis

Drug-induced phospholipidosis is a toxicity characterized by an accumulation of intracellular phospholipids and drug within the lysosomes of cells. Microscopically, this appears as abnormal vacuolation within the cytoplasm of cells, often as so-called "foamy macrophages." The key ultrastructural finding is lamellar bodies within lysosomes. Phospholipidosis can be localized or generalized. The localized form affects parenchymal cells of specific tissues, notably the bile duct or kidney, likely due to higher exposure of the drug in those tissues.[144] The generalized form may be macrophage-associated with a primary effect on tissue resident macrophages (e.g., lung, liver, spleen, bone marrow, thymus) or alternatively, parenchymal-associated with effects on cells of the kidney tubules, bile ducts, liver, vascular endothelium, neurons of the CNS, and PNS. The key physicochemical characteristic of drugs that cause phospholipidosis is the presence of a cationic amphiphilic toxicophore comprising a basic amine side chain attached to a hydrophobic moiety. This toxicophore binds phospholipids and traps the drug within the acidic environment of the lysosome. The mechanism of phospholipid accumulation in the cell is often not well understood and can differ between compounds. Potential mechanisms include increased synthesis of phospholipids, dysfunction of lysosomal enzymes and membrane recycling, and altered endosomal trafficking. Drug-induced phospholipidosis is associated with multiple marketed drugs across many therapeutic classes. Classic examples include amiodarone, chloroquine, chlorpromazine, and gentamycin.[145]

Phospholipidosis occurs in animals and in humans, however in silico and in vitro systems do not necessarily predict toxicity in animals, which in turn do not always predict tissue pathology and toxicity in humans.[145,146] There is debate as to whether phospholipidosis is deleterious to cell function.[145] These potential associations, in addition to pathology findings that resemble inherited lysosomal storage disease, garner regulatory concern of the drug's safety. Phospholipidosis can therefore cause delay or attrition during drug development.

4.15.7.2 Bis(monoacylglycero)phosphate

Bis(monoacylglycero)phosphate is one of a family of phosphatidylglycerol-derived phospholipids that are located on the inner membrane of late endosomes and lysosomes and widely expressed in many tissues. BMP comprises less than 1% of total body phospholipids with the exception of the lung, which has higher concentrations as a product of the physiologic production of surfactant phospholipids that are crucial in alveolar function.[147] BMPs are involved in vesicle biogenesis within the late endosome, forming the multivesicular body structure (Fig. 5). Functional roles of BMP in the endolysosomal system include transport of lysosomal enzymes, recycling of membrane lipids, and intracellular cholesterol trafficking.[146,148] BMP is released from the intracellular environment into the circulation by exosomes.

Tissue levels of BMP were specifically enriched in the tissues of patients affected by inherited and drug-related phospholipidosis in the 1970s. Since that precedent, di-docosahexaenoyl (22:6) BMP (di-22:6-BMP) has been identified as the molecular species with highest induction in drug-induced phospholipidosis.[149] Similarly, this species is also highest in Nieman-Pick disease, the most analogous inherited lysosomal storage disorder to the toxic condition.[146]

BMP has been evaluated as a candidate biomarker for monitoring phospholipidosis in animals and humans. The biomarker is measured by mass spectrometry. BMP concentrations are approximately twofold higher in serum than plasma in healthy humans, with no reported sex differences, whereas males had slightly higher urine BMP (adjusted to urine creatinine) compared to females. Although reference intervals have not been published, species differences in BMP are apparent with serum levels in rodents higher than human, dog, and nonhuman primates. Rodent urine BMP concentration is an order of magnitude higher than other species. In rodent toxicity studies across many phospholipidosis-inducing agents (chloroquine, amiodarone, 4,4′-diethylaminoethoxyhexestrol dihydrochloride, gentamicin, azithromycin) di-22:6-BMP was demonstrated to monitor the onset, duration, and reversal of PL.[150,151,146,149] Urine di-22:6-BMP has been shown in several studies to have better diagnostic performance than serum, with the benefit of improved specificity in the context of concomitant (nonphospholipidosis) toxicity in the same target organ.[152,153] Urine di-22:6-BMP retained good diagnostic performance in the presence of nonphospholipidosis-related kidney toxicity.[130] Di-22:6-BMP has not been specifically evaluated in patients with drug-induced phospholipidosis, however it had high diagnostic accuracy (97% sensitivity and 100% specificity) for Nieman-pick disease.[146]

The role of di-22:6-BMP as a biomarker of lysoendosomal disorders has also been explored in genetic and pharmacologic models of leucine-rich repeat kinase 2 (LRRK2) depletion.[154] LRRK2 plays a role in endolysosomal trafficking and is a therapeutic target of intense interest for treatment of Parkinson's disease. However, a potential safety liability of reducing LRRK2 activity is the accumulation of lamellar bodies in type II pneumocytes of the lung, phenotypically resembling phospholipidosis. The mechanism of this cellular vacuolation is not clear and occurs in both knockout mice, and monkeys treated with several structurally variant inhibitors of

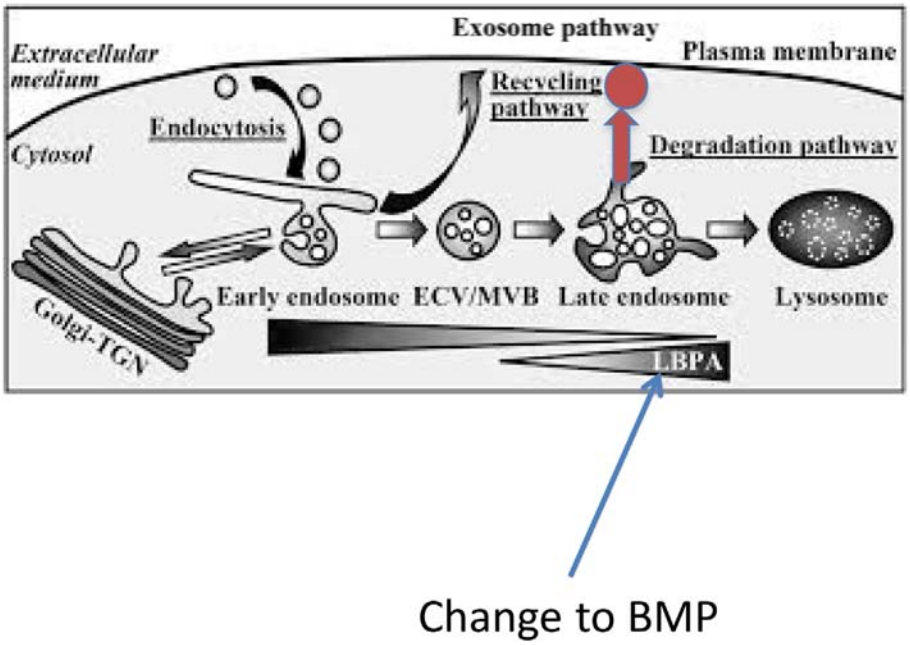

Fig. 5 Endosomal trafficking in the cell. Endosomal and exosomal movement facilitate the interchange of membrane proteins, receptors, macromolecules, and lysosomal enzymes. Early endosomes fuse to mature into larger endosomes. Mature endosomes undergo invagination of the outer membrane to form internal vesicles and form a multivesicular body or endosome. The phospholipid BMP is involved in the vesiculation process and is at high levels in these structures. Late endosomes can fuse with lysosomes or traffic to the cell membrane to be released as exosomes. Falguières, T.1; Luyet, P. P.; Gruenberg, J. Molecular assemblies and membrane domains in multivesicular endosome dynamics. *Exp Cell Res.* **2009**, *315*(9), 1567–1573.

LRRK2 kinase. Intriguingly, lamellar body accumulation in this model was related to clear decreases in urine di-22:6-BMP, indicating a more broad utility in monitoring aberrant endolysosomal trafficking.[154]

BMP shows great potential for monitoring of drug-induced phospholipidosis, however it is not specific for the tissue distribution. It is undetermined whether BMP is related to the severity of toxicity. This is an important marker in building the safety profile, and eventually a tool in population-based epidemiological studies to assist in determining the safety of drugs that induce phospholipidosis. The majority of current evidence for the diagnostic accuracy of di-22:6-BMP is derived from one laboratory-derived test. It is essential for this testing to become more widely available to allow further analytical validation and technical characterization in addition to greater data generation ensuing from improved accessibility. Only then can the potential of this promising biomarker be fully realized.

4.15.8 Future Prospects

These are still early days for the use of new safety biomarkers in regulated drug development. The value proposition of new safety biomarkers is to improve risk-benefit assessment at all stages of development. By employing new safety biomarkers where there are gaps in standard monitoring tools, drug developers are ensuring the safe conduct of clinical trials and permitting evaluation of innovative new therapies that may have previously been discontinued by unknown clinical translatability of preclinical toxicities and/or dose-escalation capped by perceived safety risk.

The exploratory use of emerging safety biomarkers is a break in the convention for safety assessment from reliance only on endpoints with a large historical database. There is still uncertainty in using emerging safety biomarkers, despite regulatory qualification and rigorous evaluation. To create a historic database and complete understanding of a new biomarker is a herculean task that has previously been undertaken by the entire medical community in the case of new clinical diagnostics for spontaneous disease. It is therefore unrealistic to believe this is also not required for safety biomarkers: it is incumbent on drug developers, regulators, and the medical community to generate this data by using the biomarkers across a broad range of scenarios. The "risk" of using emerging safety biomarkers is often defrayed by the concurrent use of routine tests or more sophisticated ancillary testing that are interpreted together to assess the presence or absence of toxicity. A necessary step in community-based qualification of new safety biomarkers is the ability to pool or aggregate data generated by drug developers to allow faster, more efficient, more nuanced, and ultimately more accurate evaluation of the utility and performance of safety biomarkers for improving risk assessment and drug development.

4.16.1 Introduction

This article on "Toxicology Prediction—Regulatory Perspective" is intended to describe and characterize the evolution of technological tools and regulatory instruments that facilitate and empower the contemporary approach to toxicology prediction, as well as current and future challenges and expectations. The section on historical perspective is a chronological encapsulation of the many events and issues that have influenced and molded the current approach to toxicology prediction, as well as the laws that allow for such implementation. Further, there is a compilation of significant documents, programs, guidances, and guidelines that have been used to describe various methods and tests performed to detect toxicity and insure the safety of products that are subject to federal regulation. This is followed by a discussion of the process involved in toxicology methods development as well as description of the key attributes that lead to validation and acceptance. A description of the tests required for safety evaluation of a new drug are followed by a table of accepted tests that have now been abandoned and a table that lists the current major tests and methods relative

to their status in 2005. A major section of this article is devoted to an extensive description of many of the latest new technologies that are being developed to detect toxicity and a table of each of the general subdiscipline areas as well as their current status compared to 2005. Finally, there is list of some of the more important critical issues in toxicology, their current status, as well as potential future directions of the technologies described and what conclusions can be drawn with respect to the overall field of toxicology prediction.

4.16.2 Historical Perspective

The historical record, going back to antiquity, has demonstrated the need for the regulation of food and much later drugs. Early English law dealt with the adulteration of food for economic gain. King John promulgated rules on contamination of flour, later referred to as the Assizes of Bread. In early America quack medicines, hidden ingredients and misbranding were typical. In 1848, Congress passed the Drugs and Medicines Act that represented the first recognition of the US Pharmacopeial Convention.

The Virus-Toxin Act of 1902 was passed in response to the production of a diphtheria vaccine that was contaminated with tetanus toxin resulting in the death of many children. This legislation was quite remarkable for its time because it provided for premarket clearance for safety and efficacy, factory inspection at every stage of manufacture, and individual batch certification of each lot of vaccine produced. This level of regulation was not achieved for drugs until another 60 years had passed and a significant number of catastrophic incidents had occurred.

The publication of "The Jungle" by Upton Sinclair in 1906,[1] as well as the rejection of US meat products by European countries lead to the passage of the Food and Drug Act of 1906, better known as the Wiley or Heyburn Act which was considered to be the first "modern" federal food and drug law which targeted adulteration and misbranding. It also established the US Pharmacopeia and National Formulary to establish and regulate reference standards. The Sherley Amendment of 1912 prohibited the use of fraudulent claims, but placed the burden of proof on the government. This resulted in weak or nonenforcement of the 1906 act due to the paucity of modern scientific techniques or tools needed to establish and prove the existence of evidence needed for prosecution. Many deaths occurred from "quack medicines" with hidden ingredients that were often extremely poisonous.[2] There was no animal testing to ensure safety until 1938.

The Federal Food, Drug, and Cosmetic Act (1938), also known as the Copeland Act was the response to a catastrophic event involving the addition of ethylene glycol as an excipient in elixir of sulfanilamide. This resulted in many deaths caused by the nephrotoxicity of the mixture. This legislation mandated, for the first time, that new drugs be tested in animals before human administration, thereby establishing premarket clearance for safety.

The next milestone piece of legislation that played a very significant role in the federal regulation of toxicity was the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) of 1947. It defined the LD-50 concept, established classes of toxicity based on the order of magnitude of doses above and below the LD-50, and required a label to be written for pesticides as well as registration with USDA. This eventually led to the setting of tolerances and measurement of persistence in the environment by Food and Drug Administration (FDA) and ultimately, regulation by EPA[3] following its establishment in 1969.

Insulin and antibiotic certification amendments ('41, '43, '49, and '52) provided for batch certification of all master lots (insulin) and batches of finished product (insulin and antibiotics) to insure purity and potency, a very important process to insure safety and efficacy. These requirements were abolished in the late 1980s (antibiotics) and the late 1990s (insulin) when synthetic and recombinant products became available and the failure rate of tested products became miniscule.[4]

GRAS list (1958). GRAS or "generally recognized as safe" is a list of food additives that have been used since antiquity without any obvious adverse effects. Of course there are substances on the list such as NaCl which would never be approved today because of our current knowledge (e.g., the role of NaCl in hypertension). Since the original list was generated in 1958, any additions to the list must have their safety substantiated by published studies to that effect.[4]

The Durham-Humphrey Act of 1951 defined the modern practice of pharmacy as well as the relationship of the physician to the pharmacist (e.g., pharmacists were no longer allowed to practice medicine in lieu of a licensed physician). It established a separate class for narcotics and physician registration numbers for prescriptions and created "legend drugs" (e.g., Rx drugs or those that require a prescription).

The Kefauver-Harris Act of 1962 was precipitated by the thalidomide incident which resulted in phocomelia (flipper arms) in many children in Europe. This catastrophe was prevented from occurring in the United States by the caution of Dr. Francis Kelsey, an FDA medical officer at the time, who reviewed this submission. The resulting legislation, known as the Kefauver-Harris Act, mandated premarket clearance for both safety and efficacy and provided for various phases of investigation before drug approval. Its major provisions included initial preclinical studies in animals, followed by human studies in three phases (IND—first in human drug studies in normal subjects at low doses; Phase 2—small number of clinical trials; and Phase 3—large-scale clinical trials) prior to approval of a new drug application (NDA). It also called for postmarket surveillance of approved drugs including adverse effect reporting at defined intervals and immediately for severe occurrences.[3,4]

"The Toxic Substances Control Act (TSCA) of 1976 provides the EPA with authority to require reporting, record-keeping and testing requirements, and restrictions relating to chemical substances and/or mixtures. Certain substances are generally excluded from TSCA, including, among others, food, drugs, cosmetics and pesticides. It addresses the production, importation, use, and disposal of specific chemicals including polychlorinated biphenyls (PCBs), asbestos, radon and lead-based paint." There are many sections in the TSCA. Some of the more important of these include Section 5 that requires premanufacture notification

Table 1 Key features of the Lautenberg Act of 2016 versus TSCA[6]

Mandates safety reviews for chemicals in active commerce
Requires a safety finding before new chemicals are allowed on the market
Replaces TSCA's safety standard—which prevented the EPA even from banning asbestos—with a health-based, as opposed to cost-oriented, standard
Explicitly requires protection of vulnerable populations, such as children and pregnant women
Enhances the EPA's authority to require testing of both new and existing chemicals
Sets aggressive, judicially enforceable deadlines for EPA decisions and compliance with restrictions
Makes more information about chemicals available, by limiting companies' ability to claim information as confidential, and by giving states and health and environmental professionals' access to confidential information needed to perform their jobs
Requires the EPA to reduce animal testing where scientifically reliable alternatives exist that would generate equivalent or better information
Requires the EPA to prioritize chemicals that are persistent and bioaccumulative, and that are known human carcinogens and have high toxicity
Retains a significant role for states in assuring chemical safety, by grandfathering in past state actions, preserving states' ability to take many types of actions, and providing for states to get waivers to act both before and after the EPA takes final action on a chemical

for new chemical substances before manufacture and Section 4 that requires testing of chemicals by manufacturers, importers, and processors where risks or exposures of concern are found. Section 8 requires the maintenance of the so-called TSCA inventory which contains more than 83,000 chemicals and new ones are being continually added. This section also requires extensive record keeping by manufacturers. There are also sections that cover compliance and enforcement.[5]

In May 2016, congress passed the Lautenberg Act by an overwhelming margin, which represents the first major update of the Toxic Substances Act of 1976 in 40 years. This landmark legislation of, which the EPA regulations have yet to be promulgated, has some important new provisions (see **Table 1**) that focus and strengthen the earlier TSCA Act, as well as compromises that were necessary to gain its passage. The new law is an enormous improvement over current law in every major respect.

4.16.3 Important Documents and Programs Relating to Toxicology Prediction and Safety Issues

4.16.3.1 Appraisal of the Safety of Chemicals in Foods, Drugs, and Cosmetics

This publication written by the staff of the Division of Pharmacology at the Food and Drug Administration (in various editions from 1955 to 1965) was the first modern compendium of tests, methods, and techniques for evaluating the safety of various chemicals in foods, drugs, and cosmetics. Often referred to as "Lehman's Bible," in 13 chapters it described the toxicological tests required to satisfy regulatory requirements demanded by the laws and regulations of the time. Areas covered included acute, subacute, chronic oral toxicity, and dermal toxicity, as well as the bioassay and evaluation of new drugs, safety evaluation of food additives, and carcinogenicity screening. It was the precursor of the FDA Redbook (see later) on food safety as well as the various guidance's on drug safety testing issued by the Bureau of Drugs later known as the Center for Drug Safety and Research.[7–10]

4.16.3.2 Current Views on Safety Evaluation of Drugs

A very comprehensive 1968 snapshot of the preclinical studies for toxicity prediction required for the initiation of various phases of clinical trials necessary for new drug evaluation and approval.[11] From an historical prospective, there are considerable contrasts between the 1968 requirements and those of the current 2016 FDA Guidances and ICH Guidelines. For instance in 1968, "prior to the beginning of a large scale clinical trial (Phase 3), we have insisted that studies of seven years duration in the dog and up to 10 years in the monkey be commenced."[11]

4.16.3.3 Redbook 2000; Revised Jul. 2007

Guidance for Industry and Other Stakeholders Containing Toxicological Principles for the Safety Assessment of Food Ingredients. This document includes an AGENCY REVIEW OF TOXICOLOGY INFORMATION submitted in support of the safety assessment of food ingredients; recommended toxicity studies; and guidelines for toxicity studies. The latter includes general guidelines for (a) conducting toxicity studies; (b) reporting results of those studies; (c) pathology considerations for those studies, and (d) statistical considerations. This is followed by guidelines for specific toxicity studies which are further broken out into short-term tests for genetic toxicity (bacterial reverse mutation test; *in vitro* mammalian chromosomal aberration test; *in vitro* mouse lymphoma TX; and *in vivo* mammalian erythrocyte micronucleus test). There are sections on Acute Oral Toxicity Tests; Short-Term, Subchronic and Chronic Toxicity Tests With Rodents and Non-Rodents; Carcinogenic and Combination Chronic Toxicity/Carcinogenic Studies in Rodents; Reproduction and Developmental Studies As Well As Neurotoxicity Studies. There is a section on additional studies that include Metabolism, Pharmacokinetics, and Immunotoxicity Studies and finally a section on human studies that includes clinical evaluation of food ingredients and epidemiology studies. This is a very comprehensive toxicological testing document generated and revised through the years by the FDA's Center for Food Safety and Applied Nutrition.[12–14]

4.16.3.4 Toxicology in the 21st Century (Tox21)—Tox21

A program introduced by the National Academy of Sciences to establish a comprehensive plan and strategy to broaden horizons for toxicity prediction in the 21st century.[15] "The goal of Tox21 is to develop more efficient and less time-consuming approaches to predict how chemicals may affect human health." Initially, the main focus of Tox21 is to help prioritize chemicals for more extensive testing using traditional methods. Tox21's ultimate aim is to develop strategies for agencies to use in regulating chemicals and reducing the current reliance on animal testing for toxicological evaluations. Some of the broad goals for the next 5 years include "Development and deployment of a suite of screening platforms for a Tox21 library; Addressing key technical limitations of *in vivo* chemical screening; Consolidation of chemical library management; Curation and characterization of legacy *in vivo* toxicology studies; Validation of high-throughput *in vitro* assays and integrated assays; Refinement and deployment of *in vitro* methods for characterizing biokinetics and pharmacokinetics"; and establishment of programs for outreach and training.[15] To achieve these goals, the objectives of the Tox21 program are to: "Identify environmental chemicals that lead to biological responses and determine their mechanisms of action on biological systems; Prioritize specific compounds for more extensive toxicological evaluation; Develop models that predict chemicals' negative health effects in humans; and Annotate all human biochemical pathways and design assays (tests) that can measure these pathways' responses to chemicals." Current screening efforts include two themes[15]:

4.16.3.4.1 Generating fit-for-purpose cellular models for secondary screening

Tox21 experts are developing a range of hepatocyte (liver), neuron, endothelial (skin), and cardiomyocyte (heart) cell models—including "disease-in-a-dish" models, 3-D culture methods, and multicellular coculture models, all derived from inducible pluripotent stem cells (iPSCs)—to further characterize hits from primary screening of 10,000 compounds (Tox21 10K library). These investigators working to advance Tox21 principles often use an iPSC-derived endothelial cell model from the National Heart, Lung, and Blood Institute to investigate tobacco lung toxicity through a grant from the FDA and NIH.

4.16.3.4.2 Developing a high-throughput gene expression core facility

Tox21 scientists have developed a high-throughput gene expression platform core facility with the goal of generating data from hundreds of thousands of samples across 1400 human genes each year. Although the team uses RNAseq technology to analyze all genes in a few samples, evaluating the effects of many compounds at multiple doses and times, each on several cell lines, requires higher throughput. To this end, the group is developing the RASL-Seq technology platform (link is external), which includes approximately 1400 human gene assays and a streamlined, automated procedure to serve both Tox21 collaborators and NCATS projects. The data analysis team is implementing a pipeline to enable data processing and statistical and systems analyses, which will be useful for RASL-Seq and RNAseq data.[15]

4.16.3.5 Toxicologic Testing Handbook[16]

A comprehensive monograph on principles, applications, and data interpretation was published by Jacobson-Kram and Keller in 2006[16] of many aspects of regulatory toxicology testing. It includes chapters on animal and *in vitro* models, acute and multidose general toxicology studies, toxicology of major organ systems, genetic and carcinogenicity studies, developmental, reproductive and juvenile studies, cancer risk assessment, nonclinical safety testing of pharmaceuticals, etc.

4.16.3.6 FDA Guidances on Safety Evaluation of Drugs

These are committee or cosensus generated documents that articulate the 'state of the art' as well as the status of scientific tools & tests for evaluation of drug safety.

4.16.3.7 Tests Required for Safety Evaluation of New Drugs

Ellis and Hastings (2006)[18] suggest in one of their chapter tables, the "Minimum nonclinical data required for most drug products before initial human exposure in the United States." These include safety pharmacology, limited pharmacokinetics, acute toxicity, local tolerance, cardiovascular, central nervous system (CNS) and respiratory system, C_{max}, AUC, studies in two mammalian species, use of the proposed route of administration, and tests for mutations and chromosomal damage. They go on to mention the need for studies involving reproduction toxicity, subacute and chronic toxicity, *in vivo* genetic studies, and a variety of specialty studies that include: abuse potential, ototoxicity, immunotoxicity, juvenile animal studies, and phototoxicity. These special studies are not always obligatory but may be required depending on the nature of the new drug being investigated or the outcome of the initial obligatory testing. Two-year carcinogenicity studies may be required if the drug yields positive findings in genetic tests or is intended for use longer than 6 months.

Many of these tests are continually being modified to reflect technological advances. The FDA does not require a specific test to be performed, but rather leaves the burden of proof on the innovator. Instead FDA publishes guidances intended for industry that reflect the agency's thoughts on what the current state of the art is in a particular area of safety testing. Examples of these finalized guidances, as well as ICH guidelines are listed in the tables below. (**Tables 2** and **3**).

4.16.3.8 Classical Methods for Toxicity Evaluation That Are No Longer Used

There are a number of classical methods that were utilized for toxicity evaluation that are no longer used. Some of the problems or reasons for abandonment of those tests include: animal welfare issues that include pain production, other types of suffering, and/ or tissue damage and/or use of too many animals; method insensitivity or production of data artifacts; replacement by *in vitro* tests or chemical analysis; lack of universal validation; generation of false positives and negatives; and finally, inability to correlate test results with biological evidence of toxicity or lack of clinical translation or relevance. Examples of some of those tests are listed in Table 4.

4.16.3.9 Current Methods for Toxicity Prediction and Safety Evaluation and Present Status

Many of the current test methods that are used to generate drug safety data in the various toxicology subdisciplines are listed in Table 5 which describes the nature of the application, the stage of use and acceptance, and the level of incorporation into regulatory documents and publications.[19]

4.16.3.10 Life Cycle of Method Development, Validation, and Adoption

Method development is an evolutionary sequence that begins with the emergence and recognition of a need for a process and/or tool that will provide a metric(s) for evaluating a particular attribute of a specific entity that requires characterization and generally quantification. This process often begins in the laboratory involving a series of sequential experiments culminating in a successful configuration or process. This usually leads to the creation of a tool that yields the data necessary to achieve the required information. Once this step has been achieved there may be a series of internal efforts to validate the new method. This is often followed by the presentation of the new method at a scientific meeting. At that point, there are several choices. The method may be published in

Table 4 Accepted tests that are no longer routinely used

Name of the test	*Type of test*	*Problems or reasons for abandonment*
Esophageal corrosion	Application of acids and bases to whole animal potential irritants and corrosives	Issues of animal welfare (pain, suffering, and tissue damage)
Eye and skin irritation	Application of acids and bases to whole animal potential irritants and corrosives	Issues of animal welfare (pain, suffering, and tissue damage)
Chick embryo assay	Injection of drugs into fertile chicken eggs	A variety of artifacts caused by physical factors; pressure, sand, and water injection cause effects
Host-mediated assay	*In vivo* mouse genotoxicity	Use of S-9 allowed *in vitro* assay
Dominant—lethal test	Chromosome damage in reproductive cells	Insensitive test
Classical LD-50's	Three to five dose levels; 10 animals per group; 14-day observation period	Use of too many animals; animal welfare issues
Rabbit head drop	Curare assay	Replaced by HPLC
Hormone bioassays	*In vivo* tests of potency and toxicity	Replaced by *in vitro* assays or chemical analysis
Unscheduled DNA synthesis (UDS)	DNA repair assay	Detected limited set of chemical and damage; lack of universal validation
Sister chromatid exchange (SCE)	Chromatid rearrangements	Lots of false positives; no correlation with disease or biological end point
Comet assay	DNA strand break assay	Presently, unique utility not demonstrated
DNA adducts	Drug–DNA interactions	Cannot identify specific damage; no direct relationship with disease or biological end point
Rabbit pyrogen assay		Limulus amoebocyte assay is the *in vitro* substitute

an appropriate journal for which peer review represents the first step of validation or prior to this, the method and appropriate samples are distributed to other investigators in the field as part of a collaborative study. The successful completion of this joint study can yield an initial element of validation that might be followed by publication whereas failure of the study might prompt the method to be modified or abandoned and discarded.

There are a number of important criteria that play a critical role in determining whether a regulatory method or test will gain acceptance and adoption. It should be translatable to relevant human end points. This means that the animal model, if one is utilized, has to be appropriate in terms of simulating human response. A notable example of a problem in this area has to do with pain measurement and the effectiveness of various analgesic drugs. The often used rodent tail flick or hot plate methods measure cord reflex pathways and do not represent pain perception that requires participation of higher centers in the brain. The latter require animal models that require Skinnerian paradigms.[20] Tests must also produce meaningful data that is easy to replicate (robust and reliable) in other laboratories. This means that there must be a paucity of false positives and false negatives and the results must be predictable in terms of human safety. The test should not only be considered useful, but also have a wide consensus of its utility. From a practical point of view, the test or methods should, where possible, be inexpensive or justifiable in terms of cost and time to complete. The ultimate challenge with respect to acceptance and adoption is whether the method generates data that is sufficient to convince FDA and other domestic and international regulatory bodies or agencies of its utility and value.

In the event that a method is published, there a very strong possibility that other groups will begin using it to generate data that may reinforce the applicability and the utility of the method. This is the beginning of the validation process that goes beyond the initial publication acceptance based on peer review. At this point, there is the possibility that many of the laboratories may generate false positives or false negatives that may lead to method abandonment. However, if this further peer review establishes the utility of the method, the following two processes may occur: (a) the method may begin to be widely used by academics to establish metrics for phenomenological and mechanistic studies with subsequent publication and (b) widespread publication may instill a perception that the method has potential for importance in regulatory decisions. This may be followed by drafting of a guidance that mentions or incorporates the method, which is then peer reviewed by the regulatory community. This step is the very beginning of the adoption process that is often followed by publication of the draft in the Federal Register calling for comments which represent additional peer review. Once this draft guidance has been finalized and published it may then be cited or incorporated into widely recognized monographs and other documents on safety toxicology methods. This further encourages wide use in laboratories of all sectors, especially those in the pharmaceutical industry. This ultimately leads to the method being widely endorsed by a variety of government agencies with regulatory functions related to safety toxicology. The final step in the adoption of a method is generally its acceptance by a wide body of international governments and agencies and its incorporation into documents such as regulatory guidances and guidelines. This action essentially completes the life cycle of a method from its conception to adoption and widespread utilization. It should be noted, however, that during the life cycle of a validated method there may be revisions and significant improvements prompted by technological advancements. These events often lead to the development of new methodologies and retirement of earlier ones, completing the life cycle as shown in Table 4. In summary, the vast majority of validated, adopted tests or methods for toxicity prediction are robust, reliable, easy to conduct and replicate in various laboratories, and

justifiable in terms of cost and timeliness. They generate meaningful toxicity data, are translatable to humans, and address relevant regulatory safety issues (Fig. 1).[19,20]

4.16.3.11 The Continuing Evolution of a Global Consensus on Regulatory Toxicology (ICH, etc.)

There has been a continuing trend of international cooperation among regulatory agencies within the United States, Europe, and Japan to forge a consensus on requirements for safety testing. Some examples of international regulatory agencies and organizations that evaluate and/or validate methodology for drug safety approval include:

CPMP—Committee for Proprietary Medicinal Products
ECVAM—European Center for the Validation of Alternative Methods
EEC—European Economic Community
EMEA—European Agency for the Evaluation of Medicinal Products
EPA—Environmental Protection Agency
FDA-BVM—Bureau of Veterinary Medicine (now Center for Veterinary Medicine)

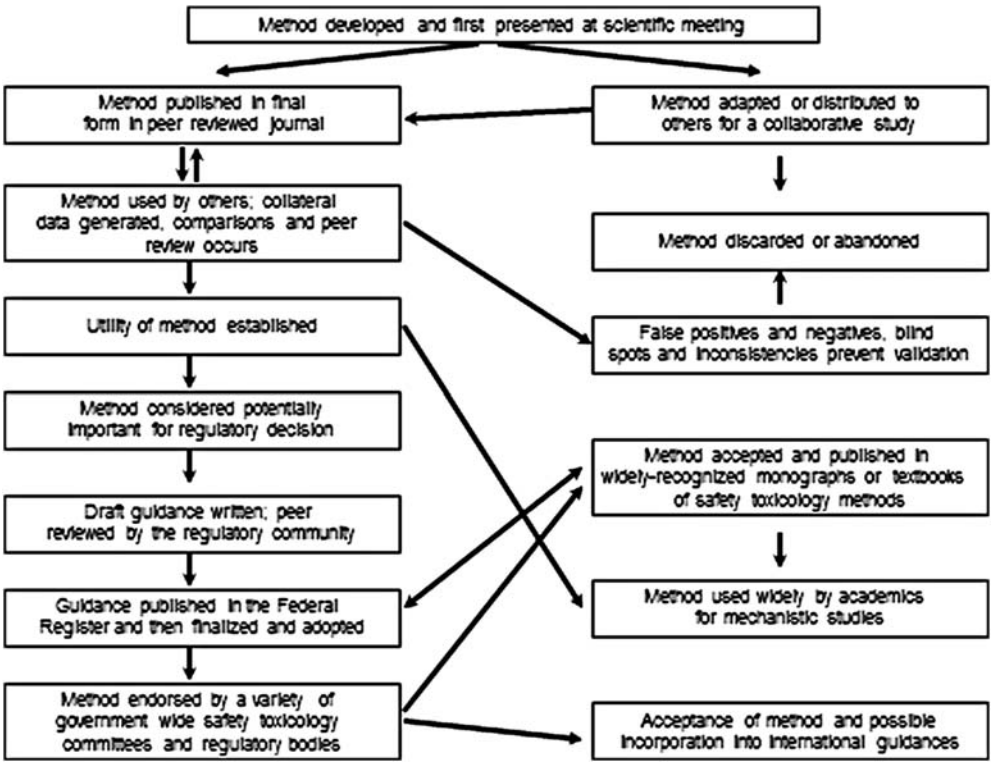

Fig. 1 Decision tree—acceptance of a safety toxicology method. Copyright 2006 from *Biological Concepts and Techniques in Toxicology: An Integrated Approach* edited by Jim E. Riviere. Reproduced by permission of Taylor and Francis Group, LLC, a division of Informa plc.

FDA-CFSAN—Center for Food Safety and Applied Nutrition
FDA-CBER—Center for Biologics Evaluation and Research
FDA-CDER—Center for Drug Evaluation and Research
FDA-CDRH—Center for Devices and Radiological Health
FDA-PTCC—Pharmacology/Toxicology Coordinating Committee (CDER)
HESI—Health and Environmental Sciences Institute
ICCVAM—Interagency Coordinating Committee on the Validation of Alternative Methods
ILSI—International Life Sciences Institute
ICH—International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use
JPMA—Japanese Pharmaceutical Manufacturers Association
MHLW—Ministry of Health, Labor, and Welfare (Japan)
OECD—Organization of Economic Cooperation and Development
USP—United States Pharmacopeia

Many of these groups meet on a regular basis to discuss safety issues, resolve differences, and arrive at a consensus that ultimately results in the issuance of guidances or guidelines (ICH) for regulatory studies.[17] These may serve as an example of best scientific practice or "state of the art" in terms of the design of preclinical studies that predict toxicity that is translatable to clinical trials. This tendency toward worldwide standardization of requirements for the generation of regulatory preclinical toxicity studies has in many ways been necessitated by the globalization of the pharmaceutical industry where mounting costs make it almost impossible to run multiple sets of safety studies to satisfy different geographical regulatory requirements.[21]

4.16.4 Minimally- or Noninvasive Approaches to Assess Chemical and Drug Effects—Indicators of Efficacy and Toxicity

4.16.4.1 Preclinical Imaging as a Translatable Biomarker

Minimally invasive imaging allows repeated observation of the structure and function of internal organs of laboratory animals under normal conditions and during toxicity or disease onset, progression, and recovery without significantly disturbing the subject.

Certain imaging signatures, or biomarkers, can serve as indicators of treatment efficacy and/or toxicity and can be readily replicated in clinical-imaging studies to ensure and enhance the effectiveness and safety of regulated products.[22]

Preclinical imaging can assist regulatory agencies to address newly developing technologies and the safety of new and existing medicines and other regulated products by (1) developing imaging biomarkers that increase the number of tools available for more thorough safety assessments of new chemicals, medical devices, drugs, and foods to help protect human health and well-being and (2) translating new preclinical methods and biomarkers into the clinical setting that allow scientists to enhance clinical practice, optimize clinical trials, and develop precision/personalized medicine treatments. Likewise, imaging approaches may identify toxicity following environmental chemical exposure.[23,24]

Real-time minimally invasive data collection over the lifetime of an animal model is now possible with the use of bioimaging. New technologies including magnetic resonance imaging (MRI), magnetic resonance spectroscopy, positron emission tomography (PET), optical Imaging, 3-D ultrasound, and computerized tomography are among the approaches available today which have demonstrated utility for safety assessment studies. Non- or minimally invasive imaging is the ideal medium for biomarker development because similar methods can be used in humans and laboratory animals, thus minimizing the assumptions in data interpretation and reducing uncertainty during product development or risk assessment. However, the routine use of imaging approaches for safety assessment studies has been slow to occur in part due to the lack of guidelines for application to traditional animal models and biomarker validation.

4.16.4.2 Emerging Imaging Biomarkers

Neuroimaging has tremendous advantages for identifying potential biomarkers of toxicity, primarily because it is less invasive than other procedures. Additionally, longitudinal studies can be completed and test animals can serve as their own controls. MRI and PET are two imaging techniques of potential utility for monitoring aspects of neurotoxicity (**Table 6**). MRI can provide *in vivo* information on cell toxicity by detecting changes in characteristics of the relevant tissue, such as cellular integrity, cell density, and water redistribution. There are several applicable MRI methods, but T2 relaxation is most useful in this context as it is simple, can result in evenly distributed time course scans, and can produce quantitative maps. Micro-PET imaging allows for functional imaging at the molecular level and thus, can provide valuable insights into biochemical, physiological, and pathological processes during the expression of toxicity *in vivo*.[22,25,26] PET imaging requires positron-emitting ligands which can be designed to track specific end points such as cellular membrane disruption thought to be associated with apoptosis or gliosis. The collection of data over multiple time points within the same subject is just one of the advantages of these imaging methods.

Molecular imaging technologies offer unique opportunities for conducting minimally invasive studies and PET is an imaging modality that is applicable at the molecular level and can provide valuable insights into biochemical, physiological, pathological, and pharmacological processes *in vivo*.[26–30] Dynamic imaging also has great potential to advance our understanding of chemical and drug-related toxicity processes, including those associated with neuronal plasticity, neurodegeneration, and neurotoxicity.[26]

4.16.4.3 Small Animal PET Imaging (Micro-PET)

PET technology was originally developed in the 1960s and the first human brain PET study was performed in 1975.[31,32] Recently, PET has become a relatively routine clinical imaging modality used in the diagnosis of cancer, cardiac disease, and neurological disorders. Similarly, micro-PET for rodents, nonhuman primates, and other animals has developed into an important research tool with increasing spatial resolution.[33–35] Micro-PET imaging provides an excellent bridging platform for extrapolating preclinical data to the human condition.[22]

Radioactive tracers are molecules labeled with short-lived positron-emitting radionuclides such as O-15, N-13, C-11, and F-18. After injection of a radiotracer, the labeled molecule can bind to highly specific targets in the laboratory animal and, thus, characterize the biodistribution of that specific tracer. The radiation emitted by the labeled tracer is then detected by the PET scanner allowing for the detection, localization, and quantification of signal intensity. By utilizing numerous radioactive tracers, multiple biological or pathological processes such as perfusion, metabolism, receptor binding, and protein expression can be qualitatively

Table 6 Different techniques of neuroimaging

Anatomy	*Physiology*	*Metabolism*	*Molecular*	*Functional*
X-Ray	USG	MRSI	PET	fPET
MRI	MRSI	PET	MRI	fMRI
CT	SPECT			OI
USG	PET			IR
	IR			

MRI, magnetic resonance imaging; *CT*, computed tomography; *USG*, ultrasonography; *MRSI*, magnetic resonance spectroscopic imaging; *PET*, positron emission tomography; *SPECT*, single photon emission computed tomography; *IR*, infrared; *fPET*, functional PET; *fMRI*, functional MRI; *OI*, optical imaging.[22]

and quantitatively assessed.[32,33,35] Several radiolabeled tracers have been developed to identify subcellular events associated with programmed cell death or apoptosis, glucose metabolism or microglial activation, and inflammation.[36,37]

4.16.4.3.1 [^{18}F]-Annexin V

In contrast to normal cells, phosphatidylserine (PS), one of the four major phospholipids that make up the cell membrane, externalizes from the intracellular to extracellular side of the plasma membrane in cells undergoing apoptosis.[38–41] The redistribution of PS to the exterior of the cell membrane in the early stages of apoptosis precedes most other apoptotic cascade hallmarks and serves as a signal to macrophages and adjacent normal cells to phagocytize and digest the components of the apoptotic cells.[42–44] Therefore, externalized PS is a target for the early *in vivo* detection of cells undergoing programmed cell death.[45]

4.16.4.3.2 [^{18}F]-DFNSH

[^{18}F]-5-(dimethylamino)-*N*′-(4-fluorobenzylidene) naphthalene-1-sulfonohydrazide ([^{18}F]-DFNSH) belongs to a newly developed group of small tracers that contain a fluorescent dansyl core. One of its advantages is that DFNSH can be synthesized with high yield and efficiency. Previous *in vivo* studies[46] have demonstrated that DFNSH is incorporated in the cytoplasm of different types of apoptotic cells. The mechanism underlying the intracellular uptake of DFNSH may relate, in part, to the complex membrane alterations that occur during apoptosis.[47]

4.16.4.3.3 [^{18}F]-FDG

[^{18}F]-FDG is the most widely used tracer for glucose metabolism assessment in the brain and other tissues and the uptake of [^{18}F]-FDG by neurons can be used to evaluate neuronal metabolic activation.[25,48,49]

4.16.4.3.4 [^{18}F]-FEPPA

CNS injury is often accompanied by an increase in activated microglia at the site. The peripheral benzodiazepine receptor (PBR) is expressed on the outer mitochondrial membrane of activated microglia and has been reported to be a sensitive biomarker for the detection of neuroinflammation. The PBR, also known as translocator protein (18 kDa) (TPSO), was first identified in 1977 and subsequently distinguished from the central benzodiazepine receptor structurally, functionally, physiologically, and pharmacologically.[50,51] In the CNS, PBRs are mainly located in glial cells, particularly microglia and astrocytes, with the highest densities found in the olfactory bulb, choroid plexus, and ependymal lining of the ventricles.[52,53] In the CNS, PBRs participate in multiple physiological functions including neurosteroid synthesis, nutritional support of neurons, and modulation of CNS immune reactions. PBR expression in the brain is significantly increased in response to a wide variety of CNS insults.[54,55]

Experimental results show that such increases in PBR are mainly due to activated glial cells. In response to intercellular signaling induced by neurotoxicant exposure, microglial activation is usually initiated several hours after exposure and can last for several days after injury onset.[56–58] In their activated state, microglia undergo morphological changes, accumulate and proliferate at the damage site, synthesize pro-inflammatory cytokines, and release toxic molecules and metabolites to eliminate damaged cells. Various studies have demonstrated that PBRs are involved in numerous nervous system disorders such as multiple sclerosis, cerebral ischemia and stroke, epilepsy, brain damage, and neurodegenerative diseases.[52,59–62] Following exposure to neurotoxicants or other forms of insult, PBR levels increase significantly in astrocytes and microglia in damaged brain areas in a time-dependent and region-specific fashion. After brain injury, immunolabeling of PBRs has been shown to increase in mitochondria and other cellular compartments.[26,52,63,64]

4.16.4.3.5 [^{18}F]-FLT

FLT, a thymidine analog, is incorporated into cells and phosphorylated by thymidine kinase (TK) 1, leading to its intracellular trapping. The phosphorylated FLT that is trapped within cells does not get incorporated into the cellular DNA because it lacks a 3′-hydroxyl group. TK 1 is a cytosolic isozyme of TK and its activity closely parallels that of cellular proliferation.[65] Therefore, the retention of [^{18}F]-FLT within the cells represents an *in vivo* marker of cell proliferation. [^{18}F]-FLT has been used in conjunction with PET imaging *in vivo* for the minimally invasive detection of endogenous neural stem cell proliferation in the normal and ischemic adult rat brain.[66,67]

4.16.4.4 MRI Applications

Preclinical MRI in laboratory animals can be utilized to target specific brain areas to be examined for classical neuropathology. This approach offers a dramatic improvement over the current practice of selecting three to five routine, but arbitrary brain sections for traditional analyses.[23] Those MRI-targeted areas can be assumed to include the neuropathology produced by exposure to an environmental agent, new or unknown compound, or drug. Because each subject can serve as its own control, longitudinal investigations can provide information on the onset of toxicity and its apex and regression. This advantage can decrease animal usage in routine preclinical toxicological studies and improve the statistical power of the resulting data. This approach also allows for the optimization of time of sacrifice and selection of an appropriate stain for definitive neuropathology. This is particularly important because a large number of neurodegenerative processes occur within a limited time after exposure and the evidence of such neurotoxicity can be scavenged away over time. Thus, use of an appropriate stain at the suboptimal time can result in false negative findings. Just as importantly, MRI images can inform the selection of appropriate stains. For example, if the MRI signal is concentrated in

white matter areas, myelin stains would be indicated. Finally, utilization of whole brain MRI to optimize target location for subsequent neuropathology accomplishes what would typically require more than 60 sections if only routine neuropathology techniques were employed. The impact of this approach on safety evaluation of new drug submissions could be considerable with respect to an enhanced ability to detect potential neurotoxicity by: (1) identifying precise location(s) and time course of drug-induced lesion development; (2) optimizing time of tissue sample collection; and (3) identifying an appropriate histological stain based on lesion location and tissue type (white matter vs. gray matter).

4.16.4.5 Blood-Borne Sampling: DNA Fragments and Micro-RNA

Liquid biopsies or sampling of blood-borne products have the potential to change medical oncology practice by providing a rapid and convenient method to interrogate DNA mutations present in the cell-free DNA fraction of blood via a routine blood draw. This allows for safer (i.e., nonsurgical) and more frequent monitoring as well as strategies to better screen for cancers enabling an earlier diagnosis. Cell-free circulating tumor DNA are small pieces of tumor in the blood (DNA shed products). For many years, researchers have sought to identify a cancer biomarker available with minimal invasion, namely, to find evidence in the blood (a specific molecule) that indicates the presence of disease, especially cancer and neurotoxicity.[68] Many cancers develop slowly and insidiously over a 10–20-year period and are lethal because they are diagnosed too late. Reducing cancer deaths through prevention and early detection, when such cancers are still potentially curable, are important public health strategies. Applications of liquid biopsies include: (1) early cancer detection, (2) assessment of molecular heterogeneity of overall disease, (3) monitoring of tumor dynamics, (4) identification of genetic determinants for targeted therapies, (5) evaluation of early response to therapy, (6) monitoring for minimal residual disease, and (7) assessment of the evolution of resistance to therapy in real time.

4.16.4.6 Three-Dimensional Cell Culture Models With an Emphasis on Neural Stem Cells

Use of stem cell models to explore issues relevant to toxicant-induced brain damage can advance our understanding of brain-related biological processes, including those critical for normal processes such as neural plasticity as well as those associated with the expression of toxicity.[69,70] Advances in the understanding of stem cell biology and neuroscience have opened new avenues of research for detecting early life stress-induced neurotoxicity and developing potential protection/prevention strategies against toxicant-induced neuronal injuries.[71,72] The classical definition of a stem cell requires that it has the capacity to self-renew and that it possesses potency. Self-renewal is defined as the ability of the stem cell to go through multiple cycles of cell division while maintaining its undifferentiated state. Potency refers to the ability of the stem cell to differentiate into specialized cell types.[73,74] Stem cell biology, when exploited with high-throughput molecular biological approaches including genomics, proteomics, and metabolomics, can be utilized to enhance the understanding of complex biological processes—such as apoptosis—that are associated with prolonged pediatric anesthetic exposure or other perinatal exposures. In addition, the study of stem cell biology can provide the building blocks necessary to construct relevant models of developing biological systems. As these models evolve and become integrated, they can provide the intermediate components necessary for informing a developmental biology/toxicology approach. The field of toxicant/drug-related toxicology has employed multiple scientific disciplines in attempts to identify the basic characteristics of chemicals or drugs that can result in harmful, acute, and/or chronic effects on the developing nervous system. Such characteristics continue to be defined at the molecular, biochemical, cellular, and physiological levels. The developing nervous system can vary dramatically in its susceptibility to neurotoxic insults depending on the developmental stage. Because of the complexity and temporal features underlying the expression of developmental neurotoxicity, this area of study may benefit greatly from the use of *in vitro* models including stem cell. Stem cell biology, in the context of toxicological problems, might provide an important focal area around which information can be arrayed in the form of a biological model. The goal of applying a stem cell biological approach to problems in developmental toxicology is to predict the functional outcomes of component-to-component relationships using integral *in vitro* models that allow for the directional and quantitative descriptions of responses at the cellular level. The stimuli that elicit such responses may be environmental alterations, exposures to drugs or other chemicals, or infectious agents.

The development of the CNS is initiated early in life by the induction of neural stem cells and neural progenitor cells; this stage in development is known as neural induction. The nervous system is one of the earliest organ systems to differentiate from the blastula-stage embryo. Neurogenesis is critical for nervous system development and maintenance. During neurogenesis, neural stem cells generate neural progenitors that mature into functional neurons. Pharmacological enhancement of neurogenesis represents a potential therapeutic approach for the treatment of the neuronal loss occurring in neurodegenerative diseases, such as stroke, brain damage, Parkinson's disease, and Alzheimer's disease.[71,72] Accordingly, there is great interest in using neural stem cells as tools for studying the adverse effects associated with exposure to drugs and other compounds.

4.16.4.7 Microphysiological Models

Recent advances in biomedical research have offered a broad range of approaches and tools that have enhanced our capability to practice evidence-based medicine and evidence-based regulation and thereby to improve human health. "Human-on-a-chip" and "human organ construct" microphysiological systems are new and emerging technologies that have the potential to correlate *in vivo* with *in vitro* and to simulate human organ systems. The human-on-a-chip technology uses *in vitro* human organ constructs in which the various cells communicate. Those chips and constructs are designed to reflect biological activity similar to the *in vivo* situation.

The organ on a chip can then be used to determine if drugs and chemicals can elicit *in vitro*, the physiological activity of a human organ observed *in vivo*. These microphysiological systems have the potential to be used to assess basic biology and physiology, as well as the pharmacology and toxicology of drugs and chemicals, to study organ–organ interactions, and/or to be used as a human disease model.[75]

The use of human cells is an enormous advantage because it eliminates the need to extrapolate across species, but even so, there may be the requirement that different cell types interact in a three-dimensional relationship in order to provide prediction of the intact human. The immediate environment of the cells in culture, including cell types (single or multiple origins), the need for specialized media to keep them in a differentiated state (e.g., presence of growth factors, cytokines, and other hormones), and the three-dimensional configuration can all affect outcome measures. Many animal stem cell studies have provided the principles and strategy for the use of human stem cells in 3-D and other organotypic *in vitro* models.

Another important consideration of simulating human outcomes is the quantification of chemical exposure. Absorption, distribution, metabolism, and elimination are features that must be quantified. The linking together of several organs on a chip to simulate an intact human on a chip is a possibility with well-constructed and well-tuned fluid dynamic systems. Microfluidic control of multiple organ systems is possible, and models envisioned by bioengineers have been developed. The challenges include the requirement for each organ type to have its own specialized media yet be connected so that the human circulatory system can be replicated.

4.16.4.8 Computational Toxicology

The applications of computational sciences, including bioinformatics and "big data," have great potential to improve the health and well-being of our communities through the development and use of chemicals, drugs treatments, and tools to manage the safety of foods and drugs. Examination of the "state of the art" in global trends, initiatives, and case studies reveals that data sets, analytical tools, skills, and expertise are rapidly developing, in many cases via large international collaborative consortia. However, significant research is still required to realize the potential regulatory applications of those technologies. While there is significant excitement in the possibilities offered by precision medicine to enhance treatments of serious and/or complex diseases, there is a clear need for further development of mechanisms to securely store, curate, and share data, integrate databases, and standardize quality control and data analysis procedures. Greater understanding of the biological significance of the data is also required to fully exploit vast data sets that are becoming available. The application of bioinformatics in the microbiological risk-analysis paradigm is delivering clear benefits both for the investigation of food-borne pathogens and for decision-making on clinically important treatments. While computational sciences and the advent of big data will have many beneficial applications, high-quality data, validated tools, and standardized processes will inform the regulatory science required to ensure the appropriate introduction of these applications.[76]

4.16.4.9 Global Trends, Initiatives, and Opportunities of Bioinformatics Approaches and Big Data

Emerging technologies are providing new opportunities to improve the health of our communities through the development and use of clinically important drugs treatments and tools to manage the safety of the food supply. Those technologies continue to rapidly generate and utilize large data sets for regulatory application. However, the use of such data sets also requires the development of policies, strategies, and approaches to appropriately curate, analyze, and interpret the data. This uniform understanding will strengthen the scientific evidence base and those advanced methodologies will produce tools to support regulatory decision-making, drug development, clinical application, and improved management of the food supply. Initiatives are underway globally aim to strengthen evidence-based application, thereby maximizing the opportunities made available by the emerging technologies.

Technologies such as next-generation sequencing (NGS) combined with bioinformatics analysis, have the potential to revolutionize food safety and the disease treatment. NGS enables human genomes to be sequenced rapidly and cost effectively, and tools are now available for analyzing the resulting large data sets, providing a mechanism for treating patients individually to enhance health outcomes as well as improving the success rate in the development of new therapeutic treatments. Individual treatment of patients or small groups of like patients (precision or personalized medicine) could take into account their genetic variation, environment, and lifestyle.[76]

To address these challenges, several countries/regions are implementing programs to support the application of precision medicine.[77] The United States is implementing the multifaceted Precision Medicine Initiative to develop high quality, curated databases, and interoperable standards and requirements that address privacy and enable secure exchange of data across systems. This initiative is focused on the determination of genomic drivers of diseases such as cardiovascular disease or cancer and identification of appropriate biomarkers. Those biomarkers can then be used to develop more effective treatments and improve understanding of the environmental, genetic, biochemical, and other factors predictive of disease risk, response to therapy, and disease outcomes.[78]

The current situation for NGS resembles the challenges faced about 10 years ago when microarray technologies were the principal tool for gene expression assessment. At that time, the realization generated a number of FDA efforts to utilize and evaluate those technologies with intercenter and cross-community collaborations. Examples include the FDA's Voluntary Exploratory Data Submission program to develop standards and bioinformatics solutions to receive and evaluate those new data in the review process[79] and the FDA-led community-wide microarray quality control consortium to address quality control and proper use of those new genomic methodologies.[80] Therefore, partnerships and cooperation among the regulatory agencies of different countries

are crucial for building consensus and best practices to expedite the translation from the exploratory nature of NGS to regulatory application.

Recent developments in the tools and applications of predictive toxicology are also significantly changing the way in which the risk of adverse events is assessed for chemicals used as drugs, and those added to foods or used for other purposes. One of the methodological approaches, quantitative structure-activity relationships (QSARs) is a well-established multidisciplinary methodology that integrates biological, chemical, and computational models to provide a new paradigm for chemical risk assessment.[81] Barriers to the acceptance of QSARs in regulatory settings range from scientific concerns (e.g., relevance, reliability, and interpretability) and practical considerations (e.g., availability and ease of use, portability/interoperability), to policy change that permit paradigm shifts that could incorporate QSARs into a modern toxicological framework with comprehensive assessment and credible outcomes. Those barriers have been addressed through the initiatives of regulatory agencies and multilateral bodies. Scientific concerns have been addressed for the use of QSARs through the development of globally accepted reporting formats for models and predictions and also guidance on how to interpret the prediction results. Guidance on use of QSARs for pesticides and other chemical categories has been established.[82] QSAR may also be used in concert with other strategies, thus positioning QSAR models as a part of integrated approaches to testing and assessment.

4.16.4.10 Application of Bioinformatics

Bioinformatics and novel approaches to using big data offer exciting possibilities for developing targeted medicine and therapeutics as well as postmarket monitoring of the safety of drugs. Personalized/precision medicine is the way of the future.[83] Significant resources are being devoted to realizing the potential of this approach that involves cross-sector collaborations and multidisciplinary approaches. A range of data sources and bioinformatics techniques are being exploited in the development of those approaches, such as electronic health records, patient data, genomic sequences, metadata, and predictive toxicology.

Many different types of big data exist and the power of analysis and data mining is generated from the analysts' ability to integrate many different layers of data sets for the synthesis of new information. Big data can include both structured and unstructured data sets and can be records with narratives and descriptors as well as databases of reports of adverse effects. In some cases, each database may require its own lexicons and rules. To support good regulatory decision-making, data sets must be of good quality, robust, verified, and have sufficient metadata. Big data poses new regulatory challenges and require new skill sets and new knowledge for successful interpretation.

4.16.5 Lessons Learned and Challenges That Reflect and Focus on Contemporary Critical Issues

1. Carcinogenicity testing of drugs need not be compulsory or obligatory, especially 2-year studies, if appropriate genetic and mutagenicity testing is negative.
2. Heavy funding cannot always buy technological advancement; time elapsed to allow the maturation of the technology as well as the development of collateral tools is often also required.
3. *In vitro* models have played a very important role in advancing the science of toxicity prediction, but there remain instances when the use of whole animal models is unavoidable and obligatory.
4. Toxicity prediction cannot rely solely on technological advances; insight into fundamental biological processes is not only necessary but critically needed to advance knowledge that is necessary to fully understand observed toxicological phenomenology.
5. Mechanistic toxicology studies cannot be conducted until the toxicological phenomenology is reliably and robustly reproduced in successful experiments that form the basis and foundation for mechanistic experiments.
6. The value of nonclinical studies relies heavily on the extent to which findings are translatable to clinical trials. A large percentage of animal models have been shown to translate poorly, particularly those involving sensory perception of pain by higher centers. For example, tail flick response in mice is a cord reflex and does not serve to measure pain originating in higher centers in the brain. Another modeling issue involves measurement of immunotoxicity, which is poorly characterized in rodents unless they are humanized.
7. Delivery of drugs to alveolar areas of the lungs is poorly understood since concentrations within that domain are rarely measured in contrast to aerosol concentrations and particle size distributions delivered to the nose and mouth that have been well characterized.
8. The period for chronic drug exposure has been progressively reduced from 7 years in dogs and 10 years in nonhuman primates, 40–50 years ago, to 6 months in rats despite the fact that certain approved drugs are given to older patients with chronic progressive diseases for the rest of their lives.
9. There is no formal testing of drugs for toxicity in geriatric animal models, although drugs are given to older patients for very long durations.

4.16.6 Horizons—A Vision of Future Directions for Toxicity Prediction and Safety Evaluation

Prediction of toxic responses has and will continue to benefit from the many technological breakthroughs described in this article (see **Table 7**). The capacity to image the brain in the living animal and in conscious humans opens up a whole new set of

Table 7 Critical issues and challenges for emerging technologies and methodologies

Genomics	Gene expression not necessarily always correlated with toxicity; comparison and validation of various platforms still in progress; informatics efforts to interpret data at an early stage; statistical models still being developed
	Refinement of initial statistical and interpretation models underway with exposure, agent metabolites, and stage of development issues under consideration
Proteomics	Labor intensive; correlation with toxicity in early stages
	Throughput still an issue, but new statistical approaches and chemical libraries are coming available
Metabolomics	Initial cost and resource outlay is quite extensive; relies more on pattern recognition than recognition of individual metabolites
	Powerful translational approach because of minimally invasive nature; analysis time shrinking based on faster software
Lipidomics	*A new and emerging technology that allows the analysis of 1100 or more lipids in a single sample. A very promising approach for characterizing CNS toxicity, particularly in brain samples*
PET imaging	Issues involving sensitivity and resolution
	Development of specific ligands has afforded unprecedented selectivity for identifying cancers and CNS metabolism
MRI	Very expensive initial outlay; limitations on acceptable or approved field strength for human studies impacts resolution; still extremely expensive and not widely used by preclinical researchers
	Although standards for preclinical assessments have not been universally accepted, cost-saving approaches for time and location of sample analysis has been developed
Biomarkers for toxicity	Issues of specificity; may be nonspecific, for example, generalized inflammation; not many validated for safety toxicity evaluation
	Guidelines for biomarker validation have been used to develop acceptable biomarkers for regulatory decision-making. Qualification of a biomarker for a specific context of use is now a commonly accepted practice
High-throughput screening	Very resource intensive; used only by very large well-endowed organizations; cross validation difficult
	Major data sets have been generated and data made available for many researchers to evaluate
Photo cocarcinogenesis	Expensive; chronic duration; uses many hairless mice
	New transgenic animals have reduced time to tumor and are undergoing assessment
Ames test	Does not detect the mutagenic effects of some antibiotics, metals, or proteins
	New more inclusive genetic tests have been developed that allow multiple species and tissue types to be evaluated
QTC–IKR	Does not directly correlate with Torsade de Points, but relates to the K^+ channels which is the first step in the production of arrhythmias
	In vitro approaches have been developed, but not fully accepted to assess cardiovascular toxicities
Combinatorial chemistry	Lack of sufficient information on novel chemical classes to make decisions; requires a large database; often requires large amount of proprietary information that must be protected and/or is not available to all
	New bioinformatics and NMR-based strategies have been developed and are undergoing validation
In vitro substitutes	Lack of immunocompetency; repair mechanisms absent; still need to use animals for tissue and cell harvesting
	Stem cells/3-D cell culture and microphysiological systems are under development
Nanotechnology	Methodology for safety evaluation in its infancy; toxicity of nanoparticles and nanoparticlized drugs relatively unexplored
	Several nanomedicines have been approved and standards for general assessments are under development

Statements in italics as of 2016 and others as of 2005.

opportunities to observe the ongoing physiology of this vital organ. The life cycle of a toxic agent can be observed in real time through its many stages which allows optimization of time of animal sacrifice, location of specific brain areas for sectioning as well as the choice of histological stains. This is necessary for precise visualization and characterization of the nature and extent brain lesions. The use of various imaging software algorithms can be utilized to quantify the extent of brain lesions, using precise cell counts, as a percentage of the overall section examined.[84]

The utilization of various imaging modalities will allow for the characterization of many aspects of thought processes (pathway sequences) that may be influenced by a variety of new psychotomimetic drugs intended for therapeutic purposes, but not without the potential for neurotoxicity. This is of particular importance when these agents are intended for use in children whose nervous systems are not yet mature and where normal future development may be inadvertently disrupted. Real-time imaging of the mechanism of action of drugs as they interact with diseased or damaged areas of the nervous system might allow the optimization of dosing regimens, as well as the prevention of drug-induced toxicity that might occur with overexposure or persistence in the brain.

Another exciting area that has begun to emerge is the use of humanized rodents (mice) for toxicity testing. This animal model is particularly useful for prediction of immunotoxicity in humans resulting from administration of large, high-molecular-weight therapeutic proteins. The humanized mouse has the potential to emulate these effects and allow characterization of their incidence and progression. This type of toxicity evaluation was previously unattainable because of species differences in immunomechanisms.[85]

Another area that has great potential for enlarging the scope of toxicity prediction is the characterization of the human microbiome with its potential for influencing the toxic outcome of a vast array of drugs that are administered orally.[86] Very little attention has been paid to the role of the gut flora in influencing drug action and toxicity. Characterization of the microbiome in patients that have a particular disease and humanizing the microbiome of the animal model for evaluating drug toxicity might, if translatable, vastly improve the prediction of toxicity of certain drugs in preclinical studies.

The use of microphysiological systems to simulate the dynamic functions of various organs is a big step forward beyond the routine use of varies types of cell culture systems. These may allow rapid *in vitro* screening of drugs with the additional advantage of incorporating physiological mechanisms that involve flow (microfluidics) and motion characteristics. An excellent example of this is the so-called "lung on a chip" which has an alveolar cell layer that has a "vascular" side with simulated blood flowing past it and an air or "lung" side. Mechanical distortion of this layer of cells simulating breathing allows lung function to be emulated. Bacteria introduced on the air side are quickly killed by the blood interface on the other side. This is a very valuable model for testing agents to counteract lung infection. The model is only really effective when respiration is simulated by the mechanical distortion of the alveolar cell layer.[87,88]

Nanotechnology has yielded a significant number of new nanoformulated drugs. At present, the FDA treats these new submissions as all others in terms of evaluation for safety and efficacy. This appears to be appropriate in the absence of any significant unique nanospecific adverse effects. There are, however, certain nanoformulation characteristics that have the potential to generate toxicity prediction issues in the future.[89] These include: (a) characterization of particle size distribution and standardization of individual particle size distribution, (b) stoichiometry (e.g., does a mole of nanoformulated drug have the same potency or toxicity as the same drug substance formulated using particles with standard size distributions or is potency and toxicity a function of particle area exposed to a tissue or receptor), (c) What is the distribution and disposition of dendrimers (nanoparticles) once they deliver drug to a target. Do they then accumulate in organs such as liver and spleen and are they toxic at these sites? What is the biological half-life of these "delivery shells" and what is the nature of their toxicity (vacuolation, etc.)?

The "omic" technologies have seen an explosion of new innovation that promises to generate a significant boost in the available capabilities for toxicity prediction. In the last 10 years, genomics has had the benefit of vastly improved and refined statistical and interpretation models. There are now libraries available to characterize genes that are significantly altered in their levels of expression by drug treatment. These tools are able to relate those alterations to physiological and pathological processes, some of which are reflective of significant toxicity. Proteomics is still quite labor intensive; however, there are data libraries and statistical approaches to identify vast arrays of peptides and characterize and utilize pattern recognition tools (principle component analysis, etc.) to identify global changes that have toxicological significance. The use of mass spectrometry and capillary electrophoresis has accelerated the analytical portion of the process. Metabolomics has made significant strides in terms of shortening analysis time with faster software that relates findings to significant treatment-related metabolic changes that are directly relatable to significant toxicologic effects.

Lipidomics offers the most recent exciting addition to the "omic" technologies and offers great promise in identifying treatment-induced toxic changes in the nervous system. This has been a largely ignored area for toxicity prediction, especially in light of the fact that the brain has the highest percentage of lipids, second only to adipose tissue itself. Analysis of changes in brain and spinal cord lipids may vastly alter our overall concept of toxicity patterns in the nervous system.[90,91]

The imaging technologies, discussed extensively earlier, offer significant opportunities for new types of toxicity prediction and detection, especially in the nervous system. The ability to do this in the living organism, in real time, (in the conscious state in humans) is a very exciting prospect, especially since cost is decreasing and MRI is rapidly becoming a biomarker for toxicity. PET imaging, which in the past has had sensitivity and resolution issues, is seeing the development of specific ligands for identifying cancers and providing a window on CNS metabolism that informs toxicity-predictive efforts.

Structure-activity relationships (SAR) and computer modeling offer many opportunities for expanding future capabilities for toxicity prediction. The development of reliable SAR modules for various classes of toxicity based on large chemical structure data sets gives both the researcher and the NDA reviewer a first glance at the potential for toxicity of new compounds. This process is based on algorithms that detect chemical signals embedded in the structure of new compounds under investigation and determine their similarity to the virtual toxicophore that is generated by the data set within the module for a given type of toxicity.[92] The sensitivity and selectivity of some of these modules is rather impressive (80–90%), particularly for carcinogenicity. This type of analysis represents the very first tier of toxicity evaluation that endeavors to predict what might be seen in subsequent tiers of investigation: *in vitro* → animal species → humans. SAR evaluation will play a larger role as a prelude to the use of ever improving *in vitro* models which precedes the use of animals in preclinical studies.[93]

The use of computer models has already begun to play a rather large role in toxicity prediction.[94] Target organ function, involving the physiological, pharmacological, and pathological responses are being modeled in silico, following the "virtual" administration of drugs and toxic agents. In other systems whole body physiological responses to virtual drug stimuli are being modeled and are generating responses that are referred to as those of a "virtual human." The latest frontier in the use of computer modeling involves the use of search engines that launch the so-called "spiders" that search the vast array of published information in millions of publications on the Internet using tools to read and interpret written language. They gather bits and pieces of information from a myriad of sources and compare and combine them to synthesize new information entities. These consist of answers to posed questions and various new conclusions based on the combination of information from different sources. This approach could be one of the ultimate tools used to advance toxicology prediction in the near and possibly distant future.[95]

4.16.7 Conclusions

The prediction of toxic responses is a constantly evolving science whose methodology is advanced by technological innovations that are often driven by regulatory imperatives stemming from adverse effects reports and, at times, occasional catastrophic incidents

that trigger legislative remediation. At times, legislation can indirectly or secondarily give birth to a whole new subdiscipline of toxicology such as alternatives to animal testing that resulted from the passage of the Animal Welfare Act, the formation of Institutional Animal Care and Use Committees (IACUCs), as well as the establishment of powerful animal welfare coalitions. The specter of being unable to work with animals on the same scale as in the past has given a tremendous boost to the development of very elegant *in vitro* systems, advances in tissue and organ culture, and the so-called organ or organism on a chip. The development and validation of a whole series of important biomarkers for toxicity has greatly streamlined the process and shortened the time involved in new drug development and approval. These biomarkers are qualified for a very specific context of use and have often detected significant toxicity of lead compounds in preclinical stages of testing rather than Phase 2 of clinical trials saving enormous amounts of money (often three orders of magnitude in dollars spent) and, more importantly, prevented adverse effects, suffering, and possible deaths in clinical trials. The advances made in toxicological methodology have made it possible to reduce drug lag and eventually enable the passage of prescription and ultimately generic drug user fee legislation (PDUFA and GDUFA) that has brought enormous amounts of funding to support the federal drug evaluation process and allowed the fulfillment of very tight evaluation deadlines. This has greatly accelerated the approval process without compromising safety or confirmation of efficacy. Finally, the astounding advances in various types of imaging (discussed earlier) have not only opened a brand new set of opportunities to evaluate toxicity, noninvasively in a multitude of organ systems in living organisms, but has given a brand new insight into fundamental aspects of human biology and physiology. The partnership between the science of predictive toxicology and legislative regulatory initiatives has contributed greatly to the advancement of each of these activities and this complementary relationship has contributed considerably to the enhancement of quality of life.

PREFACE

Previous editions of *Comprehensive Medicinal Chemistry*, published in 1990 and 2006, provided an integrated reference source that encompassed all major aspects of drug discovery research. The third edition follows this tradition and considerably expands its scope and content.

The trailblazing scientific discoveries of the 21st century have brought new opportunities for drug discovery research. The discipline of medicinal chemistry continues to evolve as it adapts to these new opportunities and strives to solve new challenges. Covered in the new edition are not only the breakthrough therapies of the past decade in cancer, hepatitis C, heart failure, dyslipidemia, cystic fibrosis, multiple sclerosis, HIV, etc., but also extensive discussion of new business models in drug discovery research, shifting industry demographics, emerging technologies, *in silico* drug discovery tools, experimental ADME and toxicology, and biologics medicine. The tone of this edition is prospective in which contributors identify outstanding issues and paths forward in their area of expertise. The aim is to provide drug discovery scientists in industry, government, academia, and research organizations with a contemporary global perspective on the field that includes a look ahead in selected areas.

The eight individual volumes fulfill these objectives and include extensive discussion of biomolecular therapeutics, drug targeting and delivery, development of chemical biology tools, data collection and analysis, *in silico* models as predictors for biological properties, identification/validation of new targets, approaches to quantify target engagement, new methods for synthesis of drug candidates such as green chemistry, development of novel scaffolds for drug discovery, and the role of regulatory agencies in drug discovery.

The individual volume editors have done an outstanding job to identify topics and contributors to meet these goals and we thank them for their hardwork and diligence. In volume 1, Ana Martinez and Carmen Gil recruited an international group of contributors who provide chapters on the emerging role of organizations other than traditional pharmaceutical companies in drug discovery, the evolving science of chemical biology, and new organic chemistry contributions to the discipline. In volume 2, Helmut Buschmann, Norbert Handler, and Andrea Wolkerstorfer have accomplished a seemingly impossible task and attracted world-leading experts across the wide field of drug discovery enabling technologies, covering contemporary thinking in a wide range of key disciplines that enable modern medicinal chemistry and drug discovery and development. The computational enabling technologies are the focus of volume 3, in which Andy Davis and Colin Edge have assembled chapters covering both ligand-based and protein structure–based advances as well as exciting new methodologies and case studies exploiting these. Alan Wilson identified experts in the fields of pharmacokinetics and toxicology who describe a wide range of contemporary advances in prediction and analysis of pharmaceutical properties and drug safety in volume 4. In volume 5, Ian Collins, Louis Lombardo, and Will Watkins have assembled leading experts to discuss high impact drug discovery accomplishments over the past decade in cancer chemotherapeutics, immunology and inflammation, and infectious diseases therapeutic areas. Ved Srivastava edited volume 6 on biologic medicines, a significant and rapidly evolving area where medicinal chemistry plays an important role. The chapters in this volume provide timely information on not only protein-based drugs, such as monoclonal antibodies and therapeutic proteins, but also peptides and nucleic acid–based therapeutics. Volume 7, edited by Adrian Hall, Santhosh Neelamkavil, and Rob Jones, presents a detailed account of the major advances in CNS, metabolic, and cardiovascular fields over the past decade and the promising new opportunities. Joerg Holenz edited volume 8 that presents case histories of successful drug discovery and strategic differentiation that have resulted in commercialized drugs and candidates in advanced clinical trials.

We are truly grateful to the publishing team at Elsevier that includes Gemma Tomalin, Rachel Gerlis, Marise Willis, and Sean Simms for their assistance and support throughout the process. With their expertise, this project became what we believe is a noteworthy and valuable resource for the discipline of medicinal chemistry. We look forward to the response and feedback of our colleagues who will use this information in their own work.

Samuel Chackalamannil, David P. Rotella, and Simon E. Ward

EDITORS-IN-CHIEF: BIOGRAPHIES

Dr. Samuel Chackalamannil

Dr. Chackalamannil obtained his PhD in chemistry from Yale University in 1984 and subsequently worked in drug discovery research at Schering-Plough Corporation and Merck Research Laboratories, where he was a distinguished fellow when he left in 2011. Since then, he has been teaching at Ernest Mario School of Pharmacy, Rutgers University, New Jersey.

Dr. Chackalamannil has significant accomplishments in the discovery of new medicines. He led the discovery of vorapaxar (Zontivity®), an FDA-approved antiplatelet drug for the prevention of heart attack and stroke. His group also discovered a PDE-5 inhibitor clinical candidate dasantafil and an adenosine A2a antagonist clinical candidate for the treatment of Parkinson's disease. Altogether, he was responsible for the discovery of nine development candidates in cardiovascular, central nervous system, and metabolic disease areas.

Dr. Chackalamannil is a coinventor of 62 allowed US patents and numerous patent applications worldwide. He has published 81 peer-reviewed articles and has coauthored a book. He has also given numerous lectures at international meetings and academic institutions.

Dr. Chackalamannil is a two-time recipient of the Thomas Alva Edison Award for Emerging Technology Patent and a two-time recipient of the Presidential Award for Discovery at Schering-Plough Research Institute. He has chaired several sessions at American Chemical Society national meetings and Gordon Research Conference on Medicinal Chemistry and was an organizer for Chemistry as a Life Science Symposium.

Dr. David Rotella

Dr. Rotella earned a PhD in medicinal chemistry from The Ohio State University and carried out postdoctoral research in organic chemistry at Penn State University. He joined the faculty at Montclair State University in July 2011 as the Margaret and Herman Sokol Professor of medicinal chemistry after a successful career in the pharmaceutical industry. He is an expert in the discovery and optimization of small molecule drug candidates for use in metabolic, cardiovascular, cancer, and central nervous system diseases. His current research is focused on discovering new lead compounds for use in parasitic and central nervous system diseases. He has coedited the seventh edition of *Burger's Medicinal Chemistry* and is a senior editor for the Royal Society of Chemistry's Drug Discovery book series. He has authored over 40 peer-reviewed articles, is an inventor on 8 issued US patents, and has contributed 10 book chapters.

Simon E. Ward

Simon Ward has an MA in natural sciences and PhD in synthetic organic chemistry from Cambridge University, UK. He has a wide-ranging experience of drug discovery in both large and small companies (GlaxoSmithKline, Knoll Pharmaceuticals, Vernalis, Chiroscience, BioCrea) and specialist experience of discovering and developing drugs for central nervous system indications. He has led multidisciplinary project teams and medicinal chemistry groups from target identification through to early clinical studies, delivering multiple clinical development candidates across indications. He is a fellow of the Royal Society of Chemistry. He is currently a professor of medicinal chemistry at the University of Sussex, UK, and the director of the Sussex Drug Discovery Centre, which he established within the University of Sussex in 2010.

5.01.1 Introduction

Cancer is one of the leading causes of death in the Western world. Still, 50% of patients diagnosed with cancer die from the disease or the treatment. Reasons for the development of cancer apart from age are multiple, complex, and often poorly explored. Tobacco smoke, dietary reasons, physical inactivity, alcohol, and obesity are among the main risk factors.[1] In the United States, the estimated number of cancer deaths for 2015 is 589,430. The likelihood of developing cancer in life is 43% for men and 38% for women (http://www.cancer.org/).

Despite the advances in targeted cancer therapies, current treatment options are still mainly based on surgery, radiation, and chemotherapy. However, numerous drugs that target special properties of a given malignancy (eg, gain of function of signaling pathways, overexpression of proteins, and changes in metabolism) are currently being developed or have entered routine clinical practice. These compounds aim to increase patient benefit, such as reduced side effects compared with chemotherapy and possibly even prolonged life span.

This article describes the basics of cancer biology as well as targets for clinical intervention, how to identify new targets, and the challenges we currently face in the development of novel, targeted small-molecule cancer therapeutics.

5.01.2 Cancer Biology and Hallmarks of Cancer

Cellular transformation and tumorigenesis arise from multiple processes. Induction of tumor formation can be based on mutations in three types of genes: oncogenes, tumor suppressor genes, and stability genes. Invasive cancer typically develops only when several genes are defective, which increases the complexity and heterogeneity of cancer.[2] The delineation of the pathways through which these genes act can be organized into biological capabilities necessary for tumor growth and progression. These core hallmarks of cancer as defined by Hanahan and Weinberg[3] include sustaining proliferative signaling, evading growth suppressors, resisting cell death, enabling replicative immortality, inducing angiogenesis, and activating invasion and metastasis. Further underlying and enabling these characteristics are emerging hallmark capabilities: genome instability, tumor-promoting inflammation, deregulating cellular energetics, and evading immune destruction (**Fig. 1**). Nonetheless, tumor pathogenesis is complex and requires, in addition to the hallmarks listed in the preceding text, a repertoire of seemingly normal cells forming tumor-associated stroma contributing to the development and expression of the hallmark capabilities. Therefore, only selective cotargeting of multiple cores and emerging hallmark capabilities as well as enabling characteristics in mechanism-guided combinations will result in more effective and durable therapies for human cancer.

5.01.2.1 Sustaining Proliferative Signaling

Whereas normal tissues carefully control the production and release of growth-promoting mitogenic signals, cancer cells, through deregulating these signals, become powerful entities with structure and function of their own kind that are able to proliferate without control. In fact, cancer cells acquire the capability of inducing and sustaining positively acting growth stimulatory signals by different ways:[4] (i) producing growth factor ligands themselves, (ii) sending signals to stimulate normal cells within the assisting tumor-associated stroma, (iii) deregulating receptor signaling by structural alterations in the receptor molecules, and (iv) elevating receptor protein levels displayed at the cancer cell surface (see sections "Kinases and Inhibitors," "Targets in Protein Folding and Degradation," and "Targets in Cancer Epigenetics").

5.01.2.2 Evading Growth Suppressors

Tumor suppressor genes negatively regulate cell proliferation. The two prototypical tumor suppressors encode the RB (retinoblastoma-associated) and TP53 proteins that operate as central control nodes within two key complementary cellular regulatory circuits that govern the decisions of cells to proliferate or, alternatively, activate senescence and apoptotic programs.[3] These two regulating tumor suppressors operate as part of a larger network that is wired for functional redundancy. In cancer cells, growth suppression is often circumvented due to inhibitory/loss of function mutation in tumor suppressors. Cell-to-cell contact inhibition is eliminated in various types of cancer leading to metastasis; the mechanism for the elimination of this cell-to-cell contact

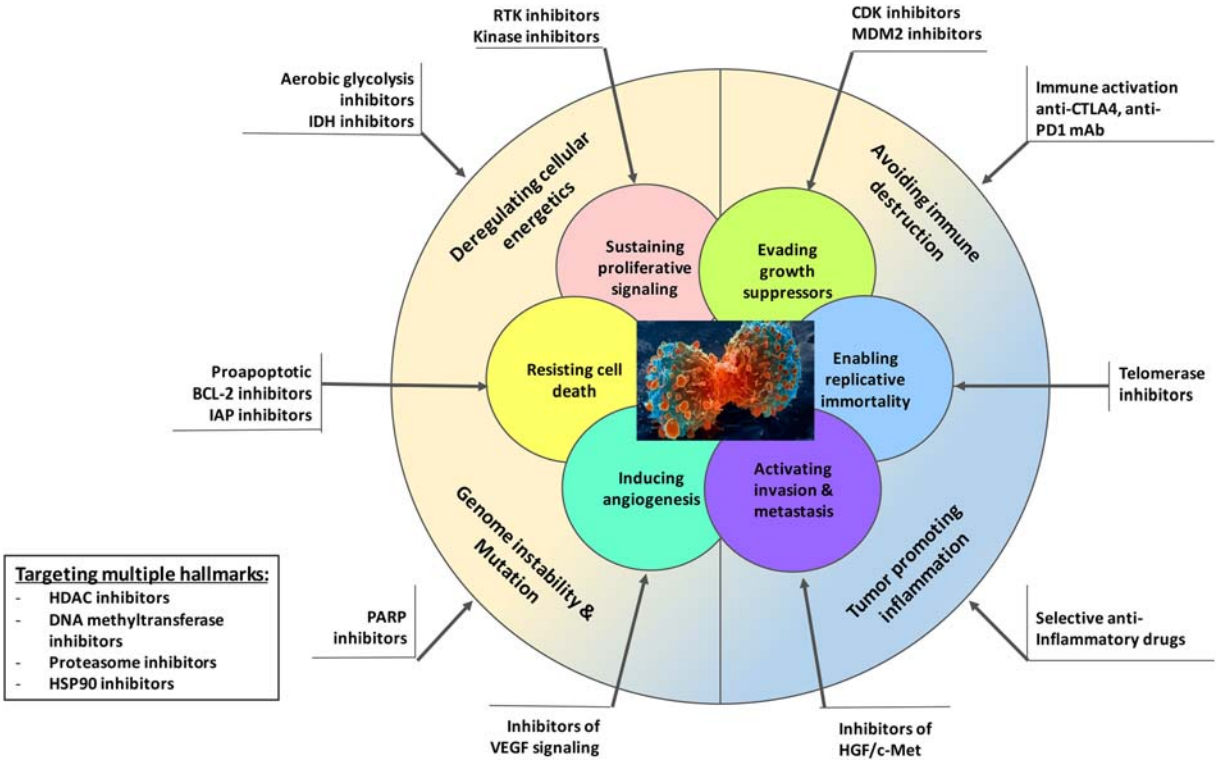

Fig. 1 Hallmarks of cancer and interfering treatments.

inhibition occurs by limiting the emission of mitogenic signals and counterbalancing inappropriate proliferation signals[3] (see sections "Kinases and Inhibitors," "Targets in Induction of Apoptosis," and "Targets in Protein Folding and Degradation").

5.01.2.3 Resisting Cell Death

Programmed cell death, apoptosis, is a process that results in suicide of malfunctional cells in order to maintain proper physiology of the whole body. Apoptosis serves as a natural barrier to cancer development; however, apoptosis is weakened in those tumors that succeed in progressing to states of high-grade malignancy and resistance to therapy.[5] The apoptotic program is compiled of both upstream regulators and downstream effector components that can be affected/mutated in cancer to resist apoptosis.

Autophagy represents an important cell physiological response for generation of nutrients as well as for degradation of malfunctional proteins that, like apoptosis, normally operate at low levels. However, autophagy can be induced in cellular stress situations, the most obvious of which is nutrient deficiency occurring during cancer growth.[6]

In contrast to apoptosis and autophagy, necrotic cell death releases pro-inflammatory signals into the surrounding tissue microenvironment. Although necrosis has historically been viewed much like organism death, cell death by necrosis is clearly under genetic control in some circumstances, rather than being a random and undirected process.[7] During tumor progression, necrosis-induced inflammation leads to growth stimulation (see sections "Stress Response and Cancer," "Kinases and Inhibitors," and "Targets in the Induction of Apoptosis").

5.01.2.4 Enabling Replicative Immortality

In contrast to normal cells, cancer cells require unlimited replicative potential. Most normal cell lineages in the body are able to pass through a limited number of successive cell growth and division cycles. There are two distinct barriers to proliferation: senescence, an irreversible entry into a nonproliferative but viable state, and crisis, which is a stage of extreme telomere dysfunction that is characterized by cell death. On rare occasions, cells emerge from a population in crisis and exhibit unlimited replicative potential; this transition has been termed immortalization. Telomeres, the protecting ends of chromosomes, are centrally involved in the hallmark of unlimited proliferation.[8] Thus, telomere maintenance has been confirmed as a condition critical to the neoplastic state (see section "Targets in Genomic Instability").

5.01.2.5 Inducing Angiogenesis

The tumor-associated neovasculature, generated by the process of angiogenesis, addresses the tumor's requirement of sustenance in the form of nutrients and oxygen as well as removing metabolic waste and carbon dioxide. In a healthy adult, angiogenesis is turned on only transiently. In contrast, during tumor progression, an "angiogenic switch" is almost always activated and remains on, causing normally dormant vasculature to continually sprout new vessels that help sustain expanding neoplastic growths.[9] The angiogenic switch is governed by angiogenic regulators such as vascular endothelial growth factor A (VEGF-A) and thrombospondin 1. Angiogenesis is induced early during the development of invasive cancers, and tumor neovasculature is characterized by precocious capillary sprouting, convoluted and excessive vessel branching, distorted and enlarged vessels, erratic blood flow, microhemorrhaging, leakiness, and abnormal levels of endothelial cell proliferation and apoptosis (see sections "Kinases and Inhibitors," "Targets in Protein Folding and Degradation," and "Targets in Neovascularization").

5.01.2.6 Activating Invasion and Metastasis

As carcinomas arising from epithelial tissues progress to higher pathological grades of malignancy, reflected in local invasion and distant metastasis, the associated cancer cells typically develop alterations in their shape as well as in their attachment to other cells and to the extracellular matrix. It has also become apparent that signaling between cancer cells and cells of the neoplastic stroma is involved in the acquired capability for invasive growth and metastasis.[10]

A developmental regulatory program, referred to as the "epithelial–mesenchymal transition" (EMT), has become prominently implicated as a means by which transformed epithelial cells can acquire the abilities to invade, to resist apoptosis, and to disseminate.[11] As for the plasticity in the invasive growth program, carcinoma cells that have undergone an EMT during initial invasion and metastatic dissemination may pass through the reverse process, termed the mesenchymal–epithelial transition (MET) (see section "Kinases and Inhibitors").

5.01.2.7 Genome Instability and Mutation

Genomic instability, and thus mutability, grants cancer cells genetic alterations that drive tumor progression. In tumorigenesis, cancer cells often increase the rates of mutation. This mutability is achieved through increased sensitivity to mutagenic agents. Indeed, the defects in genome maintenance and repair are selectively advantageous and therefore instrumental for tumor progression (see section "Targets in Genomic Instability").

5.01.2.8 Tumor-Promoting Inflammation

Every neoplastic lesion contains immune cells, but inflammation caused by innate immune cells designed to fight infections and heal wounds can instead result in their inadvertent support of multiple hallmark capabilities, thereby manifesting the tumor-promoting consequences of inflammatory responses (see section "Stress Response and Cancer").

5.01.2.9 Deregulating Cellular Energetics

Major reprogramming of cellular energy metabolism is needed in order to support continuous cell growth and proliferation. Tumor cells replace the oxidative metabolic program that operates in most normal tissues to provide cellular building blocks also under hypoxic conditions (see section "Targets in Tumor Metabolism").

5.01.2.10 Avoiding Immune Destruction

Highly immunogenic cancer cells may well evade immune destruction, in particular by T and B lymphocytes, macrophages, and natural killer cells, by disabling components of the immune system that have been dispatched to eliminate them (see section "Targets in Immuno-Oncology").

5.01.3 TIDVAL: Target Identification and Validation

In the early 20th century, the physician and Nobel laureate Paul Ehrlich (1854–1915) developed the concept of "magic bullets," meaning drugs chemically designed to very selectively hit the desired target (in his case, killing germs/bacteria) without affecting the normal tissue of the host.

The first "magic bullet" was the chemotherapeutic agent arsphenamine (trade name: Salvarsan), the first effective treatment for syphilis; it was introduced in 1910 and very successfully marketed until 1943, when it was replaced by penicillin.[12]

Today, targeted therapies are established (at least as component of therapy) for many kinds of diseases, for example, breast, colorectal, lung, and pancreatic cancers, lymphoma, leukemia, and multiple myeloma,[13] and are the focus of drug development efforts in many disease areas, especially in cancer research.

According to the "magic bullet" concept, the drugs developed for targeted cancer therapies are intended to selectively interact and interfere with the functions of defined cancer-specific biomolecules that are essential for deregulation of cell growth and proliferation, for cell transformation, and for tumor maintenance, progression, and metastasis. Small molecules that are able to pass the cell membrane are mostly developed for intracellular targets, for example, enzymes (signal transduction and metabolism), receptors, ion channels, or regulatory proteins. In contrast, large molecules, for example, antibodies, interact with tumor-specific cell surface proteins, for example, cytokine or growth factor receptors and tumor antigens, or with soluble plasma proteins, for example, receptor ligands, cytokines, and hormones involved in the regulation of tumor cell growth. The tumor cells can be affected either directly by action of small molecules or binding of antibodies or indirectly via recruitment and activation of humoral or cellular immunity (complement, killer cells, cytotoxic T cells, or macrophages). Antibodies are also used as carriers (Ab-drug conjugates) for cytotoxic molecules or specific inhibitors or activators to the designated target at the tumor site.[14]

Conventional chemotherapies using cytotoxic chemicals that unspecifically kill rapidly dividing cells are often associated with strong undesired side effects, since they also affect normal, noncancer cells throughout the body. In contrast, targeted therapies aim to reduce the collateral damage by specifically affecting only cancer cells.

5.01.3.1 Target Identification

Prerequisites for starting rational drug design and for developing a targeted drug (or for casting a magic bullet) are a thorough understanding of biological regulatory mechanisms and the identification of defined and valid targets (mostly proteins) that are altered only in the disease phenotype and are essential for the onset or the maintenance of the disease. Possible targets may be identified by examining (mining) general knowledge available in the literature and open-access databases and by intensive investigation of the disease pathobiology comparing characteristics of healthy and disease phenotypes. Generally, the evolution of malignant cells is a multistep process involving sequential acquisition and accumulation of different genetic alterations finally resulting in deregulation of the cellular signaling pathways and networks.[15] Therefore, the finding that one or two genes or proteins are modified or mutated may not be sufficient to understand or explain a malignant phenotype. In addition, manifold interactions, for example, positive or negative feedback loops, compensatory mechanisms, and redundancies, have also to be taken into consideration.[16] Modifications of genes or proteins, like overexpression or deletion, gain or loss of function by mutations, and deregulation of signaling pathways and functional networks detected in the disease context, are only the basis for identification and validation of potential drug targets. Only targets that are proved to be essential for the establishment or maintenance of the disease, and are druggable, are considered to be validated targets.[17]

There are several different approaches to the identification and validation of novel drug targets:

1. Comparative investigations of disease and normal phenotypes in tissues and cell lines aim to detect differentially modified genes or proteins (expression, activity, and regulation). Further characterization of these potential targets with biochemical or cell-based assays measuring their biological activities and the consequences for cell viability of their inhibition or activation may result in elucidation of their physiological roles and their relevance for the disease.
2. In phenotypic screening (also called "forward pharmacology" or "phenotypic drug discovery"), compound libraries are screened in cell-based assays or in animal models for selection of compounds that affect a certain phenotype by causing a desired physiological response, for example, growth inhibition of cancer cells or the reversal of a genetically induced defect.[18] Further investigation of active compounds in order to track down their mechanism of action by studying their influence on cellular regulatory pathways and their interactions with cellular molecular components may contribute to the discovery of unknown disease mechanisms and novel therapeutic targets.
3. Moreover, already established drugs can be investigated for their potential to interact with additional targets in different disease models. Identification of new targets for a marketed drug resulting in an extended full target profile may open up opportunities for novel therapeutic applications (drug repositioning) and expansion of the drug's life cycle.[19]

For new targets, pharmacological tools, either small-molecular-weight compounds or antibodies, are often not available or neither potent nor specific enough; therefore, impairment of target function by methodologies including meganucleases,[20] transcription activator-like effector nuclease (TALEN),[21] zinc finger nucleases,[22] clustered regularly interspaced short palindromic repeat-associated (CRISPR-Cas) proteins,[23,24] RNA interference (RNAi) with short interfering RNA (siRNA) or short hairpin RNA (shRNA),[25] and the PROTAC (proteolysis targeting chimeric molecule) approach[26] in combination with the concept of synthetic lethality is used to generate information on the interactions of cancer genes.[27]

TIDVAL needs a broad skill base and expertise in a large panel of biological and biochemical disciplines and requires effective and forthright transfer of knowledge and experience between academic and industrial researchers. A vital prerequisite for successful programs is the close collaboration of experts from different fields with experience in biochemistry, enzymology, crystallography, biochemical and biological assay design, molecular modeling, structural biochemistry, regulatory and signaling pathways, molecular pathology, toxicology, systems biology, and bioinformatics (analysis of "omics" and "big data"), as well as awareness of novel technologies and assay platforms.

Generally, the search for new targets starts with mining the publicly available information for differences between normal and disease phenotypes. During the last decades, major advances in biological methods and experimental technologies have led to a dramatic increase and accumulation of information that is collected in scientific publications and textbooks or is available on

websites of research institutes as well as of pharmaceutical and biotechnology companies. Enormous data sets can be generated from genomic and proteomic experiments and from biochemical and cell-based high-throughput and high-content assays.

Many of these websites are open-access portals to databases providing links and tools for searching and analyzing large data sets that are continuously collected and compiled from contributions of a network of a growing number of different scientific research and technology teams. The open access to the data should enable researchers to avoid duplication of efforts and to discover new and interesting interrelationships between disease-relevant modifications of genes, proteins, and signaling networks in different cancer types.

A few examples of open-access databases and the links to their home pages are presented here:

Catalogue of Somatic Mutations in Cancer (COSMIC) from the Wellcome Trust Sanger Institute, the United Kingdom—http://cancer.sanger.ac.uk/cosmic
Cancer Cell Line Encyclopedia (CCLE)—https://www.broadinstitute.org/software/cprg/?q=node/11
Cancer Genome Anatomy Project (CGAP) from the National Cancer Institute—http://cgap.nci.nih.gov
CanSAR from the Institute of Cancer Research and Cancer Research UK—https://cansar.icr.ac.uk/
The International Cancer Genome Consortium (ICGC)—https://icgc.org/[28]

A more comprehensive collection of databases is given in the recently published review article: Pavlopoulou et al., Human cancer databases.[28]

5.01.3.2 Target Validation

Validation of identified targets requires experiments proving their involvement and their relevance for the disease process, in which the target's role must be clearly defined. Depending on the nature of the target, modifying its biological activity by suppression or upregulation of its expression, or by inhibition or activation with tool compounds, should provoke a beneficial effect on the disease phenotype.

Expression levels may be modified by gene knockout resulting in loss of gene expression or gene knock-in resulting in expression of a modified/mutated protein.[29] Alternatively, gene expression can be regulated transiently or in an inducible manner at the RNA level (without changing the genetic code) by messenger RAN (mRNA) degradation with RNAi using shRNA or siRNA. This posttranscriptional reduction of gene expression is usually not complete resulting in downregulation, but not total elimination of the gene function (knockdown).[30]

Recent major advances in technologies allow for genome editing by targeted, permanent gene modifications using TALENs or CRISPR-Cas proteins.[23,24] Both methods work by cutting both DNA strands at a specifically targeted site, allowing for gene disruption or knockout, or, alternatively, gene modification (editing) by introduction of deletions, insertions, or specific point mutations. The more convenient and easier-to-use CRISPR-Cas technology has rapidly developed to a mainstream method, and the power of the system for easy and efficient alteration of genome sequences and gene expression simplifies the creation of cells and animals with designed properties and suitability as disease models.

One major challenge remaining after target identification and proving its relevance for the disease is druggability. Only targets that are druggable are valid targets for drug discovery. Approximately 15% (c. 3000) of all human genes are known disease genes, and 10–15% of all human genes are believed to be druggable based on sequence comparisons with those genes encoding proteins that are known targets of small molecules. There is only a 25% overlap of the disease genes with the group of the druggable genes implying a limited number of potential drug targets. However, expanded and diversified compound libraries based on new small-molecule scaffolds or natural products, and including larger, peptide-like molecules, may enable the modulation of large interaction interfaces (protein–protein interactions and DNA–protein interactions), thereby increasing the number of potential drug targets.[31]

Taken together, the process of TIDVAL underpins the development of targeted drugs and has evolved to a major effort needing the collaboration of experts from many different research and technology fields, which are constantly expanding and advancing. Access to public information and data collections and the availability of computational tools to mine, correlate, and interpret the vast amount of data that are accumulating continuously are essential for a successful targeted drug discovery program.

5.01.4 Stress Response and Cancer

Cancer is a complex collection of genetic and epigenetic disorders that can be integrated into common hallmarks.[3,32] In this respect, the stress phenotypes of cancer that include various stressors such as DNA damage and replication, oxidation, proteotoxicity, as well as mitotic, metabolic, and oxidative stress have recently emerged as important features of many tumor types.[32,33] As tumors display components of chronic inflammation, these stress phenotypes are not unique to cancer as they can be found in chronic inflammations or other immunologic disorders as well.

5.01.4.1 DNA Damage and Replication Stress

Cells are continuously faced with endogenous stress during replication and exogenous stress during exposure to ultraviolet (UV) radiation, which can ultimately lead to DNA damage. Following DNA damage, normal cells arrest proliferation, induce cellular senescence, or elicit apoptosis to preserve genomic integrity.[33,34] In contrast, cancer cells have learned to replicate in the presence of DNA damage thanks to the activation of the DNA damage response (DDR).[33–35] Increased DNA damage can occur due to shortening of telomeres leading to double-strand breaks (DSBs) at telomeric ends, which result in translocations and gene amplification events (see genomic stability).[36] Oncogene activation in precancerous lesions has been shown to increase DSBs and genomic instability.[37] Mutation of genes involved in either DNA repair programs (excision, cross-link, or mismatch repair) or the DDR pathways (such as ATM (ataxia telangiectasia mutated) and p53 signaling) can lead to increased DNA damage, inappropriate cell cycle progression, and genomic instability.[34,37] The DDR is a complex signal transduction pathway that has the ability to sense DNA damage and transduce this information to the cell to influence cellular responses to DNA damage.[34,37] Mutations in DDR genes result in a broad spectrum of disorders including disruption of homeostasis of the nervous, immune, and reproductive systems and can also lead to premature aging or cancer predisposition.[37] The notion that DDR pathways enhance sensitivity to agents that interfere with this stress response has been exploited by developing kinase inhibitors for ATM, ataxia telangiectasia and Rad3-related protein, DNA-dependent protein kinase, and checkpoint kinase 1, that indeed exhibit selective toxicity toward cancer cells and are being tested in the clinic.[38] Cancers defective in homologous recombination-mediated DNA repair due to loss of function of BRCA1 and BRCA2 (breast cancer gene) are particularly sensitive to cisplatin.[39] As these tumors also depend on other forms of DNA repair such as base excision repair, they are sensitive to inhibitors of enzymes that facilitate the repair of single-stranded DNA breaks like poly ADP ribose polymerase (PARP1).[40] While BRCA2 mutant cells are addicted to PARP1 function, the PARP1 inhibition is tolerated in normal cells because of functional compensation from homologous recombination-mediated repair.[40,41] As an extension of this principle, cancer cells with already elevated levels of DNA damage and replication stress cannot repair the additional damage and are therefore more vulnerable to the further extensive DNA damage resulting from radiation or chemotherapy that is lethal without a normal DDR pathway. This may explain how stress overload of the DDR pathway has been exploited therapeutically by radiation and chemotherapy.

5.01.4.2 Mitotic Stress

Chromosome missegregation often results in a shift in chromosome distribution and finally into the chromosome instability phenotype.[42] This phenotype is in part the result of defective pathways involved in the various checkpoints of chromosome segregation during anaphase where the spindle assembly checkpoint (SAC) plays a central role,[42] as well as the presence of extra centrosomes,[43] all of which stresses the mitotic apparatus.[42] Mitotic stress also occurs following activation of oncogenes like Ras or loss of function of tumor suppressors like p53 in the presence of an intact mitotic machinery.[42,44] Therefore, cancer cells with mutations that alter the fidelity of mitosis such as aneuploidy or weakened mitotic spindle regulatory machinery are likely to be more sensitive to catastrophic genomic instability caused by stress overload.[45] Thus, inhibiting the SAC may lead to lethality as a result of stress sensitization. Interfering with proper spindle–kinetochore attachment by the microtubule stabilizer taxol, an established anticancer agent, results in stress overload.[46] Inhibitors of mitotic kinases such as polo-like kinase, aurora kinases, monopolar spindle 1 kinase, NimA-related kinase, mitotic checkpoint serine/threonine-protein kinase, and Haspin and many others also promote stress overload, and some of them are currently undergoing clinical trials.[47]

5.01.4.3 Metabolic Stress

Multiple molecular mechanisms, both intrinsic and extrinsic, converge to alter cellular metabolism and provide support for rapid ATP (adenosine triphosphate) generation to maintain energy status, increased biosynthesis of macromolecules, and an appropriate cellular redox state in order to satisfy the energetic demands of rapidly dividing cancer cells (see tumor metabolism).[33,48] Most cancer cells have an increased glucose uptake and produce ATP by glycolysis, secreting a large amount of lactic acid, even under high oxygen conditions, while normal cells derive the bulk of their ATP through mitochondrial oxidative phosphorylation.[33,48] This glycolytic switch allows tumor cells to adapt to a low oxygen environment and promotes the acidification of the microenvironment, which in turn promotes tumor invasion and suppresses immune surveillance.[49] Thus, tumor cells activate biosynthetic pathways, reduce reactive oxygen species (ROS) by generation of NADPH (nicotinamide adenine dinucleotide phosphate), and adapt to the changes in oxygen availability in the tumor.[32,33,49] Therefore, inhibition of the glycolytic and biosynthetic pathways in a tumor cell will lead to stress overload due to incompatibility with the proliferative drive. Switching off pyruvate kinase (PK) can negatively impact the tumorigenic state, presumably by shunting pyruvate to the tricarboxylic acid (TCA) cycle and away from glycolysis.[50] The finding of an inherited mutation in protein kinase RNA activated (PKR), a tissue-specific isoform of PK, which causes the rare hematologic disorder known as PK deficiency,[51] triggered the discovery of AG-348 (Agios), a novel first-in-class activator of PKR that is being evaluated in the clinic.[52] Activating mutations in the NADP-dependent enzyme isocitrate dehydrogenase 1 (IDH1) and IDH2, which convert isocitrate to α-ketoglutarate (αKG) to produce NADPH, have been found in various tumors.[53] Mutated IDH1 and IDH2 are able to generate detectable levels of the oncometabolite αKG, which has been successfully used as response biomarker (BM) for AG-221 (Agios), an IDH2-specific inhibitor in advanced clinical trials for acute myeloid leukemia (AML) bearing the IDH2 mutation (https://clinicaltrials.gov/ct2/show/NCT02577406).

Glutamine is a known cell culture ingredient needed for robust cancer cell proliferation. In fact, many tumor cells are critically dependent on this amino acid.[33,54] The Myelocytomatosis Viral Oncogene Homolog (MYC) oncogene promotes not only proliferation but also the production of accompanying macromolecules and antioxidants that are required for growth.[54] Recent studies have shown that in MYC-dependent transformation, MYC stimulates and increases glutamine uptake by directly inducing the expression of the glutamine transporters slC5A1 and slC7A1,[33,54,55] which themselves are dependent on mTOR (mammalian target of rapamycin) activity.[56] In an amino acid-rich environment, mTOR not only is active and regulates protein translation but also inhibits autophagy. When extracellular amino acids are limiting, resulting in reduced mTOR activity, autophagy recycles intracellular constituents as a way to provide an alternative source of amino acids. Rapamycin, an inhibitor of the target of rapamycin (TOR), mimics the effect that amino acid starvation has on protein translation, cell cycle arrest, ribosome biogenesis, and autophagy.[56] Thus, glutamine flux regulates mTOR activity, translation, and autophagy to coordinate cell growth and proliferation.

In summary, targeting key metabolic enzymes in cancer cells may effectively attenuate tumor cell proliferation.

5.01.4.4 Oxidative Stress

Cancer cells typically generate more ROS than normal cells, a hallmark of oxidative stress response due to both, oncogenic signaling and downregulation of mitochondrial function.[57] Hypoxia in the tumor microenvironment leads to ROS production, which initiates mitochondrial damage and further ROS generation.[33,57] Oncogenes stimulate ROS production, facilitating oncogene-induced senescence causing oxidative damage to DNA, proteins, lipids, and other cellular components, and therefore pose a significant cellular stress.[57] Elevated ROS promotes activation of HIF-1 (hypoxia-inducible factor) by hypoxia, which itself promotes the glycolytic switch and angiogenesis observed in tumors.[57] To alleviate oxidative stress, cancer cells switch to glycolysis and downregulate mitochondrial function. Increasing ROS production is therefore expected to cause stress overload in cancer cells.[57] In support of this notion, it has been shown that inhibitors of pyruvate dehydrogenase kinase (PDK) stimulate mitochondrial oxidative phosphorylation and ROS production and selectively elicit apoptosis in cancer cells but not in normal cells.[58] Similarly, reducing the cellular ROS buffering capacity through the inhibition of glutamate–cysteine ligase can markedly increase the radiosensitivity of cancer cells.[32.a]

5.01.4.5 Hypoxia and Nutrient Stress

Tumor hypoxia, due to poor and abnormal tumor vasculature, is one of the best studied cell stress responses and is a poor prognostic factor in a number of malignancies.[57,59] Hypoxia alters transcription through the stabilization of HIF, which increases glycolytic capacity, decreases mitochondrial respiration, stimulates vessel sprouting via VEGF-A and angiopoietin-2, protects tumor cells from acidosis, and promotes the secretion of lactate (see section "Targets in Neovascularization").[57,59] Drugs targeting either HIF-1 or its effector pathways have been effective in various clinical settings by sensitizing tumor cells toward hypoxic stress.[60] If nutrients are not properly provided to tumor cells, they experience nutrient stress and resort to autophagy for survival, and, as hypoxia inhibits signaling via mTOR, this may facilitate the induction of autophagy.[56,61] Although impaired autophagy could contribute to oncogenesis by promoting genomic instability and cytokine release, autophagy is critical for the survival of apoptosis-resistant tumor cells during nutrient or growth factor restriction. It is therefore to date unclear which tumors may benefit from activation or inhibition of autophagy.[62]

5.01.4.6 Proteotoxic Stress

Aneuploidy and gene copy number changes alter the relative balance of growth and survival signals promoting tumorigenesis. The corresponding increases and decreases in transcript levels produce imbalances of the proteome.[33,63] Increased levels of unfolded protein aggregates in cancer cells burden the protein folding and degradation machineries resulting in a proteotoxic stress.[33,63,64] The heat shock response pathways with their heat shock proteins (HSPs) promote the proper folding and/or proteolytic degradation of proteins. The heat shock response is one of the countermeasures of this type of proteotoxic stress (see protein folding and degradation).[64,65] Pharmacological, genetic, and clinical evidence supports the notion that sensitizing tumor cells toward proteotoxic stress can strongly suppress tumorigenesis.[64–66] The chaperone activity of heat shock protein 90 (HSP90) requires its ATPase activity, which can be blocked by various HSP90 inhibitors and may display its antitumor effect either by destabilizing key HSP90 client proteins like cyclin-dependent kinase (CDK) 4 and human epidermal growth factor receptor 2 (HER2) or by sensitizing tumor cells to elevated general proteotoxic stress.[67] A convenient method of inducing protein unfolding is temperature elevation. Hyperthermia is being extensively investigated as a tumor treatment in combination with chemotherapy.[68] Unfolded proteins are generally turned over by the ubiquitin proteasome pathway.[69] Thus, a second key component of the proteotoxic stress response pathway is the proteasome.[69,70] Bortezomib (Velcade, Millennium Pharmaceuticals) was the first proteasome inhibitor showing clinical efficacy in multiple myeloma.[70] Proteasome inhibition leads to the stabilization of a particular subset of proteins that might be responsible for the antitumorigenic activity. More recently, the imbalance of proteins in cancer cells has also been addressed by targeting the ubiquitin-activating enzymes.[69,71] Moreover, using PROTACs, which are small molecules that inhibit the function of their target proteins by targeting them for degradation by the ubiquitin proteasome system, allows for rapid target identification and might be used as therapeutic strategy.[72]

5.01.5 Targets With Clinical Relevance

Many patients have profited from targeted cancer therapeutics over the last decade, and multiple novel compounds have started the development process. Besides classical kinases, targets in other areas relevant for cancer growth and tumorigenesis have been validated and are being utilized for the identification of innovative tumor therapies.

5.01.5.1 Kinases and Inhibitors

5.01.5.1.1 Introduction

Posttranslational modifications like phosphorylation, glycosylation, ubiquitination, nitrosylation, acylation, methylation, lipidation, and proteolysis, which are known to increase the diversity of the proteome, influence various aspects of normal and pathological physiology.[73] Aberrant phosphorylation in eukaryotes is associated with a variety of disorders ranging from cancer to inflammatory diseases, diabetes, infectious diseases, cardiovascular disorders, cell growth, and survival.[73,74] Kinases are enzymes that catalyze the transfer of phosphate groups from ATP (adenosine triphosphate) to proteins or lipids. A set of divergent kinases play essential roles for eukaryotic signaling. These include various protein kinases like murine sarcoma viral oncogene homologue B (BRAF), Abelson murine leukemia viral oncogene homologue 1 (ABL), ALK (anaplastic lymphoma kinase), and kinases that are able to phosphorylate phosphatidylinositol, such as PI3Ks (phosphatidylinositol 3-kinases) and phosphatidylinositol 4-kinases (Fig. 2).[75] Many human malignancies are associated with deregulated activation of protein or lipid kinases due to mutations, chromosomal rearrangements, and/or gene amplification.[32,74,76]

The human kinome, that consists of, all protein kinases in the genome, contains typical and atypical protein kinases as well as pseudokinases.[77] The latter make up 10% of the human protein kinases and are either inactive or only weakly active due to lack of at least one of three motifs in the catalytic domain that are essential for catalysis.[78] Despite lacking the ability to phosphorylate substrates, pseudokinases are still very important in regulating diverse cellular processes as indicated by the regulation of the serine/threonine-protein kinase STK11 by STE20-related adaptor alpha and the "activation" of JAK2 (Janus kinase) by mutation (C617F) of its JH2 pseudokinase domain.[78]

5.01.5.1.2 Kinase structure

The business end of protein kinases consists of a small, mostly β-structured N-lobe, connected by a short hinge fragment to a larger alpha-helical C-lobe. ATP binds in the cleft between the N- and C-terminal lobes of the kinase domain where the adenine group of ATP is sandwiched between hydrophobic residues and makes contact via hydrogen bonds to the hinge.[79] In most kinases just N-terminal of the hinge, deep in the ATP pocket is an important residue called the "gatekeeper," which is often mutated in kinase alleles resistant to inhibitors. This gatekeeper is not present in PI3K or mTOR. The gatekeeper controls the access to the hydrophobic

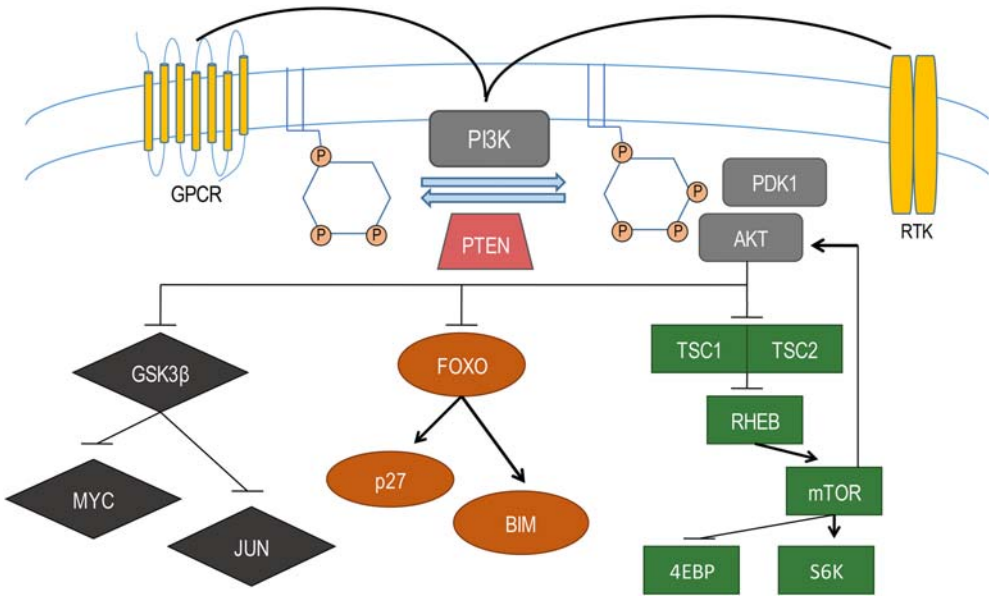

Fig. 2 The canonical PI3K signaling pathway. PI3K can be activated by G protein-coupled receptors (GPCRs) or receptor tyrosine kinases (RTKs) and then catalyzes the phosphorylation of phosphatidylinositol bisphosphate (PIP2) to PIP3. Subsequently, a cascade of kinases becomes activated leading to elevated translation, transcription, and growth. *PTEN*, phosphatase and tensin homologue; *PDK1*, 3-phosphoinositide-dependent protein kinase-1; *AKT*, protein kinase B; *GSK3β*, glycogen synthase kinase 3 beta; JUN, JUN kinase; FOXO, forkhead box protein O3; TSC, tuberous sclerosis complex; RHEB, Ras homologue enriched in brain; 4EBP, eIF4E binding protein; S6K, ribosomal protein S6 kinase.

"back pocket" of the kinase.[79,80] An outstanding structural element of the ATP binding sites is the activation loop (also called activation segment or A-loop) with its N-terminal Asp-Phe-Gly-motif (DFG-motif) whose orientation is pivotal for the access of the protein substrate sites.[79,81] Other elements required for catalysis are the C-helix, the catalytic loop, and finally the aforementioned DFG-motif[79,81,82] (see http://www0.nih.go.jp/mirror/Kinases/pkr/3D/xray/2cpk/2cpkwalk.html).

5.01.5.1.3 Receptor tyrosine kinases (RTKs)

RTKs are membrane-spanning receptors for growth factors, cytokines, and hormones. They consist of an extracellular region with the binding site for their ligand, a hydrophobic transmembrane domain, and an intracellular catalytic domain containing the kinase activity. Ligand binding stabilizes receptor dimerization and induces activation of intracellular phosphorylation processes that then induce activation of a signaling cascade such as PI3K and MAP kinase (mitogen-activated protein kinase) signaling. RTKs regulate many cellular processes and are key components in oncogenic transformation and tumor growth/development. Most relevant RTKs in cancer biology are EGFR (epidermal growth factor receptor), VEGFR (vascular epithelial growth factor receptor), KIT (mast/stem cell growth factor receptor), and HER2neu/ErbB2.[4]

5.01.5.1.4 Kinase activation in cancer

Kinase signaling pathways drive many of the hallmark phenotypes of tumor biology, including proliferation, survival, motility, metabolism, angiogenesis, and evasion of antitumor immune responses. Activation of kinase signaling derives from genetic and epigenetic events. Most frequently, somatic point mutations of kinases and RTKs, which induce gain of function, are present in tumor cells, for example, BRAF (V600), PI3K (E542, E545, and H1047), and KIT (D816). Many kinases that become independent of normal regulatory mechanisms due to constitutively activating mutations are oncogenic and transforming. Overexpression of kinases and deletion of negative regulators can also intrinsically activate cancer-stimulating signaling. Most frequent overexpression has been observed for RTKs, for example, EGFR and HER2, as well as CDK4 and CDK6.[83] Driver kinases are those with genetic alterations that contribute to the transformation of a normal cell to a proliferating cancerous cell. Several driver kinases have been identified and validated in human malignancies and disorders[32,76] by genome-wide screening for kinase amplifications, translocations, or mutations in conjunction with proteomic technologies (see section "TIDVAL: Target Identification and Validation"). These studies have revealed how the mutational status of kinases may be associated with various cancer conditions.[74,76,84]

5.01.5.1.4.1 Example: PI3K/mTOR inhibitors

The PI3K/mTOR signaling cascade serves many physiological and pathophysiological functions and is of major importance for cancer and inflammatory diseases.[75,85] Class I PI3K consists of four isoforms, PI3K α, β, γ, and δ, each with particular functions. The PI3K signaling pathway is frequently activated in human cancers inducing oncogenic transformation, growth, and survival. Pathway activation can be induced by gain of function mutations in PI3K or downstream effector proteins, loss of function mutations in the negative regulator of PI3K and PTEN (phosphatase and tensin homologue), or hyperactivation of an upstream receptor like HER (**Fig. 2**). mTOR is a major downstream target of PI3K signaling that is part of two complexes, mTORC1 and mTORC2 with distinct function.[75,83,86] Many drugs targeting the PI3K or the mTOR pathways are currently in clinical development for both adult and pediatric cancers.[85,87]

Rapamycin was the first mTOR inhibitor discovered. The marketed rapalogs Afinitor™ (everolimus, RAD001, Novartis) and Torisel™ (temsirolimus, CCI-779, Wyeth/Pfizer), which allosterically inhibit mTORC1, have been approved for various cancer[88] and noncancer indications.[89] These inhibitors have recently been joined by the PI3Kdelta inhibitor idelalisib (Zydelig, GS1101, CAL101, Gilead Sciences), which has been approved for various lymphoma indications.[90] Drug candidates inhibiting all the class I PI3Ks including mTORC1 and mTORC2 (dual PI3K/mTOR inhibitors) or all the class I PI3Ks without affecting mTOR (panPI3K inhibitors) or individual isoforms of the class I PI3K (isoform-selective PI3K inhibitors) or imTORC1/mTORC2 only (mTOR inhibitors)[85] have reached various stages of clinical development (http://clinicaltrials.gov/). In summary, there is a competitive landscape for PI3K/mTOR inhibitors, with multiple drugs in development having reached phase III clinical trials (ie, bursalisip (BKM120, Novartis), taselisib (GDC0032, Roche/Genentech), duvelisib (IPI-145, Infinity Pharmaceuticals), and alpelisib (BYL719, Novartis)). Duvelisib is being tested in lymphoma clinical trials. GDC0032 and BKM120 have recently entered phase III clinical trials in breast cancer in combination with the estrogen receptor (ER) degrader fulvestrant. Dual PI3K/mTOR inhibitors like PQR309 (Piqur Therapeutics) are following.

5.01.5.1.4.2 Example: CDKs and their inhibitors

CDKs and their associated cyclins regulate the cell cycle.[91] The human genome encodes 21 CDKs, although only 7 (CDK1, 2, 3, 4, 6, 10, and 11) have been shown to have a direct role in the cell cycle. According to the classical model, CDK4 or CDK6 regulate events in the early G1 phase of the cycle, CDK2 triggers the S phase, CDK2 and CDK1 regulate the completion of the S phase, and CDK1 is the master regulator of mitosis.[91] A second group of CDKs, which are not directly involved in the cell cycle regulation (CDK7, CDK8, CDK9, CDK10, and CDK11), regulates cellular transcription, especially of mRNA transcripts with rapid turnover.[91] Although CDKs and their respective cyclins are not commonly mutated in cancers, their respective inhibitor families, CDKN1 (INK2) and CDKN2 (INK4), show often loss of function due to mutations or epigenetic modulation.[91,92] CDK activity is needed for normal cell division, but in tumors, the CDK is hyperactivated. In particular, the cascade involving CDK4/CDK6-cyclinD, the endogenous protein inhibitor CDKN2A (INK4A or p16), the RB tumor suppressor RB, and the transcription factor E2F has been found to be altered in many cancers.[91,92] Although the importance of CDKs in normal cellular growth is undoubted, recent preclinical studies in which

researchers knocked out the various CDKs showed that CDK2, CDK4, and CDK6 are dispensable for the cell cycle of most normal cell types, while CDK1 is not.[92] As CDK1 appears to be essential for the division of normal cells, inhibiting CDK1 in cancer shows a much narrower therapeutic window with the same type of toxicities as traditional chemotherapy. In contrast, CDK4/CDK6 inhibitors may show a better therapeutic window as certain cancers may be addicted to CDK4/CDK6 activity and therefore will respond to these agents even though most normal cells may not require them for proliferation. Therefore, some of the early pan-CDK inhibitors have been discontinued.[91,93] At present, Pfizer (palbociclib), Lilly (abemaciclib), and Novartis (LEE011) are developing selective CDK4/CDK6 inhibitors that appear to be less toxic and have shown strong progression-free survival (PFS) in ER-positive breast cancer.[91,94]

5.01.5.1.5 Approved kinase inhibitors

Since the approval of fasudil in 1995, sirolimus in 1999, and imatinib in 2001, the number of approved kinase inhibitors has increased to 36 with many others still in preclinical development (**Table 1**). These inhibitors are mainly for oncological indications and are directed against only a handful of protein and lipid kinases, leaving 70% of the kinome untapped (**Table 1**). Despite these successes in kinase drug discovery, the development of kinase inhibitors with outstanding selectivity, the identification and validation of driver kinase(s) in diseases, and the emerging problem of resistance to the inhibition of key target kinases remain major challenges. Kinase inhibitors with outstanding selectivity are likely to become important not only for minimizing side effects and allowing chronic treatment of non-life-threatening diseases.[76,95]

Most of the approved kinase drugs are active against more than one type of cancer. Only few of them have been used for the treatment of non-oncological indications (tofacitinib for rheumatoid arthritis, nintedanib for idiopathic pulmonary fibrosis, everolimus for organ rejection of heart and kidney transplants, and fasudil for cerebral vasospasm; **Table 1**). On the other hand, there are multiple kinase drugs for one single indication. For example, imatinib, nilotinib, dasatinib, bosutinib, and ponatinib have all been approved for CML (chronic myeloid leukemia), while sorafenib, sunitinib, everolimus, temsirolimus, axitinib, and pazopanib are indicated for various stages of renal cell cancer. Ceritinib and crizotinib are indicated for non-small cell lung cancer (NSCLC) with ALK translocations, while gefitinib, erlotinib, afatinib, and osimertinib are indicated for NSCLC with activated EGFR. Finally, vemurafenib alone or the combination of dabrafenib with trametinib is indicated for metastatic melanoma with BRAF V600 mutations (**Table 1**).

5.01.5.1.6 Kinase inhibitor mode of action

With a few exceptions, such as the rapalogs (sirolimus, everolimus, and temsirolimus), trametinib, or cobimetinib, all of the small-molecular-weight kinase inhibitors are directed toward the ATP binding site (see **Table 1**). The conservation of the ATP binding in the human kinome causes these "ATP mimics" to often cross-react with many other different kinases resulting in compounds with promiscuous profiles, for example, dasatinib[96] and sunitinib.[97]

Kinase inhibitors show different modes of binding to kinases. In principle, one can divide kinase inhibitors into those that bind covalently or reversibly to the kinase.[83,95] ATP-competitive inhibitors bind to the hinge region of the kinase[79,81,95,98]; allosteric kinase inhibitors are non-ATP-competitive and do not have physical contact to the hinge. As they exploit binding sites and regulatory mechanisms that are unique to a particular kinase, they, therefore, show the highest degree of selectivity.[79,81,95,98] Similarly, agents targeting the extracellular domains of RTKs act outside the kinase domain. These include peptide mimetics, "peptoids" or antibodies,[99] or small molecules like SSR128129E (Sanofi), which targets the extracellular domains of the fibroblast growth factor receptor (FGFR).[100]

Targeting the allosteric sites of protein kinases may also lead to the identification of activators rather than inhibitors, which could be useful for therapeutic intervention or as pharmacological tools. There are a few protein kinases that require activation rather than inhibition to fulfill their therapeutic task as in the case of 5′-adenosine monophosphate-activated protein kinase (AMPK) and the insulin receptor for which activators have been identified.[101] Protein kinase C (PKC) activation by exogenous compounds acting at the diaclyglycerol binding site can have tumor-promoting or tumor-suppressive effects.[102] Another example of kinase activators includes a mimetic of the brain-derived neurotrophic factor that activates tropomyosin receptor kinase B or neurotrophin receptor kinase 2.[103] In some cases, kinase inhibitors can lead to unintended paradoxical activation either directly or via modulation of feedback loops. The most striking example is the paradoxical effect of BRAF inhibitors, which can activate the MAPK pathway in certain genetic backgrounds resulting in the promotion of hyperproliferative toxicities.[104] There is currently no general strategy for the identification of allosteric kinase inhibitors or activators as most of them have been discovered serendipitously by diverse approaches ranging from phenotypic screenings to highly sophisticated structure-based drug design.

5.01.5.1.7 Kinase mutations and resistance

Deregulation of protein kinase activity by gain of function mutations is essential to maintain the oncogenic state, and in many instances, these mutations can be linked to specific cancers.[84] Inhibitors are being and have been designed to specifically target kinase alleles with gain of functions.[74,105] Despite these successes, it should be emphasized that patients who benefit from these kinase inhibitors often relapse after an initial response (see section "Challenges of Targeted Cancer Therapy"). Multiple mechanisms of resistance have been and are being elucidated to improve the efficacy of these types of targeted therapies. Drug resistance to kinase inhibitors can occur either by compensatory mechanism or by mutations reducing the affinity of the kinase to its inhibitors.[76,106] Approaches to overcome resistances include the development of inhibitors that can tolerate mutations, that bind covalently to their target, or that bind to allosteric sites. Another option is targeting another protein in the same pathway or targeting alternate, activated pathways in combination with the first inhibitor used.[96,107]

Table 1 Approved kinase inhibitors as of Dec. 2015

Year	*Generic name (compound code, trade names)*	*Kinase target*	*Disease*	*Company (year, type)*
1995	Fasudil (HA-1077) [5181]	ROCK1/2	Cerebral vasospam, PAH	Asahi Kasei (1995, type 1)
1999	Sirolimus (Rapamune) [6031]	mTOR	Kidney transplants	Pfizer, Wyeth (1999, type 3)
2001	Imatinib (STI571, Glivec, Gleevec) [5687]	ABL, PDGFR, KIT	CML, Ph + B-ALL, CMML, HES, GIST	Novartis (2001, type 2)
2003	Gefitinib (ZD1839, Iressa) [4941]	EGFR	NSCLC	AZ (2003, type 1)
2004	Erlotinib (OSI-774, Tarceva) [4920]	EGFR	NSCLC, pancreatic cancer	Roche, OSI (2004, type 1)
2005	Sorafenib (BAY 43–9006, Nexavar) [5711]	VEGFR2, PDGFR, KIT, FLT3, BRAF	RCC, HCC	Bayer, Onyx (2005, type 2)
2006	Sunitinib (SU11248, Sutent) [5713]	VEGFR, KIT, PDGFR, RET, CSF1R, FLT3	RCC, imatinib-resistant GIST	Pfizer (2006, type 1)
2007	Lapatinib (GW2016, Tykerb) [5692]	EGFR, ERBB2	BC	GSK (2007, type 1.5)
2007	Dasatinib (BMS-354825, Sprycel) [5678]	ABL, PDGFR, KIT, SRC	CML	BMS (2007, type 1)
2007	Nilotinib (AMN107, Tasigna) [5697]	ABL, PDGFR, KIT	CML	Novartis (2007, type 2)
2009	Everolimus (Rad001, Certican, Zortress, Afinitor, Votubia) [5889]	mTOR	RCC, SEGA, transplantation	Novartis (2009, type 3)
2009	Temsirolimus (CCI-779, Torisel) [5892]	mTOR	RCC	Pfizer, Wyeth (2009, type 3)
2011	Crizotinib (PF-02341066, Xalkori) [4903]	MET and ALK	NSCLC with ALK translocations	Pfizer (2011, type 1)
2011	Vandetanib (ZD6474, Caprelsa) [5717]	RET, VEGFR1-2, FGFR, EGFR	MTC	AZ (2011, type 1)
2011	Ruxolitinib (INC424, Jakafi) [5688]	JAK2	IMF with JAK2V617F mutations	Novartis, Incyte (2011, type 1)
2011	Vemurafenib (PLX4032, RG7204, Zelboraf) [5893]	BRAF	Metastatic melanoma with BRAFV600E mutations	Roche, Plexxikon (2011, type 2)
2011	Axitinib (AG013736, Inlyta) [5659]	VEGFR, KIT, PDGFR, RET, CSF1R, FLT3	RCC	Pfizer (2012, type 1)
2012	Regorafenib (BAY 73-4506, Stivarga) [5891]	VEGFR2, Tie2	CRC, GIST	Bayer (2012, type 2)
2012	Pazopanib (GW-786034, Votrient) [5698]	VEGFR, PDGFR, KIT	RCC	GSK (2012, type 1)
2012	Tofacitinib (CP-690550, Xeljanz, tasocitinib) [5677]	JAK3	RA	Pfizer (2012, type 1)
2012	Cabozantinib (XL184, BMS-907351, Cometriq) [5887]	VEGFR2, PDGFR, KIT, FLT3	MTC	Exelexis (2012, type 1)
2012	Ponatinib (AP24534, Iclusig) [5890]	ABL	Imatinib-resistant CML with T315I mutations	Ariad (2012, type 1)
2012	Bosutinib (SKI-606, Bosulif) [5710]	ABL	CML resistant/intolerant to therapy	Pfizer (2012, type 1)
2013	Dabrafenib (Tafinlar) [6494]	BRAF	Metastatic melanoma with BRAFV600E mutations	GSK (2013, type 2)
2013	Trametinib (Mekinist) [6495]	MEK	Metastatic melanoma with BRAFV600E mutations	GSK (2013, type 3)
2013	Afatinib (Gilotrif, Tomtovok, Tovok) [5667]	EGFR	NSCLC with EGFR-activating mutations	BI (2013, covalent)
2013	Ibrutinib (PCI-32765, Imbruvica) [6912]	BTK	MCL, CLL	Janssen, Pharmacyclic (2013, covalent)
2014	Ceritinib (LDK378, Zykadia) [7397]	ALK	NSCLC with ALK translocations	Novartis (2014, type 1)
2014	Idelalisib (CAL101, GS1101, Zydelig) [6741]	PI3Kdelta	CLL, FL, and SLL	Gilead, Calistoga, ICOS (2014, type 1)
2014	Nintedanib (BIBF 1120, Vargatef, Intedanib) [5936]	VEGFR, PDGFR, FGFR	Idiopathic pulmonary fibrosis	BI (2014, type 1)
2014	Alectinib (AF802, Aliens) [7739]	ALK	ALK-rearranged NSCLC (brain mets)	Roche, Chugai (2014, type 1) appr. in Japan
2015	Palbociclib (PD-0332991, Ibrance) [7380]	CDK4/6	Advanced (metastatic) BC	Pfizer (2015, type 1)
2015	Lenvatinib (E7080, Lenvima) [7426]	VEGFRs multikinase	Thyroid cancer (DTC); kidney cancer	Eisai Co (2015, type 1)
2015	Cobimetinib (GDC-0973, XL-518, Cotellic)	MEK	Melanoma in combination with vemurafenib	Roche, Exelexis (2015, type 3)

Table 1 Approved kinase inhibitors as of Dec. 2015—cont'd

Year	Generic name (compound code, trade names)	Kinase target	Disease	Company (year, type)
2012	Radotinib (Supect)	BCR-ABL, PDGFR	CML	Ilyang, Daewoong Pharmaceutical (2015, type 2). Approved in South Korea only
2015	Osimertinib (mereletinib, AZD9291; Tagrisso)	EGFR (T790M)	NSCLC with EGFR-activating mutations or T790M	AZ (2015, covalent)

CML, chronic myeloid leukemia; *Ph+ − B-ALL*, Philadelphia chromosome-positive B-cell acute lymphoblastic leukemia; *CMML*, chronic monomyelocytic leukemia; *HES*, hypereosinophilic syndrome; *GIST*, gastrointestinal stromal tumor; *NSCLC*, non-small cell lung cancer; *RCC*, renal clear cell carcinoma; *HCC*, hepatocellular carcinoma; *BC*, breast cancer; *SEGA*, subependymal giant cell astrocytoma; *MTC*, medullary thyroid cancer; *IMF*, interstitial myelofibrosis; *CRC*, colorectal cancer; *RA*, rheumatoid arthritis; *MCL*, mantle cell lymphoma; *CLL*, chronic lymphocytic leukemia; *FL*, follicular lymphoma; *SLL*, small lymphocytic leukemia; *PAH*, pulmonary arterial hypertension; *Rock*, Rho-associated protein kinase; *RET RTK*, rearranged during transfection RTK; *CSF1R*, colony-stimulating factor 1 receptor; *JAK*, Janus kinase; *VEGFR*, vascular endothelial growth factor receptor; *mTOR*, mammalian target of rapamycin; *SRC*, proto-oncogene tyrosine-protein kinase Src; *BTK*, Bruton's tyrosine kinase; *ABL*, Abelson kinase; *BCR*, breakpoint cluster region; *PDGFR*, platelet-derived growth factor receptor; *FLT3*, fetal liver kinase 3; *ALK*, anaplastic lymphoma receptor tyrosine kinase; *MET*, MET receptor = hepatocyte growth factor receptor (HGFR); *MEK*, MAP2K, mitogen-activated protein kinase kinase; *FGFR*, fibroblast growth factor receptor.
The 36 kinase inhibitors approved to date are shown with generic name, compound code, trade name, primary indications, year of approval, company, and mode of binding. *GSK*, Glaxo Wellcome; *AZ*, AstraZeneca; *BI*, Boehringer Ingelheim. The chemical structures and biochemical profiles of the 36 approved kinase inhibitors can be viewed in the IUPHAR database (http://www.guidetopharmacology.org/GRAC/LigandListForward?type=Approved&database=all).

5.01.5.1.8 Outlook

The future of protein kinase-targeted therapeutics in cancer appears promising, despite the fact that several protein kinase inhibitors that have entered human clinical trials are not very specific and did not achieve the anticipated results. This situation may be improved by the upcoming second generation of kinase inhibitors with a better selectivity that will be applied to a genetically better defined patient population. The development of kinase inhibitors for non-life-threatening indications where chronic regimens are being used will require a priori a better target selectivity to minimize side effects. Identification of highly selective kinase inhibitors and activators should lead to an expansion of the chemical and biological kinase space as well as to an improved understanding of their therapeutic limitations and potentials.

Reversible, noncovalent kinase inhibitors can be classified as type 1, type 2, and type 3 reversible kinase inhibitors.[98] *Type 1 inhibitors* fulfill all the criteria of an ATP mimetic by binding to the hinge and targeting an active conformation of the kinase (often referred to as DFG-in). The type 1.5 inhibitor is a subtype of the type 1 inhibitor that binds to an inactive kinase conformation (DFG-in conformation, typical of an active kinase, but the C-helix is pushed out). *Type 2 inhibitors* bind to the inactive, so-called DFG-out conformation, maintaining contacts to the hinge region and usually displaying an ATP-competitive behavior similar to type 1 inhibitors. The transition of the active DFG-in to the inactive DFG-out conformation exposes an additional hydrophobic pocket adjacent to the ATP site that is used by type 2 inhibitors locking the kinase in the inactive conformation. *Type 3 inhibitors* are non-ATP-competitive (allosteric) kinase inhibitors that have no physical contact to the hinge. As they exploit binding sites and regulatory mechanisms that are unique to a particular kinase, they, therefore, show the highest degree of selectivity. Type 3 inhibitors can bind either to the kinase domain (close to or removed from the ATP site) or to sites that are located outside of the kinase domain (rapamycins).

5.01.5.2 Targets in Induction of Apoptosis

Programmed cell death, apoptosis, is a tightly regulated suicide program that plays a critical role in maintaining the survival/death balance. It is part of the machinery that eliminates cells with disturbed function. Impaired apoptosis can lead to the development of cancers or autoimmunity; increased apoptosis can induce degenerative disease.[108] DNA-damaged cells that do not undergo apoptosis can form cancerous lesions. Therefore, cancer cells frequently exhibit apoptotic defects resulting not only in oncogenicity but also in resistance to cytotoxic cancer treatments that induce apoptosis as a mode of action.[109] Affected cells survive beyond their intended life span and are protected from oxidative stress and hypoxia—both common features of solid tumors.

Apoptosis is initiated by different pathways. The so-called extrinsic (death receptor-dependent) or the intrinsic (mitochondrial) pathway is the most relevant in the cancer context. The intrinsic and extrinsic pathways activate upstream caspases, caspase 9 and caspase 8, respectively, and converge further downstream in the caspase activation cascade.[110] Caspases are intracellular proteases that cleave key cellular components and activate degrading enzymes (**Fig. 3**).[108,109,111]

Activation of the extrinsic pathway is triggered by cytokine ligands binding to death receptors of the tumor necrosis factor (TNF) family. An intracellular binding site recruits adaptor proteins like procaspases to form a death-inducing signaling complex that triggers caspase activation,[112] which initiates apoptosis. Tumor necrosis factor α (TNFα), Fas ligand (FASL), and tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) are the most prominent death receptor ligands.

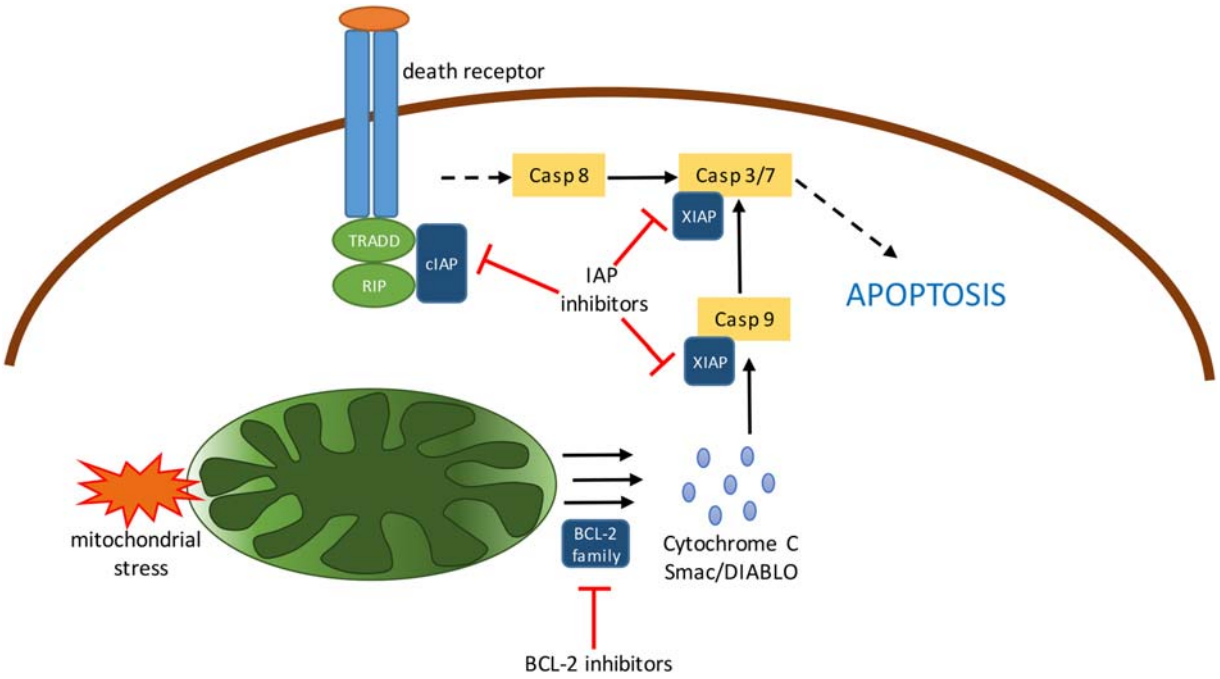

Fig. 3 Apoptosis is often inhibited in cancer. Induction of apoptosis can be achieved via the inhibition of apoptosis inhibitors of the IAP family or the BCL-2 family.

The intrinsic pathway can be activated by stress factors including DNA damage through radiation or UV as well as viruses or growth factor deprivation. In response to these stress factors, mitochondrial membrane permeabilization allows for mitochondrial proteins like cytochrome-c and Smac (second mitochondria-derived activator caspase, inhibitors of apoptosis (IAP) binding protein with low p*I*) to diffuse into the cytosol. IAPs are direct inhibitors of caspases (see succeeding text). Smac can activate caspases by neutralizing IAPs.[113] A complex called the apoptosome forms and starts the cascade of caspase activation resulting in apoptosis.[114] B-cell lymphoma 2 (BCL2) family members with antiapoptotic (BCL-2, BCL-XL, MCL1, BCL-W, A1, and BCL-B) and proapoptotic (eg, BAX, BAK, BIM, BCL-XL, BID, and BAD) functions regulate the permeabilization of the mitochondrial membrane.[5,115]

IAP proteins regulate apoptosis by binding to caspases and inhibiting their activity. All members of the IAP family (eg, XIAP, cIAP1/2, livin, and survivin) contain a Baculovirus IAP Repeat (BIR) domain that mediates the interaction with caspases and other proteins.[116] While XIAP is the strongest inhibitor of caspases, cIAP1/2 has additional roles in other signaling processes that induce apoptosis, particularly NFkB (nuclear factor "kappa-light-chain-enhancer" of activated B cell) signaling.[117] IAPs are overexpressed in most cancer cell lines and many cancers and correlate with poor prognosis and chemoresistance.[118]

Mechanisms that are used by tumor cells to evade apoptosis include imbalance of BCL-2 family proteins, impaired death receptor signaling, reduced caspase expression, and increased expression of IAPs. Particularly, overexpression of BCL-2 has been shown to protect many tumors, such as prostate cancer, glioblastoma, and lymphoma from apoptosis.[119] A central regulator of apoptosis genes is p53, a tumor suppressor that is mutated in about 50% of all cancers.[110,120]

Induction of apoptosis has been investigated in the clinic using two mechanisms: (1) IAP inhibition and (2) BCL-2 inhibition. IAP inhibitors target the BIR domains of IAP proteins and release caspases from IAP inhibition. IAP inhibitors with peptidomimetic and nonpeptidomimetic structures interrupt the protein–protein interaction between IAPs and caspases as well as the indirect apoptosis suppression of cIAP1/2 through cIAP proteasomal degradation and NFkB activation.[121] As single agents, IAP inhibitors induce apoptosis only in a small subset of cell lines but have a broader efficacy spectrum in vivo. Compounds seem to be particularly effective in combination with death receptor ligands like TRAIL.[121,122] Examples of IAP inhibitors in clinical phase I/II are birinapant (TL32711, TetraLogic), LCL161 (Novartis), and ASTX660 (Astex).

BCL-2 inhibitors target the BCL-2 family of antiapoptotic proteins that are commonly overexpressed in a wide range of solid and hematologic cancers. Besides efforts targeting the expression of BCL-2, direct small-molecule inhibitors are under clinical investigation. Preclinical data demonstrated synergistic cytotoxicity by combining induction of apoptosis with conventional therapy to overcome resistance.[123] ABT-263 (navitoclax, AbbVie) and the BCL-2 selective ABT-199 (venetoclax, AbbVie) are currently in clinical phase II trials in NSCLC (ABT-263 only), leukemia, and lymphoma and are showing positive results, particularly in hematologic malignancies with high BCL-2 overexpression and in combination.[124] Other clinical stage compounds are the pan-BCL-2 inhibitors obatoclax (GX15-070, Teva) and gossypol (AT-101, Ascenta) (www.clinicaltrials.gov).

5.01.5.3 Targets in Tumor Metabolism

Tumorigenesis is characterized by uncontrolled growth and proliferation. To maintain this process, tumor cells undergo major metabolic transformations. Alterations in nutrient metabolism can be induced by genetic mutations or epigenetic changes that might be targetable for therapy.[125] Oncogenes and tumor suppressors can regulate nutrient metabolism, and mutations in metabolic enzymes play a role in the development of cancer.[54]

5.01.5.3.1 Glucose metabolism

The so-called Warburg effect is part of metabolic reprogramming and has been known since the 1920s. Cancer cells use much more glucose than normal cells and transform glucose into lactate by aerobic glycolysis instead of metabolizing glucose by oxidative phosphorylation and shuttling the products of glycolysis into the TCA cycle.[126] These metabolic changes enable the generation of precursors for the formation of new biomass.[127] In many cases, metabolic events do not appear to be oncogenic drivers but can be induced by other events during oncogenesis. For example, activation of the PI3K pathway results in high rates of aerobic glycolysis through alterations of enzymes and glucose transporters.[125]

Targets that are involved in glycolytic changes have been suggested for the development of tumor therapeutics. 2-Deoxyglucose is an inhibitor of hexokinase 2 (HK2), an enzyme that is part of the glycolysis machinery and that, at the same time, binds to mitochondria. The HK2–mitochondria interaction facilitates immortalization of tumor cells. HK2 inhibition has shown some efficacy in patients with solid tumors at high concentration. Optimized inhibitors might give better clinical benefit.

Another targetable glycolytic enzyme is 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase 3 (PFKFB3). PFKFB3 is upregulated in low-pH, hypoxic tumors through Hif-1α as well as by the oncoprotein Ras and insulin signaling. The PFKFB3 inhibitor PFK158 (Advanced Cancer Therapeutics) has shown downregulation of glycolytic flux and inhibition of tumor growth in models and in a first clinical trial (Fig. 4).[128]

PK influences the fate of glycolytic products. PK catalyzes the final step of glycolysis from phosphoenolpyruvate to pyruvate, which is then either shuttled into the TCA cycle for ATP production or excreted as lactate (see Warburg effect). PKM2 is an isoform of PK that is specifically expressed in proliferating cells. Its activity is low and it acts as a sensor for amino acid generation. Due to slow metabolism of glucose mediated by PKM2 in cancer, upstream glycolytic intermediates become available for the formation of new cellular building blocks.[127] Furthermore, PKM2 exhibits activity as a transcriptional regulator and promoter of the Warburg

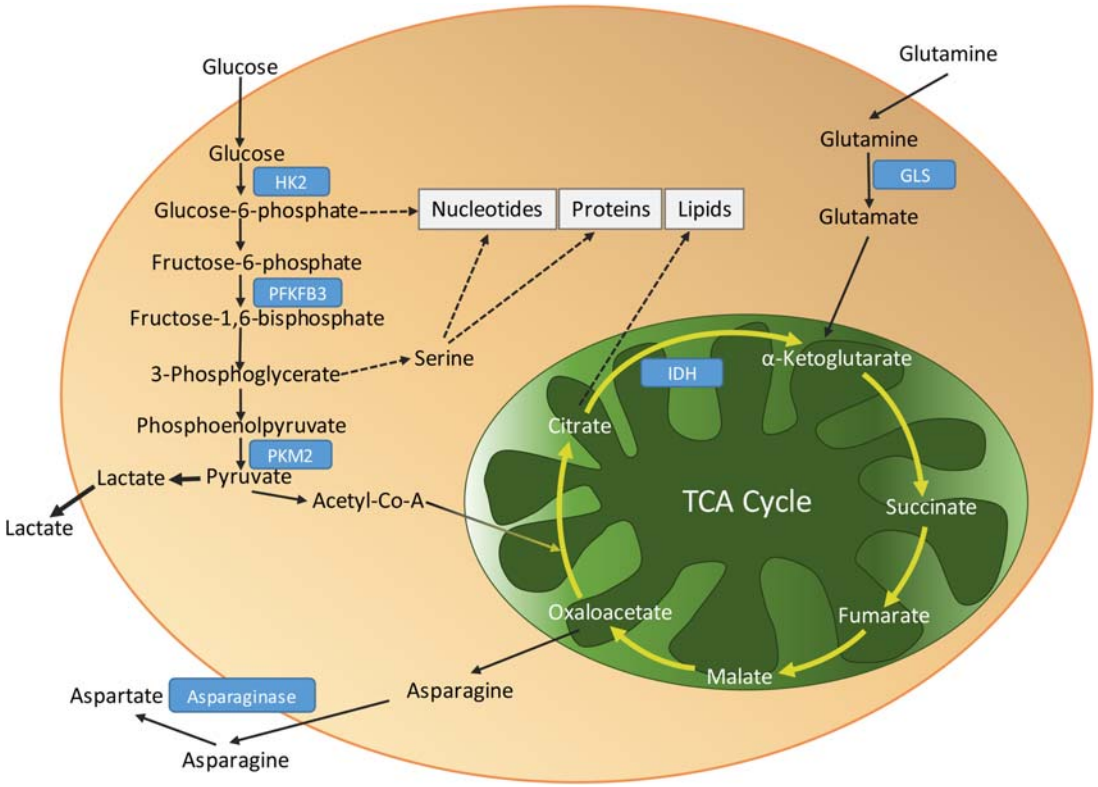

Fig. 4 Metabolic targets in tumor therapy. Metabolic reprogramming in cancer cells can be found in glucose and amino acid metabolism as well as during oxidative phosphorylation. Several targets that are particularly important for metabolic homeostasis of cancer cells can be targeted for therapy (*highlighted in blue*).

effect.[129] In vitro and in vivo studies indicate that activators of PKM2 might inhibit tumor growth, while PKM2 inhibitors give opposing results.

5.01.5.3.2 Amino acid metabolism

In cells with high proliferation rates, precursors for macromolecular synthesis are built from glycolytic intermediates and from products of the TCA cycle. Glutamine is a nonessential amino acid that plays an important role in anaplerotic mechanisms as it can be converted to αKG, a precursor of lipids, nucleotides, and other nonessential amino acids.[125] In cancer cells, glutamine demand is bigger than supply by the cell's own synthesis. Glutamine thus becomes conditionally essential (**Fig. 4**).[54] Furthermore, glutamine maintains redox homeostasis and ATP production in many cells. Glutaminase (GLS) is an enzyme involved in glutaminolysis that is upregulated in several cancers, for example, by overexpression of Myc. GLS is essential for Myc-driven tumors like neuroblastoma and renal cell carcinoma.[130] GLS inhibitors like CB-839 (Calithera) are under development and are being tested in clinical trials for solid and hematologic tumors[131] (www.clinicaltrials.gov).

In a subset of melanoma and hepatocellular carcinoma that lacks the ability to produce arginine, recombinant pegylated arginase can reduce tumor growth. The enzyme depletes arginine and cells that depend on an external supply die because of arginine starvation.[132] In certain leukemic cells, the same situation occurs due to their inability to produce asparagine. Asparaginase is approved for the treatment of acute lymphocytic leukemia in adults and children and is mostly used as combination agent. Clinical trials in other hematologic malignancies are ongoing (www.clinicaltrials.gov).[133]

5.01.5.3.3 TCA cycle

In some cancers, the TCA cycle does not work properly due to mutations in the metabolic enzymes fumarate hydratase (FH), succinate dehydrogenase (SDH), and IDH 1/2. FH and SDH are tumor suppressors and mutation leads to loss of function. IDH mutations change the function of the enzyme causing synthesis of a normally low concentration metabolite, (R)-2-hydroxyglutarate (2HG), and consumption of NADPH.[131,134] 2HG is a tumor marker for patients with IDH mutant tumors and has been suggested to inhibit enzymes that alter cellular epigenetics (**Fig. 4**).[135] Forty percent of adult gliomas and 50% of chondrosarcomas harbor mutations in IDH1 or IDH2.[136] Small-molecule inhibitors of IDH1/2 [eg, AG-120 and AG-221 (Agios)] are under clinical investigation in IDH-mutated tumors. Initial results indicate a good safety profile and signs of efficacy in phase I.[137]

5.01.5.4 Targets in Immuno-Oncology

The immune system is able to distinguish between the body's own and foreign cells. The changes that happen during oncogenic transformation result in expression of neoantigens that are sufficient to identify cancer cells as foreign. This ends in the eradication of subclinical tumors/cancer cells by the host immune cells.[138] Nevertheless, cancer cells frequently evade the immune system and proliferate to form a tumor.

During the noninhibited immune response to cancer cells, specific cancer cell antigens are released from the cells and presented on major histocompatibility complex class I and class II (MHCI or MHCII) of dendritic cells (DCs) or antigen-presenting cells (APCs), respectively. DCs and APCs travel to the lymph node where they present antigen to specific T lymphocytes. T cells are primed and activated by these antigens. Cancer cells can present peptides from tumor-specific antigens bound to MHCI. Previously activated T cells that infiltrate the tumor recognize cancer cells expressing their cognate antigen. They bind to this MHC complex via their T-cell receptor and kill their target cancer cell.[138]

T-cell activation is only partially understood. For full activation, additional costimulatory receptors need to form complexes with their counterparts on the respective APC or cancer cell besides the MHC recognition.[139] Additionally, T-cell activation is regulated by inhibitory cytokines [interleukin (IL) 10 and transforming growth factor (TGF) β] or activating cytokines (IL2 and IL12). Activation of PI3K/mTOR signaling inhibits T-cell activation (see section "Kinases and Inhibitors").

5.01.5.4.1 Tumor-induced immunosuppression

Tumors evolve to evade the immunologic response through different processes. Tumors and their microenvironment establish an immunosuppressive environment in which nearly every step of an effective antitumor response is inhibited:

1. Lack of "danger signals" from innate immune cells. Bacteria or viruses are recognized as "foreign" by DCs leading to their activation. Cancer cells can be well tolerated, and one reason is impaired DC maturation and poor DC recruitment. Mediators of DC maturation defects are vascular endothelial growth factor (VEGF), TGFβ, IL10, macrophage colony-stimulating factor, and IL6.[140] Another mechanism to evade DC and T-cell recognition is loss of MHC expression.[141]
2. Suppressed recruitment of T cells to the tumor site. T cells fail to invade the tumor at normal levels due to changes in cytokine production and barrier formation in the tumor vasculature.[142]
3. The tumor microenvironment produces an immunosuppressive milieu. Endothelial cells express mediators that suppress or kill effector cells, for example, indoleamine 2,3-dioxygenase (IDO), programmed cell death protein ligand 1 (PD-L1), and IL-10.[140,143] Hypoxia and low pH within solid tumors also negatively affect T lymphocytes.[144]
4. Resistance to T cell-mediated killing. T cells eliminate targets through the perforin/granzyme B pathway. Tumor cells express enzymes that inhibit granzyme B.[145]

5. Extrinsic suppression of CD8+ effector T cells by regulatory T cells (Tregs). Tregs are recruited to the tumor and undergo local expansion. Tregs mediate immunologic tolerance by secretion of immunosuppressive molecules that suppress T cell activity by direct killing of effector T cells and DCs, starvation of effector T cells leading to apoptosis, and inhibition of DC function.[146]
6. Tumor cell counterattack. Some tumors express the death receptor ligand FasL and TRAIL that can kill T cells directly.[145,147] Expression of IDO mediates suppressive effects on T cells and activates Tregs.[148]
7. Cancer cells take control over immune checkpoints. When antigen/MHC binding to the TCR is accompanied by engagement of costimulatory receptors, T cells will be primed/activated. Simultaneous engagement of coinhibitory receptors results in T-cell inhibition. Inadequate presentation of costimulatory ligands on tumor cells induces tolerance and insufficient priming and activation of immune cells toward their target antigens (see section "Immuno-checkpoint inhibitors").[28]

Cancer immunotherapy implements ways to promote the host's immune response against cancer cells and increase antitumor immunity. These methods include blockade of immune checkpoints and cytokine therapy. Lately, also treatment with modified, autologous T cells has been investigated (see section "CARs").

A major question is: Which immunosuppressive step is the best to be altered with therapy? One option is to distinguish between tumors with and without T-cell infiltration. For tumors with sufficient T-cell infiltration, the assumption that proper T-cell activation is the major issue can be made. In tumors without T-cell infiltration, most likely, the microenvironment forms a significant barrier. This information might serve as a decision support for choosing the most effective therapy. Combinations with other immune-stimulating drugs or different oncological therapeutics might be beneficial.

5.01.5.4.2 Immuno-checkpoint inhibitors

Immune checkpoints are coinhibitory receptors expressed on the cell surface of immune cells. These receptors inhibit the activation/priming of T cells or DCs when they are activated during MHC recognition. Normally, immune checkpoints are expressed on cells of the immune system in order to prevent overshooting immune reactions against self-antigens.[149] But cancer cells also express checkpoints to evade the host's immune response. Therefore, blocking the immunosuppressive effect of immune checkpoints can stimulate an immune response against cancer. Antibodies directed against two checkpoints have been approved by the FDA (US Food and Drug Administration): ipilimumab, an anti-CTLA4 (cytotoxic T-lymphocyte activation marker 4) antibody, and nivolumab and pembrolizumab, anti-PD-1 (programmed cell death protein 1) antibodies.

CTLA4 is an immune checkpoint receptor that is normally exclusively expressed on T cells. A variety of tumors overexpress CTLA4, which is associated with poor prognosis.[150] CTLA4 regulates early T-cell activation and counteracts the costimulatory receptor CD28. Depending on engagement of CTLA4 or CD28, T cells are activated or inhibited when the TCR interacts with antigen presentation on MHC. Ipilimumab prevents the inhibitory mechanisms of CTLA4 blockade and leads to uninhibited T-cell activation.[151]

PD-1 is another immunosuppressive coreceptor highly expressed on T lymphocytes. Upon activation, the receptor inhibits kinases that are involved in late, peripheral T-cell activation. The PD-1 ligands PD-L1 and PD-L2 are cell surface proteins that are overexpressed on some tumors like melanoma, glioblastoma, and lung cancer. They induce inactivation of T cells at the site of immunologic effect as well as T-cell apoptosis and downregulation of cytokine production. The PD-1 antibodies nivolumab and pembrolizumab block the interaction between PD-L1/2 and PD-1 inducing effector immune response.[151,152]

Anti-PD1 and anti-PDL1 monotherapy responses in patients range between 13% and 38%, and sometimes, even tumor eradication has been observed. Most cases of autoimmune side effects are treatable with steroids.[138] Nonresponders most likely have another (additional) form of tumor immunosuppression. Therefore, it would make sense to combine immunotherapy approaches, for example, chimeric antigen receptors (CARs) (see succeeding text) with PD-L1/PD-1 inhibitors. Combination of PD-1 with CTLA4 antibodies has shown a different immunologic profile and led to longer PFS than single-agent treatment in a particular group of melanoma patients.[153]

5.01.5.4.3 Cytokine therapy

ILs are cytokines that play an important role as immune modulatory proteins. They alter immune responses by binding specific receptors and influencing growth, differentiation, activation, and chemoattraction. ILs can induce pro- and anti-inflammatory responses.[154] For example, IL12 has immune stimulatory and antiangiogenic effects when delivered to the tumor in a targeted fashion or through gene therapy. Decrease in tumor burden has been observed in models of different cancer types like ovarian cancer and mesothelioma when treated with IL12.[155]

High-dose IL2 is approved to treat stage 4 solid cancers. First approval by the FDA was granted in 1992. IL2 therapy has a 15% response rate (RR) in metastatic renal cell carcinoma and a 21% RR in metastatic melanoma.[156] Five to ten percent of patients with metastatic renal cell carcinoma even experience complete remission. IL-2 stimulation improves T-cell proliferation and survival leading to unspecific immunologic effects on the tumor. Major side effects observed are autoimmunity directed against the kidneys and liver.[157]

5.01.5.4.4 CARs

Immunologic killing of cancer cells can also be induced by genetically modifying the patient's own immune cells. T cells are isolated from the patient's blood and expanded in culture. Then they are transfected with CARs comprising an antibody fragment directed against a tumor marker (usually CD19 or CD4) fused to T-cell receptor signaling domains. These CAR-expressing T cells are

infused back into the patient. Interaction between CARs and the target cell surface protein expressed on cancer cells induces physiological T-cell activation. T cells expressing CARs recognize the tumor cells and kill them.

The CAR approach has shown good signs of benefit in hematologic malignancies like lymphoma.[158] To increase the performance and persistence of engineered T cells, second- and third-generation CARs are under development. The approach is limited to antigens expressed on the cell surface and so far has not shown efficacy in solid tumors. The main toxicities observed with CAR treatment are the depletion of healthy B lymphocytes and the release of cytokines ranging from minor severity to lethal toxicity.[159]

5.01.5.5 Targets in Protein Folding and Degradation

Many signal transduction pathways that are altered in cancer are known, and direct inhibitors targeting proteins involved in these pathways are under development or have entered clinical practice. Another approach to target cancer signaling is the alteration of oncoprotein synthesis, folding, and degradation. These strategies have the potential to overcome resistances or to target so far undruggable proteins like Kirsten Rat Sarcoma Viral Oncogene Homolog (KRAS).[160]

5.01.5.5.1 Intervention in protein folding

Chaperones facilitate protein maturation, folding, and protection against heat stress. HSP90 is a chaperone protein that is critical for the homeostasis of over 600 client proteins. Cancer cells particularly depend on proteins that are under HSP90 control as several mutated and nonmutated oncoproteins like ALK, HER2, BRAF, EGFR, Met, JAK2, v-Src as well as androgen, ERs, HIF1α, VEGFR, breakpoint cluster region (BCR)-ABL, and AKT (protein kinase B) are affected by HSP90 activity.[161] Furthermore, HSP90 regulates apoptosis through interaction with NFkB.[162] Other clients like BCL-2, BRCA, and CDK1/4 are involved in resistance implying that HSP90 inhibitors might be good combination partners for therapies that evoke resistance. For example, the HSP90 inhibitor ganetespib is active in EGFR inhibitor-resistant tumors.[163] HSP90 buffers cellular stress induced by oncogenic transformation and tumor growth.[164] HSP90 is often overexpressed in cancers and associated with poor prognosis.[165] Inhibition of HSP90 leads to ubiquitin-mediated degradation of client proteins followed by inhibition of linked pathways. Finally, beneficial effects on several of the hallmarks of cancer can be observed.[67]

First-generation HSP90 inhibitors showed high levels of toxicity. Therefore, next-generation inhibitors from different chemotypes are under clinical development.[67] The most advanced compounds are ganetespib (Synta), which is under clinical investigation for NSCLC, as well as NVP-AUY922 (Novartis) and AT-13387 (Astex).[166]

5.01.5.5.2 Inhibitors of protein degradation

The balance between protein synthesis and degradation is tightly regulated. Most proteins are being degraded via the ubiquitin proteasome system. Ubiquitin-activating and ubiquitin-conjugating enzymes as well as ubiquitin ligases tag proteins with ubiquitin. Targets include a variety of enzymes and short-lived and non-properly folded proteins. Tagged proteins are recognized and degraded by the proteasome, a multiprotease complex. Blocking the proteasome leads to accumulation of defective proteins and can subsequently cause cell death. Increased proteasomal activity has been observed in malignant cells as these cells have a higher rate of protein synthesis. Furthermore, proteins that are degraded via the proteasome include molecules relevant for cell growth, cell cycle and proliferation, and other tumor relevant processes. Inhibition of the proteasome induces downregulation of angiogenesis, growth, and survival as well as induction of apoptosis. Cancer cells are more sensitive to proteasome inhibitors than normal cells.[167]

The first proteasome inhibitor, bortezomib (Velcade, Millennium Pharmaceuticals), is approved for patients with non-Hodgkin's lymphoma and multiple myeloma. Bortezomib binds to the 26S proteasome and inhibits the degradation of many cellular proteins. The mechanism of action is poorly understood as a vast number of proteins are affected by bortezomib. Treatment success is accompanied by severe side effects on neurons and blood cells,[168] and relapses often occur. Therefore, combination efforts have been investigated to gain a long lasting effect. Ixazomib (Ninlaro, Takeda) is the only orally bioavailable proteasome inhibitor that is approved by the FDA. Ixazomib targets the 20s proteasome and shows efficacy in multiple myeloma and has a better safety profile than bortezomib.[169] Carfilzomib (Kyprolis, Onyx) is an irreversible inhibitor that binds to the 20s proteasome and is approved for treatment of multiple myeloma.[170] Three other second-generation proteasome inhibitors are under clinical investigation not only in multiple myeloma but also in lymphomas, leukemias, and solid tumors: delanzomib, oprozomib, and marizomib.[167 a,b]

More specific inhibitors of protein degradation are in clinical development. E1, E2, and E3 ubiquitin-modifying enzymes are involved in targeting proteins for degradation. Distinct ubiquitin-modifying enzymes target a small family of cancer-relevant proteins and thus represent potentially more selective cancer targets. For example, the ubiquitin ligase MDM2 (murine double minute 2 homologue) is involved in the degradation of the tumor suppressor p53. Its inhibition keeps levels of p53 up. Inhibitors of the protein–protein interaction between p53 and MDM2 are under clinical investigation in leukemias, sarcomas, and other tumors.[171]

5.01.5.6 Targets in Cancer Epigenetics

Processes that modify chromatin—the macromolecular complex of DNA and histone proteins—and lead to alterations in the transcriptional potential of the cell are termed "epigenetics." There are different types of epigenetic modifications such as DNA methylation and histone acetylation or methylation that influence transcription and DNA repair (**Table 2**).[172] It is widely accepted

Table 2 Epigenetic modifications of DNA and histone proteins

DNA modifications	*Histone modifications*
Methylation, hydroxymethylation, formylation, carboxylation	Acetylation, methylation, phosphorylation, ubiquitylation, sumoylation, ADP ribosylation, deamination, proline isomerization, crotonylation, propionylation, butyration, formylation, hydroxylation, O-GlcNAcylation

that epigenetic modifications play a role in nearly every step of tumorigenesis. Genomic initiatives have found mutations in key enzymes that regulate epigenetic alterations. For example, histone methylase MLL2 and histone demethylase UTX are mutated in follicular lymphoma and acute lymphoblastic leukemia (ALL), respectively.[173]

5.01.5.6.1 DNA methylation

All tumors investigated so far show changes in their so-called epigenome. A well-described phenomenon in cancer cells is the hypermethylation of CpG island regions in promoters that leads to subsequent gene silencing.[174] Tumor suppressor genes are often targeted by these silencing effects, but also microRNAs with growth inhibitory functions and genes involved in cell cycle, DNA repair, apoptosis, and metabolism can be inhibited.[175] DNA methyltransferases 1, 2, and 3 are targets of the approved hypomethylating agents azacitidine (Vidaza, Celgene) and decitabine (Dacogen, Otsuka/Astex/Eisai/Janssen).

5.01.5.6.2 Histone modifications

Histone modification patterns are numerous and complex. In most cases, neither the mechanisms establishing these modifications nor the impact of modification patterns has been understood. Modifications can influence the electrostatic interaction between DNA and histone proteins leading to a more relaxed or condensed chromatin structure.[176] It is clear that histone modifications can substantially influence transcription and other DNA template processes.[172] Histone modifications are reversible and dynamically changing from activating to repressing patterns, and cross talk between modifications has been observed.[177]

Histone acetylation patterns are altered in cancer. Enzymes involved in histone acetylation/deacetylation are histone lysine acetyltransferases and histone deacetylases (HDACs).[178] So far, 18 HDAC proteins are known that target acetylated histone and nonhistone proteins. HDAC inhibitors restore a set of aberrantly silenced genes and induce growth arrest, differentiation, and apoptosis of tumor cells.[179] Three HDAC inhibitors have been approved for the treatment of T-cell lymphoma: belinostat (Beleodaq, Topotarget), romidepsin (Istodax, Celgene), and vorinostat (Zolinza, Merck). Other HDAC, partly specific, inhibitors are under development.[176]

5.01.5.6.3 Histone acetylation readers

Proteins that can bind to acetylated histones are able to "read" the epigenetic code. About 46 proteins that contain a bromodomain belong to this class. Bromodomain proteins translate the code of lysine acetylation into various phenotypes. Their functions include chromatin remodeling, histone modification, and transcriptional activation.[172,180] The Bromodomain and extraterminal domain (BET) family of proteins contains two bromodomains and an extra terminal domain. Members of this family are BRD2, BRD3, BRD4, and BRDT proteins. BET proteins regulate the expression of several oncogenes, like c-Myc and Bcl-2.[181] Inhibitors do not have the same effect on all cancers as the molecular context is an important factor determining the impact on regulatory mechanisms. Tissue-specific toxicities of inhibitors of certain bromodomain classes have been observed in rodents. Stem cell depletion, alopecia, and immunosuppression are among the observed side effects.[182] A large number of bromodomain inhibitors have been patented.[180] For example, OXT015 (OncoEthix) is currently being tested in different cancers. Other BET inhibitors like RVX000222 (Resverlogix) are under evaluation for oncological as well as non-oncological malignancies.[181]

5.01.5.7 Targets in Genomic Stability

Telomeres are protective caps of 5–10 kbp at the end of each chromosome. They prevent misrecognition of chromosomal ends as DNA breaks, which would lead to activation of DNA repair machinery and subsequently result in chromosomal instability. Telomeres cannot be replicated completely as DNA polymerase cannot replicate DNA toward its end. Therefore, during each cell division, part of the telomere is lost.[183] In normal cells, telomere shortening functions as a molecular clock and triggers senescence (irreversible cell cycle arrest) or apoptosis, preventing abnormal cell division and chromosomal instability.[184] With age, more and more cells experience telomere shortening, and for a few of those cells, senescence fails. Chromosomal instability then will be lethal to those cells as a second step of control.

5.01.5.7.1 Telomerase inhibitors

Cancer cells proliferate in an uncontrolled manner as they are able to overcome proliferative blocks induced by telomere shortening and chromosomal instability. One mechanism to maintain telomeres at stable length is activation of telomerase, a telomere-specific reverse transcriptase. Telomerase can add a six-nucleotide repeating sequence, 5′-TTAGGG, to the 3′ end of a chromosome.[185]

Telomerase activation has been observed in 90% of human cancers, while most normal cells have inactivated telomerase.[186] Tumor cells that do not have elevated telomerase activity use alternate pathways to maintain telomeres.[187] The expression of telomerase is regulated by tumor suppressors like p53 and oncogenes like Sp1 and Myc.[188] The deletion of telomerase inhibits the formation of tumors in vivo. For example, telomerase-deficient mice do not develop BCR-ABL-induced leukemia.[189] Stem cells in general and cancer stem cells (CSCs) in particular display elevated telomerase activity to maintain their prolonged proliferative activity.[190] Targeting telomerase appears to be a promising cancer therapy not only because most types of cancer depend on telomere maintenance but also because their stem cell population might be depleted by telomerase inhibitors.

Besides telomere extension, the catalytic component of telomerase, Telomerase Reverse Transcriptase (TERT), influences other signaling pathways involved in carcinogenesis including Wnt and PI3K. Through these pathways, telomerase regulates its own expression in a feedback system.[191]

Telomerase is a potential target for immunotherapy (see immuno-oncology). GRNVAC1 (VAC-1, Asterias Biotherapeutics) and GV1001 (Tertomtide, Kael-GemVax) are under clinical investigation as immune therapeutics and cancer vaccines. GRNVAC-1-treated AML patients showed a high rate of immune response and favorable outcome. Imetelstat (GRN163L, Johnson & Johnson) is a lipid-conjugated oligonucleotide that directly binds to the template region of telomerase RNA and is being evaluated for myelodysplastic syndrome and different neoplasms (www.clinicaltrials.gov).[192]

5.01.5.7.2 PARP inhibitors

DNA damage can occur through different processes: (1) exposure to UV light or chemicals, (2) spontaneous DNA-damaging events, and (3) failure in DNA processing. DNA damage repair (DDR) includes a variety of cellular responses to DNA damage including cell cycle arrest, regulation of DNA replication, and DNA repair as well as senescence and apoptosis. DNA repair is essential to maintain DNA integrity. While nucleotide excision repair fixes damage caused by UV, alkylating agents, or chemotherapeutics, base excision repair fixes damaged DNA bases. DNA mismatch repair is responsible for base/base mismatches and larger loop insertions or deletions, while Double strand break (DSB) repair mechanisms [homologous recombination repair (HRR) and nonhomologous end joining] join broken DNA ends. Depending on the cell cycle status, the DDR is different.[183,193] Targeting tumors that lack specific functions of the DDR with targeted DNA-damaging agents has a greater therapeutic window than using unspecific DNA-damaging chemotherapeutics as these cells are particularly sensitive.

Most cancers have lost one or more DDR pathways leading to uncontrolled growth and genomic instability on the one hand and a greater dependency on the other pathways on the other hand. If a cancer cell depends on a single DDR pathway for survival, targeting this pathway provides the potential for high cancer cell-killing activity while sparing normal cells of the body, a phenomenon termed synthetic lethality (**Fig. 5**).[193,194]

PARP is an essential component of the machinery that repairs single-strand DNA breaks. During this process, PARP binds to the DNA single-strand break, which activates its catalytic domain. PARP hydrolyzes NAD^+ and forms poly ADP ribose (PAR) chains that recruit DNA repair proteins which are required for relaxation of chromatin. PARylated PARP dissociates from the DNA and allows for completion of DNA repair. PARP inhibitors trap the inactivated protein at the damaged DNA and thus block cellular DNA replication and induce deleterious DSBs,[195] which would normally be repaired by homologous recombination repair (HRR). If this mechanism is defective, cells acquire an extent of DNA instability that leads to cancer cell death. A prominent example of HRR deficiency is a mutation in BRCA1 or BRCA2, typically found in breast and ovarian cancer. Therefore, cancers carrying a BRCA1/2 mutation are particularly responsive to PARP inhibitors.[196] This finding was verified in clinical trials of PARP inhibitors tested in BRCA-mutated breast cancer. For example, olaparib (Lynparza, AstraZeneca) showed an overall RR of 26% and a stable disease rate of 42% in a phase II study in patients with advanced cancers and a germ-line BRCA1/2 mutation.[193,197] Several trials are ongoing that investigate combinations of PARP inhibitors with DNA-damaging chemotherapy as well as with targeted

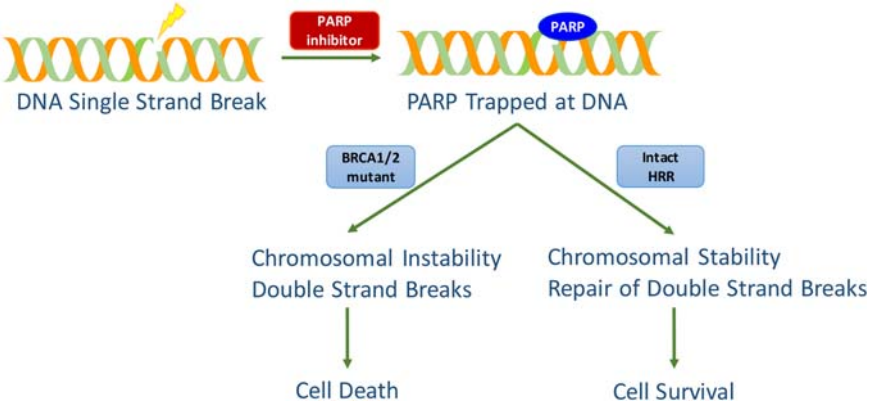

Fig. 5 Synthetic lethality. PARP inhibitors exhibit their potential in cells with BRACA1/2 mutation leading to irreparable chromosomal instability and cellular crisis that results in cancer cell death.

therapeutics. Olaparib is the first PARP inhibitor that has been approved for treatment of BRCA-mutated ovarian, breast, and prostate cancer.[197] Niraparib (Tesaro, MSD), rucaparib (Clovis Oncology), veliparib (Abbott), and talazoparib (Medivation) are currently undergoing clinical trials in BRCA-mutated cancers and in combination with radiation, chemotherapy, or targeted therapeutics (www.clinicaltrials.gov).

5.01.5.8 Targets in Neovascularization

The formation of new blood vessels from preexisting vessels is called angiogenesis. It has been shown that tumors stay dormant as long as they cannot form a new, internal vasculature. The neovasculature within a tumor provides oxygen and nutrients to cancer cells. Furthermore, cells of the newly formed vessels secrete growth factors (angiocrine signaling).[198] The main pathway driving neovascularization is constituted of the VEGF family and its receptors: VEGFR1, 2, and 3. VEGFRs are RTKs (see section "Kinases and Inhibitors") that form dimers in the cell membrane. VEGF signaling induces cell division, migration, vascular permeability, and chemotaxis of endothelial cell precursors.

Inhibitors of VEGF and VEGFR that have been approved or are at present under development target the main angiogenesis transmitting factors, VEGF-A and VEGFR2. Besides kinase inhibitors that target VEGFR [vatalanib (Bayer Schering), sunitinib (Pfizer), cediranib (AstraZeneca), and nintedanib (Boehringer Ingelheim)], the antibodies cetuximab (Merck, ImClone, Bristol-Myers Squibb), trastuzumab (Roche), and panitumumab (Amgen) also inhibit VEGF signaling at different nodes. Single-agent activity of VEGF signaling inhibitors has been observed in renal cell carcinoma, hepatocellular carcinoma, pancreatic neuroendocrine tumors, soft tissue sarcomas, and colorectal cancer. In other cancers, combination therapy has shown efficacy.[198,199] Overall, anti-VEGF treatment exhibits less therapeutic success than expected, although VEGF signaling is elevated in almost all solid tumors.

VEGF expression is upregulated by the hypoxia-inducible transcription factors HIF1α and HIF2α, which have been shown to be important in different models including renal cell carcinoma.[200] Other oncogenic factors that upregulate VEGF expression are p53 inactivation or Src, Ras, and EGFR activation as well as inflammatory cytokine stimulation.[198] As few cancers depend on VEGF, VEGF inhibition only leads to short periods of growth delay in the majority of cancers. A reason for this can be that metastatic tumors co-opt existing vessels for their energy supply and are therefore not affected by inhibition of angiogenesis.[201] VEGF therapy can induce the so-called vessel normalization observed in preclinical models and in clinical settings. Tumor vessels are immature; they exhibit higher permeability and elevated interstitial fluid pressure leading to hypoxia in the tumor tissue and an abnormal microenvironment. Vessel normalization induces improved perfusion and better oxygen coverage due to reformation of vessel architecture.[202] Consequently, the alterations of vasculature in cancers induced by VEGF pathway inhibition can positively influence uptake and potency of drugs given in combination. For example, bevacizumab potentiates the efficiency of immunotherapeutic treatment and sunitinib improves delivery of systematically administered chemotherapeutics. These data suggest a role of VEGF inhibitors as combination agents.[202,203] Resistance to VEGFR inhibition occurs due to upregulation of alternate proangiogenic pathways via HIF1α.[204]

In addition to VEGF, other pathways that influence neovascularization are angiopoietin (vessel maturation and angiogenesis) and Notch (tip and stalk formation). Angiopoietins, Ang-1, Ang-2, and Ang-3, are cytokines that regulate angiogenesis, inflammation, and vascular extravasation. They bind to and act via the vascular receptor kinase Tie2. Angiopoietins play a role in the initial step of neovascularization, the disruption of the two vessel layers: endothelial and perivascular cells. Ang-2 is upregulated at sites of tumor angiogenesis in cancers such as melanoma, malignant gliomas, and thyroid, renal, gastric, lung, neuroendocrine, and breast tumors. Moreover, Ang-2 is associated with poor survival in breast cancer and other malignancies.[205] Ang-1 contributes to the stabilization of newly produced vessels through activation of antiapoptotic pathways mediated by AKT. Inhibition of angiopoietin is currently being evaluated as single agent or in combination. For example, combining angiopoietin inhibitors with VEGF inhibitors might lead to synergism in inhibiting neovascularization. Trebananib (Amgen) is an Ang-1- and Ang-2-neutralizing peptibody that is currently in clinical trials as a single agent in patients with prostate cancer and in combination with the VEGFR inhibitor sunitinib in renal cell carcinoma.[206]

5.01.6 Biomarkers

5.01.6.1 Definition

Throughout the last two decades, the concept of the so-called BMs as a powerful tool driving rational drug development has entered all phases of targeted cancer therapy development. They are also a core component of the "personalized medicine" concept, which ultimately aspires to define the most efficient treatment for any given patient. While the term has been (mis-)used as a vague umbrella in certain cases, the Biomarkers Definitions Working Group has provided a comprehensive definition that is widely recognized, namely, "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes or pharmacologic responses to a therapeutic intervention."[207]

To date, BMs are core components of targeted therapy development programs. As early as during the lead discovery phase, BMs contribute to evaluate target engagement and immediate impact on biological processes. In clinical development and beyond, "predictive BMs" help to identify patients who are likely to benefit from a given targeted agent. Importantly, predictive BMs can also define patient populations who will not benefit from a specific therapy or might even be at risk of developing severe drug-related toxicities. The so-called monitoring BMs contribute to monitoring safety, efficacy, and disease progression. In order to

respect the scope of this article, we will focus on examples of BMs that have been instrumental in developing targeted cancer therapies in the clinic. The majority of BMs currently applied in the clinic are genetic mutations, gene expression, and total protein levels (http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/InVitroDiagnostics/ucm301431.htm). The advent of next-generation sequencing is providing large data sets for single patients at a reasonable cost. However, comprehensive and meaningful analyses of these data and translation into clinical benefit for the patient remain challenging. Other technologies such as noninvasive imaging techniques and mass spectrometry are also being explored in the context of BM development. Mass spectrometry-based assays are providing metabolite profiles and can detect posttranslational protein modifications that could reflect the active state of proteins more adequately than immunohistochemical approaches that mainly detect total protein levels and are largely of qualitative nature.

While the BM concept is widely applied in the preclinical setting, examples of BM translation into the clinical routine remain scarce. Reasons for this phenomenon are discussed later in the paragraph on challenges and perspectives.

5.01.6.2 BMs in the Clinic

The first targeted cancer therapy that formally integrated a BM to select patients that were likely to respond was Herceptin. Herceptin (generic name: trastuzumab, Roche/Genentech) is a monoclonal antibody that targets the HER2/Neu receptor, which is overexpressed in more aggressive types of breast cancer.[208] Breast cancer patients with normal expression of HER2/Neu—a significant fraction of the breast cancer patient population—do not respond to Herceptin. Therefore, HER2/Neu expression levels became a predictive BM for Herceptin response. Eighteen months prior to the biological license application (BLA) of herceptin to the FDA, Genentech initiated a partnership with the diagnostics company DAKO to develop a commercial test to identify patients who overexpress the HER2 gene (http://www.gene.com/media/product-information/herceptin-development-timeline). In May 1998, DAKO submitted a premarket approval application to the FDA for the diagnostic HercepTest® at the same time as Genentech submitted the BLA for Herceptin. Four months later, the FDA simultaneously approved Herceptin and HercepTest® to facilitate the identification of HER2/Neu-overexpressing patients. When used in this context, BMs are often referred to as "companion diagnostics." To date, 10 companion diagnostics for HER2/Neu expression have been approved or cleared by the FDA (http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/InVitroDiagnostics/ucm301431.htm).

The next great breakthrough in the field of targeted cancer therapies was Glivec (United States: Gleevec; generic name: imatinib, Novartis), a small molecule inhibiting the ABL kinase approved for the treatment of CML by the FDA in 2001. Contrary to the varying levels of HER2/Neu expression in breast cancer patients, the vast majority of CML patients carry a chromosomal rearrangement, the so-called Philadelphia chromosome that results in high levels of the BCR-ABL fusion protein that drives the disease.[209] Therefore, a predictive BM to select patients was not needed in this setting. However, companion diagnostics were subsequently developed as the indication for Gleevec treatment was broadened to gastrointestinal stromal tumors (GISTs) and aggressive systemic mastocytosis (ASM). In both cases, the drug inhibits c-KIT, a close relative of the ABL kinase. While the companion diagnostic test for GIST patients detects protein levels of c-KIT by immunohistochemistry, the test applied to ASM patient samples detects the D816V mutation in the c-Kit receptor (http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/InVitroDiagnostics/ucm301431.htm).

The EGFR receptor is overexpressed in 40–80% of NSCLC.[210] These findings prompted the development of gefitinib (trade name: Iressa, AstraZeneca), an EGFR inhibitor. Given the large fraction of NSCLC patients with EGFR overexpression, results from the initial clinical studies showing RRs of only 10–19% lagged behind expectations. Owing to the high unmet need for treatment options in relapsed NSCLC, gefitinib received accelerated approval nonetheless based on RR of only 10.6%. While the RR was low, the responding fraction of patients showed remarkable results.[211] It was also noted that responders were frequently female and nonsmokers. This prompted in-depth comparisons of responders with nonresponders, which eventually revealed that mutations in the EGFR gene were the decisive factor.[211,212] For yet unknown reasons, these mutations frequently occur in nonsmoking patients from East Asia (35% of NSCLC), compared with only 10% of NSCLC patients from the United States.[211,212] Given the clear correlation between EGFR mutation status and response to gefitinib, EGFR mutation status has become a powerful BM to determine which patients should be treated with EGFR inhibitors. Five companion diagnostic tests for EGFR mutation status have currently been approved by the FDA (http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/InVitroDiagnostics/ucm301431.htm).

The BRAF kinase is an important component of the MAPK/ERK signaling pathway, which relays growth-promoting extracellular signals to the cell nucleus.[213] In 2002, Davies et al. reported that a large fraction of metastatic melanomas carried a particular mutation in the B-Raf gene, namely, V600E.[214] The mutation results in increased kinase activity, which is sufficient to transform NIH3T3 cells.[214] Subsequent studies revealed that mutated BRAF drives approximately half of all melanomas as well as several other cancers at lower frequencies.[215] In analogy to the BCR-ABL fusion in CML, this provided a strong rationale to target mutated BRAF in melanoma patients. Among other companies, Plexxikon was the most successful company in developing a targeting compound, vemurafenib (trade name: Zelboraf),[215] that received FDA approval in 2011 for treatment of metastatic melanoma. Importantly, selection of patients based on BRAF mutational status had resulted in an unprecedented unconfirmed overall RR of 81% in a phase I clinical trial.[216] Similar to the approach chosen for Herceptin, a diagnostic test detecting the V600E mutation was developed in parallel to clinical development of the targeting compound to enable patient selection.[215]

Several actively recruiting clinical studies in lung cancer [such as BATTLE-2 (NCT01248247) and Lung-MAP (NCT02154490)] are currently assigning patients to specific treatment arms based on their mutational status across a gene panel. Results are awaited to judge the predictive power of the respective BMs used for patient stratification.

5.01.6.3 Challenges of BMs and Future Perspectives

Although BM-based prospective patient selection has led to impressive overall RRs ranging from 50% to 80% in a few early-phase clinical trials,[217] the clinical success rates for investigational drugs in general remain low and are even declining if presented as a function of research and development expenditures, which have doubled over the past 10 years.[218] At present, only 1 in 10 drug indications that enter the clinic eventually receives FDA approval.[218] BMs have been perceived as one of the potential remedies to improve this sobering situation. While the potential use of BMs to predict and monitor patient responses to treatment has been widely recognized, the actual implementation remains challenging. Only a small subset of well-characterized BMs are currently serving as surrogates of clinical end points.[219] In order to serve as a surrogate for a clinical end point, both clinical relevance and validity of a given BM have to be established.[219] Importantly, the relationship between such surrogate end points and true clinical end points requires continuous reevaluation.[219] De Gramont and colleagues have summarized challenges and potential solutions for the evaluation of BMs for targeted cancer therapies in a recent review article.[220] They portray high levels of biological complexity and interpatient variability as particular challenges. Rather than relying on a single BM, the authors propose the use of BM panels, which are likely to be more robust and reflect complex biological processes more accurately.[220] From a technical perspective, the evolving nature of BM data leaves room for different interpretations.[220] Moreover, standardization of sample collection, processing, and robustness of BM assays remain areas that need improvement. These efforts should be supported by universal guidelines on specimen acquisition and standardized analytic methods.[220] Even to date, many FDA-recognized pharmacogenomic BMs are so-called laboratory developed tests (LDT). The LDT is a type of in vitro diagnostic (IVD) test that is designed, manufactured, and used within a single laboratory, sometimes even referred to as "home-brewed test" (http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/InVitroDiagnostics/ucm407296.htm; "Regulation of Clinical Tests: in vitro Diagnostic (IVD) Devices, Laboratory Developed Tests (LDTs), and Genetic Tests"—https://www.fas.org/sgp/crs/misc/R43438.pdf), invoking potentially considerable variability in the test results. Given the growing impact of LDTs on health-care choices for a larger patient population, the FDA decided in 2014 to broadly regulate LDTs using a risk-based approach ("Regulation of Clinical Tests: in vitro Diagnostic (IVD) Devices, Laboratory Developed Tests (LDTs), and Genetic Tests"—https://www.fas.org/sgp/crs/misc/R43438.pdf).

If a BM is to be used as a decisive tool in clinical treatment decisions, a high degree of stringency has to be applied to its validation. Consequently, development and validation of a BM can be as difficult as bringing a drug to the market: only 1 in 10 BMs coupled to drug development actually reaches the clinic.[220] Given that both challenges and potential benefit of BMs are considerable, public–private partnerships are formed around the world to identify, validate, and apply new BMs.[221] While improvements in technologies and standardization will be important, a deeper understanding of basic and cancer biology will be at least equally valuable to transform BMs into valid end points for patient outcome.

5.01.7 Challenges of Targeted Cancer Therapy

Several therapeutics for targeted cancer therapy are currently being explored, are under development, or have already reached the clinic. Despite promising data that have fostered high hopes for better tolerable treatment options or even cure, the field faces tumor characteristics that make the development of therapeutics more challenging than initially expected. Tumors evade therapeutic agents due to their heterogeneity and due to formation of resistance by changing their driving features.

5.01.7.1 Tumor Heterogeneity

Tumors undergo an evolution as the disease progresses. Whole exome sequencing approaches show that mutational events and copy number alterations occur early in tumor evolution. Additional somatic events have been observed only in some of the tumor cells in later stages leading to distinct heterogenic cell populations within one tumor.[222] While the majority of mutations will not be beneficial for the tumor and result in cancer cell death, a distinct subset will help the tumor to adapt to its environment and necessities occurring during tumor growth or to evade therapy (see succeeding text). The formation of subclones within a tumor is independent and occurs at different locations and points in time and differs from tumor to tumor. Several studies have analyzed tumor heterogeneity by single-cell sequencing.[223] Up to 70% of all mutations in renal cell carcinoma cannot be detected in all regions of the tumor, while NSCLC tumors and metastases show a high degree of concordance.[224] Metastatic lesions can form from different cell populations within the primary tumor and then start their own evolutionary process. Each metastasis can have different genetic features and, therefore, different sensitivities to cancer drugs.

Tumor heterogeneity has been observed in several cancer types including renal cell carcinoma, lung cancer, breast cancer, leukemia, pancreatic cancer, and prostate cancer.[224,225] Designated clinical studies, such as TRACERx (NCT01888601) and DARWIN (NCT02183883), investigate whether formation of subclonal populations and changes in driver mutations are associated with PFS in patients with NSCLC.[226]

As mutations occur, oncogenic drivers may change. Targeted therapeutics do not necessarily hit all types of cells within one tumor. In order to be efficacious, personalized medicine approaches will have to consider the entire mutational landscape of each tumor and predict therapeutic combinations. In some cases, minority subclones drive the progression of the tumor mass, which makes prognostic and therapeutic predictions extremely difficult. Technical possibilities like high-throughput second- and third-generation sequencing of biopsies, single cells, cell-free tumor DNA, or circulating tumor cells provide an opportunity to analyze tumor/metastasis genetics in a more comprehensive manner. Another option is the use of patient-derived xenografts that carry the whole population of a tumor from a patient and might help to model the evolution of the tumor. However, at present, these techniques are too expensive to be covered by the public health systems, and we still have to learn how to best analyze the vast amount of data generated.

5.01.7.2 Tumor Evolution and Development of Resistances

One of the main challenges of almost any cancer therapy is the presence or development of resistances. Resistance to classical chemotherapy, and radiation, as well as to newer targeted approaches, can occur during the course of treatment leading to relapse. In many cases, novel therapeutics were even ineffective from the beginning in the clinical setting due to existing resistance mechanisms.[227] The decision to use a targeted therapy is often based on the presence of the target in the primary lesion. But, as mentioned in the preceding text, because of the heterogeneity of a tumor, the therapeutic response might not be the same within the cancer mass. Therefore, a tumor can evolve not only during adaptation to initiate growth and formation of metastasis but also under treatment.[227] Less sensitive cell populations become dominant and enable the tumor to (re-)grow under a specific therapy (Fig. 6).

Several resistance mechanisms have been defined: (1) mutations in the target protein, (2) acquisition of new mutations in the same pathway, (3) acquisition of driver mutations in a different pathway, (4) enhanced antiapoptotic protein expression, (5) high expression of drug efflux pumps, and (6) cross talk with the tumor microenvironment. On top of these cell intrinsic mechanisms, different types of cells can repopulate the tumor: smaller parts of the heterogenic tumor mass that are resistant to therapy, cells that were quiescent, and CSCs.[227]

5.01.7.3 CSCs

CSCs are the root of cancers and resist chemo- and radiotherapy. Therefore, these cells can repopulate a tumor and lead to relapse, even after years. CSCs comprise minorities in a cancer population. They are highly tumorigenic in vivo and display properties normally attributed to stem cells: self-renewal, pluripotency, and differentiation into more specialized cancer cell types.[228] CSCs are difficult to investigate in vitro as they are rare and quickly lost in tissue culture. They can be enriched by a fluorescence-activated cell sorter (FACS) using cell surface markers like CD133, exclusively expressed on stem cells. Leukemia CSCs exhibit a $CD34^{+}/CD38^{-}$ phenotype.[229] CSCs can be grown in tumor spheres in culture or *in vivo*. In animal models, they form tumors enriched in CSCs from a minimal amount of cells established by serial dilutions.[230]

CSCs are multidrug-resistant. They often have a higher threshold for induction of apoptosis due to upregulation of antiapoptotic proteins and have a high level of multifunctional efflux transporters that pump anticancer therapeutics out of the cell.[231] Active pathways that promote survival and self-renewal in CSCs are Wnt, Notch, and Hedgehog.[232] Therefore, agents targeting one of those three pathways or antiapoptic proteins like Bcl-2 and XIAP can eliminate or sensitize CSCs to standard therapy and might have the potential to reduce likelihood of relapse.[232] Other therapeutic options under investigation are antibodies targeting surface proteins expressed on CSCs. These antibodies either are coupled to cytotoxic agents or induce phagocytosis by the so-called eat-me signals. CSCs can be targeted to macrophage-mediated cell removal by inhibition of the cell surface protein CD47 and become eliminated by the immune system.[233] Attempts have been made to differentiate CSCs, for example, with recombinant IL15. The self-renewal capacities and tumorigenic properties of the CSC population were successfully blocked leading to increased sensitivity to chemotherapeutic agents.[234]

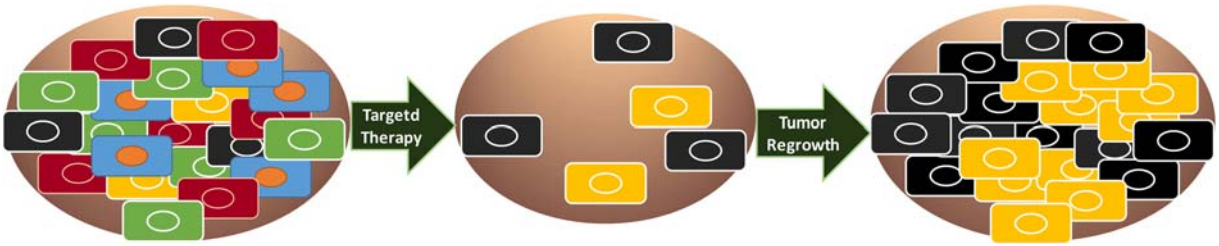

Fig. 6 Tumor heterogeneity. Upon treatment of a heterogenic cancer cell population with any targeted therapeutic, only sensitive cells will die. Resistant clones survive. The tumor progresses from these clones and forms new oncogenic dependencies.

5.01.7.4 Examples of Resistance and Approaches to Overcome Resistance

The most commonly found point mutation leading to resistance to kinase inhibitors that is concomitant with relapses affects the gatekeeper residue, whose size and shape regulate the properties of the hydrophobic pocket located at the back of the ATP binding site.[235] Mutations of the gatekeeper residue as well as other kinase domain mutations confer resistance to a wide spectrum of kinase inhibitors without affecting the kinase activity and may explain a fraction of cases of acquired resistance. The resistance mechanisms to kinase inhibitors in cancer treatment are multiple but result mostly in the restoration of activity of the original "cancer-addicting" pathway. This can occur either by conformational changes in the kinase domain or by reactivating the pathway downstream and/or parallel to the targeted kinase.[76,84,86,236] All of these mechanisms demonstrate the plasticity of cancer cells and the many ways by which a tumor can evade targeted therapies. The only way to approach these problems is to use rational combinations of drugs, a mainstay in cancer therapy.

The HER2 antibodies trastuzumab and lapatinib are part of the first-line therapy for HER2-positive breast cancers. Resistance is induced through downstream activation of the HER2 signaling pathway, for example, through activation of PI3K signaling (PTEN loss and PIK3CA mutation).[237]

One of the most prominent cases of acquired resistance is the often short-lived efficacy of the BRAF inhibitor vemurafenib in melanoma patients with the activating V600E BRAF mutation. Different mechanisms including upregulation of other parallel pathways like MAP kinase and Neuroblastoma RAS Viral Oncogene Homolog (NRAS) signaling have been suggested from patient samples, cell lines, and patient-derived xenografts.[238]

Colorectal cancers that acquire resistance to EGFR blockade are very likely to have a resistance mutation in the KRAS or NRAS gene. Gain of function mutations in KRAS reactivates MAP kinase signaling downstream of EGFR.[239]

Another form of resistance is the cell adhesion-mediated interaction with the tumor microenvironment described for multiple myeloma and leukemia.[240] Cell–cell contact of leukemia cells with bone marrow stromal cells leads to persistence of resistant clones.[241] Integrins mediate cell–cell contact and play a central role in this process. Furthermore, secretion of stromal proteins can activate growth pathways.[242]

To circumvent target-dependent drug resistance, "second-generation" kinase inhibitors have been developed. Inhibitors that bind covalently to the ATP binding site of EGFR have been developed for the emerging resistance to gefitinib and erlotinib.[243] Several of these covalent agents are in late-stage clinical trials.[73] As an example, the BTK inhibitor ibrutinib has been rationally designed to bind covalently to Cys481 of the kinase and was recently approved for B-cell malignancies.[244] Although ibrutinib has shown impressive clinical results, patients that progressed under treatment revealed a C481S mutation in their BTK that abrogates the covalent binding to ibrutinib.[245]

Additional approaches have attempted to develop noncovalent inhibitors that can tolerate amino acid exchanges at the gatekeeper position. Imatinib (Gleevec, Novartis) inhibits the tyrosine kinase BCR-ABL, which is present in the majority of CML patients. BCR-ABL mutations occur in high frequency in patients that develop imatinib resistance. These mutations prevent imatinib from binding to its target. Some patients even had multiple mutated clones.[246] Meanwhile, several ATP site-directed inhibitors active against the T315I ABL1 gatekeeper mutant, like nilotinib and dasatinib, that also target the mutated protein have been approved or are under investigation.[247]

In order to equally target kinases with gatekeeper mutations, these types of compounds display a rather low selectivity. Such so-called dirty inhibitors can have deleterious side effects that may lead to a withdrawal from the market for safety concerns.[248] A further approach is to target the kinase outside the ATP binding sites with the goal to combine ATP site-directed inhibitors with allosteric inhibitors[95] or to combine different kinase inhibitors targeting kinases in the same pathway, as in the case of vemurafenib where the emerging resistance is not due to mutations in BRAF (V600E) itself but rather in the downstream kinase MEK1.[249] Unfortunately, only a very limited number of non-ATP-competitive kinase inhibitors have thus far been identified, which could also be used to address the resistance caused by mutations in the ATP binding site.[95]

Understanding resistance mechanisms is an extremely important step to reduce the risk of relapse and to successfully treat a larger number of cancer patients. In order to make treatment regimens more efficient, it is necessary to use targeted therapies in logically chosen combinations. Knowledge about subclones within the tumor and likelihood of evolutionary development might give the chance to predict rationales for combination therapy that would tackle upcoming resistances.[222]

5.01.8 Summary

Targeted cancer therapy is directed against particular features of cancer cells or the tumor microenvironment. Currently, a broad spectrum of drugs interfering with the hallmarks of cancer, like sustaining proliferation, evading immune response, or genomic instability, is being developed or entering the market. At the same time, more basic research that characterizes cancer biology and reveals potential novel targets is nurtured by the availability of improved technology and big data sets. Many drugs resulting from those efforts would be most beneficial when used for personalized medicine, as single agent or in combination. In order to evaluate and predict treatment success and the best combination options, several obstacles like choice of BMs and knowledge about tumor evolution and development of resistances need to be overcome.

5.02.1 Introduction: Kinase Inhibitors in Cancer

In the 15 years which have passed since the Food and Drug Administration (FDA) approval of imatinib in May 2001,[1] more than 25 small molecule kinase inhibitors have been approved by that agency for the treatment of various types of cancer.[2] As the single largest class of new cancer drugs developed in this period, kinase inhibitors have rapidly established themselves as widely used standards-of-care (SOC) and have transformed the treatment of many cancers, notably chronic myelogenous leukemia,[3] nonsmall cell lung cancer (NSCLC),[4] renal cell carcinoma,[5] and idiopathic myelofibrosis (IMF).[6] Along with antibodies targeting the extracellular binding domain of receptor tyrosine kinases (such as trastuzumab[7] and bevacizumab[8]) these new agents have been at the forefront of the development of personalized medicine[9] (also called stratified or precision medicine); exploiting molecular diagnoses to identify the most appropriate patient group for the drug, based on a detailed understanding of its molecular mode of action.

With such rapid progress the technical demands placed on new kinase inhibitors are typically much greater than those of the "first-generation" inhibitors. Clinical experience with the early compounds has often shown the limitations of suboptimal selectivity, modest pharmacokinetic properties, and, typically, an inability to suppress resistance mechanisms. Fortunately our understanding of how these and other issues can be addressed has developed dramatically over the past decade. Indeed, it has become clear that in a number of cases the precise biology which can be effected by the kinase inhibitor can be "tuned" by attention to detailed aspects of the inhibitor's binding mode and kinetics, meaning that novel inhibitors have the potential to open up research in kinase targets which were previously thought to be of limited interest. Using a range of published examples this article aims to highlight how medicinal chemistry is now delivering a new generation of highly selective kinase inhibitors which are already delivering a step-change in clinical benefit in many tumors. Clearly most focus is on areas such as Bcr-Abl, epidermal growth factor receptor (EGFR), and ALK inhibition where the field has had the greatest time to mature and where the limitations of current inhibitors are best understood. However, the lessons from the first-generation inhibitors can also be applied in the design of compounds against more novel targets, and this has been illustrated in the section on kinases which control the DNA-damage response (DDR).

5.02.2 Kinases and Cancer

The rationale for targeting kinases as a potential treatment for cancer has become increasingly sophisticated, as increasing amounts of genetic information has become available with the development of relatively low cost sequencing. When the first kinase

inhibitors entered clinical trials in the mid-1990s the decision as to which tumor type to target was made either on the basis of total protein expression in biopsies or based even more simplistically on the way the compounds behaved in preclinical xenograft models.[10] It is now recognized that achieving good clinical activity typically requires identification of the oncogenic driver which the tumor has become addicted to for growth and survival. In these cases the kinase acts as an oncogene, and those tumor cells which are oncogene addicted can be killed all the time the kinase being targeted remains a critical component of that oncogenic drive. Clearly there are also examples where kinase inhibition can be effective without the kinase being itself an oncogene although this would typically be in combination. A good example of this "nononcogene addicted" approach will be discussed later in the section describing kinases involved in the repair of DNA damage where kinase inhibitors prevent full repair of DNA damage which can lead to additional cancer cell death.

Although there are just over 500 kinases in the human genome, there are 5 main ways in which they can present as targets for cancer treatment.

5.02.2.1 Kinase Fusion Proteins

Imatinib, the first small-molecule kinase inhibitor to be approved for the treatment of cancer targets Bcr-Abl.[11] This form of Abl is a fusion protein formed from the gene fusion of part of the *Bcr* gene (chromosome 22) with the *Abl* gene (chromosome 9). Bcr-Abl is only formed through this gene translocation, and consequently the chimeric kinase only occurs in individuals with chronic myelogeneous leukemia (CML).[12] The discovery that all CML is due to Bcr-Abl and the fact that the underlying gene translocation can readily be identified through the characteristic shortened allele of chromosome 22 (the so-called Philadelphia chromosome[13]) led to a major breakthrough in kinase inhibitors as, for the first time, patients could be selected on the basis of underlying pathogenomic events.[14] Furthermore, the simplicity and robustness of the genetic assay required to identify patients ensured both rapid uptake of the drug by the medical community and the ability to treat early-stage patients with considerable success.[15] More recent attempts to achieve greater levels of Bcr-Abl inhibition by targeting alternative binding sites on the kinase will be covered in more detail.

Several other kinase fusion proteins are now known, but in general, despite their being constitutively active, and typically transforming, they are generally rare events and are consequently found in relatively small numbers of patients.[16] In some cases, such as the EML4–ALK fusion which is found in 3–4% of lung adenocarcinoma,[17] the number of patients involved is sufficiently large to support full drug development and crizotinib was approved in this indication in 2012.[18] That said, the provisional approval of crizotinib was achieved using single-arm studies using a response-based endpoint which was a very novel regulatory approach compared to typical approvals in lung cancer.[19] The supporting companion diagnostic test uses a break-apart fluorescence in situ hybridization (FISH) assay,[20] a technique which is potentially applicable to other kinase fusion proteins, although in the future the use of next-generation sequencing (NGS) may become more routine.[21]

Other kinase fusion proteins occur in such low frequency that it is debatable whether formal trials will be carried out or whether patients with these genetic aberrations may be treated with medicines in an "off-label" setting. Among the more notable examples are fibroblast growth factor receptor (FGFR) fusions (reported in glioblastoma[22] and extrahepatic biliary tract carcinoma[23]), Ret fusions (reported in lung cancer[24]), and platelet-derived growth factor receptor (PDGFR) fusions (reported in chronic myelomonocytic leukemia).[25] It is interesting to note that in contrast to Abl and ALK (which are both discussed later in this article), these fusion proteins have been found with a number of nonkinase fusion partners, suggesting that the fusion partner may be less important for constitutive activation, rather it is the loss of autoregulatory domains on the wild-type (WT) kinase which is transforming.[26] In terms of a challenge for development of novel inhibitors, targeting fusion proteins presents no specific issues to medicinal chemistry although preclinical assays need to be developed and selectivity over the full-length WT kinase can be difficult to achieve. The bigger issue is more often around the practicality of running clinical trials in populations who may be difficult to identify due to the rarity of the genetic event.[27]

5.02.2.2 Activating Mutations

The development of EGFR tyrosine kinase inhibitors has been fundamental to understanding how activating mutations can play a critical role.[28] When gefitinib[29] and erlotinib[30] were first trialed in lung cancer patients they were used without any further patient selection. Trials in combination with SOC chemotherapy showed no benefit of adding the EGFR inhibitor, while monotherapy results were modest and, in the case of gefitinib, did not lead to full FDA approval.[31] Within the gefitinib data however it was clear that certain patient groups did derive significant clinical benefit; thus women typically did better than men, nonsmokers did better than those with a history of smoking while more Asian patients seemed to have responses than those of Caucasian origin.[32] In 2004 a paper from Lynch et al. provided both an explanation for these data and, critically, a testable hypothesis by highlighting the role of a number of mutations in EGFR which were more common in those patient groups who responded to erlotinib or gefitinib treatment.[33] Two particular genetic events were highly prevalent in the responder groups, namely, a point mutation at position 858 (L858R) and also deletions in a region of exon 19.[34] The IPASS trial explored this hypothesis in an Asian patient population and in 2008 was able to demonstrate striking activity with gefitinib compared to a SOC chemotherapy regimen in a group of NSCLC patients who had been selected on the basis of genetic aberration.[35] This trial was the first lung cancer trial to demonstrate the value of prospective patient selection and led to both the approval of gefitinib (and a companion diagnostic test) and heralding a transformation in the treatment of lung adenocarcinoma.

While the use of first-generation EGFR tyrosine kinase inhibitors has rapidly become a SOC for these patients, the great majority of patients do relapse, most commonly through the acquisition of a secondary kinase mutation (although there are a number of other mechanisms of resistance which are documented).[36] Approaches to find the so-called third-generation EGFR inhibitors, which can target the acquired mutations alongside preserving activity against the original primary mutation, are described in more detail later. The success of these agents is further proof that constitutively active kinases, such as the various mutant forms of EGFR, can be highly oncogenic and tumors which carry them typically remain "addicted" to signaling through the primary oncogenic mechanism.[37] In terms of drug design, the ability to predict which acquired mutational forms of the kinase may be important has increased as our knowledge of the different resistance mechanisms has increased. In particular, mutation of the "gatekeeper" residue to introduce a more bulky amino acid (which typically sits above the entry to the selectivity pocket) is often observed as these gatekeeper mutations are often poorly inhibited by compounds targeting the active site of the WT kinase.[38] Preclinical evaluation of potential gatekeeper mutations has been described for certain kinases and inhibitors can now be designed to be active for these kinase forms even before they have been observed in clinical studies.[39]

With a clear link established using EGFR, a number of other mutated kinase variants have been either validated or proposed as promising anticancer targets. Mutated forms of the receptor tyrosine kinase c-Kit are known to drive gastrointestinal stromal tumors (GIST),[40] while mutations in FGFR3 are involved in certain bladder tumors.[41] Intracellular kinases can also be found with activating mutations such as B-Raf (melanoma),[42] AKT1 (breast and endometrial cancers),[43] and the lipid kinase PI3Kα (ER+ve breast cancer).[44] While many of these mutations are relatively uncommon, they are typically easy to detect if suitable biopsy material can be collected. The challenge of developing novel kinase inhibitors capable of targeting specific mutations with high selectivity is not to be underestimated and is highly dependent on the structures of the mutated forms of the kinase. However the availability of large (and validated) kinase screening libraries together with the ability to generate structural information which can guide development of pharmacophore models makes this a realistic aim for many kinases in a way which would not have been possible even a few years ago.

5.02.2.3 Upstream Pathway Activation

The majority of kinases are cytosolic or nuclear, that is they are not activated by extracellular ligands but rather by intracellular signal transduction, often phosphorylation by other kinases.[45] Consequently there are many kinases which are validated targets for cancer which have no reported activating mutations or where mutational load is only partially responsible for their oncogenic drive. The two best known examples in oncology are the mitogen-activated protein kinases (MAPK) and AKT signaling pathways both of which are widely disregulated in human cancer.[46,47] Thus MEK inhibitors have been demonstrated to show significant activity in B-Raf mutant malignant melanoma.[48] In this case the mutant B-Raf signals exclusively through MEK, so the link between activating mutation and kinase inhibitor is well established.[49] What makes this example particularly interesting is the possibility of targeting multiple points in the signaling cascade to achieve better responses. This approach was first demonstrated to have clinical utility through the successful use of a combination of B-Raf and MEK inhibitors in B-Raf mutant malignant melanoma.[50]

The other well-known example of pathway activation is the canonical PI3K/AKT/mTOR signaling pathway.[51] In this case, pathway activation is even more complicated and can be driven by a range of cell surface and cytosolic factors as well as by dynamic responses driven by the pathway itself in response to kinase inhibitors.[52] Pathway activation can be driven by mutations (in either the p85 subunits of the type I PI3 kinases or in AKT)[53] although functional loss of the phosphatase tumor suppressor Phosphatase and tensin homolog (PTEN) is likely a more significant intrapathway cause of pathway disregulation.[54] In parallel there are well-understood examples of the so-called cross-talk between the major intracellular signaling pathways such that blockade of MAPK signaling can lead to activation of PI3K/AKT/mTOR signaling.[55]

Another clinically important signaling pathway is that involving the Jak2 kinase which is central to the control of hematopoesis and which consequently plays a critical role in the development of myeloproliferative neoplasias such as IMF and polycythemia rubra vera (PRV).[56] The initial interest in Jak2 as a target came from the discovery by a number of groups in 2005 that a mutated form of Jak2 (V617F) was found in approximately 50% of patients with myelofibrosis and more than 85% of those with polycythemia.[57] When the first Jak2 inhibitors (including ruxolitinib which is now registered for this indication) were taken into clinical studies efforts were made to ensure that the drug could be tested in both V617 and Jak2 WT patients with the obvious concern that the latter might be significantly less responsive.[58] In reality the Jak2 mutation status was not found to be a significant predictor of response to Jak2 kinase inhibitors, and no genetic patient selection assay was required to support approval of ruxolitinib. In practice, all IMF patients have constitutively active Jak2 signaling; half the time this is caused by mutation in Jak2, but the other half is due to genetic disregulation of proteins higher up the signaling cascade, such as the thrombopoietin receptor (MPL).[59]

In terms of generating novel inhibitors to target cancers where there are a range of molecular aberrations which are driving signal transduction, the key issue is often around "combinability" and scheduling. That is to say, future treatment will require synergistic use of two or more kinase inhibitors, either to target parallel signaling pathways or to prevent upregulation of resistance pathways. The dynamics of the latter processes is often quite fast and consequently kinase inhibitors which can be dosed for relatively short periods and then withdrawn may be of particular interest and value. One example that will be discussed in more detail is when kinase agents are given to potentiate the tumor cell killing effects of either chemotherapy- or radiotherapy-induced DNA damage (see "**Kinases in the DDR**" section). While this may not seem to be a major change, it is interesting to note that only one of the kinase inhibitors currently approved by the FDA is routinely administered in combination with chemotherapy (lapatinib), and oral dosing on a continuous basis is the overwhelming choice of clinical schedule.[60]

5.02.2.4 Protein Overexpression

In some cases the cause of excessive kinase activity is not that the kinase has become activated (or become insensitive to growth inhibitory signals) but rather the intracellular levels of kinase protein have increased, leading directly to increased flux through the pathway. From a biochemical perspective the increase in protein levels will only lead to an increase in pathway output if the rate of the phosphorylation reaction which the kinase catalyzes is pseudo-first order with respect to kinase concentration, that is the reaction is not limited by availability of kinase substrate or cofactors. While this is often true, it is also important to recognize that in many cases the cancer cell will respond to any increase in pathway signaling through a range of adaptive mechanisms which will typically seek to suppress the pathway, dampening down the effect of the protein overexpression.

The underlying reason for the presence of unusually high protein levels can be due to excessive gene transcription, increase in mRNA message stability, or downregulation of pathways (such as ubiquitinylation) which in an untransformed cell would lead to protein degradation through the 26S proteosome.[61] Whatever the underlying cause, protein overexpression is usually relatively easy to detect in patient-derived tumor samples using immunohistochemistry (IHC) assays.[62] One interesting recent observation comes from patients who have a deletion in exon 14 of the c-Met oncogene.[63] This deletion has been shown to remove a region of the protein which is typically ubiquitinylated; consequently if the aberrant form of c-Met protein cannot be readily be ubiquitinylated and cleared by the proteosome, its levels will build up and consequently kinase activity will increase.[64]

The most important current example of treating cancer by inhibiting a kinase which is overexpressed is probably in HER2+ve breast cancer.[65] HER2+ve breast cancer accounts for ~20–25% of newly diagnosed cases of breast cancer with roughly half of these cases also showing estrogen receptor positive lineage markers (ER+ve).[66] Current treatments are dominated by trastuzumab,[67] which targets the extracellular domain of the HER2 (ErbB2) kinase although a number of small-molecule kinase inhibitors (including lapatinib[68] and neratinib[69]) have shown good clinical activity, suggesting that small-molecule kinase inhibitors have value in this setting and might have some benefit in patients with cranial metastases due to better drug penetration to the brain. Perhaps the most critical issue which has emerged in HER2+ve breast cancer is the most simple—who to treat? While the IHC assay used in support of trastuzumab has clear cut-offs which are relatively easy to use in clinical practice,[70] it is clear that many patients with lower levels of overexpression (HER2 ++ rather than +++) do get benefit with anti-HER2 treatments when they are used. For the development of novel inhibitors, it is critical to understand how protein overexpression is going to be evaluated clinically and the importance (or not) of the exact level of overexpression. This highlights that protein overexpression is a continuous variable which will require cut-offs to be established to guide clinical practice, in contrast to the detection of kinase fusions or mutations. These genetic events are by their very nature, either present or absent, although even here the enormous heterogeneity in most solid tumors is such that biopsies from distinct sites in the same tumor can often present very differently.[71]

5.02.2.5 Gene Amplification

The final major mechanism by which kinases can become inappropriately activated in cancer cells is through gene amplification.[72] While this is clearly linked with downstream protein expression the correlation is not absolute and critically the method of detection is DNA based rather than by quantification of protein levels.[73] In practical terms, selection of patients based on gene amplification has all the same issues of setting cut-offs as does IHC when scoring protein levels, and the same caveats about needing to understand who to include in the treatment population apply. In general terms, selecting patients by gene amplification (e.g., using a FISH assay[74]) tends to identify a smaller number of patients than if the same group were evaluated for protein levels. However, there are a number of important clinical examples where patient groups selected on the basis of high gene amplification have responded well, in contrast to use of an IHC-based test which may include excessive numbers of nonresponders, thereby compromising the response rate to the novel therapy.

Although the use of gene amplification as a routine method for selection patients for kinase-based therapy is not yet established, it is often used in combination with the IHC test for HER2 to select patients with gastric and breast cancer for trastuzumab.[75] Gene amplification assays are however being developed as the most promising methodology for patient selection linked with emerging use of c-Met and FGFR inhibitors.[76,77]

5.02.3 Clinical Lessons Learned From First-Generation Inhibitors

Without the information which has already been gleaned from the clinical development of first-generation kinase inhibitors such as gefitinib, we could not understand the parameters which need to be controlled in order to deliver compounds which can optimally treat a patient with a carcinoma that is, to a greater or lesser degree, "kinase addicted." And while the great majority of kinase inhibitors do not show the debilitating toxicities associated with chemotherapy (such as hair loss, sterility, gastrointestinal toxicity, and neutropenia) they still make significant demands of the patient. Only by understanding the limitations of these early compounds from the patients' perspective can we identify ways to replace these compounds with true "best-in-class" drugs and ensure that inhibitors of new kinase types are better suited to long-term clinical utility.

For the majority of cancer patients, their families, their friends, and their physicians the most worrying limitation of first-generation inhibitors is lack of efficacy. For those patients who see no clinical benefit the question immediately arises as to whether the diagnostic methodology used to match the kinase inhibitor to the underlying genetic aberration(s) is appropriate. As we have

seen above, there remains no simple answer to this problem although it is clear from analysis of "superresponders" by NGS that increased levels of deep sequencing will, in time, allow increasing numbers of patients to receive a "personalized treatment."[78] For those patients who are fortunate enough to achieve a partial response the issue quickly becomes how durable the clinical benefit will last before acquired resistance occurs. While limited durability is undoubtedly linked to suboptimal target engagement in some patients, the emergence of drug-resistant kinase variants is well documented for kinases such as EGFR,[79] ErbB2,[80] ALK,[81] Abl,[82] and c-Kit.[83]

Given what is now an extensive clinical experience with these first-generation inhibitors a number of clear lessons emerge which need to be considered as new compounds progress into clinical studies. This comes down to some very basic parameters which the compound needs to satisfy. Although there are many risks with the development of an inhibitor of a novel, nonvalidated kinase target, it surely makes sense before spending millions of dollars on a clinical development program to find a compound with the potential to be truly best-in-class. First, does the compound engage its molecular target hard enough, long enough, and is it able to access the target in potential sanctuary sites (such as the brain)? Second, does it have the appropriate selectivity to target only the physiologically relevant form of the target and avoid dose-limiting off-target toxicities? Third, does the inhibitor have the ability to inhibit the predicted resistant mechanisms and prolong therapeutic benefit? Finally, can the new drug combine successfully with established and/or novel treatments, avoiding unwanted drug–drug interactions and other liabilities?

5.02.3.1 Target Engagement

A number of first-generation inhibitors do not achieve optimal target engagement; that is, on the basis of basic pharmacology they do not inhibit the protein sufficiently to shut down its activity to the required level. In the majority of cases this is due to the fact that the compounds lack selectivity for the desired target compared and as dose levels increase the compound starts to inhibit other targets, causing unwanted pharmacology before the target kinase has been completely "shut down." Examination of the 25 FDA-approved kinase inhibitors shows that over half of them have dose-limiting toxicities (DLTs) which are most likely *not associated* with the primary mechanism of action. Put another way, if these compounds had been more selective could they have been dosed to higher levels and shown greater efficacy? There is emerging data with a number of new kinase inhibitors to demonstrate that achieving greater target engagement may lead to greater clinical efficacy, and the story of second-generation ALK inhibitors will be covered later (see "**Design of ALK Inhibitors With Potency Against Mutations**" section).

For those cancer types which are associated with the development of secondary metastatic tumors in the brain (e.g., epidermal growth factor receptor mutation (EGFRm) NSCLC,[84] HER2 + ve breast cancer,[85] or triple negative breast cancer (TNBC)[86]) there is a critical need to ensure that the inhibitor can access the brain. If the inhibitor lacks the physicochemical properties to cross the blood–brain barrier (BBB),[87] or is a substrate for one of the major efflux transporters,[88] drug levels in the brain and cerebrospinal fluid will be below those necessary to achieve effective kinase inhibition and the brain may become a "sanctuary site," where metastatic lesions can develop away from the drug.[89] Design of kinase inhibitors which cross the BBB is possible although the relative size and complexity of many kinase inhibitors means this can be nontrivial. That said, the properties of small-molecule inhibitors which can be expected to increase the level of brain penetration are well known in the literature around a range of central nervous system (CNS) targets, and these lessons can be applied to the design of novel kinase inhibitors.[90]

5.02.3.2 On-Target Selectivity

The early literature of kinase inhibitors is dominated by the simple question of whether high selectivity (with respect to other kinases) was a positive property or whether the polypharmacology of many first-generation inhibitors was actually intrinsic to their clinical activity.[91] Although the question remains unanswered in a number of cases the movement toward precision medicine means that the objective of most new drug discovery programs is high selectivity against one (or certainly no more than 2 or 3) target kinases. In many major indications (e.g., Bruton's tyrosine kinase (BTK) inhibitors in chronic lymphocytic leukemia (CLL),[92] ALK inhibitors in NSCLC,[93] or c-Met inhibitors in papillary renal cell carcinoma[94]) highly selective inhibitors are already providing data which suggests that greater on-target selectivity may well provide meaningful additional clinical benefit. However in a number of more niche indications, such as the use of Ret inhibitors in medullary thyroid cancer, it remains less clear whether compounds without vascular endothelial growth factor receptor (VEGFR) activity will be evaluated in the near future.[95,96]

Secondary kinase activity while undesirable may of course not limit therapeutic benefit if the DLT is driven by a different pharmacology, or if optimal target engagement can still be achieved. Inhibition of kinases such as VEGFR[97] and the cell cycle kinases (cyclin-dependent kinases (CDK)[98], aurora kinases,[99] and polo-like kinases[100]) can be dominant in many settings. A number of first-generation inhibitors have been successful while having poor selectivity, but it is clear that if our ambition is to treat patients with earlier, less advanced, disease the patient's willingness to tolerate side effects will be much reduced. This is not just about compounds having severe (Common Terminology Criteria for Adverse Events Grade 3) toxicities; it is a recognition that in earlier disease patients will be on treatment for much longer periods of time, potentially years. Over these longer timescales the ability to tolerate chronic low-level toxicities becomes much more important.[101]

With the increase in understanding of how to design selective small-molecule kinase inhibitors (driven by empirical structure–activity relationship (SAR) data-sets and protein structural information) it is becoming possible in many cases to design inhibitors to have selectivity for mutant (or fusion) proteins over the WT kinase.[102] This is an exciting development which has the opportunity to further increase therapeutic index in settings such as EGFR-mutant NSCLC where the first-generation of inhibitors is limited by

skin rash and gastrointestinal toxicity which are driven by WT EGFR.[103] New generation compounds which are "WT sparing" are currently being explored in the first-line setting where it may be possible to both increase the number and durability of clinical responses *and* at the same time reduce rash and diarrhea. If this approach is successful it is likely we will see a number of new (best-in-class) inhibitors able to selectively target kinases which become cancer targets as a consequence of genetic mutation.

5.02.3.3 Targeting Resistance

The selection applied by the blockade of a pathogenomic driver not only will kill cells which are reliant on that pathway for survival but also provides a survival advantage for any clones which can avoid total dependence on the molecular target being inhibited. This form of Darwinian survival advantage[104] was first observed in the classical chemotherapy of bacterial pathogens where drug-resistant clones can be generated (both clinically and in culture) if the drug exposure was maintained at a sublethal concentration.[105] This form of clonal selection is so well established that it has been considered a clear proof of mechanism demonstrating that the bacterium has been forced into an adaptive response.[106]

In oncology the development of resistance in response to a selective kinase inhibitor was first explored in those CML patients who relapsed on imatinib following an initial response.[107] Careful follow-up of these individuals highlighted a number of mechanisms including increased Abl protein expression[108] and the evolution of a range of single-point mutations in Abl.[109] Curiously the spectrum of resistant mutations was found to be highly dependent on the specific kinase inhibitor being used with very different resistant profiles being recorded with nilotinib[110] and dasatinib.[111] However, both these compounds were "defeated" by the T315I mutation, a protein where the threonine gatekeeper had been mutated to an isoleucine.[112] Although it has subsequently been possible to develop compounds capable of inhibiting the Abl gatekeeper mutant the observation that the mutations in the gatekeeper residue are peculiarly difficult to target has been seen with other kinases, notably EGFR and HER2.[113,38]

Given that there are a finite number of possible gatekeeper mutations (based on the possible single-nucleotide changes which can give mutant kinases retaining the ability to fold) it is now possible to explore activity against these mutants before a compound has even entered the clinic. This approach can either exploit structural chemistry approaches or can generate the actual kinases for screening. While such studies need confirmation from clinical data it is clear that compounds which include activity against gatekeeper and other relevant mutant forms of the kinase should enjoy major advantages in clinical practice.[114]

5.02.3.4 Combinability

Given the concerns described earlier, and the polyclonal nature of solid tumors, it is perhaps a surprise that the vast majority of first-generation kinase inhibitors are actually approved for use as monotherapy. Currently only lapatinib is prescribed in combination with chemotherapy[60] while the use of kinase/kinase combinations is currently restricted to the use of trametinib and dabrafenib for the treatment of B-Raf mutant malignant melanoma.[115] Given everything we have learned about the underlying causes of cancer and the nature of acquired resistance, the concept of "combinability" should be of paramount concern in the selection of any new kinase inhibitor. While it is certainly possible that two kinase inhibitors may not be easy to codose due to their having overlapping on-target toxicities, it is a very different matter if a combination cannot be dosed due to a liability (such as a PK interaction) which is fundamentally down to suboptimal inhibitor design. As kinase inhibitors will undoubtedly be used more and more in combination, the avoidance of off-target toxicities and drug–drug interactions will become increasingly critical in compound selection.

Of course, combination treatment does not necessarily mean concomitant dosing of both agents on continuous schedules at the same doses used when given as monotherapy treatment, although there are examples, such as the use of anti-VEGFR and anti-EGFR therapies where this has been very successful, such as in first-line EGFR-mutant NSCLC. Another good example is the combination of B-Raf inhibitors with MEK inhibitors where concomitant dosing is the current SOC.[116] However other kinase inhibitors may be better tolerated on episodic schedules, and consequently the kinetics of drug elimination become more important and compounds with shorter clinical half-life may have advantages over those which can achieve very flat pharmacokinetic profiles with low peak/trough ratios. Dinaciclib is a CDK9-selective inhibitor which has been demonstrated to be active given by i.v. infusion on a weekly schedule. Furthermore, by limiting the period of time where the kinase inhibitor is present at biologically effective concentrations, the off-target effects of inhibiting the cell cycle kinases CDK1 and CDK2 are dramatically reduced.[117]

In summary, despite the success of a number of first-generation inhibitors which do not match up to the four criteria described, it is clear that novel kinase inhibitors need to be much better designed if they are to realize the full benefits that may be achieved in a world of precision medicine with molecular diagnosis at the heart of the way in which cancer is treated. The next sections will highlight examples which show how various research groups are pushing the boundaries of our current understanding and, in doing so, are starting to generate clinical data which offers a step-change in the way kinase inhibitors are used for the treatment of cancer.

5.02.4 Bcr-Abl Inhibitors

5.02.4.1 Chronic Myeloid Leukemia and the Discovery of Imatinib

A reciprocal translocation between chromosome 9 and 22 leads to the short Philadelphia (Ph) chromosome[118,119] containing the oncogene Bcr-Abl (breakpoint cluster region–Abelson leukemia) which is the drive for initiation of CML.[120] The Bcr-Abl fusion

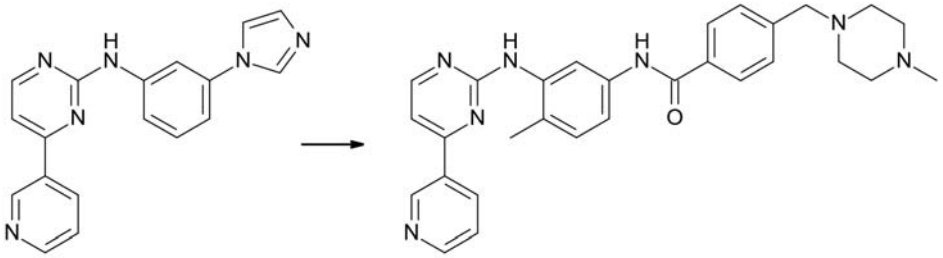
protein contains a truncated regulatory domain which leads to a constitutively activated Abl tyrosine kinase domain, which in turn drives the proliferation of stem cells in bone marrow and the progression of this aggressive hematological disorder. In 2001, <3 years after the start of Phase I studies, imatinib (Glivec, Gleevec) was approved for the treatment of CML, ultimately transforming how the disease is currently treated.[121] The discovery of imatinib also represents an industry landmark being the first kinase inhibitor to receive regulatory approval and at the same time heralding the era of targeted drug therapies in cancer. The recommended dose for imatinib is 400 mg QD, with a higher dose of 600 mg QD for accelerated/blast phases of the disease. Imatinib is a relatively selective kinase inhibitor, being shown to inhibit c-Kit and PDGFR in addition to Bcr-Abl. At the time this high selectivity was attributed to the observation that imatinib bound to and stabilized an inactive DFG-out conformation of the kinase (a type II mechanism) although more extensive characterization of other type II inhibitors discovered subsequently has shown that high selectivity does not necessarily follow from such a mechanism, and indeed, many inhibitors which exhibit a type I mechanism (binding to the active DFG-in kinase) can show high degrees of selectivity.[122]

The discovery of imatinib followed a high-throughput screen with compound **1** found as a promising if modestly potent inhibitor of c-Abl (Fig. 1) albeit the screen was in fact seeking to identify Protein kinase C (PKC)-α inhibitors.[123] SAR studies led to replacement of the imidazole in **1** with a benzamide moiety which boosted Bcr-Abl potency, and critically, addition of a methyl group onto the central ring resulted in abrogation of PKC-α and CDK1 activities. This "flag-methyl" is a feature of numerous subsequently characterized DFG-out kinase inhibitors. In order to overcome poor bioavailability, a solubilizing basic side chain was appended to the benzamide although in subsequent structures this basic group was additionally shown to make key hydrogen-bonding interactions with Ile360 and His361. The pyridine of imatinib forms the key hinge hydrogen bond to Met318. The anilino NH donates a key hydrogen bond to the gatekeeper Thr315 with the amide carbonyl bonding to Ala380. The benzamide ring occupies the pocket vacated by the shifted Phe in the DFG sequence.

Imatinib is able to reduce the number of Ph + stem cells in the bone marrow and normalizes peripheral white blood cell counts although it cannot completely deplete Ph + stem cells. It is thought that this is because stem cells in a quiescent state are not dependent on Bcr-Abl signaling, which is why patients invariably relapse on therapy.[124] However despite its enormous clinical impact, for some patients imatinib proved to be relatively ineffective against more advanced stages of the disease, including against other Ph + leukemias such as acute lymphoblastic leukemias (ALL), due to the emergence of significant acquired resistance. Rates of resistance vary according to the stage of the disease, with resistance much higher in later stages. In newly diagnosed cases resistance rates are low, in the region of 3–4% of patients, but in end stage blast phase, can be as high as 80%.

5.02.4.2 Mechanism of Resistance to Imatinib

A variety of mechanisms of resistance to imatinib have been reported in both clinical samples and through preclinical in vitro studies, but the major mechanism is via single-point mutations in the kinase domain which render imatinib unable to efficiently inhibit Abl kinase activity.[125] The transforming potential of these mutations varies significantly, with patients experiencing different prognostic outcomes depending on their mutational profile; a specific mutant may not always confer resistance to imatinib, and the presence of a mutant may not always explain drug resistance. As with EGFR inhibitor treatment, some mutations have been shown to preexist at low levels in newly diagnosed patients and may be selected for under the pressure of imatinib drug therapy. Other studies have shown that these point mutations more typically arise during treatment although this remains an area of significant debate.[125] To date over 100 single-point mutations have been detected in patients treated with imatinib. Lack of imatinib activity against the gatekeeper T315I mutation may be rationalized by the loss of the hydrogen bond between Thr315 and the aniline-NH of imatinib which is further compounded by a clash between the aniline ring and Ile315. Gatekeeper mutations have been observed as



1
c-Abl IC_{50} = 3300 nM

Imatinib
c-Abl IC_{50} = 188 nM
Kit IC_{50} = 413 nM
PDGFRβ IC_{50} = 386 nM

Fig. 1 From screening hit to imatinib.

an escape mechanism in other targeted therapies such as in the use of gefitinib and erlotinib in EGFR mutation positive NSCLC, as will be discussed in "Optimizing Kinase Inhibitors for Selectivity and Acquired Resistance for Lung Cancer" section. Reduced activity against the L248V mutant has been postulated to be due to both a poorer topological fit with imatinib and also to a destabilization of the protein inactive conformation to which imatinib prefers to bind. Similarly, this destabilization of the inactive form of the kinase is thought also to be relevant with the gatekeeper T315I mutation leading to an activated kinase state. Resistance by M351T is thought to be due to an indirect consequence of an increase in protein entropy which disfavors inhibitor binding. All of these mutants are considered highly prevalent, and all are still able to efficiently bind adenosine triphosphate (ATP) and thus drive cellular signaling.

In some cases overexpression of Bcr-Abl has been linked to resistance,[125] and while increasing the dose of imatinib may be effective in some cases, the relative lack of potency of imatinib limits this approach. In addition, studies have implicated the overexpression of Src family kinases in CML disease progression, and this has provided a rationale for the testing and ultimate approval of dual Src/Abl tyrosine kinase inhibitors (the Src family kinases consist of Src, Fyn, Lck, Lyn, Hck, Yes, Blk, and Fgr). Bcr-Abl is known to directly phosphorylate Src kinase, and Lyn kinase is overexpressed in cells resistant to imatinib therapy. Patient samples taken before and after therapy with imatinib have also demonstrated activation of Lyn and Hck. Resistance to imatinib may also occur as a consequence of it being a substrate for the multidrug resistance-associated P-glycoprotein (PgP), where overexpression of PgP in tumor cells has been shown to limit uptake of imatinib.

5.02.4.3 Second-Generation Therapies

Following an understanding of the mutations that lead to imatinib resistance, second-generation inhibitors have been developed which are able to effectively inhibit most of these mutations although these agents are unable to inhibit the key gatekeeper T315I mutation (in which the usual threonine gatekeeper is replaced with a more bulky isoleucine). This mutation is seen in 15–20% of clinical samples and so represents a significant escape mechanism following imatinib treatment. Kinase inhibitors that have been launched to address the emergence of imatinib resistance are shown in Fig. 2. However, in a number of cases these inhibitors were not specifically designed to target imatinib-resistant populations, rather their broader Bcr-Abl mutant activity was discovered through serendipity.

5.02.4.3.1 Nilotinib

Nilotinib (Tasigna) is an analog of imatinib that demonstrates superior potency and a broader profile of activity against imatinib-resistant mutants. The compound was discovered through structure-based design efforts aimed at understanding why certain

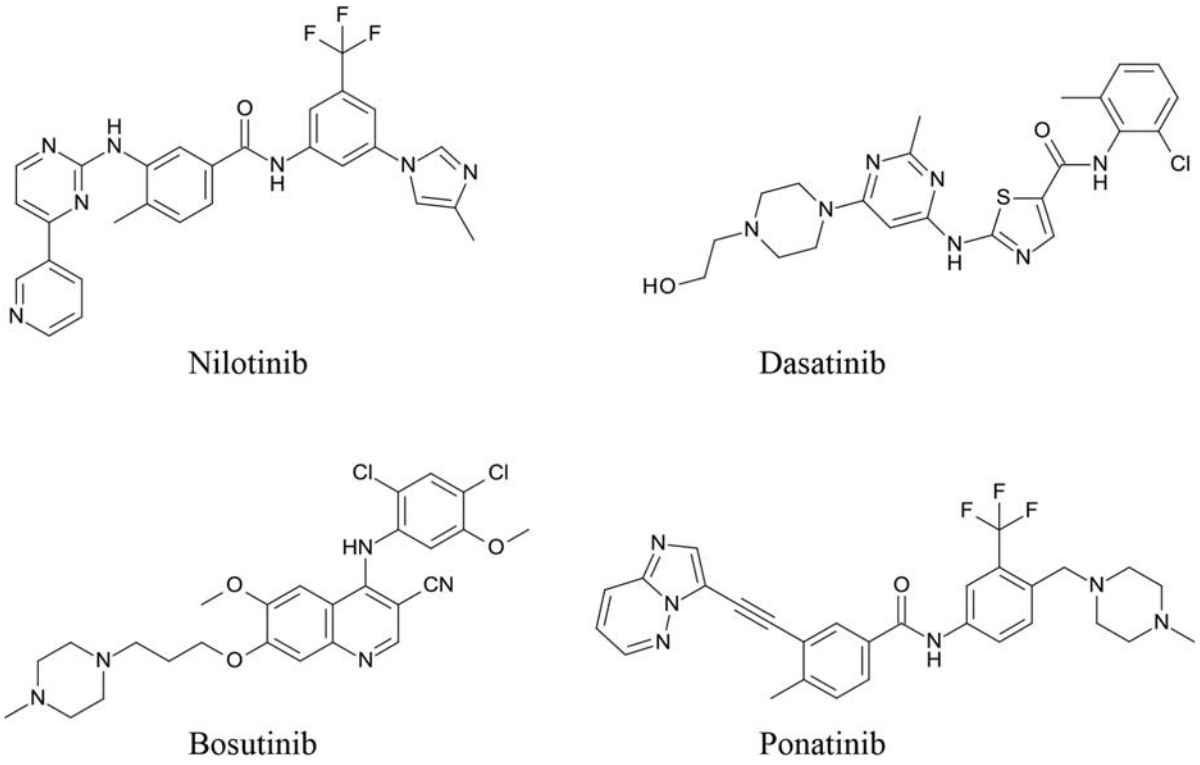


Fig. 2 Bcr-Abl inhibitors that address the emergence of resistance to imatinib therapy.

mutations confer imatinib resistance.[126] Nilotinib contains much of the same architecture of imatinib but differs in the nature of the group that occupies the DFG pocket. Not only is nilotinib much more potent than imatinib (about 30-fold more potent), it sustains activity against 32 out of 33 clinically relevant Bcr-Abl mutants. That nilotinib is active against most of the mutants that drive resistance to imatinib is thought to be due simply to its increased affinity for Abl, allowing it to overcome the shift in equilibrium toward the active state of the kinase which is typically seen with most of the mutants. The increased affinity of nilotinib is thought to be related in part to the observation that it is a better fit in the DFG pocket compared with imatinib. However, there is also a likely contribution from a weak electrostatic interaction between the trifluoromethyl substituent and the polarized C atom of the Ala380 carbonyl. It was approved as a first-line treatment for CML in 2010 with a recommended dose of 300 mg BID; although for patients resistant to or intolerant of imatinib, the dose is 400 mg BID in the chronic or accelerated phases of the disease. Interestingly, it has a distinctly different safety profile to imatinib and patients are generally not cross-intolerant to these agents. Significant fluid retention can be observed in imatinib-treated patients which has been attributed to the off-target inhibition of PDGFR. However, this assertion is questionable given that this is not a common side effect of nilotinib treatment despite it being a significantly more potent PDGFR kinase inhibitor.[127] As with imatinib, point mutations also occur on nilotinib therapy, ultimately leading to the emergence of clinical resistance. In a cell-based screen, point mutations in eight amino acids were observed following nilotinib treatment. However, all of the mutants proved to be sensitive to higher doses of nilotinib. Around 20 different mutations have been observed in Phase I trials for nilotinib affecting around 40% of patients although no differences in clinical outcome were observed based on the mutational status in this study, and patients with mutations continued to respond to treatment.[127]

5.02.4.3.2 Dasatinib

Dasatinib (Sprycel) was initially identified as a dual Lck/Src inhibitor.[128] Like many Src inhibitors it was subsequently shown to possess potent activity against all Src-family kinases, Bcr-Abl, and a wide range of imatinib-resistant Bcr-Abl mutants, including 21 out of 22 clinically observed forms of the kinase. There is a high degree of homology between Src and Abl in their active states and dasatinib, being a type I inhibitor, binds exclusively to the active form of Bcr-Abl. Interestingly, the reverse is not generally true, i.e., DFG-out Abl inhibitors do not typically possess potent Src activity. For example, imatinib and nilotinib do not inhibit Src kinases, thus it was presumed that Src is unable to adopt a DFG-out conformation. Dasatinib, like nilotinib, was approved in 2010 for first-line treatment with a recommended dose of 100 or 140 mg QD for accelerated/blast phases of disease, including in patients resistant or intolerant to imatinib. Cell-based mutational screens have demonstrated the emergence of some mutations that confer resistance to dasatinib that are also coincident with imatinib and nilotinib resistance. However, as with nilotinib, in the clinic many patients harboring mutations in the kinase domain continue to respond to treatment. The exception to this is the T315I gatekeeper mutation which typically leads to clinical failure. In 2011 the FDA identified that dasatinib may increase the risk of pulmonary arterial hypertension, a rare but serious adverse event associated with an increase in blood pressure in lung arteries.

5.02.4.3.3 Bosutinib

Bosutinib is another example of a therapy originally designed as a Src inhibitor that has demonstrated clinical activity against many of the imatinib resistance mutants by virtue of its potent Bcr-Abl activity.[129] Hits optimized from a Src-dependent yeast screen delivered bosutinib, and its activity against Bcr-Abl was deconvoluted after showing an antiproliferative phenotype in a panel of leukemic cell lines. Like dasatinib, bosutinib is a type I kinase inhibitor although unlike the other agents utilized in the treatment of CML, including dasatinib, it shows no appreciable activity against either c-Kit or PDGFR. Despite this, bosutinib is now known to inhibit a range of other seemingly unrelated kinases including Csk and Axl and is classed as a multitargeted kinase inhibitor in the manner of dasatinib. As with the other second-generation inhibitors, bosutinib inhibits all imatinib-resistant mutants with the exception of T315I. Bosutinib was approved in 2012 at a dose of 500 mg QD for the treatment of all phases of CML in patients who are resistant to or intolerant of prior Bcr-Abl therapies, a more limited indication than seen for other second-generation therapies.

5.02.4.4 Addressing the Gatekeeper T315I Mutation

The gatekeeper T315I mutation was identified very early in the clinical use of imatinib, and while subsequent agents have addressed a spectrum of the observed mutations that emerge upon imatinib treatment, the T315I mutation continues to represent a key unmet medical need. Conceptually, it could be envisaged that there are two orthogonal approaches to targeting the T315I gatekeeper mutant. The first approach, and the most widely explored, is to develop ATP-competitive inhibitors (type I or type II) that retain high affinity for the T315I gatekeeper mutant. The second and potentially complimentary approach to inhibiting the T315I gatekeeper mutant, as well as other clinically relevant Bcr-Abl mutants, is to seek to identify allosteric inhibitors that are non-ATP competitive and have a distinct mode of action. Allosteric inhibitors could also be combined with existing ATP-competitive agents to deliver additive activity with the potential to inhibit a wider spectrum of clinically relevant Bcr-Abl mutants. Conceptually, this would enable a "double-hit" strategy, whereby the kinase is simultaneously inhibited by two distinct inhibitors with nonoverlapping binding sites as well as possessing different modes of inhibition. In addition to offering the potential for synergism, a "double-hit" strategy may also reduce the emergence of resistance in the clinic.

5.02.4.4.1 Ponatinib: An ATP-competitive inhibitor of T315I

Ponatinib was originally developed as a multitargeted kinase inhibitor and is an example of a type II inhibitor with a relatively promiscuous profile.[130] In addition to Bcr-Abl mutants, it has potent activity against FLT3, FGFR, and VEGFR family kinases, together with c-Kit and PDGFR. Unusually for an agent with this mechanism it also retains potent Src inhibitory activity, and not only does it inhibit all imatinib-resistant Bcr-Abl mutants, but it is also able to suppress emergence of resistance mutations in cellular systems in vitro. While this compound shares some structural similarity to nilotinib in the region of the gatekeeper/DFG pocket, it is noteworthy that ponatinib is able to effectively inhibit the T315I mutation whereas nilotinib does not. Docking studies have highlighted a steric clash between the amino group on the pyrimidine ring of imatinib and the bulkier isoleucine residue which is not seen with ponatinib. Additionally, loss of the threonine removes a hydrogen bond between the hydroxyl of the amino acid and the amino group seen with imatinib. The same interaction is not relevant in the binding of ponatinib. Ponatinib was approved in 2012 for patients with T315I-positive CML or T315I-positive Ph + ALL for whom no other tyrosine kinase therapy is indicated. However, a series of patient safety events led to the temporary suspension of sales in Oct. 2013 due to the observation of life-threatening blood clots and severe narrowing of blood vessels. This suspension was lifted in Dec. 2013, with a new Black Box Warning applied, together with a risk evaluation and mitigation strategy (REMS).

5.02.4.4.2 Allosteric Bcr-Abl inhibitors

In 2006 researchers from Novartis and the Scripps Research Institute reported on the first successful effort to identify an allosteric inhibitor of Bcr-Abl.[131] Using an unbiased differential cytotoxicity screen, GNF-1 (Fig. 3) was identified as a moderately potent inhibitor with an IC_{50} of 400 nM in Bcr-Abl expressing cells versus an IC_{50} of 40 μM in cells that did not express Bcr-Abl. A follow-up medicinal chemistry optimization effort, starting from GNF-1, generated 350 related analogs and revealed a clear cellular SAR across the series. An early lead to emerge from this effort was GNF-2 which retained the 4-trifluoromethoxyaniline group appended off the pyrimidine core. GNF-2 had increased potency over GNF-1 with an IC_{50} in Bcr-Abl-dependent cells of 138 nM. In the same antiproliferative assay, the established Bcr-Abl inhibitor imatinib had a cellular IC_{50} of 190 nM. Upon further profiling, GNF-2 was confirmed to be specific for Bcr-Abl-transformed cell lines (K562 and SUP-B15) but did not block proliferation in cells transformed with other oncogenic kinases. Further characterization of GNF-2 highlighted that the compound was unable to block Abl kinase activity in vitro (unlike imatinib) but was able to block Bcr-Abl signaling in the cell which pointed to either a different mechanism of action or that potentially GNF-2 was inhibiting a different component of the Bcr-Abl signaling complex. However, evidence that the molecular target for GNF-2 was in fact Abl was provided initially through chemoproteomic studies. Using an affinity probe (GNF-2 immobilized onto Sepharose beads) it was shown that endogenous Bcr-Abl could be scavenged from cell lysates prepared from Bcr-Abl-dependent cells. Performing the same affinity chromatography screens in the presence of either ATP or imatinib failed to displace Bcr-Abl from the GNF-2 affinity beads. In contrast, competition experiments using

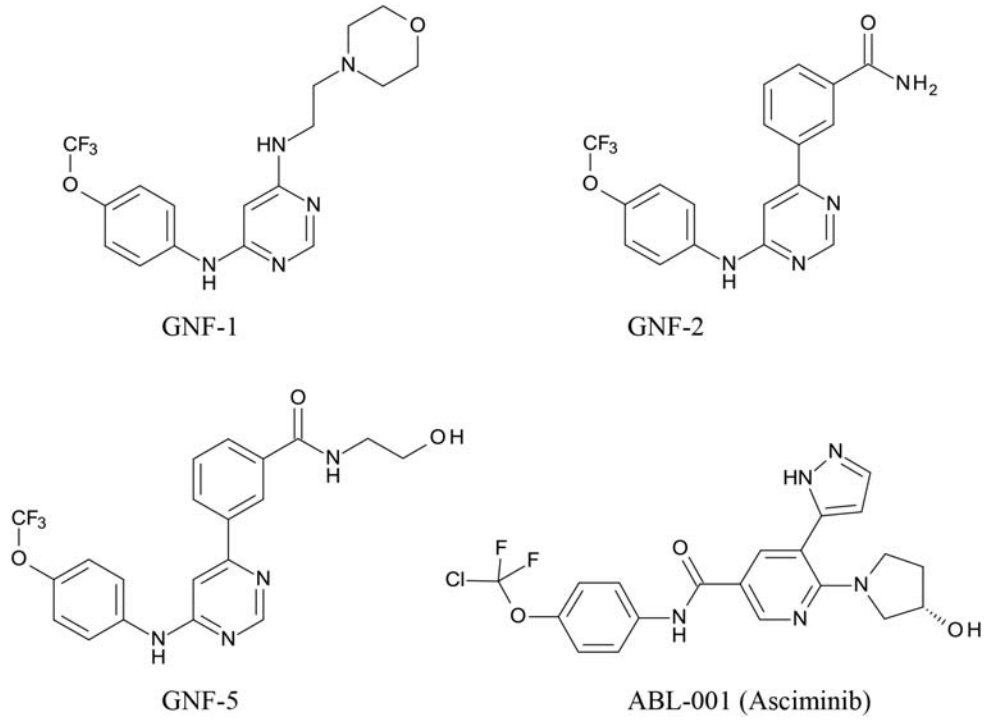

Fig. 3 Allosteric inhibitors of Bcr-Abl.

a truncated N-myristoylated peptide of Abl (residues 2–16) blocked the capture of Abl using the same GNF-2 affinity beads which suggested that the compound bound to the myristate-binding cleft of Abl. This hypothesis was further strengthened following the observation that single-point mutations introduced into the myristate-binding cleft (A337N and A344L) induced resistance to GNF-2 but did not significantly affect the activity of imatinib. Furthermore, combination experiments with imatinib and GNF-2 highlighted a moderate synergy which was also potentially consistent with the evidence that both compounds bound to Abl but targeted different regions of the protein. This hypothesis was subsequently validated through solution NMR studies in combination with X-ray crystallography which both confirmed that GNF-2 bound to the myristate-binding cleft in Abl and had a unique mode of action.[132] The binding mode was consistent with the observed SAR and explained the importance of the para-substituted trifluoromethoxy group and the need for the aniline NH which is required for a through water hydrogen bond with the backbone carbonyls of A433 and E462. Mechanism of action studies, including detailed enzyme kinetics, defined that GNF-2 and related analogs mimic the endogenous role of the N-terminal myristoyl group in Abl, in that they induce and stabilize a clamped catalytically inactive state, whereby the SH2 and SH3 domains of Abl bind into the kinase domain resulting in inhibition of kinase function.[133]

Combining two compounds that inhibit the same oncogenic kinase, but which have distinct modes of action including binding to different regions of the target protein (e.g., combining an ATP competitive with an allosteric inhibitor), could be envisaged conceptually as offering two potential advantages over established monotherapy approaches. First, there is the potential that the combination is synergistic such that greater target inhibition can be achieved from the same clinically tolerated dose of the respective single agents. Potentially this could enable resistant mutants that would otherwise be insensitive to the single agent alone at clinically tolerated drug exposures to be successfully inhibited though the use of a combination partner drug with a different mode of action targeting the same kinase. A second hypothetical advantage is the potential to delay the emergence of resistance in the clinic leading to a more resilient therapeutic strategy. In this regard, a carefully selected drug combination whereby there is a nonoverlapping mutant sensitivity would mean that under drug pressure the cancer cell would need to develop mutations that confer resistance to both drug molecules in order to remain "fit" and thus able to proliferate. In order to understand this potential further, the Novartis group performed combination experiments with imatinib (1 μM) and GNF-2 (5 μM) which led to a 90% reduction in the generation of resistant clones from Bcr-Abl-dependent cells compared with imatinib alone.[133] In addition, using a cellular barcode methodology (ClonTracer) to track cell lineage, clonal responses to imatinib, nilotinib (ATP competitive), and GNF-2 in KCL-22 cells (an acute myeloid leukemia (AML) cell line harboring the Bcr-Abl translocation) were determined.[134] In these experiments, resistance to the allosteric inhibitor emerged more rapidly than with the ATP-competitive inhibitors. Moreover, there were a greater number of GNF-2-resistant clones in each replicate compared to resistant populations of either imatinib or nilotinib. However, the pattern of resistance for the ATP-competitive inhibitors was largely distinct when compared to the GNF-2-resistant populations with only a small number of overlapping mutations conferring resistance to both mechanisms. For example, the gatekeeper mutation in Abl, T315I, was highly enriched in the imatinib- and nilotinib-resistant populations, whereas the A337V mutation, which is in the myristate-binding cleft, was highly prevalent in the GNF-2-resistant populations, consistent with its novel mode of action. Modeling the data from these cellular barcode experiments also suggested that most if not all of the resistant clones were preexisting which supports the concept of codosing both ATP competitive and allosteric Bcr-Abl inhibitors together in order to delay the emergence of resistance in the clinic.

Synergistic activity was also observed when combining allosteric and ATP-competitive inhibitors.[132] GNF-5 (**Fig. 3**), a close analog of GNF-2 with comparable cellular activity but with improved pharmacokinetic properties, was profiled in both in vitro and in vivo experiments to understand potential advantages of combining allosteric and ATP-competitive inhibitors. Against Bcr-Abl-dependent cells harboring the gatekeeper mutation (T315I), a combination of GNF-5 (at a concentration of 2 μM) and nilotinib showed potent inhibition of proliferation (IC_{50} for nilotinib of ~0.8 μM) which was moderately synergistic with a combination index of 0.6. Similar cooperativity was observed against WT Bcr-Abl-dependent cells. Against recombinant Abl kinase, a combination of GNF-5 and nilotinib exhibited synergistic activity against both WT and the T315I gatekeeper mutant with the IC_{50} of nilotinib increasing fivefold against the T315I mutant in the presence of GNF-5 at 10 μM. Evidence of cross-talk between the distal myristate-binding cleft and the ATP-binding site was confirmed using hydrogen-exchange mass spectrometry. Upon GNF-5 binding, changes in the peptides surrounding both the myristate-binding cleft as well as the ATP-binding site were observed in WT Abl. In contrast, no changes were observed with the E506K myristate site mutant thus providing clear evidence that GNF-5 binding directly affects the conformation of amino acid residues in the ATP-binding site, providing a basis for how the allosteric inhibitor is able to enhance binding of nilotinib to mutant and WT Abl.

In a human CML disease model driven by the T315I Bcr-Abl mutant, dosing with either GNF-5 or nilotinib alone failed to deliver any significant activity.[132] In contrast, combining the two inhibitors at the same respective doses delivered significant efficacy with the normalization of both blood counts and spleen weights being observed without any evidence of acute toxicity. In mice transplanted with transduced bone marrow harboring the T315I Bcr-Abl mutant, a combination of GNF-5 and nilotinib showed a significant survival benefit compared to mice treated with either inhibitor alone or vehicle. Median survival for animals treated with either GNF-5 or nilotinib alone was 28 or 32 days, respectively. In contrast, in the combination group all animals survived to day 50 which was the end of the dosing schedule. After a further 46 days of observation, 4 out of the 5 animals on study had survived with no observable disease.

The discovery and characterization of novel allosteric inhibitors to Bcr-Abl has for the first time validated a kinase "double-hit" strategy that has the potential to treat mutant T315I-positive CML/Ph + ALL. Through binding to the myristate site on Abl, the allosteric inhibitors GNF-2/5 are able to induce/stabilize an inactive state of the kinase that results in the inhibition of Bcr-Abl signaling in the cell. Moreover, the allosteric inhibitors synergize with existing ATP-competitive inhibitors to enable the in vitro/in vivo

targeting of the difficult to inhibit T315I Abl mutant. A potential further benefit of the "double-hit" approach is the opportunity to suppress the emergence of resistance. This was conceptually demonstrated in vitro through combining GNF-2 with imatinib and has the clear potential to be a relevant strategy in the clinic. However, GNF-5 has only modest potency which limits its potential as a clinical drug candidate. To resolve this deficiency, the Novartis group, through a fragment-based hit generation effort followed by a traditional medicinal chemistry lead optimization campaign, identified ABL-001 (Fig. 3) which possesses overall excellent developability properties and has increased potency as an allosteric inhibitor compared with GNF-5.[135] ABL-001 was progressed into clinical studies and is currently being investigated in a Phase I trial in leukemia patients, both as a single agent and in combination with ATP-competitive inhibitors such as imatinib and nilotinib.

A similar myristate-binding cleft is present in a small number of other kinases including Src family members; however it is not understood whether this pocket is generally amenable to identifying allosteric inhibitors. The concept of combining an allosteric inhibitor with a suitable ATP-competitive inhibitor to enable a "double-hit" approach appears to be a valid medicinal chemistry strategy that could be used more broadly to develop novel cancer treatments that may deliver both increased clinical efficacy and delaying the emergence of resistance.

5.02.5 Optimizing Kinase Inhibitors for Selectivity and Acquired Resistance for Lung Cancer

5.02.5.1 Introduction

In this section we will discuss a selection of drugs and clinical candidates that have been developed for NSCLC, a disease for which there has been significant progress in segmentation of patients according to genetic status,[136] focusing on inhibitors of EGFR ("Design of Mutant Selective EGFR Inhibitors" section) or anaplastic lymphoma kinase (ALK, "Design of ALK Inhibitors With Potency Against Mutations" section). These targets are being discussed together because there are a number of similarities between the drug discovery efforts that have addressed them in recent years. Success in the clinic against both targets initially depended on an understanding of how to select patients that would be sensitive to such agents, and further success has depended upon an understanding of resistance mechanisms and how to target specific mutations that are relevant to those resistance settings.

5.02.5.2 Design of Mutant Selective EGFR Inhibitors

EGFR was one of the early kinases to attract interest from the pharmaceutical industry, as an approach to treating cancer patients. The first patients on EGFR inhibitors (as part of a more general interest in the Her family) were filed in the 1990s, and yet this is still a highly active area of research which has seen recent breakthroughs, over 20 years later. Achieving success in the clinic has required an understanding of the mutation status of EGFR in patients, and consequently the medicinal chemistry strategies have had to adapt to target particular mutations and consider selectivity margins, in this case against the WT form of EGFR. In this section we will describe the early clinical candidates for EGFR ("Early inhibitors of EGFR, targeting activating mutations" section), go on to describe medicinal chemistry tactics to target the T790M mutation ("Design of T790M mutant selective EGFR inhibitors" section), and then provide a future outlook ("Future outlook" section).

5.02.5.2.1 Early inhibitors of EGFR, targeting activating mutations

Many of the early reported EGFR inhibitors used a quinazoline hinge binder (Fig. 4), linked off C4 with a lipophilic aniline moiety to access a lipophilic region of the ATP pocket (the so-called selectivity pocket)[137] although this was not the first reported series to inhibit EGFR.[138] The first marketed EGFR inhibitors used related templates, but with the addition of a solubilizing side chain to improve solubility and optimized anilines, such as gefitinib (Iressa, launched 2002)[139] and erlotinib (Tarceva, 2004).[140] These inhibitors (Fig. 4) were discovered by screening versus the WT form of EGFR and are potent inhibitors against the WT. Initially it was not understood that the mutation status of EGFR was correlated to response rate, neither was the mutation status assessed in the early clinical trials. However, it was observed that certain groups of patients had higher response rates in trials with these agents, specifically nonsmokers, people with Asian ethnicity and females, and subsequently the connection between response rate and EGFR mutation status was made.[141] Patients with mutated forms of EGFR (such as L858R and exon 19 deletion), which

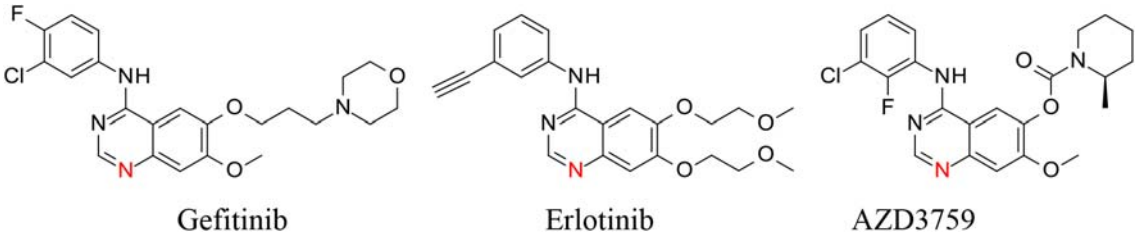

Fig. 4 Reversible quinazoline-based EGFR inhibitors. Throughout this section, structures are orientated with the assumed hinge-binding motif at the bottom (key donor/acceptor atoms in *red*), with the solvent channel[137] group to the right where this is known.

have reduced affinity for ATP and have been described as "activating mutations," respond well with gefitinib and erlotinib, and these agents are now marketed drugs for NSCLC patients with EGFR activating mutations.

5.02.5.2.2 Design of T790M mutant selective EGFR inhibitors

While the majority of NSCLC patients with EGFR activating mutations respond well to these agents, they generally relapse and become resistant to treatment. While a wide variety of acquired resistance mechanisms have been reported,[142,143] a common mechanism is by secondary mutations in EGFR itself, of which the most common is a mutation of the threonine gatekeeper of the kinase to methionine (T790M).[144] The inhibitors shown in Fig. 4 do not have significant activity against the double mutants, so developing inhibitors against the L858R/T790M and exon 19 deletion/T790M forms of EGFR became a priority. The challenge is that the T790M mutation increases the affinity for ATP,[145] and therefore developing inhibitors against these double mutants are more difficult, particularly in a cellular setting where high concentrations of ATP compete effectively with an inhibitor. An additional challenge is that the larger gatekeeper in T790M may make it harder to position a group into the selectivity pocket or reduce direct interactions with the gatekeeper for molecules that have been optimized against the Thr gatekeeper.

A particularly successful tactic to target the T790M mutation has been the addition of a covalent warhead at just the right position to bind irreversibly to one of the cysteines accessible in the EGFR-binding site. The resulting irreversible inhibitors overcome the difficulty with ATP competition in cells. Thus addition of an acrylamide to specific positions within the anilino quinazoline template led to a number of compounds that have progressed into the clinic, including those shown in Fig. 5. Canertinib was the first irreversible inhibitor to enter clinical trials and progressed as far as Phase II.[146] This compound, along with other irreversible inhibitors such as afatinib[147] (Gilotrif, approved 2013) and dacomitinib[148] (Phase III), employs the same selectivity pocket group as gefitinib, whereas neratinib[149] (Phase III) employs a larger group that is capable of pushing out the C-helix, in a similar manner to the reversible inhibitor lapatinib. Reversible binding of these quinazoline inhibitors into the ATP pocket places the acrylamide in close proximity to the cysteine (C797), which can then result in covalent bond formation and deactivation of the kinase, as shown in the published WT structure of afatinib.[150] These inhibitors still have activity against the WT and single (activating) mutant forms of EGFR but also have significant activity against the double mutant forms although they were not designed to target the T790M mutation. They should therefore in theory be effective compounds for patients who harbor both single (activating) mutations and double (activating + T790M) mutations of EGFR.

In practice, the limitation with these agents has been tolerability, which can limit the dose and therefore limit the efficacy. The toxicities that have been described, chiefly rash and diarrhea, have been attributed to the fact that these compounds inhibit WT EGFR more potently than T790M containing mutants. This clinical data suggested that inhibitors that target both single activating and double (T790M) mutants, but have selectivity over the WT form, would be desirable. A number of approaches that have resulted in such compounds have been described preclinically, and several compounds have subsequently progressed into the clinic. Fig. 6 shows some examples, where an acrylamide has been used as before to obtain potency against the mutant forms of the kinase in cells. However, these examples differ from those in Fig. 5, in that the acrylamide has been added to a scaffold that has some inherent degree of selectivity versus the WT form, and not the quinazoline template used previously. Scientists from the Dana-Farber institute reported one such approach in 2009,[151] which included a crystal structure of WZ4002

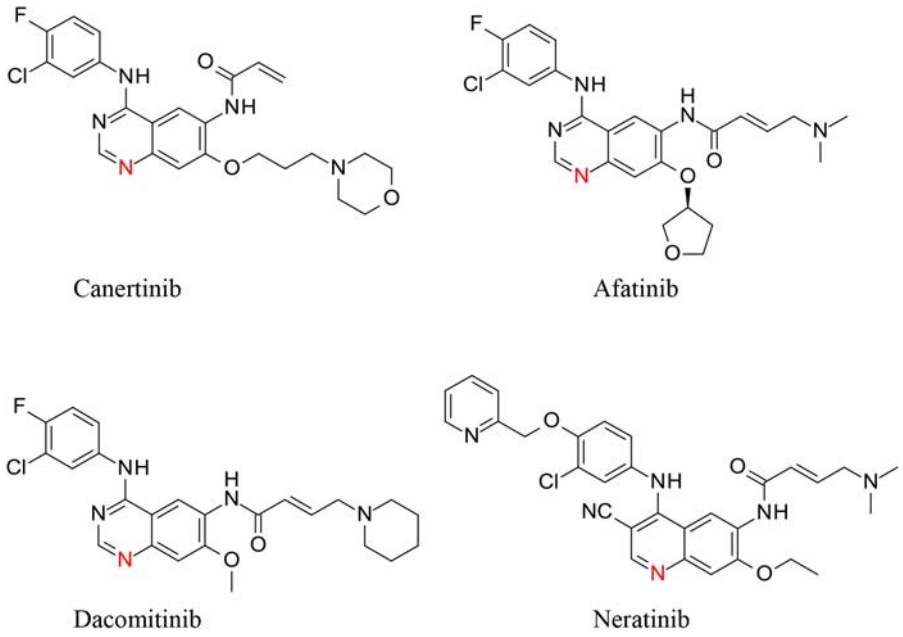

Fig. 5 Irreversible quinazoline-based inhibitors that target single and double mutants.

(Fig. 6, Gatekeeper pharmaceuticals) covalently bound to the active conformation of EGFR. The acrylamide group that covalently targets the Cys797 residue is attached to the phenolic group in the 4 position of the anilinopyrimidine hinge binder. The aniline contains a piperazine and a methoxy group ortho to the aniline that was reported to improve kinase selectivity. By switching templates from quinazoline to anilinopyrimidine, this compound now hits the single (activating) mutations and the double (T790M + activating) mutations, with a margin over WT; an attractive profile as this profile could achieve efficacy and tolerability. The chlorine substituent at the C5 position of the pyrimidine ring contacts the lipophilic gatekeeper residue (Met 790) and may contribute to its potency versus the T790M mutant.[151]

At this point no clinical trials have been initiated on the Gatekeeper compounds. However, both Clovis and AstraZeneca (and other companies, more recently) progressed compounds from their programs into the clinic. Rociletinib/CO-1686 (Fig. 6, Clovis) progressed as far as Phase III clinical trials, although Clovis had to modify the disclosed data on confirmed response rates as the efficacy data matured,[152] and has since terminated its clinical development. This compound uses a similar template to WZ-4002, in that it has an anilinopyrimidine hinge binder and targets Cys797 with an acrylamide attached to the aryl ring in the C4 position of the pyrimidine (now O linked). There are subtle differences in the solvent channel (acetyl vs methyl piperazine)

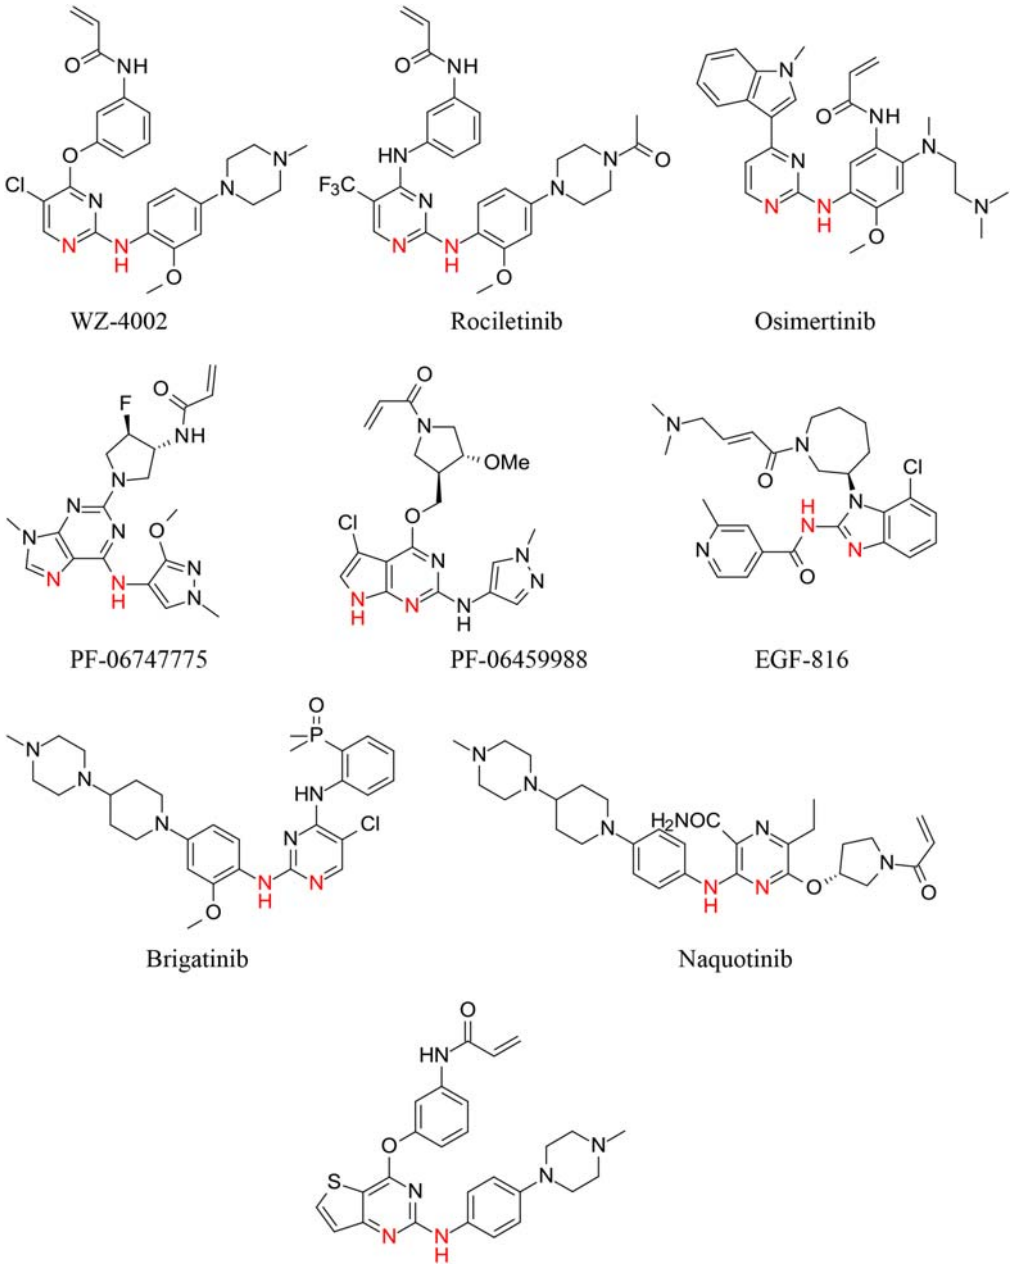

Fig. 6 EGFR covalent inhibitors that target single and double mutants, with selectivity versus wild type.

and the pyrimidine C5 substituent that points toward the gatekeeper (CF_3 vs Cl). This compound has a similar profile of greater activity against both single and double mutants versus WT. Clovis have published data on their compounds suggesting a greater L858R/T790M to WT margin than observed for WZ4002, when comparing mechanism of action (MoA) cell assays that measure pEGFR, although the margins look similar between rociletinib and WZ4002 when measuring relative GI_{50} values in antiproliferative assays.[153]

AstraZeneca has also progressed a mutant selective compound into the clinic and recently obtained FDA approval of osimertinib (AZD9291, Tagrisso **Fig. 6**) launched in 2015. The research program that ultimately led to the discovery of osimertinib initially involved work to find reversible inhibitors that showed a favorable level of selectivity between the double mutant and WT EGFR forms. Next, internally developed insight was applied to add an appropriately placed acrylamide onto the scaffold to achieve improved cell potency. Although this work was initiated prior to the Dana-Farber disclosure of WZ-4002,[154] a similarity can be seen in that the hinge-binding motif is an anilinopyrimidine in both cases. However, there are significant differences too. The AstraZeneca series used a bicyclic aromatic group directly linked to the C4 of the pyrimidine, and the acrylamide was positioned in a different place—added to the solvent channel aniline.[154] Further rounds of evolution of the chemical structure involved migrating the basic group from the acrylamide side chain onto the aniline ring, changing the bicyclic aromatic group and removing the chlorine at C5 of the pyrimidine to ultimately arrive at osimertinib.[155] This compound achieved the desired profile in vitro (potent double-mutant activity, potent single-mutant activity, and good WT selectivity against both mutant forms). It also showed promising xenograft activity and was subsequently nominated for clinical trials, where in recently disclosed data (European Cancer Congress 2015), it achieved an objective response rate of 66.1% in patients with EGFRm NSCLC and the T790M mutation. It is noteworthy that the clinical development phase of osimertinib through to regulatory agency approval was particularly fast, 2 years and 8 months from the start of clinical trials to US approval. Both osimertinib (Apr. 2014) and rociletinib (May 2014) received Breakthrough Therapy designation from the FDA, highlighting the significant unmet medical need for these potential therapies.

Another noteworthy example from a structural viewpoint is PF-06747775 (**Fig. 6**, Phase I). Although this compound uses a different chemical scaffold, it places the acrylamide in a similar position to target Cys797, as reported in both AACR and ACS presentations in 2015. Pfizer has also reported the optimization and discovery of a preclinical compound PF-06459988.[156] Although these last two Pfizer compounds look structurally related, the binding modes to the hinge are dissimilar (see **Fig. 6**, hinge-binding motif in red), and the substituents on the core are switched round to be consistent with that binding mode change. This publication is noteworthy in that it emphasizes the generation of estimated K_i/K_{inact} values quickly and in high throughput, to drive optimization of hit compounds.[156] Other noteworthy WT selective inhibitors that have progressed into the clinic include EGF-816 (**Fig. 6**, Novartis, Phase II),[157] olmutinib (Hanmi, launched in Korea in 2016), brigatinib (Ariad, Phase II), and naquotinib/ASP-8273 (Astellas, Phase III) although the medicinal chemistry efforts toward these compounds have not yet been reported.

These irreversible inhibitors of T790M containing mutants, with selectivity over the WT, represent an exciting new paradigm for treating NSCLC patients. They can also be viewed as a significant milestone for medicinal chemistry, as the design brief for the compounds arose from previous clinical understanding of the importance of activities against specific mutations and a selectivity requirement.

More recently, preclinical approaches have been disclosed that target the T790M active/WT sparing profile with noncovalent inhibitors. As previously discussed, this is a challenging approach as activity in cells is difficult to achieve against the sensitizing mutations due to high ATP affinity. However, there are reasons to persevere with this approach.[158] There are hypothetical risks with the covalent mechanism of time-dependent inhibition of WT, or from idiosyncratic toxicity from off-target activities. However these potential issues have not apparently manifested themselves in the clinical trials for agents such as rociletinib or osimertinib, as these compounds were well tolerated in an oncology setting. Another possible reason is to avoid resistance mechanisms that may occur in response to treatment with a covalent inhibitor. This latter point has some support from the literature. Mutations have been observed in vitro when cancer cells are challenged by the agents in **Figs. 5** and **6**, most notably the C797S mutation where the cysteine that is targeted by the covalent inhibitors is mutated to a nonreactive serine.[159,160] The C797S mutation has also been observed in some patients whose tumors have progressed on osimertinib in clinical trials.[161]

Collaborative efforts between Argenta and Genentech have been described to this end, with some example structures given in **Fig. 7**. The discovery of compound **10**[162] started from a Jak2/Tyk2 inhibitor, which was subsequently optimized to improve activity versus T790M-containing mutants such as T790M/L858R, with selectivity against WT and general kinase selectivity. The data (**Fig. 7**) suggest a successful optimization at the enzyme level, with modest but promising cell activity. In a subsequent publication,

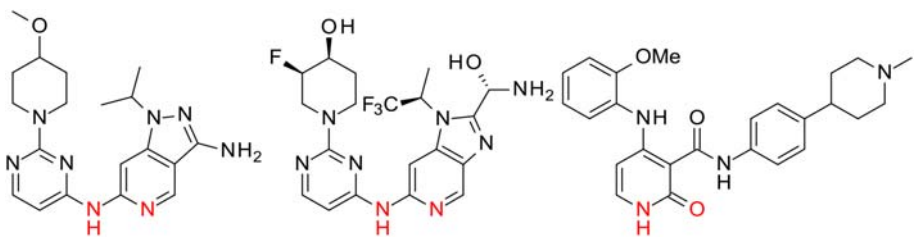

Fig. 7 EGFR reversible inhibitors that target single and double mutants, with selectivity versus wild type.

additional optimization of the same series was disclosed,[163] including an investigation into the effects of fluorination on the ring, leading to compound **42** (in the reference) which had improved H1975 pEGFR cell potency (0.26 μM) and showed PD activity in a H1975 xenograft model measuring pathway inhibition (pEGFR, pERK, and pAKT) at 300 mg kg^{-1}. In a separate publication,[164] authors from the same organizations have published efforts to optimize a series of pyridones. The original hit suffered from poor WT selectivity and general kinase selectivity but was successfully optimized to more selective lead compounds, such as compound shown (compound **29** in the reference).[164] Submicromolar cell potency in a T790M/L858R cell line (0.43 μM) and good cell selectivity (23 × versus WT cell line) were achieved for this compound. While further improvements in cell potency may be necessary for this noncovalent approach to be successful, these efforts show promise.

5.02.5.2.3 Future outlook

The drug discovery of EGFR inhibitors already has a long history, with early success in the identification of marketed drugs that treated the sensitizing mutations of EGFR, which can claim to be the first targeted therapies for lung cancer. Despite that long history, EGFR remains a highly active kinase target today. The design of covalent compounds that are efficacious against particular mutations, while sparing the WT, has yielded compounds that have given exciting efficacy in the clinic, including one recently approved marketed drug.

Further efforts are underway to treat other mutations, such as the C797S mutation which necessitates the development of noncovalent inhibitors, and there may still be further opportunities by defining additional patient populations and designing compounds with profiles to address that population. Another relevant primary mutation is the exon 20 insertion, which may not be well treated by all current therapies[165,166] although there are reports of in vitro exon 20 activity for both osimertinib[167] and EGF-816.[157] In addition, as EGFR inhibitors are increasingly considered as candidates for combination approaches (e.g., with other targeted agents, with chemotherapy, or with immunotherapy), additional challenges may arise in the design of future inhibitors to suit those combination approaches, or potentially to investigate alternative (e.g., allosteric) mechanisms. Indeed, an allosteric inhibitor was recently disclosed by Novartis (GTC, San Diego, Mar. 2016). This compound was efficacious against the L858R/T790M/C797S mutant when combined with cetuximab, but interestingly it was reported to have weak activity against the Ex19del/T790M mutant, which was rationalized structurally by the shorter loop to the C-helix preventing binding (publications are expected in due course).

An additional consideration for future drug discovery efforts may be to include brain penetration as a key part of the design brief, as the improved treatment of lung cancer patients may result in an increased rate of brain metastases, for which the prognosis is worse. Such an effort has already been reported toward a CNS-penetrant anilinoquinazoline compound AZD3759 (**Fig. 4**) that can target the sensitizing mutations of EGFR, which was designed to be brain penetrant (unbound brain:plasma drug concentration $K_{puu} = 1.3$ in rat, $K_{puu} = 0.5$ in cynomolgus monkey).[168] Similar efforts may be expected for other mutations. Osimertinib has also been shown to have good CNS penetration in mouse models, with resulting efficacy in a PC9 mouse brain metastases model, and has shown early clinical evidence of activity in patients with EGFRm advanced NSCLC and brain metastases.[169]

5.02.5.3 Design of ALK Inhibitors With Potency Against Mutations

While this story has emerged more recently than EGFR, the focus of medicinal chemistry efforts against anaplastic lymphoma kinase (generally shortened to ALK, not to be confused with the activin receptor-like kinases which are often denoted as ALK1-ALK7) has a number of similarities with EGFR. This target is of interest for the treatment of a wide variety of cancers, but for the purposes of this article we will focus on the implication of ALK fusions in lung cancer, as these prompted a renewed focus on this target and ultimately the development of crizotinib as an efficacious agent for ALK-positive NSCLC patients, covered in "**Design of crizotinib as an effective inhibitor of WT ALK**" section. However, it should be noted that ALK fusions are not as common as EGFR mutations are among NSCLC patients.[136,170] As for EGFR, medicinal chemistry programs have subsequently focussed on activity against a key gatekeeper mutation for ALK (L1196M) that is not well treated by crizotinib, and these efforts resulted in a number of clinical candidates and recent approvals and will be covered in "**Design of ALK inhibitors that can target the L1196M gatekeeper mutation**" section. Activity against a number of other mutated forms of the kinase has also been reported as relevant to NSCLC patients, and some recent medicinal chemistry publications that report data versus these mutants will be covered in "**Future outlook**" section.

5.02.5.3.1 Design of crizotinib as an effective inhibitor of WT ALK

Crizotinib was initially designed as a potent inhibitor of c-Met by scientists at Sugen (now Pfizer) and was the result of a series of optimization steps and scaffold hops from a structurally distinct indolin-2-one hit (**Fig. 8**),[171] where the hinge-binding donor–acceptor motif has been changed from the lactam in the indolin-2-one core to an aminopyridine. This scaffold was reported to be a more efficient way to link to the lipophilic poly-halogenated selectivity pocket group. A polar/basic side chain (piperidine-substituted pyrazole) was employed in the solvent channel, which achieved a dramatic improvement in ligand lipophilicity efficiency (LLE or LipE, in this case defined as enzyme pIC_{50}–$clogD_{7.4}$). Although this compound was designed for c-Met, entering Phase I trials in 2006, it was subsequently found to be a potent inhibitor of ALK. As the link between ALK fusions and NSCLC emerged in 2007, in particular the EML4–ALK fusion, this compound was repositioned for ALK-positive NSCLC patients and was ultimately approved for that indication in 2011, just 4 years after the discovery of the relevance of ALK fusions in this setting.

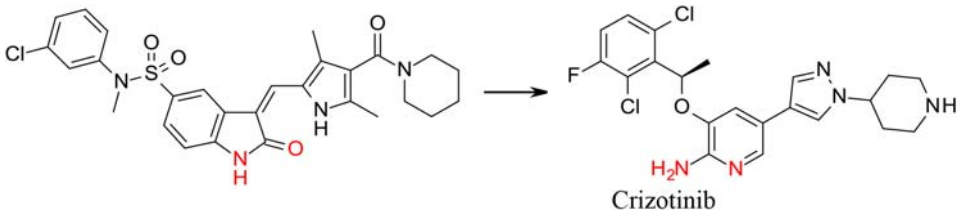

Fig. 8 Scaffold change from indolin-2-one to aminopyridine to give crizotinib, hinge binder in *red*.

5.02.5.3.2 Design of ALK inhibitors that can target the L1196M gatekeeper mutation

While crizotinib achieved Breakthrough Therapy designation and was the first agent to be approved in the ALK-positive NSCLC setting, resistance to crizotinib has been observed in a similar manner to the emergence of the double activating/gatekeeper mutations observed for EGFR. Thus, patients that relapsed on crizotinib have been observed to harbor a number of ALK mutations for which crizotinib has limited efficacy, of which the most frequent one is again a mutation of the gatekeeper residue to methionine (L1196M for ALK, cf. T790M for EGFR) although the frequency of L1196M for ALK is not as marked as T790M for EGFR, as the ALK mutations are more diverse.[170] This finding has led to a number of medicinal chemistry programs to identify a "2nd generation" of ALK inhibitors that can target L1196M although, unlike EGFR, selectivity over WT ALK is not required to manage tolerability.

Novartis has reported their optimization of a bis-anilino pyrimidine series, which ultimately led to ceritinib (FDA approved 2014).[172,173] The reported design of this compound started with TAE-684, a potent inhibitor of ALK. The base was optimized to avoid a reactive metabolite liability with their startpoint (Fig. 9), which can generate a 1,4-diiminoquinone intermediate, by changing it from a N-linked base to a C-linked base. In addition, the alkoxy group was optimized to maximize kinase selectivity, to give LDK-378/ceritinib. Ceritinib was reported to be a highly potent inhibitor of ALK at enzymatic level (0.2 nM), with good inhibitory activity against ALK (41 nM) and EML4–ALK fusion (2.2 nM) in Ba/F3 cells,[173] but the early medicinal chemistry papers did not report activity (or optimization) versus mutant forms of ALK that are important to the setting of crizotinib resistance.

Subsequently ceritinib has been reported[174] as being active against four of the mutations present in models of acquired resistance to crizotinib, including the gatekeeper mutation L1196M, but not active versus two others (G1202R and F1174C). Crystal structures of crizotinib (2XP2) and ceritinib (4MKC) have been compared to rationalize the activities versus the relevant mutant forms (Fig. 10).[174] The chlorine on the pyrimidine core is hypothesized to be important for L1196M activity (hydrophobic interaction with the more lipophilic gatekeeper), plus there is the potential for unfavorable interactions between the NH_2 and chiral methyl groups on crizotinib and Met1196. By contrast, neither crizotinib nor ceritinib have significant activity versus G1202R, a residue in the solvent channel. This is consistent with the fact that both drugs have large basic side chains in that region of the binding site, which may not be compatible with mutation of Gly to a large basic residue (Arg).

After a promising Phase I trial in NSCLC ALK+ patients who had progressed after treatment with crizotinib, ceritinib received a Breakthrough Therapy designation from the FDA in Mar. 2013 and was approved in 2014, once again demonstrating the impressive speed in development that targeted therapies with a clear patient selection hypothesis and beneficial profile can achieve.

Chugai has reported the optimization of a tetracyclic series of ALK inhibitors. Starting with a weak hit (Fig. 11) the core was changed to a pyrrole,[175] and then the side chains were optimized[175,176] for kinase selectivity, cellular activity, and metabolic stability to give alectinib, now licensed to Roche. The hinge binder (hydrogen bond acceptor) in this case is thought to be the ketone, with the basic group pointing along the solvent channel (Fig. 11). Alectinib is a potent inhibitor of WT ALK, as well as L1196M, F1174L, and R1275Q mutations. Similar to ceritinib, alectinib showed a promising objective response rate (59%) in a Phase I trial in NSCLC ALK+ patients who had progressed after treatment with crizotinib and was subsequently granted a Breakthrough Therapy designation by the FDA (Sep. 2013) and was approved by the FDA in 2015.

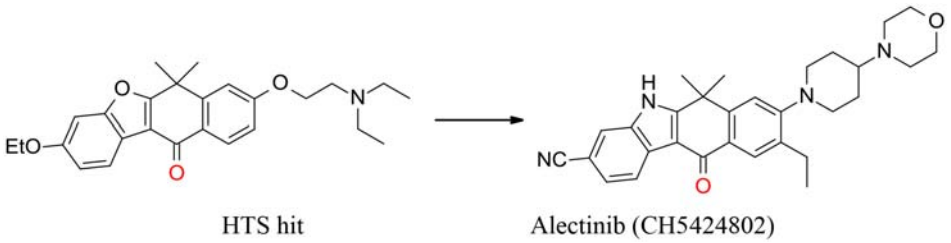

Fig. 11 Scaffold hop and optimization to give alectinib.

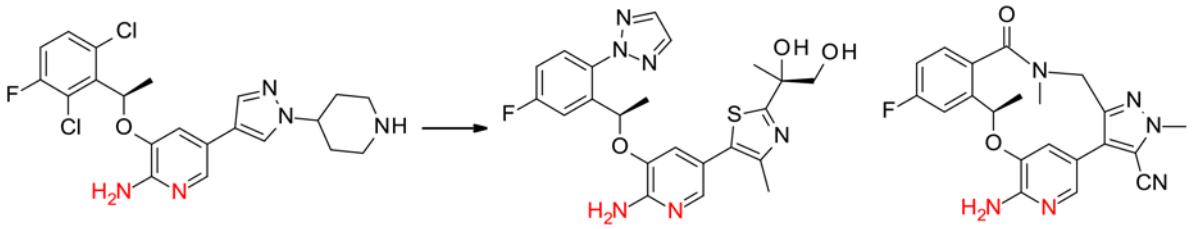
Pfizer has reported two approaches to modify the structure of crizotinib directly, to increase L1196M activity (Fig. 12). In one approach,[177] the pyrazole group and the substituents on the benzyloxy group were modified to increase potency, using both structure-based design and LLE-driven SAR approaches. This resulted in compound **8e** (in the reference) as shown in Fig. 9, which is still 10-fold more active against WT in cell assays, but as both WT and L1196M potencies have been increased it is now a suitable tool compound to target both in vivo. Another reported approach[178] used macrocyclic analogs of crizotinib to increase potency against both WT and L1196M. This approach led to the discovery of lorlatinib (PF-06463922, Fig. 12), currently in Phase II clinical trials for ALK- and ROS-positive NSCLC patients. Lorlatinib has been reported as being active against a number of clinically relevant ALK mutations, including the G1202R mutation.[179] Additionally, it is a modestly brain penetrant molecule, with a measured free brain to free plasma AUC ratio of 0.2 in rat,[178] so may offer the potential to treat patients with brain metastases.

5.02.5.3.3 Future outlook

The "2nd generation" of ALK inhibitors discussed in "**Design of ALK inhibitors that can target the L1196M gatekeeper mutation**" section succeed in having sufficient potency against the L1196M mutation but lack broad spectrum activity against all of the reported ALK mutations. Therefore there may be opportunities to develop further inhibitors that address these mutations, which may be efficacious with patients that relapse after treatment with crizotinib and/or ceritinib. Two recently published approaches approach this by subtle modifications of the known 2nd generation compounds. Thus one approach has been reported[180] where the structure of alectinib was modified to improve potency against a number of mutations, but especially against the G1202R mutation. The G1202R mutation has been reported to be the most frequent mutation present in patients that relapse after treatment with



Crizotinib (Xalkori)	Compound 8e in reference[179]	Lorlatinib
WT: 80 nM	0.8 nM	1.3 nM
L1196M: 843 nM	6.6 nM	21 nM

Fig. 12 ALK cell IC_{50} data for analogs of crizotinib in WT and L1196M cell lines.

ceritinib. This optimization required modification of the basic side chain to a substituted pyrazole (**Fig. 13A**), as this group may avoid a steric clash with the larger arginine present in the mutated form. In another approach, the basic aniline of ceritinib was modified to a tetrahydroquinoline (THIQ) group although this change only gave a modest improvement to G1202R activity at the enzyme level, and the resulting inhibitor (**Fig. 13B**, compound **8** in Ref. 173) was a significantly more promiscuous inhibitor across the kinome.[181]

It seems likely that the remaining opportunities to target a diverse ALK mutation profile will continue to be addressed with medicinal chemistry efforts. These efforts may come from known ALK inhibitors although in principle screening for new chemical series that may be developable against this profile could also be an attractive approach. Aiming for broad activity against all clinically relevant ALK mutations is likely to bring in the additional challenge of maintaining general kinome selectivity, so careful optimization will be required, ideally with the support of X-ray crystallography.

5.02.5.4 Conclusion

A feature of the recent approved drugs that are discussed in this section for both targets is their speed through development. This has been facilitated, in many cases, by designation by the FDA as a Breakthough Therapy.[182] Examples of compounds in this section with that designation are osimertinib and rociletinib for EGFR, and crizotinib, ceritinib, alectinib, and brigatinib for ALK. This speed has been achieved by having a clear genetic hypothesis for patient selection, combined with high-quality compounds from a medicinal chemistry perspective. In this context, success may require a careful consideration of the required target profile, for example, achievement of activity versus clinically relevant fusions and mutations and (e.g., WT) selectivity, in addition to primary potency, pharmacokinetic properties, and more generic safety criteria. Medicinal chemists have played an important role in selecting and evolving compounds that meet such specific target profiles, and this has required significant expertise in kinase drug design

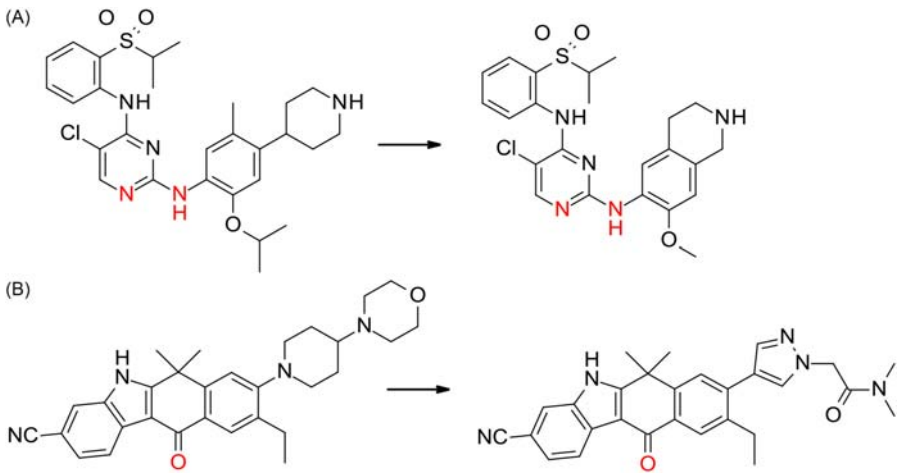


Fig. 13 (A) Optimization of alectinib to increase potency against the G1202R mutant[180] and (B) optimization of ceritinib.[181]

(including structural understanding) coupled with a suitable project cascade to demonstrate in vitro and in vivo activity against particular mutant forms of the kinase.

5.02.6 Kinases in the DDR

5.02.6.1 Introduction

Every one of our cells experiences tens of thousands of DNA-damage events per day through normal cell function, DNA processing, or environmental factors. The DDR is an integrated group of biological pathways evolved to recognize, signal, and promote the repair of damaged DNA in order to suppress genomic instability.[183–188] In human cells there are five major DDR pathways: homologous recombination (HR), nonhomologous end joining (NHEJ), mismatch repair (MMR), base excision repair (BER), and nucleotide excision repair (NER) as well as replication stress and cell cycle checkpoint pathways.[187] Cancers have high levels of genomic instability, an underlying hallmark of cancer,[189] associated with a greater propensity to accumulate DNA-damage through defects in the DNA-repair machinery and failure of one or more cell cycle checkpoints which serve to halt cell division so that DNA-damage may be repaired. The use of DNA-damaging chemotherapy and radiotherapy to kill cancer cells relies on this principle but is also associated with damage to normal tissue leading to significant toxicity. DNA-damage leads to cell death if sufficiently high and left unrepaired and is the concept behind DDR inhibition for cancer therapy.[183–188] DNA-repair processes are a potential mechanism of resistance to DNA-damaging agents, and therefore inhibition of DDR pathway targets has been actively investigated as chemo- and radiosensitizing agents. DDR defects are common in tumors which can become dependent on the remaining DNA-repair pathways. Targeted DDR therapies aim to improve outcome for patients by taking advantage of these specific tumor cell abnormalities, thereby limiting normal tissue toxicity.[187,188]

Kinases play a central role in the DDR. The phosphatidylinositol 3-kinase-related kinase (PIKK) family of proteins in particular has been an area of intense focus for drug hunters. ATM (ataxia telangiectasia mutated), ATR (ataxia telangiectasia and RAD3-related), and DNA-PK (DNA-dependent protein kinase) are three PIKK proteins with key roles in the DDR. Together with SMG-1 (suppressor of morphogenesis in genitalia-1), TRRAP (transformation/transcription-associated protein), and mTOR (mammalian target of rapamycin) they make up the PIKK family of proteins.[190–193] The PIKK protein family are sometimes referred to as Class IV PI3 kinases, but they are functionally distinct from the PI3K classes I–III and do not phosphorylate lipids.[194] While many inhibitors of PI3 kinases and mTOR have entered advanced clinical testing and some have been approved, identification of clinical quality inhibitors of ATM, ATR, and DNA-PK has proved more challenging.[195] The first compounds identified typically lacked the global properties to make good drugs, but some did possess high potency and selectivity for their primary target to clearly demonstrate in preclinical studies the therapeutic potential of DDR pathway modulation. Recent years have seen the advancement of DDR inhibitors optimized for potency and selectivity together with the required physicochemical, pharmacokinetic, and toxicology properties to support clinical investment (summarized in **Fig. 14**). While none have been approved, the first compounds are moving in sight of late-stage clinical testing where their full potential in the fight against cancer will become clear.

5.02.6.2 ATM

Ataxia-telangiectasia (A-T), the human autosomal recessive disorder, is caused by mutation of the *ATM* gene which codes for the serine/threonine protein kinase ATM.[196,197] A-T cells display hypersensitivity to ionizing radiation (IR) failing to repair DNA

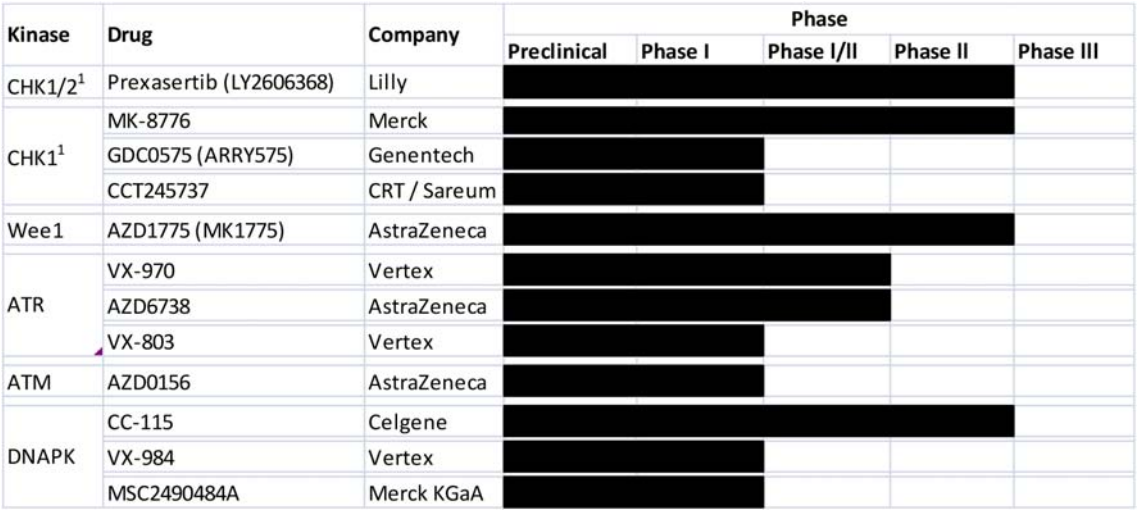

Fig. 14 Inhibitors of DDR kinases in the clinic.

double-strand breaks (DSBs) and to arrest the cell cycle following DNA-damage with an inability to mediate cell cycle checkpoints.[196,197] ATM plays a key role in many cell signaling pathways and is a key component of DNA DSB detection and NHEJ and HR repair pathways as well as regulation of cell cycle checkpoints.[198,199] A-T and other ATM-deficient cells are hypersensitive to agents where DNA DSBs is the primary driver of cytotoxicity.[197–199] ATM phosphorylates a wide range of proteins linked to DNA DSBs in response to DNA-damage including H2AX, KAP1, and 53BP1.[200] Phosphorylation of additional downstream targets such as p53, checkpoint kinase (CHK) 2, and BRCA1 indicate ATM's complex and multifaceted cellular function, linked to a range of other key cellular process/responses in various pathophysiological conditions involving DNA-damage and beyond.[201]

5.02.6.2.1 ATM inhibitors

KU-55933 (Fig. 15), one of the first potent and selective ATM inhibitors to be reported, was identified from an extensive SAR study exploring PIKK kinase (DNA-PK and ATM) activity of a series of 2-morpholino-pyran-4-ones and 2-morpholinothiopyran-4-ones.[202,203] Highly divergent SAR between DNA-PK and ATM is evident with only the thianthrene KU-55933, from a large number of analogs tested, showing potent inhibition of ATM kinase activity.[203] KU-55933 is a potent ATM enzyme inhibitor ($IC_{50} = 12$ nM) with impressive selectivity for ATM over DNA-PK, ATR, mTOR, and PI3 kinase.[202] In one of the first reports highlighting the importance of the morpholine group as a kinase hinge-binding motif, Hickson et al. replaced the oxygen atom of the morpholine in KU-55933 with a carbon, thus removing the ability to accept a key hydrogen bond resulting in loss of kinase activity.[202] The quinazoline CP-466722 was identified following a directed screen of 1500 compounds selected on the basis of known and predicted kinase pharmacophores. KU-55933 and CP-466722 have been shown to recapitulate the phenotype of A-T cells. KU-55933 rapidly inhibits IR-induced phosphorylation of p53 (ser-15) with an IC_{50} of ~0.3 μM and complete ablation at 10 μM. KU-55933 does not impact UV-induced phosphorylation of H2AX (ser-139) or CHK1 (ser-345), characteristic of ATR inhibition at a concentration of 10 μM. KU-55933 and CP-466722 inhibit IR-induced H2AX (ser-139) phosphorylation in ATM WT cells but not A-T cells, indicative of selective inhibition for ATM over related proteins such as DNA-PK.[202,204] KU-55933 alone was shown not to affect the clonogenic survival of HeLa cells at concentrations up to 10 μM but was shown to sensitize IR-induced cytotoxicity using a range of IR doses.[202] In addition, KU-55933 sensitizes HeLa cells to the topoisomerase I/II inhibitors etoposide, doxorubicin, and camptothecin.[202] While KU-55933 alone had no effect on cell cycle progression, the combination with IR and agents such as etoposide resulted in an increase in the G2M population indicating KU-55933 inhibits the ATM-dependent elements of cell cycle checkpoints.[202]

KU-55933 and CP-466722 do not possess the drug-like properties to be developed further, as they have low aqueous solubility and high lipophilicity. Introduction of hydrophilic groups on the tricyclic ring of compounds such as KU-55933 has been explored

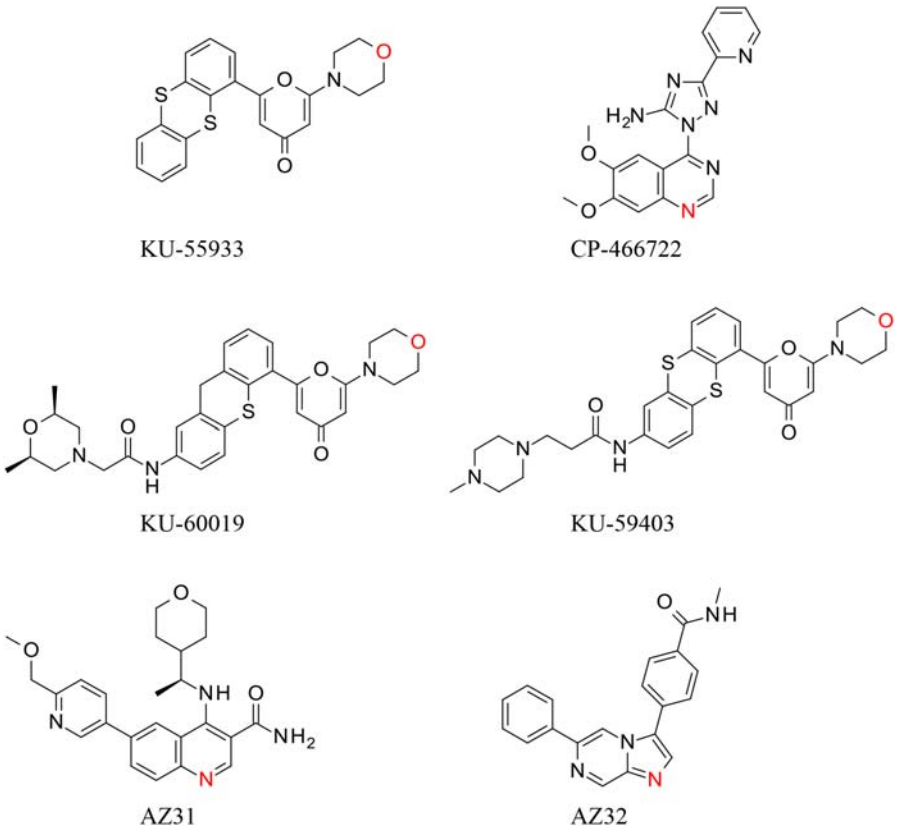

Fig. 15 ATM inhibitors (assumed hinge-binding atoms highlighted in *red*).

in an attempt to improve physicochemical properties.[205] With no ATM structure available medicinal chemistry design was directed through the use of homology modeling to guide positioning of the hydrophilic group.[205] The thioxanthene KU-60019[206] and thianthrene KU-59403[207] achieved some improvement in physicochemical properties and improved potency in enzyme assays (ATM $IC_{50} = 6.3$ and 3 nM, respectively) while retaining very high selectivity versus related PIKKs (ATR, DNA-PK, mTOR) and PI3Ks. A more profound improvement of cellular potency was seen with KU-60019 being an effective chemosensitizer at a concentration of 3 μM, while KU-59403 appears more potent still, effective at 1 μM.[206,207] These compounds show 10-fold greater potency blocking IR-induced phosphorylation of ATM targets compared with KU-55933 but are not significantly cytotoxic alone.[206,207] KU-59403 enhances the cytotoxicity of the DNA DSB-inducing agents camptothecin, etoposide, and doxorubicin.[207] No consistent enhancement of cytotoxicity with KU-59403 was observed in cell lines with mutant p53 compared with WT p53, with LoVo colorectal tumors (p53 WT) shown to be particularly susceptible to inhibitor-induced etoposide sensitization.[207] When KU-59403 is dosed at 50 mg kg^{-1} i.p., peak plasma concentration reached 5 μM at 4 h with concentration in tumor measured at 1.9 μM, in excess of the 1 μM concentration shown to be effective.[207] Dosed immediately prior to etoposide (12.5 and 25 mg kg^{-1} i.p. BID for 5 days), KU-59403 resulted in a dose-dependent increase in tumor growth delay, increasing etoposide efficacy by 190% at the highest dose. Sequencing of the agents is important to achieve efficacy, with ATM inhibition required concurrently with induction of DNA DSBs. The combination of KU-59403 with irinotecan in SW620 colorectal cancer xenografts was also effective using the same combination schedule. In both cases KU-59403 alone did not result in significant antitumor efficacy and the combinations did not lead to unacceptable toxicity as measured by reduced body weight.[207]

Glioblastoma multiforme (GBM) is the most common and aggressive primary brain tumor in adults. More effective treatments have been sought to improve on the existing standard treatment of surgical resection followed by temozolomide and radiation.[208] Around one-third of GBM have p53 mutations and ~80% harbor other cell cycle checkpoint defects leading to investigation of ATM inhibitors in this setting.[209] KU-60019 has been shown to reduce glioma cell migration and invasion and to potently radiosensitize p53-mutant human gliomas in vivo.[206,210,211] KU-60019 has low BBB penetration with very low concentrations of drug detected in the brain following systemic administration.[210] However, in two studies, KU-60019 was administered direct to the tumor to circumvent the BBB and achieve meaningful drug concentrations in the brain.[210,211] Biddlestone-Thorpe et al. demonstrated the combined effect of KU-60019, dosed through locally positioned mini-pumps, and radiation in mice bearing human orthotopic gliomas.[211] This combination led to effective ATM inhibition (measured by γH2AX and p-Ser824-KAP1) and to a significant increase in survival of mice compared with either KU-60019 or radiation given alone.[211] Delivery of KU-60019 has also been explored by convection-enhanced delivery (CED), a method of direct drug delivery to the brain through one or more catheters which are surgically placed into the tumor mass, around the tumor or into the resection cavity.[212] KU-60019 infused over 30 min led to fast and extensive diffusion followed by rapid draining and excretion from the brain by 24 h.[210] Mice infused with KU-60019 by CED, dosed three times to mimic clinical practice, immediately followed each time by 3 Gy radiation showed an increased survival and reduced tumor burden compared with KU-60019 or radiation alone.[211] Gliomas which were p53-mutant were shown to be more radiosensitive in combination with KU-60019 than genetically matched p53 WT lines. A trend to increased survival of mice treated with KU-60019 alone could link with the observed effect on glioma cell migration and invasion, potentially indicative of an additional benefit in controlling tumor growth between radiation fractions.[206,211] Importantly in these short-term mouse studies, KU-60019 did not appear to worsen the toxicity of radiotherapy in normal brain tissue.

Local delivery through CED is an established clinical technique for direct intracranial treatment of GBM and has the advantage of bypassing the BBB, thus improving efficacy with compounds unable to effectively penetrate the CNS. Local delivery may also reduce systemic toxicity, but the benefits of CED need to be balanced with the complexity and cost of the procedure. AstraZeneca has described two potent and specific ATM inhibitors with good oral bioavailability which differ in their ability to penetrate the BBB.[213] AZ31 and AZ32 are potent ATM enzyme ($IC_{50} < 0.0012$ and < 0.006 μM, respectively) and cell ($IC_{50} = 0.046$ and 0.31 μM, respectively) inhibitors with good selectivity over ATR (pCHK1 HT29 cell $IC_{50} > 30$ and > 23 μM, respectively).[213] AZ31 was shown to radiosensitize a panel of GBM cell lines, with p53-mutant lines among the most sensitive, and both compounds benefit from high free exposure in plasma following oral dosing.[213] AZ31 is highly effluxed in an MDR1 overexpressing MDCK line (efflux ratio = 10.7) and had limited (3 h) free exposure over the ATM cell IC_{50} in mouse brain following an oral dose of 100 mg kg^{-1}.[213] In contrast, while AZ32 is less potent, it is highly permeable with low efflux (efflux ratio = 0.4) and achieves free exposure for 22 h over the ATM cell IC_{50} in mouse brain. The difference in permeability/efflux is presumably a result of physicochemical properties such as lipophilicity, hydrogen bond donors, and polar surface area. AZ31 effectively radiosensitizes p53 mutant HT29 subcutaneous xenografts but does not significantly sensitize a syngeneic p53-defective intracranial mouse glioma model. In contrast the CNS-penetrant ATM inhibitor AZ32 results in significant improvement in survival in the intracranial model when given orally prior to fractionated whole brain radiation.[213]

The effective in vivo radiation- and chemotherapy-sensitization demonstrated by the compounds described above has provided impetus to identify ATM inhibitors for the treatment of human cancers. To date AZD0156 is the first and only ATM inhibitor to enter clinical development. AZD0156 is currently active in a Phase I trial in solid tumors in combination with the poly ADP-ribose polymerase (PARP)1/2 inhibitor olaparib (NCT02588105).

5.02.6.3 ATR

ATR is a serine/threonine protein kinase with a key role in the DNA replication stress response (RSR) activating DNA-damage checkpoints.[214,215] Replication stress is a hallmark of cancer and can be broadly defined as the slowing or stalling of replication fork

progression or DNA synthesis.[216,217] This can result from DNA-damage lesions or through lack of factors (e.g., sufficient nucleotide pools) which prevents replication proceeding in a coordinated fashion. One possible consequence of persistent replication stress is generation of stretches of replication protein A (RPA)-coated single-stranded DNA and activation of primarily ATR-dependent DDR pathway repair.[183,218] ATR inhibitors have shown promise for the treatment of cancer through exploiting tumor cell dependency on RSR for viability showing preferential cell killing in tumor cells where baseline replicative stress levels are high.[219] Therefore ATR inhibitors have potential for use in combination with replicative stress-inducing radiation or chemotherapy.[217,220] The loss of ATM in tumor cells also creates a synthetic lethality-like dependency leading to a greater reliance on ATR to maintain viability.[221] In ATM-deficient tumor cells, the activity of ATR inhibitors is enhanced in combination, and for some compounds single-agent efficacy has been demonstrated.[217,220]

5.02.6.3.1 ATR inhibitors

The earliest pharmacological tool ATR inhibitors were identified largely from known inhibitors of related targets. These compounds had weak potency, nonspecific ATR activity, and/or poor drug-like properties.[217] Subsequently inhibitors whose primary pharmacology is driven through selective ATR inhibition have been generated, combined with the properties required to enable detailed preclinical in vitro and in vivo target assessment. The clinical ATR inhibitors are derived from two distinct chemotypes: the aminopyrazines VX-970 and VE-821 from Vertex and the morpholinopyrimidine AZD6738 from AstraZeneca (**Fig. 16**).

VE-821 was the first selective aminopyrazine lead compound to be described arising from a 2-benzamido-3-amino-6-arylpyrazine screening hit.[221–223] The kinase-binding mode of this series has been extensively characterized with the N-4 pyrazine nitrogen together with the adjacent amino group forming a hydrogen bond acceptor–donor pair to the ATR hinge. Charrier et al. showed that addition of the 4-sulfonylmethyl group found in VE-821 led to an increase in potency, maintained selectivity versus PIKK family targets, and crucially improved cellular potency measured through inhibition of CHK1 (Ser-345) phosphorylation, a direct measure of ATR activation ($IC_{50} = 0.8\ \mu M$).[222] VE-821 was shown to potentiate multiple classes of chemotherapy and radiation particularly in tumor cells with mutant p53 or with loss of ATM.[221,223] Despite the utility of VE-821 as an in vitro tool compound, potency and physicochemical properties limited its further development. Exploration of SAR of the anilide moiety led to the discovery that the amide group could be productively replaced with a range of heterocyclic groups without loss of potency.[222] Surprisingly groups such as benzoxazole, which are unable to form the same hydrogen-bonding network to the protein observed with VE-821, have similar levels of ATR enzyme inhibitory potency. The SAR which led to the identification of VX-970 has not been described, but it is clear that the 4-(methylamino)methyl phenyl moiety linked through either isoxazole or oxadiazole to the aminopyrazine hinge binder is a key motif common to the majority of the compounds made.[217] VX-970 benefits from enhanced ATR enzyme ($IC_{50} < 0.0002\ \mu M$) and cellular potency ($IC_{50} = 0.019\ \mu M$) with high cellular selectivity over ATM and is also highly selective in a panel of kinase enzyme assays.[224] VX-970 shows potent tumor growth inhibition in vivo across multiple tumor types in combination with SOC chemotherapy agents but does not significantly inhibit tumor growth as monotherapy in the models and schedules published (up to 6 consecutive days of oral administration).[224–226] The apparent lack of monotherapy activity with VX-970 is interesting when compared with inhibitors from the morpholinopyrimidine series (vide infra). Exposure of VX-970 appears good with the concentration of VX-970 measured in tumor maintained in large excess of the ATR cellular IC_{50} for an extended duration (>24 h) following oral doses of VX-970 at 60 mg kg^{-1}.[225] At this dose, VX-970 alone shows a modest reduction in pCHK1 (Ser-345) and increased γH2AX consistent with the observed antitumor activity.[224–226] When VX-970 is given in combination with DNA-damaging chemotherapy and/or radiation, a far greater effect on tumor ATR and DDR biomarkers is observed together

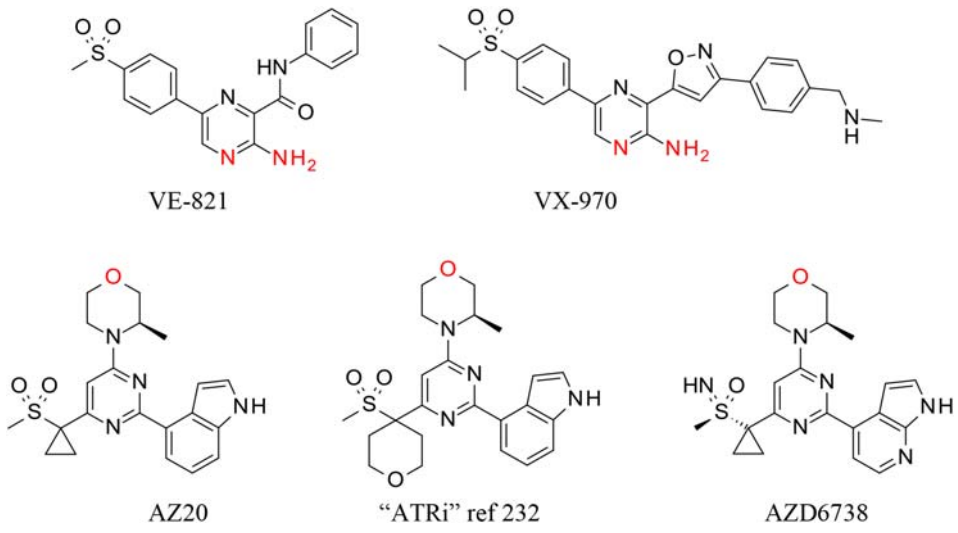

Fig. 16 ATR inhibitors (assumed hinge-binding atoms highlighted in *red*).

with marked increase in efficacy compared with chemotherapy or radiation alone.[224–226] VX-970 combines with different classes of DNA-damaging agents, with platinum agents such as cisplatin producing the most synergistic effects, and was shown to enhance the therapeutic efficacy of IR and gemcitabine in xenograft models of pancreatic cancer,[224] of irinotecan in colorectal xenograft models,[225] and of cisplatin in patient-derived lung tumor xenografts.[226] The enhancement of in vivo efficacy in combination in these mouse models is seemingly well tolerated; the combination of VX-970 with cisplatin resulted in some albeit not significant reduction in body weight, which was reversible with animal weight regained between cycles of treatment.[225]

AstraZeneca reported the discovery of AZ20 from a screening campaign identifying the high-quality sulfonylmorpholinopyrimidine series generated from an earlier mTOR program.[227] The 4-indole moiety was found to be critical for ATR potency with other isomers of indole losing potency and substitution for other heterocyles nonproductive. A medicinal chemistry campaign with the goal of maintaining the attractive physicochemical properties of this series while improving potency for ATR, e.g., by maximizing LLE was prosecuted.[227] Unsubstituted indole and sulfonyl groups were found to be preferred motifs, but improvements in both potency (for ATR) and selectivity (over PI3K) were obtained from cyclization adjacent to the sulfonylmethyl group and crucially by addition of a methyl group to the morpholine hinge binder motif.[227] Potency was found to be highly dependent on the stereochemistry of the morpholine 3-methyl group with the (*R*)-enantiomer possessing 100× higher potency than the corresponding (*S*)-enantiomer in cellular assays.[227] AZ20 has low aqueous solubility (10 μM at pH 7.4) driven by efficient packing in the solid state that is dominated by centrosymmetric methylsulfone to methylsulfone contacts leading to a high crystalline melting temperature (204°C).[227] AZ20 was also found to be a time-dependent inhibitor (TDI) of CYP3A4. Despite these shortcomings, AZ20 has been successfully utilized to explore the in vivo pharmacology of ATR inhibition by virtue of high target specificity and high free exposure in vivo, maintaining concentration over the target IC_{50} for 12 h in mouse following a single oral dose of 50 mg kg^{-1}.[227] LoVo tumors, which are MRE11A (ATM pathway) deficient and characterized by diffuse pan-nuclear γH2AX staining suggestive of high replication stress, have been shown to be sensitive to AZ20 ($GI_{50} = 0.20$ μM following 72 h continuous exposure).[227] In contrast to VX-970, AZ20 was shown to significantly increase tumor γH2AX levels as monotherapy in vivo. AZ20-treated mice bearing LoVo xenografts resulted in significant inhibition of tumor growth (TGI = 78%, $P < 0.0005$) following 21 days continuous dosing.[227,228] The reasons behind this key difference are not clear, but it should be noted that the described studies are likely to result in differences in free exposure versus potency and use quite different dosing schedules.

Menezes et al. usefully demonstrated the therapeutic potential of ATR inhibitors based on mutation or deletion of ATM with compound "ATRi" from the same family as AZ20 (**Fig. 16**).[229] Compound "ATRi" (ATR enzyme $IC_{50} = 0.00023$ μM; ATR cell $IC_{50} = 0.13$ μM) leads to regression in ATM-deficient Granta-519 mantle cell lymphoma (MCL) xenografts but has minimal impact on the growth of ATM-WT JVM-2 tumors using a dose and schedule shown to be selective for ATR inhibition.[229] The sulfoximine morpholinopyrimidine AZD6738 maintains excellent potency for ATR in enzyme ($IC_{50} = 0.002$ μM) and cell ($IC_{50} = 0.074$ μM) assays combined with high specificity in a large kinase panel, including all of the related PIKK targets, while overcoming the main liabilities of AZ20.[230–232] AZD6738 has much higher aqueous solubility (661 μM at pH 7.4) and is devoid of measurable CYP3A4 TDI activity while maintaining high bioavailability in preclinical species.[230] We can speculate that replacement of the indole ring in AZ20 with the more electron-deficient 7-azaindole moiety in AZD6738 reduces the propensity for ring oxidation and subsequent formation of reactive metabolites that could bind covalently to the CYP heme. The improvement in aqueous solubility is likely a combination of reduced lipophilicity ($LogD_{7.4} = 1.9$ for AZD6738 compared with 2.7 for AZ20), and disruption of the sulfone–sulfone contacts seen in AZ20 albeit the melting temperature remains high. Reduction in lipophilicity and introduction of a hydrogen bond donor has a slight impact on the permeability of AZD6738 in Caco-2 cells compared with AZ20, but permeability remains high for AZD6738 which has an excellent PK profile with high fraction absorbed, low clearance, and high bioavailability in preclinical species.[230] The sulfoximine group has subsequently been highlighted as a useful fragment for use in drug discovery[233,234] and is found in other molecules in clinical development such as the pan-CDK inhibitor BAY-1000394.[235]

Similar to the results demonstrated with AZ20, exposure of AZD6738 results in a durable increase in tumor γH2AX compared with normal tissue such as bone marrow and GI, suggestive of a positive therapeutic index.[231] Continuous oral dosing schedules with AZD6738 are well tolerated with body weight loss dose limiting,[232] and single-agent tumor growth inhibition has been demonstrated in LoVo xenografts with less effect in ATM-proficient models such as HT29.[231] Duration of drug exposure and persistence of γH2AX have been shown to correlate with the antitumor efficacy in vivo.[231] Durable tumor regression without unacceptable toxicity has also been shown with AZD6738 in combination with the PARP1/2 inhibitor olaparib.[236] In a primary explant model (HBCx-10) of TNBC with BRCA2 and TP53 gene mutations, antitumor efficacy of the combination was significantly greater than either olaparib or AZD6738 dosed alone.[236] In a further study, AZD6738 has been shown to inhibit the growth of NSCLC cells inducing a DDR.[232] AZD6738 treatment synergized with cisplatin in ATM-deficient NSCLC cells resulting in rapid cell death.[232] In vivo the same combination of AZD6738, 25 mg kg^{-1} administered orally daily over 14 consecutive days, with cisplatin, 3 mg kg^{-1} administered IP on days 1 and 8 of a 2 week cycle, was well tolerated and led to robust tumor regression of ATM-deficient H23 tumors.[232] The combination led to limited body weight loss similar in extent to cisplatin treatment alone, further demonstrating the tolerability of ATR inhibitors in preclinical mouse models.[232]

To date three compounds have entered human clinical trials: VX-970, AZD6738, and VX-803; the structure of VX-803 has not been disclosed. VX-970 and AZD6738 are currently being tested in Phase I/II clinical trials across multiple tumor types. In these trials VX-970 is administered as a short i.v. infusion with episodic dosing regimens despite showing preclinical utility as an oral agent. Multiple combinations are being explored with a range of DNA-damaging agents reflecting the preclinical activity demonstrated. In a Phase I study in refractory advanced solid tumors, VX-970 monotherapy and VX-970 + carboplatin combination therapy were explored.[237] Paired tumor biopsies taken 1 h before and after VX-970 administration following carboplatin separated

by 24 h showed a 73% reduction in pCHK1 biomarker at the recommended Phase II dose of 90 mg m^{-2}.[238] Encouragingly early signs of clinical efficacy were noted. A patient with metastatic colorectal cancer with complete ATM-loss treated with monotherapy VX-970 and a patient with platinum-refractory metastatic high-grade serous ovarian cancer with BRCA1 + TP53 mutations treated with VX-970 in combination with carboplatin were reported with clinical responses.[237] VX-970 exploration is ongoing in Phase I/II studies across tumor types with cytotoxic chemotherapies (NCT02157792) and the PARP1/2 inhibitor veliparib and cisplatin in patients with refractory solid tumors (NCT02723864). The second compound from Vertex, VX-803, looks to be orally dosed and is being explored in early trials as monotherapy and in combination with carboplatin in patients with solid tumors and lymphoma (NCT02278250). Phase I/II studies with AZD6738 are underway as monotherapy and in combination with radiation in head and neck cancer (NCT02223923), and with carboplatin, olaparib, or the anti-PD-L1 checkpoint inhibitor durvalumab in advanced solid tumors (NCT02264678). The reported combination trial with cancer immunotherapy indicates a potentially exciting new approach, whereby ATR inhibitors could be used to prime an immune response.

ATR drug discovery remains a highly active field with further compounds from additional series being reported. New patent applications describing novel ATR inhibitors are emerging such as from the Spanish National Cancer Research Centre (CNIO),[239] who have an ongoing collaboration with Merck Serono, and most recently from Bayer Pharma[240] and Atrin.[241] It is clear from the continuing interest in discovery of new ATR inhibitors that further compounds will be identified that are likely to enter clinical development in the near future.

5.02.6.4 DNA-PK

DNA-PK is a serine/threonine protein kinase from the same family as ATR and ATM.[190,191] DNA-PK, made up of a catalytic subunit (DNA-PKcs) and the Ku70/80 heterodimer, plays a key role in NHEJ the preeminent pathway for repair of DNA DSBs in mammalian cells.[242,243] DNA DSBs are considered the most cytotoxic of DNA lesions, and mammalian cells have evolved two major pathways to repair them in cells: HR and NHEJ.[244,245] The kinase activity of DNA-PKcs is essential for successful NHEJ; the Ku70/80 heterodimer senses and binds to the DNA DSB ends, and it is this DNA–Ku complex that binds DNA-PKcs to form DNA-PK resulting in activation of the catalytic activity of the enzyme.[242,243] Inhibition of NHEJ through inhibition of DNA-PK activity offers a unique approach to enhance the cancer cell toxicity of DSB-inducing IR and chemotherapeutic agents. Multiple substrates are known for DNA-PKcs involved in NHEJ and the DDR more widely, the best characterized of which is DNA-PKcs itself.[242,243] Autophosphorylation occurs on a number of sites and is associated with kinase inactivation and dissociation from the DNA–Ku70/80 complex. In addition to its central role in NHEJ, the role of DNA-PKcs in the regulation of mitosis and other cellular processes has been described.[242] DNA-PKcs has been shown to interact with PLK1 and to phosphorylate CHK2 during mitosis.[242,243] The activity of DNA-PKcs outside of NHEJ is quite likely different, with the observation that the catalytic activity of DNA-PKcs can be independent of Ku70/80.[242,243]

5.02.6.4.1 DNA-PK inhibitors

Wortmannin (Fig. 17) was described initially as a potent irreversible inhibitor of PI3 kinases but then was also shown to bind covalently forming ATP-site adducts with DNA-PK, ATM, and ATR.[246,247] For DNA-PK in particular, Wortmannin has good potency ($K_i \sim 120$ nM) and its mechanism of action in sensitizing cells to IR is recognized as most likely driven through inhibition of DNA-PK and inhibition of DNA DSB repair,[248] but the compound suffers from poor stability.

The importance of the arylmorpholine pharmacophore is nicely demonstrated by IC87361, a potent DNA-PK inhibitor ($IC_{50} = 0.034$ μM) with selectivity over PI3Kα ($IC_{50} = 3.8$ μM).[249] Treatment of cells with IC87361 alone did not induce cytotoxicity, but the combination with radiation in mouse tumor models resulted in a slowing of tumor growth compared with radiation alone with no apparent toxicity to normal tissues.[249] Willmore et al. identified the 2-(morpholin-4-yl)-benzo[h]chomen-4-one NU7026.[250] NU7026 is an ATP-competitive and highly selective inhibitor of DNA-PK, with a 60-fold greater potency for DNA-PK compared to PI3Ks, and is inactive against both ATM and ATR.[251] NU7026 demonstrated the ability of DNA-PK inhibitors to potentiate chemotherapeutic-induced DSBs from agents such as etoposide while having no effect as a single agent. Further SAR investigation from the same group led to the discovery of the 2-*N*-morpholino-8-dibenzothiophenyl-chromen-4-one NU7441 with further enhancement of potency ($IC_{50} = 14$ nM) and specificity for DNA-PK (at least 100-fold selectivity over PIKK family kinases).[252] Treatment of cells with NU7441 substantially retarded the repair of IR-induced and etoposide-induced DSBs and the clonogenic survival of both p53-mutant and p53-WT human colon cancer cell lines.[253] In vivo proof of concept with NU7441 has been demonstrated in mice bearing SW620 xenografts. The combination of NU7441 and etoposide increased etoposide-induced tumor growth delay twofold without exacerbating toxicity to unacceptable levels.[253] The high lipophilicity of these compounds results in low aqueous solubility (KU7441 pH 7.4 aqueous solubility < 0.3 μM) and high protein binding (hu free drug = 0.04%), properties that restrict full in vivo evaluation and further development. To address these limitations, the addition of water-solubilizing primary and secondary amine groups linked through a polar amide was investigated. Compounds such as KU60648 were developed that retain the high level of potency for DNA-PK ($IC_{50} = 5$ nM) described for NU7441.[254] KU60648 has much lower plasma protein binding and higher aqueous solubility, albeit variability between assays was observed.[254] KU60648 was unexpectedly found to also inhibit PI3Kα ($IC_{50} = 0.004$ μM), but it did retain selectivity over mTOR, ATM, and ATR.[254] The dual kinase activity profile is mirrored in cells; KU60648 potently inhibits the autophosphorylation of DNA-PK ($IC_{50} = 0.019$ μM in MCF7 cells) and PI3K-mediated AKT phosphorylation ($IC_{50} = 0.039$ μM in MCF7 cells).[254] KU60648 potentiated the cytotoxicity of anticancer agents and IR, and in contrast to the DNA-PK selective inhibitors described before, drug

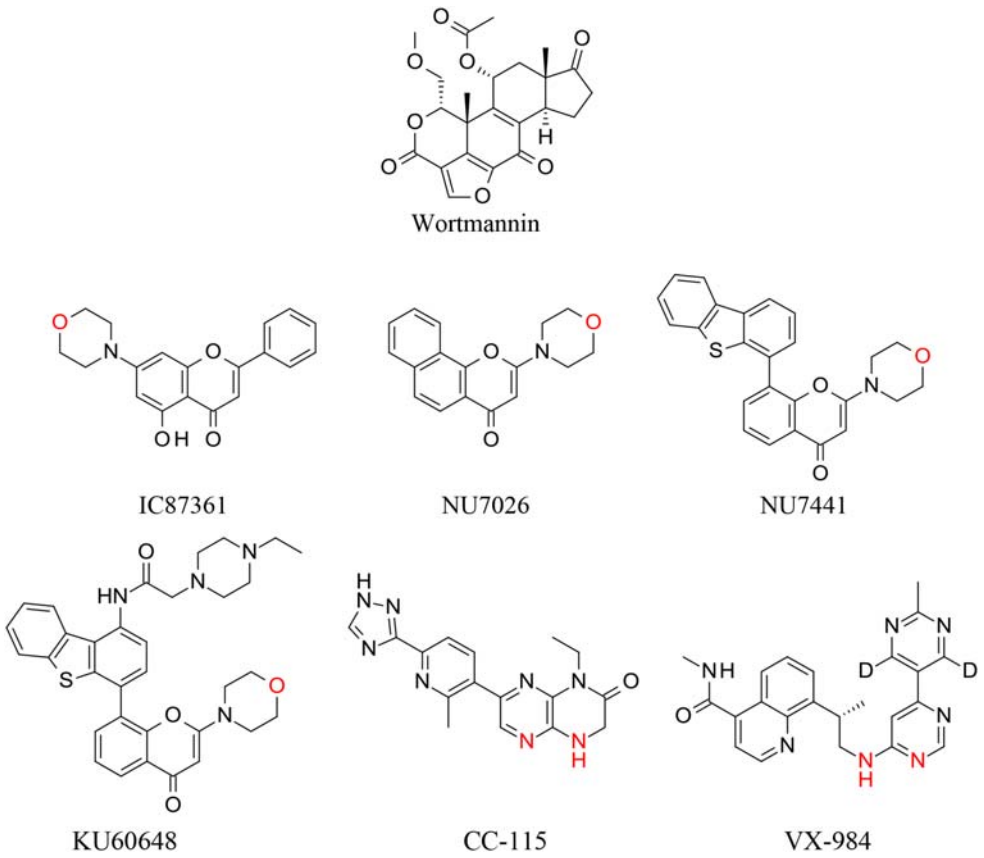

Fig. 17 DNA-PK inhibitors (assumed hinge-binding atoms highlighted in *red*).

treatment alone was found to inhibit cell proliferation.[254] Treatment with KU60648 alone delayed the growth of MCF7 xenografts and increased tumor growth delay in combination with etoposide in both SW620 and MCF7 xenograft models by up to 4.5-fold.[254] In rat toxicity studies however, KU60648 was not well tolerated perhaps linked to its nonspecific kinase activity profile. In addition, despite the addition of solubilizing groups, the biopharmaceutical properties of compounds such as KU60648 negated further development investment.[205]

Three DNA-PK inhibitors each from a chemotype not previously described have entered clinical development. CC-115 from Celgene is a dual mTOR, DNA-PK inhibitor derived from an earlier mTOR-selective compound series.[255] Screening CC-115 in a panel of kinase assays led to the discovery of DNA-PK as an equipotent target while it was shown to be selective against PI3Ks, ATR, and ATM.[255] It does not appear that the dual mTOR and DNA-PK inhibitory activity profile of CC-115 was a result of rational design and preclinical characterization of CC-115 detailing the benefit or otherwise of adding DNA-PK activity to mTOR has yet to be reported. However, the distinct activity profile may allow a differentiated clinical positioning. A Phase I study of CC-115 administered orally to patients with advanced solid tumors and hematologic malignancies is underway (NCT0135362). MSC2490484A from Merck Serono is also in a Phase I study in patients with advanced solid tumors with alterations in DNA-repair mechanisms (such as BRCA and ATM), or CLL in combination with radiotherapy (NCT02516813). The structure of MSC2490484A has not been released. A third compound, VX-984 from Vertex, is an ATP-site inhibitor of DNA-PKcs, deuterated to slow the rate of oxidative metabolism by aldehyde oxidase.[256] VX-984 is a highly potent and ATP-competitive inhibitor of DNA-PKcs enzyme ($K_i = 0.002$ μM) and in cells (autophosphorylation in A549 $IC_{50} = 0.088$ μM) with high selectivity over PIKKs.[256] VX-984 showed minimal effects on cell viability as a single agent but in combination with radiation decreased clonogenic survival of a range of human lung cancer cell lines.[256] In vivo, oral administration of VX-984 inhibited DNA-PKcs autophosphorylation in a dose-dependent manner and potentiated the antitumor efficacy of IR in an NSCLC PDX mouse model.[256] A first in human study of VX-984 is recruiting to evaluate safety and tolerability administered alone and in combination with i.v. dosed pegylated liposomal doxorubicin (PLD), in patients with advanced solid tumors or lymphomas (NCT02644278). PLD is a drug formulation where doxorubicin is delivered encapsulated in a bilayer sphere of lipids.[257] It has been reported that the size of the liposome particles results in a greater deposition of the encapsulated drug in the tumor compared with other tissues resulting in a differential toxicity profile through the enhanced permeability and retention (EPR) effect.[258] It may also be the case that a change in PK profile is equally important in any observed effect; the development of nanomedicines in oncology is of significant interest for classical cytotoxic and targeted agents.[259]

5.02.6.5 WEE1 and CHK1

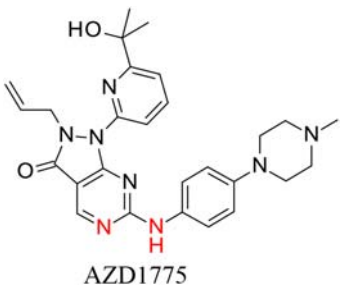
WEE1, a dual-specificity protein tyrosine kinase,[260–263] and CHK1, a serine/threonine protein kinase,[264–266] are activated in response to DNA-damage and function as key regulators of the G2-M and S-phase checkpoints protecting the cell from apoptotic cell death until DNA-damage is repaired. CHK1 is activated through phosphorylation by ATR in response to replication stress or DNA-damage inducing radiotherapy or chemotherapy.[266] WEE1 and CHK1 inhibitors have potential as chemosensitizing drugs inducing G2/M checkpoint escape and releasing the tumor cell from cell cycle arrest, resulting in mitotic catastrophe.[267] A potential synthetic lethality occurs in tumors with mutated p53 which plays a key role in G1-S checkpoint regulation.[268] Abnormalities in the p53 pathway are common in the majority of human cancers.[269] Tumor cells lacking a functioning G1 checkpoint have greater dependency on the S and G2-M checkpoints, whereas loss of checkpoint regulation is thought to be compensated in normal tissue by functioning p53. Therefore a favorable therapeutic index is expected when WEE1 or CHK1 inhibition is combined with DNA-damaging agents in tumors lacking functioning p53. Inhibition of WEE1 kinase has been shown to be effective in p53 WT tumors. Regulation of G2-M arrest and DNA-repair pathways is highly complex, and the impact of WEE1 inhibition is likely determined through mechanisms of cell cycle regulation other than p53 or defective DNA-repair pathways independent of cell cycle regulation.[261] WEE1 signals through phosphorylation and inhibition of CDK1 and 2.[260] Knockdown or inhibition of WEE1 causes abnormally high CDK1/2 activity in S-phase cells that eventually results in an induction of DNA DSBs. Likewise, inhibition of CHK1 alone can result in replication fork collapse and formation of DNA DSBs. Therefore WEE1 and CHK1 inhibitors may also be anticipated to have antitumor activity in the absence of added chemotherapy.

5.02.6.5.1 WEE1 inhibitors

A single WEE1 inhibitor AZD1775 (MK-1775, Fig. 18), developed by Merck & Co. Inc. and licensed to AstraZeneca, is under clinical investigation, and a small number of additional compounds have been reported in the preclinical phase. AZD1775 was developed from a screening hit derived from a small chemical compound library aimed at identification of inhibitors of WEE1 enzymatic activity.[270,271]

The medicinal chemistry design of AZD1775 has not been reported. AZD1775 contains a recognizable anilino-pyrimidine kinase hinge-binding motif and is an ATP-competitive inhibitor of WEE1 ($IC_{50} = 5.2$ nM), is orally bioavailable, and has shown to be highly selective for WEE1 in a panel of 223 protein kinase assays.[270] Activity of AZD1775 for a single additional kinase, Yes ($IC_{50} = 14$ nM) was demonstrated within 10-fold of the WEE1 potency.[270] AZD1775 inhibited phosphorylation of CDC2 at Tyr15 in WiDr cells (human colorectal cancer cell line with mutated p53) pretreated with gemcitabine ($EC_{50} = 85$ nM) and potently induced pHH3, reflecting premature mitotic entry resulting from abrogation of DNA-damage checkpoints, in combination with gemcitabine and platinum agents.[270] AZD1775 was shown to selectively sensitize p53-deficient tumor cells to a range of DNA-damaging agents such as gemcitabine, platinum agents, and radiation, potentiating tumor growth inhibition without significant increased toxicity in mouse in vivo models across multiple tumor types.[270] Inhibition of CDC2 phosphorylation and induction of pHH3 phosphorylation was demonstrated in tumor and correlated with antitumor efficacy in vivo.[270] Single-agent efficacy of AZD1775 has been demonstrated in NSCLC (A427 and SK-MES-1) and colorectal (LoVo) xenograft models. Sensitivity has been linked to PKMYT1 expression providing a potential foundation for exploring the anticancer activity of AZD1775 independent of cytotoxic combinations.[271]

In early clinical trials as a single agent in refractory solid tumors, AZD1775 was administered orally twice daily over 2.5 days per week for up to 2 weeks in a 21-day cycle.[272] The MTD was established at 225 mg with common toxicities including myelosuppression and diarrhea. Proof-of-mechanism was demonstrated by target modulation and DDR in paired tumor biopsies with a reduction in pY15-CDK and increased γH2AX. Encouragingly, single-agent activity was shown with partial responses in two patients (one with head and neck cancer and one with ovarian cancer) both carrying *BRCA1* mutations.[272] AZD1775 is being evaluated in numerous Phase II clinical studies as monotherapy and as a potentiator of DNA damage in combination with SOC therapies in patients with NSCLC, head and neck, gastric, breast, and ovarian cancers. Multiple trials have investigated AZD1775 in ovarian cancer, and in 2012 AZD1775 received Orphan Drug designation in the European Union for this indication. Promising clinical efficacy was established in a Phase II study (NCT01164995) in combination with carboplatin in patients with chemotherapy-resistant p53-mutated ovarian cancer.[273] Dosing of AZD1775 followed the same schedule (225 mg BID for 2.5 days) with concomitant dosing of



AZD1775

Fig. 18 WEE1 inhibitors (assumed hinge-binding atoms highlighted in *red*).

carboplatin AUC5 by short (30 min) i.v. infusion on day 1, following a 21-day cycle. This combination was tolerated albeit toxicity to bone marrow was common.[273] Out of 22 evaluable patients, 6 showed a confirmed partial response (PR), while 9 patients exhibited stable disease (SD).[273]

In addition to combinations with chemotherapy and radiation, the combination of WEE1 inhibitors with CHK1 or PARP1/2 inhibitors has been investigated in preclinical studies, and these novel–novel combinations have started to be investigated in the clinic. The key role played by CHK1 and CHK2 in cell cycle control and the link between BRCA1 and CHK1 modulation in the G2-M checkpoint control together with the marked sensitivity of BRCA1-mutated tumors to PARP1/2 inhibitors, provides a rationale for exploring inhibitor combinations of these targets. Simultaneous inhibition of CHK1 and WEE1 has been demonstrated to have a strong synergistic cytotoxic effect in MCL cells, associated with deregulation of the cell cycle and increased activity of CDK1 and 2.[274] The combination of AZD1775 with the CHK1 inhibitor PF-00477736 in JeKo-1 xenografts led to marked tumor regression at tolerated doses, providing a potential rationale for testing this combination in the clinic albeit no such studies have started.[274] The radiosensitizing efficacy of AZD1775 and the PARP1/2 inhibitor olaparib in pancreatic cancer has been demonstrated in MiaPaCa-2 xenografts, where radiosensitization from this combination was associated with G2 checkpoint abrogation and persistent DNA damage.[275] A Phase I multicenter, dose escalation study of AZD1775 combined with olaparib in refractory solid tumors is currently recruiting (NCT02511795). In addition, other novel agent–novel agent combinations underway include a Phase I study of AZD1775 in combination with the anti-PD-L1 inhibitor durvalumab (MEDI4736) in patients with advanced solid tumors (NCT02617277).

5.02.6.5.2 CHK1 inhibitors

The concept of modulating DNA-damage checkpoints to enhance the efficacy of DNA-damaging agents has been demonstrated in preclinical studies with small-molecule inhibitors of CHK with varying CHK1/2 selectivity. The compounds that remain active in human clinical trials are summarized in **Fig. 14**. Many CHK1 inhibitors have been developed and have entered clinical trials, demonstrating tolerability with DNA-damaging agents.[276] However, further progression has proven difficult, and development of many of these compounds has since been terminated for toxicity or business-related reasons.[277]

LY2603618 (rabusertib, **Fig. 19**) and MK-8776 (SCH-900776) were in clinical trials but have since been discontinued. The biaryl urea motif in LY2603618 is an atypical ATP-site binder identified following a HTS against catalytic CHK1 activity. X-ray crystallography revealed a strong conformational preference of the biaryl urea structure with intramolecular hydrogen bonds between the pyrazine N1 and the distal urea N−H with the oxygen of the alkoxy moiety further stabilizing the bioactive conformation.[278] In this conformation, the carbonyl and remaining urea N−H form a recognizable hydrogen bond donor/acceptor pair to the kinase hinge. Both pyrazine nitrogens are important for CHK1 activity with an observed interaction between the 2nd pyrazine nitrogen and a conserved water molecule in the active site. Appending amines, particularly conformationally constrained cyclic amine groups on the alkoxy, led to large increases in potency and provided a valuable way to modulate physicochemical and pharmacokinetic properties.[278] Cyclic amines with reduced basicity (e.g., morpholine) were found to be equipotent and benefitted from reduced hERG potency. LY2603618 is a potent CHK1 inhibitor ($IC_{50}=0.007$ μM) with selectivity over CHK2 ($IC_{50}=12$ μM) and >100-fold selectivity in a panel of protein kinases. LY2603618 is a potent inhibitor of CHK1 activity in cells inhibiting CHK1 autophosphorylation

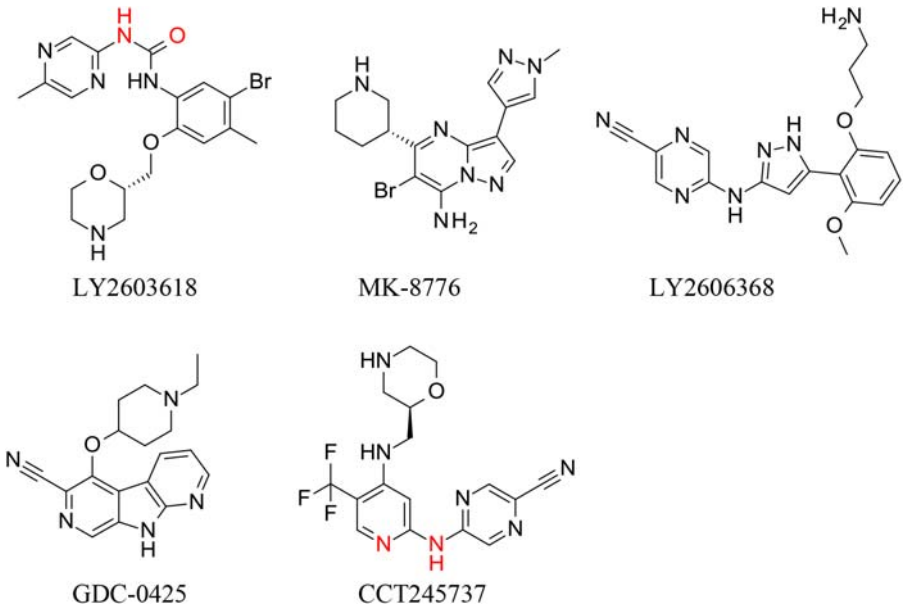


Fig. 19 CHK1/2 (assumed hinge-binding atoms highlighted in *red*).

(Ser-296) following treatment with doxorubicin in HeLa cells ($EC_{50} = 0.12$ μM following 24 h treatment with 100 nM doxorubicin). A concentration of 250 nM of LY2603618 is effective at potentiating the potency of gemcitabine in p53 mutant, but not in p53 WT cells. LY2603618 treatment led to an increase in the mitotic marker pHH3 (Ser10) in HeLa cells treated with doxorubicin indicating inactivation of the G2/M DNA-damage checkpoint. In p53-mutant Calu-6 xenografts CHK1 autophosphorylation is strongly inhibited by coadministration of 200 mg kg^{-1} LY2603618 with gemcitabine for at least 24 h. In efficacy studies, LY2603618 treatment alone has little effect on tumor growth but enhances the antitumor efficacy in combination with gemcitabine and with pemetrexed in pancreatic and NSCLC xenograft models, respectively.[279,280] Scheduling of the combination is key to efficacy with enhanced tumor growth inhibition obtained only when LY2603618 was given 24 h after the DNA-damaging agent.[279,280] In combination with gemcitabine, durable efficacy was also demonstrated in a p53-WT pancreatic patient explant model (PAXF1869) using the same offset dosing schedule; interestingly the PAXF 1869 model contains a mutation in the *CHK2* gene and CHK2 contributes to the p53-dependent G1-S checkpoint.[279] The results of three early clinical studies with LY2603618 have been published.[280–282] In these studies LY2603618 has been administered as a short (1 h) i.v. infusion in combination with pemetrexed, pemetrexed, and cisplatin and with gemcitabine. In each case scheduling of LY2603618 has followed the reported optimized preclinical 24-h gap schedule. In the absence of validated biomarkers to assess PD, the biological effective dose was established based on achieving exposure in excess of that shown preclinically to generate the maximal PD response and used as a surrogate to establish a dose for later-stage studies. Early signs of clinical responses were reported at doses considered tolerated, albeit with signs of hematological toxicity, but despite these reports the development of LY2603618 has now been discontinued.

MK-8776 (SCH900776) is a more potent inhibitor of CHK1 ($IC_{50} = 3$ nM) than CHK2 ($IC_{50} = 1500$ nM) and other cell cycle kinases such as CDK2 ($IC_{50} = 160$ nM) and leads to synergistic antitumor activity in combination with DNA-damaging agents which activate CHK1 such as gemcitabine and cytarabine.[283,284] In a Phase I trial, MK-8776 was administered as an i.v. infusion in combination with cytarabine to patients with relapsed refactory acute leukemias. Complete remissions occurred in 8 of 24 patients with DLTs including corrected QT interval prolongation.[285] The clinical combination of MK-8776 with gemcitabine has also been explored. In contrast to the 24 h gap schedule utilized for LY2603618, MK-8776 was administered with only a 30 min interval to gemcitabine. Despite this, the combination led to a PR in two patients and SD in 13 others.[286] The development of MK-8776 may have been discontinued although a Phase II trial in AML (NCT01870596) is recorded as ongoing.

A second-generation compound from Lilly LY2606368 (prexasertib) is active in Phase II studies. LY2606368 contains a cyanopyrazine group linked via an amine to a pyrazole core. LY2606368 is a potent ATP-competitive inhibitor of CHK1 ($K_i = 0.9$ nM; $IC_{50} < 1$ nM) and, in contrast to LY2603618, also potently inhibits CHK2 ($IC_{50} = 8$ nM).[287] Otherwise LY2606368 is highly selective in a panel of 224 protein kinases with an $IC_{50} < 100$ nM for 5 kinases.[287] In cells LY2606368 potently inhibits both CHK1 and CHK2 autophosphorylation ($EC_{50} < 1$ and < 31 nM, respectively) and potently abrogated the doxorubicin-activated G2-M checkpoint in p53-deficient HeLa cells ($EC_{50} = 9$ nM).[287] Interestingly LY2606368 is broadly and potently antiproliferative as a single agent with IC_{50} values typically < 50 nM in sensitive cell lines. Treatment with LY2606368 alone was shown to result in DNA DSBs together with dysregulation of DNA-damage checkpoints. LY2606368 was shown to reduce CHK1 autophosphorylation and increase DDR markers such as γH2AX in Calu6 xenografts in vivo and episodic dosing of LY2606368 led to tumor growth inhibition without excessive body weight loss.[287] LY2606368 is being assessed as both a single agent and in combination with cytotoxic agents in the clinic. Administration of LY2606368 as monotherapy by short i.v. infusion over 1 h using an episodic schedule of 1 or 3 consecutive doses per day every 2 weeks has been reported.[288] Drug exposure at the MTD was found to match the exposure in preclinical mouse xenografts that achieved antitumor activity. LY2606368 has shown early clinical activity; from 45 patients in the study, 2 had a PR and 15 others exhibited SD with DLTs all hematological related.[288] A Phase I study of GDC-0425,[289] an orally bioavailable compound dosed in combination with gemcitabine in solid tumors or lymphoma (NCT01359696), has completed, but there are no reports describing this molecule's preclinical characterization or clinical results.

CCT245737 is the newest CHK1 inhibitor to enter clinical development. CCT245737 was discovered following a multiparameter optimization campaign aimed at identifying compounds with high selectivity for CHK1 over CHK2 and other protein kinases such as CDK1, balancing lipophilicity, and basicity for potent CHK1 activity with effective cellular potency and favorable PK properties without detrimental activity such as inhibition of the hERG ion-channel.[290] An orally dosed drug was the goal to give maximum flexibility of dosing for use as a single agent and in combination with DNA-damaging agents. The CCT245737 series binds through the 2-aminopyridine moiety to the kinase hinge with nitrile and N-4 of the pyrazine interacting with an atypical conserved water leading to high kinase selectivity.[290] CCT245737 is an ATP-competitive and highly potent inhibitor of CHK1 ($IC_{50} = 1.4$ nM) with >1000-fold selectivity over CHK2 and CDK1. CCT245737 potently inhibits cellular CHK1 and CDK1 phosphorylation induced by gemcitabine at 0.5 μM and results in DNA DSBs and abrogates cell cycle checkpoints.[290,291] CCT245737 potentiates the cytotoxicity of gemcitabine across a range of human tumor cell lines and achieves high free exposure in mouse from oral doses.[291] The in vitro PD activity is recapitulated in vivo with the same 24 h gap schedule described for other CHK1 inhibitors in combination with gemcitabine. Single-agent CCT245737 at 150 mg kg^{-1} had marginal antitumor inhibition alone but the combination with gemcitabine led to significant increase in tumor growth delay over gemcitabine treatment alone in HT29 and SW620 xenografts without unacceptable body weight loss. Similar tolerated antitumor efficacy was demonstrated in combination with the topoisomerase 1 inhibitor irinotecan and as a single-agent activity in a MYC-driven model of B-cell lymphoma.[291] CCT245737 is recruiting in two Phase I studies, administered orally in patients with advanced cancer (NCT02797964) and in combination with either gemcitabine or gemcitabine plus cisplatin in patients with advanced cancer (NCT02797977). A PD marker of CHK1 activity, pS296 CHK1, will be explored clinically to define dose and schedule.[291]

5.02.6.6 Summary and Outlook

The collective DDR offers a rich source of anticancer drug targets. Kinases in particular provide validated and druggable new drug targets to exploit for a new generation of cancer therapies. The DDR is fundamental to genomic integrity in normal cells leading to a concern over the expected toxicity from targeting particular DDR proteins. However it is clear from the published preclinical studies in mouse models, using highly potent and specific small-molecule inhibitors, that pharmacological DDR kinase inhibition is not overtly toxic and a positive therapeutic index can be achieved. Moreover DDR inhibitors are now being successfully applied in the clinic. A number of key therapeutic concepts are utilized in targeting the DDR in cancer cells offering the potential for selective tumor cell killing. First, cancer cells have high DNA-damage load, exhibiting replication stress and a reliance on DDR for survival. Second, the loss of specific DDR capability through mutations is common and leads to an exploitable DDR dependency. Third, potentiation of the cytotoxicity of DNA-damaging chemotherapy and radiotherapy through combination with DDR inhibitors is an important therapeutic strategy particularly in the context of DDR dependency.

A major advance in recent years has been the progression of multiple compounds into human trials (Fig. 14). It is clear that DDR inhibitors with high specificity are preferred over compounds that inhibit multiple targets as they are most likely to achieve greater tolerability. In some cases different organizations have arrived at compounds targeting the same kinase with quite different properties, such as preferred route of administration. The impact of these differences on both efficacy and tolerability will become clear as the clinical data matures. It is interesting that AZD1775 is the only WEE1 kinase inhibitor reported in clinical development. As the clinical utility of AZD1775 becomes evident (and any limitations also) further compounds will no doubt be developed. The use of early compounds, even without properties suitable for development, has enabled detailed preclinical proof of principle studies to be completed encouraging the development of improved inhibitors for clinical use. These preclinical studies reveal the exciting therapeutic potential of DDR kinase inhibitors to enhance the efficacy of a range of established anticancer drugs across multiple tumor types. The detailed preclinical studies have been influential supporting clinical trial design, for example, identification of the optimal combination partner and schedule, responsive tumor type, and required biological effective dose. These results demonstrate wide ranging potential for clinical use and the ongoing trials reflect this diversity of opportunity. Combinations with DNA-damaging chemo, radiotherapy, or novel agents are being explored for all of the compounds described. Inhibitors of some DDR kinases (e.g., ATR, WEE1, and some CHK1 inhibitors) have demonstrated potent single-agent antitumor activity in appropriate tumor subsets (e.g., tumors lacking functional p53 or with loss of ATM). There is some overlap between sensitive tumor types and combination partners between DDR targets. However, the precise mechanisms of DNA-damage and repair are quite different and likely therefore to lead to complementary activity such as the responsive patient segments between targets.

Early clinical responses are encouraging, and some compounds are advancing into the later stages of development albeit none yet are being explored in trials which will lead directly to regulatory approval. The combination of DDR kinase inhibitors with DNA-damaging chemotherapy and/or radiotherapy has led to toxicity particularly where there are overlapping toxicities such as to the bone marrow. However, success has come from careful scheduling, selection of the appropriate agent based on a clear mechanistic rationale supported by preclinical evidence for a synergistic combination. Biomarkers to identify likely responders will be especially important to achieve a favorable therapeutic index. In particular circumstances, selective delivery to the tumor or judicious choice of route of administration may prove to be important. Novel agent–novel agent combinations such as with PARP1/2 inhibitors or the combination with immunotherapies are now being explored clinically, offering an exciting extension to combinations with classical cytotoxic agents that have been the focus to date.

DDR inhibition is a distinct therapeutic strategy that has received much interest from drug hunters, and targeted DDR kinase inhibitors are set to form a new wave of drugs for the treatment of cancer and potentially other diseases.

5.03.1 Introduction

The fundamental signaling role of kinases in cell function and survival has long been recognized as a potentially critical point for pharmacological intervention. The medicinal chemistry of kinase inhibitors has grown in importance over the past several decades (see 50002, Selective kinase inhibitors for cancer), from the development and commercial success of early inhibitors such as Gleevec®, first approved by the FDA in 2001, to more than 28 FDA-approved kinase inhibitors as of January 2016.[1] These molecules have found use among a variety of different cancers and malignancies and have made a tremendous impact on patients' lives. While the number of approved entities has risen dramatically over the years, there exist two fundamental challenges to the development of new drugs that must be overcome. Key among these challenges is minimizing activity versus the other human kinases (which number >500), which share the common adenosine triphosphate (ATP)-binding pocket most often targeted. Even if this selectivity hurdle can be met, the compound must be further optimized to achieve sufficient systemic exposure for 24 h kinase inhibition with once- or twice-daily dosing. One means of overcoming these hurdles is to utilize designed covalent inhibitors of target kinases. When the amino acid residues targeted by covalent inhibitors (most often cysteine) are shared by only a small group of kinases, this approach provides an extremely successful way of imparting selectivity. Furthermore, covalent binding by its nature avoids the need for systemic exposure to provide target coverage, as the inhibition lasts until new protein can be resynthesized. This review will provide an overview of the key concepts to be considered before embarking on a medicinal chemistry campaign using a covalent approach.

We will begin with a review of key considerations that should be analyzed with respect to the protein of interest. Is a targetable cysteine present? What other proteins share this cysteine? What is the protein turnover of this protein? Under what context is this measured? What is the potential for mutation and subsequent loss of efficacy? What risks are being taken by utilizing inhibitors that covalently modify proteins and can these be mitigated? Most fundamentally, what are the best ways to assess and optimize on-target efficacy using this approach?

The next portion of the review will look in detail at published efforts to inhibit specific kinases by utilizing covalent inhibitors. The examples will be grouped by protein target of interest, with particular focus placed on those targets (BTK, EGFR/HER2, and FGFR) where the approach has resulted in evaluation of covalent inhibitors in a clinical setting. Pioneering work that helped drive understanding will be highlighted, and the evolution of design elements and drug optimization strategies will be discussed. In cases where efforts have led to actual drug approvals (most notably with HER2, EGFR, and BTK inhibitors), emerging second-generation approaches and potential therapies will also be highlighted.

Finally, emerging trends in the field will be considered. Given the large number of kinases potentially targetable by covalent inhibitors, the field is likely to remain a vibrant area of research and an important source of new treatments for patients.

5.03.2 The Advantages of Covalent Kinase Inhibitors in Cancer

5.03.2.1 Achieving Highly Selective Kinase Inhibitors

Protein kinases, through the posttranslational phosphorylation of a wide variety of proteins in the body, play a critical role in human physiology. Dysregulation of these kinases, via activating mutation or upregulation, is implicated with a variety of different cancers. Recognition of this has led to focused efforts from the medicinal chemistry community to yield marketed drugs. However, due to the conserved nature of the nucleotide-binding pocket in kinases, many of these drugs have minimal selectivity versus the other kinases expressed.[2] Selective inhibition of kinases has been achieved by targeting binding pockets exposed in alternative kinase conformations, such as imatinib, which binds to the "DFG-out" conformation of c-Abl,[3] and lapatinib, which binds to the "C-helix-out" conformation of EGFR and HER2. Targeting nonconserved cysteines provides an attractive approach to achieving selectivity as many of these noncatalytic cysteines are in accessible regions of the catalytic binding site and share sequence alignment with a small subset of the broader kinase family. A recent analysis revealed that over 200 kinases contain an accessible cysteine near the ATP-binding pocket. These were categorized broadly into four distinct groups based on the common location of the cysteine.[4] These are highlighted in **Fig. 1**, which depicts the location of kinases sharing homologous cysteines within the phylogenetic tree.[5] Examples of selective kinase inhibitors targeting kinases in each of these classes will be described in detail in Sections "**Assessment and Optimization of Covalent Kinase Inhibitors in Cancer**" to "**Covalent Inhibitors of HER Family Kinases.**" A more recent exercise evaluated accessible cysteines predicted to be accessible in kinases in the "C-helix-out" and "DFG-out" conformations further broadening the potential targets amenable to cysteine targeting.[6]

It should be noted that the cysteine residues are not necessarily conserved across kinase genetic families. For example, the well-studied group 3F kinases share a common cysteine and include multiple members of the Tec (BMX, BTK, ITK, RLK, and TEC) and ERBB/HER (EGFR, ERBB2, and ERBB4) families. Group 3F also includes MKK7 (STE7 family), BLK (Src family), and JAK3 (Tec family), which are unique within their families in harboring a cysteine in this position. Structural differences among family members and patterns of cellular distribution allow for further selectivity to be realized, even where a targeted cysteine is shared by multiple kinases.

5.03.2.2 The Benefits of Prolonged Residence Time via Covalency

Many recent reviews have highlighted the concept of drug–target residence time as a factor, which should be optimized and exploited by medicinal chemists.[7] Covalent irreversible inhibition pushes this concept to an extreme case, wherein the inhibitor remains bound to protein and pharmacologically active until new protein is synthesized. If protein turnover is sufficiently slow (see in the succeeding text), the effect of a covalent inhibitor manifests itself long after clearance of the molecule from systemic circulation. This allows the possibility of achieving prolonged inhibition with relatively short periods of systemic exposure, lowered overall pharmacokinetic area under the curve (AUC), and potentially lower overall total body burden of drug. A second advantage arises from the fact that irreversible inhibition fundamentally changes the equilibrium toward bound complex. In cells, inhibitors must compete with the native endogenous kinase ligand ATP, which is present at concentrations of roughly 5 mM. The reduced cellular potency of many kinase inhibitors relative to inhibition of isolated kinases (cellular shift) due to high Km (ATP) can be mitigated with covalent inhibitors.[8] When assessing the selectivity of a covalent inhibitor, it is important to consider these benefits rather than relying on standard kinase inhibition assays. Noncovalent off-target inhibition should be transient, and therefore, the functional selectivity in vivo is underestimated by simple binding or activity assays, particularly as the drug clears rapidly from systemic circulation. On the other extreme, it should be noted that inhibitors possessing electrophilic moieties with very high intrinsic reactivity are prone to react with endogenous cellular cysteines such as glutathione, thereby reducing on-target cellular potency and leading to additional safety issues.

5.03.3 Assessment and Optimization of Covalent Kinase Inhibitors in Cancer

5.03.3.1 On-Target In Vitro Activity

In many instances, standard assays utilized in noncovalent medicinal chemistry campaigns targeting kinases are useful when screening for or optimizing covalent inhibitors. However, there are several caveats that should be noted when assessing data from these assays. Equilibrium measurements, IC_{50}s, while often reported and used for rank ordering inhibitors are technically inappropriate for use with covalent inhibitors where the off rate is very slow. These are often used due to assay simplicity, but longer incubation times will lead to more complete inhibition, and therefore, conditions should be rigorously controlled when producing "IC_{50} apparent" values, and caution should be taken when data are compared from different sources. While more time consuming, determination of a k_{inact}/K_i value is a preferred method of assessing the reactivity of a covalent inhibitor. In a crude sense, this differentiates the contribution of reversible binding-driven noncovalent interactions (K_i) from the irreversible covalent bond formation kinetics (k_{inact}). However, assuming typical incubation times are used (0.5–2 h), an IC_{50} apparent is reflective of physiologically relevant exposure, and the term IC_{50} will be used in this article when literature data are reported.

Validation that covalent bonding to a cysteine of interest is of critical importance when initiating a lead optimization campaign. In many instances, simple structure–activity relationships (SAR) allow one to determine that covalent bonding is occurring at a protein site of interest. A sharp reduction in activity by replacement of the electrophilic moiety (e.g., reduction of an acrylamide to an ethyl amide) is a typical hallmark of covalent inhibitors. Other indirect methods of confirming cysteine engagement include single-point mutation of the putative reactive cysteine. This should coincide with the loss of activity. Additionally, with irreversible

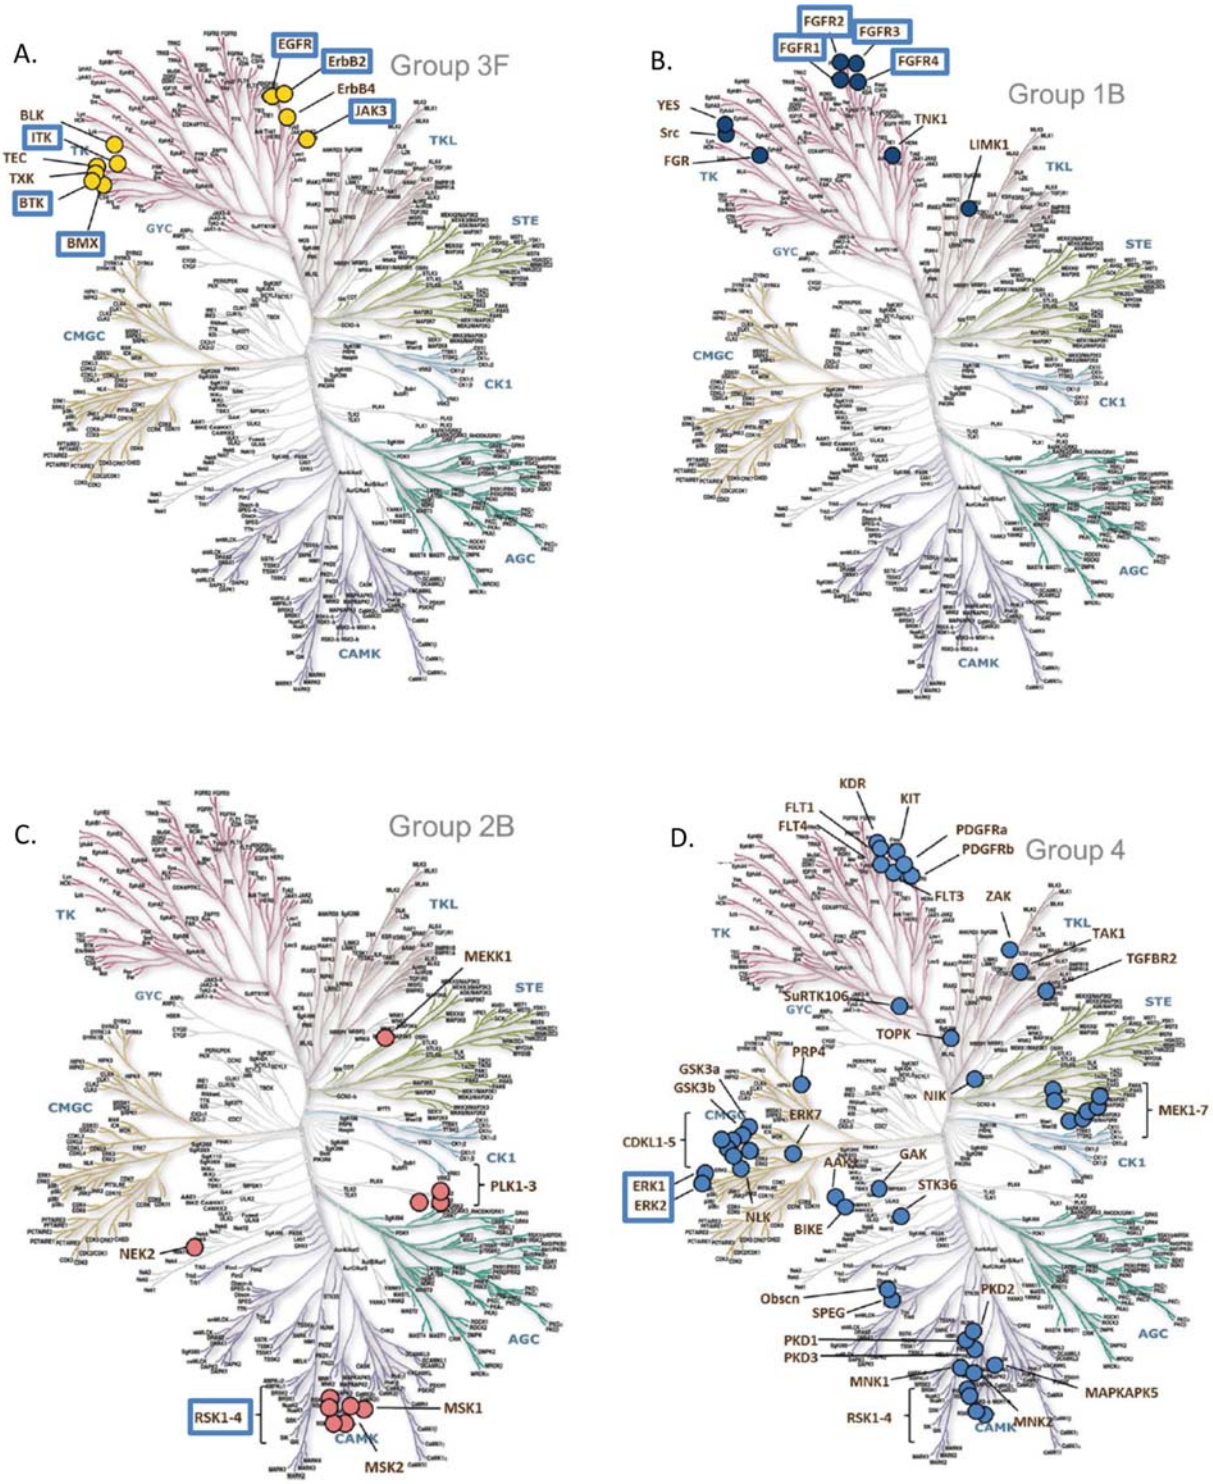

Fig. 1 The human kinome (adapted from Ref. 5 and courtesy of cellsignalling.com). Each phylogenetic tree highlights kinases containing shared targetable cysteines from a specific cysteine class. Kinases boxed in blue are proteins targeted covalently and discussed in this article. (A) group 1B, (B) group 2B, (C) group 3F, and (D) group 4 kinases.

covalent inhibitors, mass spectroscopy analysis allows unequivocal detection of the inhibitor bound to protein or peptide fragment from enzymatic digestion. Most informative for the medicinal chemist is confirmation of binding via x-ray diffraction as this confirms the covalent nature of the inhibition and also allows a snapshot of other critical binding (noncovalent) interactions and provides solid basis for structure-based optimization.

5.03.3.2 Structure and Reactivity of Covalent Electrophiles

Various electrophiles have been incorporated into covalent inhibitor designs and undoubtedly play a critical role in the success of this approach. The electrophile should be sufficiently reactive to engage the cysteine of interest after an initial binding event mediated by noncovalent interactions brings it into proximity. Preferably, the electrophile should not indiscriminately react with sulfhydryl groups present in off-target proteins or other endogenous thiols (such as glutathione). Among the more reactive groups (Fig. 2), the chloroacetamides, vinyl sulfonamides, and unsubstituted alkynyl amides have been incorporated into relatively selective inhibitors and found utility as chemical biology probes. Similarly, α,β-unsaturated esters and aldehydes are presumably too reactive to have found utility in kinase drug development. However, to date, kinase inhibitors utilizing these electrophiles have not been reported as clinical-stage drug candidates. As will be highlighted in individual examples later, the most prevalent electrophiles among approved drugs and clinical-stage inhibitors are the acrylamides, acrylamides substituted with pendant allylic amines, and butynamides. For Michael acceptors, substitution at the beta position greatly reduces the intrinsic reactivity. However, pendant allylic amines can serve to deprotonate nearby thiols and thereby assist the formation of the covalent adduct. Besides providing a linkage to the critical kinase hinge binding site, the substitution on the amide nitrogen is also critical to reactivity. Generally, acrylamides have been shown to be functionally inert with respect to common thiols such as glutathione, standing in contrast to more reactive electrophiles such as chloroacetamides.[9] The intrinsic reactivity can be modulated by steric and electronic factors, and a variety of attempts to experimentally determine reactivity have been undertaken. The rate of reaction with glutathione was assessed for a wide variety of chemical reactive groups (CRGs) incorporated into small fragment like molecules.[10] In addition to rank ordering functional groups for intrinsic reactivity, the data were compared with predicted reactivity from quantum chemical calculations to identify in silico methods with greatest prognostic value. The reactivity of aniline-based acrylamides with glutathione has also been assessed in the context of an EGFR inhibitor program.[11] The authors found that reactivity increased with electron-withdrawing groups and trended with EGFR IC_{50} measurements. A more recent study produced similar findings and also found a correlation between NMR chemical shifts of acrylamides and reactivity.[12] The reactivity of approved drugs can provide guidance and benchmarks when using these data. Generally, the intrinsic reactivity should be matched to the cysteine of interest, with selectivity driven by the proximity effect due to the concentration of inhibitor in its binding pocket. This should mitigate the possibility of unwanted side effects due to undesired modification of other thiols.

5.03.3.3 Safety Concerns

Despite the advantages discussed earlier and their immense promise as therapeutics, safety concerns have arisen over the development of drugs designed to permanently modify proteins, even to treat life-threatening conditions such as cancer. The risk is quite understandable, given the association between idiosyncratic adverse drug reactions (IADRs) and the potential of drugs to generate reactive metabolites, which can irreversibly bind proteins.[13] Besides permanently inhibiting a protein, covalent inhibitors remaining bound to proteins or protein fragments raise the risk of haptenization and potentially severe allergic responses. It should be noted that the reactivity of reactive metabolites associated with IADRs is typically much greater than that of the electrophiles described earlier. Of note, the overall daily dose of a drug has been shown to correlate well with the rate of IADRs and there are no examples of IADRs with drugs dosed below 20 mg/day.[14] Intriguingly, irreversible kinase inhibitors have great potential to meet this requirement due to the attributes described earlier (the lack of ATP competition and extended inhibition due to covalent mechanism of action). Nonetheless, efforts have been made to determine the propensity of a designed covalent inhibitor to react indiscriminately with cysteine-containing proteins.

Existing methods used in screening for reactive metabolites can be utilized for the purpose of assessing off-target activity, with the important caveat that these should be run without metabolic activation if one is to determine the intrinsic off-target liabilities of the parent drug. Typically, surrogates of native thiols such as glutathione are used to assess intrinsic reactivity of covalent kinase inhibitors.[15] Similarly, depletion of free drug after incubation in whole blood can be a sign of indiscriminate binding of a reactive inhibitor to proteins. In addition to being an operationally simple assay, it more closely mimics thiols in a native protein environment. More intricate methods have also been developed not only to look at reactivity but also to quantitate and identify proteins, which react with electrophilic inhibitors. Cravatt and coworkers have recently utilized activity-based protein profiling (ABPP) to demonstrate that at high concentrations in cells, a large number of kinases and nonkinase off-target proteins can react with

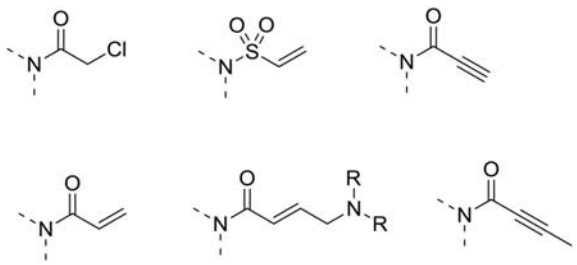

Fig. 2 Electrophilic moieties commonly used in covalent kinase inhibitors.

seemingly very selective acrylamide-based inhibitors.[16] In this study, structural analogs of ibrutinib (see 7.08.4) incorporated an alkyne to allow coupling to an azide-rhodanine tag via click chemistry. After incubation in cells or cell lysates at varying concentrations, incorporation of the tag allows one to visualize the proteins to which the probes bound via SDS-PAGE and in-gel fluorescence scanning. Using this method, Cravatt and coworkers uncovered multiple expected bands for the covalent binding of the probes to BTK and EGFR and unexpected bands, indicating the attachment to unrelated enzymes, which also contain reactive cysteine moieties. The use of covalent reversible inhibitors targeting RSK highlights a possible way to eliminate the risk of permanent modification of off-target proteins while benefiting from the long residence time and selectivity of irreversible inhibitors.[17] This concept has since been applied to BTK and FGFR,[18] as well as EGFR,[19] and is clearly an emerging area of the field. Regardless of reactivity, as with noncovalent drugs, standard safety assessments (time-dependent inhibition, genotoxicity, hERG, drug–drug interactions, etc.) must be taken into account with covalent inhibitors.

5.03.3.4 Pharmacodynamics of Covalent Inhibitors

The key advantages of covalent inhibitors rely on their ability to permanently modify and inhibit the protein of interest, thereby preventing signaling until new protein is produced. Protein turnover rate of a target of interest is therefore a critical element to understand when beginning a covalent inhibitor program. If protein synthesis takes place too quickly, unbound inhibitor must remain present to inhibit the newly formed protein. However, when protein synthesis is slow, prolonged inhibition with an irreversible inhibitor is expected even after the inhibitor has been cleared from systemic circulation. In this scenario, a disconnection exists between pharmacokinetics (PK) of the inhibitor and its pharmacodynamic (PD) effect.[20,21] For receptor tyrosine kinase EGFR, the rate of protein turnover is thought to be highly dependent on cell lines studied and the activation state of the receptor signaling pathway, with more rapid turnover when activated by EGF (1–4 h) and relatively slow turnover (7–28 h) under nonstimulated conditions.[22–24] Meanwhile, for the nonreceptor kinase BTK, a more consistent turnover rate has been estimated to be between 18 and 24 h.[18] With slower rates of protein turnover, high levels of target engagement and inhibition are expected for irreversible inhibitors long after clearance of the molecule. Methods to evaluate potential extended PD effects in preclinical and clinical studies are therefore fundamental to the development of covalent drugs given the challenges to predicting inhibition from PK exposure alone or simple cell-based turnover studies. Assessing in vivo target engagement during preclinical studies with model organisms or more critically in a clinical setting is crucial for development of drugs that cause a desired pharmacological effect while providing the greatest possible safety window possible. Noninvasive methods of determining target engagement can be challenging and include in vivo imaging techniques and ex vivo chemoproteomic analysis of human blood samples.[25] However, many targets are not amenable to these techniques or the readouts can be ambiguous if the effects measured are not directly proximal to the enzymatic activity (e.g., if multiple enzymes can perform the same function). Activity-based protein profiling (ABPP) methods, utilizing irreversible inhibitors that incorporate a reporter group, allow for ex vivo assessment of samples. For kinases inhibited by covalent inhibitors with prolonged target engagement, covalent inhibitor probe molecules can be designed for this purpose. If the probe molecule is cell-permeable, the probes can be used to monitor the level of target protein engagement ex vivo at different time points after administration of a drug. At certain time periods after dosing, blood or tissue samples can be harvested, and if the kinase of interest has been covalently modified, added probe molecule cannot bind, and the reporter signal is blocked. The amount of protein bound (percent occupancy) can then be estimated by comparison with control samples where no inhibitor is present. If full occupancy is achieved, probe molecules are able to bind only as new protein is produced and signal is restored, allowing an assessment of the role of protein turnover in an in vivo system. This ability to directly measure the occupancy of a drug on target allows preclinical and clinical assessment of target coverage requirements expected for efficacy. This has been used with great success in the development of BTK inhibitors (*vide infra*).[26]

5.03.4 BTK Inhibitors

5.03.4.1 Introduction of Target Biology

Bruton's tyrosine kinase (BTK) is a critical enzyme for the development and function of B cells, and genetic defects leading to X-linked agammaglobulinemia resulted in its discovery. It is believed to play an important role in a variety of hematologic malignancies and cancers and is implicated in a variety of autoimmune diseases and inflammatory conditions.[27] As such, great effort has been made by the medicinal chemistry community to identify potent and selective inhibitors of this enzyme. Along with 10 other kinases (including EGFR, HER2, JAK3, and ITK described in the succeeding text), BTK contains a cysteine (C481) that is accessible from the ATP-binding pocket with small-molecule inhibitors.[28] While noncovalent medicinal chemistry approaches have resulted in selective and potent inhibitors, to date, only covalent inhibitors have reached clinical efficacy studies. Ibrutinib (**1**) (**Fig. 3**), the first commercialized BTK inhibitor, is marketed as Imbruvica® and has now been approved for the treatment of a variety of cancers including chronic lymphocytic leukemia (CLL), mantle cell lymphoma (MCL), and Waldenström's macroglobulinemia.[29,30] Several groups have subsequently progressed covalent BTK inhibitors into the clinic. These compounds have been designed from various kinase inhibitor scaffolds and possess differentiated electrophilic warheads, with significant effects on intrinsic activity on BTK and inhibition selectivity within the 11 kinase "Cys family."

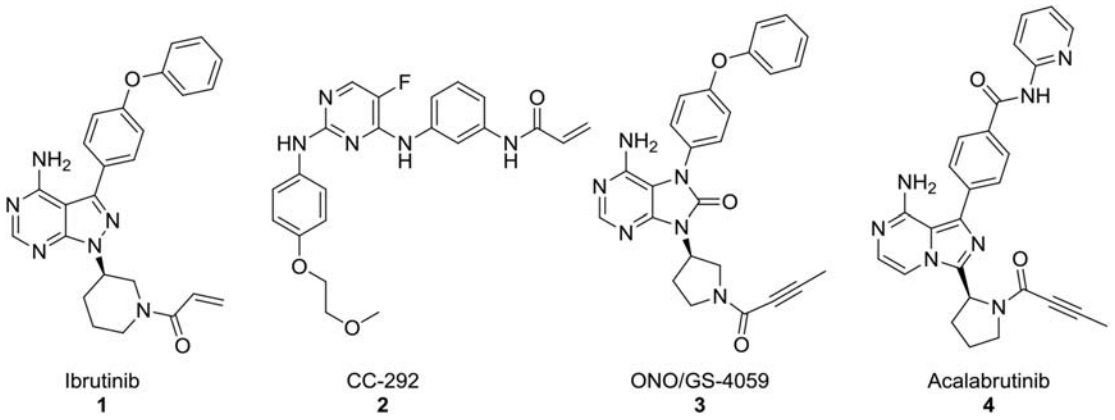

Fig. 3 Clinical-stage covalent BTK inhibitors.

5.03.4.2 Development of Clinical Covalent BTK Inhibitors

Using PCI-29732 (**5**) as a starting point, a variety of electrophiles and linker combinations were evaluated for their ability to engage C481 (Fig. 4).[31] While vinyl sulfonamides, chloromethyl amides, and alkynyl amides all exhibited excellent potency, the acrylamide using the (*R*)-piperidine linker was preferred. As expected by the covalent mechanism, compound **1** exhibited improved selectivity compared with **5**, which was reported to strongly inhibit both LCK and LYN. Furthermore, in preliminary arthritis models, efficacy was achieved with doses that did not require sustained exposure due to the irreversible inhibition of BTK. Subsequently, the utility of **1** for the treatment of B-cell malignancy was demonstrated by its effectiveness in treating naturally occurring canine B-cell non-Hodgkin lymphoma (NHL).[26] A partial response was seen in three of eight dogs at dosages between 2.5 and 20 mg/kg per day helping provide validation of the potential utility in clinic.

Critical to understanding mechanism and correlating level of BTK inhibition and effect, a prolonged inhibition of BTK was monitored by labeling peripheral blood mononuclear cells (PBMCs) with a fluorescently labeled analog of **1**. The BODIPY-FL fluorophore was attached via an aminoethyl piperizine linker to the electrophilic site of compound **1** to afford compound **6** (Fig. 5). Critically, probe **6** is cell-permeable and maintains activity against BTK. After treatment of B-cell lymphoma line DOHH2 cells with **6**, irreversibly bound proteins in cell lysates were resolved by electrophoresis and the predominant band identified as BTK. Binding of **6** could be completely blocked by prior treatment of cells with **1**, therefore providing a platform for preclinical and clinical measurement of BTK target occupancy via a competitive binding assay. This assay format was used successfully to confirm BTK occupancy in the canine lymphoma model earlier and subsequently with clinical PBMC samples. Similarly, modification of other clinical-stage BTK inhibitors described in the succeeding text resulted in cell-permeable probes utilized to assess occupancy in clinical studies. For example, CNX-500 (**7**) was developed as a probe and used for analysis of BTK occupancy in an ELISA-based format.

Clinically, **1** has shown excellent efficacy, with particularly high response rates in CLL and MCL,[32] resulting in breakthrough designations and subsequent approvals across a variety of hematologic cancers. In CLL, partial responses were seen in 89% of 85 patients.[29] Importantly, excellent activity has been seen in CLL patients with the difficult to treat del(17p) abnormality. Aside from excellent clinical activity, the side effects reported have been relatively mild with grade 1–2 diarrhea as the most frequently occurring event and diminished occurrence of grade 3 or greater events over prolonged treatment (3-year follow-up).[33]

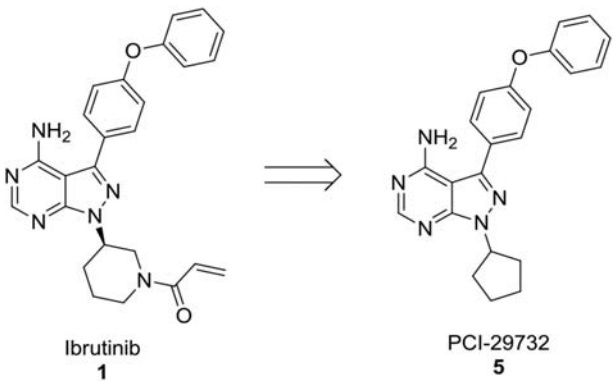

Fig. 4 Structural design evolution of ibrutinib.

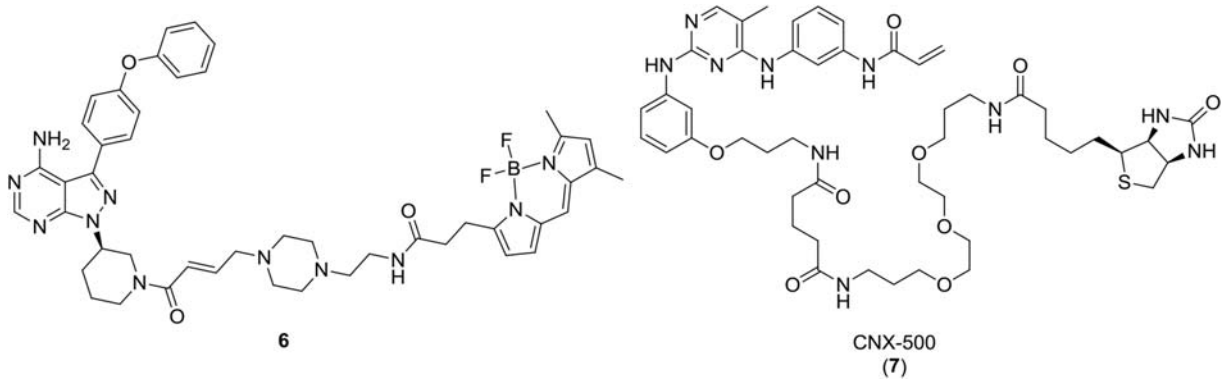

Fig. 5 Covalent BTK probe molecules.

From a pharmacokinetic standpoint, **1** is able to achieve excellent occupancy and inhibition of BTK long after clearance of the drug from systemic circulation. As described in the Section "The Benefits of Prolonged Residence Time via Covalency," this is a favorable attribute for an irreversible inhibitor as a lower AUC is required for efficacy. Interestingly, PK is highly dependent on whether **1** is dosed in a fed or fasted state, with a *c.* 40% reduction in exposure if dosed in the fasted state.[34] Furthermore, **1** is almost exclusively metabolized by CYP3A4, and there is therefore an associated risk for drug–drug interactions (DDI). Clinical trials in healthy volunteers found that administration of **1** after treatment with the CYP3A4 inhibitor ketoconazole greatly increased exposure, with the dose-normalized AUC increasing from 71.4 to 1599 ng·h/mL and dose-normalized C_{max} increasing c. 29-fold. This was associated with a reduction of the primary circulating metabolite PCI-4527 (the diol resulting from oxidation and hydrolysis of the acrylamide).

The selectivity of **1** in standard biochemical assays likely underrepresents the high selectivity within the kinome due to the disconnection between PK and PD. Even for kinases where the apparent IC_{50} is quite low, the concentration of drug is only transiently above this level, and the effects are therefore mitigated. Within the 10 kinases, which contain a homologous cysteine, however, the selectivity profile is significant. Among these 10, EGFR is known to be associated with side effects, such as often severe rashes on the face and upper body and indeed is inhibited by **1** ($IC_{50} = 5.6$ nM).[26] However, the inhibition of other kinases may possibly be of clinical benefit. For example, the inhibition of ITK ($IC_{50} = 2.2$ nM) is reported to be critical for the possible synergistic effect of **1** when coadministered with immune checkpoint inhibitors.[35]

Following the success of ibrutinib, multiple C481-targeting inhibitors have advanced into trials for treatment of hematologic malignancies. Avila and Celgene optimized an aminopyrimidine scaffold, attaching an acrylamide via an aniline linkage, culminating in CC-292 (**2**).[36] Compound **2** is a potent ($IC_{50} < 0.5$ nM and $K_{inact}/K_I = 7.69 \times 104\ M^{-1}\ s^{-1}$) and selective BTK inhibitor, which has no reported EGFR activity in cell-based assays. Clinically, **2** was tolerated at doses up to 1000 mg QD (once daily) and 500 mg BID (twice daily); however overall response rates did not achieve those of ibrutinib.

More recently, two BTK inhibitors containing a methyl alkynamide warhead have reached clinical studies. ONO/GS-4059 (**3**) utilizes a urea-based scaffold to display a phenoxy phenyl group in a similar position to that in **1**, with the electrophilic warhead attached via a pyrrolidine ring. Compound **3** is reported to have an $IC_{50} = 2.0$ nM and results of phase I studies have been published.[37] Treatment in patients with B-cell malignancies was well tolerated up to 600 mg QD and 300 mg BID in CLL with grade 3 or 4 adverse events occurring in 14% of patients in the CLL cohort. Initial efficacy looks promising with 66% of patients with CLL or MCL remaining on trial (median therapy duration of 21 months). From a pharmacokinetic standpoint, the drug is cleared rapidly with $T_{1/2}$ values between 6.5 and 8 h and shows dose linear increases in AUC. Using a twice-daily dosing regimen (240 mg or 300 mg), exposures did not change significantly from day 1 to day 28, highlighting a lack of drug accumulation.

Scientists from Acerta have advanced the imidazolopyrazine-based BTK inhibitor **4** into clinical trials, and it is reportedly advancing into phase III efficacy studies.[38] In addition to building from a different scaffold, inhibitor **4** also differs in that it displays the butynamide electrophile at the 2-position of the pyrrolidine ring relative to the scaffold versus the 3-position in compound **3**. Meanwhile, the phenoxyphenyl system common to **1** and **3** has been replaced with a pyridinyl benzamide group. A publication describing noncovalent BTK inhibitors with the same scaffold mentions that this substitution provides improved kinase selectivity.[39] The compound inhibits BTK slightly less potently (reported $IC_{50} = 5.1$ nM) but has a more selective inhibition profile compared with **1** with only BMX, TEC, TXK, and ERBB4 having $IC_{50} < 1$ μM among kinases containing the common cysteine. Based on reported phase I and II data, the drug is well tolerated with 53 of 61 patients remaining on treatment (median therapy duration of 14.3 months) with nausea (4 patients) being the most common grade 3 or 4 adverse event. Activity is encouraging, with an overall response rate of 95% across all cohorts. In contrast to **1**, the phase II expansion cohort was dosed twice daily (100 mg BID), presumably to maintain greater than 90% occupancy at BTK over 24 h. This may be critical for efficacy and possibly preventing progression to the more lethal Richter's transformation in this patient group.

5.03.4.3 Covalent BTK Inhibitor Outlook

With the approval of **1** for treatment of a variety of hematologic malignancies and multiple other covalent BTK inhibitors at various stages of clinical trials, a clearer vision of the safety and efficacy of this approach will emerge. Given the potential for BTK inhibitors as a component in combination therapies, their utility is likely to be tested in settings beyond blood cancers. One unique benefit of using covalent approaches will remain the ability to monitor the BTK occupancy of a clinical inhibitor ex *vivo*. This has been demonstrated with BODIPY-based probe **6** and with biotinylated probes such as **7** in an ELISA-based format. Regardless of approach, the ability to target-specific levels of occupancy throughout a dosing cycle is critical not only to maintain efficacy but also possibly to prevent or minimize protein mutation or transformation.

Intriguingly, the level of off-target (non-BTK) occupancy in theory can also be monitored. As an alternative to the direct readout probe approaches, a second option utilizes "two -step" bioorthogonal activity-based probes.[40] The cell-permeable and potent BTK inhibitor **8** (Fig. 6), incorporating a pendant alkyne to the phenoxyphenyl ring found in **1**, has been used as a surrogate to investigate the panproteome reactivity of compound **1**.[16] After incubating cells with **8** at varying concentrations, a reporter molecule containing an azide handle can be attached via "click" chemistry to allow visualization and identification of proteins that are likely irreversibly modified by **1**. Similarly, reactive terminal alkynes (**9**) or azides (**10**) have been attached to the electrophilic acrylamide center via a spacer similar to compound **6**.[41]

5.03.5 Covalent Inhibitors of HER Family Kinases

5.03.5.1 Introduction of Target Biology

The human epidermal growth factor receptor (HER) family of receptor tyrosine kinases (RTKs) is a well-established target for treating multiple types of solid tumors, most notably EGFR+ (positive) nonsmall-cell lung cancer (NSCLC) and Her+ breast cancer. The four members, epidermal growth factor receptor (EGFR; also known as HER1 (ErbB1), HER2 (ErbB2), HER3 (ErbB3), and HER4 (ErbB4)), play critical roles in various signaling pathways, leading to cell growth, proliferation, differentiation, and survival.

5.03.5.2 Covalent HER Family Kinase Inhibitors

Activating mutations in EGFR are responsible for a significant percentage of NSCLC malignancy (10–15% for European descent; c. 30% for patients of East Asian descent). First-generation, noncovalent EGFR inhibitors such as erlotinib (**10**) and gefitinib (**11**) (Fig. 7) showed dramatic clinical responses in patients with the most common EGFR mutations (L858R mutation in exon 21 and delE746-A750 in exon 19). Discovery of oncogenic drivers such as EGFR and specific targeting has been a major breakthrough in targeted cancer therapy and led to a paradigm shift in cancer treatment. However, patients often acquire drug resistances, often as a result of mutations that render drugs significantly less active.

In approximately 60% of patients that developed resistance to first-generation EGFR inhibitors, a point mutation occurred at the gatekeeper position of the EGFR kinase domain (T790M). There are two proposed mechanisms for the loss of clinical efficacy of first generation of EGFR inhibitors associated with the single amino acid mutation of threonine to methionine: (1) The mutated methionine residue possesses a bulkier side chain that can sterically impede the binding of the reversible inhibitors and disrupt the formation of a crucial water-mediated hydrogen bond between inhibitors and T790M EGFR;[42] (2) T790M EGFR was shown to have an increased affinity for ATP, resulting in reduced cellular potency for first-generation noncovalent ATP-competitive EGFR inhibitors.[43] It was found that the T790M-mutant EGFR remains sensitive to covalent irreversible EGFR inhibitors, such as EKB-569 (**12**, pelitinib) and HKI-272 (**13**, neratinib).[42] The activity toward mutant EGFR was attributed to the irreversible mechanism of action of covalent inhibitors, overcoming competitive binding of ATP. A number of these second-generation covalent EGFR inhibitors

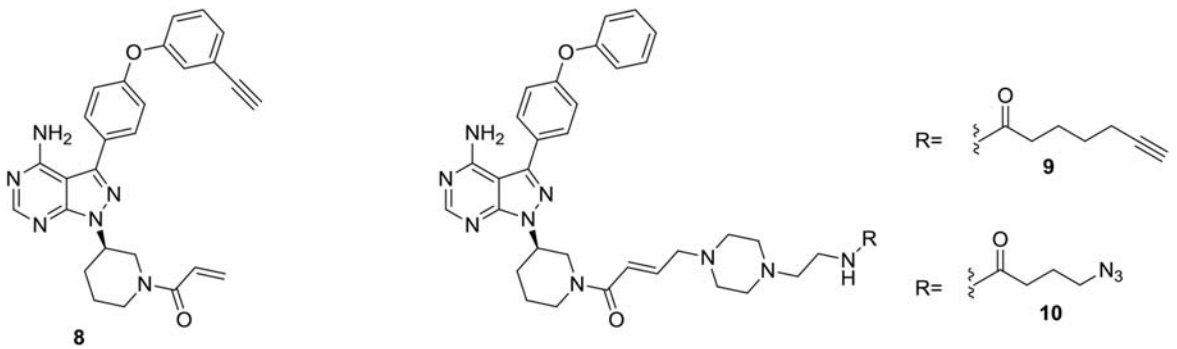

Fig. 6 Covalent BTK bioorthogonal probe molecules.

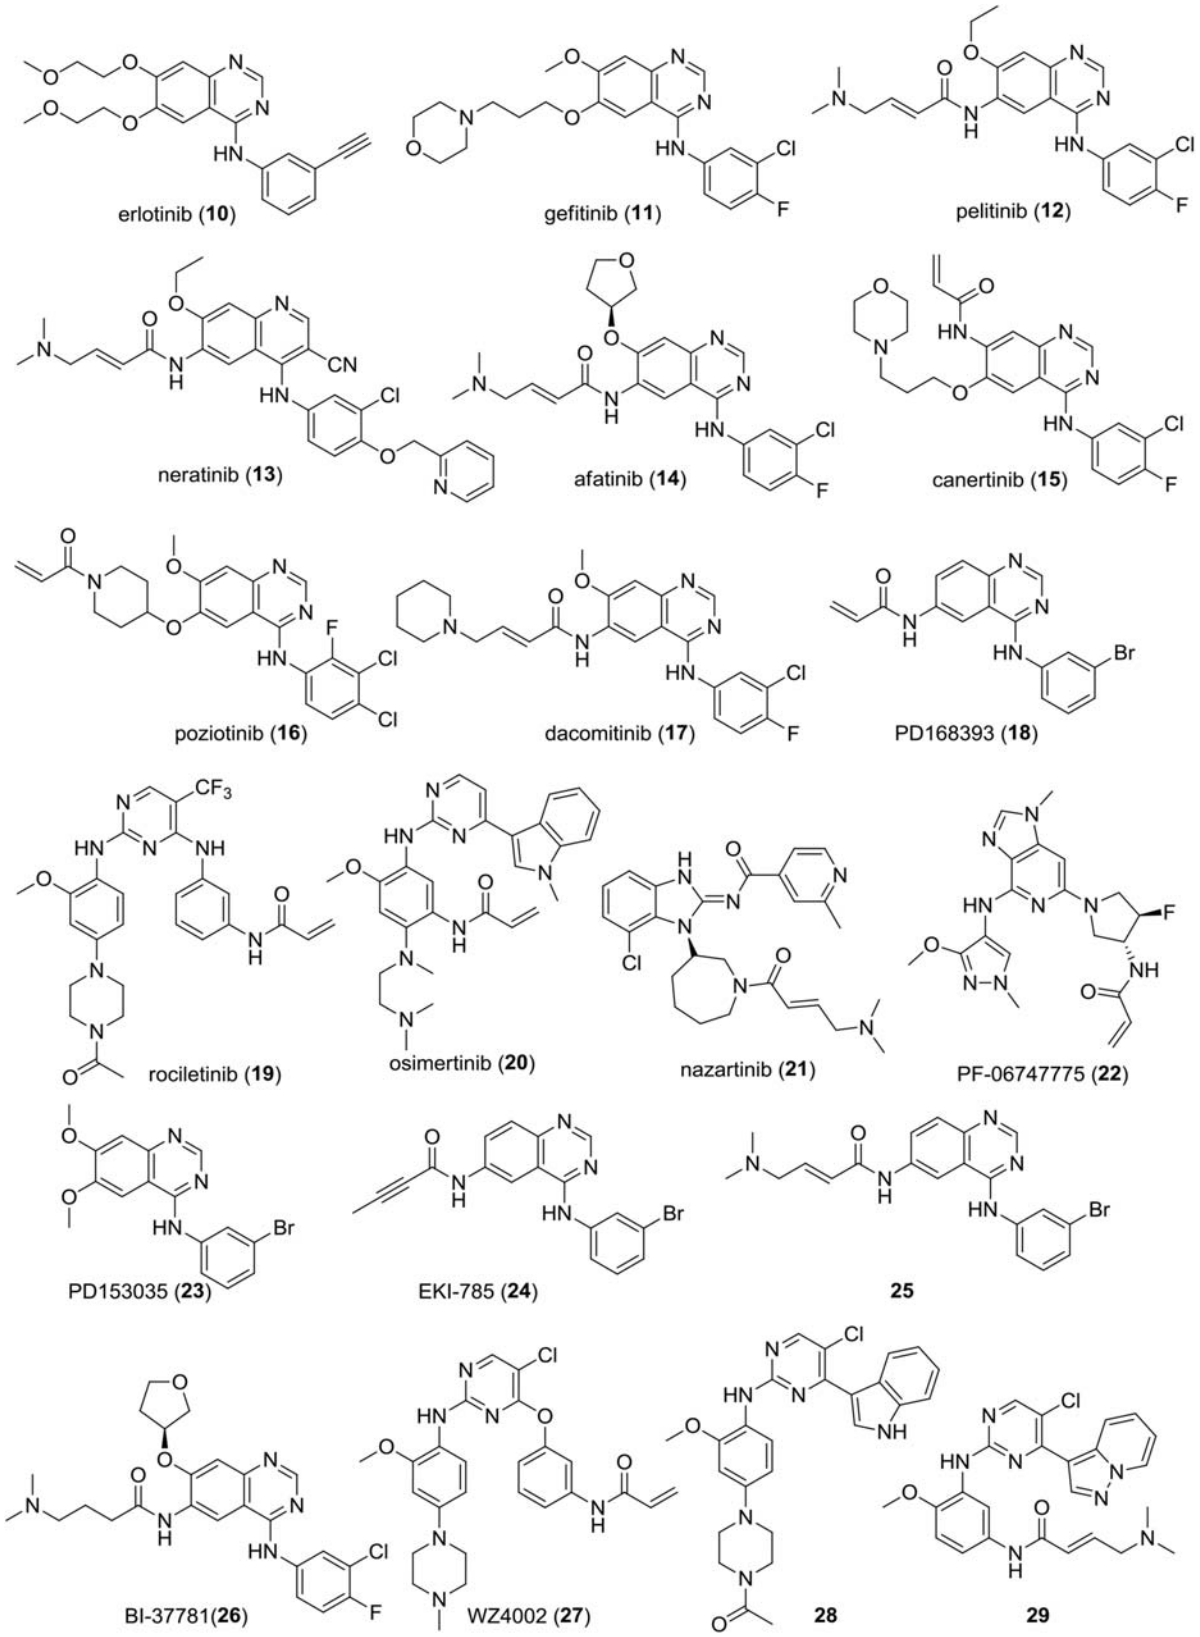

Fig. 7 Chemical structure of EGFR inhibitors.

were advanced into clinical trials, including **12**, **13**, afatinib (**14**, BIBW2992), canertinib (**15**, CI1033), poziotinib (**16**, HM781-36B), dacomitinib (**17**, PF299804), and PD168393 (**18**). Some of these drugs were developed as pan-HER inhibitors for HER+ breast cancer due to their concurrent activity against HER2, such as **13** and **18**.

Although second-generation irreversible HER family inhibitors are able to inhibit T790M-mutant EGFR in vitro, and thus progressed into clinic, these agents have not been shown to induce compelling responses in patients that have failed first-generation tyrosine kinase inhibitors (TKIs).[44] This is likely due to their potent inhibition of wild-type (WT) EGFR and consequent dose-limiting toxicities including diarrhea and skin rash, which prevented them from reaching exposures in the clinic required to inhibit T790M in tumor tissue. Therefore, third-generation, WT-sparing covalent EGFR inhibitors were developed, and multiple compounds have advanced into clinic trials, including rociletinib (**19**, also known as CO-1686/AVL-301/CNX-419), osimertinib (**20**, AZD9291), nazartinib (**21**, EGF816), and PF-06747775 (**22**).

5.03.5.3 Second-Generation Irreversible HER Family Inhibitors

The pioneering work by the Wyeth group in the area of covalent EGFR inhibitor discovery was partly driven by uncovering unique intellectual property derived from a quinazoline scaffold utilized in potent and reversible EGFR inhibitors[45] such as PD153035 (**23**) disclosed by Parke-Davis. Modeling efforts using the crystal structure of **10** bound to EGFR contributed to the design and evaluation of compounds with an acrylamide Michael acceptor group attached at diverse positions on the 4-anilinoquinazoline core including the 6- and 7-positions of the bicycle and various positions on the aniline group. This led to the discovery of PD168393 (**18**) with the acrylamide at the 6-position, exhibiting exceptional potency against EGFR (IC_{50} of 2 nM). Washout experiments provided substantial indirect evidence that **18** was indeed an irreversible inhibitor. Interestingly, Parke-Davis independently discovered compound **18** at almost same time and confirmed its irreversible inhibition of EGFR by mass spectral studies and identified C773 as the target residue.[19] The first preclinical candidate from the effort was EKI-785 (**24**), containing 6-butynamide as the electrophile. Despite good in vitro and in vivo activity, poor oral exposures due to poor aqueous solubility together with histological findings in the kidneys prevented its advancement into clinic. Though simple alkyl substitutions of the acrylamide olefin resulted in the loss of activity, it was found that incorporation of a basic water-solubilizing group in compound **25** maintained potent EGFR inhibition. By measuring the relative amounts of Michael addition products with glutathione, the order of reactivity was found to be **25** > **18** > **24**. The enhanced reactivity of **25** was hypothesized to be the result of the dialkylamino group functioning as an intramolecular general base catalyst for the Michael addition reaction. Further optimization effort led to the discovery of two clinical molecules, first **12** (EGFR IC_{50} of 8 nM and HER2 IC_{50} of 378 nM) and then **13** with more potent HER2 activity (pEGFR IC_{50} of 92 nM and pHER2 of 59 nM).[45] Phase I studies of **13** with once-daily doses in the range of 40–500 mg determined the maximum-tolerated dose to be 320 mg, with grade 3 diarrhea as a dose-limiting toxicity. In Phase II trial of patients with advanced NSCLC where disease had progressed following treatment with **10** or **11**, no meaningful clinical benefit was observed. Despite the preclinical data supporting **13** in overcoming T790M mutation, no patients with a known T790M mutation responded.[46] This could be due to insufficient drug exposure achieved in clinic; as in particular, the patients initially receiving 320 mg/day received a reduced dose of 240 mg/day due to dose delays and dose-limiting diarrhea. Because of its significant HER1/HER2/HER4 activity, **13** is currently undergoing multiple phase III clinical trials to evaluate its efficacy in HER2+ breast cancer patients as single agent or in combination.[47]

Structurally related **14** is currently the only marketed second-generation covalent EGFR inhibitor, approved for first-line treatment of patients with metastatic NSCLC with EGFR exon 19 deletions or exon 21 (L858R) mutations. Compound **14** potently inhibited wild-type EGFR (IC_{50} of 0.5 nM) and oncogenic mutants EGFRL858R (0.4 nM) and EGFRL858R/T790M (10 nM). Compound **14** also displayed nM activity-inhibiting proliferation of H1975 cells (EGFRL858R/T790M) with EC_{50} of 92 nM, whereas its corresponding noncovalent analog BI-37781 (**26**) was ineffective even at very high concentrations (>4 μM).[48] In two randomized, open-label, multinational phase III trials, progression-free survival (PFS) was significantly prolonged with **14** compared with pemetrexed plus cisplatin (LUX-Lung 3) or gemcitabine plus cisplatin (LUX-Lung 6) in treatment-naïve patients with advanced NSCLC with activating EGFR mutations.[49] Phase III trial (LUX-Lung 5) demonstrated clinical benefit in patients with NSCLC progressing after treatment with **10** or **11**. Despite no difference in overall survival, PFS and overall response rate (ORR) were significantly improved with **14** plus paclitaxel compared with paclitaxel alone (5.6 months and 32.1% vs. 2.8 months and 13.2%). The common side effects were in line with anticipated wild-type EGFR inhibition.[50] Given the marginal clinical benefits, if any, for nonmutant-selective irreversible EGFR inhibitors, it was clear that to better evaluate the potential of irreversible EGFR inhibition in treating acquired secondary mutation, new molecule was necessary. In particular, minimizing the dose-limiting toxicities of diarrhea and rash via improved selectivity against wild-type EGFR would be desirable to attain the maximum drug concentration in plasma and in tumors required to inhibit T790M EGFR.

5.03.5.4 Third-Generation Irreversible Mutant-Selective EGFR Inhibitors

Discovery of WZ4002 (**27**) marked a significant advance in discovering next-generation mutant-specific EGFR inhibitors that could overcome gatekeeper T790M mutation while sparing wild-type EGFR.[51] The pursuit started with synthesis of a focused library of common kinase inhibitor core scaffolds where one of the side chains was modified with an acrylamide group at a position that molecular modeling predicted to react with C797 of EGFR. Then, the library was screened for compounds that could inhibit the growth of PC9GR EGFRdel19/T790M and PC9 EGFRdel19 cell lines but was not toxic up to 10 μM against EGFR wild-type cells.

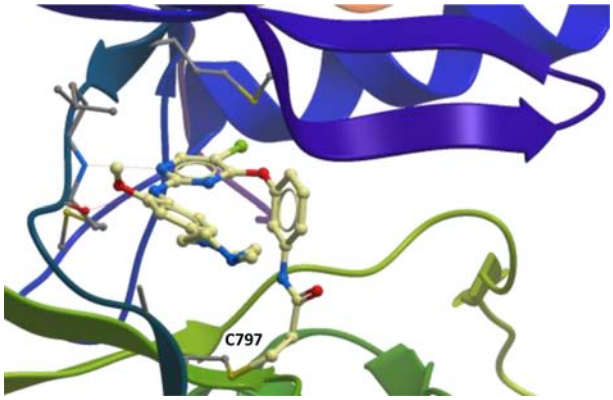

Fig. 8 WZ4002 (**27**) covalently bound to EGFR 696-1022 T790M mutant (PDB code, 3IKA; 2.9 Å).

27, with an aminopyrimidine core, was one of the three hits that possessed 300-fold lower EC_{50} (14 nM) against PC9GR EGFR-del19/T790M than **13** (>3.3 μM). It was more potent against EGFR double-mutant Ba/F3 cells (EC_{50} of 8 nM) than WT EGFR Ba/F3 cells (EC_{50} of 113 nM). Mass spectrometry studies confirmed a covalent mechanism of action and C797 as the site of modification. Crystallographic studies provided insight into why **27** was much more effective against L858R/T790M EGFR than **13**. In contrast to **13** that wrapped around the gatekeeper residue, **27** approached but did not surround the gatekeeper residue. While both compounds are irreversible inhibitors, the binding mode of **27**, together with the increased ATP affinity for the T790M mutant, accounts for its greater potency against T790M mutants versus better activity of **13** in WT EGFR. (Fig. 8).

5.03.5.4.1 Development of rociletinib (19)

Though **17** did not advance into clinical testing, structurally related **19** was discovered as the first mutant-selective inhibitor that progressed into clinical studies for patients with EGFR-mutant advanced NSCLC who have received prior EGFR therapies.[52–54] Compound **19** potently inhibited proliferation in the mutant-EGFR NSCLC cells with EC_{50} values ranging from 7 to 32 nM albeit with much weaker EC_{50} of 547 nM for WT EGFR A431 cells.[54] Cellular time-dependent inhibition and target occupancy studies were conducted in H1975 EGFRL858R/T790M cells, taking advantage of the lack of binding of L858R-specific EGFR antibody to ligand-bound protein.[53] H1975 cells were treated with 500 nM (c. 10-fold EC_{50}) of **19** for 1 h, followed by wash off of excess compound. Recovery of EGFR modulation and target occupancy by **19** was evaluated over time. Approximately 50% of activity was recovered at 16 h, which is consistent with reported mutant protein turnover rate under these conditions.[53] To determine time-dependent inhibition of EGFRL858R/T790M kinase, H1975 cells were treated with 500 nM **19** for 5–60 min and evaluated for EGFR modulation. Inhibition occurred rapidly with more than 50% EGFR signaling modulation achieved within 15 min of compound exposure and complete inhibition at 30 min. In line with in vitro observations, in vivo PK/PD experiments in H1975 xenograft model showed that maximum pharmacodynamic modulation (>90%) was observed at 6 h postfinal dose despite plasma exposure of **19** dropping fivefold at 100 mg/kg dose. Tumor regressions were observed in dose groups of either 100 mg/kg once daily (QD) or 50 mg/kg twice daily (BID), where BID schedule was statistically superior to QD schedule.[54] Immunohistochemical analysis of normal mouse skin from **26**-treated animals showed no inhibition of WT EGFR, confirming that compound **19** was wild-type sparing. Clinical evaluation of **19** supported significant benefit for NSCLC patients with the EGFR T790M mutation with no dose-related diarrhea or rash, clearly differentiated from previous EGFR inhibitors. Compound **19** won FDA breakthrough drug designation based on an overall tumor response rate that was reported early on at more than 50%. However, the final response rate reported for its 500 mg dose was lowered to 38%. The agency's review also noted serious adverse events in the studies of **19**, singling out hyperglycemia and QTc prolongation leading to torsades de pointes—a lethal irregular heart rhythm—which would require a "black box" warning if the drug is approved for marketing. Further clinical development of **19** was recently halted, which highlights the challenges and the need for optimization of covalent drug molecules.

5.03.5.4.2 Osimertinib (20)

Compound **20** is the first mutant-selective EGFR approved to treat T790M-positive NSCLC patients who progressed on or after EGFR inhibitor therapy. Its discovery started with testing a selected set of internal AstraZeneca compounds against the EGFR wild-type and double-mutant enzymes using biochemical assays to look for desirable hits suitable for medicinal chemistry optimization.[11] In the screen, a series of compounds were found to be active against double-mutant EGFR with selectivity over wild type, represented by **28** with a pyrimidine core containing an indole headgroup. It had an IC_{50} of 9 nM against the double mutant with 88-fold selectivity over wild-type EGFR, albeit with a large enzyme to cell drop-off of around 90-fold when it was tested in double-mutant cellular assays (IC_{50} 0.77 μM). The lead optimization effort focused on reducing lipophilicity, using $LogD_{7.4}$ measurement as a surrogate to improve upon in vivo clearance. Effort was also focused on modulating compound reactivity with glutathione (GSH) to find a "reactivity window" to achieve sufficient chemical reactivity toward the active-site residue while balancing against

unwanted target binding that could lead to high compound clearance and/or idiosyncratic toxicity. Using **14** as a reference compound with limited off-target effects, a half-life of 25 min (disappearance of electrophile on incubation) was adopted as the upper limit to the window of reactivity to work within. The optimization resulted in the identification of an in vivo tool compound **29**. Compound **29** potently inhibited H1975 EGFRL858R/T790M cells with EC_{50} of 96 nM and very weakly inhibited WT LoVo cells with EC_{50} of 23 μM. Its LogD7.4 and half-life against GSH were found to be 3.6 and 352 min, respectively. **29** had good bioavailability in rat (F = 45%) and showed 134% tumor growth inhibition (TGI) in the PC9-activating EGFR-mutant xenograft model versus modest 46% TGI in the WT EGFR-driven A431 xenograft model when dosed at 60 mg/kg/day. Assessment of kinome selectivity for this series of compounds revealed significant off-target inhibition of IGF1R (IC_{50} of 4 nM for **29**), which also bears a methionine gatekeeper residue. While IGF1R inhibitors have been employed in a clinical setting, they have been associated with dose-limiting toxicity of hyperglycemia, which was observed as a side effect for **19**. Further optimization effort led to the identification of **20** with improved rat PK (rat F = 45%) and improved IGF1R selectivity (IC_{50} of 2.9 μM) while maintaining good cellular activity for T790M EGFR (H1795 EC_{50} 24 nM) and selectivity against WT EGFR (LoVo EC_{50} 264 nM).[55] Daily dosing of 5 mg/kg of **20** induced profound and sustained regression in multiple mutant EGFR xenograft models and transgenic models. Although, in mice, the pharmacokinetic half-life of **20** is only approximately 3 h, phospho-EGFR staining remained significantly diminished even after the 30 h time point, consistent with its expected irreversible mode of action.[56] The development of **20** represented one of the fastest successful development programs—going from the start of clinical trials (2013) to approval (2015) in just over two and a half years and satisfying an unmet patient need. The FDA approval of **20** is based on data from the two AURA phase II studies (AURA extension and AURA2), which demonstrated efficacy in 411 EGFR T790M NSCLC patients that had progressed on or after prior EGFR TKI treatment. In those trials, overall objective response rate (ORR) as a measurement of tumor shrinkage was 59% (95% CI, 54–64%). In a separate part of the AURA study in 63 patients, ORR was 51%, and median duration of response was 12.4 months. It was worthy to note that common side effects of **20** include rash and diarrhea, commonly observed in patients treated with nonselective EGFR inhibitors. However, the severity of the side effects seems to be reduced, with, for example, 0.5% of grade 3–4 rash observed in patients treated with **20** versus 6% of grade 3–4 rash observed in patients treated with **10**.

5.03.5.5 Acquired Resistance to Third-Generation Covalent EGFR Inhibitors

The clinical success of third-generation mutant-selective covalent EGFR inhibitors for the treatment of T790M-positive patients was again met with new resistance within months.[57] In a reported study of **20**, 6 out of the 15 resistant patients (all positive for T790M mutation before treatment) developed a mutation that substitutes a less nucleophilic serine residue for the reactive cysteine residue (C797S), while four lost T790M mutation despite the presence of the underlying EGFR-activating mutation.[58] This point mutation of C797S compromises the irreversible bond formation as the nonactivated serine residue at this location no longer undergoes Michael addition at physiological conditions, leading to a substantial loss of potency. Furthermore, with the change in mechanism of action from covalent irreversible inhibition to noncovalent reversible inhibition, the benefits of sustained pharmacodynamics are lost. Particularly troublesome, the C797S mutation is refractory to all existing EGFR therapies.[58] Interestingly, resistance mechanisms for **19** include the loss of T790M mutation, EGFR amplification, and transformation to small-cell lung cancer, where 6 out of 12 patients lost T790M mutation.[59] It is interesting to note that the loss of T790M, not C797S mutation, is a common resistance mechanism identified for the two structurally differentiated inhibitors.[60] This may be due to the loss of favorable interactions both compounds make with the gatekeeper methionine residue of the T790M EGFR mutant. Therefore, it will be interesting to see the clinical performance of other wild-type-sparing covalent EGFR inhibitors, which maintain potent activity against both T790 wild type and T790M-activating EGFR mutants. One such compound in clinical evaluation is EGF816 (**21**).[61] Compound **21** had potent cellular activity for inhibition of proliferation of mutant EGFR cell lines: H3255L858R (EC_{50} 9 nM), HCC827del19 (EC_{50} 11 nM), and H1975L858R/T790M (EC_{50} 25 nM). Furthermore, **21** was selective against WT EGFR cell lines: HN1 (EC_{50} 5.8 μM) and MGH025 (ALK+, EC_{50} 29.7 μM). C797S mutation, MET amplification, and epithelial–mesenchymal transition (EMT) were found to be the major mechanisms of acquired resistance to **21** in preclinical models.[61] Phase I/II trials of **21** are ongoing for NSCLC patients harboring EGFR mutations (ClinicalTrials.gov identifier, NCT02108964). Clinical efficacy readouts and tracking the development of resistance mechanisms of **21** will further advance our understanding of the prospects and the potential concerns of emerging resistance with third-generation mutant-selective covalent EGFR inhibitors.

5.03.6 Covalent Inhibitors of FGFR Family Kinases

5.03.6.1 Introduction of Target Biology

The human fibroblast growth factor receptor (FGFR) family of receptor tyrosine kinases (RTKs) consists of four isomers FGFR1-4, which are sensors of a diverse family of eighteen FGF ligands. FGFRs are key regulators of fibrogenesis, embryogenesis, angiogenesis, metabolism, and many other processes of proliferation and differentiation.[62] Dysregulation of FGFR signaling through mutation, chromosomal translocation, gene amplification, or overexpression has been linked to numerous cancers and resistance to cancer therapies.[63] For example, FGFR1 amplification and translocation occur in various cancers including squamous nonsmall-cell lung carcinoma; FGFR2 amplification, mutation, and translocation are observed in gastric cancer and other cancers; FGFR3 is commonly amplified in bladder cancer; FGFR4 is amplified in multiple cancers, including hepatocellular carcinoma.[64]

5.03.6.2 Covalent FGFR Family Kinase Inhibitors

Supported by compelling genetic data implicating FGFRs in cancers, several small-molecule ATP-competitive inhibitors have been discovered and are being evaluated in clinical studies, which include the noncovalent selective pan-FGFR inhibitors NVP-BGJ398 (**30**),[65] AZD4547 (**31**),[66] LY2874455 (**32**),[67] and JNJ-42756493 (**33**)[68] (Fig. 9). While early-stage clinical results from selective pan-FGFR inhibitors show a clear signal of biological activity, preclinical in vitro studies have suggested the possibility of gatekeeper residue mutation as an emerging mechanism of resistance.[69]

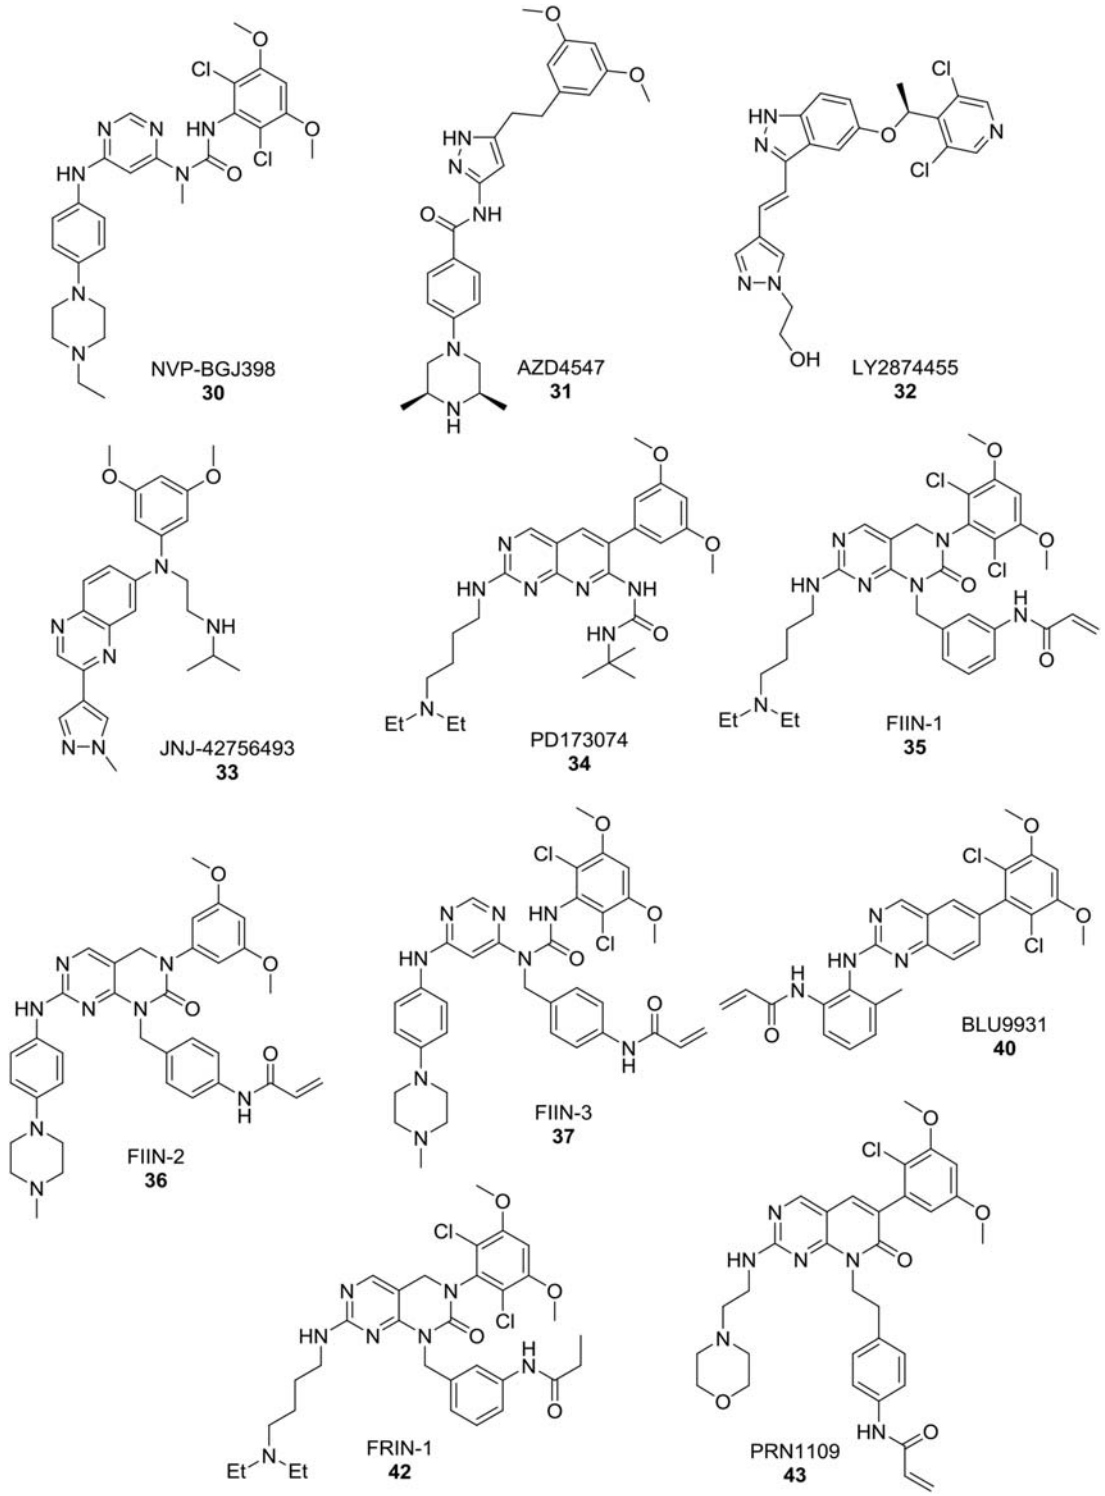

Fig. 9 Chemical structures of FGFR inhibitors.

All FGFR kinases have a valine residue at the kinase gatekeeper position, in contrast to other tyrosine kinases such as EGFR, which possesses a threonine gatekeeper whose mutation to a larger hydrophobic methionine residue in clinic leads to drug resistance.[42] Gatekeeper FGFR1 V561M mutation was reported to induce strong resistance to the noncovalent FGFR inhibitor PD173074 (**34**).[70] Similarly, FGFR3 V555M was found to be cross-resistant to **34** and **31**.[71] Somatic FGFR4 V550M mutation was reported in 9% of embryonal rhabdomyosarcoma tumors[72] and 13% of neuroendocrine breast carcinomas.[73]

Given the precedence of covalent EGFR inhibition overcoming gatekeeper EGFR T790M mutation in treating NSCLC, covalent FGFR inhibitors such as FIIN-1 (**35**),[70] FIIN-2 (**36**), and FIIN-3 (**37**)[69] were discovered and shown preclinically to maintain potent antiproliferative activity toward Ba/F3 cells expressing gatekeeper FGFR mutations.[69] Two covalent pan-FGFR inhibitors TAS120 (**38**, structure not disclosed)[74] and PRN1371 (**39**, structure not disclosed),[75] targeting the FGFR family conserved cysteine in the kinase P-loop, have been advanced into clinical trials. Isoform-selective irreversible FGFR4 inhibitors such as BLU9931 (**40**)[76] and BLU-554 (**41**, structure not disclosed), targeting the unique hinge C552, have also been discovered and developed to treat FGFR4-dependent cancers, with limited off-target activity against other FGFR family members.[76]

5.03.6.2.1 FIIN-1 (35)

The design of **35** was based on using the pyrimidopyridine **34** as the lead scaffold, given its selectivity for FGFR and available cocrystal structure with FGFR1.[70] Inspection of the crystal structure implicated that C486 in the P-loop of FGFR1, which was mutated to alanine, was approximately 10 Å away from the pyridine nitrogen of **34**. Switching to a bioisosteric pyrimido[4,5]pyrimidine core allowed attachment of a benzyl linker group, which provided a suitable vector to install an acrylamide warhead group to engage C486. The properly displayed acrylamide was combined in **35** with optimized back-pocket substituents for improved FGFR activity and selectivity. Compound **35** has potent binding affinity for FGFRs with K_d values of 2.8, 6.9, 5.4, and 120 nM for FGFR1/2/3/4, respectively, in agreement with corresponding biochemical IC_{50} values of 9.2, 6.2, 11.9, and 189 nM. Evaluation of selectivity against a panel of 402 kinases using Ambit KINOMEscan® technology at 10 μM concentration showed excellent selectivity, including kinases such as c-Src, TNK1, and YES that have a P-loop cysteine at the same positions as the FGFRs. The importance of the acrylamide function was confirmed by significant loss of activity for the isosteric propyl amide analog FRIN-1 (**42**). Compound **35** potently inhibited the proliferation of MCF10A cells with inducible FGFR1 with IC_{50} of 2.7 nM, as compared with the 10-fold activity loss for **42** in the same system (IC_{50} of 29 nM). In line with the importance of covalently targeting C486, **35** and **42** were found to be equally potent for the same cell line with C486S FGFR1 mutant. Compound **35** was active in a number of FGFR-dependent cancer cell lines versus EC_{50} of 14 nM and 30 nM for KATO III and SNU-16, two gastric cancer cell lines with FGFR2 amplification and activation. Compound **35** was also evaluated for its activity against the V561M gatekeeper mutant of FGFR1 in HEK293 cells transiently transfected with WT FGFR1 or V561M FGFR1. It was found that **35** could effectively block autophosphorylation of FGFR1 V561M at high concentration (10 μM) while the noncovalent inhibitor **42** was inactive. However, further optimization would be required to obtain an inhibitor with a useful level of potency against the V561M mutant.[70]

5.03.6.2.2 FIIN-2 (36)/FIIN-3 (37)

SAR work around side chains and core scaffolds of **35** led to two compounds **36** and **37** with improved activity for inhibiting the proliferation of Ba/F3 cells engineered to be dependent on WT FGFRs and V564M FGFR2.[69] The key new feature of **36** was the replacement of the aliphatic amine in **35** with a stronger hinge-binding group, 4-(4-methylpiperazine-yl) aniline. Compound **36** incorporated a pyrimidyl urea core that could form a *pseudo*-six-membered ring, a feature of **30**, which might provide greater rotatory flexibility for the substituted phenyl group binding in the back pocket. Additionally, both **36** and **37** display the acrylamide moiety at the *para*position of the benzyl linker, in contrast to the *meta*position in **35**. Both compounds inhibited WT FGFRs with EC_{50} values in the 1–93 nM range and maintained potent activity against V564M FGFR2 (58 nM for **36** and 64 nM for **37**), as compared with 1000 nM for **35** and 1500 nM for **30**. In line with this observation, **36** and **37** showed less than fivefold loss for FGFR1 V561M mutants in both H2077 and H1581 lung cancer cells, whereas the noncovalent inhibitor **30** had an over 50-fold activity loss.[69] The cocrystal structure of **36** with FGFR4 confirmed its covalent mechanism of action engaging the conserved cysteine (C477 for FGFR4) (Fig. 10).

5.03.6.2.3 TAS-120 (38)/PRN1371 (39)

At least two covalent pan-FGFR inhibitors, **38** (ClinicalTrials.gov identifier, NCT02052778) and **39** (ClinicalTrials.gov identifier, NCT02608125), have been advanced into clinical trials for patients with advanced solid tumors. PRN1371 (**39**) is structurally related to PRN1109 (**43**).[75] Both **39** and **43** are potent pan-FGFR inhibitors yet with very favorable kinome selectivity. Compound **39** also conveyed high potency against cell lines harboring FGFR amplifications, mutations, and translocations. For example, **39** inhibited SNU16 (FGFR2 amplification) gastric cancer cell proliferation with EC_{50} of <5 nM. Oral dosing of **39** induced rapid tumor regression at 15 mg/kg BID, and intermittent dosing at 20 mg/kg also resulted in prolonged tumor regression. It will be interesting to see whether **38** and **39** will outperform the noncovalent FGFR inhibitors being studied in clinic and whether cysteine mutation will emerge as a potential resistance mechanism, as observed in the cases of BTK and EGFR.

5.03.6.2.4 BLU9931 (40)/BLU-554 (41)

The high sequence homology between FGFRs presents significant challenges to develop isoform-selective FGFR inhibitors. However, a unique cysteine residue C552 in the hinge of FGFR4 (tyrosine for FGFR1–3) was exploited to discover selective FGFR4 inhibitors to treat hepatocellular carcinoma (HCC) with potentially fewer dose-limiting side effects associated with

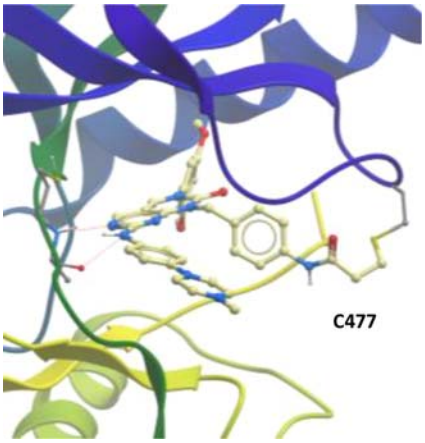

Fig. 10 Bound structure of FIIN-2 (**36**) to FGFR4 (PDB code, 4QQC; 2.4 Å).

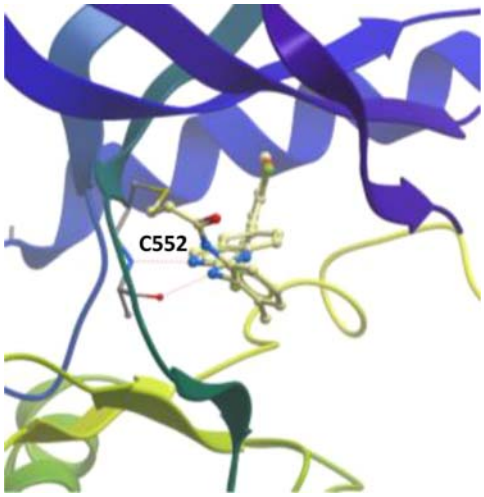

Fig. 11 Bound structure of BLU9931 (**40**) to FGFR4 (PDB code, 4XCU; 1.7 Å).

pan-FGFR inhibition. Only six other kinases possess a cysteine at the equivalent location but with low overall sequence similarity: MAPKAPK3, MAPKAPK2, p70S6Kb, TTK, PI4K, and ChaK1. Similar to **35**–**37**, the discovery of BLU9931 (**40**) was also based on the scaffold of **34**, whose dimethoxyphenyl substituent was important for its high potency and good kinome selectivity, occupying a hydrophobic pocket near the gatekeeper valine in all FGFR family members including FGFR4.[76] It was found that an acrylamide at the *ortho*position of the aniline of an anilinoquinazoline hinge-binding core, substituted with the dichlorodimethoxyphenyl group, was capable of forming a covalent bond with C552 of FGFR4 (Fig. 11). Further introduction of a 3-methyl substituent on the aniline ring led to the identification of **40** with optimal FGFR4 potency (IC_{50} of 3 nM) and selectivity over FGFR1–3 (IC_{50} values of 591, 493, and 150 nM, respectively). The methyl substituent forces the aniline ring to adopt a nonplanar dihedral rotation, better positioning it in proximity to covalently react with C552 sulfur, while introducing a significant steric clash with the tyrosine side chains of FGFR1–3. The nonreactive propylamide analog exhibited much less potent inhibition of FGFR4 enzyme activity (IC_{50} of 938 nM). Compound **40** also potently inhibited the proliferation of the HCC Hep3B cell line with EC_{50} of 70 nM. Moderate bioavailability of **40** (F% of 18 and $t_{1/2}$ of 2.5 h at 10 mg/kg dose in mice) enabled preclinical in vivo evaluation of FGF4 inhibition. With a 100 mg/kg twice-daily dose, **40** caused tumor regression in a Hep3B xenograft model, and at 300 mg/kg twice-daily dose, it caused tumor regression in LIXC012 (an HCC patient-derived cell line) tumor-bearing mice.[76] Further optimization of this chemical series resulted in the identification of BLU-554 (**41**), which is undergoing phase I clinical trials in patients with hepatocellular carcinoma and cholangiocarcinoma (ClinicalTrials.gov identifier, NCT02508467).

5.03.7 Other Kinase Targets for Covalent Inhibition

5.03.7.1 Akt

PI3K/Akt signaling pathway is an important mediator of cellular processes, and Akt dysregulation is directly associated with neoplastic transformation and malignant progression, as well as increased resistance to cancer therapies.[77] Akt features a regulatory pleckstrin

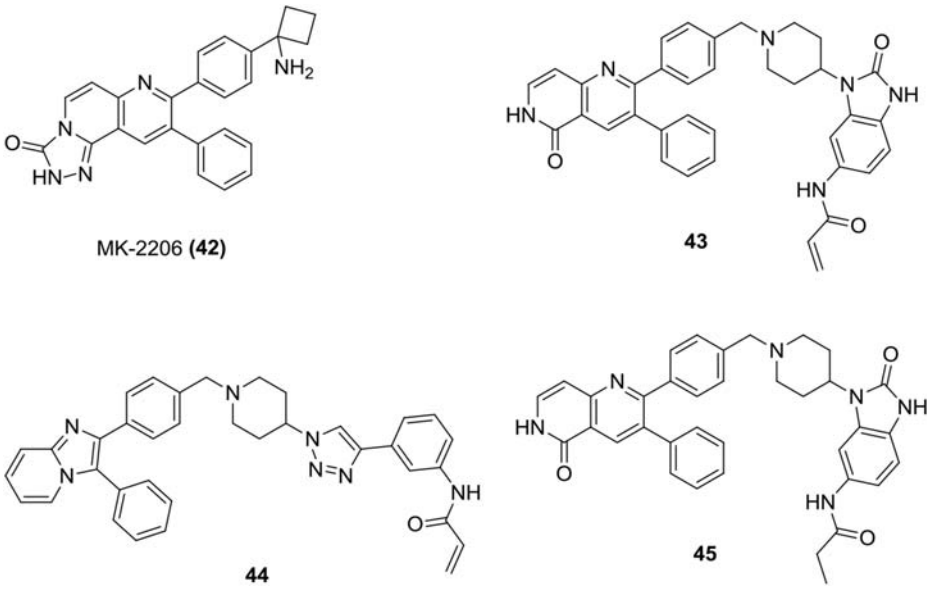

Fig. 12 Chemical structure of Akt inhibitors.

homology (PH) domain, along with the catalytic kinase domain, allowing for membrane attachment upon growth factor stimulation and activation. Allosteric PH domain-dependent Akt inhibitors (Fig. 12), such as MK-2206 (**42**), bind to a unique pocket at the interface of the regulatory PH and the kinase domain, stabilizing the inactive "PH-in" conformation.[78] Analysis of x-ray structures of full-length Akt in complex with allosteric inhibitors revealed the close proximity of a disulfide bridge between C296 and C310, which are known to be redox-sensitive, and therefore potentially amenable for targeted covalent inhibition. Based on two different chemical scaffolds, two probe compounds **43** and **44** featuring an acrylamide warhead group were prepared to target C296 and C310.[78]

While **44** had weak activity against Akt (IC_{50} of 372 nM), **43** exhibited a subnanomolar IC_{50} (0.2 nM) against Akt, significantly more potent than isosteric nonreactive propyl amide analog **45** with IC_{50} of 7.5 nM. Kinetic characterization of **43** further supported a covalent mode of action with K_{inact}/K_i of 3.29 $\mu M^{-1}\,s^{-1}$. Treatment of Akt1 with **43** resulted in mass increases corresponding (587 Da) to formation of a 1:1 adduct of Akt1 and **43**. Trypsin digestion of **43**-treated Akt1 and subsequent ESI-MS/MS analysis suggested mutually exclusive modification of either C296 or C310 with no preference, which was in line with the accessibility for either cysteine located on the flexible activation loop. **43** also exhibited excellent kinome selectivity. At 1 μM concentration, it was found to only inhibit significantly Akt1, Akt2, and Akt3 (98%, 96%, and 83%). No significant inhibition was observed for kinases with analogous cysteines such as PKCθ (35%), MAPKAPK2 (30%), MELK (30%), and 43 additional kinases harboring analogous cysteines (<30% inhibition). Furthermore, **43** induced dose-dependent decreases of pAkt1 in PC3 and BT474 cancer cell lines while demonstrating selectivity against c-KIT and Erk1/2 in GIST-T1 cells.[78]

5.03.7.2 BMX

Bone marrow kinase on chromosome X (BMX) is a member of the TEC family of nonreceptor cytosolic tyrosine kinases, which includes BTK, ITK, TEC, and TXK. BMX is expressed in hematopoietic cells of the myeloid lineage and potentially plays an essential role in various diseases of inflammation, cardiovascular disease, and cancer.[79] In particular, increased BMX activity and expression have been associated with prostate cancer (PCa) and castration-resistant prostate cancer (CRPC).[80] In order to determine the pharmacological consequences of inhibition of BMX kinase activity in PCa, Gray and coworkers sought to develop potent and selective covalent BMX inhibitors, targeting C496 at the lip of the ATP-binding site analogous to C797 of EGFR and C481 of BTK.[80] They performed a search for inhibitors with modest binding affinity and selectivity for BMX in their internal database of kinase inhibitor selectivity profiles generated from using the KINOMEscan approach for ATP-competitive pharmacophores. Subsequent modeling studies of the top hits in a published BMX crystal structure (PDB code, 3SXR) gave a probable binding conformation, which was used to design BMX-IN-1 (**46**) with a properly positioned electrophile-targeting C496 (Fig. 13).[80]

Compound **46** was found to be a potent and selective BMX inhibitor with IC_{50} of 8 nM and an S(10) selectivity score of 0.01 using the KinaseScan approach at 1 μM concentration against a panel of 442 kinases. The only significant off target was BTK with IC_{50} of 10.4 nM, which possesses an equivalently placed cysteine as BMX C496. Compound **46** was demonstrated to potently inhibit the proliferation of TEL-BMX-transformed Ba/F3 cells with an IC_{50} of 25 nM. The approximately isosteric analog BMX-IN-1R (**47**), in which the electrophile acrylamide is replaced with a nonreactive propyl amide, was inactive in TEL-BMX-transformed Ba/F3 proliferation assay. Furthermore, C496S TEL-BMX Ba/F3 cells were resistant to **46**. However, **46** only inhibited the proliferation of a panel of prostate cancer cell lines at single-digit micromolar concentration. Therefore, additional experiments are required to further assess whether BMX is a therapeutically useful target.[80]

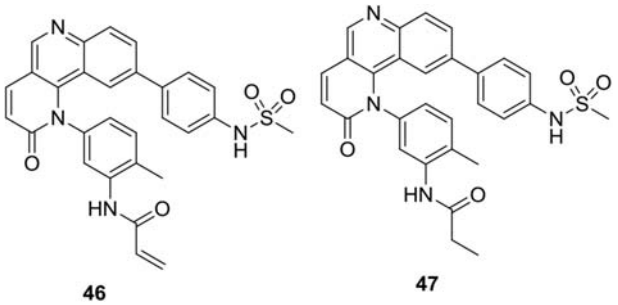

Fig. 13 Chemical structure of BMX inhibitors.

5.03.7.3 CDK7

The first covalent CDK7 inhibitor was discovered through cell-based screening and kinase selectivity profiling of a library of ATP-site-directed kinase inhibitors, in an effort to discover new kinase inhibitors that regulate gene transcription.[81] THZ1 (**48**, Fig. 14), an aminopyrimidine with an acrylamide warhead group, was identified as a low nanomolar inhibitor of cell proliferation (IC_{50} of 50 nM in Jurkat T-ALL cell line) and biochemical CDK7 activity (IC_{50} of 3.2 nM). Kinome-wide profiling and kinetics studies showed that CDK7 is the only target with time-dependent inhibition, suggestive of covalent binding. Corresponding noncysteine reactive analog **49** showed comparatively less activity on CDK7 (IC_{50} of 146 nM) and reduced antiproliferative potency (IC_{50} of 2008 nM in Jurkat T-ALL cell line).

Mass spectrometry identified the site of covalent modification by **48** as C312, a residue outside the kinase domain. Computational studies predicted that the reactive acrylamide of **48** would be positioned in close proximity to C312. Mutation to serine (C312S) prevented **48** from covalently binding to CDK7. Sequence alignment of the 20-member CDK family suggested the uniqueness of C312, providing a structural basis for the covalent selectivity of **48**.[81]

Cancer cell line profiling suggested broad cellular activity of CDK7 inhibition, and a subset of cancer cell lines, including T-ALL, were exceptionally sensitive to **48**. This correlated to transcriptional modulation of the RUNX1 super-enhancer. Pharmacological activity of **48** was confirmed in xenograft mouse models of multiple cancer types,[81–83] justifying continued investigation of clinical potential of CDK7 inhibition.

5.03.7.4 ERK1/2

The RAS/RAF/MEK/ERK pathway plays a central role in many cellular processes, and its deregulation has been associated with multiple human tumors. Direct ERK1/2 inhibition not only provides an option in tumors with mutational activation of RAS or Raf genes but also may overcome acquired resistance to RAF and MEK inhibitors where RAS/RAF/MEK/ERK pathway reactivation has occurred.[84]

In-house screening by AstraZeneca using an ERK2 biochemical assay and subsequent SAR identified a series of potent and reversible ERK inhibitors including **50** (Fig. 15) with ERK2 IC_{50} up to 44 nM and good kinase selectivity (>75% inhibition of only four kinases out of 125 kinase panel). Based on cocrystal structure information of **50** with ERK2 (Fig. 16), inversion of aniline amide allowed installation of an acrylamide warhead group to engage C166 and concurrent modification to a more potent aminopyridine core, resulting in **51** with ERK2 IC_{50} of 8.5 nM. It maintained good kinase selectivity with >75% inhibition of four kinases out of 125 kinase panel. Compound **51** inhibited A375 cell line with IC_{50} of 57 nM. Its reversible matched pair compound **52** had ERK2

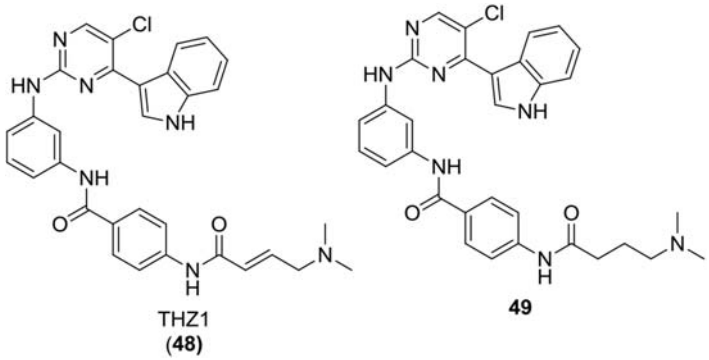

Fig. 14 Chemical structure of CDK7 inhibitors.

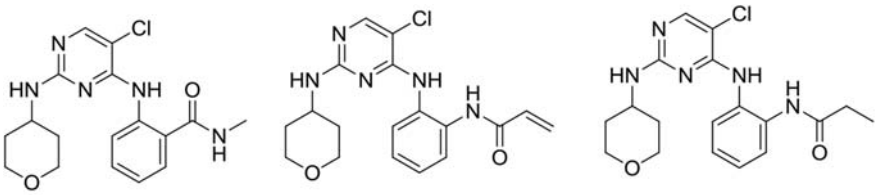

50 51 52

Fig. 15 Chemical structure of ERK1/2 inhibitors.

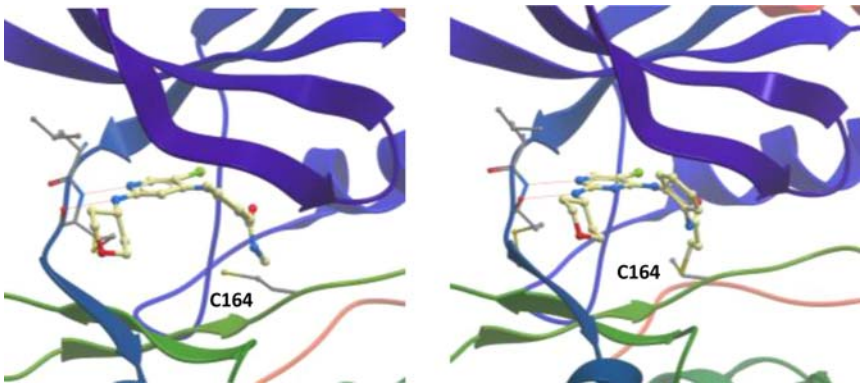

Fig. 16 (A) Left, bound structure of **50** to human ERK2 (PDB code, 4ZZN; 1.3 Å); (B) right, bound structure of **52** to human ERK2 (PDB code, 4ZZO; 1.6 Å).

IC_{50} showed significantly weaker activity across the assays. Mass spectrometry confirmed covalent binding of **51** to ERK2, which was not observed with **52** as expected. Further profiling in preclinical animal models would be needed to assess the efficacy and safety of covalent ERK inhibition, which could be used to guide potential clinical development.

5.03.7.5 ITK

The nonreceptor tyrosine kinase interleukin-2-inducible T-cell kinase (ITK) is a member of the TEC kinase family. It is expressed mainly in immune cells such as T cells, mast cells, NK cells, and NKT cells. ITK positively regulates T-cell receptor (TCR) signaling and plays a role in many T-cell responses; therefore, ITK inhibition has been pursued as potential treatment for a number of autoimmune, inflammatory, and malignant diseases that may involve normal or neoplastic T cells.[85,86]

Covalent ITK inhibition was reported for ibrutinib, which may have contributions to its clinical efficacy in B-cell malignancies.[29,87] This was not unexpected given that C442 of ITK is at an analogous position to C481 of BTK, which was targeted by **1** for covalent modification. In an effort to discover a more potent and specific covalent ITK inhibitor, screening of the Pfizer corporate compound repository yielded a potent hit (**53**) with an IC_{50} of 73 nM in the presence of 1 mM ATP (Fig. 17).[85] A solved x-ray crystal structure (Fig. 18) confirmed the engagement of C442 by **53** through a covalent bond between the β-carbon of the acrylamide group of **53** and the cysteine sulfhydryl (C-S distance 2.0 Å). Further optimization of the back-pocket group led to compound **54** with improved biological activity with a biochemical ITK IC_{50} of 2 nM and an IC_{50} of 48 nM in a human whole-blood assay. However, **54** retained significant BTK activity, and its fast in vivo clearance prevented further pharmacological studies.

To develop a more selective covalent ITK inhibitor, a different approach was undertaken by installation of warhead groups to engage C442 on existing selective noncovalent ITK scaffolds.[86] This led to the discovery of PRN694 (**55**) with biochemical IC_{50} of 0.3 nM for ITK. Profiling against potential off-target kinases with a cysteine analogous to C442 in ITK showed high potency against ITK and RLK with IC_{50} of 0.3 nM and 1.4 nM, as well as the other TEC family member BTK with IC_{50} of 17 nM. Kinetic analysis of **55** revealed time-dependent inhibition of ITK and RLK, whereas occupancy studies showed that the inhibition of BTK was reversible, with only 27% occupancy of BTK after 6 h. Furthermore, durable in vivo ITK inhibition was achieved for **55**, supported by its occupancy of ITK being 98%, 95%, and 54% at 1, 6, and 14 h, respectively, after a single 20 mg/kg intraperitoneal dose in mice.[86] Additional studies showed that **55** was a potent inhibitor of Th1 and Th17 cell differentiation and cytokine production, and in vivo administration of **55** markedly reduced disease progression in a T-cell-adoptive transfer model of colitis, providing further support for the therapeutic potential of ITK inhibition in certain inflammatory diseases.[88]

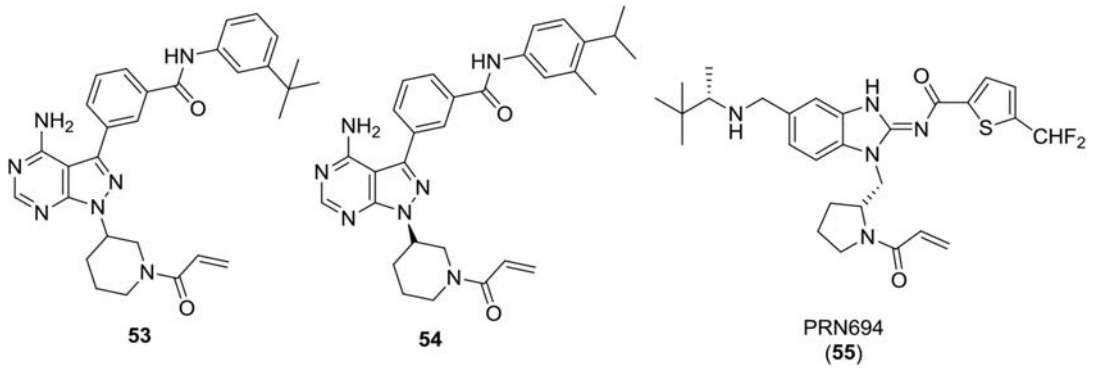

Fig. 17 Chemical structure of ITK inhibitors.

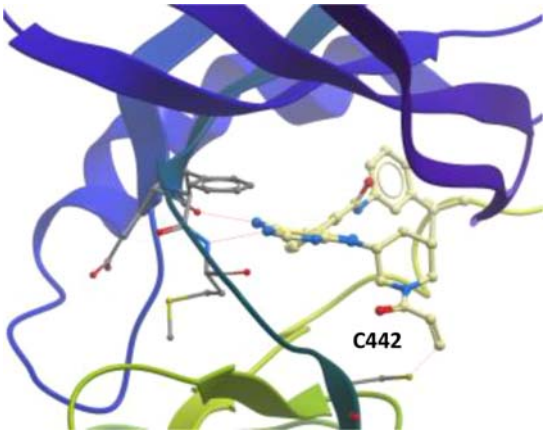

Fig. 18 Bound structure of **53** to human ITK (PDB code, 4HCT; 1.5 Å).

5.03.7.6 JAK3

The Janus kinase family, comprising of JAK1, JAK2, JAK3, and TYK2, and their downstream effectors play important roles in regulating multiple cytokine signaling pathways. Given the importance of the JAK family in autoimmune disease and cancer, many small-molecule ATP-competitive inhibitors (Fig. 19) with different isoform-selectivity profiles have been developed, including ruxolitinib (**56**, JAK1/2 inhibitor) approved for myelofibrosis and tofacitinib (**57**, pan-JAK inhibitor) approved for rheumatoid arthritis.[89] The high degree of structural homology, particularly in the active site of kinase domains, posed a significant challenge to the discovery of highly selective inhibitors to better understand pharmacological contributions of individual family member in diseases. JAK3 is expressed predominantly in immune cells and is a potential therapeutic target for autoimmune diseases. JAK3 mutations have also been associated with certain cancers such as natural killer/T-cell lymphoma.[90]

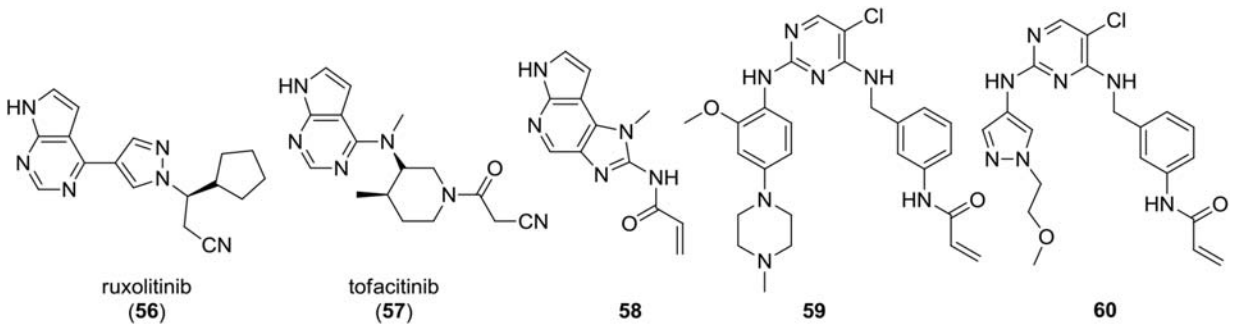

Fig. 19 Chemical structure of JAK3 inhibitors.

Despite > 80% homology in the active sites for JAK3 versus JAK1/JAK2/TYK2, there is a unique cysteine residue in JAK3 (C909) in the ATP-binding site, analogous to EGFR and BTK, thus presenting a great opportunity to achieve potency and selectivity through a covalent approach.[91] One approach undertaken was to use docking experiments in available crystal structures of JAK family kinase domains, which led to tricyclic JAK3 inhibitor **58**.[91] Compound **58** had potent JAK3 activity with $IC_{50} < 3$ nM, and kinetic studies and mass spectrometry profiling confirmed its irreversible covalent modification of C909. Compound **58** was selective against JAK family members (JAK1 $IC_{50} = 4$ μM; JAK2 $IC_{50} = 1.6$ μM; TYK2 $IC_{50} > 50$ μM) and ten other kinases with cysteine residues at analogous positions (ITK $IC_{50} = 0.83$ μM; BTK $IC_{50} = 14$ μM; EGFR $IC_{50} = 11$ μM). Compound **58** also showed potent inhibition of JAK3/IL-2 signaling pathway with IC_{50} of 19 nM in U4C epithelial cells while being inactive against JAK1- or JAK2-driven signaling pathways. Unfortunately, **58** was not suitable for in vivo studies to assess JAK3 pharmacology due to its unfavorable pharmacokinetics.[91]

A different approach was adopted to discover another potent and selective JAK3 inhibitor **59** by optimizing EGFR inhibitor **27** (Fig. 20), a T790M-mutant EGFR inhibitor with observed off-target JAK3 activity (K_d of 150 nM).[89] Syntheses and profiling of a small set of analogs led to **60**, where the ether linkage of **27** was replaced with an aminomethylene (-$NHCH_2$-) linkage, which had a greatly improved JAK3 activity (IC_{50} of 4.8 nM). In T-ALL-1 cells, IL-2-induced STAT5 phosphorylation was completely inhibited by **60** at 1 μM concentration. However, oral administration of **60** at 75 mg/kg QD for 8 days in genetically engineered models (GEM) of lung adenocarcinoma in mice did not show any effect on the tumor growth despite reasonable pharmacokinetic properties. More comprehensive investigations with these potent and selective JAK3 inhibitors are required to further elucidate the role of JAK3 in relevant disease models.

5.03.7.7 PI3Kα

The family of lipid phosphoinositide 3-kinases (PI3Ks) plays a key regulatory role in many cellular processes including proliferation and survival. There are three classes of PI3Ks, which includes the best studied class I PI3Ks consisting of a p110 catalytic subunit and a p85 regulatory unit. The PI3K class I family has four isoforms α, β, γ, and δ. PIK3CA, the gene that encodes the p110α subunit, is mutated in up to 30% of human cancers.[15] Multiple pan-PI3K inhibitors have been advanced into clinical development, but a selective PI3Kα inhibitor would have a more favorable safety profile by sparing toxicities due to inhibiting other isoforms.

Examination of the ATP-binding site and nearby residues of PI3Kα identified C862 as a unique cysteine residue (L or Q at the analogous position for other isoforms) that might be amenable to a covalent inhibition strategy to achieve selectivity. A series of design cycles exploring linker spacing and electrophiles based on x-ray structure of GDC-0941 (**61**, Fig. 21) bound to PI3Kα resulted in the discovery of CNX-1351 (**62**) as a potent and selective PI3Kα inhibitor with an uncommon dimethylenone warhead group.[15] Compound **62** had a PI3Kα biochemical IC_{50} of 6.8 nM, and its activity for β, γ, and δ was much weaker with IC_{50} values of 166 nM, 240 nM, and 3020 nM, respectively. Mass spectrometry experiments confirmed covalent binding of **62** to PI3Kα but not to the other class I isoforms. Trypsin digestion and subsequent peptide analysis further confirmed modification of C862. x-Ray crystallography of **62** with PI3Kα was obtained and supported the computational binding mode (Fig. 22). Broader profiling of **62** against a panel of 60 kinases, representing all branches of the kinome tree, showed excellent selectivity as no kinases were inhibited by greater than 40% using 1 μM concentration. Compound **62** also showed potent growth inhibition of SKOV3 ovarian cancer cells and MCF-7 breast cancer cells with PIK3CA-activating mutations (GI_{50} of 78 and 55 nM, respectively). Though prolonged PI3Kα occupancy and inhibition of p-Akt was achieved in vivo with **62** (100 mg/kg ip) despite poor pharmacokinetic properties, further optimization was needed to improve upon **62** to yield a more suitable selective and durable PI3Kα inhibitor for further studies and preclinical development.[15]

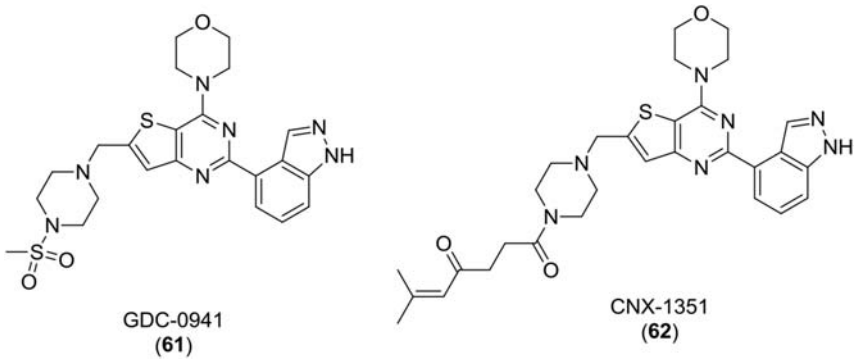

Fig. 21 Chemical structure of PI3Kα inhibitors.

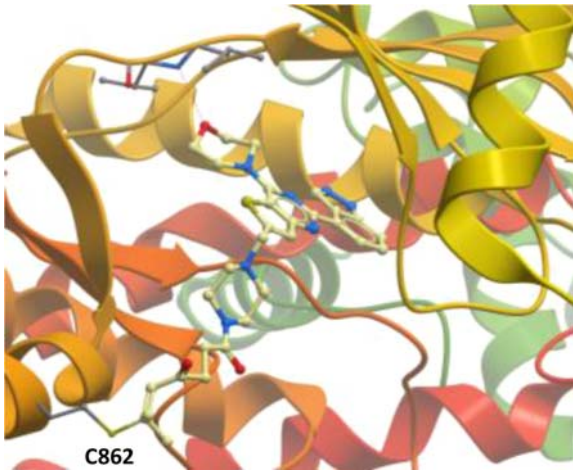

Fig. 22 Bound structure of **62** to human PI3Kα (PDB code, 3ZIM; 2.8 Å).

5.03.7.8 Miscellaneous Kinases

There have been reports of additional novel covalent kinase inhibitors, such as JNK-IN-8 (**63**) for JNK,[92] RMM-46 (**64**) for MSK/RSK,[93] (5*Z*)-7-oxozeaenol (**65**) for TAK1,[94] **66** for c-SRC,[95] and DHM25 (**67**) for mTOR (Fig. 23).[96] These new covalent inhibitor tools helped better understand the biology and pharmacology of functions of their respective kinase targets and potentially set good foundational research work for discovering novel cancer drugs modulating the activity of these kinases.

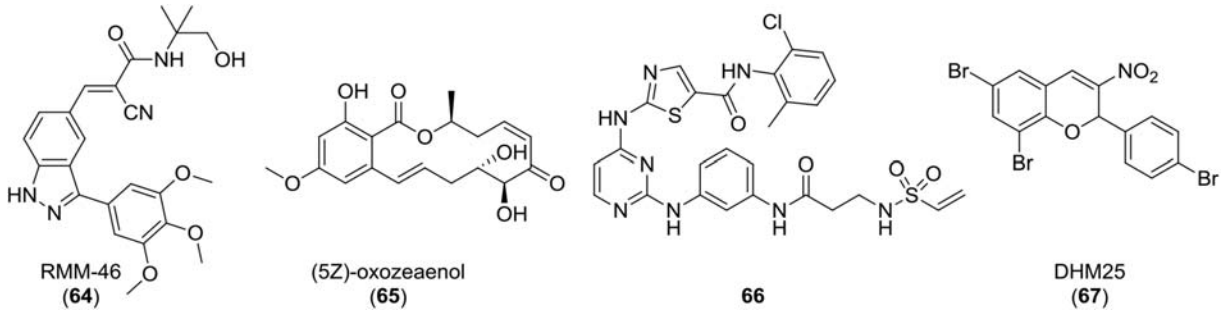

Fig. 23 Chemical structure of additional covalent kinase inhibitors.

5.03.8 Emerging Strategies and Technologies

5.03.8.1 Covalent Reversible Cysteine Inhibition of Kinases

The concept of covalent reversible inhibition has been exploited in drug discovery efforts of protease and proteasome inhibitors, leading to multiple approved drugs such as bortezomib[97] and boceprevir[98] that target reactive catalytic amino acid residues in the active site. However, covalent reversible targeting of noncatalytic cysteine was not reported until the recent discovery that cyanoacrylates and cyanoacrylamides react with cysteine thiols reversibly, as exemplified by inhibition of RSK2 with compound **68** (Figs. 24 and 25).[17] It was found that incorporation of a nitrile group converts irreversible acrylamide Michael acceptors into electrophiles with unanticipated facile yet reversible reactivity with cysteine thiols under physiological conditions. It was rationalized that the electron-withdrawing cyano substitution renders the β-carbon more susceptible to nucleophilic attack and also stabilizes the resulting carbanion, thereby accelerating the thiol addition reaction. On the other hand, the electron-withdrawing cyano substitution drastically increases the α-CH acidity of the thiol adducts, facilitating rapid elimination of thiol adducts when nonbonded interactions between inhibitor and protein are lost, particularly upon protein unfolding after trypsin digestion or denaturing.

Inhibitors that form a covalent reversible bond with a noncatalytic cysteine of the target may provide a broadly applicable platform that facilitates "residence time by design" and the ability to modulate and improve the duration of target engagement in vivo.[18] The application of this concept in medicinal chemistry was powerfully demonstrated in studies with inhibitors of two kinases with importance in oncology, BTK (Section "**Assessment and Optimization of Covalent Kinase Inhibitors in Cancer**") and FGFR (Section "**Covalent inhibitors of HER family kinases**"). Systematic studies of a series of reversible covalent BTK inhibitors with inverted cyanoacrylamide warhead groups identified potent and selective analogs that demonstrated residence times spanning from minutes to 7 days. An inverted cyanoacrylamide **69** with a branched-alkyl capping group remained bound to BTK for more than 18 h after clearance from the circulation. The research effort has resulted in the discovery of PRN1008 (**70**, structure not disclosed), which is currently in phase II clinical development to treat pemphigus vulgaris, a rare, potentially life-threatening autoimmune disease associated with painful chronic blistering of the skin and limited treatment options (ClinicalTrials.gov identifier, NCT02704429). Despite some potential limitations such as high steric demand for accommodating branched-alkyl capping groups, cysteine targeting with inverted cyanoacrylamides is likely to be broadly applicable for targets with solvent-exposed noncatalytic cysteines. Furthermore, additional covalent reversible chemistries have emerged, expanding the tool boxes available to successfully target cysteines of interest.[99]

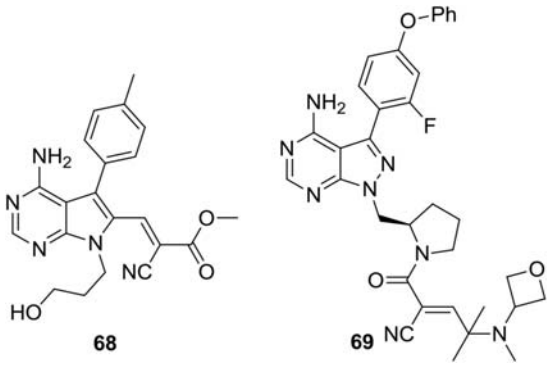

Fig. 24 Chemical structures of covalent reversible inhibitors.

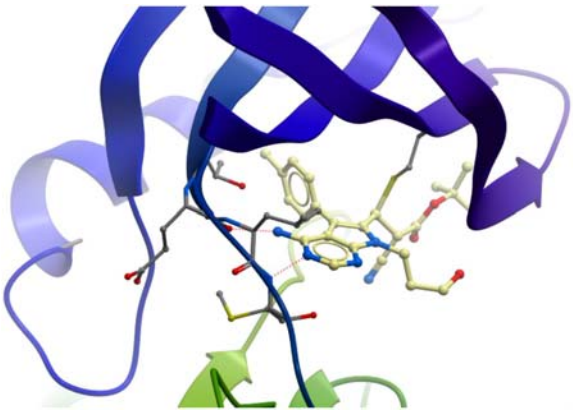

Fig. 25 Compound **68** bound to RSK2 (PDB code, rD9U; 2.4 Å).

The on-target activity of covalent reversible inhibitors with extended residence time is in theory functionally equivalent to that of covalent irreversible inhibitors. Therefore, they could achieve similar levels of target occupancy and thus efficacy in cancer treatment. Though the safety requirements for single agents in oncology indications are typically lower than for nonlife-threatening diseases, an improved safety profile could make covalent reversible inhibitors more amenable for combination therapies. In addition, the increased intrinsic reactivity of covalent reversible warhead groups could be advantageous for targeting cysteines that are less reactive toward classical covalent irreversible electrophiles.

5.03.8.2 Non-cysteine-Targeting Covalent Inhibitors

Cysteine's nucleophilic thiol group and its relatively low abundance in proteins make noncatalytic cysteine residues ideal for targeting with covalent drugs to achieve high levels of selectivity, potency, and durability. Targeting noncatalytic amino acid residues other than cysteine has been much more challenging, though there have been a number of reported covalent inhibitors targeting lysine residues.[5,96,100] Multiple nonselective inhibitors (Fig. 26) were found to covalently engage the conserved lysine involved in the kinase phosphate transfer reaction, including irreversible wortmannin (**71**),[101,102] FSBA (**72**),[103–106] and fluorosulfonylbenzoate (**73**).[107] Interestingly, members of a novel class of pyrrole aldehydes typified by **74** were found to be selective covalent inhibitors of IGFRK, targeting the same catalytic lysine residue.[108] Compound **74** inhibited IGFRK autophosphorylation with IC_{50} of 0.11 μM. Though only modestly selective against closely related IRK with IC_{50} of 0.6 μM, **74** was inactive against ten other kinases with $IC_{50} > 100$ μM. The key aldehyde functionality apparently formed a Schiff base with the IGFRK active-site residue K1003, and the covalent complex could be trapped by borohydride reduction and studied by mass spectroscopy after trypsin digestion. A crystal structure of **74** bound to IRK confirmed the covalent interaction with K1030, corresponding to K1003 in IGFRK that had been modified by reductive alkylation with aldehyde **74**.

Selective targeting of a nonconserved lysine was recently reported for covalent inhibition of CDK2 by NU6300 (**75**).[100] Inhibitor **75** was discovered serendipitously as an intermediate to synthesize a library of analogs of a known CDK2 inhibitor NU6102 (**76**). Kinetic studies and mass spectroscopy experiments suggested covalent inhibition of CDK2 with K_d of 1.31 μM and K_{inact} of $5.0 \times 10^{-3}\ M^{-1}\ s^{-1}$. The solution of a crystal structure of **75** bound to CDK2/cyclin A (Fig. 27) confirmed the covalent bond formation of the side-chain ε-amino group of K89 that lies just outside the CDK2 ATP-binding cleft with the vinyl sulfone group of **75**. Assessment of its selectivity against 131 protein kinases identified 13 kinases that exhibited less than 20% activity in the presence of 1 μM **75**, among which only Aurora A, Mst2, and GCK (MAP4K3) showed a > 50% additional loss of activity. It will be interesting to see whether further optimization can generate suitable lead molecules to study CDK2 pharmacology and validate the approach of covalently targeting noncatalytic lysines. Discovery of drug-like warhead groups for reaction with lysine certainly will play an important role.[109]

5.03.8.3 Screening Approaches to Discover Covalent Inhibitor Leads

Installing covalent warhead groups to reversible inhibitor scaffolds has been a very successful approach, resulting in three approved covalent kinase drugs: ibrutinib, afatinib, and osimertinib. Despite the success, there are certain limitations to the approach, such as the necessity of existing lead molecules and a reasonable understanding of their binding mode to guide the installation of the warhead group, from either cocrystal structures or computational studies.

A complementary lead discovery approach is to identify compounds with a covalent mechanism of action by screening a library of compounds incorporating electrophiles that are capable of trapping the targeted amino acid residues of interest. There are a number of factors that one should consider for such an approach including: the nature of the warhead groups, the size of the library, the appropriate construct of the target protein, the screening method, and hit triage and confirmation studies. While incorporating highly reactive electrophiles might increase the hit rate, it could also generate increased numbers of promiscuous hits, which would pose greater challenges for subsequent hit elucidation and optimization. Given the proved utility of the acrylamide unit as a drug-like warhead group for cysteine, it is not surprising to see growing interest in studying the construction and screening of acrylamide- and cyanoacrylamide-containing libraries.[93,110–113] Mass spectroscopy has been a popular screening method given its high throughput and general applicability and simplicity to look for the desired mass of protein–ligand adducts.[93,113] As an example of hit confirmation, the loss of activity against the C436V RSK2 mutant was used to confirm the covalent mechanism of action for the fragment screening hits of a small library of cyanoacrylamides.[114] Improvement in mass spectroscopy studies and workflow has enabled the screening of approximately 1000 acrylamide-containing compounds.[113] It remains to be seen whether future effort in this area will deliver clinical molecules to help cancer patients.

5.03.8.4 Virtual Screening of Covalent Inhibitors

With the resurgence of covalent inhibitors, there has been growing interest in computational studies of covalent docking of ligands with an electrophile group targeting the amino acid residue of interest.[115,116] Some key obstacles to this approach include combining classical noncovalent scoring with covalent restraints and bond energies and developing compound libraries that are suited to covalent modification of the protein residue of interest. Recent progress in covalent docking has largely been restricted to retrospective recapitulation of covalent complexes or to screens of a few hundred compounds.[117–119] The potential benefit of prospective, large-scale covalent docking screens was recently demonstrated in finding new inhibitors against targets with previously unknown covalent ligands.[114] Much work and progress are still needed for virtual screening of covalent inhibitors to become a routine approach in covalent drug discovery.

5.03.9 Conclusions

Targeted covalent bond formation has evolved into a key component of the medicinal chemist's armamentarium when looking to discover drugs targeting kinases of importance in the oncology field. High-profile successes with clinically approved EGFR and BTK inhibitors attest to the importance of the approach, and treatment with these drugs has had profound benefits for those affected by cancer. Emerging targets such as FGFR hold promise for further successes in the near future. The efforts of numerous scientists and organizations referenced herein have also led to a greater understanding of the science underlying the development of covalent kinase inhibitors. This has resulted in a better understanding of which proteins might be targeted by this approach and how to best identify, optimize, and develop covalent inhibitors so that they can reach patients.

5.04.1 Introduction

The DNA damage response (DDR) consists of an elegantly orchestrated network of pathways signaling not only for repair of DNA lesions but also for activation of checkpoints that arrest the cell at key points in the cell cycle. When DNA was first discovered it was thought to be a very stable molecule because it is essential that it remains essentially unchanged from one generation to the next. However, thanks to the pioneering work of Thomas Lindahl, we now know DNA is continuously subject to an astonishing amount and spectrum of damage at an alarming rate, which would be incompatible with life if it were not dealt with at a similar rate. Lindahl, Modrich, and Sancar were awarded the Nobel Prize for Chemistry in 2015 for their ground-breaking work on DNA repair, underscoring the importance of the understanding of DNA repair.[1]

The most common lesions are base modification and DNA breaks caused by reactive oxygen species (ROS). ROS are generated at a high level due to normal metabolism, and this is increased during inflammation. It is estimated that these lesions occur at a rate of 10,000–100,000 events/cell/day. In general, they are repaired by the base excision repair/single-strand break repair (BER/SSBR pathway described by Lindahl.[2,3] Failure to repair these lesions before DNA replication leads to the collapse of replication forks and single-ended double-strand breaks (DSBs). Other common endogenously formed lesions can arise from errors of replication when the wrong nucleotide is incorporated by mistake (base mismatch), or one more or one less nucleotide is inserted (Indels, usually in a string of the same nucleotide)—leading to a loop. Although the polymerase DNA polα has a proof-reading function, it is not infallible, requiring the DNA mismatch repair (MMR) to repair the error, as first demonstrated by Modrich.[4] Natural exogenous sources also damage DNA, such as UV light, which causes cyclobutane pyrimidine dimers (CPD). These lesions kink the DNA and are repaired by nucleotide excision repair (NER) that Aziz Sancar described.[5] These are just three of the types of DNA damage and repair, but there are many sources and types of DNA damage. There are seven basic repair pathways to cope with them, the additional ones being: direct repair, nonhomologous end-joining (NHEJ), homologous recombination DNA repair (HRR), and interstrand cross-link (ICL) repair.

Direct repair is the simplest type of repair, and it involves the direct reversal of the lesion. Alkylations at the O^6-position of guanine from dietary nitrosamines or as a result of erroneous methylation by *S*-adenosylmethionine (SAM) are removed by methylguanine DNA methyltransferase (MGMT) leaving behind the natural base, guanine. Two highly cytotoxic lesions are DSBs and ICLs. DSBs arise from ROS-induced damage and background ionizing radiation (IR) and the prime natural source of ICLs are lipid peroxidation products, e.g., acrolein.[6] NHEJ is the simplest way of dealing with DNA DSB, and this process can occur at any phase of the cell cycle (although it is suppressed during S-phase). However, the fidelity of NHEJ is not completely accurate. When the sister chromatid is available, i.e., late S-phase and G2, it can be used as a copy for high-fidelity repair of DSB by the HRR pathway. The repair of ICLs is highly complex and involves elements of both NER and HRR, especially the Fanconi proteins.

Of course, it is no good having multiple repair pathways if the cell does not stop its proliferation long enough for repair to be completed. The cell proliferation cycle starts with G1, the period from the birth of the daughter cell to when DNA synthesis starts in S-phase, after S-phase the cell goes into G2 before progressing into mitosis or M-phase when the two identical daughter cells are born. For the cell to retain its genomic integrity, and hence vitality, any DNA damage occurring during G1 must be repaired before the cell enters S-phase and any occurring during G2 must be repaired before the cell divides. Damage occurring during S-phase must be repaired immediately or during G2. Failure to both arrest and repair will lead to mutations in the daughter cells, and most likely, cell death. To ensure cell survival the DDR is engaged. Two principal kinases, ataxia telangiectasia mutated (ATM) and ataxia telangiectasia and Rad3-related (ATR), are involved in transducing the signal from DNA damage to the different outcomes, which are cell-cycle arrest and DNA repair or, if the damage is too great, cell death. There is some overlap in their targets, but on the whole ATM signals via checkpoint kinase 2 (CHK2) and p53 to arrest the cell in G1 and ATR signals via checkpoint kinase 1 (CHK1) to S and G2/M arrest. An overview of the lesions and DDR pathways involved is given in **Fig. 1**.

These DDR pathways pose both challenges and opportunities for cancer therapy.[7] Inhibiting DNA repair or impairing DNA damage checkpoint signaling can sensitize cells to genotoxic anticancer agents (**Fig. 2A**). For example, IR (e.g., radiotherapy) causes base damage and single-strand breaks (SSBs) that depend on the BER/SSBR pathway for repair, and also DSBs that are repaired by NHEJ and HRR. Therefore inhibiting BER/SSBR, NHEJ, or HRR can increase the radiosensitivity of tumor cells. Similarly cisplatin and carboplatin cause both intra- and interstrand cross-links in the DNA. The former are repaired by NER and the latter by ICL repair, the NER intermediates, and the stalled replication forks, which arise due to the ICL, trigger ATR-dependent checkpoint signaling. Therefore inhibition of ATR will sensitize cells to cisplatin. This approach risks also increasing the sensitivity of normal cells. This means that the ratio of the dose that produces toxicity relative to the dose that is effective—termed the therapeutic index—may be unchanged, and the doses may just be lower. For example, the first studies to use inhibition of DNA repair as

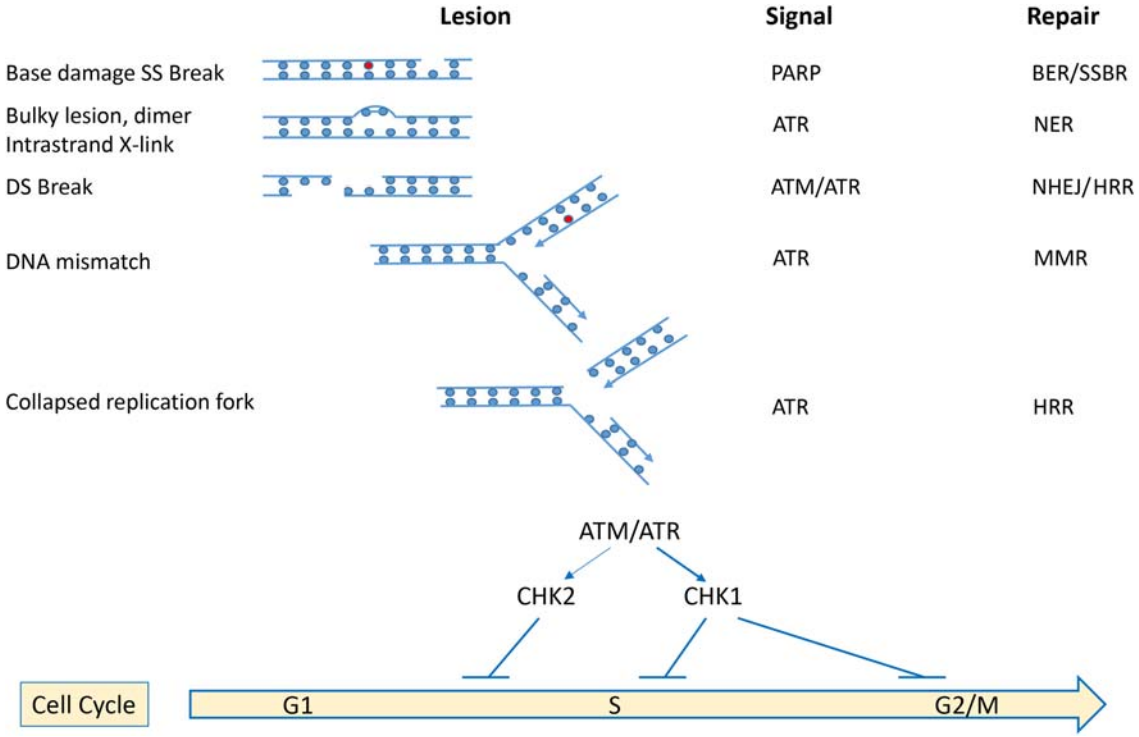

Fig. 1 DNA lesions and activation of the DNA damage response. Base damage and single-strand breaks are signaled via PARP for BER/SSBR, ATR is activated by various lesions to effect S/G2 arrest and DNA repair, and ATM activates cell-cycle arrest and repair of DSBs.

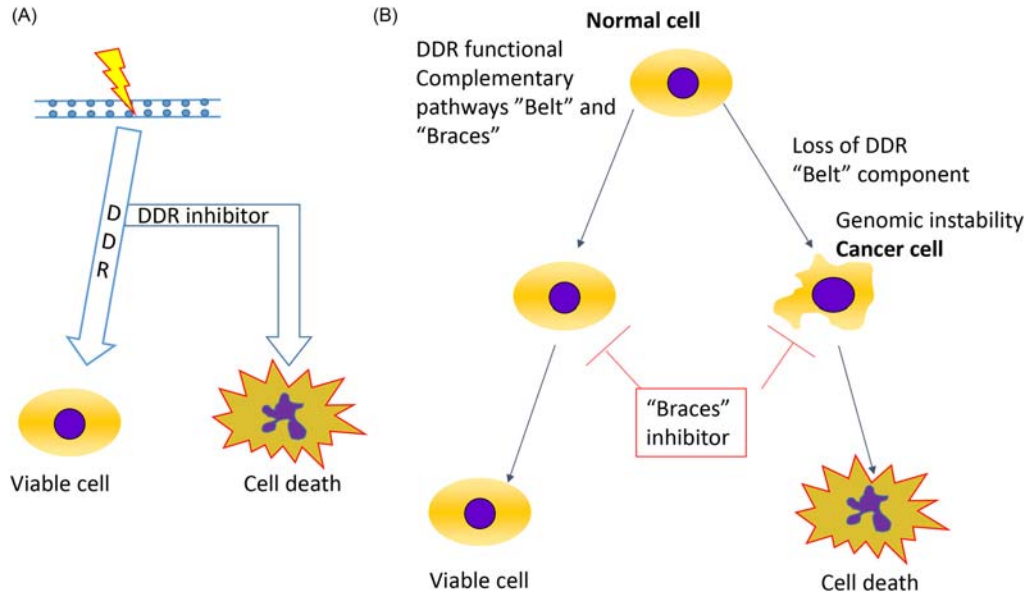

Fig. 2 The rationale for the use of DDR inhibitors in combination with DNA-damaging agents and as single agents for synthetic lethality. (A) Where a DDR pathway promotes survival following exposure to a DNA-damaging anticancer agent, inhibition of a key element of that pathway can increase the sensitivity or overcome resistance. (B) Cells frequently employ back-up pathways to counteract the lethal effects of common endogenous damage in a "belt and braces approach." Dysfunction in one DDR pathway, the "belt," leads to cancer development but also increased reliance on the back-up "braces" pathway such that inhibition of this "braces" pathway results in cell death by synthetic lethality.

a strategy to sensitize tumors to genotoxic agents employed inhibitors of methylguanine methyltransferase (MGMT). MGMT conducts the direct repair of O^6-alkylguanine—the most cytotoxic lesion caused by alkylating agents. Despite being a promising approach in preclinical studies these MGMT inhibitors have not shown clinical utility in combination with alkylating agents because of concomitantly increased toxicity.[8] However, because cancer cells generally have dysfunctional DDR they tend to be more sensitive to genotoxic stress, and so there will still be a therapeutic index, but how great that is will depend on the cancer phenotype.

One way of increasing the therapeutic index is to exploit the principle of "synthetic lethality." Synthetic lethality is when inactivation of two proteins, or pathways, results in cell death, but inactivation of either alone does not compromise viability. This principle is particularly applicable to the molecular derangements that occur in cancer.[9] One of the enabling characteristics of cancer is "genomic instability"[10] that is frequently caused by loss of an element of the DDR. Therefore targeting the DDR using the synthetic lethal approach is particularly applicable in cancer. Dysfunction of one element of the DDR creates genomic instability because either DNA damage will not be repaired efficiently or the cell will not arrest its proliferation cycle properly. This makes it more likely that the damage will be passed to the next generation and that mutations will accumulate. The accumulation of mutations can lead to cancer. Inhibiting one aspect of the DDR can have preferential cytotoxicity to a cell that already has a DDR dysfunction. It exploits the "belt and braces" approach that cells employ for critical functions such that if the "belt" is lost the "braces" can perform the same function, albeit in a different way. Cells that have lost the "belt" are exquisitely vulnerable to an attack on the "braces" (**Fig. 2B**).

The most common DDR defect is the loss of the G1 checkpoint by various means, most frequently, but not exclusively, by p53/pRb pathway disruption.[11] Both p53 and pRb are classic tumor suppressor genes and function primarily to trigger the G1 checkpoint. Many tumor suppressors are DDR proteins, e.g., BRCA1/2, the breast and ovarian cancer susceptibility genes, which play key roles in HRR.[12] Other DDR components may also be considered tumor suppressors, e.g., mutations in MMR genes are associated with Lynch syndrome that confers colon and ovarian cancer susceptibilities.[13] DDR dysfunction can also result in "non-oncogene addiction," whereby loss of one DDR component may be compensated for by upregulation of another DDR component on which the tumor cell depends to maintain sufficient integrity of its genome for survival. This imbalance of the DDR poses both challenges, e.g., if the upregulated component confers therapy resistance, and opportunities to exploit defects. Inhibitors of the DDR have been developed both to be used in combination with DNA-damaging agents to overcome resistance, and as single agents to exploit vulnerabilities caused by DDR dysfunction. For this approach to work, it is important to identify determinants of sensitivity and robust biomarkers are needed to identify whether a tumor has that determinant. Such biomarkers are necessary to be able to target tumors appropriately and spare patients unnecessary side effects if their tumor is likely to be unresponsive. Identification of the synthetic lethality of PARP inhibitors (PARPi) in BRCA mutant cells is the classic example as will be described in the next section.

5.04.2 Poly(ADP-Ribose) Polymerase (PARP)

5.04.2.1 PARP Discovery and Function

The enzyme we now call PARP1 was discovered in the 1960s by workers in Strasbourg and Tokyo.[14,15] The observation that led to its discovery was the rapid consumption of NAD^+ when cells were exposed to alkylating agents (the first chemicals used to treat cancer).[16] The ADP-ribose polymer product was found before the enzyme and originally thought to be a type of nucleic acid. PARP1 is activated by DNA breaks arising directly through, e.g., oxidative cleavage of the backbone, BER intermediates, and trapped topoisomerase I. PARP1 binds to the nick in DNA via its zinc fingers causing it to change to its active conformation. Active PARP1 consumes NAD^+ as a substrate to produce polymers of ADP-ribose attached to itself and nuclear proteins, especially histones. The powerful negative charge of the polymers helps both loosen chromatin to facilitate repair and also recruits XRCC1, the scaffold protein for the enzymes DNA polb and ligase III, which effect repair. The creation of the PARP1 knockout mouse led to the discovery of a second DNA damage-activated PARP, PARP2,[17–19] and subsequently, based on sequence homology, a family of 17 PARP-like enzymes were discovered.[20] Only six have the ability to polymerize ADP-ribose, and the others have mono-ADP ribosylation or unknown activity. PARP1 is the principal DNA damage-activated PARP, followed by PARP2. There is substantial functional redundancy between these two enzymes but not complete overlap. Genetic deletion of either PARP1 or PARP2 independently results in viable and fertile mice with only mild pathologies, but deletion of both enzymes is embryonically lethal[21] underscoring their important function. PARP1 and 2 both function in DNA SSBR and PARP1 also participates in DNA DSB repair, either through interaction with DNA-dependent protein kinase (DNA-PK) or via an alternative NHEJ pathway.[22,23] PARP3 may also cooperate with PARP1 in DSB repair although this enzyme may not have polymerization activity.[24]

5.04.2.2 PARP Inhibitors

PARPi were first developed to elucidate the function of PARP and were based on the PARP catalytic mechanism, that is, the cleavage of NAD into ADP-ribose (for polymer formation) and nicotinamide as a by-product. Nicotinamide exerts a weak feedback inhibition, and the early PARPi were simple analogues of nicotinamide, the benzamides. A pivotal moment in the development of PARPi was in 1980 when 3-aminobenzamide (3AB) (**Fig. 3**) was first shown to inhibit DNA repair and to enhance the cytotoxicity of a DNA-methylating agent, MMS.[25]

PARPi discovery and development has been undertaken by a number of academic groups since the 1980s, with a shift to the pharmaceutical industry with time. During the 1990s PARPi of increasing potency and specificity were discovered using various approaches. One approach, based on the notion that elaboration of nicotinamide/benzamide would identify novel inhibitors,

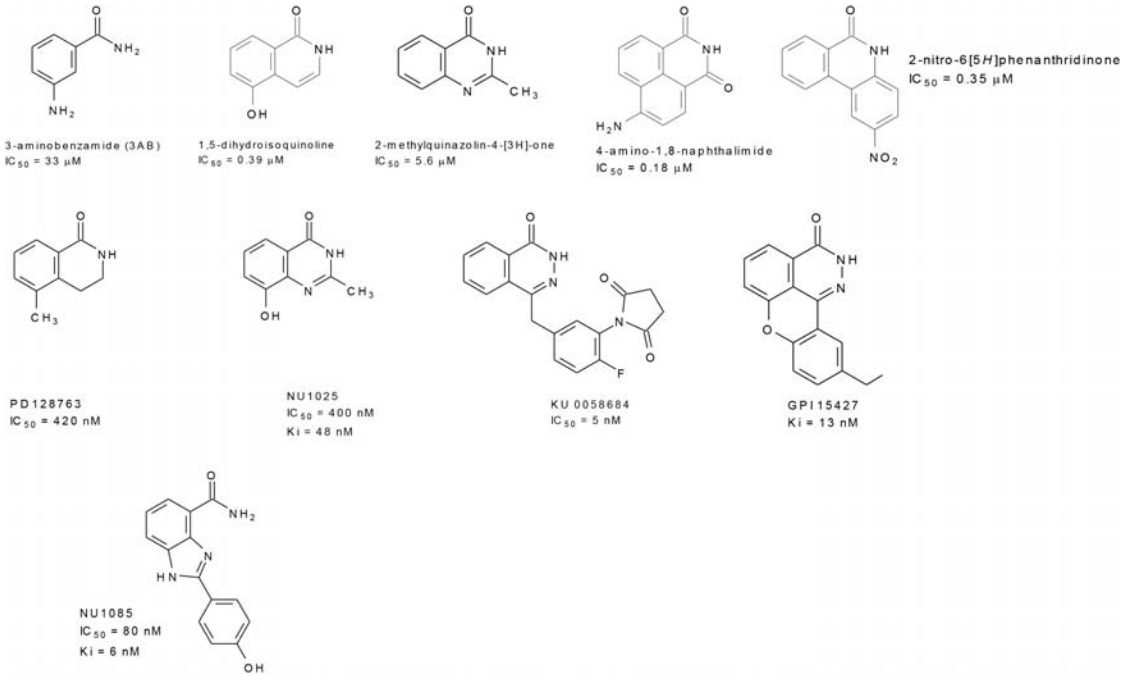

Fig. 3 First- and second-generation PARP inhibitors. 3-Aminobenzamide, the first PARPi, and the compounds identified by Banasik et al.[26] are shown on the top row, while those identified by synthetic chemistry or screening of compound libraries are shown below.

was to search for chemicals that contained this pharmacophore, the so-called analogue by catalog approach. Screening 170 commercially available compounds for their PARP inhibitory activity identified several potent compounds, making a major contribution to inhibitor design[26] (Fig. 3). Several of these compounds have been used as leads for subsequent drug development by various groups, including PJ-34 (Fig. 3) and subsequently INO-1001 (Fig. 4) that entered clinical trials.[27,28] Screening of the Maybridge compound library led to the identification of compounds with potent PARPi activity, e.g., KU0058684 (Fig. 3), similar to those identified by Banasik et al. that led ultimately to the development of olaparib[29] (Fig. 4). Using a conventional synthetic chemistry approach to develop structure–activity relationships (SARs) led to the identification of PARPi with increased potency,

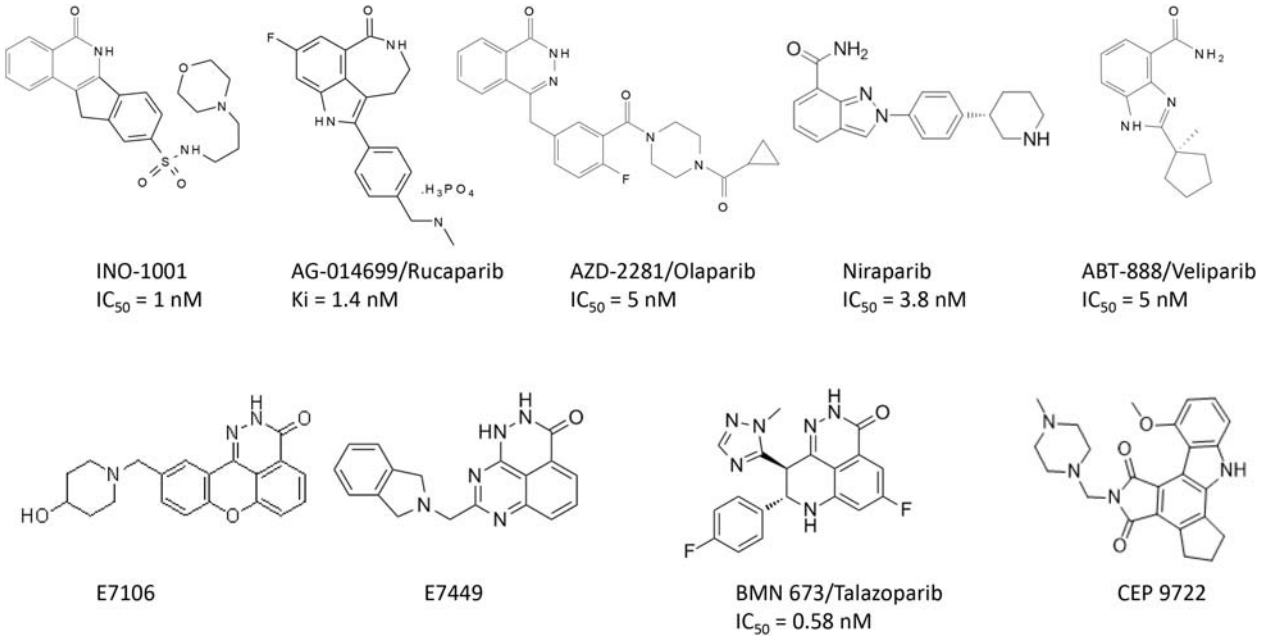

Fig. 4 PARP inhibitors that have entered clinical trial.

including PD128763 and the NU compounds including NU1025 and NU1085 (Fig. 3), ABT-888 (Veliparib), and MK-4827 (Niriparib)[28] (Fig. 4). The third approach was to use structure-based drug design by crystallization of inhibitors in the NAD^+-binding site of the PARP1 catalytic domain, and this demonstrated several key interactions that confirmed SAR and analogue by catalog data.[30,31] This structure-based drug design approach led to the development of AG014699 (rucaparib, Fig. 4) that was the first PARPi to enter clinical trial in cancer patients.[32,33]

5.04.2.2.1 Chemosensitization and radiosentitization

Consistent sensitization of DNA-methylating agents, IR, and topoisomerase I poisons has been observed across a wide spectrum of PARPi and validated by genetic knockdown in cells and mouse models.[34] Sensitization of other genotoxic agents by PARPi has also been reported, but the sporadic nature of the reports suggests that they may be peculiar to an individual PARPi, so possibly an off-target effect, or cell line dependent. For example, sensitization of cisplatin may be dependent on a defect in HRR since AZD2281 (olaparib) selectively sensitized BRCA2 defective cell lines, but not BRCA2-proficient cells to platinum therapy.[35]

Inhibition of PARP activity has a greater impact on repair than does loss of the enzyme. The mechanism that was originally proposed, on the basis of some elegant experiments in Lindahl's lab in the early 1990s, was that inhibition of PARP1 activity did not prevent DNA binding but did inhibit its dissociation from the DNA, driven by auto-poly(ADPribosylation). Therefore, PARP1 remained bound to DNA breaks obstructing repair. This was based on the observation that repair of SSB by nuclear extracts was unaffected by the depletion of PARP1 but abrogated by depletion of NAD^+ or the addition of 3AB in extracts containing PARP1.[36] This has been verified by chromatin immunoprecipitation experiments that showed an increase of the binding of PARP1 to DNA in the presence of an inhibitor.[37] Recently it was proposed that the ability of inhibitors to "trap" PARP1 on DNA was independent of catalytic inhibitory potency and via an allosteric mechanism,[38,39] but further investigations demonstrate that trapping is due to catalytic inhibition.[40]

Monofunctional DNA-methylating agents are the most potent activators of PARP, and prior to 2005 when the synthetic lethality of PARPi with BRCA mutations was identified, most of the initial drive to develop PARPi was as sensitizers of these agents. DNA-methylating agents currently used in anticancer therapy include dacarbazine (DTIC) and temozolomide (TMZ), currently largely used to treat brain tumors and melanoma. TMZ and DTIC methylate purines, and PARP is critical to the repair of this by BER/SSBR. Early studies showed that PD128763 and NU1025 (Fig. 3) were about 50× as potent as 3AB in increasing TMZ-induced DNA-strand breakage and cytotoxicity.[41] Various preclinical PARPi have been demonstrated to enhance TMZ in a variety of cell lines from different cancer types and, where studied, independently of p53 status.[42–44] Defects in MMR confer resistance to TMZ and studies of MMR-deficient and -proficient cells demonstrated that PARPi preferentially potentiated TMZ in the MMR-defective cells, overcoming resistance.[45–47] Since only tumors lack MMR, PARP inhibition, in combination with TMZ, represents a potentially selective therapeutic approach. Many of the PARPi that have entered clinical trials have been shown to potentiate TMZ in the preclinical setting. ABT-888 (veliparib) was shown to enhance TMZ cytotoxicity preferentially during S-phase, indicating that an accumulation of replication-associated DSBs was largely responsible for cell death.[48] The most potent PARPi, BMN 673 (Fig. 4) potentiated TMZ in a variety of breast and lung cancer cell lines, independently of BRCA status.[49] The cellular potentiation of TMZ by PARPi has been confirmed in xenograft studies in a huge variety of tumor types.[34] Since TMZ is largely used in the treatment of brain tumors the inhibitors that are able to cross the blood–brain barrier, ABT-888 (veliparib) and GPI-15427 (Fig. 3) and the closely related drugs E7016 and E7449 (Fig. 4), are particularly relevant. Both E7016 and ABT-888 (Fig. 4) have demonstrated enhancement of TMZ, or a combination of IR and TMZ, antitumor activity in in vivo models of glioblastoma.[50,51]

The limited application of TMZ and DTIC in cancer chemotherapy compared to the topoisomerase I poisons, which PARPi also sensitize cells to make the latter combination more attractive. Topoisomerase I poisons are used in the treatment of a variety of cancers; irinotecan is used to treat colorectal cancer, and topotecan is used in the treatment of small-cell lung cancer, and ovarian and cervical cancer. Topoisomerase I catalyzes the transient single-strand breakage, and reannealing of DNA to relieve torsional strain and the topoisomerase I poisons, such as the camptothecins, cause the accumulation of SSB by preventing reannealing. NU1025 was shown to increase camptothecin-induced DNA breaks and cytotoxicity in L1210 cells,[52,53] and later several studies confirmed potentiation with camptothecins (topotecan and irinotecan) and related drugs in a variety of models, independently of p53 status, in human cancer cell lines and xenografts.[34]

The most commonly administered genotoxic agent for cancer therapy is IR with radiotherapy being used at some stage in the treatment of around 50% of cancer patients. Early studies revealed that 3AB radiosensitized mammalian cells[54] and numerous studies have demonstrated the ability of PARPi in general to radiosensitize both cells and xenografts.[34] Where studied, radiosensitization appears to be greatest in S-phase cells, possibly because by inhibiting their repair, SSB accumulate, leading to the much more toxic collapsed replication forks. This hypothesis is supported by the increase in both γH2AX and RAD51 foci following exposure to radiation and PARPi.[55] On the other hand, PARP1 is proposed both to participate in DNA DSB repair either through cooperation with NHEJ or through a role in alt-NHEJ.[56,22,23]

5.04.2.2.2 Vasoactivity of PARPi

Another interesting feature that may lead to greater chemo- and radiosensitization in vivo than is observed in vitro is the observed vasoactivity of two clinically active PARPi (olaparib and rucaparib) as well as nicotinamide, which may indicate a class-effect. The vasoactive effects of AG14361 and AG014699 have been shown to lead to increased tumor perfusion with the implication that this improves drug delivery and oxygenation.[57,58] Using preconstricted rat arteries both inhibitors had a direct effect on the blood vessels' smooth muscle, and AG014699 was more potent than the common antihypertensive drug, hydralazine.[58] Similarly,

radiosensitization by olaparib in xenograft studies was found to be at least partly due to increased perfusion of the tumors, thereby reducing the hypoxic radio-resistant fraction.[59] Nicotinamide itself and simple analogues have long been known to cause vasodilation, improve oxygenation, and cause radiosensitization in preclinical studies,[60] and nicotinamide has been used as a radiosensitizer in clinical trials.[61,62]

5.04.2.2.3 Single-agent activity

The most exciting use of PARPi is as single agents, based on the paradigm-shifting studies demonstrating the synthetic lethality (Fig. 2B) of PARPi in tumors defective in HRR.[63,64] These initial studies demonstrated that concentrations of a panel of PARPi that were noncytotoxic to cells with functional HRR killed cells lacking BRCA2, XRCC2, XRCC3 or with silenced BRCA2.[63] Additionally, the PARPi KU0058948 and KU0058684 were particularly cytotoxic to BRCA1- and BRCA2-defective mouse embryonic stem cells.[64] The proposed mechanism is dependent on the high rate of endogenously ROS-induced SSBs; inhibition of PARP1 prevents their repair, so when they meet the advancing replication fork this results in collapsed replication forks that require HRR for repair. When HRR is defective these lesions prove lethal (Fig. 5). This is likely to be a tumor-specific therapy because HRR defects are relatively common in tumors but very rare in normal tissues.[65,66]

Defects in HRR in tumors are associated with more than just germline mutations in BRCA1 and 2, since mutations in these genes can arise in spontaneous cancers and BRCA1 can be silenced epigenetically, which also confers hypersensitivity to PARP inhibition.[67] HRR is a complex process involving several components including ATM, ATR, CHK1, MRN (MRE11/RAD50/NBS1), several FANC proteins, and RAD51 and its homologues. The loss of any one of these components can confer HRR dysfunction and cause PARPi sensitivity.[68] In addition, under hypoxic conditions, which are a common feature of cancer cells due to their deranged vasculature, HRR appears to be downregulated thereby conferring a "contextual synthetic lethality" with PARPi.[69]

Some interesting data are emerging regarding the interaction of PARP and the phosphoinositol-3 kinase (PI-3K)/mammalian target of rapamycin (mTOR) pathway. Phosphatase and tensin homolog (PTEN), a commonly mutated tumor suppressors in human cancer, is involved in the PI-3K pathway and has also been implicated in HRR. Some studies show that PTEN loss or disruption conferred sensitivity to PARPi.[70,71] However, subsequent data suggest that PTEN loss is not a universal indicator of PARPi sensitivity.[72,73]

5.04.2.2.4 Combinations with molecularly targeted agents

As PARPi have progressed in the clinic an increasing number of studies have assessed the potential of PARPi in combination with molecularly targeted agents, most commonly kinase inhibitors of various descriptions.

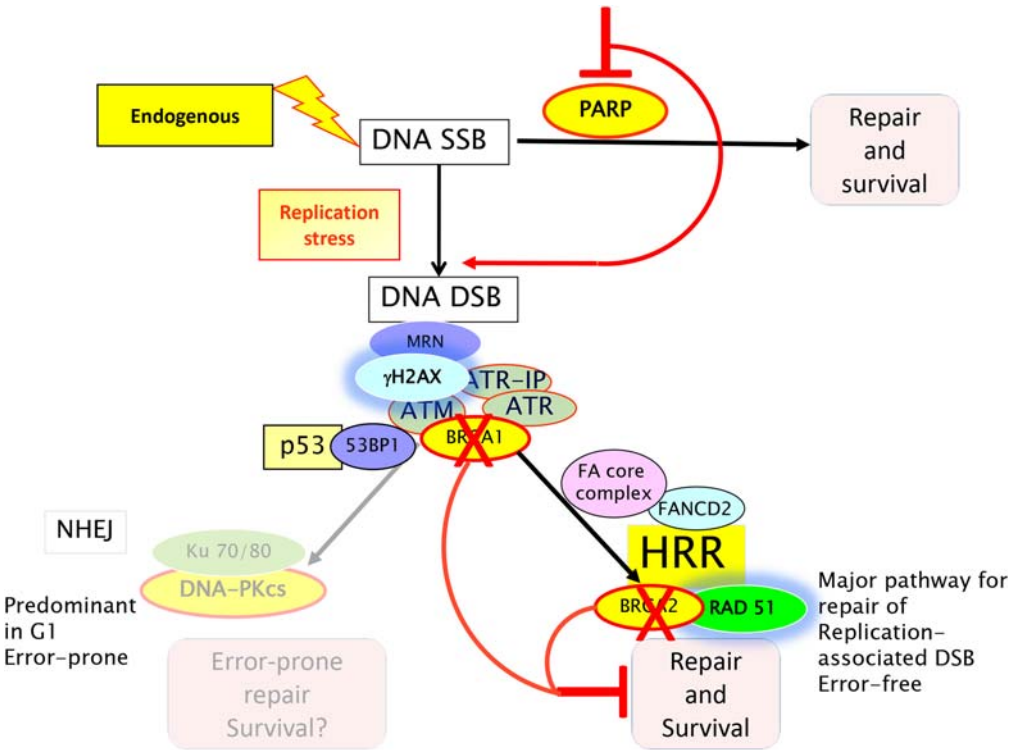

Fig. 5 The synthetic lethality of PARP inhibitors. Due to the high level of endogenously generated DNA single-strand breaks, inhibition of their repair by PARPi leads to replication stress that is repaired by HRR, of which BRCA1 and 2 are key components. When HRR is compromised, e.g., due to BRCA1/2 mutations the DNA cannot be repaired and the cells die.

Many studies have investigated PI-3K inhibitors. However, PI-3K-like kinases (PIKKs) include mTOR and those PIKKs involved in the DDR: ATM, ATR, and DNA-PKcs, so data on PI-3K and mTOR inhibition may deserve some cautious interpretation. It is possible that the effect of the inhibitors may be due to so-far unidentified interactions with the other DDR PIKKs. For example, the dual PI-3K/mTOR inhibitor, NVP-BEZ235 has been shown to inhibit ATM, ATR, and DNA-PKcs.[74,75] Studies indicate that PI-3K inhibition downregulated BRCA and reduced RAD51 focus formation, indicating a negative impact on HRR, and that PI-3K inhibitors increased the antitumor activity of PARPi in breast cancer models.[75-78] Recent studies indicate that PARP inhibition causes PI-3K/mTOR activation and that inhibition of PI-3K can be synergistic with the PARPi BMN 673 in small-cell lung cancer models.[79] Another PIKK, mTOR may also be implicated in HRR, and data indicate that mTOR inhibition suppresses HRR and sensitizes triple-negative breast cancer cells to PARPi in vitro and in vivo.[80–82] Because there are somewhat conflicting data regarding the targeting of the PI-3K/mTOR pathway for PARPi sensitization, further work is needed to determine if the effectiveness of these combinations is cell-type or drug-specific. Nevertheless the data so far present promising avenues to pursue. Receptor tyrosine kinases that act via PI-3K signaling may also be good targets for PARPi sensitization. EGFR and IGFR inhibitors have also been shown to suppress HRR function and increase the sensitivity of cells to PARPi.[83,84] Histone deacetylases (HDACs) may be necessary for HRR function, and HDAC inhibitors have been shown to reduce the expression of BRCA1 and RAD51, increase DNA damage, and sensitize cells to PARPi.[85,86]

Targeting cell-cycle control with CHK1 inhibitors sensitizes cells to PARPi as discussed later, for example, three different CHK1/2 inhibitors in combination with four different PARPi resulted in increased DNA damage and cell death.[87] Other studies showed that CDK1 regulates BRCA1 activity and that CDK1 inhibition increased the sensitivity of lung cancer cells, xenografts, and spontaneous lung cancers in mice to the PARPi, AG-014699 (rucaparib) without significant toxicity.[88] Subsequent studies showed that the CDK1 inhibitor, dinaciclib, inhibits HRR and sensitizes multiple myeloma cells to PARPi.[89]

Taken together, these data offer exciting possibilities for the combination of PARPi with other molecularly targeted agents.

5.04.2.3 Clinical Development of PARP Inhibitors

5.04.2.3.1 Combination chemotherapy

The first Phase I trial of PARPi in cancer patients was initiated in 2003. AG014699 (rucaparib) was given in combination with TMZ as the synthetic lethality of PARPi had not been revealed at this stage. In this study, of 33 patients with advanced solid tumors, PARP inhibition was seen at all doses.[33] The average tumor PARP inhibition was greater than 90% at 5 h (range 46–97%), and an increase in DNA SSB was seen in all patients treated with PARP-inhibitory dose. There was encouraging evidence of activity observed, and rucaparib alone was not associated with observed toxicity, but it increased the myelosuppression associated with TMZ, particularly at the maximum dose of rucaparib (18 mg/m^2), including thrombocytopenia and neutropenia. The safe dose for Phase II studies in combination with full-dose TMZ was determined to be 12 mg/m^2.

When rucaparib (at 12 mg/m^2) was combined with TMZ in a Phase II trial of patients with metastatic melanoma, there was a response rate of 17.4% among the 46 patients that were entered into the study with improved progression free survival (PFS).[90] However, just as observed in the Phase I trial, myelosuppression was seen in more than half of the patients, and the dose of TMZ had to be reduced by a quarter.

Other studies have investigated the combination of TMZ and PARPi. Following on the rucaparib study in melanoma patients a double-blinded Phase II study of veliparib in advanced metastatic melanoma (stage III or IV) revealed an increase in PFS of 2 months in the placebo-treated patients compared to 3.6 or 3.7 months in the veliparib (20 or 40 mg) arms. The patients having the best responses expressed low levels of ERCC1. Unfortunately, this did not translate to an increase in overall survival.[91] Similarly, the combination of olaparib with dacarbazine (DTIC, similar to TMZ) in patients with melanoma was well tolerated, but no objective response was demonstrated.[92]

TMZ and dacarbazine are used in the treatment of brain tumors, including glioblastoma multiforme (GBM) because they readily cross the blood–brain barrier. The most advanced PARPi that also penetrates the brain is veliparib, and this has been used in combination with these alkylating agents. In a Phase I/II trial of patients with glioblastoma, the combination of veliparib and TMZ was well tolerated, but there was no difference in PFS and overall survival when compared to TMZ alone.[93] However, these were unselected patients, and translational studies in patient-derived GBM xenografts reveal that those with hypermethylation of the 0^6-methylguanine-DNA-methyltransferase (MGMT) promoter responded better to the combination of TMZ + veliparib.[94] This has now formed the basis of an ongoing phase II/III trial of the combination of veliparib and TMZ in GBM patients with MGMT promoter hypermethylation (NCT02152982).

The combination of veliparib and TMZ has also been trialed in patients with hepatocellular cancer in a Phase II trial. Sixteen patients with hepatocellular cancer were administered with 40 mg OD of veliparib over 7 days and 150 mg/m^2 of TMZ over 5 days.[95] However, even though the combination regime was well tolerated in the patients, survival benefit was not observed and the study had to be discontinued.

Veliparib, in combination with TMZ, has also been evaluated in the pediatric population. In a Phase I trial, 29 children with recurrent brain tumors were given escalating doses of veliparib and TMZ as a fraction of established doses in the adult population.[96] The combination therapy was well tolerated in the children, and although objective response was not seen, a small fraction of the patients had stable disease for more than 6 months.[96] Having established the recommended phase II doses, a phase I/II clinical trial is now ongoing to evaluate the efficacy of the combination regime in children with brainstem gliomas.

PARPi have also been evaluated in combination with topoisomerase poisons. In the first published study, Kummar and colleagues evaluated the effect of the combination of 10 mg of oral veliparib in combination with varying doses and schedules of intravenous topotecan in 24 patients with refractory solid tumors and lymphomas.[97] PARP inhibition of greater than 75% was observed in three paired tumor biopsy samples and by >50% in peripheral blood mononuclear cells (PBMCs) from 19 of the 23 patients. The combination resulted in an increase in γH2AX in both circulating tumor cells and PBMCs suggesting that repair was inhibited. Some limited efficacy was observed: Stable disease in four out of six patients at dose-level 1 of topotecan (1.2 mg/m^2) but dose-limiting myelosuppression was observed in four/six patients, necessitating dose reductions and schedule changes.[97] A similar Phase I study with olaparib in combination with topotecan in patients with solid tumors also observed a dose-dependent increase in dose-limiting neutropenia as well as gastrointestinal toxicity and established an MTD of topotecan of 1 mg/m^2 × 3 days in combination with olaparib at 100 mg bid. This combination was not pursued due to lack of increased efficacy of the combination.[98] The tolerability and efficacy of PARPi and irinotecan were evaluated in a Phase I study of patients with advanced solid tumors who were administered with 100 mg/m^2 of irinotecan on days 1 and 8 of a 21-day cycle and escalating doses of veliparib.[99] Veliparib decreased ADP-ribose polymer levels at all doses, and there was evidence of increased DNA damage. Anti-tumor activity was observed at all doses with partial response in almost 20% of the 35 patients.[99] Olaparib has also been investigated further with irinotecan in patients with colorectal cancer: 11 patients who received continuous olaparib with irinotecan every 3 weeks had higher than expected toxicity, but a schedule of intermittent olaparib with irinotecan every 2 weeks was better tolerated. Toxicities were hematological and gastrointestinal, and the best response was stable disease for 4–13 months. The recommended schedule for Phase II was olaprarib 50 mg po BID days 1–5 and irinotecan 125 mg/m^2 every 2 weeks.[100]

Combinations with topoisomerase II poisons have also been evaluated. The safety profile of the triple combination of 100 mg dose of veliparib with cisplatin (75 mg/m^2 on day 1) and etoposide (100 mg/m^2 on days 1–3) in a 21-day cycle was evaluated in patients with small-cell lung cancer and was well tolerated with minimal adverse effects.[101]

The combination of PARPi with platinum-based chemotherapy has also been evaluated in a number of studies. This followed the confirmation of antitumor activity of this combination regime in preclinical studies.[39,102] Olaparib, in combination with cisplatin, was administered to patients with advanced solid tumors in a Phase I trial. The patients were given 50 mg BD of olaparib and 60 mg/m^2 of cisplatin, with a favorable objective response rate observed in more than 40% in patients with BRCA 1/2-mutated ovarian cancer and 71% among patients with BRCA1/2-mutated breast cancer.[103]

Not all combination studies have demonstrated clinical efficacy. In another Phase I study of the combination of olaparib with gemcitabine in patients with pancreatic cancer, escalating doses did not achieve desired clinical efficacy.[104] These findings suggest that while certain PARPi combination therapies offer exciting novel treatment strategy in some malignancies, they are not particularly effective in other cancers.

Lee and colleagues evaluated the safety profile of olaparib in combination with carboplatin in patients with BRCA-mutated breast or ovarian cancer and established 400 mg BD of olaparib as a tolerable dose.[105] In another study, olaparib was administered in combination with cisplatin and gemcitabine in patients with advanced solid tumors, but myelosuppression was observed even at relatively lower doses, which could limit the effectiveness of this combination therapy in further trials.[106] The long-term use of olaparib following combination therapy was evaluated in a study of 21 patients with breast, ovarian, and fallopian tube cancers who were initially administered with olaparib plus carboplatin and/or paclitaxel and then olaparib monotherapy.[107] In patients with initial response to the combination therapy, this response was maintained with long-term use of olaparib monotherapy and was well tolerated although adverse effects of myelosuppression, fatigue, and pain were observed in some patients.

It appears that there is an association between myelosuppression and PARPi. Establishing a therapeutic window of these combinations, which could be narrow in certain combinations, could reduce these adverse events and encourage progression from bench to bedside. Despite this shortcoming, the trial results from PARPi in combination with other chemotherapy agents are very encouraging indeed and could eventually be established in standard clinical care.

5.04.2.3.2 Exploiting the synthetic lethality of PARPi in HRR-defective cancers

The most exciting clinical use of PARPi is as a single agent to exploit HRR defects in tumors by synthetic lethality. The first Phase I trial of olaparib was as a single agent and as soon as the data regarding the synthetic lethality of PARPi in models of BRCA mutant cancer became known, the patient population was enriched for those with germline BRCA 1/2-mutations. In this pivotal study of 60 patients with or without BRCA-mutated cancers, objective antitumor response was observed only in the patients with BRCA mutation when they were administered with 200 mg of olaparib or more twice a day in 4-week cycles. Out of 19 pretreated breast, ovarian, or prostate cancers there were 12 responses (nine partial or complete, two stable disease, and one tumor marker decrease). Most of the responses in ovarian (8), the two breast and one prostate cancer responders were BRCA2 carriers. The side effects were mild, mostly nausea and fatigue with no significant increase in side effects among the mutation carriers.[108] PARP inhibition by more than 90% was observed in patients that received 60 mg or more of olaparib twice daily. When the dose was increased to 400 or 600 mg twice a day, toxicity was observed in three patients. These include mood change in a patient with advanced ovarian cancer, thrombocytopenia in a patient with mesothelioma, and somnolence in a patient with metastatic breast cancer. This publication provided a significant further stimulus to the clinical development of PARPi as single agents, with the most advanced being olaparib, niriparib, and rucaparib, and the highly potent talozaparib (BMN 673) more recently advancing rapidly in clinical trials. In another trial of olaparib in patients with BRCA-mutated advanced breast cancer, women were given either 400 mg BD oral olaparib or 100 mg BD of oral olaparib. The objective response rate was 41% in the cohort with the higher dose and 22% in the cohort with lower dose of olaparib.[109] Olaparib has also been evaluated in BRCA-mutated ovarian cancer in a Phase II trial where women

with either BRCA1 or BRCA2 mutations were administered with 400 mg BD ($n=33$) of olaparib and another cohort with 100 mg BD ($n=24$). The objective response rate was 33% in the first cohort that received 400 mg BD olaparib compared to 13% in the cohort that received the lesser regime.[110] This confirms that response is highly dependent on dosing, but this will have to be balanced with potential adverse effects.

Olaparib has demonstrated its greatest efficacy in ovarian cancer. In a Phase II trial where the efficacy of olaparib was evaluated in women with high-grade ovarian cancer and triple-negative breast cancer with and without BRCA mutation, 90 women received 400 mg BD of olaparib.[111] In the ovarian cancer cohort, the objective response rate was 41% among women with BRCA mutation and 24% in women without BRCA mutation. Surprisingly, there was no improvement in the response rate in the breast cancer group. The fact that there was response in women without BRCA mutation is probably because there are other defects that result in compromised HRR besides BRCA mutation.

The efficacy of another PARPi, rucaparib, was evaluated in a Phase II multicenter trial of patients with BRCA-mutated breast or ovarian cancer.[112] Escalating doses of rucaparib were administered and were well tolerated. Although the objective response rate was disappointing at 2%, more than 40% of the patients had stable disease for more than 3 months. More importantly however, it was observed that patients that were maintained on oral rucaparib following intravenous rucaparib had a higher response rate of 15%, suggesting that continuous therapy is needed for sustained response, although it will be important to monitor potential side effects in long-term use.

To evaluate the efficacy of veliparib as a single agent, 50 patients with BRCA-mutated recurrent ovarian cancer were given 400 mg BD oral veliparib.[113] The overall objective response rate was 26%, with a higher response rate of 35% observed in platinum-sensitive patients compared to 20% in platinum-refractory patients.

Niraparib has also been evaluated in patients with BRCA-mutated malignancies and sporadic cancer. Escalating doses of niraparib were administered to patients with BRCA-mutated ovarian and breast cancers as well as patients with sporadic ovarian cancer, prostate cancer, and nonsmall-cell lung malignancies.[114] The maximum tolerated dose of niraparib was 300 mg/day. Partial response was reported in 8 out of 20 patients with BRCA-mutated ovarian cancer, and antitumor activity was observed in patients with sporadic ovarian, prostate, and nonsmall-cell lung malignancies.[114] These findings suggest that while the antitumor activity of PARPi was previously mostly limited to BRCA-mutated cancers, PARPi could also be beneficial in sporadic cancers.

The promising results from these trials led to an international, randomized, double-blind, placebo-controlled trial of olaparib in women with platinum-sensitive serous ovarian cancer (Study 19). Patients were randomized to receive 400 mg olaparib BID (136) or placebo (129). The median PFS was 11.2 months in the olaparib group and 4.3 months in the placebo group in the patients with BRCA mutations, with similar findings in patients with wild-type BRCA (PFS = 7.4 months vs. 5.5 months).[115] Although Phase III trials on olaparib are still ongoing, the results from the Study 19 Phase II trial were compelling enough to convince the National Institute for Health and Care Excellence (NICE) in the United Kingdom to recommend Olaparib for the management BRCA-mutated ovarian, fallopian tube, or peritoneal cancers in women.[116]

5.04.2.3.3 PARPi in combination with molecularly targeted agents

The effects of PARPi in combination with molecularly targeted agents are currently being studied. There is an ongoing Phase I study of the effects of the combination of veliparib (ABT-888) and CDK inhibitor, dinaciclib (SCH727965), in advanced study tumors (NCT01434316). In another ongoing Phase I/II trial, EGFR inhibitor, gefitinib in combination with olaparib (AZD2281) is being trialed in patients with advanced nonsmall-cell lung cancer (NSCLC) (NCT01513174). Although many of the studies are ongoing, there have been some results published on the combination of PARPi with molecularly targeted agents. The combination of the VEGF inhibitor, bevacizumab, and olaparib showed no dose-limiting toxicities and was well tolerated in a Phase I trial in patients with advanced solid tumors.[117] To assess the efficacy of olaparib with the VEGFR inhibitor, cediranib, 28 patients with ovarian and breast cancer were administered with varying doses of olaparib and cediranib.[118] An overall response rate of 44% was observed in the patients with ovarian cancer with a clinical benefit of 61%, while no response rate was seen in the breast cancer patients.[118] Dose limiting toxicities were reached at 30 mg cediranib OD and 400 mg BD of olaparib, and a combination dose of cediranib 30 mg OD and olaparib 200 mg BD was therefore recommended for a Phase II trial. In the subsequent Phase II trial, 90 women received either the combination of olaparib 200 mg BD and cediranib 30 mg OD or olaparib monotherapy 400 mg BD. An improved PFS was observed in the combination group (17.7 months vs. 9.0 months).[119] A Phase III trial of this combination therapy is now ongoing (NCT02446600).

5.04.2.3.4 PARPi in combination with radiation

About 60% of all cancer patients receive radiotherapy at some part of their therapy, and while many show excellent responses some have high levels of intrinsic radioresistance. There is good preclinical evidence to suggest that combining PARP inhibition with radiotherapy should be clinically beneficial. To date, veliparib is the most studied PARPi in combination with radiotherapy in the clinical setting. In a Phase I study of 22 patients with peritoneal carcinomatosis, patients were administered with 80–320 mg OD of veliparib for three cycles and 60 cGy of fractionated whole abdominal radiation on days 1 and 5 for 4 weeks.[120] Although no objective responses were observed, prolonged disease stability was observed in patients with ovarian and fallopian cancer.

The combination of PARPi and radiation therapy has also been evaluated in patients with brain metastases from primary solid tumors. In a Phase I trial, 81 patients with brain metastases were administered with whole brain radiation therapy and increasing doses of veliparib. The combination was well tolerated with better median survival time than initially predicted.[121] Veliparib was also investigated in combination with capecitabine and radiotherapy in patients with rectal cancer.[122] The combination was well

tolerated, and 28% of the patients had complete responses. However, despite these promising results, there are fewer clinical trials involving PARPi and radiotherapy than combination chemotherapy, and progression to standard clinical therapy has been slower.

The current status of ongoing clinical trials with PARPi is given in Table 1.

5.04.2.3.5 Biomarkers to detect HRR deficiency

Since PARPi therapy has been proven to be effective in HRR-deficient tumors, which is caused by more than just BRCA mutations, having biomarkers to detect HRR deficiency will help identify patients that are likely to benefit from PARPi therapy. It is clear that mutational screening for germline BRCA1 and 2 defects will only identify a small subset of HRR-defective tumors and will not detect sporadic tumor-specific mutations or epigenetic silencing events such as methylation of the *BRCA1* gene, which is observed in up to 30% of sporadic ovarian cancers and breast cancers.[123] There are several studies carried out to establish ways of identifying tumors with HRR deficiency including BROCA screening which identifies loss of function mutations in a panel of genes, mostly involved in HRR that are associated with breast and ovarian cancer,[124] loss of heterozygosity (LOH), telomeric allelic imbalance (TAI), large-scale state transition (LST) scores, gene expression profiling,[125] immunohistochemical analysis of TMAs,[97] or ex vivo functional assays,[126–129] all of which have been reported with varying degrees of predictive power.

Table 1 PARP inhibitors in clinical trials

Compound	*Latest stage of development and trial details*	*Clinical trial identifier(s)*
Olaparib	Phase I in combination with radiotherapy (or radiotherapy plus chemotherapy) in various tumor types (oesophageal, head and neck, breast)	NCT01460888, NCT02229656, NCT02227082, NCT01758731
	Phase II as a monotherapy, maintenance monotherapy, and in combination with chemotherapy in various tumor types (prostate, nonsmall-cell lung)	NCT01682772, NCT02679963
	Phase III as monotherapy, maintenance monotherapy, and in combination with chemotherapy or cediranib in multiple tumor types (ovarian, breast, pancreatic, gastric)	NCT02502266, NCT02446600, NCT02032823, NCT02184195, NCT02000622, NCT02282020, NCT01874353, NCT02446600
	Phase IV as maintenance monotherapy in ovarian cancer	NCT02476968
Rucaparib	Phase II as a monotherapy in various tumor types (pancreatic, breast)	NCT02042378, NCT01074970
	Phase III as maintenance monotherapy in ovarian cancer	NCT01968213
Veliparib	Phase II in combination with temozolomide in small-cell lung cancer	NCT01638546
	Phase III in combination with chemotherapy in multiple tumor types	NCT02163694, NCT02106546, NCT02264990, NCT02152982, NCT02470585
Niraparib	Phase I in combination with temozolomide or irinotecan in Ewing Sarcoma	NCT02044120
	Phase III as maintenance monotherapy in ovarian cancer	NCT01847274
Talazoparib	Phase II as a monotherapy in BRCA1/2 mutation-associated ovarian cancer	NCT02326844
	Phase III as a monotherapy in metastatic breast cancer	NCT01945775
BGB-290	Phase I in combination with BGB-A317 in advanced solid tumors	NCT02660034
E7016	Phase I in combination with temozolomide in advanced solid tumors	NCT01127178
E7449	Phase I/II in combination with carboplatin and eribulin mesylate in BRCA-mutated cancers Terminated due to lack of funding	NCT02396433
	Phase I/II as a monotherapy and in combination with temozolomide (TMZ) or with carboplatin and paclitaxel in advanced solid tumors	NCT01618136
CEP-9722	Phase I in combination with gemcitabine and cisplatin in patients with advanced solid tumors or mantle cell lymphoma This study has been completed	NCT01345357
	Phase I as single-agent therapy and as combination therapy with temozolomide in patients with advanced solid tumors This study has been completed	NCT00920595

Currently, detecting HRR deficiency is not standard clinical practice, but there are ongoing studies to validate various methodologies. LOH score has been used to identify tumors deficient in BRCA1, BRCA2, and Rad51C.[130] LOH is strongly associated with BRCA 1/2 mutations,[130,131] and therefore it could potentially be used to identify patients that could benefit from PARPi. LOH has been used to identify BRCA-mutated ovarian, pancreatic, and breast cancers[130–132] with high sensitivity. Based on these findings Myriad developed the HRD assay, which has been used to support clinical trials with olaparib.[115,133] The presence of germline and somatic mutation in several key HRR genes has been shown to be associated with sensitivity to platinum therapy and improved survival.[134] This has formed the basis of many clinical studies of PARPi and other chemotherapy agents in the treatment of HRR-deficient tumors.[135–137]

Quantification of TAI has been shown to identify tumors that are sensitive to DNA-damaging agents.[136] Triple-negative breast cancers sensitive to cisplatin-based chemotherapy have been shown to have high levels of TAI.[136] It has been established that low expression of BRCA1 is associated with high levels of TAI with a corresponding positive response to cisplatin, therefore suggesting that TAI could identify tumors that are HRR deficient.[138]

As these scores have been shown to be individually capable of identifying tumors that are HRR deficient and sensitive to anticancer agents, there are some suggestions that combining the scores could offer further potential clinical benefit. In a study of 86 patients with triple-negative breast cancer who received cisplatin or carboplatin, the mean HRD-LOH/HRD-LST score was significantly higher in patients that responded than patients that did not in the subgroup of patients without BRCA1/2 mutations.[139] The combination of these scores is now known as "HRD scores," and if its use does progress to clinical setting, it could facilitate the identification of patients that are likely to benefit from certain anticancer agents, therefore optimizing their clinical management.

BROCA-type genomic profiling has been shown to identify defective HRR.[124,140] Using a combination of BROCA screening, SNP analysis, and LOH, a new diagnostic test was developed by Foundation Medicine, Inc., and this has been used to identify HRR-deficiency in a Phase II study of rucaparib in ovarian cancer (Ariel 2).[141] The overall response rate (Recist + CA-125) was 82% in patients identified as being carrier of BRCA mutation (median PFS = 9.4 months) and 45% in patients identified as HRR-deficient using the screen (PFS = 7.1 months), but only 21% in the biomarker-negative patients (PFS = 3.7 months). The commonest mutation in the biomarker-positive group that responded to rucaparib was RAD51C.

Assessing HRR function in viable tumor cells would be an alternative approach that could capture all previously identified and currently unknown defects. This has the advantage of identifying tumors in which HRR has been restored by secondary mutations in BRCA1 or 2 or through inactivation of 53BP1 or DNA-PK, but it relies on the availability of viable patient material that can be exposed to DNA damage ex vivo. RAD51 foci, together with BRCA1 and FANCD2 foci, have been successfully measured in fresh breast tumor biopsies, following ex vivo irradiation[128,142] in a study of AML primary cultures, ascites cells from patients with ovarian cancer, and pleural effusions from patients with both primary lung cancer and lung metastases from other primary cancers following exposure to PARPi.[126,127,143,144] NSCLC may be associated with HRR defects as one study found that RAD51 costaining with proliferating cell nuclear antigen (PCNA) in breast and NSCLC explants treated with cisplatin revealed that 3/13 NSCLC lacked the ability to form RAD51 foci,[143] and another study revealed that 3 out of 4 primary cultures of NSCLC cells were unable to form RAD51 foci after rucaparib exposure.[144] RAD51 foci may be measured in formalin-fixed tumor biopsies taken after chemotherapy, a low RAD51 score correlated with a favorable response to treatment.[145,146]

5.04.2.4 DNA-Dependent Protein Kinase

The repair of DNA DSBs is crucial to survival if left unrepaired DSBs will trigger cell death. Natural sources of DSBs are ROS, trapped topoisomerase II complexes, and environmental sources of irradiation. DSBs may be repaired by the rapid and efficient NHEJ pathway, in which DNA-PK is a key component. DNA-PK is a trimeric protein consisting of the DNA-binding components Ku70 and Ku80 and the catalytic subunit, DNA-PKcs. Because NHEJ rejoins broken DNA ends without reference to a second template it is responsible for not only DSB repair during G1 or G0 phase but also operational during other cell-cycle phases.[147] Cells lacking DNA-PKcs are very sensitive to IR and topoisomerase II poisons, such as doxorubicin and etoposide that are used clinically.[148] DNA-PK activity seems to be upregulated in several cancer types and is generally a predictor of poor prognosis.[149] Increased DNA-PK activity not only confers resistance to radiotherapy and some chemotherapies but also, somewhat antiintuitively, confers genomic instability (an enabling characteristic of cancer). NHEJ, the simple religation of broken DNA double-strand ends can lead to the loss of nucleotides and the introduction of errors, and DNA-PK may also compete with HRR, the high-fidelity DSB repair pathway.[150] DNA-PK may also negatively impact on genomic stability through interaction with Snail1 and decreased checkpoint signaling.[149] DNA-PKcs is therefore an attractive target for anticancer therapy for multiple reasons, not just the inhibition of DSB repair.

5.04.2.4.1 DNA-PK Inhibitors

The first identified inhibitor was wortmanin, (Fig. 6) a fungal metabolite that is a pan PI-3K inhibitor, which was shown to enhance the cytotoxicity of IR and etoposide.[151]

DNA-PKcs is a PIKK family member, and in the search for inhibitors most have targeted the ATP-binding domain with PI-3K inhibitors often being the starting point for drug development. Achieving selectivity of inhibitors for DNA-PKcs over other PIKKs, ATM, ATR, mTOR as well as the different PI-3K isoforms, has been a challenge. The PI-3K inhibitor LY294002 was found to have equivalent activity against DNA-PKcs and mTOR in in vitro assays[152] and was used as a "hit" compound for subsequent drug

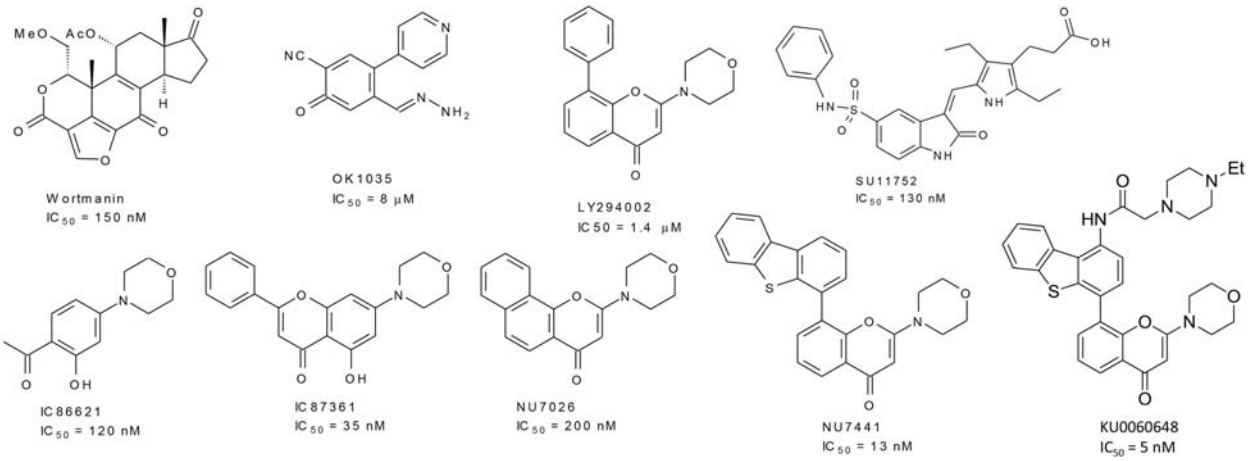

Fig. 6 DNA-PK inhibitors.

discovery that led to the identification of NU7026, NU7441, and KU-0060648 (Fig. 6) with improved selectivity and potency although the last compound was also found to be a PI-3K inhibitor.[153] These inhibitors increased DNA DSB induction/persistence and enhanced the cytotoxicity of IR and topoisomerase II poisons (doxorubicin and etoposide) in a variety of cell culture models of human cancers and with some limited in vivo efficacy data.[154–156] NU7441 has also been shown to potentiate mitoxantrone cytotoxicity in primary cultures of human chronic lymphocytic leukemia (CLL) cells.[157] Early inhibitors of DNA-PKcs include OK-1035 and SU11752 (Fig. 6) that inhibit DNA-PKcs in an ATP-competitive manner and inhibit repair of X-ray-induced DNA damage (OK-1035) and sensitize cells to radiation-induced cytotoxicity (SU11752) with increased specificity for DNA-PKcs.[158,159] Another series of PIKK inhibitors with selectivity for DNA-PKcs includes IC86621 (Fig. 6) that increase IR-induced DNA DSBs and enhance the cytotoxicity of IR and etoposide in cells with functional DNA-PKcs but not those lacking DNA-PKcs, and, in combination with fractionated irradiation, prolonged the survival of tumor bearing mice.[160] Further development of this series led to IC87361 (Fig. 6), which increased the radiosensitivity of endothelial cells in vitro and tumor vascular cells in vivo from wild-type mice but not those that from SCID mice that were deficient in DNA-PKcs.[161] The dual mTOR/DNA-PK inhibitor CC-155 was found to inhibit the growth of PC-3 prostate cancer xenografts as a single agent.[162]

5.04.2.4.2 Clinical Development of DNA-PK Inhibitors

There are a few ongoing clinical trials of DNA-PK inhibitors in various tumors, all at Phase I (Table 2). In the first-in-human Phase I trial of CC-155, which is a dual DNA-PK and TOR kinase inhibitor, 44 patients with various malignancies were administered with increasing dose of 0.5–40 mg. There was a complete tumor response in a patient with endometrial cancer, partial response in a patient with melanoma, and 18 (41%) of the patients exhibited stable disease.[163] When the established dose of 10 mg twice daily was administered to a further 62 patients, stable disease was observed in 64% of patients with prostate cancer, 53% of patients with head and neck squamous carcinoma, 21% of patients with GBM, and 22% of patients with Ewing's sarcoma. These findings offer promising prospects for DNA-PK inhibitors in future clinical setting.

MSC2490484A (chemical structure undisclosed) is another DNA-PK inhibitor that is currently in Phase I trial for CLL (NCT02316197). It is also being evaluated in combination with radiotherapy in advanced solid tumors (NCT02516813).

Table 2 DNA-PK inhibitors in clinical trial

Compound	*Latest stage of development and trial details*	*Clinical trial identifier(s)*
MSC2490484A	Phase I as a monotherapy in advanced solid tumors or chronic lymphocytic leukemia	NCT02316197
MSC2490484A	Phase I in combination with radiotherapy in advanced solid tumors	NCT02516813
CC-115	Phase I as a monotherapy in various advanced solid tumors and hematological malignancies	NCT01353625, NCT01421524
CC-122	Phase I as a monotherapy in advanced solid tumors, nonHodgkin's lymphoma, or multiple myeloma	NCT01421524

5.04.2.5 ATM/CHK2 Signaling

The signaling of DNA DSBs to cell-cycle checkpoints is equally important for survival. ATM is key PIKK that signals DSB to cell-cycle arrest. The Ataxia Telangiectasia Mutated (ATM) gene was discovered through the study of the autosomal recessive disorder, ataxia-telangiectasia (A-T). As well as having poor coordination (ataxia) and small dilated blood vessels (telangiectasia), growth and mental retardation, and immunodeficiency, individuals with A-T are extremely radiosensitive and are cancer prone.[164–167] The study of cells from people with A-T revealed that the reason for their radiosensitivity was most likely due to a failure to induce G1 arrest after irradiation and progress into S-phase with damaged DNA.[168–170] Subsequently, A-T cells were also found to have reduced DSB repair.[171] In the absence of DSBs ATM remains in inactive homodimers or multimers but is activated to undergo autophosphorylation at serine1981 and dissociate into monomers. There is some uncertainty about what activates ATM in response to DSB, whether it needs to locate somehow to the break to be activated by the MRN (MRE11-Rad50-Nbs1) or whether it can be activated while still distal to the break by DSB-induced conformational change of chromatin.[172] Further phosphorylations at serine367 and serine1893 do seem to be MRN dependent, and all three are needed for full activation, with serine1981 being the most critical. This is of course a simplified version of events; ATM sets off a cascade of phosphorylation events in response to DNA DSBs.[173] Activated ATM phosphorylates target proteins in the DDR pathway, some of which are themselves kinases, setting off a surge of activating and repressing phosphorylation events to effect cell-cycle arrest. Like DNA-PK, ATM phosphorylates histone H2AX contributing to the accumulation of γH2AX into foci at DSBs.

ATM activates G1 arrest by direct phosphorylation of p53 at serine 15 and activating phosphorylation of CHK2, which then also phosphorylates p53 at serine 20. These phosphorylations lead to the stabilization of p53 by preventing the binding of the E3 ubiquitin ligase, MDM2, and hence proteasomal degradation. The stabilization of p53 is also enhanced by the phosphorylation of MDM2 by ATM.[174] The accumulation of p53 results in G1 arrest by transactivation of p21, a repressor of CDK2-mediated G1/S transition. The extreme hypersensitivity of A-T cells to DSB-inducing agents and the persistence of DSBs in nonreplicating A-T cells suggested that ATM might also play a role in DSB repair. In response to IR, ATM is reported to phosphorylate BRCA1,[175] a key component of the HRR DNA DSB repair pathway. In addition, Artemis, a nuclease involved in the processing of complex DSBs prior to repair by NHEJ, has been identified as a target of ATM, and ATM has been shown to be an upstream component of the NHEJ pathway.[176]

Several publications have suggested a role for ATM in HRR, largely based on the observation that key HRR components, e.g., CtIP and BRCA1, are targets for ATM phosphorylation.[175,177–179] This proposal is supported by the slower recruitment of RAD51 to DSBs in A-T cells.[180] However, there are substantial phenotypic differences in ATM-deficient and HRR dysfunctional cells when it comes to the sensitivity to different types of DNA damage. A-T cells are highly radiosensitive but are not particularly sensitive to DNA cross-linking agents, such as cisplatin[181,182,164]; conversely HRR-defective BRCA1/2 or RAD51 mutant cells are very sensitive to DNA cross-linking agents but not particularly radiosensitive.[183–186] Studies in mice suggest that while BRCA1 is crucial for HRR, ATM is dispensible although ATM inhibition may interfere with HRR.[187] Other studies also show that inhibition of ATM appears to have more profound effects than does ATM deletion, which could reflect additional off-target effects of the inhibitors or that the inhibitors trap ATM at the DSB and block repair in the same way that PARPi are proposed to trap PARP.[188]

5.04.2.5.1 ATM Inhibitors

The radiosensitivity of individuals with A-T and cells derived from them suggested that targeting ATM might be a means to enhance the radio-responsiveness of tumor cells. The first inhibitors of ATM were the pan-PIKK inhibitors, caffeine and wortmanin (**Fig. 6**), but since they also inhibited DNA-PKcs and ATR it was not possible to attribute their radiosensitization purely to ATM.[189,190] The PI-3K inhibitor LY294002 (**Fig. 6**) that was found to also inhibit DNA-PKcs and ATM was used as the starting point for the development of ATM inhibitors as well as DNA-PK inhibitors. The first selective ATM inhibitor to be described was KU55933 (**Fig. 7**).[191] KU55933 was a potent radiosensitizer in two human colon cancer cell lines, with 10 μM concentration causing a 4- to 20-fold reduction in survival.

KU55933 also enhanced the cytotoxicity of the topoisomerase II poisons etoposide, amsacrine and doxorubicin, and the topoisomerase I poison, camptothecin. It profoundly decreased the G1- and S-phase fraction of etoposide-treated cells. Interestingly, KU55933 also sensitized cells lacking DNA-PKcs, suggesting that the checkpoint activation and DNA repair functions of ATM both contribute to its prosurvival activity. The cellular specificity of KU55933 for ATM was shown by its total lack of radiosensitization in A-T cells.[191] KU55933 was also able to induce cells that had become senescent following treatment with low-dose hydrogen peroxide, doxorubicin, or camptothecin to undergo apoptosis.[192] Although ATM signals to cell-cycle checkpoints via p53, chemosensitization and radiosensitization by KU55933 and a later more potent analogue, KU59403 (**Fig. 7**), was not p53-dependent. Equal sensitization by both drugs observed in matched pairs of p53 wild-type and mutant cells.[193]

Screening a compound library identified CP466722 (**Fig. 7**) as an ATM inhibitor,[194] exposure to CP466722 (6 μM) for 4 h did not affect HeLa survival but reduced survival of irradiated HeLa cells and resulted in reduced G1 and increased G2/M accumulation after irradiation.

Two more analogues of KU55933 with sufficient potency and suitable pharmacological properties to be used in tumor xenograft models have been reported: KU-60019 and KU-59403 (**Fig. 7**).[193,195,196] KU-60019 inhibited p53 and CHK2 phosphorylation and was also a potent radiosensitizer of glioma cells with ATM function but not A-T cells, confirming its specificity. It also inhibited cell migration and invasion and AKT phosphorylation, which was interpreted as ATM regulating an ATK phosphorylase.[196] However, it

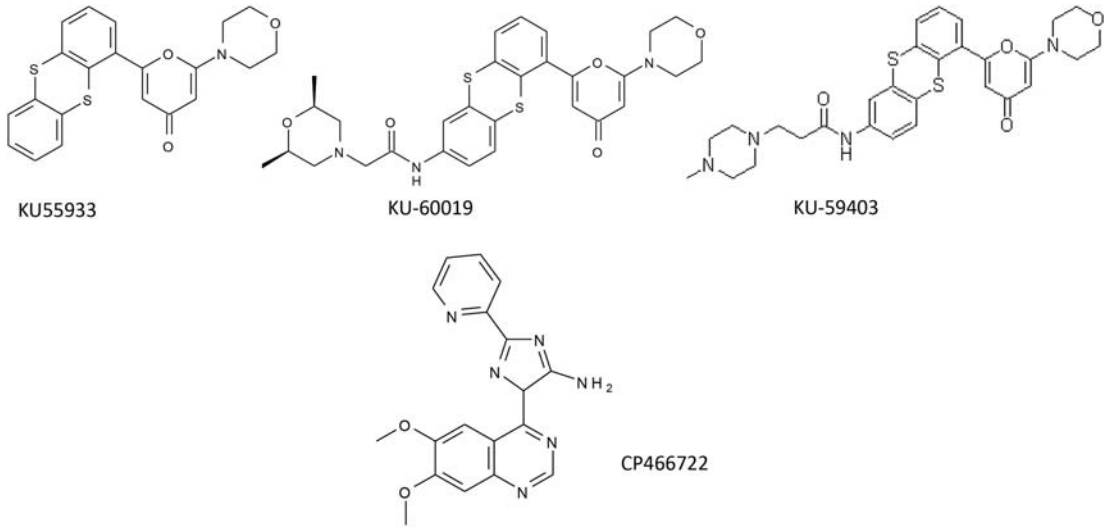

Fig. 7 ATM inhibitors.

is possible that it may affect PI-3K or mTOR in the cellular milieu despite the lack of in vitro activity. Subsequent studies by the same group showed that continuous exposure to KU-60019 at nanomolar concentrations potentiated radiation and radiation + TMZ sensitivity in the glioma model without affecting normal astrocytes.[197] In in vivo models of glioma (orthotopic xenografts) KU-60019 administered intracranially increased the survival of mice given cranial irradiation. In these studies both the intrinsic radiosensitivity and the radiopotentiation by KU-60019 were greater in the p53-mutant xenografts than the wild-type ones.[195] Similarly, for the radiosensitization of glioblastoma-initiating cells, in vitro and in an orthotopic model by intracranial administration, KU-60019 was more effective in cells expressing low levels of p53 but high levels of PI-3K (which may also suggest an activity of KU-60019 against the PI-3K pathway).[198] In contrast, chemo- and radiosensitization by KU-59403 as well as KU-55933 was not p53 dependent, and KU-59403 enhanced the cytotoxicity of topoisomerase I and II poisons and irradiation in a panel of cell lines, irrespective of p53 status. In in vivo studies sufficient concentrations of KU-59403 were achievable after intraperitoneal injection to increase the sensitivity of colon cancer xenografts to both etoposide and irinotecan.[193]

5.04.2.5.2 CHK2 Inhibitors

The downstream signaling of ATM is to a large part mediated by phosphorylation of CHK2 on Thr68 and other residues in the N-terminus, which triggers a conformational change and autophosphorylation that is necessary for full CHK2 activation. CHK2 blocks the cell cycle by stabilization of p53 and inactivating phosphorylations of the CDC25 family[199] and may promote DNA repair via phosphorylation of BRCA2[200] making it an attractive target for the sensitization of DNA-damaging anticancer agents.

NSC109555 was identified as a CHK2 inhibitor in a high-throughput screen of a 100,000-compound library using an immobilized metal ion affinity-based fluorescence polarization assay[201] (Fig. 8). This compound was found to increase the cytotoxicity of gemcitabine in a panel of pancreatic cell lines, which may have been mediated by increasing ROS levels.[202] PV1019 (Fig. 8) is

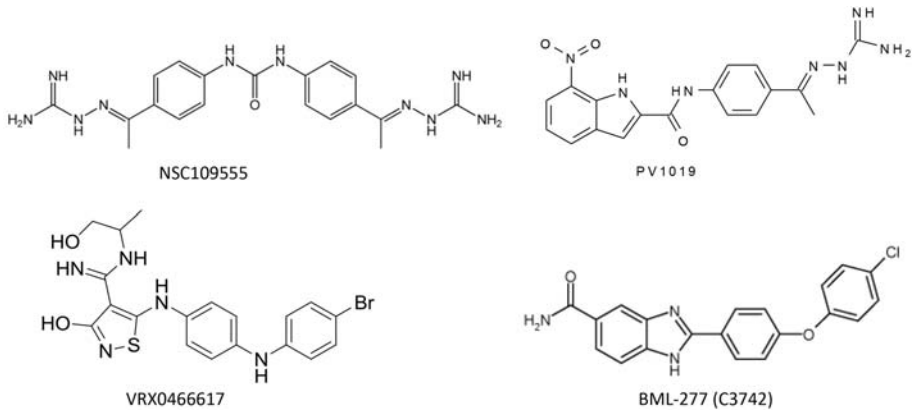

Fig. 8 CHK2 inhibitors.

a derivative of NSC109555 and was confirmed as a competitive inhibitor of CHK2 with respect to ATP. In cell-based studies PV1019 inhibited CHK2 autophosphorylation. It also potentiated the antiproliferative activity of topoisomerase I poisons and IR in a panel of human cancer lines. In cells expressing high levels of CHK2 PV1019 was growth inhibitory as a single agent.[203] Using a fragment-based approach supported by X-ray crystallography, identified CHK2-binding scaffolds and a hydrophobic area near the binding site that had the potential for exploitation in further design of CHK2 inhibitors to improve potency and selectivity.[204] However, so far these early hits have not led to CHK2 inhibitors suitable for cell-based studies. Other CHK2 inhibitors that have been reported include CCT241533 (**Fig. 8**), which potentiated the cytotoxicity of PARPi AG14447 (rucaparib) and olaparib although it did not increase the cytotoxicity of DNA-damaging agents (MMC, bleomycin, and irradiation) in a panel of human cancer cell lines.[205] Several reported CHK2 inhibitors, the aryl-benzimidazole BML277/C3742, a derivative of a marine sponge debromohymenialdisine and VRX0466617 (**Fig. 8**), protect p53 wild-type cells from radiation-induced cytotoxicity so may have a chemoprotective role against normal tissue radiotoxicity. However, the general lack of chemosensitization by the class as a whole somewhat limits their clinical potential.[206–209]

5.04.2.5.3 Clinical Development of CHK2 and ATM Inhibitors

Based on promising preclinical studies, a Phase II clinical trial of LY2606368 which is a CHK1/2 inhibitor is now ongoing (**Table 3**) with recruitment of participants with BRCA-mutated breast or ovarian cancer, and other cancers likely to be HRR-defective: high-grade serous ovarian cancer, triple-negative breast cancer, and metastatic prostate cancer (NCT02203513). AZD0156, which inhibits the kinase activity of ATM and ATM-mediated signaling, is currently in a Phase I trial as a monotherapy agent and in combination with a range of chemotherapy agents in different advanced cancers (NCT02588105).

5.04.2.6 ATR/CH1 Signaling

ATM and Rad3-related (ATR) is the third, and most versatile member of the PI-3K-like family of kinases (PIKKs), which include ATM and DNA-PKcs,[210] involved in DNA damage signaling and repair. ATR is a critical in the response to DNA replication stress and a variety of other DNA lesions. It plays a crucial role in the presence of these lesions by signaling to initiate cell-cycle arrest at the S and G2 checkpoints as well as initiation of DNA repair via HRR. Many of the phosphorylation substrates of ATR are also common to ATM, and there is cross talk between the two PIKKs. Between them, ATM and ATR phosphorylate >900 sites on >700 proteins in response to DNA damage with most of their targets being involved in DNA replication, recombination and repair, and cell-cycle regulation.[211]

The major target for ATR is CHK1, and both are crucial for genome maintenance even in the absence of exogenous sources of DNA damage. Homozygous deletion of either ATR or CHK1 leads to periimplantation embryonic lethality at E7[212] or between E3.5 and E7.5, respectively.[213] Blastocysts from ATR knockout mice had increased apoptosis and chromosomal fragmentation,[212] which is an indicator of mitotic catastrophe that results from cells entering mitosis prematurely before completing DNA synthesis.[214] This was one of the first indications that ATR is critical to cell-cycle arrest. Defective G2 checkpoint activation after DNA damage or replication stress results from inactivation of ATR,[215] and defective proliferation and subsequent cell death result from CHK1 deficiency in embryonic stem cells.[216] No living humans have been identified as completely lacking either ATR or CHK1 function, underscoring the essential roles of these kinases. However, Seckel syndrome, characterized by growth retardation and microcephaly, similar to other DNA repair and checkpoint syndromes is linked to a hypomorphic mutation in ATR.[217] Lymphoblasts from Seckel patients exhibited a three- to sevenfold increase in chromosomal fragmentation following inhibition of DNA synthesis,[218] which was similar to that seen in $ATR^{+/-}$ mice.[212] Interestingly, although $ATR^{+/-}$ mice have an increased incidence of tumor formation, Seckel syndrome patients do not have an increased prevalence of cancer.

Unlike ATM and DNA-PKcs, which are activated by DNA DSBs, ATR is activated by diverse DNA lesions that give rise to stretches of single-stranded DNA (**Fig. 9A**). These occur principally at stalled replication forks, resected DSBs, and NER intermediates. Replication stress results in stalled or collapsed replication forks, depending on the severity. This situation occurs when the replication machinery encounters a DNA lesion, when the dNTP pool is depleted, or when the number of origins of replication exceeds dNTP supply. The DNA lesions that can stall/collapse the advancing replication fork are SSBs, bulky adducts, and ICLs.[219] Resection of

Table 3 ATM/CHK2 inhibitors in clinical trial; LY2606368 is a CHK1/2 inhibitor

Compound	*Latest stage of development and trial details*	*Clinical trial identifier(s)*

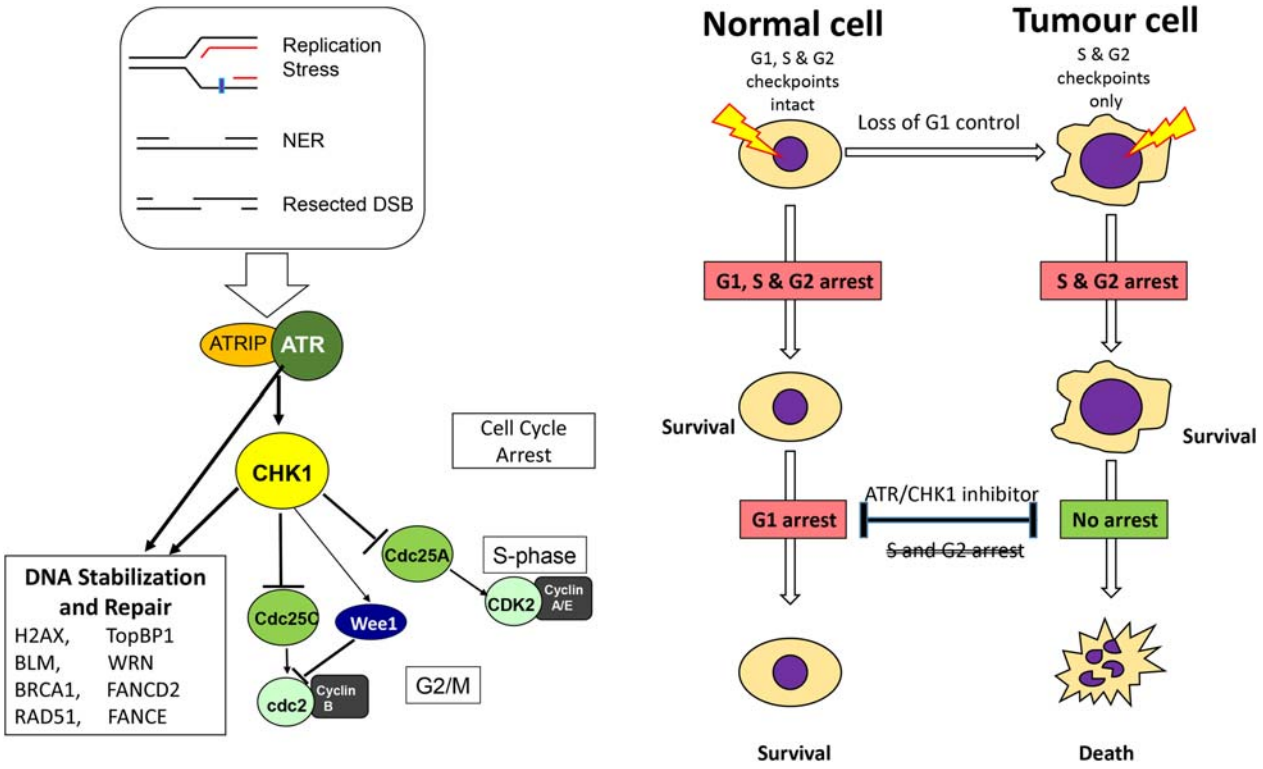

Fig. 9 ATR/CHK1 pathway and potential for cancer-specific chemo/radiosensitization. Left: The lesions that activate ATR and signaling via CHK1 to cell-cycle arrest and DNA repair. Right: Potential for specific antitumor effects of ATR/CHK1 inhibition: Cancer cells usually develop with dysfunctional G1 control making them reliant on S/G2 checkpoints such that when these are inhibited the tumor cell specifically is killed while the normal cell with a functional G1 checkpoint is not. With permission from Middleton, F. K.; Curtin, N. J. ATR as a therapeutic target. In *Advances in DNA repair in cancer therapy;* Panasci, L., Aloyz, R., Alaoui-Jamali, M., Eds.; Publisher Humana Press, Springer, New York, 2013. ISBN 978-1-4614-4740-5.

DSBs is a prerequisite step in HRR, and ATR activation by these lesions enhances the repair (see below). The NER pathway activates ATR, as in the process of removing bulky lesions on one strand of the DNA, such as UV-induced 6,4-photoproducts; it excises 20–30 nucleotides flanking the lesion and thereby exposes a region of single-stranded DNA on the nonresected strand.[220] Replication protein A coats the single-stranded DNA to prevent its degradation and is then replaced by the ATR-interacting protein (ATRIP), which is necessary for the recruitment of ATR to the lesion. Activation of ATR by DNA lesions has two functions: (i) to activate the S and G2 checkpoints via CHK1 kinase and the cdc25 family of phosphatases and (ii) to promote DNA repair.

ATR phosphorylates CHK1 on serine residues 317 and 345, which is essential for CHK1 kinase activation and often used as a marker of ATR activity.[221,222,216,223] Phosphorylation by ATR activates CHK1 triggering its autophosphorylation at serine 296.[223] CHK1 then activates cell-cycle arrest catalyzing the inactivating phosphorylation of the cell-cycle Cdc25 checkpoint phosphatase proteins.[224,225] S-phase entry is promoted by Cdc25A dephosphorylation of the CDK2/Cyclin A or E complex, and entry into mitosis follows Cdc25C-mediated activation of the Cdc2/Cyclin B complex by removing the Wee1-catalyzed inactivating phosphates on threonine 14 and tyrosine 15 of Cdc2 (Fig. 9A).[226,227] Thus, by inactivating the Cdc25 proteins the inactivating phosphorylations on CDK2/cyclinA and cdc2/cyclinB persist, thereby preventing cell-cycle transition. CHK1 also phosphorylates and stabilizes Wee1 further strengthening the prevention of the G2/M transition.

ATR also is key to the stabilization of replication forks, and activation of the ATR/CHK1 pathway promotes DNA repair. The principle repair pathway promoted is HRR, which is compromised in cells lacking ATR kinase function, and knockdown of CHK1 by siRNA also reduces RAD51 focus formation.[228,229] Key targets of ATR phosphorylation include those involved in DNA repair and the stabilization of stalled replication forks such as ATRIP, Rad17, Rad9, TopBP1, Claspin, H2AX, BRCA1, FANCD2, WRN, and BLM (some of which also feedback activate the ATR-CHK1 pathway) thus linking ATR to HRR and DNA cross-link repair.[230,231] CHK1 also targets RAD51, FANCD2, and FANCE regulating HRR and stabilizing stalled replication forks.[226] ATR may also interact with components of other DDR pathways; for instance, ATR phosphorylates DNA-PKcs, a key kinase in the NHEJ pathway.[232] The G2 arrest that accompanies MMR-mediated repair of 6-thioguanine lesions in DNA is ATR dependent,[233] and ATR may indirectly influence the BER pathway.[234]

There are two reasons why the ATR/CHK1 pathway is an attractive target for anticancer drug development: first, because of the variety of DNA lesions that activate the pathway, and second, because cancer cells are generally defective in their G1 checkpoint making them more vulnerable to inhibition of their S and G2 checkpoints (Fig. 9B).

Many of the conventional anticancer agents that are the mainstay of cancer therapy act by damaging the DNA. They may stall replication forks (i) by limiting dNTP supply or incorporation of fraudulent nucleosides; such agents are the antimetabolites that include nucleoside analogues such as gemcitabine, hydroxyurea, and the plethora of antifolates, (ii) by causing base damage DNA, e.g., by DNA-methylating agents such as TMZ or dacarbazine, or (iii) by the induction of SSBs, e.g., topoisomerase I poisons and irradiation. They may directly cause DNA DSBs, e.g., IR or topoisomerase II poisons (such as doxorubicin, mitoxantrone, or etoposide) or bulky adducts that are repaired by NER, e.g., cisplatin. The most difficult of all lesions to repair are ICLs, induced by cisplatin and the bifunctional alkylating agents. ATR is activated by all of these lesions to promote survival; therefore inhibition of ATR should promote cell killing.

The loss of G1 checkpoints in cancer cells suggests that inhibitors of the ATR/CHK1 pathway should specifically target cancer cells and not (or to a lesser extent) normal cells, which retain their G1 checkpoints (Fig. 9B). Classically loss of G1 checkpoints is attributed to defects in the tumor suppressors, p53 and pRb, which are to be found in more than 50% of all tumors, but G1 checkpoint function can have a variety of causes such as increases in the cyclins and CDKs that promote S-phase entry and loss of their suppressors.[11] Moreover, cancer cells are predicted to have a greater sensitivity to inhibitors of the ATR/CHK1 pathway in the absence of clinically induced DNA damage for the following reasons: because of activation of oncogenes that promote S-phase entry and loss of G1 control, cancer cells are more likely to enter S-phase when appropriate biomolecules (e.g., dNTPs) are limited and so have a high level of replicative stress; they have higher levels of ROS because of increased metabolic activity, mitochondrial dysfunction, various oxidases, and inflammation[235,236] resulting in approximately 100-fold higher levels of oxidative DNA lesions than in normal tissues.[237]

5.04.2.6.1 ATR Inhibitors

Inhibitors of ATR have somewhat lagged behind those of CHK1 (see below) and initial validation of the target was by genetic means. Two early independent studies using cells expressing dominant-negative kinase-dead ATR mutants showed that they were more sensitive to a variety of DNA-damaging chemotherapeutic agents, including antimetabolites, DNA cross-linking agents, and both UV and IR, and failed to engage in DNA damage-induced G2 arrest.[238,239] Caffeine (Fig. 10) was the first small molecule to be identified as inhibiting ATR, but it was weak ($IC_{50} = 1.1$ mM) and also inhibited ATM, DNA-PKcs, and mTOR making it difficult to attribute any pharmacological effect to activity against ATR. Nevertheless its UV sensitization, and possibly sensitization of TMZ + irradiation as well as its abrogation of G2 checkpoints may be attributable to ATR inhibition.[189,240] A natural product, Shisandrin B, (Fig. 10) has been identified as an ATR inhibitor. Shisandrin B abrogated UV-induced S and G2/M checkpoint induction and increased UV-induced cytotoxicity.[241] PI-3K inhibitors have also been shown to inhibit ATR, e.g., PI-103 and PI-124 (Fig. 10).[222] Indeed some of the supposedly specific PI-3K inhibitors have also been shown to inhibit ATR, such as

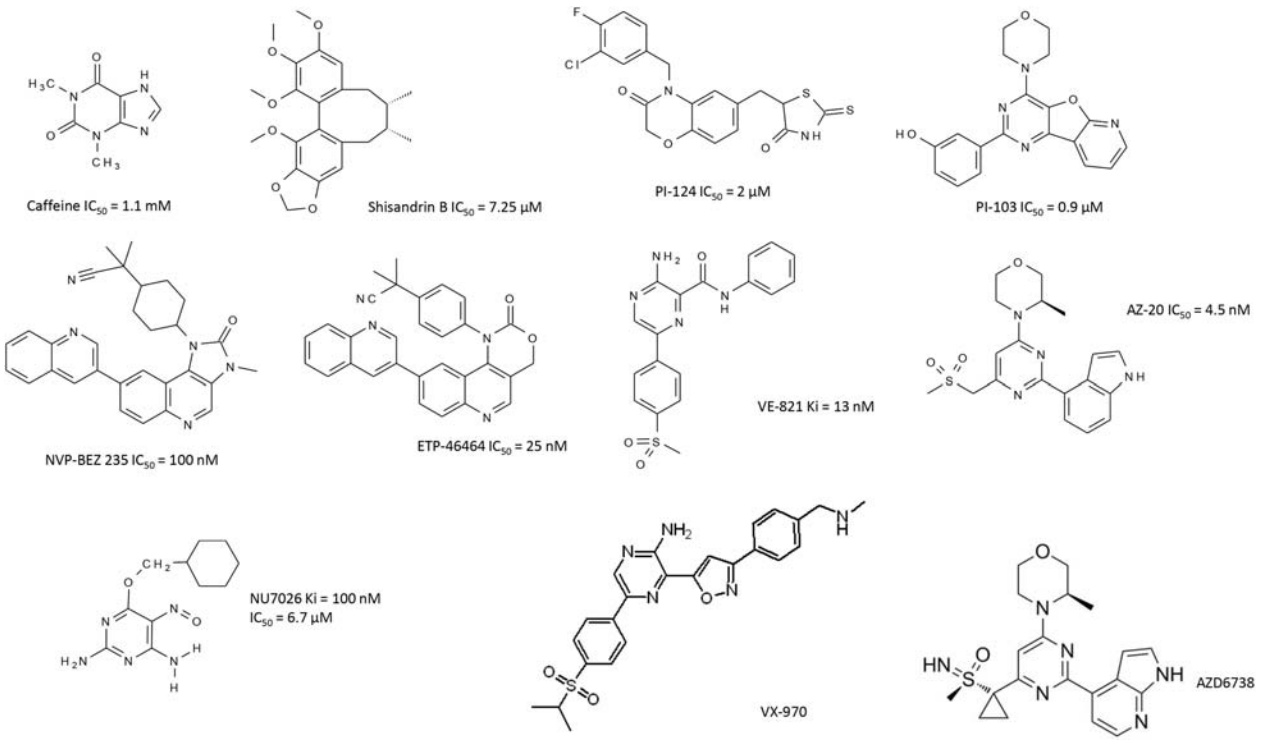

Fig. 10 ATR inhibitors.

NVP-BEZ235 (Fig. 10), which although it is claimed to be a dual PI-3K/mTOR inhibitor also inhibits ATRs (as well as ATM and DNA-PKcs).[75] Data attributing the effects of NVP-BEZ235to PI-3K or mTOR inhibition should therefore be viewed with some skepticism. This screen also identified a highly potent ATR inhibitor, ETP-46464 (Fig. 10) ($IC_{50} = 25$ nM) that inhibited the restart of stalled replication forks and abrogated S-phase arrest after HU exposure.

Unexpected potentiation of cisplatin by the CDK2 inhibitor, NU6027 (Fig. 10), led to the investigation of its potential as an ATR inhibitor. In cell-based studies, NU6027 was found to be a more potent inhibitor of $CHK1^{S345}$ phosphorylation (cellular $IC_{50} = 6.7$ μM) than it was of pRb (the CDK2 target) phosphorylation, and NU6027 increased the sensitivity of MCF7 cells to representatives of the major classes of DNA-damaging agents: the antimetabolite hydroxyurea, the DNA-methylating agent TMZ, the topoisomerase I poison camptothecin, the topoisomerase II poison doxorubicin, the DNA cross-linking agent, cisplatin, and irradiation, but not to the antitubulin agent, paclitaxel.[222] These effects could be attributed to ATR inhibition as they were not seen in cells expressing a dominant-negative kinase-dead ATR mutant. The potentiation of TMZ by NU6027 was greater in MMR-defective cells than in MMR-proficient cells, in agreement with previous suggestions that TMZ and 6-thioguanine potentiation by ATR inactivation required an intact MMR system.[222,233,242] In the studies with NU6027, mutations in p53 had different effects on the degree of sensitization depending on the DNA-damaging agent: TMZ sensitization was greatest in p53-mutant cells, but cisplatin sensitization was greater in cells with wild-type p53. The studies with NU6027 revealed that it reduced RAD51 focus formation and increased cell killing in cells exposed to the PARPi, rucaparib, and that cells defective in BER were more sensitive to single agent NU6027-induced cytotoxicity, indicating an element of synthetic lethality between ATR and the BER pathway, which has been confirmed in further studies with NU6027[243] and with other ATR inhibitors (see below).

VE-821 (Fig. 10) is a potent and selective ATR inhibitor ($K_i = 13$ nM)[244,245] that has been shown to increase the cytotoxicity of cisplatin, gemcitabine, camptothecin, etoposide, and IR, but not the antitubulin agent, docetaxel, in HCT116 colon cancer cells. VE-821 potentiated cisplatin to a much greater extent in a panel of human cancer cell lines than in normal human cell lines and was more active in cells lacking p53 or ATM. VE-821 has been investigated as a radiosensitizer in hypoxic cells. Hypoxic regions in tumors, resulting from deranged tumor vasculature, are radio- and chemoresistant and generally are associated with poor outcome. VE-821 increased the radiosensitivity in a panel of 12 human cancer cell lines, and to a greater extent in hypoxic cells. VE-821 also increased reoxygenation-induced DNA damage and decreased the survival of cells undergoing reoxygenation.[246] In a panel of pancreatic cell lines VE-821 increased gemcitabine as well as radiation-induced cytotoxicity under both normoxic and hypoxic conditions and led to the persistence of DNA damage through the inhibition of HRR (persistence of γH2AX and inhibition of RAD51 foci).[247]

Cancer cells have high levels of replication stress due to oncogene activation and hyperactive growth factor signaling making them particularly dependent on the ATR pathway for survival.[248] Knocking down ATR to 16% of normal levels was synthetically lethal in Ras-transformed cells.[249] Similarly, overexpression of cMYC has previously been shown to cause replicative stress and confer sensitivity to CHK1 inhibitors and ATR knockdown.[250,251] Cyclin E is commonly overexpressed in cancer and leads to replication stress and DNA damage by promoting S-phase entry. The ATR inhibitor, ETP-46464 was cytotoxic to cells with induced overexpression of cyclin E.[75] VE-821 alone also caused a concentration-dependent suppression of the growth and survival of two breast cancer cell lines, one with wild-type p53 and one with mutant.[252] Investigation of the single-agent activity of VE-821 in cell lines with defined DNA repair defects confirmed that loss of XRCC1 (BER) was a determinant of sensitivity to ATR inhibition and also demonstrated that deletion of BRCA2, XRCC3 (HRR), and ATM also conferred sensitivity to VE-821. Interestingly, cells lacking DNA-PKcs (but not Ku80) were resistant to VE-821, and those overexpressing DNA-PKcs were more sensitive.[253]

A more potent inhibitor with improved pharmacological properties, VE-822 (VX-970) (Fig. 10), was the first ATR inhibitor to be taken forward to clinical trial (NCT02157792). VE-822 inhibited checkpoint function and HRR and potentiated gemcitabine and irradiation in models of pancreatic cancer in vitro and in vivo. There was a substantial increase in tumor growth delay without a corresponding increase in normal tissue toxicity.[254,255] The effect of VX-970 on the sensitivity to cisplatin, gemcitabine, etoposide, oxaliplatin, and SN38 (the active metabolite of irinotecan) was determined in a panel of 35 lung cancer cell lines, with potentiation observed in most cases. Greater sensitization was seen when p53 was deleted, but by itself p53 mutation was not a significant determinant of potentiation across the panel of nonisogenic cell lines. Cisplatin sensitization was also seen in primary cultures of patients' lung tumor cells in vitro. ATR was inhibited, and impressive sensitization of the antitumor activity of cisplatin was observed in patient-derived xenografts.[255] A pharmacodynamic biomarker has been developed to evaluate the clinical activity of ATR inhibitors, using VE-821 and VX-970, based on $CHK1^{S345}$ phosphorylation after ex vivo activation of ATR with the UV-mimetic 4NQO in whole blood.[256]

Another series of ATR inhibitors was developed from an initial screening hit AZ-20 (Fig. 10), which itself showed in vitro and in vivo activity against Lovo cells and xenografts as a single agent.[257] AZD6738 (Fig.10) is a derivative of AZ-20 that entered clinical trials (NCT10955668). This inhibitor has been shown to be cytotoxic to p53 or ATM-defective patient-derived CLL cells that had been induced to proliferate ex vivo or xenotransplanted into immunocompromised mice.[258,259]

5.04.2.6.2 CHK1 Inhibitors

The first CHK1 inhibitor was a staurosporine derivative, UCN-01, (Fig. 11) that inhibits several kinases, including CHK1. Consistent with a role in CHK1 inhibition UCN-01 reduced radiation-induced degradation of Cdc25A, abrogated doxorubicin-induced G2/M arrest, and potentiated cisplatin and camptothecin cytotoxicity.[260] Further analogues of UCN-01 such as PD-321852 (Fig. 11) have been developed[261] as well as other structural types. Most are ATP competitive and, where investigated, found to bind in the hinge

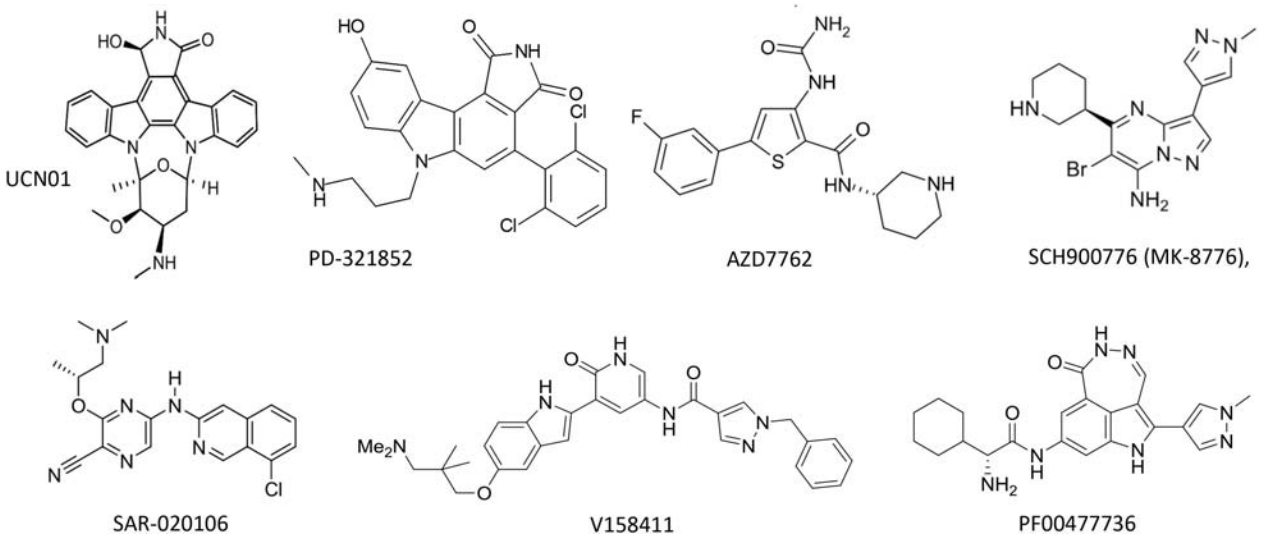

Fig. 11 CHK1 inhibitors.

region of CHK1. Some inhibit both CHK1 and CHK2, e.g., AZD7762 (Fig. 11) and XL9844 (structure not disclosed; K_i CHK2 = 2.2 nM, K_i CHK1 = 0.07 nM), and others are more selective for CHK1, e.g., SCH900776 (MK-8776), SAR-010106, and PF00477736 (Fig. 11) and CEP-3891 (structure not disclosed; IC_{50} = 4 nM). The earlier development of these inhibitors compared to the ATR inhibitors means that there are more studies of the CHK1 inhibitors in vivo and in clinical trials.

As described above, a major role of CHK1 is to transduce the signal from ATR to S and G2/M cell-cycle arrest. As expected, most CHK1 inhibitors do not affect cell-cycle progression in unperturbed cells but do block cell-cycle arrest and enhance the cytotoxicity in cells exposed to DNA-damaging agents. CHK1 inhibitors do not exactly phenocopy ATR inhibitors; even though CHK1 is thought to be the major target of ATR, key differences have been observed. For example the potentiation of cisplatin, carboplatin, and oxaliplatin cytotoxicity by ATR inhibition, seen in a variety of cell lines, was not replicated when CHK1 was inhibited. The CHK1 inhibitor, PF-00477736, unlike the ATR inhibitor NU6027, caused only modest sensitization of cisplatin and camptothecin but did enhance the cytotoxicity of paclitaxel in MCF7.[262,263] Although CHK1 inhibitors do not appear to synergize with cisplatin they do show high levels of sensitization of the antimetabolites and in particular gemcitabine, and topoisomerase I poisons such as camptothecin, which stall replication forks.[165,260,264,265] For example, PD-321852 inhibited gemcitabine-induced RAD51 focus formation and potentiated gemcitabine cytotoxicity in pancreatic cancer cell lines.[261] The dual CHK1/CHK2 inhibitor, V158411 (Fig. 11), potentiated gemcitabine, cisplatin, and the topoisomerase I poisons, camptothecin and SN38 in vitro in a p53-dependent manner and in vivo studies revealed enhancement of irinotecan anticancer activity without an increase in toxicity.[266] Some studies have investigated the radiosensitization potential of the CHK1 inhibitors: AZD7762 increased the radiation-induced cytotoxicity in a panel of human cancer cell lines.[267] There seem to be cell line-specific differences in the dependence on p53; radiosensitization by UCN-01 and CEP-3891 was dependent on p53 status in HCT116 cells, but independent in U2OS cells.[268]

Several studies have investigated the in vivo potential of CHK1 inhibitors, for example, PF-00477736 enhanced the antitumor activity of gemcitabine in mice bearing CoLo205 (human colon cancer) xenografts.[269] AZD7762 increased the antitumor activity of gemcitabine and irinotecan against human cancer xenografts in both mice and rats,[270] and XL-844 increased the efficacy of gemcitabine against PANC-1 xenografts.[271] AZD7762 has also been shown to be a radiosensitizer in lung cancer cell lines and xenograft models of lung cancer with brain metastasis resulting in prolonged survival.[272]

The cancer-specificity of the CHK1 inhibitors and the potential for synthetic lethality or synthetic sickness is postulated to be due to two key properties of cancer cells, loss of p53 and activation of oncogenes that cause replication stress. In some studies, there seems to be greater potentiation of p53 dysfunctional cells, but the differences may only be apparent in isogenically matched p53 functional and dysfunctional cells. Interestingly, CHK1 is upregulated in Myc overexpressing murine and human lymphomas, and its inactivation was cytotoxic in Myc amplified cells and prolonged the survival of Myc-lymphoma-bearing mice.[273,274] Also CCT245737 has recently been shown to have single-agent activity in MYC-driven mouse model of B-cell lymphoma.[275] In addition, recent studies in a panel of human breast and pancreatic cell lines revealed that the combination of CHK1 inhibitors (UCN-01, AZD7762) was synthetically lethal with various PARPi, including those in clinical trial (ABT-888 and AZD2281).[276]

5.04.2.6.3 Clinical Development of CHK1 and ATR Inhibitors

5.04.2.6.3.1 CHK1 inhibitors

UCN-01 has been evaluated in clinical trials in patients with melanoma, triple-negative breast cancer, and ovarian cancer.[277–279] However, the results of these Phase II trials have not been promising both as a single agent and in combination with other

chemotherapy agents mainly because of lack of efficacy. In a trial of 25 patients with triple-negative breast cancer who were administered with varying doses of UCN-01, the response rate was only 4%.[278] When UCN-01 was combined with topotecan in 29 patients with advanced recurrent ovarian cancer, only three patients achieved a partial response with no patient achieving a complete response.[279] SCH900776 has been evaluated in a Phase 1 trial, in combination with cytarabine, in patients with acute leukemia and was well tolerated.[280] It has therefore been taken into a Phase II trial in patients with acute myeloid leukemia, and the trial is currently still active but not recruiting (NCT01870596). In another Phase I trial of 43 patients with advanced solid tumor malignancies, intravenous infusion of SCH900776 was administered at dose levels ranging from 10 to 150 mg/m^2 as monotherapy followed by combination with gemcitabine 800 mg/m^2 in 26 patients or gemcitabine 1000 mg/m^2 in 17 patients.[281] SCH900776 was well tolerated as a monotherapy and in combination with gemcitabine, with 2 patients showing partial response and 13 patients demonstrating stable disease.

An initial Phase I trial of PF-00477736 in combination with gemcitabine in patients with advanced solid tumors was terminated due to business reasons (NCT00437203). However, in another Phase I trial, 36 patients were administered with 750 mg/m^2 of gemcitabine and increasing dose of PF-00477736. Partial responses were observed in three patients with squamous cell cancer of the skin, NSCLC and mesothelioma.[282] Although this combination therapy showed some clinical activity, it will be interesting to see if better response is observed in combination with other chemotherapy agents or with higher dose of gemcitabine.

AZD7762 was a promising CHK1/2 kinase inhibitor, but its development had to be halted due to safety concerns in Phase I trials. In a Phase I trial of patients with advanced solid tumors, AZD7762 was associated with cardiac toxicity.[283] LY2603618 is another CHK1 kinase inhibitor that was evaluated in a Phase I trial in combination with gemcitabine in patients with advanced solid tumors with acceptable safety profile.[284] Phase II trials of LY2603618 in NSCLC and pancreatic cancer have now been completed, and results are awaited (NCT00988858; NCT00839332). A phase I trial of GDC-0425 in combination with gemcitabine in lymphoma has been completed, and results are also awaited (NCT01359696). GDC-0575 is currently in a Phase I trial as monotherapy agents or in combination with other chemotherapy agents in solid tumors and lymphoma (NCT01564251). Despite initial setbacks, CHK1 inhibitors offer promising cancer therapy, and they could prove effective beyond hematological malignancies (Table 4).

5.04.2.6.3.2 ATR inhibitors

VE-822 (VX-970) was the first ATR inhibitor to be taken forward to clinical trial (Table 5). Following promising results in preclinical models, VX-970 is currently in Phase I/II trials in patients with small-cell lung cancer and NSCLC. There is a planned Phase II study of VX-970 in patients with ovarian, primary peritoneal, or fallopian tube cancers (NCT02595892). VX-970 has been evaluated as a monotherapy and in combination therapy. In a Phase I trial of patients with advanced malignancies receiving VX-970 monotherapy or combination therapy with carboplatin, both regimes were well tolerated and antitumor activity was observed.[285] VX-970 has also been evaluated in combination with gemcitabine in patients with advanced solid tumors—colorectal, pancreatic, breast, and NSCLC. In a Phase I study of this combination therapy, there was evidence of antitumor activity and two patients with papillary cancer and gastrointestinal stromal tumors, which are usually resistant to chemotherapy, had prolonged PFS.[286] An optimal combination dose of 210 mg/m^2 and gemtacitabine 1000 mg/m^2 was determined to be taken forward into Phase II trial. A Phase II trial of combination of VX-970 and topotecan in patients with small-cell lung cancer is currently recruiting patients.[287]

AZD6738 is another ATR inhibitor that is currently being evaluated in early phase clinical trials (Table 5). It is being investigated as a monotherapy and as a sensitizing agent to radiation therapy in patients with advanced solid malignancies in the PATRIOT trial.[288] AZD6738 is also being evaluated in combination with carboplatin, olaparib, and MEDI4736 in patients with advanced and metastatic tumors in a Phase I trial (NCT02264678). These trials offer exciting possibilities in the management of many terminal cancers, and it will be interesting to see if they progress to the bedside.

5.04.2.7 Summary, Conclusions, and Future Perspectives

There has been considerable progress in our understanding of the DDR, how it protects the living organism, and how its dysfunction can lead to the development of cancer. Moreover, as most conventional anticancer therapy acts by damaging DNA, we have learnt that the dysfunction of the DDR in cancer can lead it to be not only more sensitive to therapy (in the case where a critical pathway is lost or attenuated) but also more resistant (where the protective pathway is increased in activity). The initial rationale for inhibiting DDR pathway inhibitors was to increase response to DNA-damaging anticancer therapy by targeting survival mechanisms. However, this strategy can come at a cost in terms of exacerbating normal tissue toxicity and hence little or no improvement of the therapeutic index. The increase in host toxicity was responsible for the lack of progress of the early DDR inhibitors, those targeting MGMT to improve alkylating agent activity, beyond Phase II clinical trials. So far, combination of conventional DNA-damaging therapies with the next class of DDR inhibitors, PARPi, has also been associated with toxicities and not progressed beyond Phase II. It is possible that through careful titration of dose, both for the cytotoxic and the PARPi, and schedule adjustments that the therapeutic index may be improved. Alternatively, a subset of tumor types which are exceptionally vulnerable to this approach may be identified.

It is to be hoped that the CHK1 and ATR inhibitors, which exploit an almost universal feature of cancer cells, i.e., the dysfunction of the G1 checkpoint, to sensitize such cells to DNA-damaging therapy, turn out to be more tumor specific and less toxic in combination therapy. The trials with the early CHK1 inhibitors were associated with unacceptable toxicities, but, as these drugs lacked specificity for CHK1, it is likely that the more specific next-generation inhibitors will meet with greater success. Combinations with molecularly targeted agents, that may or may not also act by compromising DDR function, are also being investigated, but whether this will lead to an improvement in the therapeutic index remains to be seen. Combinations of DDR inhibitors with radiotherapy may be associated with fewer generalized toxicities, such as myelosuppression, but care will be needed to assess toxicities in normal tissues in the irradiation field, especially as many are late-presenting. Preclinically, DNA-PK inhibitors are the most potent radiosensitizers, but it is too early to tell if this will translate into radiosensitization with acceptable toxicity in the clinic.

A more exciting approach is to exploit defects in the DDR that are *tumor-specific* by targeting a complementary pathway and thereby selectively targeting the tumor and not the host tissues. This approach, although promising, had been paid little attention until the synthetic lethality of the PARPi in cells lacking HRR function was demonstrated. These initial laboratory findings translated rapidly into the clinic, where the progress and success has been so great that within 10 years of the publication of the preclinical data the first PARPi have been licensed for use in cancer patients. This single-agent approach does not cause unacceptable toxicity and has been remarkably effective in a subset of patients with BRCA mutations. Broadening the application to other tumors has necessitated the development of biomarkers of HRR defects. Several approaches to develop such biomarkers have been taken, and these are being used to select patients for PARPi therapy in clinical trials. However, responses in biomarker-positive tumors have not been as great as those with a BRCA mutation suggesting either that the biomarkers are not 100% reliable or that different components of the HRR pathway have greater or lesser impact on its overall function. Nevertheless, the biomarker-positive group generally responds better than the biomarker-negative one. This highlights the need for effective predictive biomarkers. Determinants of sensitivity identified in the laboratory setting need to be translated to reliable biomarkers that may be developed for routine clinical use if we are to treat those patients likely to benefit and spare those who are not from unnecessary toxicity.

5.05.1 Introduction

Nuclear receptors (NRs) function as transcription factors, and they are activated by cognate ligands (such as hormones, vitamins, and fatty acids among others) that bind to NR-response elements and regulate the transcription of genes encoding enzymes, transporters, and other proteins.[1] NRs play an important role in a myriad of human physiological processes, including development, reproduction, immune response, cardiovascular function, tumorigenesis, and metabolic homeostasis.[2] Importantly, NRs are also involved in a wide range of diseases such as cancers and metabolic syndromes (**70002. PPAR, REV-ERB & ROR Nuclear Receptors**).[3,4] NRs represent the second biggest family of drug targets, and over a third of NRs are targets of currently marketed drugs.[5] Thus, NR-directed compounds account for 13% of the Food and Drug Administration (FDA)-approved therapeutics; 20 of the top 200 most prescribed drugs target NRs.[6]

The human NR superfamily consists of 48 members, which all share a similar organization of constituent domains, including a highly variable N-terminal domain (NTD), a conserved DNA-binding domain (DBD), a similar ligand-binding domain (LBD), and a hinge region connecting the DBD and LBD (**Fig. 1**).[7–9] NRs are conventionally divided into three subgroups based on their native ligands: steroid hormone receptors (SHRs), nonsteroid receptors, and orphan receptors. The SHRs are activated by endogenous hormones and bind to hormone response elements via homodimerization, including the androgen receptor (AR), estrogen receptor (ER), progesterone receptor (PR), glucocorticoid receptor (GR), and mineralocorticoid receptor (MR). Due to the presence of the LBD and known native ligands, SHRs have received considerable attention as attractive drug targets for prostate and breast cancers among other diseases.[10,11] In particular, the human AR has been intensively studied for its critical role in the development and progression of prostate cancer (PCa), and a large number of synthetic AR inhibitors have been developed as potential therapeutics for PCa.[10]

PCa is the most commonly diagnosed malignancy in men, and the second leading cause of male cancer death in North America.[12] The majority of PCas that are diagnosed early is localized to the prostate gland, and the disease may be cured by local therapy such as prostatectomy and radiation. However, a portion of patients will have recurrence, and their diseases eventually progress to a lethal castration-resistant state (CRPC). CRPC has historically been thought to be androgen independent; however, accumulating evidence demonstrates that CRPC continues to depend on the AR transactivation, which resumes the PCa proliferation despite low levels of circulating androgens.[13]

For high-risk PCa and CRPC, androgen deprivation therapy (ADT) is the mainstay treatment that aims at reducing androgen level or blocking the AR function. ADT includes orchiectomy, estrogen, luteinizing-hormone releasing hormone (LHRH) agonists/antagonists, 17α-hydroxylase/17, 20-lyase (CYP17A1) inhibitors, and AR inhibitors/antiandrogens.[14,15] The persistent reactivation of the AR in CRPC has been indicated by clinical responses and overall survival benefits of CRPC patients from the latest ADT drugs enzalutamide and abiraterone.[16–18] This provides evidence to demonstrate that the human androgen signaling pathway continues to play a critical role in PCa and CRPC, where the AR still represents the master regulator and the most validated drug target. This article focuses on reviewing the existing and emerging AR signaling-targeted therapies, including androgen synthesis inhibitors, conventional antiandrogens, and AR inhibitors targeting alternative sites with novel mechanisms of action.

5.05.2 The Androgen Signaling Pathway

5.05.2.1 Androgens

Endogenous androgens (testosterone and 5α-dihydrotestosterone—DHT) are male sex hormones responsible for the development of the male phenotype during embryogenesis and male sexual maturation during puberty. In adult men, androgens remain critical for the development and maintenance of the reproductive system, and affect many other tissues such as muscle and bone.[19] The

action of androgens in reproductive tissues (prostate and testis) is known as the androgenic effect, while the effect in muscle and bone is known as the anabolic effect.[20]

Approximately 90–95% of testosterone is produced in the testes, and 5–10% of testosterone is synthesized in the adrenal gland. The synthesis of androgens is tightly regulated by the hypothalamus–pituitary–gonadal and hypothalamus–pituitary–adrenal axes.[21,22] The LHRH (also known as gonadotropin-releasing hormone) and corticotropic hormone (CTH), which are secreted by the hypothalamus, stimulate the release of luteinizing hormone (LH) and adrenocorticotropic hormone (ACTH) by the pituitary gland. The LH binds to LH receptors in the testis and initiates the production of testosterone; the ACTH binds to its receptors in the adrenal gland and triggers the synthesis of testosterone. The androgen biosynthesis pathway involves a number of steroidogenic enzymes, such as the CYP17A1, 3β-hydroxysteroid dehydrogenase (HSD3B1, HSD3B2), and 5α-reductase types 1, 2, and 3 (SRD5A1, SRD5A2, and SRD5A3) (Fig. 2).[23]

The majority of testosterone binds to carrier proteins such as the steroid hormone binding globulin and albumin, and only 1–2% of testosterone exists in an unbound form. The free form of testosterone enters prostate cells, and then it is converted into a more active metabolite, DHT, by the 5α-reductase enzyme. Importantly, DHT binds to the AR with higher affinity, and its biological activity exceeds that of testosterone by up to 10 times, which makes DHT the primary ligand for the AR. It has been demonstrated that aberrant regulation of androgens leads to diseases such as androgen insensitivity syndromes and PCa.[20,22,24–26]

5.05.2.2 The Androgen Receptor

The AR gene was first found to be located on chromosome X at Xq11.2 in 1981,[27] and the human AR cDNA was first cloned and sequenced in 1988.[28] The AR gene is more than 90 kb long, and codes for a 110 kDa protein consisting of 919 amino acids.[29] The AR is mainly expressed in androgen target tissues, such as the prostate, muscle, liver, and central nervous system (CNS). It is a key ligand-

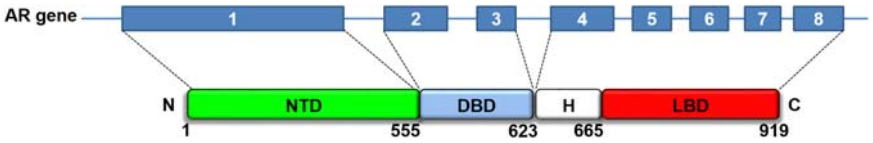

Fig. 3 Structural organization of the AR gene and protein. The exon 1 encodes the N-terminal domain (*NTD*); exons 2 and 3 encode the DNA-binding domain (*DBD*), exons 4–8 encode the hinge and ligand-binding domain (*LBD*).

activated transcription factor in healthy prostate and during neoplastic transformation. In the normal prostate, AR regulates prostate secretory function, stimulates epithelial cell renewal, and maintains cells in a differentiated state. Similar to other SHRs, the AR is organized into four functional parts including the NTD, the DBD, the hinge region, and the LBD (**Fig. 3**). These domains play different roles in the AR activity, and an understanding of these domains is essential for the development of AR-targeted therapeutics.

The NTD is encoded by exon 1, and it accounts for more than half of the size of the AR (residues 1–555), and is highly variable in the sequence compared to other SHRs.[30] This part of the protein is very flexible and intrinsically disordered in solution,[31] which has hampered the elucidation of its three-dimensional (3D) structure. The NTD has the main transactivation function region, termed the activation function 1 (AF1), which contains two transactivation units, TAU1 (residues 100–370) and TAU5 (residues 360–485).[32] The AF1 is indispensable for the full activity of the AR, and is essential for constitutively active truncated AR splice variants (ARVs) that do not contain the LBD portion. Interestingly, two motifs in NTD, the FQNLF (residues 23–27) and the WHTLF (residues 433–437), have been shown to interact with the activation function 2 (AF2) in the AR LBD region, leading to N/C intra- and/or intermolecular interactions, which are important for the transcription of some target genes.[33]

The DBD (residues 556–623) is encoded by exons 2 and 3, and is highly conserved among the SHRs. The DBD consists of two zinc fingers and a loosely structured carboxyl-terminal extension (CTE) region. The first zinc finger is proximal to the NTD, and is responsible for the DNA recognition. The α-helix of the zinc finger, termed the recognition helix, directly interacts with nucleotides in the DNA major groove. There is a P[roximal]-box region (residues 577-GSCKV-581) in the recognition helix, which is responsible for the specific recognition of the DNA response element. The second zinc finger contains the D[istal]-box region (residues 596-ASRND-600), which is the dimerization interface (**Fig. 4**). The CTE is critical for the 3D organization of the DBD, and it mediates the selectivity of the receptor to androgen response elements (AREs) on the DNA.[34] The AR DBD and CTE can recapitulate the DNA binding and dimerization of the full-length AR. The DBD structure has been resolved crystallographically as a DBD dimer bound to a direct repeat of two ARE half-sites.[35]

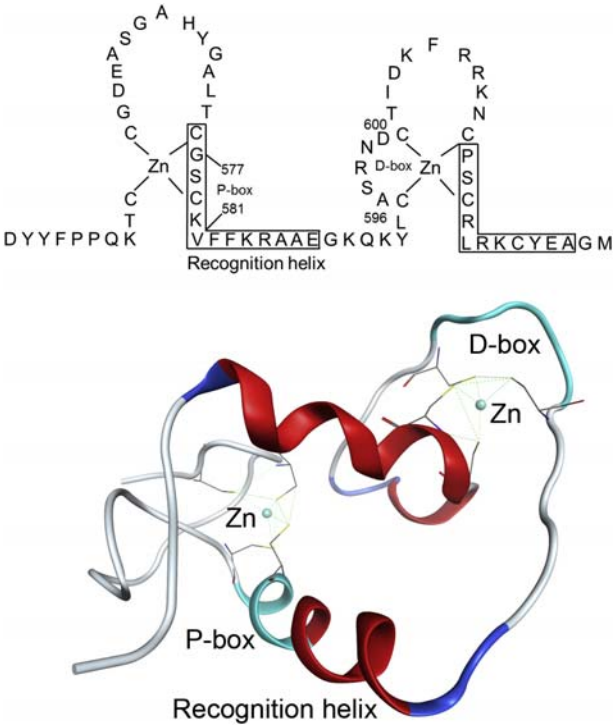

Fig. 4 (*Upper*) A schematic of the AR DBD is given to show two zinc fingers in the core of AR DBD, the P-box, and D-box residues, and residues (in boxes) that constitute two alpha helices. (*Lower*) The 3D structure of the AR DBD monomer with P-box and D-box residues colored in cyan (PDB code: 1R4I).

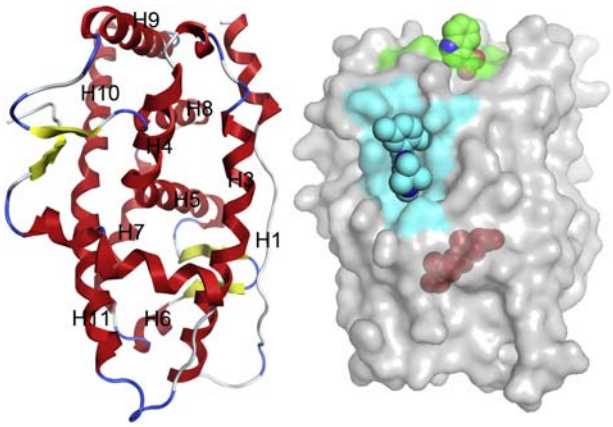

Fig. 5 (*Left*) The AR LBD structure is predominantly composed of 11 α-helices (PDB code: 3X3L). (*Right*) A surface representation of the AR LBD showing the ABS (ligand in *red*), AF2 (*cyan*), and BF3 (*green*) sites with corresponding ligands in each different binding site (PDB code: 2PIP).

The hinge region (residues 624–665) is encoded by exon 4, and it is a flexible linker that connects the LBD and DBD segments. The hinge is known for its role in the nuclear translocation through carrying a ligand-dependent nuclear localization signal (NLS, residues 617–633) spanning the hinge and DBD.[36] The NLS could bind importin-α and translocate the AR from the cytoplasm to the nucleus.[37,38] The NLS consists of two clusters of basic amino acid residues (617-RKCYEAGMTLGARKLKK-633), and this motif is highly conserved among other SHRs.

The LBD section of the AR (residues 666–919) is encoded by five AR exons (exons 4–8, exon 4 encoding both the hinge and part of the LBD) varying from 131 to 288 bp in size. The LBD consists of 11 α-helices (H) and 2 β-sheets that are arranged in three layers to form an antiparallel "α-helical sandwich" (Fig. 5). It is worth noting that the H2 is missing in the AR, but the same numbering for other helices was adopted for easy comparison with other SHRs. The androgen binds to a buried pocket in the LBD, termed the androgen binding site (ABS), which is formed by the N-terminal regions of H3 and H5, and the C-terminal regions of H10 and H11. Upon binding of the androgen, the LBD undergoes conformational changes and the H12 is repositioned to stabilize the complex. This motion allows the formation of a shallow surface groove by residues of H3, loop 3–4, H4, and H12, referred to as the AF2, which is the major interface for the intra- and/or intermolecular N–C interactions and coactivator recruitment.[39] It has been demonstrated that the AF2 preferentially binds to the FXXLF motifs, including the 23-FQNLF-27 present in the NTD, and interacts poorly with LXXLL motifs, which are commonly found in AR coactivators.[40] In recent years, another surface groove consisting of H1, loop 3–4, and H9 residues was identified on the AR LBD, called the binding function 3 (BF3). It was reported to allosterically regulate the AF2 activity;[41] however, the complete functional role of BF3 is not clear yet.

5.05.2.3 Mechanism of AR Activation

The human AR is known as an intracellular ligand-activated transcription factor. In its unliganded state, the AR is inactive and primarily resides in the cytoplasm, where it is bound to cochaperones such as the heat shock protein 90 (HSP90). Upon androgen binding, the AR becomes activated and dissociates from cochaperones. The activated AR then recruits coactivators, and undergoes a series of conformational changes, as well as translocates into the nucleus.[42] In the nucleus, the AR dimerizes via the DBD portions, further binds to AREs in the promoter and enhancer region of target genes, interacts with different coregulators, and initiates the transcription of regulated genes (Fig. 6). Notably, the AR regulates over 1000 genes,[43] including the AR itself, and its target genes such as prostate-specific antigen (PSA), transmembrane protease serine 2 (TMPRSS2), and FK506 binding protein 5 (FKBP5).

The mechanism of AR action is still not entirely clear, and increasing evidence indicates that the function of the AR is also regulated by a complex network of coregulators and cell signaling pathways. The AR serves as a scaffold for the assembly of coregulators in the promoter and enhancer region to activate or repress transcription. The AR coregulators are proteins recruited by the receptor, including coactivators such as the p160 family,[44] and corepressors such as NCOR.[45,46] In addition, the AR could also be activated by kinase signaling pathways in an androgen-independent manner, such as the phosphoinositide 3-kinase (PI3K)/AKT/mammalian target of rapamycin.[47–49]

5.05.3 Conventional Antiandrogens Targeting the AR ABS

5.05.3.1 The AR ABS

The ABS in the AR LBD is a proven druggable site for small-molecule inhibitors. All reported structures of the AR LBD maintain a three-layered sandwich fold; the only observed structural differences lie in subtle conformational changes of side chains of the ABS residues.[42] The AR ABS is a buried site that is mainly composed of hydrophobic side chains, including L701, L704, L707,

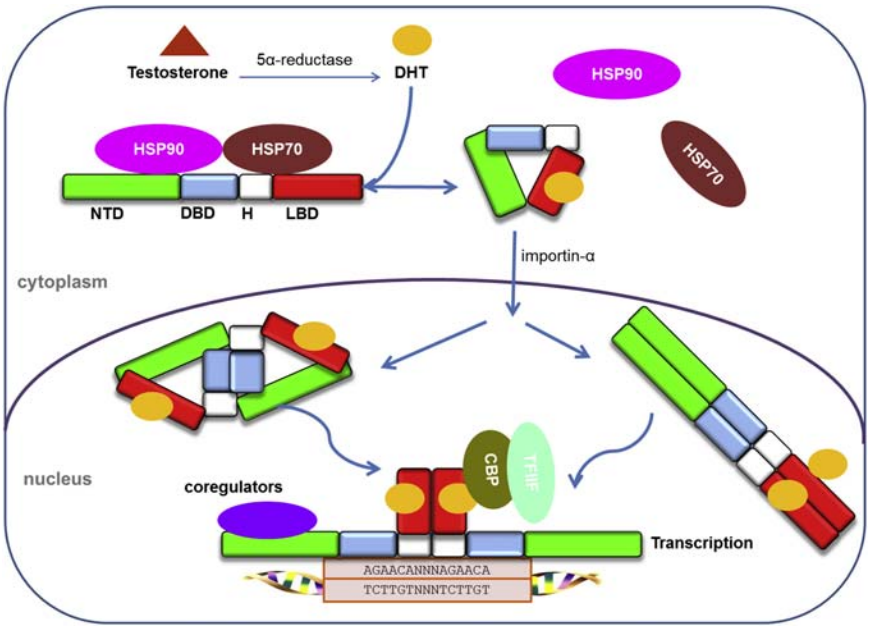

Fig. 6 The classic AR transactivation signaling pathway, involving the androgen conversion, AR activation, nuclear translocation, dimerization, and coregulator recruitment.

Q711, M742, M745, V746, M749, F764, M787, and L873, which interact with AR binders through Van der Waals interactions. There are two pairs of conserved polar patches (R752 and Q711, N705 and T877) located at opposing ends of the site, which may play a pivotal role in anchoring steroidal AR binders (Fig. 7). The ABS is known for its notable plasticity, in that it adjusts the volume to accommodate ligands of various sizes.[50,51]

So far, the agonism and antagonism of the AR have been mainly elaborated from a mechanistic perspective. In brief, the H12 serves as a "switch" to open or close the LBD according to the binding of antagonists or agonists. When agonists bind to the AR ABS,

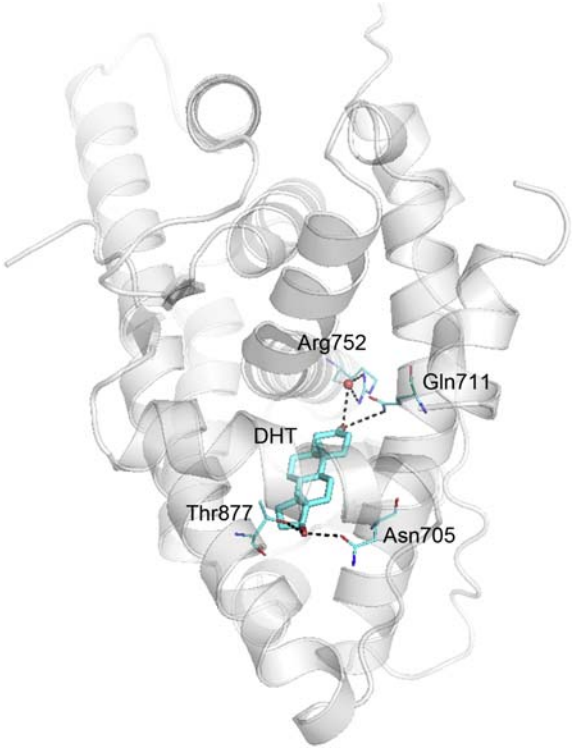

Fig. 7 Crystal structures of the AR LBD with DHT in the ABS (PDB code: 3L3X); hydrogen bond interactions were indicated by black dashes.

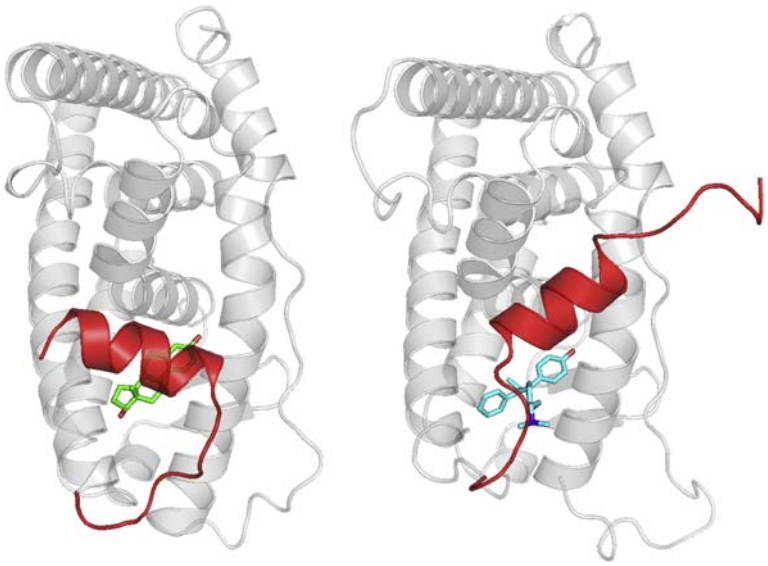

Fig. 8 (*Left*)Crystal structure of ER with estradiol in the agonistic form (PDB code: 1ERE); (*Right*) Crystal structure of ER with tamoxifen in the antagonistic form (PDB code: 3ERT). The H12 was colored in *red*.

the H12 is positioned to cover the LBD in a "closed" state, and then the AF2 is exposed that enables the recruitment of coactivators. Upon antagonist binding, the AR LBD adopts an "open" state by repositioning the H12 to occupy the AF2 site, which prevents the coactivator or recruits repressor binding, and thus blocks the receptor transactivation.[42] The agonistic form of the AR has been revealed by a plethora of crystal structures of wild-type AR LBD with agonists, or mutated AR LBD with "converted" antagonists (Fig. 7).[50–58] This demonstrates the AR LBD in a "closed" state, with coactivators such as SRC attached to the AF2 site of the receptor.

The antagonism of the AR is not clear yet, due to the infeasibility of resolving wild-type AR LBD structures containing antagonists. However, the antagonism of ER (Fig. 8), PR, and GR has been unveiled by cocrystal structures of their wild-type LBD with antagonists,[59–63] demonstrating that the H12 relocates to the AF2 and precludes coactivator binding. Based on the information from other SHRs, the AR may presumably share a similar antagonism. The H12 positioning in the antagonistic forms of SHRs is drastically diverse,[59–62] and thus, it makes realistic homology modeling of H12 in the AR difficult. Although the antagonistic conformation of the AR is absent, the availability of cocrystal structures of the AR LBD with various ligands, as well as a large number of known AR ABS binders, provides a wealth of information for developing new AR ABS inhibitors.[50–58,64,65]

5.05.3.2 First-Generation Antiandrogens

Given the importance of the AR signaling pathway in PCa, the receptor has been recognized as a major drug target for PCa and CRPC. Since the late 1960s, anti-AR drugs, also known as antiandrogens, have been developed which prevent the AR function by competing with androgens for binding to the AR ABS. Antiandrogens can be classified as steroidal or nonsteroidal AR inhibitors based on their structures. Steroidal antiandrogens (such as cyproterone acetate) tend to demonstrate partial agonistic activity, poor oral bioavailability, potential hepatotoxicity, and often exhibit lack of tissue selectivity and cross-activity toward other SHRs.[42] In addition, structural modifications of steroidal ligands are limited by the steroidal scaffold. Thus, steroidal antiandrogens are rarely used in the clinic.

In comparison, nonsteroidal antiandrogens demonstrate better specificity and oral bioavailability, and are more suitable for structural modifications and advancements. A variety of nonsteroidal antiandrogens have been reported to date, including aryl propionamides, hydantoins, phthalimides, and quinolinones. Nonsteroidal antiandrogen monotherapy can be used in advanced PCa as an alternative to castration.[66–68] The first-generation drugs (Fig. 9) such as flutamide (Eulexin®, Schering-Plough), nilutamide (Nilandron®, Sanofi-Avenis), and bicalutamide (Casodex®, AstraZeneca) have been clinically used for decades. They all act on the ABS part of the AR, where they compete with DHT for binding, and therefore block the AR transactivation. Flutamide and nilutamide were found to cause hepatotoxicity, while bicalutamide exhibited fewer side effects and had a longer half-life in patients, so it eventually replaced flutamide and nilutamide as a PCa treatment.[42]

Patients initially respond well to antiandrogens; however, after long-term administration of these drugs, resistance inevitably develops as the disease progresses into CRPC. One of the well-documented mechanisms of antiandrogen resistance is the occurrence of mutation-driven receptor promiscuity and mutation-caused bioconversion of AR antagonists into agonists. T877A and W741L/C mutations in the AR LBD are well-characterized substitutions that drive hydroxyflutamide and bicalutamide to agonize the AR, respectively.[50,69,70] In the cocrystal structures of mutated AR LBDs bound to hydroxyflutamide and bicalutamide in agonistic conformations, hydrogen bond interactions with the polar residue pair Arg752 and Gln711 are maintained, and the hydrogen

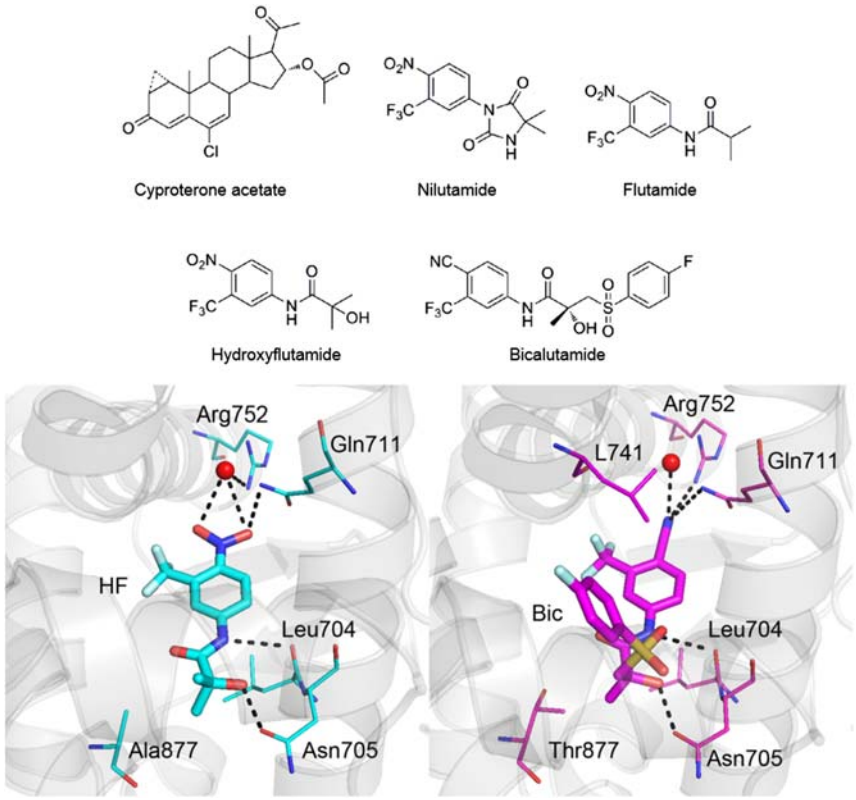

Fig. 9 (*Upper*) Chemical structures of first-generation antiandrogens; (*Lower*) Crystal structures of AR LBD-T877A with hydroxyflutamide (*HF*) and AR LBD-W741L with bicalutamide (*Bic*).

bond contact with Asn705 is also retained while the hydrogen bonding with Thr877 is missing (Fig. 9). In addition, structural modifications on bicalutamide may also lead to the occurrence of AR agonistic properties. For example, the replacement of the aryl sulfonyl in bicalutamide with a phenoxyl group resulted in tissue-selective AR modulators,[71] which act as an antagonist in the prostate, and agonist in the pituitary and muscle.

5.05.3.3 Second- and Next-Generation AR Inhibitors

The development of conventional antiandrogens as PCa therapeutics is the most intensively pursued area. Since resistance occurred with the aforementioned first-generation antiandrogens, the field evolved rapidly, resulting in second- and next-generation antiandrogen drugs aiming to overcome the resistance.[72,73]

5.05.3.3.1 Enzalutamide and ARN509

The second-generation antiandrogens, represented by clinically used enzalutamide (Xtandi®, Astellas), were developed on the basis of a hydantoin compound RU59063 (Fig. 10),[74–76] which has a very high binding affinity to the AR. Enzalutamide is also a competitive AR inhibitor, but in comparison with first-generation antiandrogens, it binds to the AR ABS with higher affinity, and exhibits improved anti-AR potency, better pharmacokinetic (PK) profiles, and better in vivo efficacy.[74] Enzalutamide also exhibits additional mechanisms of anti-AR action, including preventing AR nuclear translocation, impairing DNA binding, and affecting coactivator recruitment.[74] As enzalutamide demonstrated significant overall patient survival benefit (~5 months) for patients with metastatic CRPC,[16] it was approved by FDA for CRPC in 2012.

ARN509 is an investigational drug derived from enzalutamide with greater inhibitory activity on the AR transcription and PCa cell proliferation. As with enzalutamide, ARN509 blocks AR nuclear translocation, impairs AR binding to DNA, and prevents recruitment of coactivators. As an optimized derivative of enzalutamide, ARN509 demonstrated better antitumor effects than enzalutamide in a mouse xenograft model of CRPC.[76] Although both ARN509 and enzalutamide possess an unwanted cross-activity toward the Υ-aminobutyric $acid_A$ ($GABA_A$) receptor at low micromolar concentrations, it has been demonstrated that the steady-state brain level of ARN509 is significantly lower than that of enzalutamide, implying lower seizurogenic potential of ARN509. The phase I and II trials of ARN509 both showed favorable PSA response,[75] and the phase III trial is ongoing.

It should also be noted that despite the survival benefit of enzalutamide in CRPC, resistance is invariably developed to this drug within 1–2 years in patients with metastatic CRPC. Similarly, resistance has already been reported for ARN509. In particular,

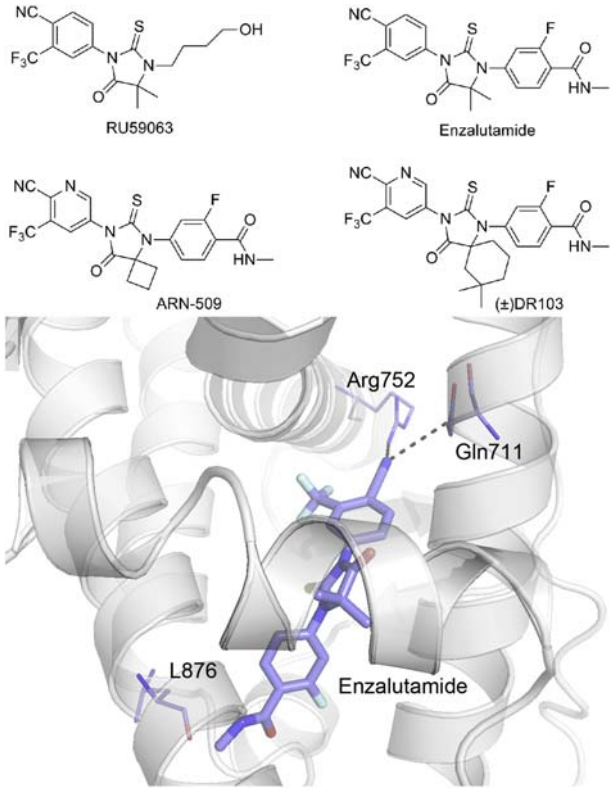

Fig. 10 (*Upper*) Chemical structures of second-generation of antiandrogens; (*Lower*) Docking mode of enzalutamide in the agonistic conformation of AR LBD (PDB code: 3V49) with F876 in the helix 11 mutated to L876.

a mutation F876L in the helix 11 of the AR LBD was implicated in rendering the agonistic effect of enzalutamide and ARN509.[77–79] Molecular dynamics simulation was performed to investigate the structural basis of such antagonist-to-agonist conversion, and it revealed that the F876L mutation could induce H12 to adopt a more agonist-like conformation. In addition, it was observed from the simulation that the geminal-dimethyl group on enzalutamide (**Fig. 10**) and the spirocyclobutyl on ARN509 lie in close proximity to helix 12, and the bulkier spirocyclobutyl moiety elicited greater displacement of the helix 12. This observation provided important insights into structural modifications on enzalutamide and ARN509 to overcome the mutation-induced antagonist-to-agonist conversion. Derivatives were created to replace the geminal-dimethyl in enzalutamide with spirocycles of greater size and complexity, such as (±)DR103, which were reported to be antagonistic to the AR bearing the F876L mutation.[77]

5.05.3.3.2 ODM-201

ODM-201 represents another nonsteroidal antiandrogen that is currently under clinical investigation. ODM-201 has a major pharmacologically active metabolite ORM-15341 (see the chemical structure in **Fig. 11**), and both of them are structurally distinct from all other antiandrogens. When docked into the ABS site of an antagonistic model of the AR LBD, ODM-201 retains the conserved hydrogen bond interactions with Arg752 and Gln711, and might form an additional hydrogen bond contact with Glu709 (**Fig. 11**).

ODM-201 and ORM-15341 have higher binding affinity to the AR with the inhibition constant (Ki) eightfold lower than enzalutamide in a radio-labeled competition assay, and they also inhibit AR transactivation more potently than enzalutamide.[80] In addition, they impair the androgen-induced nuclear translocation to the same extent as enzalutamide.[80] Remarkably, they demonstrated full antagonistic profile upon AR mutations including F876L, T877A, and W741L, which transform the pharmacology of clinically used drugs enzalutamide, flutamide, and bicalutamide, respectively.[80] ODM-201 and ORM-15341 inhibited VCaP cell proliferation in vitro, and did not affect the growth of an AR-negative cell line, suggesting the antiproliferative effect is AR-specific.

ODM-201 and ORM-15341 demonstrated more potent antitumor activity in CRPC mouse models. In comparison with enzalutamide, the PK profile of ODM-201 appeared less favorable (half-life: 1.6 h for ODM-201 vs. 18.3 h for enzalutamide) resulting in higher doses, and more frequent dosing required for ODM-201.[80] Unlike enzalutamide and ARN509, ODM-201 does not penetrate the blood–brain barrier, and no seizures were observed. The phase I/II trial showed a favorable safety profile and PSA response, and the phase III trial is ongoing.[81]

5.05.3.3.3 Abiraterone

Abiraterone acetate (Zytiga®, Johnson & Johnson, New Jersey, USA) is mainly known as an androgen synthesis inhibitor (see the chemical structure in **Fig. 12**), targeting CYP17A1 and other enzymes, which was approved for CRPC in 2009.[82] Of note, it is also

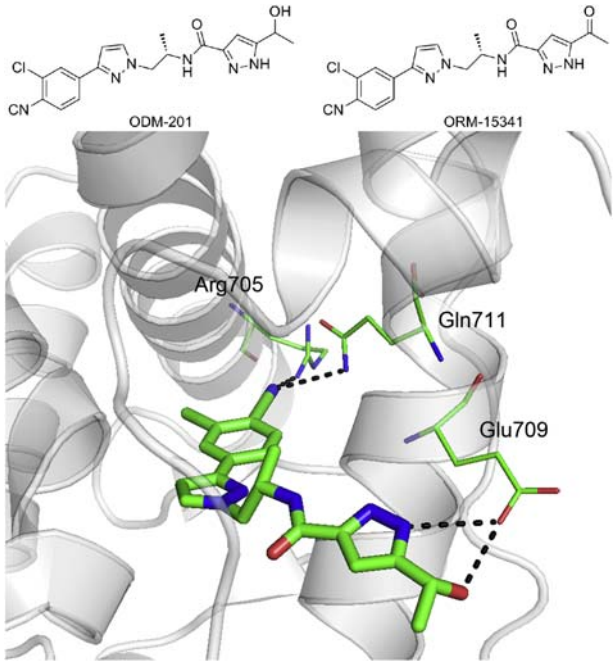

Fig. 11 (*Upper*) Chemical structures of ODM-201 and its main metabolite ORM-15341; (*Lower*) Docked pose of ODM-201 in an antagonistic model of AR LBD.

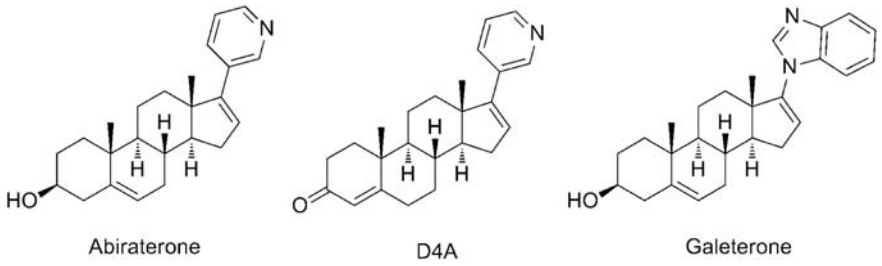

Fig. 12 Chemical structures of next-generation antiandrogens.

considered as an antiandrogen since it competitively binds to the AR as a weak AR antagonist.[83] The anti-AR profile of abiraterone contributes to its antitumoral effects, and abiraterone is clinically used as the pre- and postchemotherapy treatment for metastatic CRPC.[17,84] Resistance to abiraterone has already been reported, and the de novo intratumoral androgen production has been suggested as a mechanism of resistance to abiraterone.[85]

Recently, it has been demonstrated in mice and patients with PCa that abiraterone was converted into a more active metabolite Δ^4-abiraterone (D4A), which blocks enzymes required for androgen synthesis including CYP17A1, 3βHSD, and SRD5A. As for abiraterone, D4A also inhibits AR with potency comparable to enzalutamide.[86] The metabolite D4A has more potent antitumor activity against xenograft tumors than the parent drug abiraterone itself, and thus, direct D4A treatment may offer greater clinical and survival benefits.[86]

5.05.3.3.4 Galeterone

Galeterone (TOK-001 or VN/124-1) is an investigational drug in clinical Phase III study by Tokai Pharmaceuticals (see the chemical structure in Fig. 12). It is a steroidal C17-benzoazole compound based on natural substrates of CYP17A1, such as pregnenolone and progesterone. Galeterone modulates multiple targets in the AR signaling pathway, including CYP17A1 lyase, AR, and 5α-reductase.[87–89] It has been confirmed to disrupt the AR signaling via three distinct mechanisms of action, including: (1) Selectively inhibiting CYP17A1 lyase to prevent androgen synthesis, (2) competing with androgen for binding to the ABS, and (3) causing degradation of full-length and splice variants of the AR.[87–90]

Galeterone is a more potent CYP17A1 inhibitor than abiraterone (IC_{50} of 300 nM for galeterone vs. 800 nM for abiraterone).[87] Different from abiraterone, galeterone selectively inhibits CYP17A1 lyase but not hydroxylyase. The inhibition of hydroxylase results in mineralocorticoid excess, and thus, the selectivity makes galeterone an ideal CYP17A1 inhibitor so that galeterone

does not cause mineralocorticoid excess or require coadministration of steroids as shown in clinical trials. Galeterone competitively binds to the AR ABS, with the binding affinity comparable to bicalutamide. It suppresses AR transactivation with 10-times higher efficiency compared to bicalutamide, while it does not agonize the mutated AR. Galeterone also blocks nuclear translocation and decreases AR-regulated genes such as PSA and TMPRSS2 in CRPC and enzalutamide-resistant cell lines.[91] In addition, galeterone causes marked downregulation of AR protein expression partly due to increased AR degradation in full-length and splice variants of AR, such as AR-V7.[87,88,92] The combined effects of galeterone through CYP17A1 inhibition, AR inactivation, and degradation increase the antitumor efficacy.

Galeterone demonstrated more efficacious in vivo effects in PCa xenograft models than abiraterone or castration.[89] The clinical study phase II demonstrated that galeterone induced PSA and tumor reduction in a majority of patients, and it was well tolerated with an acceptable safety profile.[87] Since galeterone blocks multiple points in the AR signaling pathway, it may help reduce the risk of developing resistance in comparison with other therapeutics targeting the AR signaling.

5.05.3.4 The Resistance Problem of Conventional Antiandrogens

Resistance is the main problem for clinically used drugs targeting the AR signaling, including enzalutamide and abiraterone. Some mechanisms are partly involved in resistance, including AR overexpression,[93–97] gain-of-function mutations,[98–108] the emergence of ARVs lacking the LBD segment,[109–125] alternative pathways,[126–134] and the synthesis of intratumoral androgens and bypass of AR.[135,136]

AR mutations are rare in early-stage untreated PCa patients, but are found in approximately 10–30% of patients previously exposed to bicalutamide and flutamide.[98,101,137] Mutations in the LBD have been intensively studied, and a number of substitutions confer a gain of function by allowing other ligands to bind and activate the AR.[103,104] Aforementioned mutations F876L, W741L, and T877A lead to promiscuous AR activation by antiandrogens through converting AR antagonists into potent agonists.[100,107] Thus, mutations in the AR may account for one of the major mechanisms underlying CRPC progression.

Constitutively active ligand-independent ARVs were first reported in 2009,[121,123] expressed in CRPC cells and clinical samples.[114,121,123,124] So far, there have been 17 ARVs discovered, and all of them contain both NTD and DBD regions, with varying or completely absent LBD parts (**Fig. 13**).[116] Importantly, ARVs could recapitulate the transcriptional program in the absence of androgens or full-length AR.[112,118] It is believed that some ARVs such as AR-V7 are sufficient to drive resistance to antiandrogens, and none of the clinically used drugs are effective against ARVs.[112,122] A recent study of AR-V7 in circulating tumor cells from metastatic CRPC patients (treated with abiraterone and/or enzalutamide) demonstrated that ARVs represent an important predictive biomarker of CRPC and one mechanism of resistance.[113,115]

5.05.4 Novel AR Inhibitors Targeting Alternative Sites

Due to limitations of targeting the ABS, AR inhibitors directed toward alternative functional sites on the receptor (and therefore exhibiting novel mechanisms of action) are expected to circumvent the invariably developed resistance. An ever-increasing number of AR inhibitors has been reported, which target sites beyond the AR ABS, including the AR LBD surface site (AF2, BF3) inhibitors,[138–141] AR NTD binders,[142–145] AR DBD inhibitors,[146,147] and compounds addressing other AR-targeting avenues.[148–150]

5.05.4.1 AR LBD Surface Site Inhibitors

Protein–protein interactions (PPI) play an important role in AR activation, nuclear translocation, and transcription. Thus, PPI sites on the AR represent attractive targets for intervention (**20015. Small-molecule inhibitors of protein–protein interactions**). On the LBD segment of the AR, there have been two adjacent and distinct PPI sites identified—AF2 and BF3, which are important for the coregulator and cochaperone binding, respectively.[151,152] Crystal structures of AR AF2 and BF3 demonstrated that small molecules are able to bind to these large, hydrophobic exposed surface sites, indicating their potential druggability.[53,153,154]

The AF2 site is formed to recruit coactivators containing motifs such as LXXLL and FXXLF when the androgen binds to AR, and the binding of coactivators could enhance the AR activity. The AF2 site is an L-shaped cleft, and LXXLL and FXXLF form short

Fig. 13 The organizational domains of full-length AR and two clinically relevant ARVs.

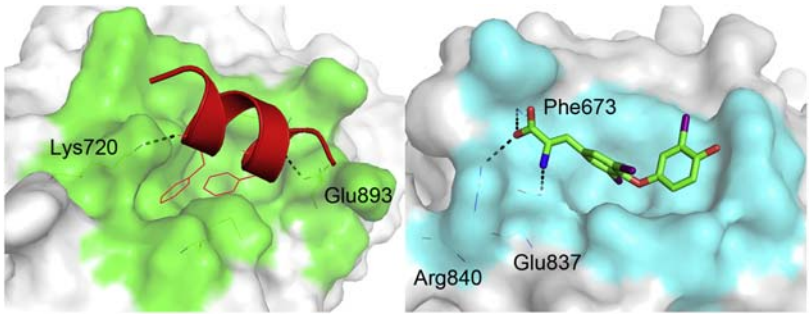

Fig. 14 (*Left*) The crystal structure of the AR LBD with a peptide in the AF2 site (PDB code: 3L3X); (*Right*) The crystal structure of the AR LBD with a small-molecule Triac in the BF3 site (PDB code: 2PIW).

α helices with L+1 (+1 representing the position in the motif), L+5 and F+1, F+5 binding to the hydrophobic cleft, forming electrostatic interactions with Lys720 and Glu893 (Fig. 14). Thus, targeting the AF2 site could disrupt the coregulator modulation of AR transactivation. This type of inhibitor has a distinct mechanism of action from conventional antiandrogens, which may provide opportunities to circumvent the mutation-driven antiandrogen resistance.

Small molecules and peptides were developed to mimic the features of LXXLL or FXXLF motifs to interrupt the AR function.[141,155–157] Small-molecule peptidomimetics (D2 in Fig. 15) were reported as AF2 inhibitors by mimicking the LXXLL motif-containing coregulators,[141] which effectively disrupt interactions of the AR and LXXLL-containing cofactors. D2 demonstrated potent inhibition of AR and PCa cell proliferation, and suppression of tumor growth in vivo. In addition, based on an ensemble of cocrystal structures of the AR LBD with the peptide in AF2, structure-based pharmacophores were generated and used for virtual screening of AF2 disruptors. A series of diarylhydrazides were identified, which inhibit the AR with low micromolar potency,

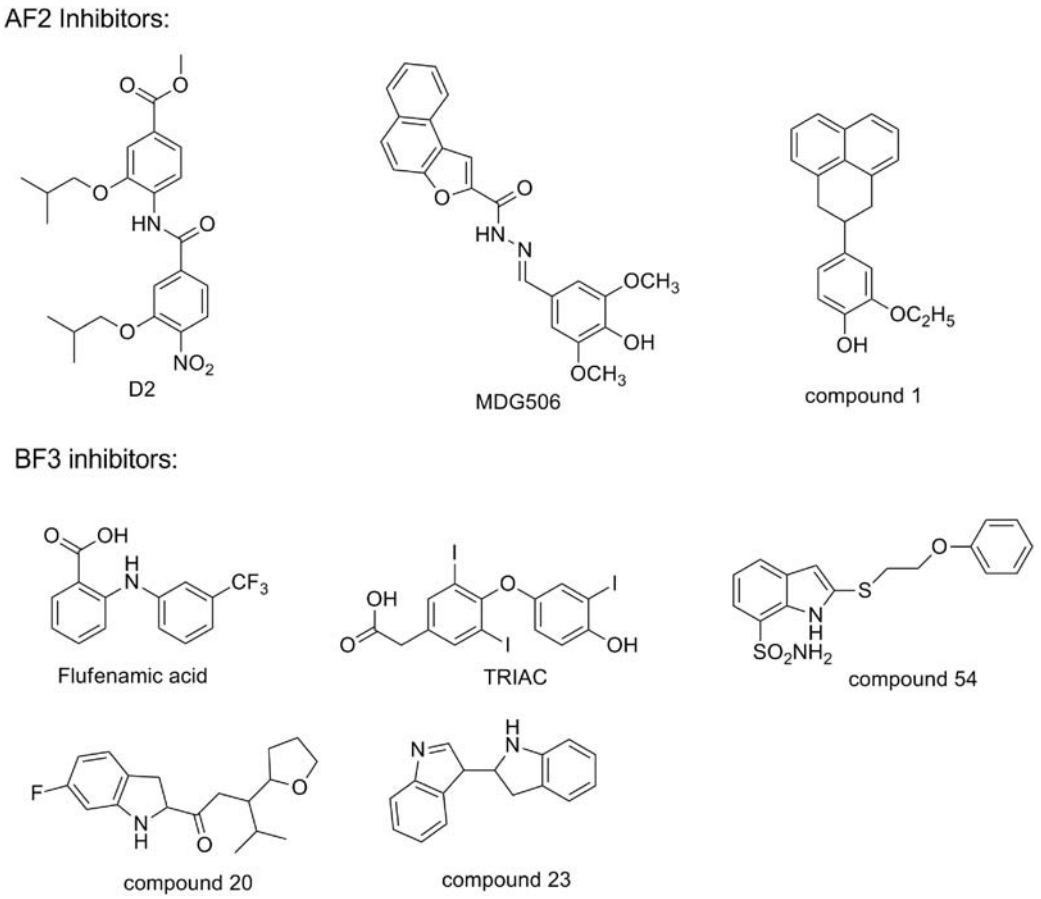

Fig. 15 Chemical structures of AR LBD surface site binders.

and demonstrate selectivity toward other NRs.[156] Molecular docking-based virtual screening also identified active AF2 inhibitors, such as 2,3-dihydro-1*H*-pyrimidines, which inhibit AR transcriptional activity, AR-positive PCa cell growth, and displacement of the SRC2-3 peptide from the AF2 site.[155] In addition to small-molecule inhibitors, peptides that have a Tyr in the +5 position were identified to suppress the AR transactivation through binding to the AF2 site.[157]

In 2007, Fletterick's group reported that some AF2 binders preferentially bind to a previously unknown area—the BF3 site (Fig. 14), which allosterically modulates the AF2 (**20013. Allosteric Inhibitors**), and may function as a PPI site for coregulators.[151,153,158] Little was known about what binds to the BF3 site until recently; it was reported that a duplicated GARRPR motif in Bag-1L functions through the BF3 site, and fine tunes the AR activity.[158] This enables developing a Bag-1L peptide displacement assay to measure the direct binding to BF3, and opens up an opportunity to screen BF3 inhibitors by blocking the AR with cochaperone interaction.[140,41]

A few chemical classes of BF3 inhibitors have been reported to date, which demonstrate potent in vitro and/or in vivo activities, such as dihydropyrimidines,[155] 1*H*-indole-2-carboxamides,[159] benzimidazoles,[139] and indoles[140] (Fig. 15). Notably, the recently reported indole-based AR BF3 inhibitors demonstrate excellent inhibition of AR transcription, PSA expression, and androgen-induced proliferation of androgen-sensitive LNCaP and enzalutamide-resistant MR49F PCa cell lines. Moreover, the reported lead compound (compound 23)[140] effectively reduces AR-dependent gene expression in PCa cells, and importantly, inhibits tumor growth in both LNCaP and MR49F xenograft models. Thus, the BF3-directed AR inhibitors may potentially become alternative therapeutic agents to treat antiandrogen-resistant forms of PCa.

5.05.4.2 AR NTD Inhibitors

The AR NTD has less than 15% sequence similarity with other SHRs. Different from other SHRs, the AF1 region in the NTD is responsible for the majority of AR transcriptional activity, and thus, the ARV lacking the LBD is constitutively active. In addition, the NTD were indicated to play a role in androgen-independent nuclear translocation.[160] Therefore, the AR NTD represents a superior target when compared with AR LBD for PCa and CRPC.[161,162] In contrast with conventional antiandrogens, potential AR NTD inhibitors may not only potently inhibit the AR but possess significant AR specificity, and, more importantly, have the capability to inhibit ARVs. Although targeting the AR NTD is intriguing, the NTD section of the AR is intrinsically disordered, which impedes the structure-based development of AR NTD-targeted therapeutics.

A compound EPI-001 (see the chemical structure in Fig. 16) represents a class of small-molecule inhibitors that interacts with the AF1 region and inhibits the transactivation of the NTD.[142,143,145] EPI-001 was identified from high-throughput screening of a library of marine sponge extracts, and it inhibits the transcriptional activity of the AR as well as ARVs, reduces AR interactions with AREs on the DNA, blocks the N–C interaction as well as PPI, and suppresses the tumor growth of CRPC xenografts.[142] EPI-001 represents a mixture of four stereoisomers due to the presence of two chiral centers in the structure, and the EPI-002 (2*R*, 20*S*) and EIP-005 (2*S*, 20*S*) are the most potent stereoisomers in terms of the in vitro AR transcriptional inhibition, and they also have better antitumor activity when tested in the LNCaP CRPC xenograft model.[143]

Recently, the detailed study of the mechanism of EPI-001 action revealed that all EPI-001 stereoisomers covalently bind to the AF1 in the intrinsically unstructured AR NTD, and that the chlorohydrin in EPI compounds is responsible for the activity and the covalent binding.[143] The EPI compounds do not bind to denatured AF1, and the secondary structure of AF1 is necessary for

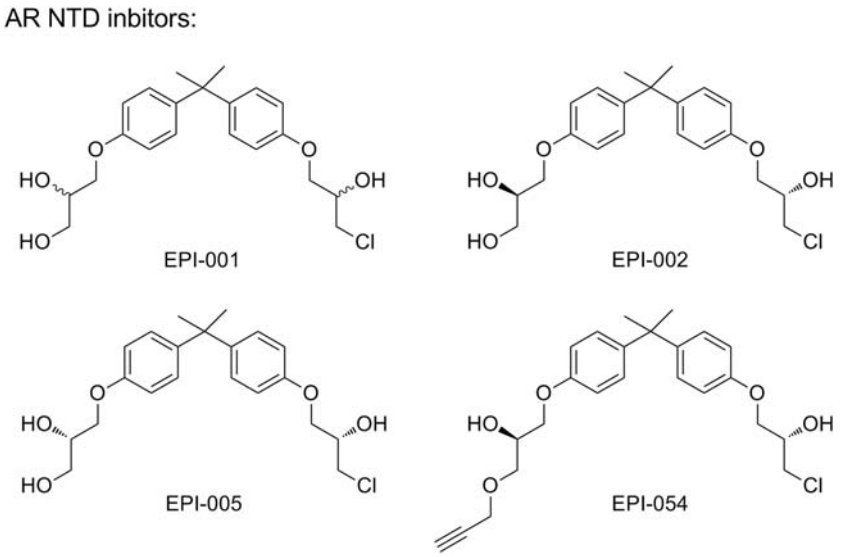

Fig. 16 Representatives of AR NTD inhibitors.

the binding of EPI-001. The effect of EPI-001 isomers was previously claimed to be specific to the AR in vitro and in vivo; however, the latest data demonstrate that EPI-001 is not a specific AR NTD inhibitor but rather is a peroxisome proliferator-activated receptor-gamma modulator with inhibitory effects on AR expression and activity in PCa.[144] In addition, EPI-001 was shown to be a reactive electrophile which forms covalent adducts with thiols.[144] ESSA Pharma Inc. has filed an investigational new drug application for EPI-506 with the FDA, and future reports of its clinical effects are expected.

5.05.4.3 AR DBD Inhibitors

The AR DBD plays an important role in the dimerization and DNA binding of AR transcription, and thus, directly targeting the DBD with small molecules may disrupt AR transactivation. More importantly, selectively targeting the AR DBD could potentially circumvent the resistance of current anti-AR therapy. Firstly, in comparison with the AR LBD and NTD parts, mutations in the DBD may more likely lead to loss of AR transcriptional activity, suggesting a low propensity of mutation-driven resistance.[163] Secondly, the DBD segment plays an important role in the transactivation and gene regulation of both full-length and splice isoforms of the AR, so targeting the DBD may simultaneously inhibit both full-length AR and ARVs. Lastly, the structure of the DBD has been solved by X-ray crystallography since 2004,[35] which provides the structural basis for rational drug discovery and design of AR DBD inhibitors.

Given the above potential advantages of targeting the AR DBD, our group utilized the crystal structure of the AR DBD for the discovery of AR DBD inhibitors. A plausible site was firstly detected underneath the P-box region, which is essential for the DNA binding, and it was hypothesized that the binding of small molecules in that site may disrupt the DBD–DNA interaction and thus inhibits the AR. Virtual screening against the intended site identified a novel chemical class of AR DBD inhibitors, represented by VPC-14228 (4-(4-phenylthiazol-2-yl)morpholine, **Fig. 17**), which potently inhibits the AR transcription in the submicromolar range.[147] Furthermore, this chemical suppresses PSA expression, and blocks AR-positive PCa cell growth as well as the growth of enzalutamide-resistant PCa MR49F cells.[147] More importantly, it inhibits the transcription of ARVs as expected.[146]

The docked pose of VPC-14228 indicates that the compound forms a hydrogen bonding contact with Tyr594 through the morpholine moiety, and the thiazole group may form π–π stacking with Phe583 in the core of the binding site. The anti-AR activity of this chemical class is very sensitive to structural modifications on the benzene ring, presumably due to the hydrophobic interactions with the aliphatic side chain of Arg609 and Lys610.[147] The site-directed mutagenesis study on key binding site residues indicates that these compounds bind to the predicted site, and efforts are underway to provide more direct evidence of binding to the DBD.[146,147]

Since the benzene ring is critical for the AR transcriptional inhibition, structural modifications on the benzene ring displayed a trend that substituents on the para-position are detrimental to the activity which may be exposed to the solvent, and addition of groups on the ortho- and meta- position of the benzene ring could be tolerated. Subsequently, heterocycles were used to replace the benzene ring, and a dibromo-imidazole led to the generation of VPC-14449 with improved cellular activity toward both full-length AR and ARVs.[146,147] These DBD inhibitors do not block the nuclear translocation of AR, which is consistent with DBD targeting in the nucleus, and the chromatin immunoprecipitation assay indicates these compounds block interactions of the AR

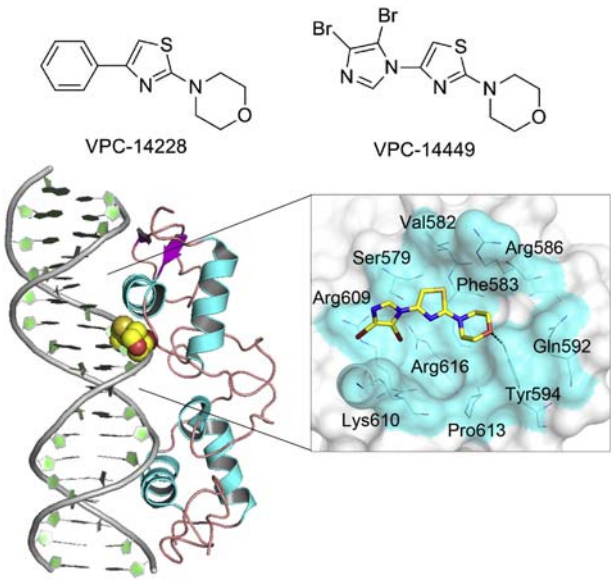

Fig. 17 (*Upper*) Chemical structures of representative AR DBD inhibitors VPC-14228 and VPC-14449; (*Lower*) VPC-14449 in the DBD–DNA interface and a zoomed-in view of VPC-14449 in the binding site.

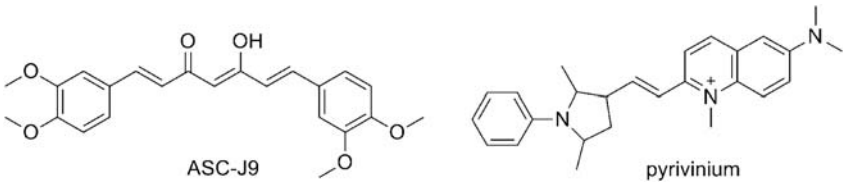

Fig. 18 Chemical structures of miscellaneous compounds targeting the AR.

with the ARE in the nucleus. VPC-14449 was shown to downregulate AR-responsive genes in LNCaP cells in a microarray analysis, and when tested in an LNCaP xenograft model, VPC-14449 reduced tumor growth and blocked PSA production.[146]

5.05.4.4 Other Nonconventional Strategies of Targeting AR Signaling

In addition to conventional and novel ways of targeting of the AR described earlier, there exists a variety of strategies for developing new AR interventions,[149,150,163–167] such as AR degradation, drug repurposing for noncompetitive AR inhibitors, and AR-targeted RNA interference.

The molecule ASC-J9 (see Fig. 18) was identified from natural products as an AR degradation enhancer,[150,167] which selectively degrades AR protein through interruption of the AR–AR selective coregulator interaction. Additionally, the ASC-J9-promoted AR degradation leads to suppression of AR transcription, AR-mediated PCa cell growth, and tumor growth in androgen-dependent and castration-resistant xenograft models.

Pyrivinium pamoate (PP) is an FDA-approved drug, which was identified as a noncompetitive AR inhibitor through drug repurposing (**10002. Drug repurposing: faster drug approval?**).[166] PP was reported to inhibit the transcriptional activity of both full-length AR and ARVs, without preventing DHT binding. However, PP displayed generic toxicity and cross-reactivity with other SHRs,[146] and the fact that PP targets multiple proteins may explain the undesired off-target effects. Recently, it has been reported that PP may inhibit initiation of transcription via the DBD,[163] but the exact mechanism of PP action on the AR is still unclear.

RNA interference is another therapeutic strategy used by silencing critical genes in PCa, such as the AR. The short-hairpin RNA against AR could inhibit tumor growth and suppress PSA,[165] and the lipid nanoparticle small-interfering RNA system and antisense oligonucleotides (**60018. Antisense Drug Discovery: Second-generation antisense oligonucleotide (ASO) mRNA/protein**) have been shown to be effective in silencing the wild-type AR and ARVs.[148,149]

Cochaperones play a critical role in the stability, activation, and maturation of AR, such as HSP90.[168,169] Thus, AR cochaperones were considered as potential targets for PCa, and cotargeting cochaperones and AR may have therapeutic merits. Recently, it was reported that combination therapy of HSP90 inhibitors with antiandrogens enhances the inhibition to AR signaling and prevents ARV-induced resistance.[170,171]

5.05.5 Summary

NRs are strongly associated with a variety of cancers, and SHRs have been extensively studied in the context of the development of anticancer agents. The ligand-binding site of SHRs, such as the AR ABS, is the conventional drug target for a variety of marketed and investigational drugs. However, residues in the ligand-binding site are prone to be mutated, which drives drug resistance. The clinically used antiandrogens target the conventional AR ABS, and they invariably develop resistance when the disease progresses into a lethal form of CRPC. To overcome the resistance, alternative target areas in the AR LBD beyond the ABS were considered, including the AF2 and BF3 sites. The AR AF2 and BF3 inhibitors block the AR function through disrupting critical coregulator binding, which have the potential to circumvent the mutation-induced antagonist-to-agonist conversion arising from targeting the ABS. These sites also exist in other SHRs such as ER, and the ER AF2 has also been targeted by small-molecule inhibitors that act as a potential treatment for ERα-positive, tamoxifen-resistant, and metastatic breast cancers.[172]

The NTD of SHRs is flexible and disordered, which precludes rational drug design of NTD-directed agents. Covalent inhibitors targeting the AR NTD exist; however, they are not very specific, and are believed to have off-target reactivity liabilities. Thus, this type of inhibitor is somewhat disfavored and underdeveloped.

The crystal structures of the DBD portion have been solved for all SHRs, which provides an opportunity for structure-based drug discovery of DBD inhibitors. Our study of targeting the AR DBD demonstrated that the DBD is a viable target for developing small-molecule inhibitors. Compared to antiandrogens as well as AR LBD surface disruptors, AR DBD inhibitors may provide greater advantages regarding addressing resistance, as they are effective in inhibiting ARVs. This strategy for developing DBD-directed drugs could be applied to other SHRs, such as ER and PR, which may provide alternative or complementary therapeutics for existing drugs.

As NR family members share sequence similarity and organizational domains, strategies applied for targeting the human AR could be applied to other NR members. This article reviewed therapeutic targeting of the AR signaling axis, which may provide insights into targeting other NRs.

5.06 Protein–Protein Interaction Inhibitors in Cancer

IR Hardcastle, Newcastle University, Newcastle Upon Tyne, United Kingdom

© 2017 Elsevier Ltd. All rights reserved.

5.06.1	**Introduction**	155
5.06.1.1	PPIs as Drug Targets	155
5.06.1.1.1	Structure of PPIs	155
5.06.1.1.2	Advantages of PPIs as drug targets	156
5.06.1.1.3	Identification and validation of PPI targets	157
5.06.1.1.4	Druggability/ligandability of PPIs	157
5.06.2	**Approaches to PPI Inhibitor Discovery**	157
5.06.2.1	Natural Products	157
5.06.2.2	Peptides and Peptidomimetics	159
5.06.2.2.1	Bcl-xL-Bak peptides	159
5.06.2.2.2	MDM2–p53 peptides	159
5.06.2.2.3	Smac-IAP peptides	160
5.06.2.2.4	Stabilized peptides	161
5.06.2.2.5	Peptide mimetics	163
5.06.2.3	High-Throughput Screening	165
5.06.2.4	Virtual Screening	166
5.06.2.5	Fragment Screening	166
5.06.3	**Examples of PPI Inhibitors**	167
5.06.3.1	Inhibitors of Bcl-2 Family PPIs	167
5.06.3.2	Inhibitors of MDM2–p53 and MDMX–p53	171
5.06.3.2.1	MDM2–p53 antagonists	171
5.06.3.2.2	Dual MDM2–p53, MDMX–p53 antagonists	178
5.06.3.3	Inhibitors of Smac-IAP PPIs	178
5.06.3.3.1	Monovalent Smac-mimetic IAP antagonists	180
5.06.3.3.2	Bivalent Smac-mimetic IAP antagonists	183
5.06.3.4	Inhibitors of Other Cancer Related PPIs	186
5.06.3.4.1	14-3-3 proteins	186
5.06.3.4.2	S100 protein inhibitors	186
5.06.3.4.3	Myc/Max inhibitors	186
5.06.3.4.4	PDZ domain inhibitors	186
5.06.3.4.5	SH2 and SH3 domain inhibitors	189
5.06.3.4.6	Ras PPI inhibitors	191
5.06.3.4.7	Other PPI inhibitors	191
5.06.3.5	Challenges in the Optimization of PPI Inhibitors	191
5.06.4	**Outlook**	191

5.06.1 Introduction

The search for novel precision medicines for the treatment of cancer has expanded beyond well-established drug targets with good precedent for "druggability," such as enzymes and receptors, to less well-described drug targets, such as protein–protein interactions (PPIs). Detailed investigations of cell-signaling networks linked to the "hallmarks of cancer"[1] have identified many PPIs as important regulatory nodes in important cellular processes. In particular, networks responsible for oncogenic signaling or tumor suppression, including those controlling cell proliferation, survival, and apoptosis, rely on PPIs.[2] The identification of PPIs as key regulators in these networks offers the promise of selective therapeutic intervention through their modulation.

This chapter discusses the structural features of PPIs and their attractiveness as drug targets. Approaches to the identification and validation of PPI targets, in particular peptide-based approaches, are reviewed. Methods for the discovery of small-molecule PPI inhibitors are discussed, such as high-throughput screening, virtual screening (VS), and fragment screens, which have been successful in the discovery of small-molecule PPI inhibitors. Inhibitors of three PPI targets have progressed to clinical trials and are discussed in detail, that is, Bcl-2 family inhibitors, MDM2–p53 inhibitors, and inhibitor of apoptosis protein (IAP) family inhibitors. Examples of inhibitors of other PPI targets in cancer are covered to highlight the biological and chemical diversity that is under investigation.

5.06.1.1 PPIs as Drug Targets

Historically, PPIs have been regarded as difficult or undruggable targets, and consequently drug discovery efforts have focused on other drug targets, such as enzymes or receptors, that have good precedent for success.[3] In contrast to enzyme and receptor drug targets, PPI targets lack intrinsic small-molecule ligand or cofactor binding sites, and the natural, small-molecule, ligands that are commonly used as starting points for drug discovery are not available.[4,5] The growth in interest in PPI targets has coincided with the introduction of many new hit discovery technologies and a reevaluation of the characteristics of screening libraries targeting PPIs. Recently, three cancer PPI inhibitor programs have yielded clinical trial candidates (Sections "**Inhibitors of MDM2–p53 and MDMX–p53**," "**Inhibitors of Smac-IAP PPIs**," and "**Inhibitors of Other Cancer Related PPIs**"). These successes demonstrate the possibility to develop highly potent and druglike small-molecule inhibitors for PPI targets and encourage the examination of other PPI targets.

5.06.1.1.1 Structure of PPIs

Analysis of the structures of PPIs in the protein database has shown that they differ significantly from enzyme active sites.[6–8] They may be significantly larger in area (1500–4660 $Å^2$) than typical drug–protein interfaces (1200–2000 $Å^2$), more circular, and

significantly flatter. Some interactions may require significant conformational change on complex formation, while others appear more rigid.[6] The polarity of PPIs also differs, burial of hydrophobic contacts may provide significant binding energy, with relatively few hydrogen bonds being present.[9] The binding energy of the interaction has also been discussed, suggesting that the usual range of ΔG is -7.0 to -17.2 kcal mol^{-1}.[7] These analyses have not encouraged medicinal chemists to seek inhibitors for such seemingly large, flat, tightly bound interfaces.

In contrast to the unpromising analyses, Bogan and Thorn identified "hot-spots" in PPIs consisting of regions near the center of the interaction, where small numbers of amino acids contribute large amounts to the binding energy.[10,11] Hot-spots frequently include large amino acid side chains, for example, Arg, Tyr, or Trp, bound to small pockets. These hot-spots may be surrounded by more polar residues, possibly to shield the hot-spot residues from solvent.[12] Alanine-scanning mutagenesis is a popular method for the identification of hot-spot epitopes.[13–15] The systematic removal of amino acid side chains by this method allows each side chain's energetic contribution to binding to be quantified. Single amino acids or clusters that give a significant increase in binding energy on mutation (at least 2.0 kcal mol^{-1}) can be defined as hot-spots. Many PPI hot-spots appear to be more compatible with inhibition by small molecules in terms of shape, size, and polarity.[5]

The concept of "hot-segments," or continuous epitopes contributing to the majority of the binding energy, was introduced by London et al.[16] This analysis categorized PPIs into either domain–domain type interactions or domain–peptide interactions, which make up an estimated 15–40% of the total. The authors estimated that more than half of domain–domain interactions include "hot-segments" and are mediated by a continuous sequence of one protein partner interacting with the other. These "hot-segments" resemble the more tractable domain–peptide interactions. In particular, PPIs mediated by α-helix to protein interfaces have been exploited successfully as drug targets, for example, Bcl-2 and MDM2–p53 PPIs (Sections "**Inhibitors of Bcl-2 Family PPIs**" and "**Inhibitors of MDM2–p53 and MDMX–p53**").

The importance of hot-spots as a measure of druggability of PPIs has inspired the development of computational tools for their prediction. The ROBETTA server allows hot-spot prediction via computational alanine scanning of PPIs.[17] HotPoint relies on an empirical model based on sequence conservation, solvent accessible surface area, and pairwise residue potentials to predict hot-spots in PPIs.[18,19] Solvent accessible surface-based hot-spot prediction for protein–protein (SASA-HS-PP) interactions uses solvent accessible surface descriptors and analysis of surface residues to score PPIs.[20]

In addition to hot-spots, small-molecule inhibitors of PPIs have been observed binding to grooves or pockets that are not visible in the free, unbound structures of the target proteins.[21] These transient pockets may become visible during molecular dynamics (MD) simulations of target proteins and are not limited to native binding sites.[22] The constrained geometrical simulation method Framework Rigidity Optimized Dynamics Algorithm (FRODA) is able to predict transient pockets on PPIs, with the advantage of a lower computational cost over conventional simulations.[23] Another analysis indicated that the small-molecule ligands show a preference for binding to pockets close to PPIs.[24] These sites may offer the possibility of growing inhibitors into the interface, or of developing allosteric inhibitors.

Some PPIs are mediated by posttranslational modifications, for example, the 14-3-3 family of proteins binds to phosphoserine within well-defined motifs on a number of protein partners.[25] The structural basis for these interactions has been revealed by X-ray structures of 14-3-3 proteins, indicating that the dimeric proteins form a conserved cleft containing a cluster of basic residues that form salt–bridge interactions with the phosphoserine residue.[26]

Other PPIs can be viewed as interactions between a recognizable domain of one protein and the surface of the partner protein. Examples include PDZ domains, SH3 domain, and WW domain interactions.[27–29]

5.06.1.1.2 Advantages of PPIs as drug targets

Despite the perceived difficulty of targeting PPIs with small molecules, the approach has gained popularity.[5] Drug discovery efforts to date have exploited only a small fraction of the "druggable genome,"[3] thus the novelty of PPIs as targets is attractive in this context from an academic and commercial standpoint. Importantly, inhibition of PPIs may offer routes to inhibit pathways with limited opportunities for intervention by enzyme or receptor targeted small-molecule inhibitors.

Another possible advantage of PPI targets relates to their structural diversity and specificity. Selective inhibition of enzymes via their substrate or cofactor binding sites presents challenges in achieving potency while retaining target selectivity. For example, ATP-competitive kinase inhibitors require profiling against large panels of kinases to establish selectivity and eliminate predictable off-target toxicities, and target selectivity is a central goal in these projects.[30] In contrast, PPIs typically lack such conserved binding sites, and the larger interface can include greater structural diversity. It can be argued that PPIs are required to encode selectivity into their interactions to ensure they bind to the correct partners to exert their biological effects. High selectivity can be observed experimentally for a number of PPI targets that bind to α-helical regions of their cognate proteins, for example, MDM2/p53 and MDMX/p53. Both mouse double minute (MDM) proteins bind to the same α-helical segment of p53, forming interactions with the identical amino acid side chains, and despite the high sequence conservation in the binding cleft of the MDM proteins, both small molecules and peptide mimetics can achieve exquisite selectivity for MDM2 over MDMX (see Section "**Inhibitors of MDM2–p53 and MDMX–p53**").

It has been proposed that PPI targets will offer reduced susceptibility to resistance mutations compared with enzyme inhibitors.[31] Clinical resistance to competitive enzyme inhibitors can occur through mutations in the enzyme active site that reduce the affinity for the inhibitor but not the substrate. It is postulated that mutations at PPIs would be less likely to have an inhibitor specific effect, due to the structural diversity of the interfaces. However, development of resistance to PPI inhibitors has been reported, for example, with MDM2–p53 inhibitors.[32] In this case, treatment with MDM2–p53 inhibitors has been demonstrated

to select for mutations causing loss of p53 function and so induce resistance to the inhibitors. Similar, pathway mutations can be expected for other PPI inhibitors.

5.06.1.1.3 Identification and validation of PPI targets

The growing importance of PPI targets in drug discovery has led to the development of a number of techniques for their identification. Several high-throughput methods have been employed based on the yeast two-hybrid method, affinity purification-mass spectrometry, DNA microarrays, protein microarrays, synthetic lethality screens, or phage display methods, as reviewed in Ref.[33] These methods are designed to evaluate all the interactions within entire genomes. Lower throughput methods have also been used to identify and characterize PPIs relying on methods such as X-ray crystallography, nuclear magnetic resonance (NMR) spectroscopy, fluorescence resonance energy transfer (FRET) assays, and surface plasmon resonance (SPR). Large, publicly accessible databases have been assembled to collate experimental data and curate them computationally.[34] In additional to experimental methods, computational approaches based on three-dimensional (3D) structural data and homology models have been designed to predict PPIs with reasonable accuracy and so identify likely signaling nodes for therapeutic intervention.[35,36]

5.06.1.1.4 Druggability/ligandability of PPIs

As previously described, the structural diversity of PPIs renders some interfaces more suitable for small-molecule inhibition than others. Methods to predict the ability of a PPI to bind small molecules, a property variously described as bindability, ligandability, or druggability, have been developed.[35,37] These approaches frequently assess the surface of the PPI for pockets suitable for binding small-molecule ligands. One such approach assesses pockets or grids in the 3D structures of PPIs to determine "druglike density," a measure of the volume, buriedness, and hydrophobicity of the region, as an indicator of drugability.[38] An alternative determines energetically favorable ligand binding sites and pockets.[39] An extension to the ligandability-based approaches is based on the physicochemical properties of the binding site as related to the ideal druglike properties of the ligand.[40] This method gave a good druggability score for the PPI target MDM2. These approaches do not easily account for the innate plasticity of many PPIs and so may give a low score for PPI targets with inducible pockets.[31]

Three classes of PPI modulators have been described.[41,42] Orthosteric inhibitors occlude the binding site on target protein. Allosteric inhibitors bind at a distant site to the PPI and may induce structural changes that prevent the partner protein binding. Transient stabilizers may interfere with the normal biological function of the PPI by stabilizing the interaction. Interestingly, there are a number of examples of natural products that act as stabilizers of PPIs.

5.06.2 Approaches to PPI Inhibitor Discovery

5.06.2.1 Natural Products

Extensive screening of natural products for cytotoxicity has been used to identify agents for cancer chemotherapy. The molecular targets for many of these compounds were elucidated subsequent to their clinical use. The vinca alkaloids and taxoids were found to share a common target, that is, microtubules formed from α,β-tubulin heterodimers. The mitotic phase (M-phase) of the cell cycle relies on the cycling of microtubules by polymerization and depolymerization of guanosine diphosphate (GDP)-bound α,β-tubulin to control the organization of chromosomes and to effect their separation during the cell division. Disruption of microtubule formation and the mitotic spindle has been shown to activate the metaphase–anaphase checkpoint, and initiate cell death.[43] Destabilization of microtubules in cells during the interphase has also been shown to affect diverse processes, including cell signaling and motility.[44]

Isolated from *Catharanthus roseus*, vinblastine (**Table 1**, **1**) disrupts microtubule polymerization at low concentrations by binding to high-affinity sites at the ends of the microtubules and stabilizing them.[45,46] Each microtubule end can bind 16–17 drug molecules, but only one or two bound molecules are sufficient to disrupt polymerization. At higher drug concentrations depolymerization is induced. An X-ray structure of vinblastine (**1**) bound to a microtubule complex shows that the drug binds into a hydrophobic groove at the interface of the α- and β-subunits and so perturbing microtubule stability.[47] The semisynthetic derivative vinflunine (**2**) has lower toxicity than **1**, possibly due to its lower affinity for tubulin.[48]

Taxol (**3**), isolated from the bark of *Taxus brevifolia* (Pacific yew), was initially thought to share the same mechanism as the vinca alkaloids, but was subsequently shown to bind to α,β-tubulin heterodimers at a different site and to produce distinc effects.[49,50] Analysis of the X-ray structure of **3** bound to GDP-bound α,β-tubulin shows the drug binding to the β-subunit close to the GDP-binding site.[51] The bound drug induces conformational changes in the heterodimer that stabilize polymer formation and override the normal control through guanosine triphosphate (GTP) hydrolysis. The abnormally sticky α,β-tubulin units form unusually stable microtubules, resulting in disruption to the M-phase and cell division. The semisynthetic derivative cabazitaxel (**4**) was selected for development because it shows reduced affinity for cellular efflux pumps such as P-glycoprotein pump-1 (P-gp).[52]

The natural product Halichondrin B (**5**) was isolated from marine sponges.[53] The scarce supply of the compound prohibited its clinical development. A simplified synthetic derivative Erubilin (**6**) showed similar cytotoxicity to the parent via the same antimitotic mechanism. Erubilin (**6**) binds to microtubules at or near the vinca domain and overlaps the GTP binding site on β-tubulin inhibiting GTP hydrolysis.[54] Erubilin **6** suppresses the addition of new α,β-tubulin heterodimers to the plus end of the microtubule but does not affect shortening at the minus end. Overall, the effect of **6** on the dynamic instability of microtubules differs from that of the vinblastine **2**.

Table 1 Natural product derived PPI drugs

Name	*Compound*	*Structure*	*Target*	*References*
Vinblastine	**1**		α,β-Tubulin	[45]
Vinflunine	**2**		α,β-Tubulin	[48]
Taxol	**3**		α,β-Tubulin	[50]
Cabazitaxel	**4**		α,β-Tubulin	[52]
Halichondrin B	**5**		α,β-Tubulin	[53]
Eribulin	**6**		α,β-Tubulin	[53]

Table 1 Natural product derived PPI drugs—cont'd

Name	*Compound*	*Structure*	*Target*	*References*
Epothilone B Ixabepilone	**7**: X = O **8**: X = NH		α,β-Tubulin	[55,56]
Temsirolimus	**9**		mTOR-FKBP12	[58]

Epothilones, for example, **7** were isolated from the myxobacteria *Sorangium cellulosum* and share a similar mechanism of action to the taxoids as promoters of tubulin polymerization.[55] Epothilones are cytotoxic in P-pg expressing cells and so offer an advantage over taxoids, which suffer from innate and acquired resistance though this mechanism. Ixabepilone **8** is a semisynthetic lactam derivative that overcomes the poor metabolic stability and pharmacokinetic (PK) properties of the corresponding lactone **7**.[56] Ixabepilone **8** showed activity in taxol resistant xenografts resulting from P-gp expression or tubulin mutations, and has shown single-agent activity in patients resistant to a number of chemotherapeutic drugs.

Temsirolimus (**9**) is a semisynthetic derivative of rapamycin, a compound that was initially developed as an antifungal and then as an immunosuppressive agent. The anticancer activity of **9** resides in its inhibition of the kinase activity of the mammalian target of rapamycin (mTOR) protein. The compound forms a complex with FK506-binding protein 12 (FKBP12), which inhibits mTOR activity.[57,58]

5.06.2.2 Peptides and Peptidomimetics

The druggability of PPIs has been assessed by the use of peptide libraries. The information gained has proved important in the validation of a number of targets. In particular, α-helical peptides binding to Bcl-2 or MDM2 have delineated potential small-molecule binding sites. The NMR and X-ray structures of these interactions have been employed in the subsequent design of inhibitors (Sections "Inhibitors of Bcl-2 Family PPIs" and "Inhibitors of MDM2–p53 and MDMX–p53").

5.06.2.2.1 Bcl-xL-Bak peptides

The structure of the Bcl-xL protein was determined by X-ray crystallography and NMR spectroscopy.[59] Further NMR experiments elucidated the structure of the Bcl-xL–Bak BH3 domain peptide interaction.[60] Bak forms an amphipathic α-helix that binds via the hydrophobic side chains of the Val74, Leu78, Ile81, and Ile85 residues into a hydrophobic groove on the surface of Bcl-xL (Fig. 1).

A 16-mer peptide corresponding to the α-helical part of the BH3 domain of Bak bound to avidly to Bcl-xL (Table 2).[60] Shorter peptides bound less tightly, and alanine scanning identified important interactions with the side chains of Val74, Leu78, Ile81, and Ile85 of Bak (highlighted red) and a hydrophobic pocket formed by Tyr101, Leu108, Val126, and Phe146 on the surface of Bcl-xL. An electrostatic interaction between Asp83 of the Bak peptide (highlighted blue) and Arg139 of Bcl-xL stabilizes the complex, and this residue is conserved within the Bcl-family.

5.06.2.2.2 MDM2–p53 peptides

The structure of the p53 and MDM2 interaction has been determined by X-ray crystallography.[61] The p53 peptide binds as an amphipathic α-helix into a twisted trough around a central cleft lined with hydrophobic residues on MDM2. Three p53 residues, Phe19, Trp23, and Leu26, bind to the hydrophobic cleft. Two intermolecular hydrogen bonds stabilize the interaction between the

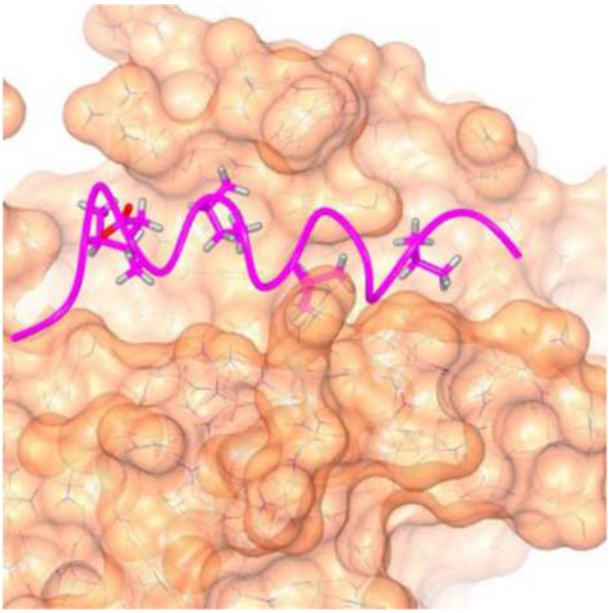

Fig. 1 NMR solution structure of Bcl-xL (ribbon—*blue*, surface—*coral*) bound to a peptide of residues 572–587 of Bak (magenta) showing the key sidechains (pdb 1BXL).

Table 2 Binding affinities of peptides to Bcl-xL

backbone of Phe19 of p53 and the Gln72 side chain of MDM2, and between the p53 Trp23 indole NH and the backbone carbonyl of Leu54 from MDM2 (Fig. 2).

Peptide inhibitors of MDM2–p53 binding have been identified using phage-display and synthetic peptide libraries, for example, IP3 peptide (Table 3, **10**; $IC_{50}=313$ nM).[62] A shortened versions of the IP3 peptide with stabilized α-helical nature included peptide **12** with fourfold improved inhibitory activity over the corresponding peptide **11**. Switching the tyrosine to a phosphonomethylphenylalanine residue (peptide **13**), to form a salt–bridge interaction with the α-amino group of Lys94 of MDM2, gave a sevenfold improvement in affinity. Optimization of the 6-position of the tryptophan residue with lipophilic groups able to fill a small cavity observed in the X-ray structure, gave a significant increase in affinity. A 6-chloro substituent was optimal, as found in the AP peptide **14** ($IC_{50}=5$ nM).[63]

5.06.2.2.3 Smac-IAP peptides

The IAPs bind to caspases via baculovirus IAP repeat (BIR) domains. In particular, human X-linked IAP (XIAP) binds caspase-9 through an interaction between its BIR3 domain and the amino terminus of the linker peptide on the small subunit of the caspase.[64] Second mitochondrial-derived activator of caspases (Smac) competes with caspases for binding to IAPs to trigger apoptosis through the N-terminal residues (AVPI) binding to the IAP BIR3 domain. Synthetic peptides including seven N-terminal residues of Smac and a cell penetrating TAT domain were found to sensitize TRAIL-induced apoptosis and cytotoxic drug treatment in cells, but did not initiate apoptosis as single agents.[65]

Fluorescently tagged tetrapeptides were used to establish the contribution of each amino acid to BIR3 binding.[66] The results showed that positions 1 and 3 of the peptide were required for affinity, while variations of positions 2 and 4 were tolerated. Peptide libraries were used to determine the SARs for the N-terminal Smac tetrapeptide binding.[67] Position 1 is limited to small L-amino acids, for example, Ala and Abu, and the NH is essential. Position 2 can be substituted with little effect on binding affinity, consistent with this residue pointing into solution, but a D-amino acid is not tolerated. Position 3 was found to require the 5-membered ring of Pro, and only the 4-membered azetidine substitution was tolerated. In position 4, aromatic rings, for example, Phe or Nal,

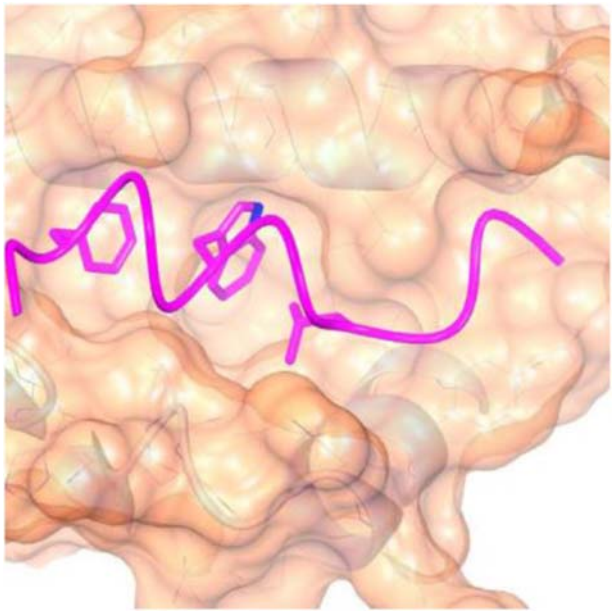

Fig. 2 X-ray structure of MDM2 (ribbon—*blue*, surface—*coral*) bound to a residues 15–29 of p53 (magenta) showing the key hydrophobic side-chains (pdb 1YCR).

[b]Aib—2-aminoisobutyric acid, Pmp—phosphonomethylphenylalanine, 6-Cl-Trp—6-chlorotryptophan, Ac3c—1-aminocyclopropyl-1-carboxylic acid.

were favored. Introduction of a non-amino acid substituent at position 4 reduced the peptidic nature of the compounds and improved activity, for example, **15** (K_d = 12 nM) (Fig. 3). Introduction of a substituent onto the proline ring resulted in improved potency, for example, **16** (K_d = 5 nM). Similar library optimization, guided by the BIR3 X-ray structure, resulted in potent peptide inhibitors, for example, **17**.[68] These studies helped establish the pharmacophore for inhibitors of the Smac-BIR3 domain interaction (Fig. 4).

5.06.2.2.4 Stabilized peptides

Peptides are naturally subject to metabolism by peptidases and so have limited utility as drugs. Modifications to the peptide backbone, for example, β-peptides;[69] the stereochemistry and sequence, for example, retroinverso peptides; or the introduction of intramolecular cross-links between amino acids known as "staples," can be used to stabilize peptides to metabolism while retaining the key interactions required for tight binding.

β-Peptides incorporate an additional backbone carbon atom, and so are resistant to proteolysis and metabolism. For example, a β_3-decapeptide, which formed a stable 14-residue helix in aqueous solution, was used as the scaffold for the p53 residues Phe19, Trp23, and Leu26 arrayed on sequential turns of the helix. Two β-peptides inhibited MDM2–p53 binding (β53-1 and β53-5) in a fluorescence polarization (FP) assay, albeit with modest IC_{50}s of 94.5 and 80.8 μM.[70,71]

Incorporation of D-amino acids can stabilize peptides to proteolysis. Mirror image phage display identified D-peptides ^{D}PMI-β (TAWYANFEKLLR) and ^{D}PMI-γ (DWWPLAFEALLR) as nanomolar inhibitors of the MDM2–p53 interaction.[72,73] Retroinverso peptides are synthesized from D-amino acids with the reverse sequence of amino acids to the original, and form helices with a left-handed turn. A 14-mer reteroinverso peptide, (D)-H_2N-Ser-Gln-Glu-Thr-Phe-Ser-Asp-Leu-Trp-Lys-Leu-Pro-Gln-Asn-Ac, inhibited MDM2–p53 binding with an IC_{50} of 14 μM compared with the natural 15-mer peptide (IC_{50} = 4.2 μM).[74]

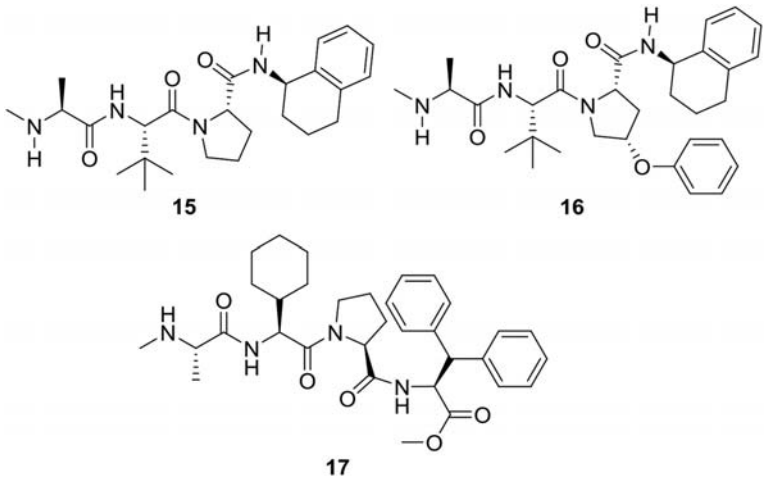

Fig. 3 Smac-mimetic IAP peptide inhibitors (**15–17**).

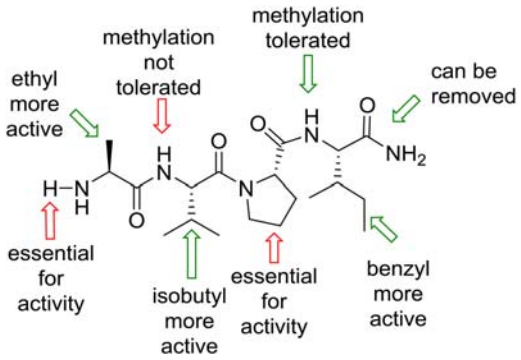

Fig. 4 Pharmacophore for Smac-mimetic IAP inhibitors.

Peptide macrocycles have many advantages as scaffolds for the development of PPI inhibitors. Macrocyclic peptides can adopt a wide range of conformations, are stabilized by intramolecular hydrogen bonding, and present a large interaction surface for comparatively low molecular mass. A variety of methods and linkers have been used to introduce conformational rigidity.

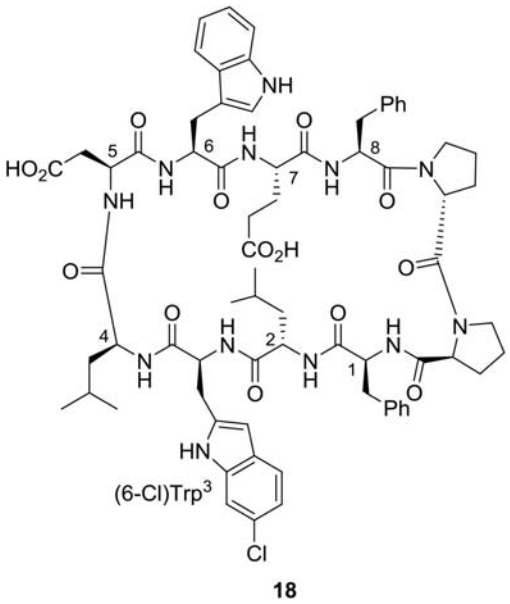
The β-hairpin motif has been used as a scaffold using a D-Pro-L-Pro dipeptide template. Computer modeling was used to design the peptide so that the critical p53 residues are aligned correctly for binding to MDM2. A library of β-hairpin compounds, with variations in the MDM2 binding residues and polar residues to improve water solubility, were evaluated in BIAcore competition assay. The Asp2, 6-Cl-Trp3 analog **18** showed reasonable potency ($IC_{50} = 0.14$ μM) (Fig. 5). The X-ray structure of **16** in complex with MDM2 (PDB code 2AXI) confirmed the β-hairpin conformation and the peptide's amphipathic nature in the bound state.[75,76]

Developed from a disulfide-bridged 11-mer macrocyclic peptide, the bicyclic peptide **19** incorporates a head-to-tail linker and a lactam cross-link. Peptide **19** inhibits the binding of a phosphotyrosine probe to the Grb2-SH2 domain ($IC_{50} = 0.35$ μM) (Fig. 6).[77] The introduction of the cross-link improved potency, selectivity, and plasma stability.

Libraries of cyclic peptides of up to 10^8-members are produced in cells via split intein circular ligation of peptides and proteins (SICLOPPS).[78] The SICLOPPS plasmid codes for a split intein that folds to form an active intein, which undergoes a series of rearrangements to generate a cyclic peptide.[79] Coupling of the SICLOPPS library method to a HIF-1 bacterial reverse two-hybrid system enabled the selection of clones expressing cyclic peptide inhibitors of HIF-1α heterodimerization.[80] One peptide, cyclo-CLLFVY, was shown to bind to the PAS-B domain of HIF-1α and disrupt heterodimerization of HIF-1 with an IC_{50} of 1.3 μM, but HIF2 dimerization was not affected.

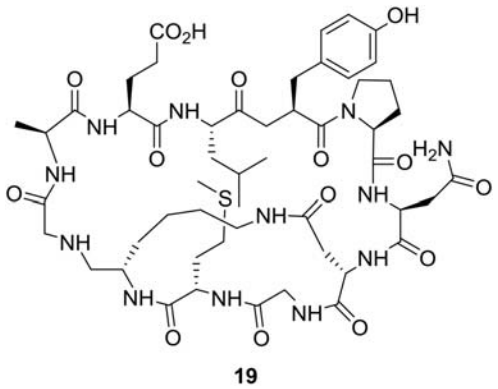
The miniature peptide, avian pancreatic polypeptide, is well folded and contains an 18-residue α-helix suitable for modification using protein grafting. The α-helix residues were varied using phage display and the libraries screened against MDM2. Miniature proteins bound to MDM2 with modest potency ($IC_{50} = 1.6$-8.8 μM). Circular dichroism (CD) spectroscopy confirmed a high degree of α-helical structure in the optimized peptides.[81]

Hydrocarbon-stapled peptides offer greater metabolic stability and defined helicity compared with linear peptides.[82] Typically, peptides are stapled by olefin metathesis between two modified alanine residues bearing olefin side chains at the α-carbon, at the i and either $i+4$ or $i+7$ positions.



18

Fig. 5 β-Hairpin inhibitor of MDM2–p53.



19

Fig. 6 Bridged 11-mer macrocyclic peptide inhibitor of p-Tyr binding to Grb2-SH2 domain.

The stapled peptide SAH-p53-8, Ac-QSQQTF*NLWRLL*QN-NH2 (* indicates the hydrocarbon staple), is a potent inhibitor of MDM2–p53 ($K_d = 55$ nM) and MDMX–p53 ($K_d = 2.3$ nM) and shows excellent helicity and cell permeability.[83,84] The peptide is cytotoxic in cells overexpressing either MDM2 or MDMX in a p53 dependent manner. Similarly, the stapled peptide ATSP-7041 (**20**) (Fig. 7) is a potent dual inhibitor of both MDM2–p53 ($K_i = 0.9$ nM) and MDMX–p53 ($K_i = 6.8$ nM), and was optimized for biophysical properties, for example, solubility and cellular potency.[85] X-ray crystallography shows that the hydrocarbon staple makes significant interactions with the surface of MDMX and contributes to the binding affinity. ATSP-7041 **20** showed activity in vivo in MDM2 and MDMX overexpressing human tumor xenografts.

The B-cell lymphoma-9 (BCL9)–β-catenin interaction is inhibited by peptides incorporating an optimized double triazole (i, $i+4$) staple (**21**) ($K_i = 0.19$ μM) (Fig. 8).[86] The double staple provided the peptide with good stability to proteolysis.

A panel of stabilized alpha-helix of BCL-2 domains (SAHBs), using an i, $i+4$ hydrocarbon staple, was used to identify the BH3 domain of MCL-1 as an inhibitor of the antiapoptotic MCL-1 protein.[87] The MCL-1 BH3 domain peptide $SAHB_A$, KALETLR*VGD*VQRNHETAF, bound avidly to MCL-1 ($K_d = 43$ nM). The peptide was subsequently used in a screen for small-molecule competitive inhibitors of MCL-1.[88]

5.06.2.2.5 Peptide mimetics

An alternative approach to stabilizing peptide PPI inhibitors focuses on the replacement of the peptide bond with more resilient linkers, while maintaining the spatial arrangement of the side chains responsible for the binding affinity. A number of approaches have been investigated and validated against cancer targets, and the p53 α-helix binding to MDM2 has been well studied.[89]

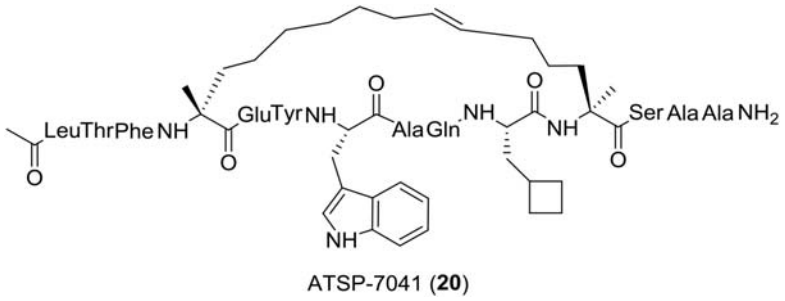


Fig. 7 Stapled peptide dual inhibitor of MDM2–p53 and MDMX–p53.

Fig. 8 Triazole stapled peptide inhibitor of BCL9-β-catenin.

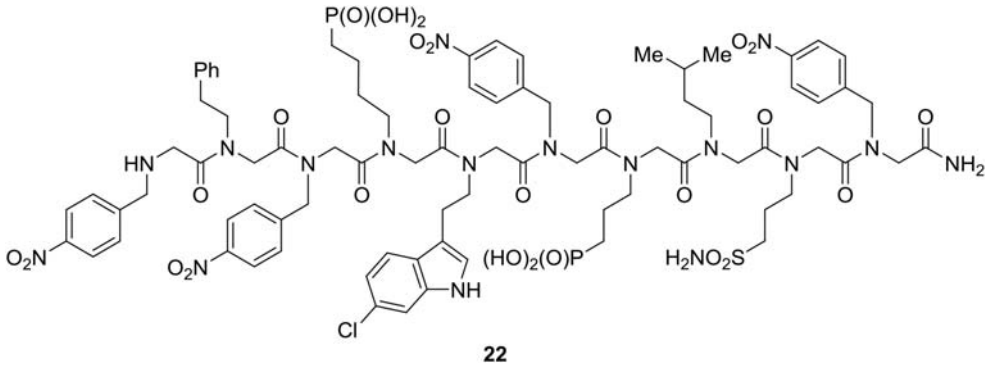

Fig. 9 Oligomeric N-substituted glycine inhibitor of MDM2–p53.

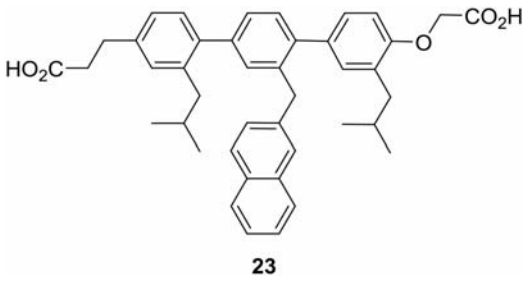

Fig. 10 Terphenyl inhibitor of MDM2–p53.

Peptoids, or oligomeric N-substituted glycines, are resistant to proteolysis, and allow a wide variety of possible side chain substituents. A helical conformation can be introduced using chiral side chains. Peptoids, mimicking the key p53 side chains, for example, (**22**) showed reasonable inhibition of the MDM2–p53 interaction (IC_{50} of 6.6 μM) (Fig. 9).[90]

Terphenyls mimic α-helical structures due to the staggered arrangement of their aromatic rings. The binding of compound **23** to MDM2 was observed by NMR, the 2-naphthylmethylene binding in the Trp23 binding ($K_i = 0.182$ μM) (Fig. 10).[91] The overall hydrophobicity of the terphenyl scaffold limits its utility as a result of which more polar alternatives have been found. Terephthalamide derivatives also act as α-helix mimics, for example, compound **24** inhibits the BH3 domain of Bak binding to Bcl-xL ($K_i = 0.78$ μM) (Fig. 11).[92]

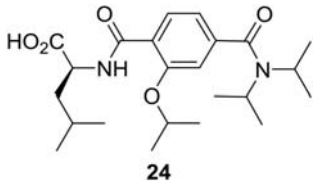

Fig. 11 Terephthalamide inhibitor of Bcl-xL-Bak.

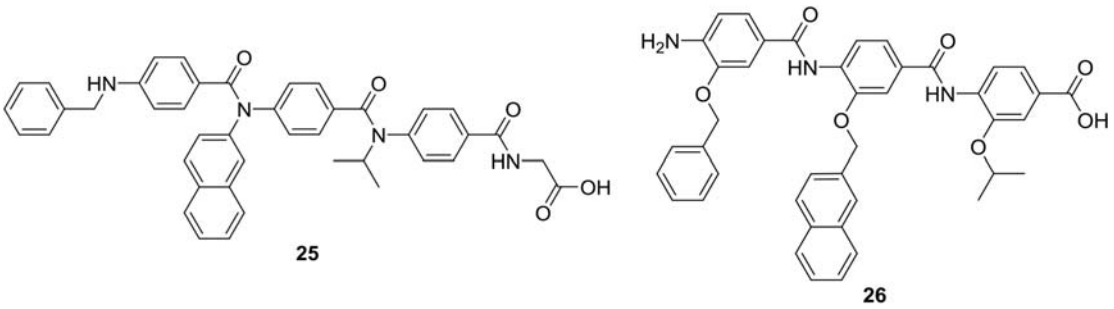

Fig. 12 Oligoamide inhibitors of MDM2–p53.

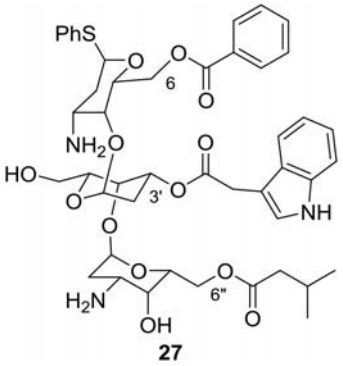

Fig. 13 α-1,4 linked oligogalactose inhibitor of MDM2–p53.

Oligoamides allow a similar orientation of side chains to the terphenyls, with the advantage of improved physicochemical properties. Two series of oligoamides, **25** and **26**, differing in the attachment point of the α-helix mimicking groups, demonstrated modest inhibition of the MDM2–p53 interaction ($IC_{50} = 2.8$ and 1.0 μM, respectively) (Fig. 12).[93,94]

Oligosacharides are alternative scaffolds for α-helix mimics. An α-1,4 linked oligogalactose system was predicted to give the necessary rod-like structure.[95] Functionalization of alternate C-6 and C-3 hydroxyl groups allowed the appendage of p53-like groups. The resulting compound **27** showed weak inhibitory activity in an MDM2 enzyme linked immunosorbent assay (ELISA) (Fig. 13).

5.06.2.3 High-Throughput Screening

High-throughput screening for PPI inhibitors is now commonplace. Screens typically rely on either FP assays that measure the displacement of a fluorescently tagged peptide from the target protein, or proximity-based assays relying on FRET, such as homogeneous time-resolved fluorescence methods. The primary screen is usually accompanied by an orthogonal, biophysical assay, such as SPR or NMR spectroscopy.

Early failures in high throughput screening (HTS) for PPI targets have prompted the rational design of PPI focused libraries.[96] PPI inhibitors may differ significantly from enzyme inhibitors, requiring a more 3D and modular shape than enzyme inhibitors, which may be more linear. PPI inhibitors may also require a higher molecular weight (MW). Statistical analysis of the cocrystal structures of reported PPI inhibitors in databases, for example, 2P2Ichem,[97] proposed a "Rule-of-Four" for generic PPI inhibitors, that is, MW > 400, number of rings > 4, and number of hydrogen bond acceptors > 4.[98] These parameters were used to build a privileged PPI library from commercial sources, and identify privileged scaffolds.[97] VS based on the pharmacophores of known MDM2

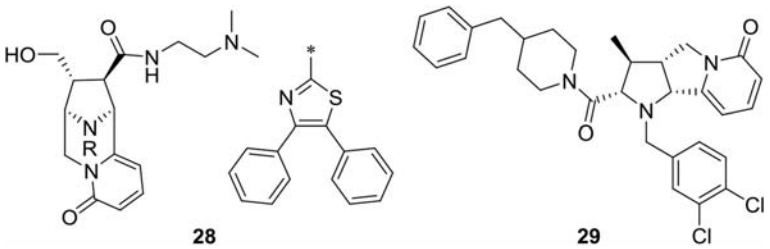

Fig. 14 Bicyclic and tricyclic inhibitors of Bcl2 interactions from DOS.

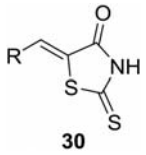

Fig. 15 The PAINS ene-rhodanine motif.

inhibitors has been used to design focused libraries.[99] The 3D characteristics required for PPI inhibitors have been calculated, and critical molecular descriptors defined, including globularity and hydrophobicity.[100]

Diversity oriented synthesis (DOS) generates structurally diverse libraries for screening from a common intermediate building block. This approach has been used to synthesize pyridone libraries as potential inhibitors of the interaction of Bax with Bcl-2 and Bcl-xL.[101] The bridged bicyclic pyridone **28** inhibited Bcl-2 and Bcl-xL ($K_i = 2.0$ and 5.7 μM, respectively), whereas the fused tricyclic pyridone **29** was selective for Bcl-2 ($K_i = 1.2$ and >100 μM, respectively) (Fig. 14).

The challenge of eliminating promiscuous, nonspecific hits, or pan assay interference compounds (PAINS) is particularly relevant for PPI assays.[102–104] A number of chemotypes, such as ene-rhodanines, for example, (**30**), have been identified for compounds, which interfere with HTS assays (Fig. 15). They can act by aggregating proteins through nonspecific interactions, or by covalent modification of proteins. Substructure filters are available for pre- or postassay assessment; however, PAINS substructures still occur regularly in hit compounds from PPI screens. For this reason, follow-up with an orthogonal assay, usually based on a biophysical technique, is necessary to have full confidence in hits from HTS assays for PPI targets.

5.06.2.4 Virtual Screening

VS may be used to identify inhibitors of PPIs in cases where there is good structural information on the target protein's binding sites or hot-spots. Computational methods for docking with PPI targets have been reviewed recently.[105] The open and hydrophobic nature of many PPIs and their limited number of hydrogen bonding opportunities presents a challenge for docking programs. Scoring functions with a component of shape complementarity are more likely to return reasonable hit structures. The flexibility of PPI binding sites also creates additional complexity, so MD simulations have been run in combination with docking.[22] For example, new inhibitory chemotypes for MDM2, for example, **31** (MDM2 $K_i = 9.9$ μM), were identified by docking using multiple structures (Fig. 16).[106] A homology model of Bcl-2 based on the X-ray and NMR structure of Bcl-xL has been used for docking-based VS, and compounds with modest potency are identified.[107,108]

Structure-based methods can establish a ligand pharmacophore, which can be used to search ligand databases. A 3D-pharmacophore of an Annexin A2 derived peptide within the binding site of the S100A10 adapter protein was used to screen a ligand database and identify hits with modest potency, for example, triazole **32** ($IC_{50} = 24$ μM) (Fig. 16).[109] A pharmacophore model of a peptide fragment of PKCε bound to receptor for activated C-kinase 2 was used to screen a compound database and identify quinoline **33** ($IC_{50} = 5.9$ μM) (Fig. 16).[110] The GALAHAD pharmacophore modeling program identified c-Myc-Max heterodimerization inhibitors with modest potency, for example, **34** (Fig. 16).[111] Combined pharmacophore and structure-based searching methods were used to identify possible MDM2 inhibitors, for example, **35** (MDM2 $K_i = 0.12$ μM) from the NCI database of publicly accessible compounds (Fig. 16).[112]

5.06.2.5 Fragment Screening

Fragment-based screening methods generate hits from small, "fragment" compounds, typically with MW <300. Compounds typically have low affinity and so the use of biophysical methods such as NMR or X-ray crystallography is required to detect the hits.[113] These methods have been applied to a number of PPI targets with success. Fig. 17 summarizes the structures of example ligands.

"SAR by NMR" is a two-step method. Firstly, low MW fragments are screened by observing chemical shift changes in the ^{15}N- or ^{1}H-HSQC NMR spectrum of the protein on binding of the ligand. Secondly, ligands in different but close proximity binding sites are

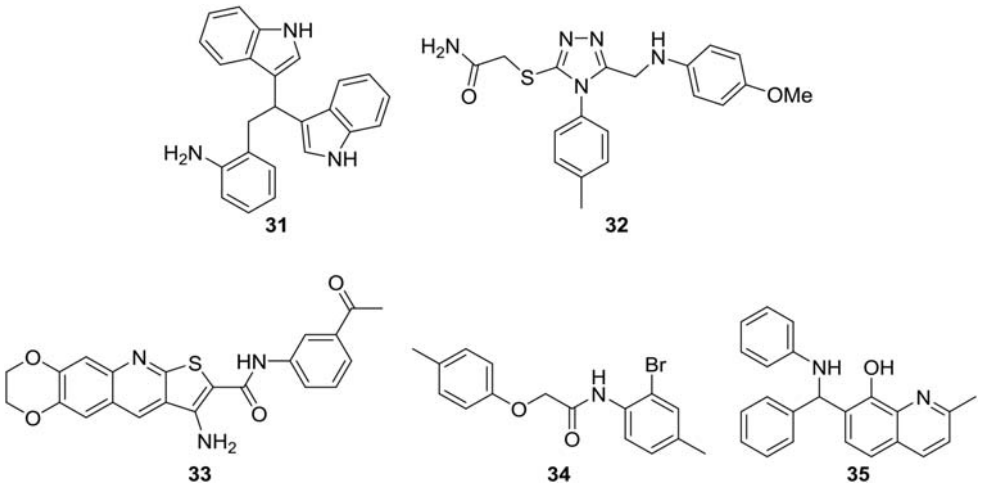

Fig. 16 Protein–protein interaction inhibitors identified using virtual and pharmacophore screening.

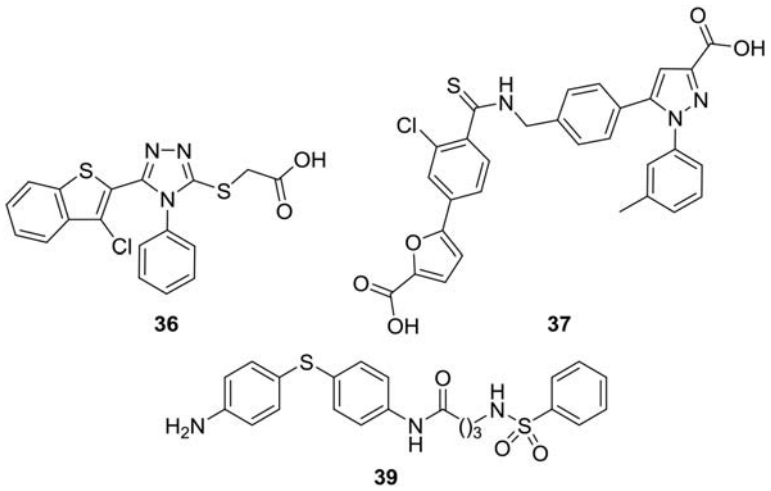

Fig. 17 PPI inhibitors identified using fragment screening.

identified. The location and binding mode of both fragments must be determined by NMR or X-ray crystallography before they can be linked using a suitable group. The goal of linking the fragments is to provide a high-affinity ligand that accesses both binding sites.[114] The structure activity relationships (SAR) by NMR method has been highly successful in identifying high-affinity ligands for Bcl-2 and Bcl-xL proteins as described in Section "**Inhibitors of Bcl-2 Family PPIs**."

Inhibitors of the DNA binding protein–replication protein A subunit (RPA70) PPI were identified from a 15,000 member fragment library using an "SAR-by-NMR" screen.[115,116] Two sets of fragment hits bound in adjacent sites and with good ligand efficiencies (LE >0.3) were selected. For one set, the fragments were "grown" by the purchase of more complex analogs giving compounds, for example, **36**, with improved potency but poorer LE (NMR $K_d = 135$ μM). For the second set, the linking of fragments was guided by X-ray crystallography giving pyrazole **37** ($K_d = 0.19$ μM).

An NMR fragment screen for inhibitors of the proapoptotic Bcl2-family protein Bid BH3 domain identified fragments binding to two adjacent subpockets. Modeling studies and library synthesis allowed the linking of fragments giving rise to sulfonamide **39**.[117] Binding of **39** to the Bid BH3 domain was confirmed by NMR and the compound decreased Smac release in a mitochondrial assay.

5.06.3 Examples of PPI Inhibitors

5.06.3.1 Inhibitors of Bcl-2 Family PPIs

Bcl-2 and related family of proteins form key nodes in the mechanism to regulate apoptosis.[118–120] The antiapoptotic proteins Bcl-2 and Bcl-xL are regulated by proapoptosis proteins (**Fig. 18**). Stimulation of the BH3-only initiator proteins (eg, Bim, Bad, and tBid)

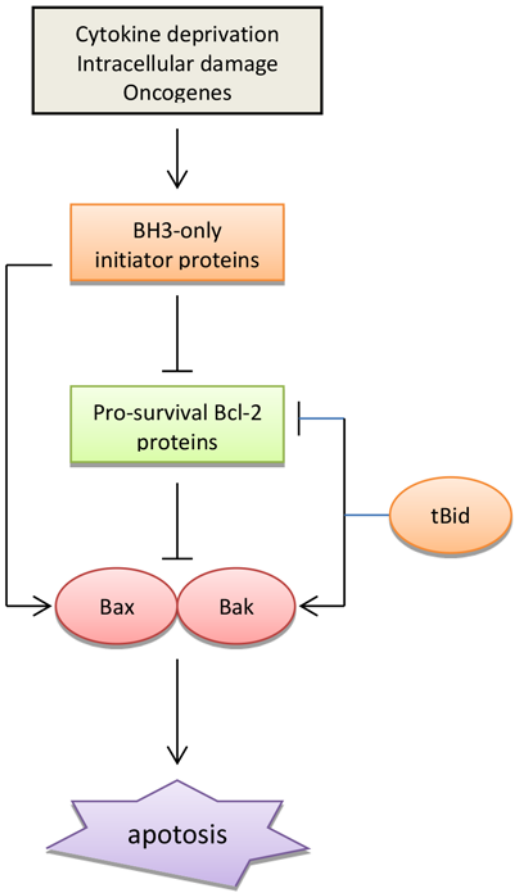

Fig. 18 Bcl-family pathways to apoptosis.

inhibits the prosurvival proteins (eg, Bcl-2 and Bcl-xL), thus allowing activation of proapoptotic effectors Bak and Bax. The proteins share Bcl homology (BH) domains, of which there are 4 (BH1-4). The *Bcl-2* gene is overexpressed in a variety of human tumors, and this has been linked to resistance to chemotherapy and radiotherapy. Inhibition of the Bcl-2-Bax PPI is an attractive target for cancer therapy.

The natural product Gossypol (**40a**) (Table 4) and the derivative Apogossypol (**40b**) are competitive inhibitors of the binding of a labeled BH3 peptide to Bcl-xL ($K_i = 0.3$ and 2.3 μM, respectively), binding to Bcl-xL was confirmed by NMR, and in cells by confocal microscopy.[121,122] Gossypol has a complex pharmacology and exherts multiple cellular effects, at least in part by acting as a BH3 mimetic.[123] In addition, polyphenolic compounds have been shown to have undesirable redox chemistry and protein reactivity.[103] Gossypol and derivatives, for example, AT-101, have been evaluated in clinical trials, but with limited efficacy.[124–126]

The structure of Gossypol docked with Bcl-2 was used as the starting point for the design of TW-37 (**41**).[127] The structure retains the extensive hydrogen bonding of one-half of Gossypol **40a** combined with a larger hydrophobic benzyl group and a hydrophobic amide to access more extensive contacts with the BH3 binding pocket. TW-37 is an inhibitor of Bcl-2, Bcl-xL, and Mcl-1.

Obatoclax (**42**) is a pan-inhibitor of Bcl-2 family proteins, including Bcl-2, Bcl-xL, MCL-1, Bcl-w, A1, and Bcl-b.[128] The inhibitor binds to the BH3 binding groove on the target proteins thus initiating apoptosis. A phase I trial of obatoclax in advanced chronic lymphocytic leukemia and solid tumors demonstrated activation of Bax and Bak, consistent with target engagement, and gave modest single-agent activity.[129,130]

SAR by NMR identified fragments bound to Bcl-xL with millimolar potency. Linking of fragments occupying subpockets in close proximity and further SAR studies enabled the identification of ABT-737 (**43**) (Fig. 19).[131,132] ABT-737 binds avidly to Bcl-xL, Bcl-2, and Bcl-w proteins that have high homology. In cells, ABT-737 antagonized Bcl-2, but did not cause apoptosis, in a similar manner to an apoptosis sensitizing Bad-BH3 peptide. The disruption of Bcl-2 family interactions in cells was confirmed by mammalian two-hybrid experiments. ABT-737 induced tumor regression in Bcl-2 overexpressing small cell lung cancer (SCLC) xenografts (100 mg kg^{-1} day^{-1} ip).[133]

Further structure-guided SAR studies resulted in the identification of Navitoclax (ABT-263, **44**).[134] Modifications to ABT-737 were designed to optimize physicochemical properties, and focused on modulating the acidity of the sulfonamide group to enhance oral bioavailability, and reduction of plasma protein binding by changing the basic amino group to a morpholine. Changes to the

backbone included switching the undesirable nitro group to trifluoromethylsulfone and replacement of one phenyl ring of the 4-chlorobiphenyl moiety with a cyclohexenyl group. Despite the high MW of the compound (974 Da) ABT-263 has acceptable oral bioavailability and PK properties.[135] ABT-263 shows mechanism-based cytotoxicity in Bcl-2 or Bcl-xL dependent cellular models. In vivo efficacy with complete regressions was observed in SCLC and acute lymphoblastic leukemia xenografts (100 mg kg^{-1} qd p.o.). A mechanism related toxicity, thrombocytopenia, was also seen, but this was reversible. A phase I clinical trial with Navitoclax in SCLC and other solid tumors confirmed the safety of the drug and preliminary efficacy was encouraging.[136] A phase II single-agent trial in SCLC showed limited efficacy so further solid tumor studies are ongoing in combination with other therapies.[137] Bcl-2 family proteins play a central role in the development of many lymphomas. A phase I study in lymphomas showed promising results and phase II studies were initiated.[138]

Structure-based modification of the ABT-737 scaffold, by grafting a celecoxib inspired pyrrole in place of the chlorobiphenyl moiety sought to exploit additional interactions in the BH3 binding site.[139] Compound **45** retained potent Bcl-2 and Bcl-xL activity, and gained Mcl-1 activity, and showed potent cytotoxicity in SCLC cell lines. Alternatively, the triphenolic group of TW-37 was merged with ABT-737 giving (**46**) that inhibits Bcl-2 and Mcl-1.[140]

An alternative scaffold for Bcl-2 and Mcl-1 inhibition was optimized with the aid of molecular modeling studies.[141] Compound **47** is a mixed Bcl-2, Mcl-1 inhibitor with potent cytotoxicity against tumor cell lines.

Preclinical data with navatoclax (**44**) suggested that a selective Bcl-2 inhibitor would induce less thrombocytopenia but retain antitumor activity, compared with mixed Bcl-2, Bcl-xL inhibitors.[142] Structure-based design of venetoclax (ABT-199, **48**) exploited differences in the P4 subpocket on Bcl-2 by moving the hydrophobic group from the thioether linker onto the central phenyl ring giving a Bcl-2 selective inhibitor. Selectivity was confirmed in cells using a mammalian two-hybrid assay. Venetoclax **48** was cytotoxic in Bcl-2 amplified non-Hodgkins lymphoma (NHL) cell lines and induced regressions in hematological tumor xenografts (100 mg kg^{-1} qd^{-1} p.o.). Venetoclax has entered clinical trials as a single agent in NHL and other tumor types with promising results.[143,144]

The Bcl-family PPI inhibitors have been developed by the use of fragment discovery and rational design. Navitoclax can be considered as the first rationally designed PPI inhibitor to enter clinical trials for cancer.

5.06.3.2 Inhibitors of MDM2–p53 and MDMX–p53

MDM2 and MDMX act as negative regulators of p53. Amplification of the *MDM2* gene occurs in around 10% of tumors. Overexpression of MDMX in the absence of gene amplification appears to be more common, observed in breast (19%), uterus (15%), testes (27%), stomach/small intestine (42%), colorectal (19%), larynx (23%), lung (18%), and melanoma (65%).[145–147] Gene amplification of *MDM2* or *MDMX* and p53 mutations appear to be mutually exclusive, suggesting that a single mechanism for disabling the p53 tumor suppressor function is necessary and sufficient for carcinogenesis. MDMX overexpression has been linked with resistance in cell lines to MDM2–p53 inhibition.

Inhibition of the MDM2–p53 PPI will release p53 from the repressive control of MDM2, and activate p53-mediated cell death. Tumor selectivity would be achieved by p53 sensing preexisting DNA-damage or oncogenic activation signals, previously blocked by MDM2. In normal cells, p53 may activate nonapoptotic pathways.

The p53 binding sites of MDM2 and MDMX have been defined by peptide mapping and X-ray crystallography (Section "MDM2–p53 Peptides"). Small-molecule inhibitors mimic the p53 α-helix binding to MDM2, and are required to fill the Phe19, Trp23, and Leu26 subpockets on MDM2 for potency. Inhibitors must also achieve acceptable pharmaceutical properties, usually by the addition of a hydrophilic group.

5.06.3.2.1 MDM2–p53 antagonists

1,4-Benzodiazepine-2,5-dione hits were identified as MDM2 binders from a diverse combinatorial library for binding to MDM2 using the ThermoFluor thermal denaturation affinity assay, and confirmed using an FP assay.[148,149] The X-ray crystal structure of **49a** in complex with MDM2 shows that the inhibitor occupies the hydrophobic p53 binding groove (Fig. 20). Further optimization yielded compounds with improved water solubility, which gave the best combination of cell-free inhibition of MDM2–p53 binding (eg, **49b**, IC_{50} 0.70 μM) (Table 5) in the FP assay and cellular activity as measured by the induction of the p53 inducible gene PIG3, and were selected for further study.[150,151]

The *cis*-imidazoline analogs, named "Nutlins" (eg, **50**, $IC_{50} = 0.09$ μM), were identified by HTS.[152] The compounds inhibit the MDM2–p53 interaction with IC_{50}s in the 100–300 nM range. The X-ray and NMR structures of **50** in complex with MDM2 show the small *cis*-imidazoline scaffold mimics an α-helical peptide by the orientation of its substituents (Fig. 20).[153,154] Nutlin-3a (**50**) has been used as a tool compound in many studies investigating the role of MDM2 and p53 in cells, because of its good potency and selectivity. Structure-guided optimization of potency, selectivity, and pharmacological properties gave improved inhibitors, for example, RG-7112 (**51**). The imidazoline heterocycle and the 4-methoxy group were found to be sites of metabolism and so were modified by two additional *cis*-methyl groups on the heterocycle, and replacement with a 4-*tert*-butyl group, respectively. Additional potency and improved PK properties were gained by modifying the hydrophilic side chain. The X-ray cocrystal structure of MDM2 with **51** shows that it binds in a similar orientation to Nutlin-3a, and the methylsulfone side chain does not make additional interactions with the protein. RG7112 (**51**) has completed phase I clinical trials and demonstrated target engagement and some efficacy with oral dosing.[155]

[a]Activity in cell-free assays.

Dihydroimidazothiazoles, for example, **52a**, were designed by modification to the Nutlin scaffold and have potent MDM2 inhibitory activity. The bicyclic scaffold fixes the 3-isopropyl group in the optimum position for access to the MDM2 Phe19 pocket. Introduction of the 4-position amide gave additional potency, and the 6-methyl group prevents oxidation of the imidazoline ring.[156,157] The X-ray structure of **52a** bound to MDM2 shows the amide side chain occupying a surface groove formed by the movement of a flexible loop. Introduction of a 3-fluoro-4-chlorophenyl group optimized interactions in the Trp23 binding pocket, and further elaboration of the amide group with a 4,7-diazaspiro[2,5]octane group gave DS-5272 (**52b**).[158] The in vitro properties of DS-5272, for example, cellular activity, solubility, and microsomal stability are reasonable. The compound showed in vivo acceptable PK properties and efficacy in a MDM2-amplified mouse xenograft model (50 mg kg^{-1} qdx4^{-1} p.o.).

The isoindolinone series resulted from the development of weak screening hits, optimized using in silico library screening and synthesis.[159,160] NMR studies with a selection of isoindolinones and MDM2 suggested plausible binding modes that were used for the design of improved inhibitors.[161,162] For example, isoindolinone **53** showed improved cellular activity over earlier compounds, inducing transcription of p53 dependent genes at comparable levels to Nutlin-3a (**50**), and was growth inhibitory in p53 wild-type HCT-116 cells ($GI_{50} = 3.7$ μM) and threefold less growth inhibitory in the paired p53 −/− HCT-116 line.[163]

A HTS of 1.4 million compound library identified the chromenotriazolopyrimidine **54a** as a MDM2–p53 inhibitor.[164] The MDM2 cocrystal structure with **54a** shows the 7-(4-bromophenyl) group occupying the Leu26 subpocket, and the 6-(4-bromophenyl) group filling the Trp23 subpocket. The chromenotriazolopyrimidine heterocycle spans the surface of the protein from phenyl "D"-ring in the Phe19 binding site to the triazole ring close to Val93 of MDM2. Potency and PK properties were optimized by introduction of a polar or acidic group at N11.[165] The acid **54b** was moderately orally bioavailable ($F = 54\%$), with improved solubility.

Computational substructure searching for compounds able to mimic the tryptophan of p53 identified the spirooxindole series, for example, MI-63 (**55**).[166,167] Optimization of the series progressed by elaboration of the amide group and addition of a 5-fluoro group, and epimerization to the most stable diastereoisomer under oxidative conditions gave compounds with improved potency and in vivo activity.[168,169] In particular, SAR405838 (**56**) showed potent MDM2 binding affinity and growth inhibitory activity.[170] The X-ray cocrystal structure of **55** bound to MDM2 shows a hydrogen bond between His96 NH and the amide side chain carbonyl group, and movement of the MDM2 N-terminus. In vivo evaluation of spirooxindole **56**, following in vitro PK profiling with mouse, rat, and human liver microsomes, showed **56** induced complete tumor regression in SJSA-1 mouse xenografts with a single oral dose (100 mg kg^{-1}). SAR405838 (**56**) was selected as the clinical candidate from the spirooxindole series and entered phase I clinical trials as a single agent and in combination with the MEK1/2 inhibitor pimasertib.

Replacement of the spirooxindole spirocyclic amide scaffold of **55** with a simpler and more flexible cyanopyrrolidine core gave rise to RG7388 (**57**).[171] The 2-fluoro substituent was important for MDM2 inhibitory potency. The amide side chain substituent modulated the PK profile and the cellular potency of the compounds, and a 4-benzenecarboxylic moiety gave improved PK and cellular potency. Further optimization focused on the introduction of groups with distinct electronic properties, with the ortho-methoxy group, **57** (RG7388), having the ideal combination of MDM2 binding affinity, cellular potency, and selectivity. RG7388 gave complete tumor regression in vivo in an SJSA-1 xenograft model (25 mg kg^{-1} p.o.), and a favorable PK profile. RG7388 (**57**) was selected as the second generation MDM2–p53 clinical trial candidate owing to its improved potency, cellular selectivity, and PK properties over RG7112 (**51**).

A combination of de-novo and structure-based design resulted in the spirooxindole RO8994 (**58**).[172] The same amide substituent as found in **57** was used giving excellent MDM2 inhibition, cellular activity, and PK profile. Compound **58** showed impressive in vivo activity in an SJSA-1 xenograft model, inducing tumor regression (6.25 mg kg^{-1} qd^{-1} p.o.).

Bioisosteric replacement of the oxindole phenyl ring with either five- or six-membered heterocycles resulted in RO2468 (**58**) and RO5353 (**59**), which both showed potent MDM2 inhibitory activity (IC_{50} = 6 and 7 nM, respectively) and excellent cellular activity (GI_{50} = 15 and 7 nM, respectively).[173] Both compounds produced tumor regression in SJSA-1 xenografts (10 mg kg^{-1} qd^{-1} p.o.) with excellent mouse PK properties.

Rational design based on the X-ray structure of the AP peptide (**14**) bound to MDM2 gave rise to the "central valine" concept.[174] An imidazole scaffold makes favorable contacts with Val23 and allows three different substituents into the Phe19, Trp23, and Leu26 subpockets on MDM2. The X-ray crystal structure of MDM2 with (**60**) allowed further structure-based optimization, targeting an interaction with His96, that stacks with the chlorobenzyl group of **60** in the Leu26 pocket.[175] A number of changes to **60** optimized the potency and solubility. Gains in potency were achieved by structure-guided modifications, for example, **61**: addition of an acid isostere to target His96, for example, 2-aminooxadiazole; replacement of the 4-chlorobenzyl with a 3-chloro-2-fluorophenyl substituent; simplification of the indole substituent to a 3-chloro-4-fluorophenyl group; and replacement of the 5-phenyl substituent with a cyclohexyl group. The ortho-methyleneamide group at the 2-position of the imidazole conferred the best combination of inhibitory activity and cellular activity. The cellular activity in this series is low compared with other series displaying similar MDM2–p53 potency, possibly indicating poor cellular uptake.

A FP-based HTS identified substituted piperidines, for example, **62a** as hits.[176] Replacement of the pyridine group with a 2-methoxyethoxyphenyl substituent gave improved potency. Substitution at the 2-position of the piperidine ring, for example, **62b**, improved the PK properties, and favored the bound conformation of the piperidine, giving additional potency.[177]

The piperidone series of inhibitors (eg, **63**) was conceived by analysis of the X-ray cocrystal structures of a number of MDM2 inhibitory chemotypes, highlighting the importance of interacting with His96 and the Leu23 pocket for potency, and efficient filling of the three MDM2 subpockets by the ligand.[178] Structure-guided optimization of the *N*-alkyl group revealed the cyclopropylmethyl group as ideal, for example, **64**.[178] The (3*R*)-carboxyl group at C3 forms a key interaction with His96. Modeling studies suggested the introduction of an additional methyl group at C3 to direct the substituent into the optimal conformation for binding. Similarly, the introduction of a methyl group at C3, to stabilize the conformation of the piperidone ring, gave a modest improvement in potency. Cell potency was optimized for the 3-(2-hydroxypentyl) analogs, for example, **63** (AM8553). AMG8553 had good in vivo PK and pharmacodynamic (PD) properties, and tumor stasis in an SJSA-1 mouse xenograft model was achieved on oral dosing (150 and 100 mg kg^{-1} qd^{-1}).

In parallel to the piperidinone series, a series of related morpholinones (64–69) was identified with acceptable potency and cellular activity.[179] Optimization of this series was guided by the knowledge gained in the piperidone series. The morpholinones showed a 5–10-fold loss of potency compared with the piperidones, but better metabolic stability in hepatocytes derived from human and other mammalian species.[180] The *N*-cyclopropylmethyl compound **64** had the best combination of potency and low clearance in human hepatocytes. **64** induced tumor stasis in SJSA-1 mouse xenografts (100 mg kg^{-1} qd^{-1} p.o.).

Further structure-guided design in the piperidone series targeted the N-substituent to optimize interactions with the "glycine shelf" region, a hydrophobic region on the surface of MDM2 formed by Gly58.[181,182] Sulfone **65** (AMG 232) showed excellent cell-free potency and cell growth inhibitory activity. The X-ray cocrystal structure of a related sulfone showed the sulfone group situated close to the Gly58 CH suggesting a favorable interaction and the Phe19 subpocket occupied by the alkyl group, directed by the α-substituent (**Fig. 20**). Complete tumor regression in SJSA-1 xenografts observed (60 mg kg^{-1} qd^{-1} p.o.), and so AMG 232 was selected for clinical trials.[183]

Alternatives to the carboxylic acid moiety able to retaining the favorable interaction with His96 were sought.[184] Replacement with carboxyl-substituted heterocycles, for example, 2-pyridyl derivative, pyrazole, and thiazoles, for example, **66**, gave equipotent compounds. A hydrogen bond between the His96 NH and heterocycle N was visible in the MDM2 cocrystal structures of the 2-pyridyl and thiazole **65** derivatives. **65** was active in the SJSA-1 xenograft model, inducing tumor stasis (50 mg kg^{-1} qd^{-1} p.o.).

The carboxylic acid group of **65** was modified to an anilide in AM-7209 (**67**), along with modifications to the sulfonamide, replacement of isopropyl chain with cyclopropyl, and addition of a 3-fluoro group to the Trp23 pocket phenyl, giving improved potency and cellular activity over the parent.[185] AM-7209 showed excellent in vivo activity and induced tumor regression in SJSA-1 xenografts (25 mg kg^{-1} qd^{-1} p.o.).

In a parallel approach, the SAR of simplified piperidones was explored by the introduction of heterocyclic and alkyl substituents to the Phe19 subpocket.[186] Compound **68** had the best LE, showed improved metabolic stability, and induced tumor regression in SJSA-1 xenografts (100 mg kg^{-1} qd^{-1} p.o.).

Recently, a series of dihydroisoquinolinones, developed from a VS hit, have been reported.[187,188] X-ray structure-guided optimization gave rise to NVP-CGM097(**69**) with excellent cellular activity and ADME properties. The binding mode of **68** differs from the majority of other potent MDM2 inhibitors, as the Leu26 subpocket is not occupied by a chlorophenyl ring, instead the C7 isopropyl ether and the C6 methyl ether occupy the subpocket. The Trp23 subpocket is filled by the C1 4-chlorophenyl group, and the Phe19 subpocket is occupied and extended by movement of the protein to accommodate the large amine side chain. NVP-CGM097 showed good PK properties in a number of mammalian species and induced tumor regression in SJSA-1 xenografts (30 mg kg^{-1} qd^{-1} p.o.). NVP-CGM097 has been selected for clinical trials.

The design of MDM2–p53 inhibitors has received considerable attention due to the strong target rationale, access to structural biology, and the structural diversity of the hit scaffolds. A number of compounds have entered clinical trials and demonstrated preliminary efficacy.

5.06.3.2.2 Dual MDM2–p53, MDMX–p53 antagonists

Overexpression or gene amplification of MDMX, the paralogue of MDM2, has been observed in a number of tumor types. MDMX acts as a central regulator of p53 activity and overexpression has been linked with resistance in cancer cell lines to MDM2–p53 inhibition. The potent MDM2–p53 inhibitors described above show minimal inhibition of MDMX–p53, and so elevated MDMX levels may produce resistance. Analysis of the peptide bound X-ray structures of MDM2 and MDMX reveals that, although the same three residues of p53 are bound, significant differences in the binding interaction result from differences in the amino acid sequences between MDM2 and MDMX.[189] In particular, differences in the Leu23 subpocket may account for the substantially different SARs. A number of small-molecule dual inhibitors of MDM2 and MDMX interactions with p53 have been reported and are summarized in Table 6.

SJ-172550 (**70**) was identified by HTS as a selective MDMX inhibitor, which showed differential cytotoxicity in a screen using *MDMX* amplified cells.[190] In combination with Nutlin-3a (**50**), SJ-172550 showed additive cytotoxicity in p53 (wt) cells. Mass spectrometry and SPR studies showed evidence of covalent but reversible modification of the MDMX protein by **70**.[191]

The 3-imidazolylindole (**71**) inhibits both MDM2– and MDMX–p53 with modest potency.[192,193] The MDMX cocrystal structure of **71** shows a similar binding mode to that seen for MDM2, the Trp32 subpocket is filled by the chloroindole, the chlorobenzyl group, and the phenyl ring occupy the Leu23 and Phe19 subpockets, respectively. Based on this observation and the SAR of known MDM2 inhibitors, a focused library was synthesized using an Ugi 4-component reaction.[194] Indole amide **72** showed 10-fold selectivity for MDMX inhibition over MDM2.

A series of pyrroles, for example, (**73**) were developed from a screening hit.[195] SAR studies demonstrated that the barbituric acid and triaryl motifs were essential for MDMX activity.

An HTS screen for MDMX–p53 inhibitors identified indolyl hydantoin RO-2443 (**74a**).[196] Analog RO-5963 (**74b**) had improved water solubility. Both compounds are potent inhibitors of MDM2–p53 and MDMX–p53. The MDMX cocrystal structure of **74a** shows an unusual dimeric sandwich-like binding mode. The 3,4-difluorophenyl moiety of one molecule of **74a** occupies the Trp23 pocket, and the Phe19 pocket of the same MDMX binding pocket is overlayed by the indole heterocycle of the other molecule of **74a**. Similarly, the second MDMX binding pocket is occupied by the alternate groups of both **74a** molecules. The more water soluble derivative **74b** activated p53 transcription in MCF7 cells (MDMX overexpressing), and induced apoptosis in SJSA-1 cells and the Nutlin-3a resistant engineered MDMX overexpressing line SJSA-X. In a panel of nine cancer cell lines, enhanced apoptosis was seen with elevated MDMX levels, demonstrating the utility of dual inhibition of MDM2 and MDMX.

The contribution of different regions of MDMX to the binding affinity of Nutlin-3a (**50**) was explored by systematic mutation of the segments to the homologous MDM2 sequence.[197] This knowledge was used in the design of a potent inhibitor dual inhibitor of MDM2 and MDMX based on the Nutlin scaffold (H109, **75**). The gain in MDMX activity was achieved by improving the Trp23 subpocket interaction with the chloroindole substituent, modification of the Leu23 subpocket interaction with the introduction of a carboxylic acid group, and introduction of hydrogen bonding beyond the Phe19 pocket. Compound **75**, inhibited MDMX–p53 binding in cells, and induced the transcription of p53 dependent genes.

Despite significant interest, the design of MDMX–p53 inhibitors has proved to be substantially more challenging than for MDM2–p53. It remains to be seen whether MDMX-selective small-molecule inhibitors can be achieved.

5.06.3.3 Inhibitors of Smac-IAP PPIs

Activation of the intrinsic pathway of apoptosis is controlled by the release of activating proteins such as cytochrome *c* and Smac.[198] Smac binds to IAP family proteins via its four terminal amino acids. XIAP binds to and inhibits caspases 3,7, and 9 via interactions with the N-terminal amino acids of the caspases and the BIR domains of XIAP. The ML-IAP proteins do not bind to caspases, instead they bind to second mitochondria-derived activator of caspases (SMAC), preventing its association with XIAP and so inhibiting apoptosis (Fig. 21).[199] In contrast, c-IAPs negatively regulate the alternative nuclear factor kappa-light-chain-enhancer of activated B cells (NF-kB) pathway by inhibiting NF-kB-inducing kinase, and activating the classical NF-kB pathway by acting on receptor-interacting serine/threonine-protein kinase 1. Amplification or overexpression of XIAP is important in hematological and solid tumors, and is associated with poor response to therapy and poor prognosis. Similarly, amplification or overexpression of c-IAPs has been identified in a large variety of tumor types. Validation of targeting the Smac-IAP interaction as a therapeutic strategy was demonstrated using cell-penetrant Smac peptides.[65] A number of XIAP and c-IAP inhibitors are in clinical trials currently in

solid and hematological malignancies, as single agents and in combination with chemotherapy.[200] Preliminary reports indicate that the compounds are well tolerated and some responses have been reported.

5.06.3.3.1 Monovalent Smac-mimetic IAP antagonists

Building on the established pharmacophore for Smac peptide inhibitors,[67,68] a number of structurally diverse of peptido-mimetic scaffolds have been used to develop potent monovalent Smac mimetics with a range of selectivity between cIAP-1 and -2 and XIAP (Table 7). Replacement of the P4 amino acid with a variety of aromatic substituents showed that 2-pyrimidinyl compound (**76**) was a selective inhibitor of cIAP-1 and -2, but >2000-fold less potent versus XIAP.[201] The selectivity was explained by an adverse lone–pair interaction in the P4 binding pocket between the pyrimidine nitrogens and the hydroxyl of Thr308 in XIAP, whereas the corresponding Arg313 in IAP-1 does not make this interaction. In contrast, the pan IAP inhibitor PS1 (**77**) makes favorable hydrophobic and dipolar interactions in the BIR3 binding cleft. Interestingly, the pan-IAP inhibitor **77** was more cytotoxic than the c-IAP-selective compound **76**, indicating that additional apoptotic stimulation is required for the induction of apoptosis by the c-IAP proteins, but not for XIAP. ML101 (**78**) was identified from tripeptide libraries and shows reasonable selectivity for binding to XIAP-BIR2 domain binding over the BIR3 domain.[202]

A number of different bicyclic isosteric replacements have been used to modify the tetrapeptide scaffold in the design of non-peptide Smac mimetics. Structure-based design established the [7,5]-bicycle as a suitable dipeptide replacement for the second and third positions.[203] Compound **79** showed potent inhibition of BIR3-IAP interactions and was cytotoxic as a single agent and in combination with doxorubicin. A [5,6]-fused bicyclic replacement for residues 3 and 4 was used in LBW242 (**80**).[204,205] The compound showed cytotoxity in a panel of leukemia cell lines as a single agent and in combination with the kinase inhibitor midostaurin. Examination of the small-molecule crystal structures of fused-ring bicycles identified the azabicyclooctane system as a suitable scaffold for inhibitors.[206] Reversal of the P3–P4 amide bond and the introduction of a 1-naphthylcarboxamide at P4 gave (**81**) that induced apoptosis in cell lines and inhibited tumor growth in a breast cancer xenograft (50 mg kg^{-1} qd^{-1} p.o.). AT-406 (**82**) was designed as a Smac mimetic incorporating a [5,8]-fused bicyclic replacement for residues 2 and 3 that makes additional hydrophobic contacts from the amide side chain to Trp323 in the XIAP BIR3 domain.[207] AT-406 is a pan-selective IAP inhibitor, and is cytotoxic in a number of cell lines. AT-406 (**82**) shows good oral PK in a number of mammalian species.

Monovalent Smac mimetics have been reported in the patent literature, for example (Table 7, **83–91**).[200] Compounds **83–85** exemplify the simplest AVPI tetrapeptide mimetics, and illustrate the diversity of modifications possible in the hydrophobic P4 subpocket. Bicyclic replacement of either amino acid residues P2 and P3 (**86** and **87**), or P3 and P4 (**88** and **89**) gave inhibitors with good potency, and the capacity to modify the physicochemical properties of the inhibitor. Compound **86** bears an acrylamide group and is reported as an irreversible inhibitor of XIAP. Inhibitor **90** retains only the N-terminal alanine of the Smac peptide, the remaining residues are replaced by a substituted pyridine giving good potency. Inhibitor **91** was discovered by fragment screening, lacks the *N*-methylalanine warhead present in the other examples, and is a potent inhibitor of XIAP and c-IAP1.

5.06.3.3.2 Bivalent Smac-mimetic IAP antagonists

The bivalent Smac mimetics were discovered following the adventitious dimerization of an alkynyl Smac mimetic (Table 8).[208] The dimer (**92**) displayed similar activity to the monomer in a FP assay, but greater potency in a cell extract assay. The compound mimics the interaction of Smac that exists as a homodimer with XIAP, and binds to two XIAP BIR domains.

Molecular modeling of the monomer of SM-164 (**93**) bound to XIAP was used to identify a linking point for dimerization and the optimal chain length.[209] The dimer showed a significant gain in potency. Analytical gel filtration and protein NMR studies demonstrated that **93** binds to the BIR3 and BIR2 domain of a single XIAP molecule. Compound **93** induces apoptosis in leukemia cell lines, and is 1000 times more potent than the monomeric compound.

The dimeric Smac-mimetic BV6 (**94**) binds strongly to the BIR2 and BIR3 domains of XIAP and c-IAP1 and 2.[210,211] Treatment of cells with BV6 led to a rapid proteasomal degradation of c-IAP1 and 2, and apoptosis. The bivalent inhibitor **95** binds avidly to XIAP and c-IAP1 and 2.[212] **95** induced apoptosis in sensitive cell lines, and sensitized all cell lines tested to TNFα induced apoptosis. Similar cellular effects were observed with the potent bivalent inhibitor AEG40730 (**96**).[213]

Similarly, the bivalent Smac-mimetic Birinapant (TL32711, **97**) is a potent XIAP and cIAP antagonist, and induces IAP down-regulation in cells.[214,215] Birinapant induced apoptosis in cell lines either as a single agent or in combination with tumor necrosis factor (TNF) and TRAIL. In addition, **97** potentiates some chemotherapy drugs in a p53-independent manner. Birinapant has single-

agent antitumor activity in patient derived xenograft models of ovarian cancer, colorectal cancer, and melanoma, and is undergoing clinical trials in solid and hematological malignancies.

5.06.3.4 Inhibitors of Other Cancer Related PPIs

5.06.3.4.1 14-3-3 proteins

The 14-3-3 family of regulatory proteins binds to many signaling proteins, including kinases, phosphatases and receptors, and is involved in mitogenic signaling, apoptosis, and cell cycle control.[216] The protein has a cup-like shape with an inner amphipathic groove, into which the ligand binds in a linear conformation. 14-3-3 proteins form homodimers, and the two inner ligand binding domains bind ligands in an antiparallel orientation. 14-3-3 proteins usually bind phosphoserine containing proteins, but proteins without phosphorylated residues are also reported to bind. The natural products cotylenin (**98**) and fusicoccin (**99**), and the immunosuppressant drug mizoribine (**100**) act to stabilize the 14-3-3 dimer and gave structural insights into the 14-3-3 ligand binding domain (Table 9).[217–219] A number of small-molecule inhibitors of 14-3-3 proteins PPIs with different proteins have been reported (Table 10). Peptide inhibitors, for example, (**101**) were identified using peptide microarrays, and induced apoptosis in cells. VS and docking yielded **102**, an inhibitor of the c-Abl/14-3-3 PPI that showed activity in imatinib resistant chronic myeloid leukaemia (CML) cell lines.[220,221] Inhibitors of 14-3-3/Raf PPI were discovered by library screening, the binding of **103** to 14-3-3 was confirmed by X-ray crystallography, although the diazo group reacted with the protein under the X-ray conditions.[222]

5.06.3.4.2 S100 protein inhibitors

The S100 family of proteins is small acidic calcium-binding proteins that regulate a number of protein partners. Small-molecule inhibitors of S100 family PPIs have been reported (Table 11). VS identified inhibitors of S100B-p53, for example, pentamidine **104**, which inhibited melanoma cell growth ($IC_{50} = 1.2$ μM).[223] The interaction of annexin A2 with S100A10 is important for cancer cell invasion, and annexin A2 is frequently overexpressed in cancers. The interaction has been well characterized by X-ray crystallography allowing the design of inhibitors. A docking-based VS identified a number of inhibitors, for example, **105**, as probe compounds.[224] A 3D pharmacophore model of the S100A10 binding site was used to screen compound databases, and identify triazoles, for example, **106**, with modest potency.

5.06.3.4.3 Myc/Max inhibitors

The oncogenic transcription factor Myc, a member of the basic helix-loop-helix leucine zipper (bHLHLZ) family, is required to dimerize with Max to act as a transcriptional regulator, so inhibitors of the Myc/Max PPI would control Myc activity (Table 12). Compounds inhibiting Myc/Max dimerization were identified from a library screen, for example, **107**, hits were confirmed by ELISA and an electrophoretic mobility-shift assay for DNA binding.[225] A "credit-card" library approach identified naphthalene bis-amides as c-Myc/Max inhibitors with micromolar potency and cellular activity.[226] A screen of 17,298 compounds identified **108** as a Myc/Max dimerization inhibitor, with reasonable selectivity against Jun/Fos heterodimerization, and **109** demonstrated c-Myc-dependant cell growth inhibition.[227] Compound **110** resulted from optimization of a screening hit.[228–231] A 3D pharmacophore model, derived from the structures of the active and inactive compounds described in Ref.,[230] was used to screen the ZINC database.[111] A circular dichroism-based assay for Myc/Max inhibition identified hit compounds, for example, phthalimide **111**, and amide **34** (Fig. 16) showed modest growth inhibitory activity in HL60 cells (IC_{50} 23 μM).

5.06.3.4.4 PDZ domain inhibitors

PDZ domains comprise ~90-amino acids forming six β-strands and two α-helices folded into a β-sandwich.[27] PDZ proteins act as scaffolds for supramolecular complexes and target proteins to specific cellular locations by binding the C-terminus of the target

protein. PDZ inhibitors have been discovered by rational design and fragment screening (Table 13). Structure-based design of a mimic for the ITXV peptide motif gave the selective irreversible inhibitor of the second PDZ of MAGI3 (MAGI3-PDZ2) **112** that prevents MAGI3 association with the tumor suppressor protein PTEN.[232] The mechanism of inhibition is reported to be the trapping of histidine by the reactive hydroxymethyl group. Further structure-based design gave rise to the modified indole carbinol scaffold **113**.[233] The indole scaffold was also used to design inhibitors of Na^+/H^+ exchanger regulatory factor 1 (NHERF1) PDZ1, which has an uncertain role in cancer, and inhibition of PDZ1 binding to the β2 adrenergic receptor (β2AR) and cystic fibrosis conductance receptor (CFTR) was demonstrated by **114**.[234] A similar scaffold was used to target the PZD domain of the Dishevelled (Dvl) protein, an activator of the β-catenin/Tcf complex, and compound **115** induced apoptosis in cell lines engineered to overexpress Dvl.[235] The ALL-1 fusion partner on chromosome 6 (AF6) protein interacts with a variety of proteins by its second PDZ domain, including kinases and breakpoint cluster region (BCR).[236] NMR-based screening identified ligands for the AF6 PZD domain, for example, **116**. The lead compound was optimized to **117** that was 25-fold more potent, and was able to inhibit BCR binding in cellular pull-down experiements.[237]

5.06.3.4.5 SH2 and SH3 domain inhibitors

Src homology (SH) domains are noncatalytic protein modules. SH2 domains bind to phosphotyrosine residues, whereas SH3 domains preferentially bind to proline rich regions of target proteins. The natural product UCS15A (Table 14, **118**) was identified

Table 14 SH domain PPI inhibitors

[a]Activity in cell-free assays.

from a screen for Src inhibitors, and shown to act in a kinase independent manner by blocking the Src SH3 domain and inhibiting interactions with target proteins.[238,239] Signal transducer and activator of transcription 3 (Stat3) binds phosphotyrosine residues on target proteins via surface hot-spots. Inhibitors based on isoxazole and thiazole scaffolds (**119a** and **119b**) were identified that inhibit the Stat3 dimerization and DNA binding, but had little cellular effect. Src homology 2 domain-containing phosphatase (SHP2) plays a key role in cell signaling, in silico screening using the SHP2 X-ray structure identified hit compounds, for example, **120**, that inhibited SHP2-mediated signaling in cells.[240]

5.06.3.4.6 Ras PPI inhibitors

The small GTP-ase protein Ras regulates cell signaling by binding to extracellular receptors, for example, EGFR, via Son of Sevenless (SoS) and downstream kinases, for example, Raf. Small-molecule inhibitors of the Ras–SoS PPI have been identified through NMR-based fragment screening and X-ray crystallography (Table 15).[241] The indole benzamidazole fragment was developed by the addition of an amino acid to improve potency and solubility, for example, **121**, which showed activity in a SoS-catalyzed nucleotide exchange assay. A Ras–SoS inhibitor was discovered by a docking-based VS, compound **122** binds to SoS and inhibits Ras signaling in cells.[242] A number of fragments including triazine **123** were identified by X-ray-based fragment screening, and bound to three distinct binding pockets, one on SoS, one at the Ras–SoS interface, and one on Ras.[243] The identification of novel allosteric binding sites offers new possibilities for the design of Ras–SoS PPI inhibitors. Deltarasin **124** is a potent inhibitor of the Ras–PDEδ PPI by binding to the prenyl binding site of PDEδ and preventing Ras farnesylation.[244] Deltarasin inhibits Ras signaling in cells, and produced tumor growth delay in Panc-Tu-1 xenografts (10 mg kg^{-1} bid^{-1} ip).

5.06.3.4.7 Other PPI inhibitors

Other PPI inhibitors have been reported against a variety of cancer targets (Table 16). Screening approaches have identified promising lead compounds (**125–130**) for β-catenin/T-cell factor,[245] cyclin-dependent kinase 2 PPIs,[246,247] elF4E/elF4G,[248,249] EWS-FLI1,[250,251] HOX–PBX/DNA,[252]and IL6-GP130.[253] Peptide mimetic compounds **131** and **132** inhibit MLL1/WDR5,[254] and Pin1,[255] respectively. Fragment screening approaches have provided hit compounds (**133–135**) for PPI targets including RAD51/BRCA2,[256] pVHL-HIF-1α,[257,258] and ZipA/FtsZ.[259] VS has been used to provide hit compounds (**136–138**) for PPI targets including IL6-GP130,[253] Ral/RALBP1,[260] and uPAR/uPA.[261]

5.06.3.5 Challenges in the Optimization of PPI Inhibitors

Empirical guidelines for the assessment of likely oral bioavailability of a given molecule have been established. Lipinski's rule of five sets limits for MW (MW < 500), hydrogen bonds (donors ≤ 5, acceptors ≤ 10), and lipophilicity (cLogP < 5).[262] Further refinements to models for oral bioavailability include properties such as rotatable bonds, polar surface area, and pK_a.[263,264] Other useful measures for assessing druglike properties during optimization include LE[265] and lipophilic ligand efficiency.[266]

The challenge for designing druglike PPI inhibitors rests with balancing the extensive lipophilic interactions required for binding affinity to the target, with the need to maintain acceptable physicochemical properties, for example, MW, cLogP, and solubility, in a single compound. Clinical candidates reported to date illustrate different approaches to this problem. The Bcl-2 inhibitor navitoclax (**44**) exceeds the MW threshold (MW 945) and lipophilicity thresholds (cLogP 12.1). In addition to addressing selectivity, the MW and lipophilicity values have been reduced for the second generation Bcl-2 inhibitor venetoclax (**48**), but the compound still falls outside of the thresholds. Despite this both compounds have been effective in clinical trials with oral dosing and so acceptable PK and PD properties can be inferred. Development of the Nutlin series of MDM2–p53 inhibitors resulted in RG7112 (**51**), which exceeds both the MW (MW 728) and lipophilicity thresholds (cLogP 10.6). The PKs of RG7112 showed high levels of interpatient variability in the phase I trial, probably linked to the poor properties of the compound.[155] Other MDM2–p53 inhibitors in the clinic have lower MWs and include either acidic or basic groups to modulate their properties and improve solubility.

The evidence to date suggests that small-molecule PPI inhibitors will frequently fail to fit some of the ideal druglike parameters that have been defined previously. Experience gained from the clinical development of Bcl-2, MDM2–p53, and IAP inhibitors may inform and refine the definitions of druglike properties. Already it seems clear that drug candidates with nonideal physicochemical properties will require exquisite levels of potency against their target to demonstrate clinical efficacy.

5.06.4 Outlook

The importance of PPI inhibitors in cancer is shown by the number of PPI targets that have been explored to date and the diversity of the approaches used. Advances in screening methods, including peptide libraries, high-throughput screening methods, and structure-based fragment discovery have produced significant gains in understanding for PPI inhibitor design. It is likely that our growing understanding of the complexities of cancer cell biology will continue to highlight PPIs as points for therapeutic intervention. As the field matures, the historical view of PPI targets as "undruggable" seems certain to be proved incorrect.[269,271,273]

5.07.1 Introduction

In order to sustain their uncontrolled growth and proliferation, cancer cells are heavily dependent on maintaining protein homeostasis under challenging cellular conditions. They require an extraordinary level of protein synthesis simply to maintain their growth rate. In addition, they must ensure that the high levels of protein produced do not simply aggregate but are maintained in an active conformation. Finally, cancer cells are heavily dependent on protein degradation processes to balance the intensive protein synthesis and prevent an unsustainable level of protein build up, leading to inevitable cell death. Each of these three areas can be targeted by cancer therapeutics.

Protein synthesis is a fundamental process that all cells must perform and both transcription and translation have been successfully targeted using small-molecule inhibitors. Although transcription has been classically targeted using drugs that interact directly with DNA, significant advances in molecularly targeted therapies designed to inhibit both these processes have been made in the last few years and these are described in "Targeting Protein Synthesis" section. In this broad area, we have seen successful approvals arise from targeting nuclear hormone receptors, for example, tamoxifen and zytiga along with drugs that target translation, such as everolimus.

Understanding of the importance of protein quality control has advanced significantly in the last 20 years. During this period, anticancer drug discovery has moved from the belief that inhibition of molecular chaperones would show no selectivity between cancer cells and normal cells, to proof in the clinic that such inhibitors can have a significant anticancer effect. Heat shock protein 90 (HSP90) has proved to be a druggable protein and has attracted much interest and activity with a range of chemotypes in the clinic but no drugs approved as yet. Heat shock protein 70 (HSP70) provides a clear resistance pathway to HSP90 inhibitors but has proven far more difficult to modulate with small molecules. Progress in the area of targeting molecular chaperones is presented in "Targeting Protein Folding" section.

Finally in this article, the field of protein degradation as a way to target cancer cells is reviewed ("Targeting Protein Degradation" section). The ubiquitin–proteasome system (UPS) has attracted much attention with significant efforts being made to target the E1, E2, and E3 enzymes involved in ubiquitination. Tagging proteins with ubiquitin can target them for proteasomal degradation and inhibition of any of the enzymes involved in this cascade could lead to an unsustainable build up of proteins and cell death. A number of clinical candidates have been disclosed in this area with several compounds entering the clinic. Inhibition of the proteasome has seen real patient benefit, starting with bortezomib (Velcade), which was approved in 2003 in multiple myeloma (MM) followed by carfilmozib in 2012. The discovery of the mode of action of thalidomide has led to an understanding of a very specific form of protein degradation and the potential for this to degrade specific protein targets is an exciting new area that is reviewed in "Degradation of Undruggable Targets in Cancer Therapy" section.

5.07.2 Targeting Protein Synthesis

5.07.2.1 Introduction

One of the hallmarks of transformed cancer cells is their ability to escape the usual checks and balances which stop normal cells undergoing uncontrolled proliferation and survival.[1] The fact that cancer cells display this trait is believed to be derived

from their addiction to oncogenes.[2] Oncogenes allow cancer cells to suppress proapoptotic pathways, manipulate their environment, and avoid immunogenic responses which would otherwise halt the spread of cancer. Targeting oncogenes with small-molecule inhibitors of their resultant proteins has been the primary focus of modern drug discovery efforts to treat cancer with molecularly targeted agents.[3] Because of the dependency of cancer cells on oncogenic proteins, inhibiting their synthesis through the inhibition of gene transcription or translation via the RNA-processing machinery represents a viable strategy for treating cancers, as nonmalignant cells are not reliant on this addiction and can cope with temporary inhibition of protein synthesis, resulting in reduced side effects and an acceptable therapeutic index for these drugs.[4]

5.07.2.2 Targeting Transcription

Excluding compounds that act through interactions with DNA, such as intercalators,[5] there are two opportunities in drug discovery to target protein synthesis, RNA transcription, and translation. RNA transcription is the first step in gene expression, copying a DNA gene sequence of bases into mRNA using RNA polymerase enzymes (Fig. 1). The RNA polymerase creates a transcription bubble by separating the two strands of DNA (Fig. 2). The process of binding the RNA polymerase to the DNA is facilitated by various transcription factors (TFs).[6] Other proteins known as activators and repressors then control the rate of transcription. This complex process affords numerous opportunities in drug discovery to inhibit the synthesis of mRNA molecules. The RNA polymerase could be directly targeted through protein–protein interaction inhibitors, blocking the formation of the transcription bubble. Because the activity of the RNA polymerase is regulated by numerous post-translational modifications, such as phosphorylation, the activity of the RNA polymerase could be controlled indirectly by targeting the enzymes involved in these transformations.[7] Finally, inhibiting the activity of other regulatory proteins within the transcription bubble, such as the TFs, could also reduce or enhance the transcriptional activity of the complex. Each of these strategies has varying potential for drug discovery, dependent on the drugability of the molecular target, selectivity, and therapeutic index.[8]

5.07.2.2.1 Targeting a TF

Since the gene transcription process is tightly regulated by TFs, a viable strategy in oncology to inhibit transcription is to inhibit the function of these proteins. TFs are commonly deregulated in cancer, with many malignant cells showing dependence on either their

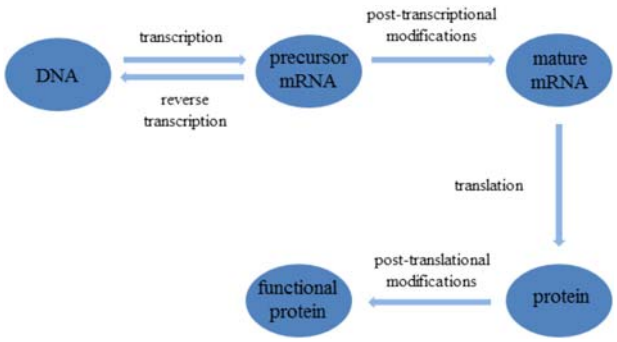

Fig. 1 Process of protein synthesis.

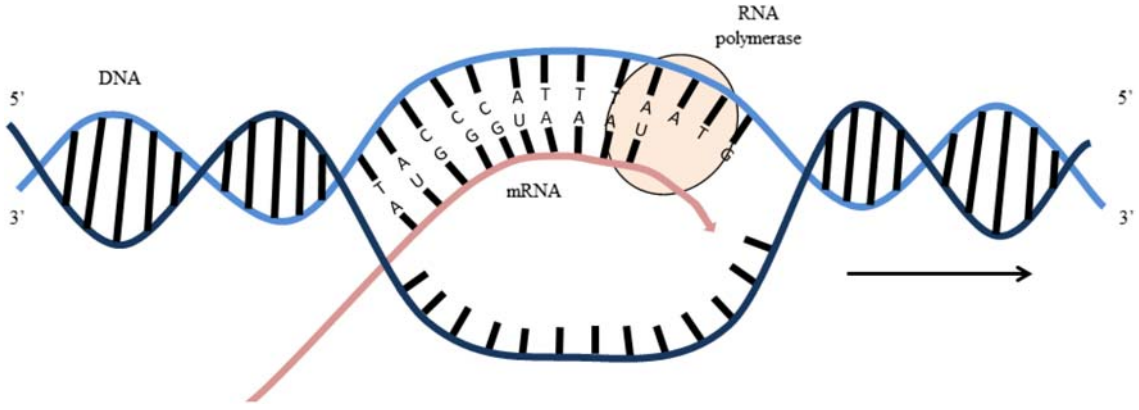

Fig. 2 Process of gene transcription.

activation or repression. Inhibiting TFs can inhibit mRNA synthesis in a gene-specific manner, in contrast to targeting the general transcription machinery.

Some of the most successful treatments realized in oncology have targeted nuclear hormone receptors. In breast cancer, ~70% of tumors rely on estrogen receptors to facilitate cell growth. Two of the compounds that target this reliance on estrogen receptors are tamoxifen **1** and raloxifene **2** (Fig. 3).[9]

Both compounds antagonize estrogen receptor-mediated transcription through direct competition with estrogen for the hormone receptor.[10] Tamoxifen was discovered in 1967 and is in fact a prodrug. The parent compound has little affinity for the estrogen receptor but following oxidation by the metabolizing enzymes CYP3A4 and CYP2D6 (Scheme 1), metabolites such as 4-hydroxytamoxifen (afimoxifene, **3**) bind the receptor with high affinity and stop cancerous cells from dividing.[11]

The increased affinity of the 4-hydroxytamoxifen is clearly explained by the crystal structure of this ligand bound to the estrogen receptor (Fig. 4). The tetrasubstituted alkene forces the three aromatic rings to adopt a propeller-like conformation, giving good complementarity with the binding pocket. This conformation also forces the benzene ring deep into the pocket and in close contact with a hydrophilic region of the protein. The hydroxyl group present in the oxidized tamoxifen metabolite makes multiple hydrogen bond contacts with the arginine-316 and glutamic acid-275 residues and a bound water molecule, interactions that would be absent in tamoxifen itself.

An alternative strategy for targeting nuclear hormone receptor-mediated transcription is to target the synthesis of the endogenous agonist ligand. Androgens, such as testosterone, are often crucial for the proliferation of malignant cells in advanced prostate cancer. To antagonize androgen receptor-mediated transcription, the frontline treatment is chemical castration, which is highly effective at halting disease progression. However, most patients will eventually relapse as despite castration, 10% of circulating testosterone remains due to peripheral conversion of adrenal steroids to testosterone, which continues to drive prostate cancer cell proliferation. By inhibiting the enzyme responsible for residual testosterone synthesis, CYP17α, a new treatment for refractory prostate cancer was developed, the prodrug abiraterone acetate.[12]

The rational design of abiraterone was based on mimicking the endogenous ligand pregenolone but replacing the methyl ketone moiety, which is oxidized by CYP17α by a group that would be resistant to oxidation but could still coordinate the heme cofactor to generate a high affinity ligand (Fig. 5). The pyridine group was designed for this task and it was subsequently revealed that the position of the nitrogen was crucial for inhibitory activity; the 2- and 4-pyridyl groups displayed little activity in contrast with the 3-pyridyl analog which displayed an $IC_{50} = 2.9$ nM. This structure–activity relationship (SAR) can clearly be rationalized with the crystal structure of abiraterone bound to the androgen receptor, as only the 3-pyridyl analog possess the correct geometry to coordinate the iron of the heme cofactor (Fig. 6).

There are many other TFs other than the nuclear hormone receptors that have been implicated in cancer. c-Myc is a transcription factor important for cell cycle progression, apoptosis, and cellular transformation and is commonly mutated in cancers to make it constituently active.[13] c-Myc has been a popular molecular target in oncology but because it is ligandless, targeting c-Myc with small molecules has proven particularly challenging, as without a small-molecule binding site, the protein is considered to have low drugability. There are many other TFs which could be potential targets in oncology, such as NRF2,[14] NFkB,[15] and HSF1,[16] which also display this difficulty. Therefore, various alternative strategies have been applied to target the function of TFs rather than relying on direct inhibition. This phenotypic approach has led to a large number of TF pathway inhibitors appearing in the literature; however, their molecular mechanisms of action are often poorly defined.

In contrast, a ligandless transcription factor that has been successfully targeted by small-molecule modulation is the "guardian of the genome" p53.[17] p53 is vital tumor suppressor protein which regulates the transcription of many genes involved in DNA damage and repair. p53 is often mutated in cancer to suppress its function and allow the cancer cell to proliferate; despite the DNA damage in the cell that would normally initiate cell cycle arrest or apoptosis. In cancer cells where p53 is not mutated, its function is often suppressed via continuous degradation by the ubiquitin ligase HDM2. HDM2 binds p53 through a protein–protein interaction and it was proposed that cancer cells that rely on HDM2 to block p53 mediated transcription. Small-molecule inhibitors of the MDM2/p53 interactions will be discussed in the section on protein degradation ("MDM2" section).

5.07.2.2.2 Targeting RNA polymerases

Because of the oncogene addiction of cancer cells to various proteins, inhibiting the general transcription machinery is also a viable strategy in oncology. The RNA polymerases, and in particular RNA polymerase II (RNAPII), are required for most mRNA transcription events. In order to carryout gene transcription, a preinitiation complex is formed by RNAPII and a number of general TFs.[18]

After the first 25–30 nucleotides are transcribed, there is a transition between transcription initiation and elongation resulting in the hyperphosphorylation of RNAPII, which is a requirement for transcription elongation and termination. This complex process gives a number of opportunities to inhibit gene transcription. Actinomycin D is a very large cyclic peptide antibiotic that inhibits RNA synthesis by intercalating DNA. However, since it binds directly to DNA it can also cause DNA damage, leading to a phenotype that differs from general transcription inhibition.[19] Another complex cyclic peptide called alpha-amanitin (**6**) (**Figs. 7** and **8**) is a well-known general transcription inhibitor. Found in the emotively named death-cap mushroom, this highly toxic compound binds RNAPII directly, dramatically slowing its DNA translocation and thus inhibiting mRNA synthesis.[20,21]

α-Amatinin, **6**, is a potent hepatotoxin, resulting in damaging side effects and leaving little therapeutic index against cancer cells versus normal cells, which has prevented its use in cancer therapy. Its complex structure makes analog synthesis a daunting task. The unique mechanism of action of α-amatinin has led to attempts to circumvent the liver toxicity of this compound by using antibody drug conjugates to block uptake into mature hepatocytes and direct the RNAPII inhibitor to cancer cells using tumor-specific antibodies. Despite some encouraging results in mouse models, it is as yet unclear whether this approach will be successful in the clinic.[22]

5.07.2.2.2.1 CDK9 inhibitors

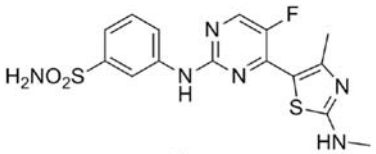
Since directly targeting RNAPII to inhibit mRNA transcription has proven particularly challenging, alternative approaches that target proteins which regulate RNAPII have been investigated. Originally discovered as ATP-competitive inhibitors of cyclin-dependent kinase 2 (CDK2),[23] aiming to antagonize cancer proliferation by exploiting CDK2's role in cell cycle arrest, it became clear that many features of the phenotype of CDK2 inhibitors could not be accounted for by the inhibition of that protein, particularly the inhibition of mRNA transcription. The cyclin-dependent kinases are a family of transferases whose function is tightly regulated by cyclins in a dimeric complex.[24] The ATP-binding site of the CDKs is highly conserved across the family, meaning that designing small-molecule CDK-selective inhibitors is challenging.[25] The original CDK2 inhibitors such as roscovitine[26] and flavopiridol, **7**[27] (**Table 1**), were less selective than was originally assumed and it was later discovered they were also inhibiting other CDKs, including the CDK most important for RNAPII-mediated transcription, cyclin-dependent kinase 9 (CDK9). CDK9 directly phosphorylates RNAPII, so inhibiting the catalytic function of CDK9 inhibits the RNAPII hyperphosphorylation crucial for efficient mRNA transcription elongation and therefore mRNA synthesis.[28]

Selectivity between different CDKs is clearly one of the greatest challenges in this field of drug discovery but also represents a big opportunity. The early pan-CDK inhibitors such as flavopiridol suffered from a poor therapeutic index due to their lack of selectivity, including kinases outside of the CDK family. It is now also appreciated that polypharmacology,[29] inhibiting multiple structurally related proteins, is often crucial for potent anticancer effects; while compounds that are too selective can have little effect on cancer progression. The apparent paradox between safety and efficacy resulting from selectivity can be difficult to resolve through rational drug design. Dinaciclib, **9** (**Table 1**), is a potent inhibitor of CDK1, 2, 5, 9 (IC_{50} = 3, 1, 1, 4 nM, respectively) but is highly selective against kinases outside of the CDK family and is a good example of this paradox.[30] Because it is difficult to rationalize the correct balance of CDK inhibition, the discovery of dinaciclib was via an in vivo phenotypic approach to maximize the therapeutic index in tumor bearing nude mice. Presumably, this was because small structural changes altered the balance between the inhibition of the four CDKs. The core scaffold was maintained in each analog, such as compound **8**, with variations focused on the 5-position of the pyrazolopyrimidine core. The ratio of maximum tolerated dose (MTD) to the minimum effective dose was then determined for each analog (**Table 1**).

Table 1 Development of dinaciclib

Compound	*Name*	*MTD (mg kg^{-1})*	*MED (mg kg^{-1})*	*TI[a] (MTD/MED)*
 **7**	Flavopiridol	<10	10	<1
 **8**	–	20	4	5
 **9**	Dinaciclib	60	5	>10

[a]Relative therapeutic indices (TI) following intraperitoneal (ip) dosing using the in vivo screening paradigm (maximum tolerated dose, MTD = 20% weight loss; minimum effective dose, MED = 50% inhibition of tumour growth; QDx7 = once a day dosing for 7 consecutive days).



10

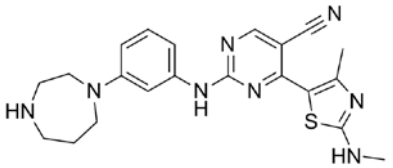
Fig. 9 Chemical structure of CDKI-73.

The pan-CDK inhibitor flavopiridol had a poor therapeutic index (<1) in this screen, which was in stark contrast to dinaciclib **9** which was advanced into further study. While this strategy did deliver a compound with an improved therapeutic index compared to flavopiridol, it did mean that PK optimization was not prioritized. Dinaciclib is not orally bioavailable so must be delivered iv, and the unusual pyridinium-*N*-oxide motif means dinaciclib has poor plasma stability. Despite these challenges, dinaciclib was advanced into multiple clinical trials for solid tumors and hematological malignancies.

A variety of core scaffolds have been shown to be good CDK9 inhibitors. CDKI-73, **10**, is a 2-anilino-4-thiazolopyrimidine (Fig. 9) that was rationally designed and optimized using protein crystal structures of CDK9.[31] This chemotype was known to display good CDK9 inhibition ($IC_{50}=4$ nM) but this activity was difficult to uncouple from the CDK2 activity ($IC_{50}=3$ nM).

By analyzing the crystal structure of 2-anilino-4-(thiazole-5-yl)pyrimidine, **11**, bound to CDK2 and through modeling binding to the more open CDK9 structure (Figs. 10 and 11), substitution at both the 5-pyrimidine and *meta*-anilino moieties was proposed to improved selectivity. These design principles lead to **11** which displayed an 80-fold selectivity for CDK9 ($IC_{50}=7$ nM) over CDK2 ($IC_{50}=130$ nM).[32]

However, even though the CDK9 activity of **11** was improved and it could be shown to inhibit RNAPII phosphorylation, its antiproliferative activity was more than 40-fold reduced, so the less selective analog **10** was progressed into further preclinical study.



11

Fig. 10 Chemical structure of compound **11**.

12 13

Fig. 12 Development of ZK3044709.

This contradiction is either a commonly observed example of a biochemical/cell assay disconnect[33] or again demonstrates the importance of polypharmacology to efficacy, especially in the field of kinase drug discovery.

Other CDK9 inhibitors include the pan-CDK inhibitor BAY1000394.[34] Lead optimization of an aminopyrimidine screening hit, **12**, led to ZK3044709[35] **13** (Fig. 12), which although had a promising preclinical profile but was unsuccessful in phase 1 clinical trials due to dose-limiting absorption and high interpatient variability.

The causes of this failure were attributed to the poor aqueous solubility and off-target activity against carbonic anhydrase II. A model of ZK3044709 indicated the importance of the sulfonamide moiety to its affinity to CAII, as this functional group is known to be an excellent zinc(II) ion chelator (Fig. 13).

Modification of this group to a sulfoximide, which can suppress this interaction, followed by optimization of the pyrimidine C5- and C6-substituents to lower lipophilicity and block liver microsome degradation, gave a clinical candidate with nanomolar pan-CDK activity, improved aqueous solubility, and greatly improved predicted human dose.

Another compound that exploits the 2-aminopyrimidine scaffold for CDK9 inhibition is LY2857785[36] **14** (Fig. 14). This CDK9 inhibitor ($IC_{50} = 11$ nM) displayed a good kinase selectivity profile, with only 5 kinases out of the 114 tested displaying an $IC_{50} < 100$ nM. Good aqueous solubility and excellent cellular activity led to numerous in vivo xenograft studies, demonstrating tumor regression from an intravenous (IV) dose.

SNS-032, **15**, is an aminothiazole-derived pan-CDK inhibitor (Fig. 15).[37] Originally designed to be an inhibitor of CDK2, it was subsequently discovered to possess transcription inhibition activity which was attributed to its potent CDK9 inhibition.

5.07.2.2.3 BRD4 inhibitors

BRD4 is a member of the BET family of bromodomains that act as genetic readers of histone acetyl lysine residues to regulate gene transcription. BRD4 has become a popular epigenetic target in oncology. As part of the general transcription machinery, BRD4 interacts with the positive-elongation factor (P-TEFb) complex, which is fundamental for transcription elongation through RNAPII, so can regulate transcription indirectly through control of the transcription preinitiation complex. Also, BRD4 has been

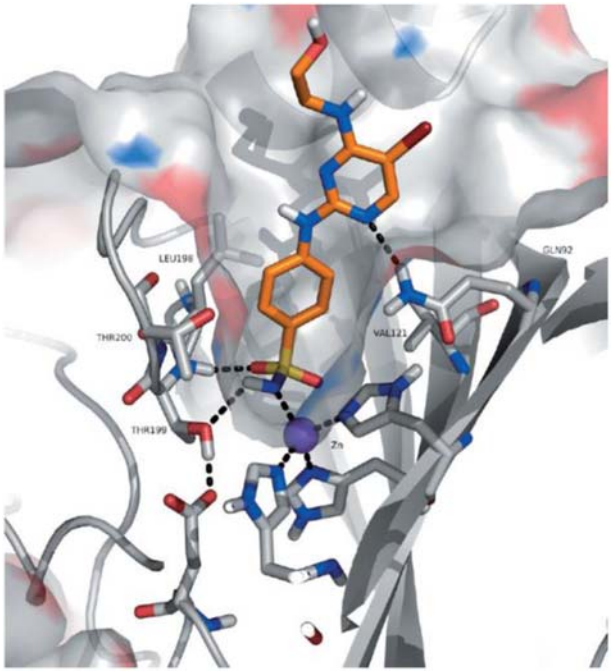

Fig. 13 Model of ZK3044709 in complex with human CAII.[35]

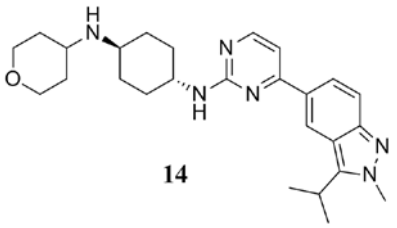
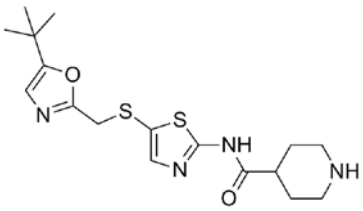


14

Fig. 14 Chemical structure of LY2857785.



15

Fig. 15 Chemical structure of SNS-032.

proposed to act as an atypical kinase that can phosphorylate serine-2 of RNAPII, regulating transcription through a more direct mechanism.[38,39]

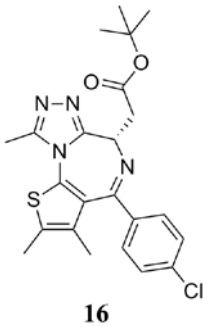
From an antiinflammatory phenotypic study, it was discovered that simple thienodiazepines possessed affinity for BRD4. By inferring SAR derived from molecular modeling of the candidate ligand, the chemical probe (+)-JQ1, **16**, was discovered which displayed a $K_d = 50$ nM (Fig. 16).[40]

Analysis of the co-crystal structure revealed that (+)-JQ1 mimics many of the interactions of the endogenous acetyl lysine complex (Fig. 17). The triazole forms a hydrogen bond with the evolutionarily conserved asparagine 140 and the ligand displayed excellent shape complementarity. Only the (*S*)-enantiomer has affinity for BRD4, which was rationalized using models predicting an energetically unfavorable diazepine conformation and through clashes with the ZA-loop region.

To develop a BRD4 inhibitor that has potential clinical use, the pharmacokinetic profile of the original chemical probe needed to be improved. OTX015, **17**, is a (+)-JQ1 analog, which replaced the t-Bu ester with a para-hydroxyacetamide (Fig. 18).[41] This compound is currently under investigation in human clinical trials for leukemia. No description was given as to why this structural change gave an improved pharmacokinetic profile.

Other chemotypes have been shown to be potent inhibitors of BRD4-mediated transcription and have been progressed to the clinic. I-BET726 (GSK1324726A, **20**, Fig. 19) was discovered via a phenotypic screen to discover upregulators of ApoA1 and most of the SAR development was carried out without knowing that the molecular mechanism of action was through inhibition of the BRD protein family.[42] From the cell-based high-throughput screen, the tetrahydroquinoline was identified to increase ApoA1 activity in a luciferase reporter assay approximately two- to threefold.

The initial hit, **18**, from the HTS contained two stereogenic centers as a mixture of both absolute and relative stereoisomers. Early SAR of the screening hit revealed that the *cis*-stereochemistry was crucial for activity, and the 2*S*,4*R*-enantiomer was more than two orders of magnitude more active than its enantiomer. Substitution at the 6-position of the tetrahydoquinoline was rationalized by



16

Fig. 16 Chemical structure of (+)-JQ1, **16**.

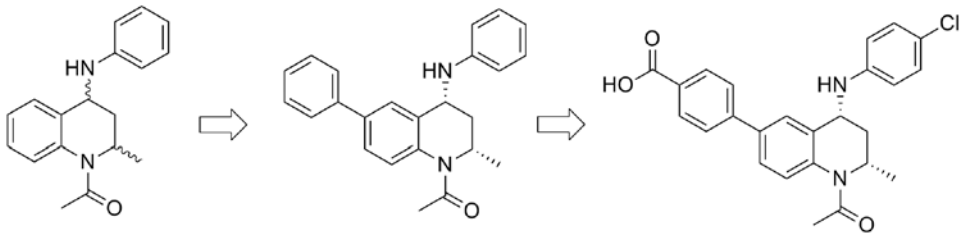
17

Fig. 18 Chemical structure of OTX015.

an overlay with pharmacophores of other ApoA1 upregulators, with substitution of this ring being well-tolerated with various substituents, which facilitated a route to PK optimization (Fig. 19). Interestingly, the carboxylic acid had little effect on cellular activity, despite the expected reduction in permeability this functional group can bring. These features were incorporated into the clinical candidate, which displayed good oral bioavailability across multiple species and activity in an in vivo mouse model. Many of these SAR features were eventually rationalized when the crystal structure of I-BET726 bound to BRD2 was solved



18 **19** **20**

Fig. 19 Development of GSK1324726A.

(Fig. 20). The tetrahydroquinoline ring was buried deep in the pocket, while the *para*-chloroaniline and para-benzoic acid were solvent exposed.

Interestingly, a second chemotype was discovered via the ApoA1 phenotypic screen, which was very similar to the (+)-JQ1 series. I-BET762, **22**, was developed from a benzodiazepine, **21**, unsurprisingly since benzene and thiazole are often used as interchangeable bioisosteric replacements, with optimization again focused on the solvent-exposed region. The carbamate was chemically unstable at low gastric pH and was replaced by an ethylamide (Fig. 21).[43]

5.07.2.3 Targeting Translation

5.07.2.3.1 Translational control in cancer

Proteins are synthesized from mRNA through translation by the ribosomes, tRNA, and auxiliary proteins. Translation occurs in four phases: initiation, elongation, termination, and ribosome recycling (Fig. 22). Initiation is the first and generally rate-limiting step of translation, where initiation factors facilitate the positioning of the translation-competent ribosome at the initiator codon of the mRNA. The 43S ribosome preinitiation complex is formed by association of the 40S small ribosomal subunit, the initiating methionyl tRNA, and a group of eukaryotic initiation factors (eIFs). The 43S ribosome complex is then recruited to the 5′ end of the mRNA, marked by a 7-methylguanosine cap. Association of the 43S ribosome complex with the 7-methylguanosine cap, which protects the mRNA from degradation and binds eIF4E, is mediated by the cap-binding complex eIF4F. The eIF4F complex is composed of a 5′mRNA, the cap-binding subunit eIF4E, the large scaffolding protein eIF4G, and the ATP-dependent DEAD box helicase eIF4A. eIF4G also interacts with the poly(A)-binding protein (PABP), which associates with the mRNA 3′ poly(A) tail. Recognition of the initiation codon by the 43S preinitiation complex leads to release of the eIFs and joining of the 60S ribosomal subunit. The formation of a translation-competent 80S ribosome is the end of the initiation and beginning of the elongation phase.[44–46]

The regulation of translation is a mechanism that is used to modulate gene expression in a wide range of biological situations. Two different modes of translational control are known: global control, in which the translation of most mRNAs in the cell is regulated, and mRNA-specific control, where the translation of a defined group of mRNAs is modulated without affecting general

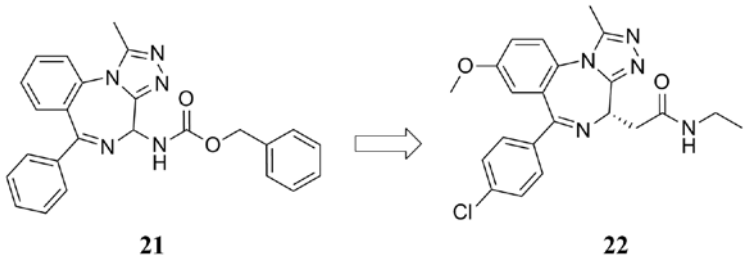

Fig. 21 Development of I-BET762 (**22**).

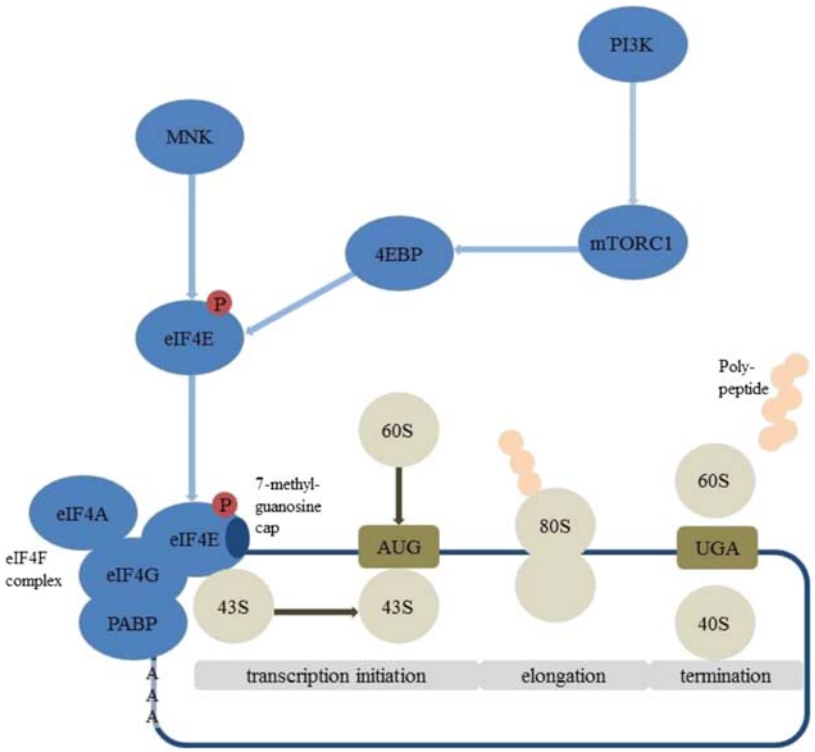

Fig. 22 Oncogenic alterations of mRNA translation. The eukaryotic initiation factor 4F (eIF4F) cap-initiation complex (eIF4G, scaffolding protein for assembly of the translation machinery; eIF4E, cap-binding subunit; eIFA, ATP-dependent DEAD box helicase that unwinds the mRNA) assembles on the 7-methylguanosine cap and interacts with the poly(A) tail binding protein (PABP) at the 3′ end of the mRNA. The 43S preinitiation complex is formed by association of the 40S ribosomal subunit with eukaryotic translation factors and the ternary complex. Recognition of the initiation codon (typically AUG) by the 43S preinitiation complex leads to release of the eIFs and recruitment of the 60S ribosomal subunit, leaving the active 80S ribosome at the initiation codon, primed to begin protein synthesis. The formation of a translation-competent 80S ribosome is the end of the initiation and beginning of the elongation phase. Termination is triggered by a stop codon (UAA, UGA, or UAG). MNK, MAPK-interacting kinase; 4EBP, eIF4E-binding protein; mTORC1, mammalian target of rapamycin complex 1; PI3K, phosphoinositide 3-kinase.

protein biosynthesis. Global regulation mainly occurs by modification of the translation-initiation factors, whereas mRNA-specific regulation is driven by regulatory protein complexes. The translation of most mRNAs is controlled at the initiation step, and involves controlling the assembly of a functional 43S preinitiation complex or altering access of preinitiation complexes to the mRNA template. The assembly and activity of the eIF4F complex is tightly regulated by signaling pathways that are involved in cancer development and progression. eIF4E is regulated by its availability, which is controlled by the eIF4E inhibitory binding proteins (4EBPs), and by its phosphorylation at serine 209 by the MAPK-interacting kinases MNK1 and MNK2. Oncogenic signaling can hyperactivate eIF4E through mTOR complex 1 (mTORC1)-dependent phosphorylation. Translation can also be regulated at the elongation stage by oncogenic signaling.[44–46]

Malignant cells often show augmented translational activity and are believed to become addicted to elevated protein synthesis. This potentially provides a therapeutic window to selectively target cancer cells.[44] Translational control is a crucial component of cancer development and progression. It directs both, global control of protein synthesis, and selective translation of specific mRNAs promoting tumor cell survival, angiogenesis, transformation, invasion, and metastasis. A number of oncogenic signaling pathways affecting translation are known to be deregulated in human cancers, including RAS–MAPK, and PI3K–AKT–mTOR. Alterations of translational control are associated with different types of cancers, disease stages, and tumor microenvironment.[44–46]

5.07.2.3.2 Inhibitors of eIF4F upstream regulators

Most strategies of inhibiting protein translation target the eIF4F complex. These strategies can be categorized into two groups: firstly, targeting upstream regulators of mRNA translation, and secondly, directly targeting the eIF4F complex. The majority of clinical candidates that inhibit protein translation, including mTOR inhibitors, and dual PI3K/mTOR inhibitors are considered upstream regulators of mRNA translation.[44]

5.07.2.3.2.1 Allosteric mTOR inhibitors—rapamycin and rapalogues

Rapamycin (Fig. 23) is a macrolide first isolated in 1972.[47] Rapamycin is produced as a secondary metabolite by *Streptomyces hygroscopius*, a soil bacterium isolated from a sample collected on Easter Island (Rapa Nui). Rapamycin was initially developed

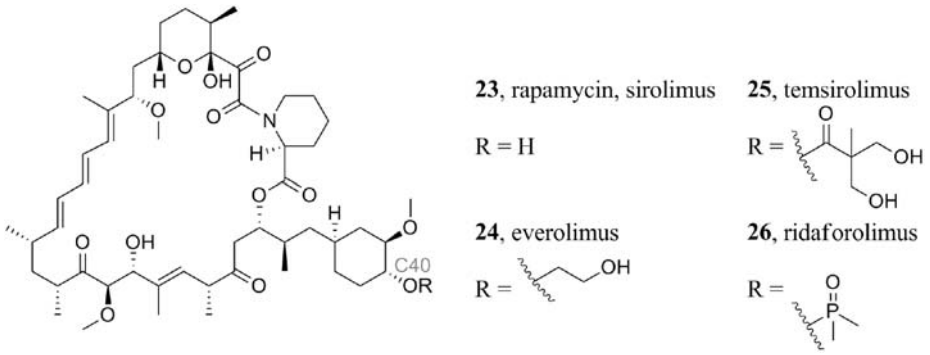

Fig. 23 Rapamycin and rapalogs.

as an antifungal agent, and shows antitumor and immunosuppressive activity in mammalian cell-culture assays. Genetic selection for rapamycin-resistant mutants in *Saccharomyces cerevisiae* (yeast) cells identified FPR1, TOR1, and TOR2 as genes that participate in rapamycin toxicity. The target proteins of rapamycin were collectively named target of rapamycin (TOR).[48] TOR and the mechanism of action were later found to be conserved from yeast to humans.[49]

Mammalian target of rapamycin (mTOR) is a protein kinase that is frequently dysregulated in cancer and metabolic disorders. mTOR belongs to the phosphoinositide 3-kinase (PI3K)-related protein kinase family. This protein family comprises proteins that enable organisms to cope with metabolic, environmental, and genetic stresses. TOR is highly conserved in all eukaryotes and is ubiquitously and constitutively expressed. TOR is a serine/threonine protein kinase that exhibits no lipid kinase activity. The kinase domain is located in the carboxy-terminal region of TOR. mTOR associates with other proteins to generate two distinct complexes called mTOR complex 1 (mTORC1) and mTORC2. mTORC1 is composed of mTOR, regulatory-associated protein of mTOR (RAPTOR), SEC13 protein 8, and proline-rich AKT substrate of 40 kDa (PRAS40, also known as AKT1S1). mTORC1 is involved in protein synthesis and cell progression and is sensitive to inhibition by rapamycin. mTORC2 is composed of mTOR, rapamycin-insensitive companion of mTOR (RICTOR), mLST8, proline-rich protein 5 (PRR5), and mitogen-activated protein kinase-associated protein 1 (MAPKAP1). mTORC2 is involved in cytoskeleton organization and cell survival and is generally insensitive to inhibition by rapamycin. Studies with rapamycin showed that mTOR is involved in translational control. Rapamycin blocks the activation of phosphorylation of S6 kinase by growth factors or nutrient stimuli and promotes the dephosphorylation of 4EBP1, thereby increasing cap-dependent mRNA translation. Both S6 kinase and 4E-BP1 are controlled by multisite phosphorylation.[50]

Inhibition of mTOR by rapamycin is dependent on the formation of a complex with the immunophilin FKBP12, which then binds mTOR in mTORC1. FKBP12 interacts with mTOR through rapamycin, which binds pockets in both proteins.[51] Therefore, rapamycin acts as a protein–protein interaction stabilizer. The requirement for a cofactor makes the mTOR-rapamycin interaction very specific.[49,52] The anticancer activity of rapamycin against a panel of human cancer cell lines was investigated by the US National Cancer Institute (NCI) in the 1980s. Rapamycin showed antitumor effects in several cancer cell lines in vitro and in vivo.[53] Semisynthetic rapamycin analogs (rapalogs) were developed to improve the pharmacokinetic properties of this natural product. The rapalogs all share the same macrocyclic lactone core structure, but differ in their substituents on the C40 hydroxyl group of the cyclohexyl ring, as shown in **Fig. 23**. Temsirolimus is a water-soluble ester derivative for oral and intravenous formulation. Temsirolimus is a prodrug that is metabolized to rapamycin (sirolimus) as the primary active metabolite. Everolimus is a hydroxylethyl ether derivative of rapamycin developed for oral administration. Ridaforolimus (deforolimus) has a phosphate group on the C40 hydroxyl group and was designed for improved aqueous solubility and oral administration. Rapalogs bind at the same binding site for FKBP12 and mTOR as rapamycin with the semisynthetic modifications of the rapalogs located outside the FKBP12- and mTOR-binding domains.[49,52] The rapalogs temsirolimus, everolimus, and rodaforolimus have all been studied in clinical trials. The most promising results have been obtained in renal cell carcinoma when treated with everolimus or temsirolimus, mantle cell lymphoma (MCL), and endometrial cancers. In other tumor types, the clinical performance of rapalogs was disappointing, for example, in glioblastoma, breast cancer, and neuroendocrine carcinoma, the objective response rate with temsirolimus was consistently lower than 10%.[49,52,54] The FDA has approved everolimus for the treatment of renal cell carcinoma, advanced hormone receptor-positive, HER2-negative breast cancer in combination with exemestane and subependymal giant cell astrocytoma (SEGA) tumors. Temsirolimus has also been FDA approved for the treatment of renal cell carcinoma. Ridaforolimus was rejected by the FDA in 2012.

5.07.2.3.2.2 ATP-competitive mTOR inhibitors

A new generation of mTOR inhibitors consists of ATP-competitive compounds that directly inhibit mTOR kinase activity. Unlike rapamycin, these ATP-competitive mTOR kinase inhibitors (TOR-KIs) inhibit both mTORC1 and mTORC2. This blocks feedback activation of PI3K/AKT signaling, thereby offering an advantage over the rapalogs which only inhibit mTORC1.[49,55] The anticancer efficacy of TOR-KIs has been shown superior to that of rapalogs in preclinical settings and a number of these compounds are

investigated in clinical trials.[56] However, mTOR inhibitors remain prone to resistance mechanisms inherent to targeting upstream signaling proteins. Several studies indicate that eIF4E and/or 4EBP expression levels affect the efficacy of PI3K and mTOR inhibitors.[44] Because of the similarity between the kinase domains of mTOR and PI3Ks, a number of ATP-competitive compounds inhibit both mTOR and PI3K. TOR-KIs can be classified into two groups, dual mTOR/PI3K inhibitors, which inhibit both kinases at similar effective concentrations, and pan-mTOR inhibitors, which have a lower IC_{50} for mTOR inhibition than for PI3K.[49]

5.07.2.3.2.2.1 Dual mTOR and PI3K inhibitors

Most of the dual mTOR/PI3K inhibitors currently in clinical trials (Fig. 24) were originally found in drug discovery programs for PI3K inhibitors, but were subsequently shown to also effectively inhibit mTORC1 and mTORC2.[57] However, more recent mTOR/PI3K inhibitors have been developed by simultaneously optimizing compounds against PI3K and mTOR.

5.07.2.3.2.2.1.1 Apitolisib (GDC-0980). Dual mTOR/PI3K inhibitors were originally developed as PI3K inhibitors but were subsequently shown to also inhibit mTORC1 and mTORC2. PI103 was the first dual mTOR/PI3K inhibitor, originally developed from a high-throughput screening for PI3K inhibitors. The original lead compound **34** (Fig. 25) has a quinazoline core structure, substituted with a morpholine and phenyl ring. This compound had an IC_{50} value of 1.3 μM for inhibition of p110α. The focus of the initial SAR investigation was to improve the potency of the lead compound. The morpholine substituent was shown to be essential for activity; any modifications gave at least a ninefold increase in IC_{50}. Substitutions in different positions of the phenyl ring were investigated. A hydroxyl-substituent in the meta-position gave an $IC_{50} = 0.075$ μM, translating into a 17-fold

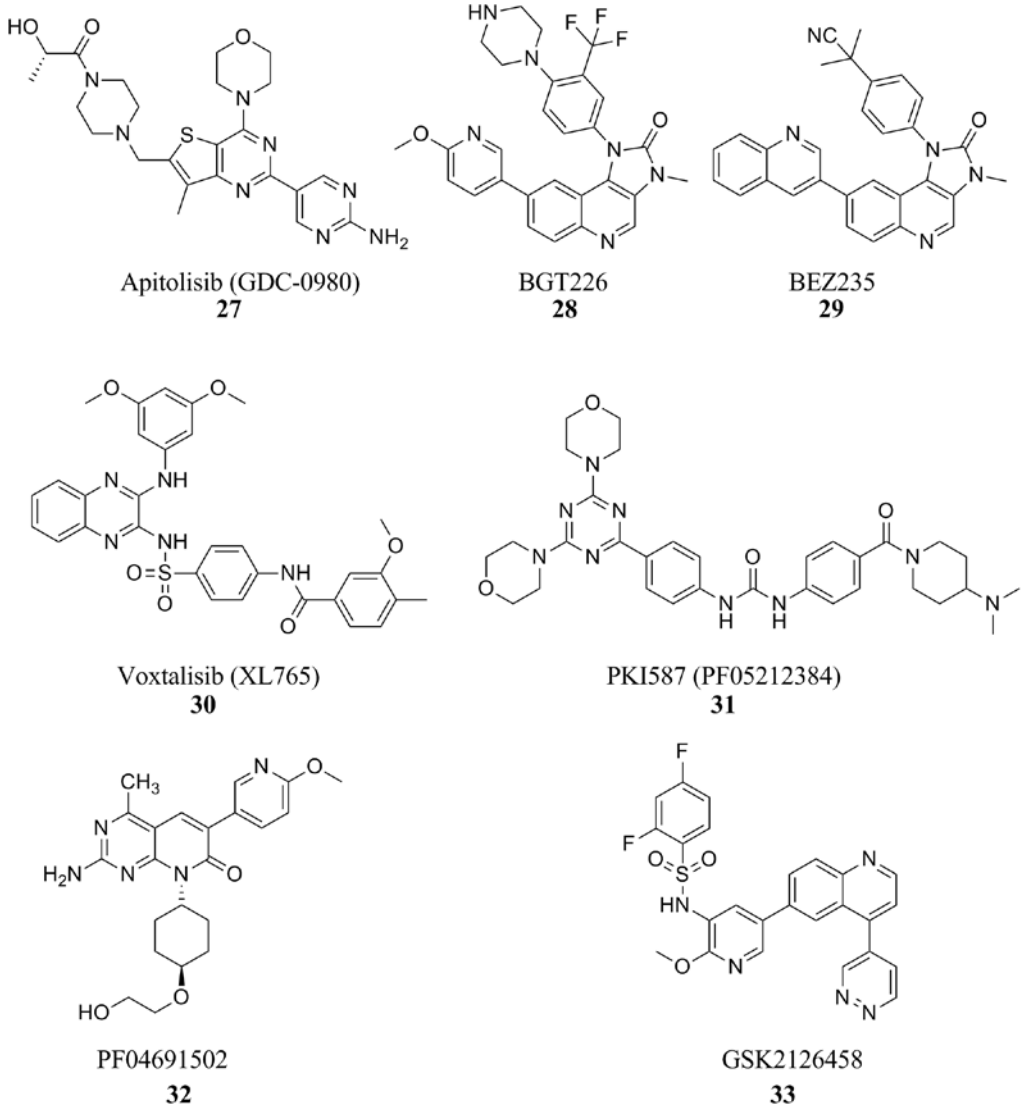

Fig. 24 Overview of dual mTOR/PI3K inhibitors in clinical trials.

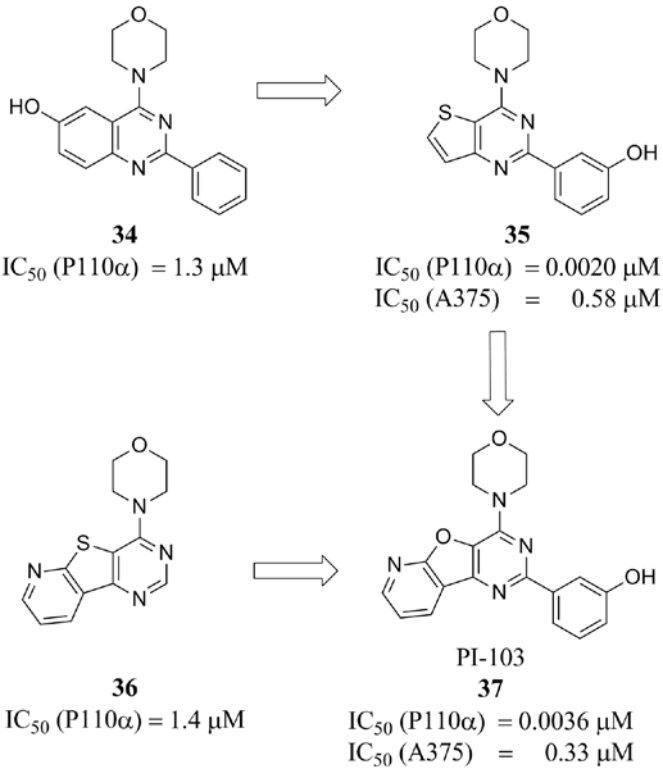

Fig. 25 Development of PI-103, **37**, from lead compounds **34** and **36** obtained in a HTS.

decrease compared to the lead compound **34**. Finally, the effect of the hydroxyl group on the quinazoline ring and replacement of the quinazoline with different bicyclic heterocycles were considered. Replacing the quinazoline ring with a thieno[3,2-*d*]pyrimidine gave compound **35**, which showed the highest activity in this series and a 750-fold improvement in IC_{50} over the original lead compound **34**. Compound **35** suppressed proliferation of A375 melanoma cells with an IC_{50} value of 0.58 μM.[58] However, the PK profile of compound **35** was unsatisfactory; the half-life of **35** was less than 10 min when dosed intraperitoneally (ip) in mice.[59] Compound **36** was identified as another hit compound from the HTS with structural similarity to compound **35**. Modifications of the tricyclic ring of compound **36** were investigated. Replacing the thiophene with a furan resulted in a 2.5-fold increase in activity, while the corresponding pyrrole was found to be inactive. Introduction of a meta-phenol in the same position as in compounds **34** and **35** gave PI-103, **37**, with an IC_{50} of 0.0036 μM (Fig. 25). PI-103 showed a potent in vitro antiproliferative effect on a range of cancer cell lines.[60] PI-103 still showed poor in vivo PK properties, such as high plasma and tissue clearance, and is now used as a tool compound.[49,61]

The crystal structure of p110α in complex with PI-103 has been solved and facilitates a better understanding of the interactions between PI-103 and PI3K (Fig. 26). The ATP-binding pocket is located in a cleft between the N- and C-terminal lobes of the kinase catalytic domain of p110α, similar to the ATP-binding sites in other protein kinases. PI-103 binds to the ATP-binding site on the p110α kinase domain. Three hydrogen bonds are formed between PI-103 and active site residues of p110α. The morpholine oxygen acts as hydrogen bond acceptor to the amide of the hinge residue Val851, explaining the importance of the morpholine substituent for activity. The hydroxyl group of the phenol makes hydrogen bonds to the carboxyl group of Asp810 and to the hydroxyl group of Tyr836. The pyridine ring extends out of the ATP-binding pocket toward solvent.[62]

A multiparameter lead optimization program to develop a drug candidate focused on improving the PK properties while maintaining inhibitory activity on PI3K and the related antiproliferative activity against cancer cells. Substitution with a methyl group in the 6-position of the thieno[3,2-*d*]pyrimidine was well-tolerated, while substitution with a methyl group at the 7-position showed a 2.6-fold decrease in potency. A range of substituents were introduced in the 6-position. The compounds PI-540 and PI-620 (Fig. 27) displayed similar potency to the unsubstituted compound **35** and showed improved in vitro stability in human liver microsomes (compound **35**: 32% remaining after 30 min incubation of 10 μM compound with 1 mg mL^{-1} human microsomes, PI-540: 85%, PI-620: 90%). Despite the encouraging improvement in microsomal stability, PK studies indicated low oral bioavailability of PI-540, **38**, and PI-620, **39**, of $\leq$10% in mouse and rat (based on 10 mg kg^{-1} IV and PO administration), which was mainly attributed to glucuronidation of the phenol group. To overcome this metabolic liability, bioisosters of the phenol group were explored.[63] A homology model of p110α suggested an interaction of the phenolic hydroxyl group with Asp810, as later confirmed in the crystal structure of PI-103, **37**, bound to p110α. Consequently the phenol group was replaced by heterocyclic groups that maintained the potential to act as a hydrogen donor.[62,63] The structurally similar PI3K selective inhibitor GDC-0941

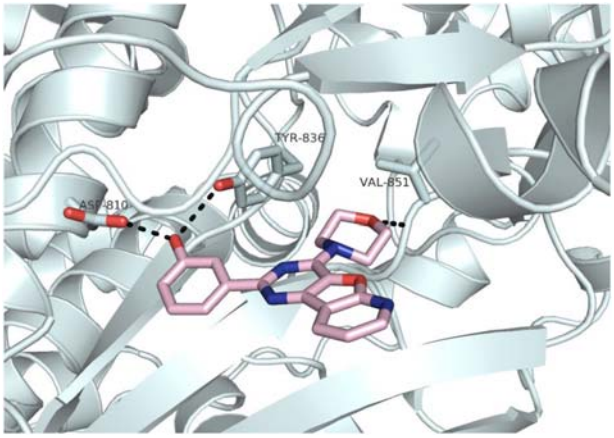

Fig. 26 X-ray crystal structure of p110α (*cyan*) complexed with PI103 (*light pink*), PDB ID: 4L23. The structure of the ligand PI103, and the key binding site residues are shown as sticks. Selected interactions are shown in *black-dashed lines*.

(Pitilisib, **40**) and the dual mTOR/PI3K inhibitor GDC-0980 resulted from this lead optimization program.[64] GDC-0980 is potent across a broad panel of cancer cell lines, with the greatest potency in breast, prostate, and lung cancers, and less potency in melanoma and pancreatic cancers. GDC-0980 has entered Phase I and/or Phase II clinical trials alone and in combination with rapalogs, platins, bevacizumab, abiraterone, and others, in solid cancers, non-Hodgkin lymphoma, breast cancer, prostate cancer, endometrial carcinoma, and renal cell carcinoma.[55,65]

5.07.2.3.2.2.1.2 BGT226 and BEZ235. The dual mTOR/PI3K inhibitor BEZ235, **29**, was generated by the structure-based design starting from a previously identified imidazo[4,5-*c*]quinoline, compound **41**. The imidazo[4,5-*c*]quinoline scaffold is considered a privileged scaffold for inhibiting the ATP-binding site of kinases. This chemotype can adopt different binding modes in the ATP-binding site, so either the quinoline nitrogen or one of the imidazole nitrogen atoms acts as a hydrogen bond acceptor with the kinase hinge region. The structural elements of the compound can then be exploited to reach unique regions of the

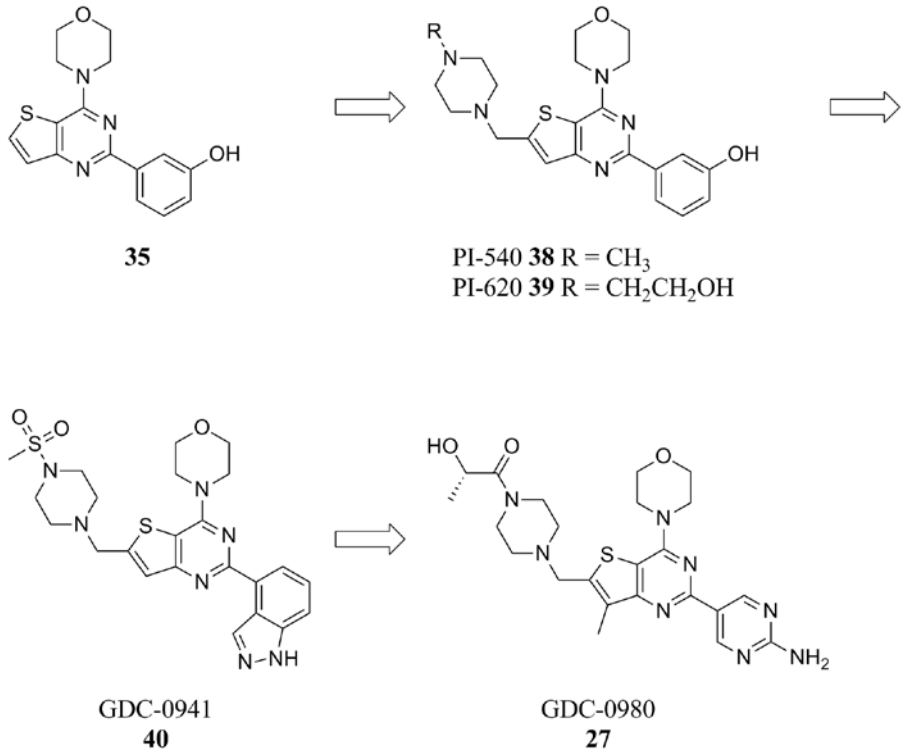

Fig. 27 Development of GDC-0980, **27**, from thieno[3,2-*d*]pyrimidine **25**.

active site of the targeted kinase, in order to achieve selectivity. Compound **41** was shown to be a potent inhibitor of PDK1 (3-phosphoinositide-dependent protein kinase-1, $IC_{50} = 34$ nM), and is also active against class I PI3K ($IC_{50} = 64$ nM for p110α, $IC_{50} < 450$ nM for the isoforms p110β, p110γ, and p110δ). Introduction of a methyl group at the 2-position of the imidazole ring resulted in a 1.5-fold improvement on the proliferation EC_{50} in U87MG (brain glioblastoma) cells, and a threefold increase in PDK1 IC_{50}. Replacing the cyanomethylene moiety, a potential metabolic weak spot, with a dimethyl cyanomethylene group resulted in a 4.4-fold increase in PDK1 IC_{50}, while retaining the effect on proliferation seen with compound **41**. Combining the dimethyl cyanomethylene group with a methyl substituent on the imidazole ring (compound **42**) improved the antiproliferation 2.9-fold. Further modification of compound **42** by changing the imidazole ring to *N*-methyl imidazolinone gave BEZ235 and resulted in further improvement in antiproliferative activity and complete loss of PDK1 inhibitory activity (Fig. 28). BEZ235 retained its activity against PI3K ($IC_{50} < 400$ nM for p110α, p110γ, p110δ, and $IC_{50} = 2.3$ μM p110β). The selectivity between PDK1 and PI3K was rationalized in docking studies, where the docking of compound **41** in the protein structure of ATP-bound PDK1 was compared to the docking of BEZ235 in the protein structure of staurosporine-bound PI3Kγ. These docking studies indicate that a carbonyl group in position-2 of the imidazole ring creates an electronic mismatch with the backbone carbonyl of Leu88 of the P-loop of PDK1. This repulsive interaction is not present in the PI3K active site, because the structural motif corresponding to the P-loop of protein kinases has a spatial arrangement where no residue matches the position of Leu88 in PDK1.[66]

In addition to PI3K inhibition, BEZ235 was also shown to inhibit mTOR activity in a kinase activity ELISA assay, and mTORC1 and mTORC2 kinase activity in immune-kinase assays. In contrast to the conventional PI3K inhibitors wortmannin and LY294002, BEZ235 showed strong antiproliferative activity in a panel of breast cancer cell lines. This antiproliferative effect has been proposed to be due to mTOR inhibition. BEZ235 was found more efficient than LY294002 in blocking AKT activation, again likely reflecting the synergistic inhibitory effects on PI3K and mTORC2. In vivo experiments also supported that mTOR inhibition contributes to the antitumor activity of the compound. In these in vivo experiments, BEZ235 displayed antitumor activity against U87MG (brain glioblastoma) and PC3M (prostate carcinoma) tumor xenografts. The observed effect on S473P-AKT levels correlated with the amount of compound present in the tumor tissue.[67,68]

BEZ235 was effective in preclinical studies as a single agent and in combination with other cancer drugs. It was investigated in several clinical trials of advanced solid tumors and metastatic breast cancer, as single agent or in combination with paclitaxel, trastuzumab, BKM120, or BKM162. The structurally similar compound BGT226 (Fig. 24), also developed by Novartis, was also investigated in clinical trials, but will not be developed further, since BEZ235 is more potent and bioavailable.[49,55]

5.07.2.3.2.2.1.3 Voxtalisib (XL765). Voxtalisib was developed as XL765 by Exelixis and was reported as the first oral dual PI3K/mTOR inhibitor with Phase I clinical trial results.[69] The medicinal chemistry underpinning the discovery of this compound has not been disclosed in the scientific literature so far.

5.07.2.3.2.2.1.4 PKI-587 (PF-05212384). The dual mTOR/PI3K inhibitor PKI-587 was developed from the original imidazolopyrimidine hit (**43**) in an extensive medicinal chemistry effort (Fig. 29). The original hit (**43**) showed high potency against PI3Kα (45 nM), and mTOR (634 nM), and was also active against PI3Kγ (1.1 μM). Replacing the imidazole ring with a triazole improved the activity against PI3Kγ (435 nM) and mTOR (250 nM), while retaining the activity against PI3Kα (83 nM). However, this new compound showed unfavorable physicochemical parameters and poor microsomal stability. The poor microsomal stability was attributed to the hydroxyl group as metabolic hot spot. Incorporation of a urea-substituent in pyrazolopyrimidines has been shown to increase metabolic stability and improve the potency against PI3K and mTOR. Hence, the 3-hydroxymethyl group on the 5-phenylsubsituent of **43** was replaced with a 4-urea group. A number of different urea substituents were explored on *N*-alkyl-7-morpholino-5-phenyltriazolo[4,5-*d*]pyrimidines, while also investigating the different *N*-alkyl groups on the triazole ring. The *N*-ethyl substituent was mostly found to be the best choice as triazole-substituent. A number of heteroaryl substituted urea

analogs were screened as phenyl-substituents. A balance between high potency in biochemical and cellular assays, physicochemical properties, and microsomal stability needed to be achieved. 2-Thiophene substituted urea analogs were highly potent against PI3Kα (2.5 nM), and mTOR (3 nM), as well as MDA-361 (breast adenocarcinoma, 81 nM), and PC3 (prostate carcinoma, 133 nM) cells but showed only modest microsomal stability ($t_{½}$ = 10 min in rat liver microsomes) and poor solubility at physiological pH (1 μg mL^{-1} at pH 7.4). 4-Pyridyl and 3-pyridyl substituted urea analogs retained potency and showed improved microsomal stability ($t_{½}$ = 27 and 19 min in rat liver microsomes). Introduction of a 4-(carboxamido)phenyl moiety in the urea appendage further improved the enzyme and cell potencies (PI3Kα IC_{50} = 2.4 nM, mTOR IC_{50} = 0.39 nM, MDA-361 IC_{50} = 28 nM, and PC3 IC_{50} = 65 nM) and retained microsomal stability ($t_{½}$ = 21 min in rat liver microsomes). Modeling studies of analogs docked in a homology model of PI3Kα based on PI3Kγ crystal structures indicated that the amide moiety is pointing away from the binding pocket toward the solvent. This position is consequently a suitable position to add substituents to improve solubility and/or metabolic stability, which should minimally impact on potency. In a screen of different amines, methylpiperazine emerged as the ideal group. The resulting compound PKI-402, **44**, showed further improvements in cell potencies (MDA-361 IC_{50} = 8 nM and PC3 IC_{50} = 21 nM) and good stability in mouse and human microsomes ($t_{½}$ = 15 min in rat liver microsomes, $t_{½}$ > 30 min nude mouse and human microsomes). PKI-402 showed in vivo efficacy in human xenograft models including MDA-361 (breast cancer), U87 (glioma), and A597 (nonsmall cell lung cancer). PKI-402 was Ames negative and selective for class I PI3K and mTOR. Selectivity was assessed in a panel of 236 human kinases, where no off-target activity (>50% inhibition) was detected at 10 μM. However, PKI-402 was not further pursued because of its poor solubility.[70]

In order to improve the low solubility of PKI-402, different scaffolds that resemble a pyrimidine core, but have lower clogP values than the triazolo[4,5-*d*]pyrimidine in PKI-402, were investigated. The 1,3,5-triazine scaffold was considered as particularly attractive. The 1,3,5-triazine resembles the pyrimidine ring and retains the position of the pyrimidine nitrogens. In addition, this ring allowed retention of the morpholine and phenylurea substituents that were essential for potency. The presence of the three

nitrogens in the 1,3,5-triazine core lowered the clogP values of the designed compounds to about 2 or lower. The morpholine moiety has been reported as essential for activity in several PI3K inhibitors, as the morpholine oxygen was hypothesized to form an essential hydrogen bond with Val851 in the hinge region of the PI3Kα binding pocket. However, the morpholine also presents a metabolic liability via oxidation in the α-position to the morpholine oxygen, causing loss of potency. In PKI-587, **31** (Fig. 29), a bismorpholine-1,3,5-triazine scaffold was envisaged to offer an advantage under conditions where one morpholine gets metabolized, still leaving intact the other morpholine to make the essential hinge region interaction. Different heterocyclic substituents on the urea were investigated. These compounds showed good potencies (PI3Kα $IC_{50} < 3$ nM, mTOR $IC_{50} < 2.3$ nM, PC3 $IC_{50} < 218$ nM) but low solubility at pH 7.4 (< 2 μg mL^{-1}). Compounds bearing a basic amino moiety with an amide linkage exhibited excellent potencies. On the basis of a well-balanced profile of encouraging potency (PI3Kα $IC_{50} = 0.4$ nM, mTOR $IC_{50} = 1.6$ nM, PC3 $IC_{50} = 13.1$ nM), and good solubility (14 μg mL^{-1}), clogP (1.2), microsomal stability and lack of Cyp inhibition, PKI-587 was chosen for further in vitro and in vivo evaluations. In vitro, tumor growth inhibition by PKI-587 correlated with suppression of phosphorylation of PI3K/mTOR signaling pathway proteins in MDA-361 cells. PKI-587 induced cleaved PARP at 30 nM, indicating apoptosis. In vivo, PKI-587 showed potent antitumor efficacy against MDA-361 tumors. PKI-587 is now investigated in several clinical trials against neoplasms, acute myeloid leukemia (AML), breast cancer, and metastatic colorectal cancer.

5.07.2.3.2.2.1.5 PF-04691502. PF-04691502 was developed from a hit from a high-throughput biochemical screen using mouse PI3Kα. Screening hits were tested for activity against mTOR and prioritized according to their ligand efficiency and kinase selectivity profile. A series of 4-methylpyridopyrimidones was chosen for further development. Compound **45** (Fig. 30), one of the early compounds, demonstrated potent activity against mouse PI3Kα ($K_i = 1.4$ nM), modest activity against mTOR ($K_i = 840$ nM), and high ligand efficiency ($LE = 0.48$).

The co-crystal structure of PI3Kγ, as surrogate of PI3Kα, with compound **45** bound into the ATP-binding site was solved (Fig. 30). The aminopyrimidine forms key interactions with the hinge residue Val882. Compared to protein kinases, PI3K has an additional amino acid residue in the hinge region, which results in a small hydrophobic pocket. The 4-methyl substituent of compound **45** fits tightly into this pocket, explaining the selectivity of compound **45** for PI3K over other kinases. As expected, the cyclopentyl substituent is positioned in the ribose binding pocket. The benzylic alcohol group is bound in the selectivity pocket, with the hydroxyl group coordinating to the Tyr867 side chain. Multiparameter optimization of compound **45** was based on physical properties-based optimization of multiple drug-like attributes, guided by structure-based drug design. Compound **45** displayed poor pharmacokinetic properties, such as high in vitro clearance. Design focused on replacing metabolic soft spots while maintaining or improving physical properties. The methyl group on the 2-amino substituent was identified as potential metabolic soft spot for dealkylation and was removed. SAR analysis of analogs indicated that the removal of the methyl group on the 2-amino substituent increased mTOR potency. This observation was supported by structural analysis of a homology model of mTOR derived from the PI3Kγ crystal structure. To address the clearance issues, the benzyl alcohol in compound **45** was replaced with isosteric groups that reduced clogP.[71] A low clogP was shown to correlate with low clearance and consequently higher metabolic stability.[72] Removing the methyl group on the 2-amino substituent and replacing the benzyl alcohol with methoxypyridine changed the clogP from 3.16 (compound **45**) to 2.7. The solubility of this compound was improved by structure-guided design. The compound **45** bound crystal structure of PI3Kγ was used to determine regions of the protein that could accommodate additional polarity. The cyclopentyl ring, binding in the ribose pocket, was identified as a potential target for the introduction of additional polar groups, such as alcohols. Replacing the cyclopentyl group with a cyclohexanol (compound **46**) improved solubility 4- (***trans*-46**) to 15-fold (***cis*-46**) while retaining excellent activity against PI3Kα and improving activity against mTOR. Plasma samples from in vivo rat and mouse PK studies of ***cis*-46** were found to contain significant amounts of ***trans*-46**. In in vivo experiments of ***trans*-46** small amounts

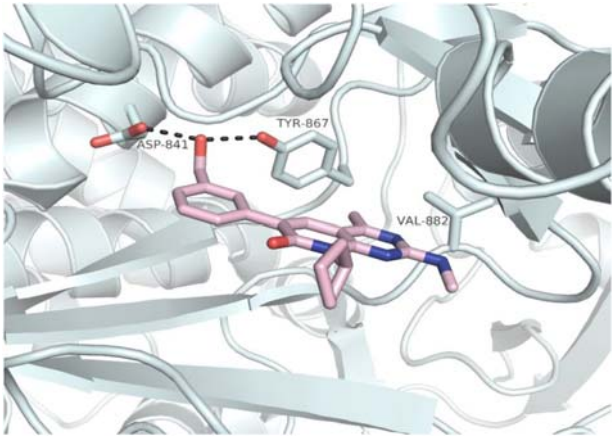

Fig. 30 Co-crystal structure of compound **45** (*light pink*) bound to PI3Kγ (*cyan*), PDB: 3ML8. The ligand structure and key binding site residues are shown as sticks. Selected interactions are shown in *black-dashed lines*.

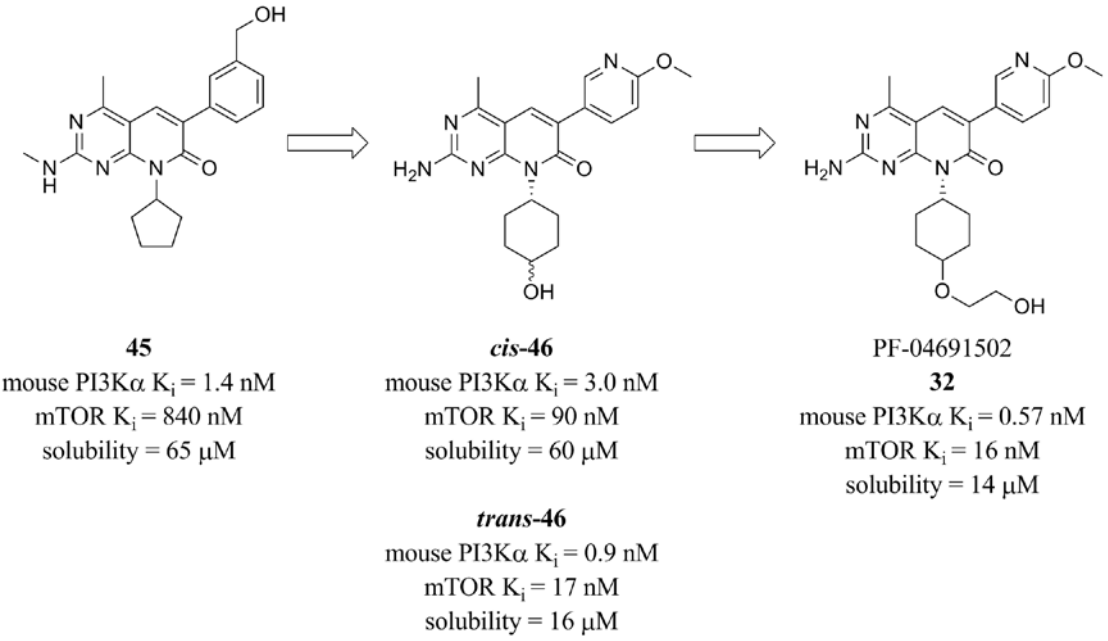

Fig. 31 Development of PF-04691502.

of *cis*-**46** were observed. It was hypothesized that the isomerization occurred by oxidation of the alcohol to the ketone, and subsequent reduction back to the alcohol, with *trans*-**46** being the major product isomer. To avoid potential in vivo isomerization, the hydroxyl group of the cyclohexanol was replaced, and a hydroxyethyl group was found to be the optimum group to give good overall properties (Fig. 31).[71]

PF-04691502 showed good selectivity for class I PI3K and mTOR. No significant inhibitory activity was observed in more than 80 protein kinases at concentrations of up to 10 μM. The cellular activity of PF-04691502 was characterized using tumor cell lines with a hyperactivated PI3K pathway, such as BT20 (breast cancer), SKOV3 (ovarian cancer), and U87MG (glioblastoma) cells. PF-04691502 exhibited good correlation between pharmacokinetics, target modulation, and efficacy in a U87MG xenograft model.[73] PF-04691502 has now been investigated in clinical trials against early breast cancer, breast neoplasms, endometrial neoplasms, and advanced cancer.

5.07.2.3.2.2.1.6 GSK2126458. GSK2126458, **33**, was developed as follow up compound to GSK1059615, **47** (Fig. 32), a dual PI3K/mTOR inhibitor that was investigated in a dose-escalation study in patients with solid tumors, metastatic breast cancer, lymphoma, and endometrial cancer. With the development of a second inhibitor, GSK intended to improve the potency, selectivity, and pharmacokinetic profile of the compound. Development of the compound relied on structure-based design based on the co-crystal structure of GSK1059615-bound PI3Kγ, as a surrogate of PI3Kα. The crystal structure of GSK1059615-bound PI3Kγ showed that the thiazolidinedione formed an interaction with the catalytic lysine (Lys833) in the ATP-binding pocket. The structure also indicated that the thiazolidinedione could potentially be replaced by larger groups and still fit into the binding pocket. Filling the empty space in the binding pocket could lead to inhibitors with improved selectivity and potency. Initial

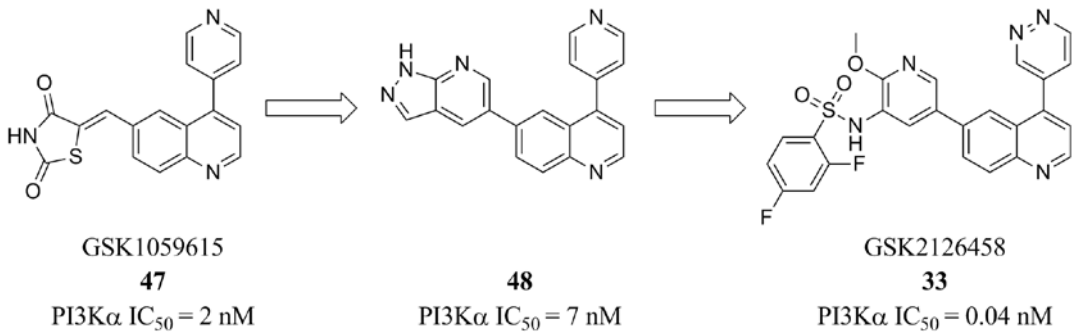

Fig. 32 Development of GSK2126458.

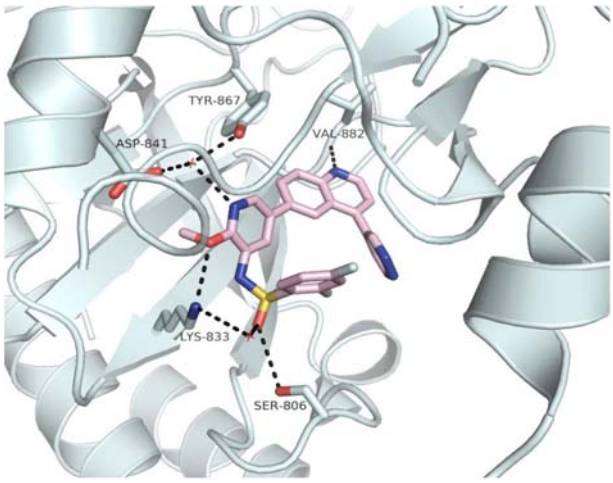

Fig. 33 Co-crystal structure of GSK2126458-bound PI3Kγ, PDB: 3L08. The ligand structure and key binding site residues are shown as sticks. Selected interactions are shown in *black-dashed lines*.

replacements of the thiazolidinedione by a phenyl ring and heterocycles resulted in a dramatic loss of activity. Molecular modeling overlays of different analogs indicated which heteroatoms were most likely to make interactions with the enzyme and aided in the design of a pyrazolo[3,4-*b*]pyridine as replacement of the thiazolidinedione (compound **48**, **Fig. 32**). A co-crystal structure of this compound with PI3Kγ was solved (PDB: 3L54) and confirmed that the nitrogen in 2-position of the pyrazole forms a hydrogen bond with Lys833 and that the pyridine nitrogen interacts with a conserved active site water molecule. Compound **48** showed promising activity; however, it displayed very low aqueous solubility and a poor PK profile, with high clearance, a short half-life, and a lack of oral bioavailability. Opening the pyrazole ring to give 2,3,5-trisubstituted pyridine analogs led to an aminopyridylsulfonamide that retained the potency of compound **48** and showed increased solubility. SAR investigations of the sulfonamide moiety showed that 2-aminoarylsulfonamides achieved oral exposure in rats, while retaining potency. Removing the 2-amino substituent increased exposure and reversal of the sulfonamide connectivity led to a further increase in biochemical and cellular potency, while maintaining the improved oral exposure. Finally, replacing the pyridine substituent in 4-position of the quinoline ring with a pyridazine gave GSK2126458 and resulted in an improvement in the CYP inhibition profile.[74]

GSK2126458 is an extraordinarily potent inhibitor of PI3Kα ($IC_{50} = 0.04$ nM) and more potent than other dual PI3K/mTOR inhibitors in clinical trials. A co-crystal structure of GSK2126458-bound PI3Kγ (**Fig. 33**) shows that the compound binds in the ATP-binding site of the protein. The pyridine nitrogen forms a key hydrogen bond with the conserved water molecule. The sulfonamide interacts with Lys833. The difluorophenyl group fills a hydrophobic region in the back pocket of the enzyme, while the quinoline nitrogen forms a hinge interaction with Val882. GSK2126458 showed excellent selectivity over protein kinases (>10,000-fold over 240 kinases), with the exception of the class IV PI3K family, including mTOR. The PK profile of GSK2126458 was studied in four preclinical species and the compound showed low blood clearance and good oral bioavailability. Efficacy was observed in BT474 (breast cancer) human xenograft models. GSK2126458 is under evaluation in clinical trials against solid tumors and idiopathic pulmonary fibrosis.[74]

5.07.2.3.2.2.1.7 SF1126. SF1126 is a prodrug developed by Semafore and consists of the nonselective PI3K inhibitor LY294002 conjugated to a RGDS peptide fragment. LY294002 is known to inhibit a number of proteins at the concentrations used to inhibit PI3K and is limited by its poor solubility and short half-life. The prodrug SF1126 was designed to improve solubility and to bind specific integrins in the tumor compartment, resulting in improved delivery of the compound to the tumor. SF1126 was tested in a dose-escalation study in patients with advanced solid tumors and was well-tolerated. In 2010, SF1126 was granted orphan drug status by the FDA for the treatment of B-cell chronic lymphocytic leukemia.[75] SF1126 is also investigated in clinical trials for patients with relapsed or refractory neuroblastoma and metastatic squamous neck cancer.

5.07.2.3.2.2.2 Pan-mTOR inhibitors (mTORC1/mTORC2 dual inhibitors)

Pan-mTOR inhibitors inhibit both mTOR complexes and are characterized by an IC_{50} for mTORC1 and mTORC2 that is significantly lower than that for PI3K. A number of pan-mTOR inhibitors are now investigated in clinical trials (**Fig. 34**), however only limited information on their development is available in the scientific literature.[49]

The first pan-mTOR inhibitor reported was PP242. PP242 was found in a screen of tyrosine kinase inhibitors. The primary goal of the screen was to identify molecules that inhibit both tyrosine kinases and PI3Ks. However, in this screen compounds with unexpected selectivity profiles were discovered. In particular, in the pyrazolo[3,4-*d*]pyrimidine scaffold small changes in structure produced considerable alterations in selectivity. One of the compounds displaying an unexpected selectivity profile was PP242. PP242 showed high potency against mTOR ($IC_{50} = 8$ nM), but was much less active against other PI3K family members

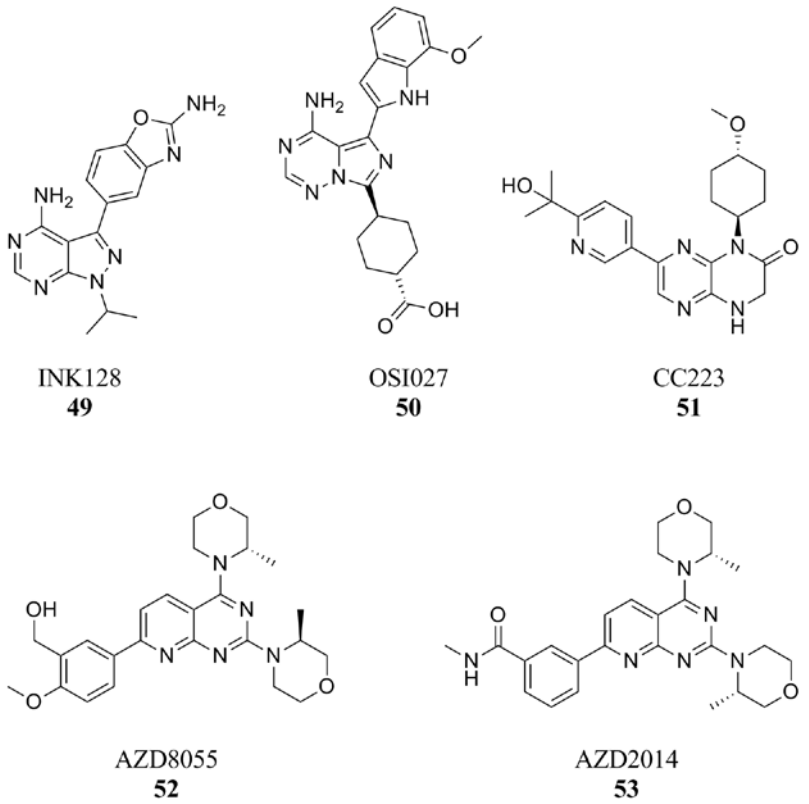

Fig. 34 Overview of pan-mTOR inhibitors in clinical trials.

(PI3Kα, PI3Kβ, PI3Kγ $IC_{50} = 1.3–2.2$ μM; PI3Kδ $IC_{50} = 0.1$ μM). PP242 was tested against 219 protein kinases and revealed remarkable selectivity. At a concentration above 100-fold its IC_{50} for mTOR, PP242 inhibited only one kinase by more than 90% (Ret) and three by more than 75% (PKCα, PKCβII, JAK2, and V617F).[76] PP242 was further developed into INK128 (MLN0128) (Fig. 34), which has been investigated in clinical trials against a number of cancers, including nonsmall cell lung cancer (NSCLC), nonhematologic malignancy, hepatocellular carcinoma, glioblastoma, gliosarcoma, advanced solid malignancies, metastatic breast cancer, and thyroid cancer.[49]

CC223, **52**, and OSI027, **50**, are both dual inhibitors of mTORC1 and mTORC2. The discovery and subsequent medicinal chemistry optimization of these compounds has not been disclosed in the scientific literature. CC223 has been in clinical trials in healthy adults to investigate the metabolism and excretion of CC223, the effect of food on the pharmacokinetics, and drug–drug interactions with ketoconazole. CC223 has also been in safety, pharmacokinetics, and efficacy studies in patients suffering from MM, diffuse large B-cell lymphoma, glioblastoma, hepatocellular carcinoma, nonsmall lung cancer, and others.[77] OSI027 is a selective dual inhibitor of mTORC1 and mTORC2. Biochemical, cellular, and in vivo evidence has been presented that indicates OSI027 is mechanistically and functionally distinct from rapamycin. The antitumor efficacy of OSI027 was evaluated in PIK3CA mutant SKOV3 and KRAS mutant OVCAR5 human ovarian cancer xenograft models. The compound has been investigated in clinical trials in solid tumors and lymphomas.[78]

5.07.2.3.2.2.2.1 AZD8055 and AZD2014. The clinical candidates AZD8055 and AZD2014 were developed from a HTS hit. Inhibition of mTOR kinase was determined in an ELISA-based assay using full-length mTOR with a recombinant 4EBP1 protein substrate and ATP. A pyrido[2,3-*d*]pyrimidine, compound **54** ($IC_{50} = 1.0$ μM, Fig. 35), was chosen as starting point for further medicinal chemistry development. The positioning of the nitrogen in the pyridine ring was essential for activity. The substituents in the 2- and 4-positions were considered for modifications. However, the morpholine substituent in the 4-position is a well precedented motif in PI3K inhibitors, where the morpholine oxygen is involved in a key hydrogen bond interaction in the ATP-binding site of PI3Kγ. By analogy, it was assumed that the morpholine substituent may be involved in a hydrogen bond interaction with Val133 in the hinge region of the mTOR kinase domain. Indeed, replacement of the morpholine by a piperidine, and thereby replacing the oxygen with a carbon, gave a significant reduction in potency. Introducing an additional carbon into the morpholine ring, by replacing the morpholine with 1,4-oxazepane, results in a change of geometry and caused a sevenfold reduction in potency. The original hit, compound **54**, had a racemic 2-methylpiperidine substituent in the 2-position. Investigation of the preferred absolute stereochemistry of the methyl substituent showed a slight improvement in potency for (*S*)-**54** over (*R*)-**54**. In general, substitution on the piperidine was well-tolerated without significant loss of potency.

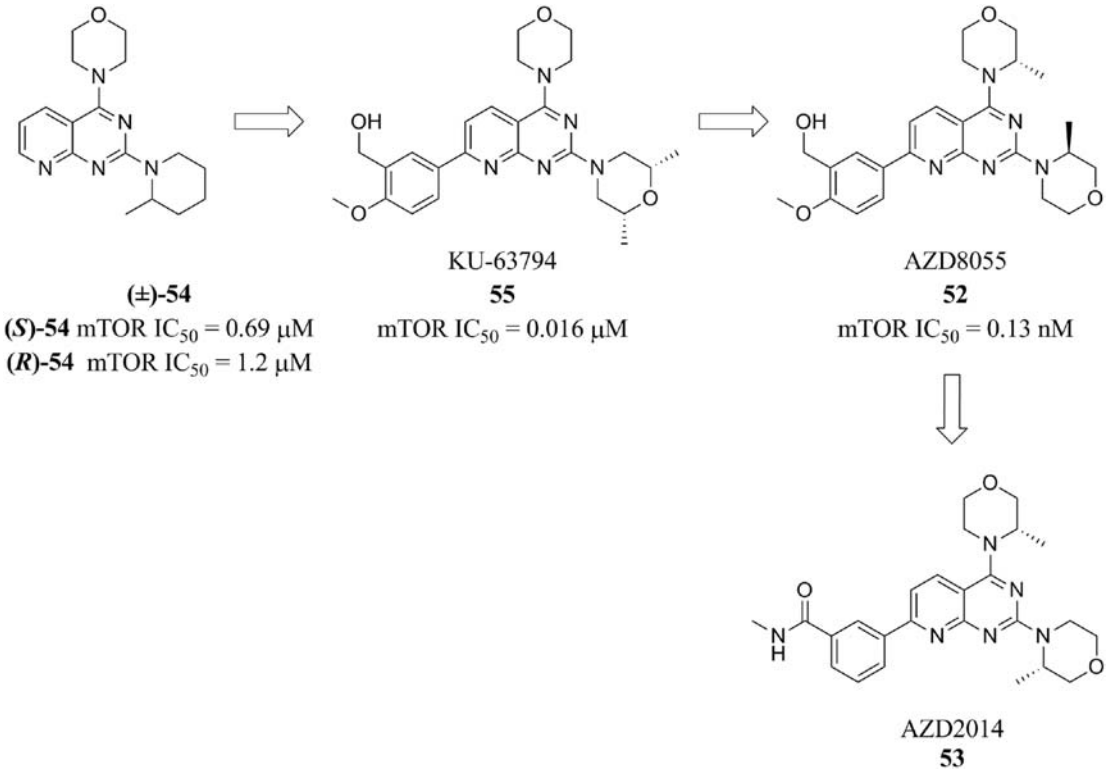

Fig. 35 Development of AZD2014.

To reduce the lipophilicity of the molecule, the piperidine was then replaced by a morpholine. An unsubstituted morpholine in the 2-position led to a dramatic loss in potency, however potency was regained by re-establishing the methyl substituents at the 2- or 3-positions of the morpholine.[79]

Docking studies using an homology model of mTOR based on a crystal structure of PI3Kγ suggested that substituents in the 7-position of the pyrido[2,3-*d*]pyrimidine could access additional space within the ATP-binding site. For the investigations of substituents in the 7-position, the dimethyl-substituted morpholine at the 2-position of the pyrido[2,3-*d*]pyrimidine was chosen, as this compound showed a good balance of potency and lipophilicity. A number of aromatic amino substituents and directly bonded aromatic or heteroaromatic substituents resulted in improved potencies. SAR around substituted analogs of a 7-phenyl substituent showed that electron-donating substituents (hydroxyl, methoxy) in the *para*-position were well-tolerated. A hydroxyl-substituent in the *meta*-position showed similar activity to the corresponding *para*-substituted analog, while for the *meta*-methoxy-substituent a 10-fold decrease in activity was observed. In this case, the presence of a hydrogen bond donor rather than an electron-donating substituent was crucial. Combining an electron-donor in the *para*-position with a hydrogen bond donor in the *meta*-position gave KU-63794, **55**. This compound showed a further increase in potency ($IC_{50} = 0.016$ μM). KU-63794 showed good selectivity over PI3K family members ($IC_{50} = 8.3$ μM for PI3Kα, >5 μM for PI3Kδ, >30 μM for PI3Kβ and PI3Kγ). No significant activity was found against a range of 200 non-PI3K related kinases at a concentration of 10 μM.[79]

Potential limitations for the clinical development of KU-63794 were its relatively low aqueous solubility (2.4 μM) and relatively high potency against the hERG ion channel ($IC_{50} = 8.3$ μM). Consequently, further optimization efforts focused on identifying highly selective compounds with increased cellular potency, improved aqueous solubility, and an improved margin to the hERG IC_{50}. A commonly used strategy to improve aqueous solubility is the introduction of a basic amine. Substituents on the 7-phenyl ring were previously found to be well-tolerated. Replacing the benzyl alcohol with a range of secondary benzyl amines gave a dramatic improvement in solubility (>1000 μM, compared to 2.4 μM for KU-63794) and a reduction in hERG potency, while mTOR inhibition improved in several analogs. Despite improved cellular potency and solubility, little oral exposure was observed, presumably due to compromised permeability and higher efflux. The 4-morpholine substituent was previously found to be essential for activity. However, replacing the morpholine with a thiomorpholine improved cellular potency. A number of analogs were investigated and consistent improvement in cellular potency and solubility was observed. The substituent in position 2 could be a wide range of cyclic and acyclic amines and aromatic substituents. When assessing the overall balance of properties, AZD8055, retaining the substituent in position 7, and bearing 3-methyl morpholine substituents in the 2- and 4-positions, was selected for preclinical development. AZD8055 is a potent inhibitor of mTOR kinase ($IC_{50} = 0.13$ nM) and displays high selectivity against other members of the PI3K family ($IC_{50} > 3$ μM against PI3Kαβγδ) and was inactive against a general panel of 200 kinases when tested at 10 μM. AZD8055 inhibits both mTORC1 and mTORC2 in cells with similar potencies and has been shown to

modulate substrates of both mTORC1 and mTORC2 in vivo. Dose-dependent tumor growth inhibition in U87-MG glioblastoma tumor xenografts was observed. AZD8055 also resulted in significant inhibition of tumor growth and/or regression in breast, lung, colon, prostate, and uterine xenograft models. AZD8055 was evaluated in clinical trials to assess the safety, tolerability, and pharmacokinetics in cancer patients and was also investigated in clinical trials in adults with recurrent gliomas and solid tumors, but is no longer in clinical development.[80,81]

AZD8055 was found to exhibit high turnover in human hepatocytes (36.4 μL min^{-1} per 10^6 cells) and showed lower bioavailability in rat (12%) than in mouse (81%). The benzyl alcohol and aryl-methoxy group on the phenyl substituent on C7 was postulated to be potential metabolic liabilities. Further medicinal chemistry development concentrated on reducing these metabolic liabilities. A primary amide was found to be an appropriate replacement of the benzyl alcohol. Aqueous solubility was further increased to >690 μM, compared to 30 μM for AZD8055. However, the rate of human hepatic turnover remained high. Methyl-substitution on the amide reduced the rate of turnover in human hepatocytes 2.6-fold, but also reduced aqueous solubility. Further reduction in hepatic turnover was achieved for the tertiary amide, however this substitution led to an inacceptable reduction in potency. Strategies to reduce potential metabolism of the methoxy group, including difluorination of the methoxy group or cyclization to give a quinazoline, did not reduce hepatic turnover. Removal of the methoxy group resulted in a compound AZD2014 with good cellular potency and low hepatic turnover (<4.2 μL min^{-1} per 10^6 cells). AZD2014 showed excellent aqueous solubility (>600 μM) and a good margin over the hERG IC_{50}. AZD2014 is now investigated in clinical trials as single agent and in combination with various other cancer medications, such as paclitaxel, ibrutinib, palbociclib, fulvestrant, and abiraterone.[80]

5.07.2.3.2.2.3 Other mTOR inhibitors

WYE132 (Wyeth) was developed from a hit from a high-throughput screen against recombinant mTOR. The original hit compound WAY001 showed sixfold higher potency against PI3Kα than mTOR. Further development led to the compounds WAY600, WYE354 and WYE687 and ultimately WYE132 (**56**, Fig. 31), which displays 5000-fold greater selectivity for mTOR over PI3K. WYE132 showed antitumor activity against MDA361 breast, U87MG glioma, A549 and H1975 lung, and A498 and 786-O renal tumors. Co-administration of WYE132 with bevacizumab achieved regression of MDA361, A498, and A549 tumors.[82]

Torin1 (**57**, Fig. 36) is a potent and selective mTOR inhibitor in vitro and in vivo. Torin 1 is limited by the low yielding synthetic route, its poor aqueous solubility, short half-life, and low oral bioavailability. Medicinal chemistry development of Torin 1 resulted in the discovery of Torin 2 (**58**). Torin 2 retains potency and selectivity of Torin 1 but is easier to produce on scale and shows improved pharmacokinetic properties.[83]

Besides ATP-competitive inhibitors, indirect mTOR inhibitors have been proposed. Metformin, an antidiabetic drug, inhibits mTORC1 and displays a strong antiproliferative effect in a range of cancer cell lines in vitro and in in vivo xenograft models. A number of clinical trials to investigate metformin as single agent or in combination with drugs including vandetanib, simvastatin, placlitaxel, sorafenib, and cisplatin are ongoing.[49]

5.07.2.3.2.3 MNK inhibition

Mitogen-activated protein kinase (MAPK)-interacting serine/threonine protein kinase (MNK) inhibition prevents MNK-mediated signaling and inhibits the phosphorylation of certain regulatory proteins, including eIF4E, that regulate the translation of mRNAs involved in tumor cell proliferation, angiogenesis, survival, and immune signaling. MNK1 and MNK2 are overexpressed in a variety of tumor cells and modulate the function of eIF4E through phosphorylation of a conserved serine (Ser209). This phosphorylation event is necessary for oncogenic transformation, but seems to be dispensable for normal development. Consequently, MNK inhibitors may provide a strategy for anticancer therapeutics.[84] An orally administered inhibitor of MNK1 (BAY1143269) has been developed by Bayer. Neither a structure of the inhibitor nor biological studies have yet been disclosed. The compound is currently under investigation in a Phase I dose-escalation and expansion studies in combination with docetaxel. An orally bioavailable inhibitor of MNK1 and MNK2, eFT508 was developed by eFFECTOR Therapeutics. Again, neither a structure of the inhibitor

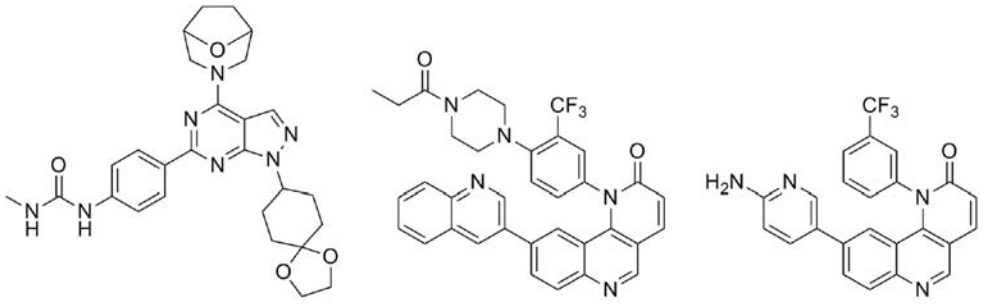

Fig. 36 Chemical structures of mTOR inhibitors.

nor biological studies have yet been disclosed. eFT508 is also currently investigated in Phase I clinical trials, with a dose-escalation and cohort-expansion study in patients with advanced solid tumors.

5.07.2.3.3 Direct inhibitors of eIF4F

Protein expression is controlled at the level of translation primarily through the activity of eIF4E, which is frequently upregulated in tumors. Antisense oligonucleotides (ASOs) targeting eIF4E synthesis showed promising antitumor activities. These ASOs act by reducing eIF4E levels. The antisense oligonucleotide LY2275796 (ISIS183750) was investigated in a Phase I dose-escalation, pharmacokinetic, and pharmacodynamics evaluation and subsequently in a Phase I/II study in combination with irinotecan in irinotecan-refractory colorectal cancer.[85] The antisense oligonucleotide ISIS eIF4E Rx by Ionis Pharmaceuticals has been investigated in safety and tolerability studies in combination with carboplatin, paclitaxel, docetaxel, and prednisone.

Other direct inhibitors of the translational machinery target the eIF4E–cap interaction or inhibit the eIF4E–eIF4G interaction. The ability of eIF4E to cause neoplastic transformation depends on its cap-binding activity. Cap analogs have been used in in vitro studies of eIF4E function, but suffer from poor permeability and stability in vivo. To overcome this limitation, prodrugs or drug delivery using virus-like particles have been explored. A high-throughput screen identified 4EGI-1 (**59**, Fig. 37) as an inhibitor of the eIF4E–eIF4G interaction.[44,86] 4-EGI-1 was shown to directly bind eIF4E by nuclear magnetic resonance (NMR) spectroscopy.[87] 4E1RCat (**60**) and 4E2RCat (**61**, Fig. 37) were found similarly. These compounds downregulate the translation of eI4E-sensitive mRNAs. Disrupting the eIF4E–eIF4G interaction was also achieved by fusion of 4EBPs to the ligand of a cancer-specific cell surface receptor. These approaches of inhibiting the eIF4E–eIF4G interaction have shown promise in preclinical models.[44,86]

The natural products hippuristanol, pateamine A, and silvestrol were initially shown to have strong tumor cell line-specific cytotoxic properties. These compounds were then shown to bind eIF4A in in vitro assays and to affect eIF4A activity. Pateamine A is an irreversible inhibitor of protein synthesis, and was consequently very toxic in vivo. Hippuristanol suffers from poor solubility and low potency. Silvestrol is at present the best studied eIF4A inhibitor and has been investigated in cancer cell xenograft models and oncogene-derived genetic mouse models. In several cases, silvestrol caused tumor regression.[88]

5.07.2.3.4 Inhibitors of ternary complex formation

Although the biochemistry of ternary complex formation and activity is well studied, understanding of the role of the ternary complex in cancer biology and its potential for exploitation as an anticancer target is limited.

5.07.2.4 Summary

Targeting oncogene addiction by inhibiting protein synthesis in cancer cells has great potential in cancer therapy. New targets will continue to emerge as our understanding of the mechanisms of gene transcription and mRNA translation improves, allowing medicinal chemists to generate molecules that more selectively control the synthesis of key oncogenic proteins. There remains an important role for general protein synthesis inhibition, especially as drug delivery techniques improve, helping to increase the therapeutic index of compounds that were previously too toxic to use. Also, our greater understanding of genetic signatures of cancer will allow us to direct compounds to those patients who will see the greatest benefit and with our improved understanding of the role of polypharmacology in the efficacy of cancer drugs, the balance between safety and efficacy can be more rationally addressed.

5.07.3 Targeting Protein Folding

5.07.3.1 Introduction to Molecular Chaperones

The cell is a molecularly crowded environment with a very high total concentration of key macromolecules such as proteins. Estimations of the total concentrations of macromolecules within the cell are in the range of 400 g dm^{-3} meaning that around 5–40% of the total volume of a cell is physically occupied by these important molecules.[89] This is very different from the situation commonly encountered in the laboratory setting where dilute solutions of macromolecules are routinely studied. This high concentration puts a particular strain on the functional macromolecules in a cell and evolution has developed mechanisms for ensuring that proteins can maintain their form and function even under such physically challenging conditions.[90] One of the key mechanisms involved in protein quality maintenance is the heat shock response. This was originally discovered as a response to raising the temperature of organisms and involves the expression and engagement of a range of proteins known as chaperones or heat shock proteins (HSPs).[91] It is now widely recognized that when mammalian cells are exposed to a variety of physiological stresses, including heat, cytotoxic drugs, UV radiation, hypoxia, low pH, or heavy metals, heat shock transcription factor 1 (HSF1) is released from an inhibitory complex with HSP90, trimerizes and binds to the heat shock response element within the promoter regions of *HSP* genes leading to an increased expression of a range of HSPs.[92] This is a vital part of the cell's effort to maintain homeostasis and cell survival.

HSPs are classified into two groups; the high molecular weight HSPs such as HSP90, HSP70, HSP60, and the small HSPs such as HSP27 and αB-crystallin. The key distinguishing feature between these two groups of HSPs is that the high molecular weight chaperones bind ATP and function through an ATPase-mediated mechanism involving a number of co-chaperones, whereas the low molecular weight HSPs do not bind ATP or act as ATPases.

5.07.3.2 HSP70 Inhibitors

There are 13 different genes coding for proteins of the HSP70 family leading to a wider number of isoforms compared to HSP90. The main isoforms are HSC70, which is constitutively expressed; HSP72, which is expressed in response to stress; GRP78 (also known as BiP), which is localized in the endoplasmic reticulum; GRP75 (also known as mortalin), which is localized in the mitochondria. The structure of the HSP70 family shares some similarity to the HSP90s with an N-terminal domain that contains the ATP-binding pocket, a substrate-binding domain, and a C-terminal domain that consists mainly of alpha helices and acts as a "lid" that closes over the bound substrate. The substrate-binding domain contains a hydrophobic groove with sufficient space to bind peptides up to seven residues long. The HSP70s execute their refolding in a similar manner to HSP90 by using the hydrolysis of ATP to ADP.[93] In contrast to the ATP-binding pocket of HSP90, the ATP-binding pocket of HSP70 belongs to the actin ATPase class of proteins[94] which depends heavily on interactions involving the phosphates of the cofactor and as such has delivered little success in finding high affinity ligands.[95] The nature of the ATP-binding pocket also leads to a much tighter binding for ATP/ADP (IC_{50} = 1.2 μM and 670 nM, respectively, in a fluorescence polarization assay) than is the case for HSP90.[96] This requires the involvement of a nucleotide exchange factor, BAG1, to enable release of ADP and catalytic turnover. A recent study has described the binding site as difficult to antagonize with small molecules[97] and a fragment screening campaign returned a very low (0.4%) hit rate indicative of poor ligandability.[98] As a consequence, there has been a variety of chemical tool compounds reported as HSP70 inhibitors but with limited evidence of actual stoichiometric and specific binding to HSP70. A detailed investigation of the reported inhibitor apoptozole has shown that it fails to bind in a specific manner to HSP70 by both SPR and fluorescence polarization, and dynamic light scattering experiments demonstrated aggregation at very low concentrations. This followed a report that the HSP70 inhibitor phenylethynesulfonamide (PES) interacts with the substrate-binding domain of HSP70 in a nonspecific manner.[99] Recently, a covalent inhibitor, novolactone has been characterized which binds between the substrate-binding domain and the ATP-binding site via residue Glu444.[100] Novolactone inhibits both the HSP40-stimulated ATPase activity and refolding activity of HSP70 by inducing a conformational change in the HSP70 protein.

The only compounds that have been shown unequivocally to bind at the ATP-binding site resulted from work at Vernalis in Cambridge. In 2009, they revealed a series of nucleoside analogs based on the structure of ATP.[101] They carried out a "fragment-type" of approach in which they started from adenosine **62** as a fragment of ATP and using a fluorescence polarization assay showed that adenosine **62** binds with an IC_{50} = 560 μM (Fig. 38). The key advance was to recognize that 8-aminoadenosine **63** was 60-fold more potent (IC_{50} = 9.4 μM) and that HSC70 in complex with BAG-1 gave crystals suitable for a structure-based design approach. 8-Aminoadenosine **63** demonstrated potent cell activity, but its biochemical potency and biomarker modulation indicated that this was largely due to off-target effects. Elaboration of the amino group led to 3,4-dichlorobenzyl analog **64** which was equipotent in the biochemical assay (IC_{50} = 9.1 μM) but much less potent in a cell-based assay (GI_{50} = 26 μM in HCT116 colon cancer cells), indicating that previous off-target activity had been reduced. Importantly, a ligand/protein crystal structure of **64** bound to HSC70/BAG-1 (Fig. 39A) showed a key π-stacking interaction of the dichlorophenyl ring with Arg272. This structure also suggested the possibility of growing from the 5′-hydroxy group of the ribose to generate a similar interaction with Tyr15 on the opposite side of the binding site cleft. Several benzyl ethers at the 5′-hydroxyl group were made and tested and the best balance of biochemical potency and cell-based potency was achieved with compound **65** (VER155008) carrying a *p*-cyanobenzyl ester at this position (IC_{50} = 0.5 μM; GI_{50} = 5 μM in HCT116). Although some derivatives possessed marginally improved biochemical IC_{50} values, none showed the same level of cellular activity as **64**. An X-ray structure of **65** (VER155008) bound to HSC70/BAG-1 showed the predicted interaction with Tyr15 and, additionally, an intramolecular hydrogen bond between the 8-amino NH and the 5′-ether

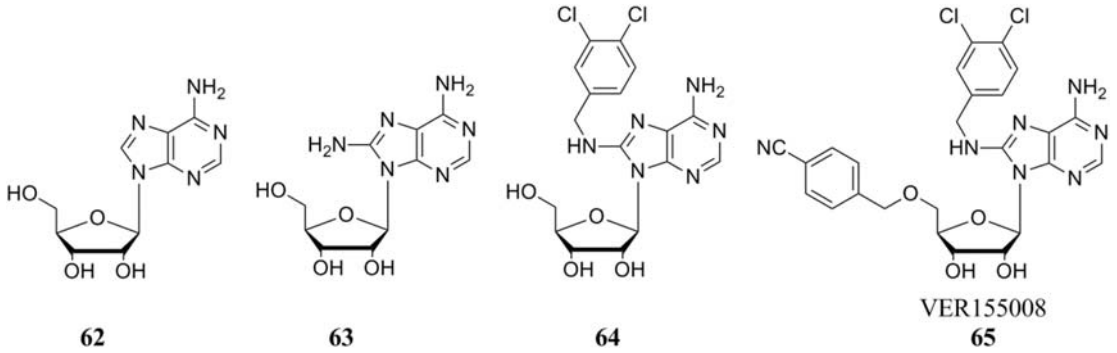

Fig. 38 Chemical structures of Vernalis HSP70 inhibitors **62**, **63**, **64**, **65**.

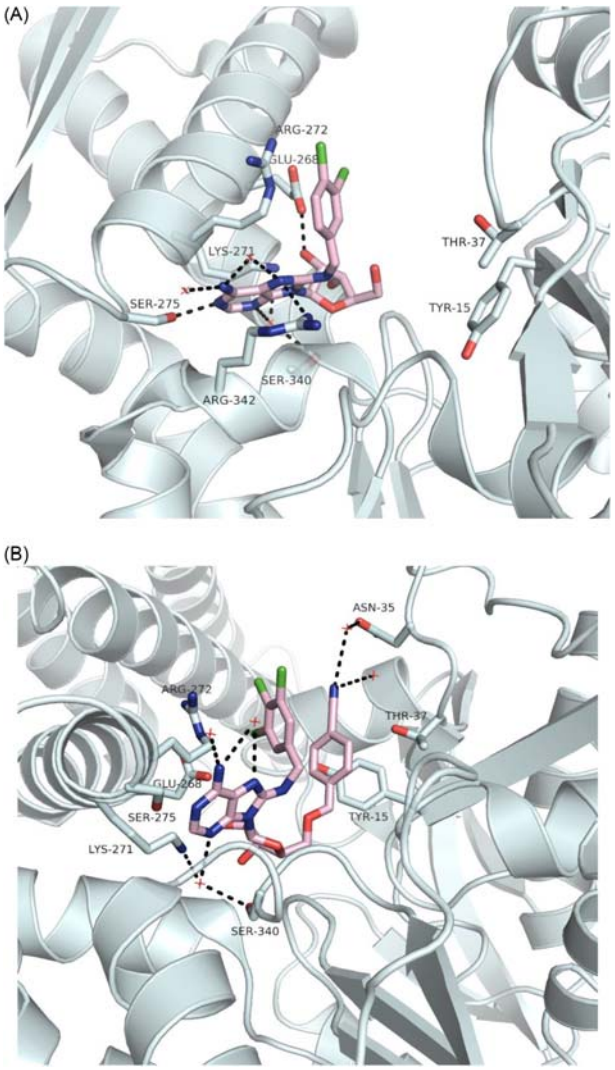

Fig. 39 (A) X-ray structure of **64** (*light pink*) bound to HSC70/BAG-1 (*cyan*), PDB: 3FZK and (B) X-ray structure of **65** (*light pink*) bound to HSC70/BAG-1 (*cyan*), PDB: 3FZW. The structure of the ligand, and the key binding site residues are shown as sticks. Selected interactions are shown in *black-dashed lines*.

oxygen that may contribute to increased potency (Fig. 39B). Exposure of HCT116 colon cancer cells to compound VER155008 led to reduction of cellular levels of HER2 and RAF-1 at concentrations only a little higher than the GI_{50} in agreement with siRNA studies. Although VER155008 was further investigated in cellular experiments,[102] it demonstrated rapid metabolism and clearance unsuitable for progression to in vivo animal model studies.

Vernalis continued development and exploration of these compounds as inhibitors of the endoplasmic reticulum isoform GRP78 but found little selectivity for either isoform except with some simpler versions which demonstrated around a fivefold selectivity for HSP70 over GRP78.[103] The only amino acid change in the ATP-binding pocket in GRP78 is replacement of Thr37 in HSP70 with Ile61 in GRP78 generating a slightly more hydrophobic binding site in GRP78. However, this is probably outweighed by the flexibility of this particular binding pocket that presents a real challenge to finding potent, drug-like compounds. A recent paper has highlighted this issue but also focused attention on a key salt bridge between Glu268 and Lys56 at the top of the binding cleft of HSP70.[104] This work started with the antibiotics sangivamycin ($K_d = 3.3$ μM) and toyocamycin ($K_d = 90$ μM) and carried out a careful analysis of factors leading to potency, identifying desolvation of the salt bridge with suitably placed hydrophobic groups as a key route to a closed conformation and potent binding.

5.07.3.3 HSP90 Family

The most significant of the HSPs is HSP90 which consists of a family of HSPs of around 90 kDa in molecular weight. It is the most abundant of all cellular proteins accounting for 1–2% of all proteins and it is highly conserved in both prokaryotes and eukaryotes.[105] It plays a key role in the proper folding, activation, and stabilization of cellular proteins and targets damaged proteins for either refolding or for ubiquitin-mediated proteasomal degradation.[106] There are four isoforms of HSP90; HSP90α and HSP90β both of which are cytosolic and found in all eukaryotes, GRP94 (glucose-regulated protein 94 kDa) that is expressed in the endoplasmic reticulum and TRAP1 (tumor necrosis factor receptor-associated protein 1) that is expressed in the mitochondria.

The HSP90 monomer consists of three domains; an N-terminal ATP-binding domain (25 kDa), a middle domain (35 kDa), and a C-terminal dimerization domain (12 kDa).[107] Clear proof of the role of the nucleotide-binding domain (NBD) was obtained in 1997 when the X-ray crystal structure of the HSP90 N-terminal domain with ADP bound was published (Fig. 40).[108] The ATP-binding pocket of HSP90 is an example of the unusual Bergerat fold class of ATP-binding site that is found in the GHKL (Gyrase, HSP90, Histidine kinase, MutL) family of ATP-binding proteins.[95] Subsequent work by the Pearl group demonstrated that an ATPase cycle drives a molecular "clamp" mechanism which is crucial for the chaperoning function of HSP90.[109] However, the engagement of HSP90 with client proteins and the fine-tuning of the chaperoning cycle are mediated by a set of co-chaperones as shown in Fig. 41.[110] In addition to chaperones HSP40 and HSP70, a variety of co-chaperones have been implicated in various aspects of the HSP90 machinery. AHA1 (activator of HSP90 ATPase 1) has been shown to activate the ATPase activity of HSP90 and hence controls the efficiency of the HSP90 cycle.[111] CDC37 (cell-division cycle 37 homologue) has been shown by structural and biochemical studies to be involved in the chaperoning of kinase clients.[112] There is evidence that transcription factor clients are delivered by the protein HOP (HSP70–HSP90 organizing protein).[113]

The list of HSP90 client proteins continues to grow and numbers several hundred proteins (https://www.picard.ch). These include a number of key, oncogenic kinases such as BCR-ABL, ERBB2, ALK, BRAF, CRAF, AKT, and CDK4. Additionally, a number of TFs have been shown to be clients, for example, the androgen and estrogen receptors. As might be expected from its range of client proteins, HSP90 has been reported to be overexpressed in both solid tumors and hematological cancers.[114] HSP90 expression levels have been shown to be associated with decreased survival in breast cancer, gastrointestinal stromal tumors (GIST), and NSCLC.[115] It

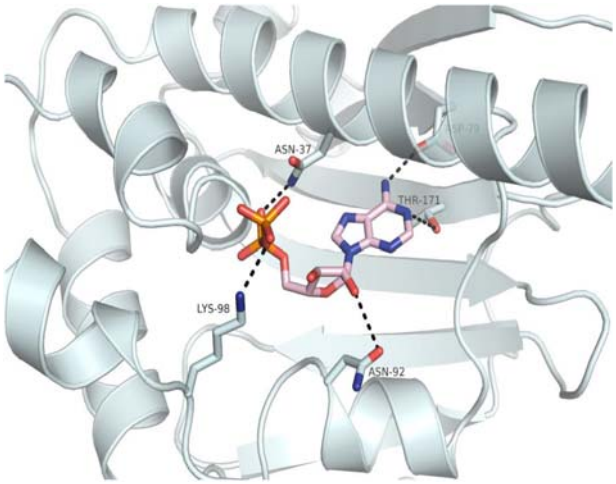

Fig. 40 X-ray crystal structure of the HSP90 NBD (*cyan*) in complex with ADP (*light pink*), PDB: 1AM1. The structure of the ligand, and the key binding site residues are shown as sticks. Selected interactions are shown in *black-dashed lines*.

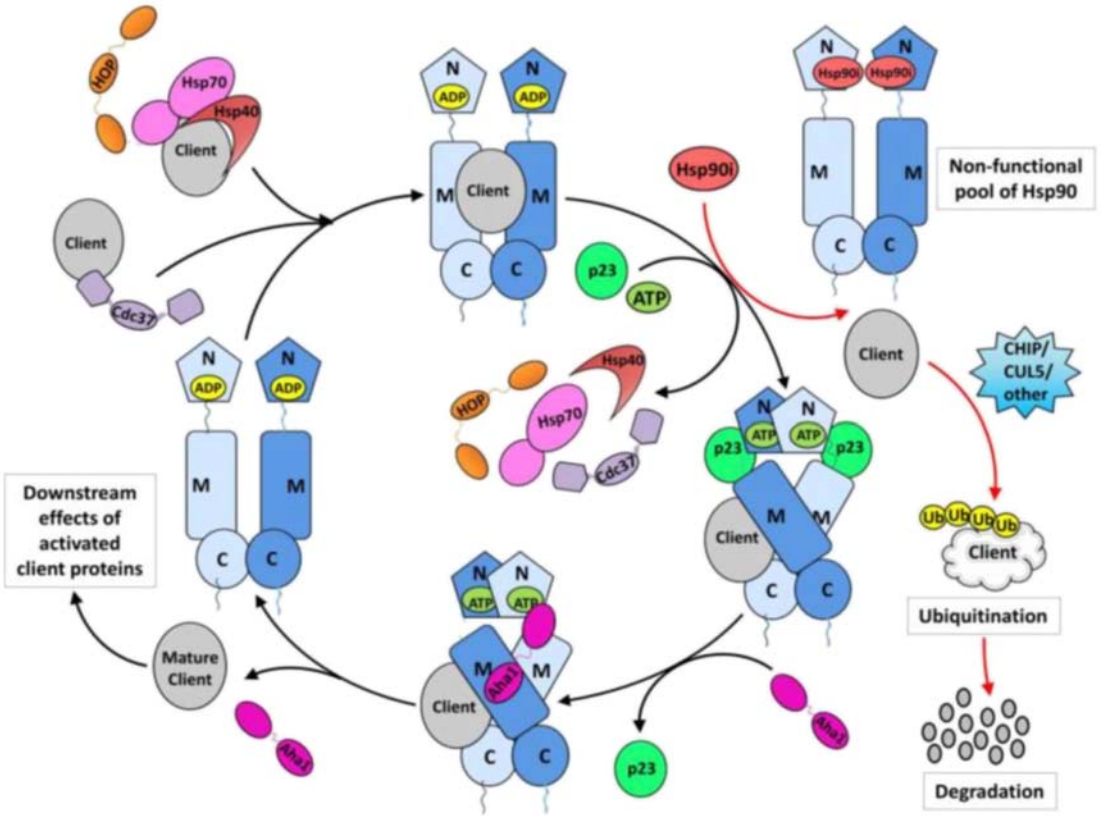

Fig. 41 The chaperone cycle of HSP90 and effects of Hsp90 inhibition. *Light* and *dark blue* indicate the domains of the two monomers of HSP90 that form the active dimer: N = N-terminal domain, M = middle domain, C = C-terminal domain. *Gray circle* represents the client protein. ADP is adenosine diphosphate and ATP is adenosine triphosphate. The client protein is bound to a complex of HSP70 (*purple*) and HSP40 (*red*) with HOP (HSP70–HSP90 organizing protein) also involved for some client proteins. CDC37 (cell-division cycle 37 homologue) delivers kinase clients to HSP90. Client binding to the HSP90 dimer followed by ATP and p23 (*green circle*) binding causes a conformational change. AHA1 (activator of HSP90 ATPase1) binding and p23 displacement promotes ATP hydrolysis and release of mature and active client protein. Competition for the ATP-binding pocket by HSP90i (HSP90 inhibitor—*red oval*) leads to release of immature client which is degraded via ubiquitination.[109]

is also apparent that oncogenic kinases activated by mutation have a greater dependence on HSP90 than wild-type kinases. The common activating BRAF mutation found in many cases of melanoma (V600E) is much more sensitive to HSP90 inhibition than wild-type BRAF.[116] Other mutant proteins that show particular sensitivity include v-SRC, BCR-ABL, mutant EGFR, and rearranged ALK. This clear molecular dependence of cancer cells on functioning HSP90 led to the hypothesis that inhibition of HSP90 would have not only an anticancer effect but would also provide a combinatorial blockade of multiple oncogenic pathways while providing a clear therapeutic window over normal cells.[117] Recently, factors involved in client recognition by HSP90 have been investigated and these shed light on why kinases are such ubiquitous clients of HSP90. It seems that it is their flexible unstructured regions particularly involving the kinase domain that are recognized by the HSP90 machinery.[118]

5.07.3.3.1 HSP90 inhibitors

Over the last 20 years, there have been significant efforts directed toward the discovery and progression of HSP90 inhibitors toward the clinic for the treatment of cancer. This has led to a large number of reviews including some excellent recent reviews to which the reader is referred.[119–121] The fact that ATP hydrolysis is a crucial part of the chaperone cycle makes the N-terminal ATP-pocket of HSP90 an important target for potential small-molecule inhibitors. Indeed, this site has seen most of the drug discovery activity involved in HSP90 inhibition.[120] All the HSP90 inhibitors in clinical trials fall into this category of inhibitor. The C-terminal domain of HSP90 is responsible for dimerization to give the functionally active homodimer and has also been reported to possess an ATP-binding site although there is no direct structural evidence for this. A small group of coumarin-containing antibiotics based on novobiocin have been reported to bind at this site. Finally, the pentapeptide sansalvamide A has been reported to bind to the middle domain of HSP90 and disrupt client protein binding. Although the vast majority of work has focused on pan-HSP90 inhibitors, there has been some recent progress in selective inhibition of HSP90 isoforms as these are differentially expressed and localized and their modulation may lead to different biological outcomes.[122]

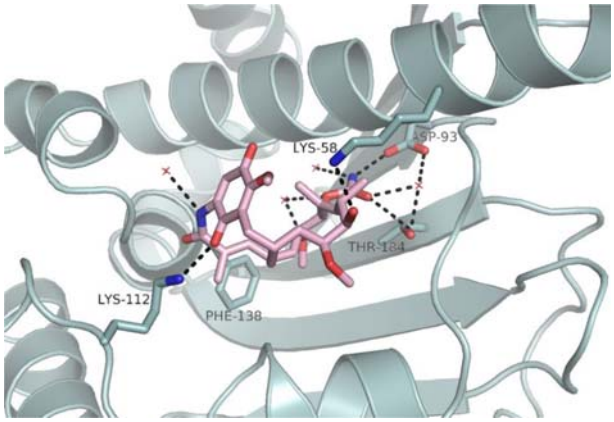

Fig. 42 X-ray crystal structure of the HSP90 NBD (*cyan*) in complex with geldanamycin (*light pink*), PDB: 1YET. The structure of the ligand, and the key binding site residues are shown as sticks. Selected interactions are shown in *black-dashed lines*.

5.07.3.3.1.1 Natural product-based inhibitors

The story of HSP90 inhibitors is a textbook example of how natural product inhibitors led the way in validating the hypothesis that HSP90 inhibition would show an anticancer effect. This effect was first demonstrated in vitro in human cancer cell lines, followed by in vivo experiments in human tumor xenografts in immune-suppressed mice and finally, using semisynthetic derivatives, in the clinic. This was followed by widespread efforts to obtain small-molecule inhibitors using high-throughput screening, fragment-based approaches, and rational approaches using structure-based drug design. This section will describe the natural product-based HSP90 inhibitors and the medicinal chemistry efforts used to progress them toward the clinic.

5.07.3.3.1.1.1 Geldanamycin-based inhibitors

Geldanamycin **66** (**Fig. 43**) is a benzoquinone-containing ansamycin antibiotic from a *Streptomyces* species first reported in 1970.[123] The structure was reported soon afterward.[124] It was originally believed to be a tyrosine kinase inhibitor and shown to cause depletion of the oncoprotein ERBB2.[125] In 1997, soon after the first crystal structure of an HSP90/ADP complex was published,[108] the structure of the HSP90 geldanamycin complex was reported at 1.9 Å resolution.[126] This reveals that geldanamycin neatly mimics the nucleotide binding in the ATP-pocket of HSP90. The macrocyclic ansamycin ring and the carbamate function are oriented toward the bottom of the pocket with the benzoquinone at the top of the pocket with the planes of the macrocycle and the benzoquinone virtually parallel (**Fig. 42**). Critically, there are several water-mediated hydrogen bond interactions which are found repeatedly in HSP90/ligand structures along with key hydrophobic interactions.

Although a potent inhibitor of HSP90 (IC_{50} c.25 nM), geldanamycin shows severe hepatotoxicity in preclinical species which along with its poor solubility rendered it unsuitable for progression into the clinic. This latter issue was addressed by preparing the semisynthetic geldanamycin derivatives 17-AAG (tanespimycin) **67** and 17-DMAG (alvespimycin) **68** by displacement of the 17-methoxy group with the appropriate amine (**Fig. 43**).

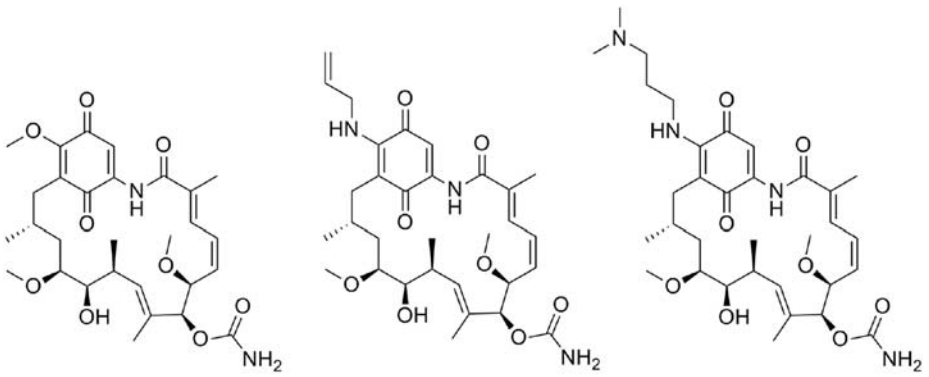

Fig. 43 Chemical structures of geldanamycin, **66**, tanespimycin, **67**, and alvespimycin, **68**.

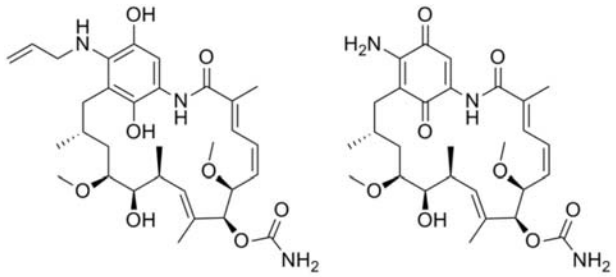

Fig. 44 Chemical structures of retaspimycin, **69**, and IPI-493, **70**.

Tanespimycin is a potent HSP90 inhibitor with an $IC_{50} = 5$ nM in a cell-free assay when HSP90 is isolated from tumor cells compared to c.500 nM when HSP90 is derived from normal cells. It has been suggested that this is due to an activated form of HSP90 in tumor cells.[127] In cell-based experiments, tanespimycin demonstrated an RB-dependent G1 growth arrest in a range of human tumor cell lines with an IC_{50} of 25–45 nM.[128] In in vivo studies in human tumor xenografts in nude mice, tanespimycin showed good growth inhibition at 50 mg kg^{-1} dosed intraperitoneally.[128] In 1999, tanespimycin became the first HSP90 inhibitor to enter the clinic. A Phase I clinical study was able to demonstrate sufficient exposure to cause depletion of key client proteins (CRAF and CDK4) at well-tolerated doses along with induction of HSP72 in both peripheral blood mononucleocytes and tumor biopsies.[129] Therapeutic benefit has been reported in various malignancies including melanoma.[130] Various combination therapies have also shown efficacy in the clinic including a study in ERBB2-positive metastatic breast cancer with traztuzumab[131] and a study in combination with proteasome inhibitor bortezomib in relapsed or refractory MM.[132] Despite these impressive results, the clinical development of tanespimycin was halted; likely due to liver toxicity and formulation issues.[133]

Alvespimycin possesses some potential advantages over tanespimycin including greater solubility leading to easier formulation and greater oral bioavailability.[134] It had similar potency to tanespimycin in a range of human cancer cell lines and showed good efficacy in a gastric cancer xenograft model on dosing at 25 mg kg^{-1} ip three times per week. In the clinic, activity has been reported for IV dosing of alvespimycin in castration resistant prostate cancer (CRPC—a complete response), melanoma (partial response), renal cancer (stable disease), and chondrosarcoma (stable disease).[135] Alvespimycin also showed clinical activity in ERBB2-positive metastatic breast cancer in combination with traztuzumab.[121]

Although tanespimycin and alvespimycin showed some promising results in the clinic, they retain the metabolic issues surrounding the benzoquinone moiety of geldanamycin. It had long been recognized that this moiety is a liability in a pharmaceutical agent owing to redox issues and hepatotoxicity. In addition, it was recognized that reduction of the quinone by the quinone reductase NQO1 (NADPH/quinone oxidoreductase I) led to a much more potent hydroquinone.[136] Loss of expression or expression of a functionally inactive form of this enzyme leads to resistance to tanespimycin and is the mechanism of acquired resistance in preclinical models.[137] Infinity Pharmaceuticals neatly addressed both this problem and the solubility problems by developing the hydroquinone hydrochloride, IPI-504 (**69**, retaspimycin hydrochloride, **Fig. 44**).[138,139] This compound has shown clinical activity in Phase II trials in NSCLC in patients with rearrangements in the anaplastic lymphoma kinase (*ALK*) gene when given intravenously. This is likely due to the fact that ALK is an HSP90 client.[140] The final example of an ansamycin-containing HSP90 inhibitor is IPI-493, **70** (**Fig. 44**), a metabolite of tanespimycin lacking the allyl group and also developed by Infinity Pharmaceuticals. This compound has been developed as an oral formulation and entered Phase I clinical trials.[141]

5.07.3.3.1.1.2 Radicicol-based inhibitors

The 14-membered ring macrolide radicicol, **71** (**Fig. 45**), was isolated from the fungus *Monosporium bonorden* in 1953.[142] In close similarity to geldanamycin, radicicol was originally thought to be a kinase inhibitor but, in 1998, was shown to bind to the

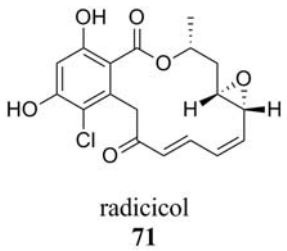

Fig. 45 Chemical structure of radicicol.

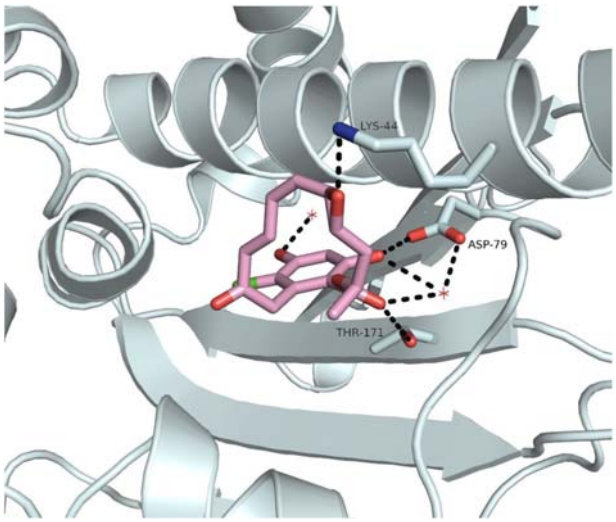

Fig. 46 X-ray crystal structure of the HSP90 NBD (*cyan*) in complex with Radicicol (*light pink*), PDB: 1BGQ. The structure of the ligand, and the key binding site residues are shown as sticks. Selected interactions are shown in *black-dashed lines*.

N-terminal domain of HSP90 and display similar biological activity to geldanamycin.[143] The structural basis of this binding has been revealed[144] and radicicol has been shown to bind in a folded, L-shaped conformation to the N-terminal ATP-binding pocket of HSP90 (Fig. 46). The resorcinol ring is buried deep in the base of the pocket with key interactions involving the hydroxyl groups in a similar manner to geldanamycin.

It will become clear in "**Resorcinol-based inhibitors**" section that the binding of radicicol to the HSP90 ATP-binding site demonstrated at this early stage the key role a resorcinol motif plays in small-molecule binding in this pocket and what an excellent match this simple structural motif is for the unusual ATP-binding site found in HSP90. Isothermal calorimetry was used to determine the K_d for radicicol binding to full-length dimeric HSP90 and a value of 19 nM was obtained. This compares with a $K_d = 1.2$ μM for geldanamycin in the same experiment.[144] Interestingly, thermodynamic analysis of their binding shows a large and favorable enthalpy change in each case, but whereas geldanamycin binding incurs an entropic penalty, radicicol binding leads to a favorable entropy change. In line with its potent HSP90 binding, radicicol exhibits potent antiproliferative activity across a wide range of human tumor cell lines. However, it is inactive in in vivo antitumor models, a fact attributed to its reactive electrophilic groups including a dienone and an epoxide leading to poor plasma stability. An oxime of radicicol, KF58333, **72** (Fig. 47), has been reported to show in vivo antitumor activity in human tumor xenograft experiments without the serious liver toxicity seen with the geldanamycin-based HSP90 inhibitors, but this has not advanced further toward the clinic.[145] The simplified but closely related pochonins isolated from a strain of *Pochonia chlamydosporia*[146] show a wide range of biological activity and pochonin D **73** (Fig. 47) has been shown to be a potent HSP90 inhibitor albeit with poor cellular activity. This led to the synthesis of a library of pochonin-based, resorcinol-containing macrolactones which included the oxime derivative **74**.[147] This compound showed a low nanomolar binding affinity for HSP90 with depletion of HSP90 clients at 35 nM and antiproliferative activity in human cancer cell lines in the range 125–320 nM. Human tumor xenograft experiments using BT474 (a breast cancer cell line) showed regressions using compound **74** dosed on alternate days at 100 mg kg^{-1} with no body weight loss. However, there have been no reports of the progression of radicicol-based HSP90 inhibitors progressing into the clinic.

Synthetic macrolactones and macrolactams inspired by radicicol have also been progressed as HSP90 inhibitors.[148,149] The macrolactams were prepared by a ring-closing metathesis reaction and have been shown to be metabolically more stable than

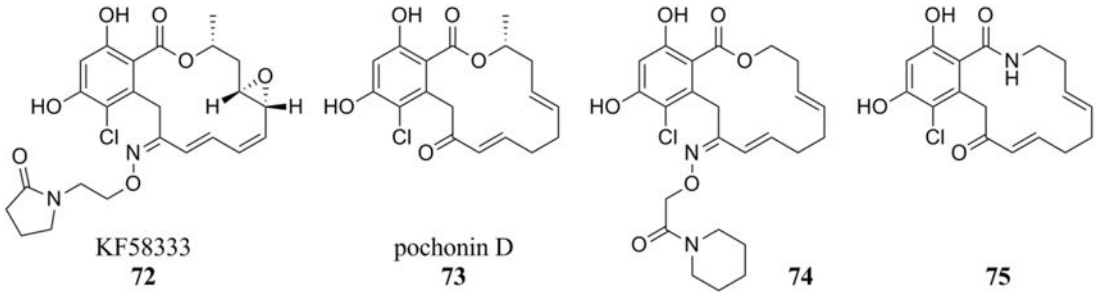

Fig. 47 Chemical structure of compounds **72**, **73**, **74**, and **75**.

the macrolactones in human liver microsome experiments and to be equivalent or superior as HSP90 inhibitors, showing the same client depletion in human colon cancer cells with cellular GI_{50} values of 600 nM. Structures of three of these compounds including macrolactam **75** (Fig. 47) were obtained in complex with HSP90 N-terminal domain and they bind in a similar manner to radicicol although with the ability to form further interactions depending on the nature of the substituents on the macrolactam ring.[149]

5.07.3.3.1.1.3 Novobiocin-based inhibitors

The natural product inhibitors described in the preceding sections all binding in the ATP-pocket in the N-terminal domain of HSP90 to exert their inhibitory effects. However, HSP90 inhibitors are known that have been reported to bind at the C-terminal region of HSP90. Epigallocatechin gallate (EGCG) **76** (Fig. 48) is a flavonoid found in green tea and in 2009 was reported to act as an aryl hydrocarbon receptor (AhR) antagonist via inhibition of HSP90.[150] EGCG showed the classic signature of HSP90 client depletion with reduction of RAF, ERBB2, and pAKT on treatment of the human ovarian cancer cell line SKOV-3 with micromolar concentrations. Using a variety of techniques including proteolysis and immunoprecipitation, EGCG was found to bind at the C-terminal domain of HSP90 and inhibit dimerization to the active form. Subsequently EGCG was tested in a CT26 colon cancer xenograft model and was shown to demonstrate efficacy at 10 mg kg^{-1} ip dosed daily.[151] Recently, Blagg has reported extensive synthetic studies and subsequent SAR around the EGCG structure (Fig. 49).[152] This led to compound **77** which demonstrated a $GI_{50} = 4$ μM in MCF-7 human breast cancer cells, an increase of potency of some 20-fold over EGCG. Compound **77** also showed the classic signature of HSP90 client protein depletion.

The coumarin antibiotics novobiocin, chlorobiocin, and coumermycin A are inhibitors of DNA-gyrase that are known to inhibit the ATPase function. Novobiocin has also been shown to target the C-terminal domain of HSP90 at a putative ATP-binding site leading to changes in interactions between HSP90, co-chaperones, and client proteins.[153] However, novobiocin **78** (Fig. 50) is only weakly active with HSP90 inhibition only observed at concentrations around 700 μM in SKBr3 human breast cancer cells. Blagg has carried out extensive studies on novobiocin in an effort to increase potency and also simplify the complex structure of this natural product.[154] This work led to compound **79** with a simplified coumarin core, a simpler amine-substituent, and unmodified noviose sugar. Subsequent efforts focused on replacing the complex sugar portion of the compound. Following the hypothesis that the noviose could be replaced by aza-sugars, Blagg and colleagues found that replacement with a simple piperidine gave analog **80** with $GI_{50} = 470$ nM in the SKBr3 cell line.[155] This simplified novobiocin analog showed the classic HSP90 inhibition signature of client protein depletion. They subsequently showed that a cyclic amine

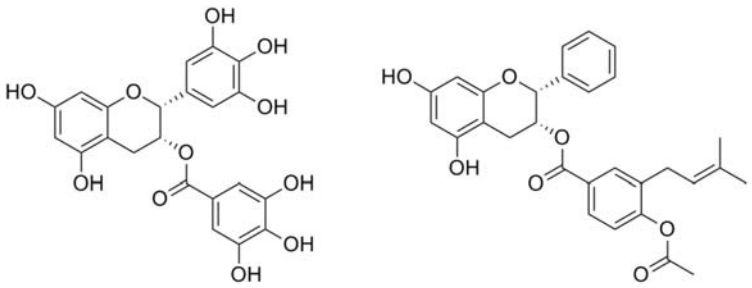

Fig. 48 EGCG **76** and SAR.

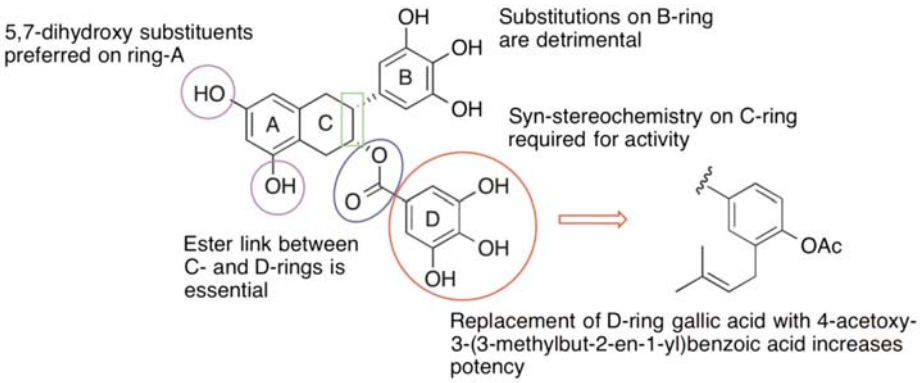

Fig. 49 Chemical structures of compounds **76** and **77**.

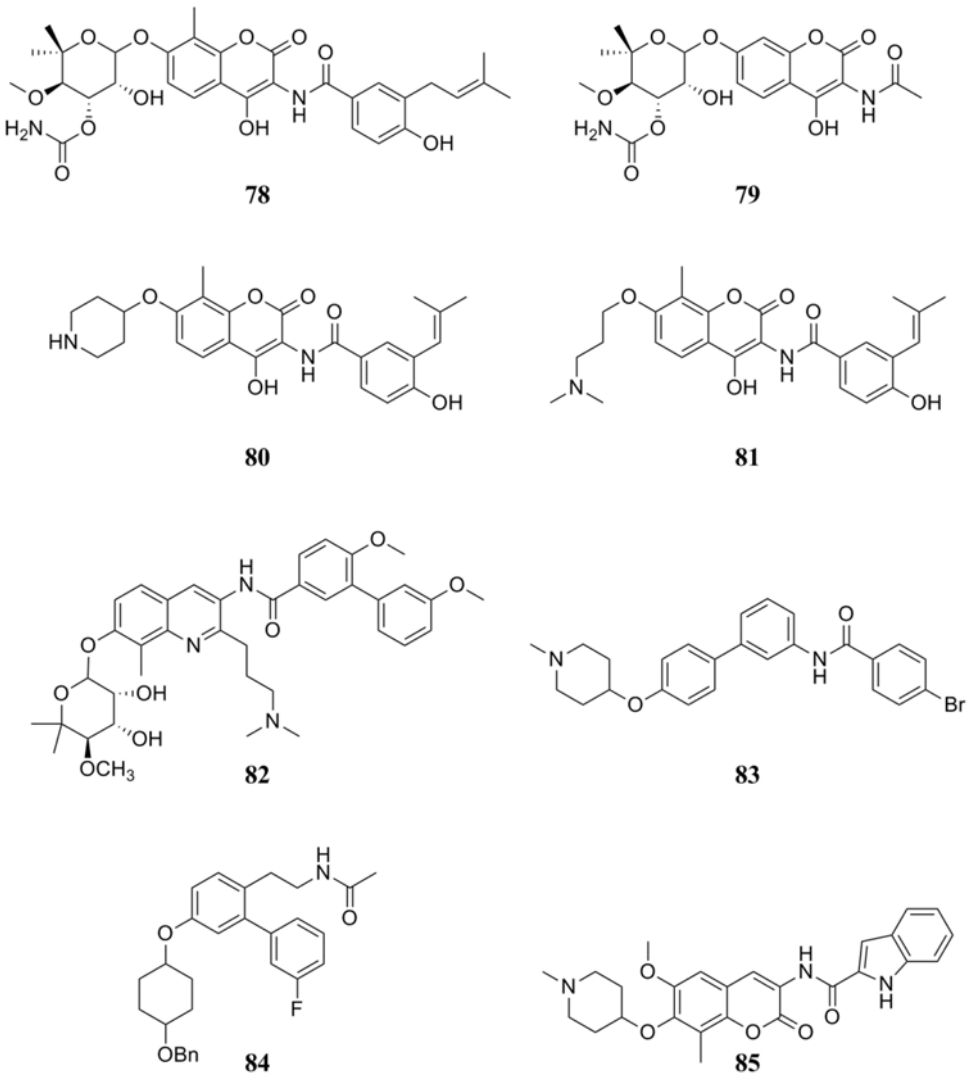

Fig. 50 Chemical structure of compounds **78**, **79**, **80**, **81**, **82**, **83**, **84**, and **85**.

is not required and prepared and tested compound **81**, which showed similar potency in the SKBr3 cell line. A wide range of SAR has been reported for these and related compounds but no compound with significantly greater potency than compounds **80** and **81** was discovered.[156] Replacement of the coumarin core has been explored.[157] Replacement with quinoline or naphthalene rings is possible and the most potent compound obtained was a quinoline derivative **82** that allowed exploration of the vector from the C-2 position which is not possible in the coumarin series. Compound **82** showed a $GI_{50} = 200$ nM in the SKBr3 cell line. Recently, using a molecular modeling approach built on extensive SAR determined around the novobiocin structure, Blagg and colleagues have designed a series of biaryl compounds as C-terminal HSP90 inhibitors.[158] The leading compound from this series, compound **83**, shows a $GI_{50} = 2$ μM in the SKBr3 cell line with the expected client protein depletion signature. Although less potent than the coumarin-containing analogs, the ease of synthesis along with drug-like nature of this compound make it an exciting lead compound from which to develop a C-terminal HSP90 inhibitor compound with in vivo activity. This approach has led to the novobiocin analog **84**, partly designed by molecular modeling using a homology model of the HSP90 C-terminal binding site.[159] It is becoming clear that these C-terminal binders are able to produce different biological effects to the more common N-terminal binders. They have a clear effect on increasing HSP70 expression, while their effect on client proteins such as ERBB2, RAF, and pAKT is notably weaker than N-terminal inhibitors. This is leading to their exploration as neuroprotective agents. Currently, the only report on the in vivo anticancer activity of novobiocin analogs is that for KU363, **85** (Fig. 50), which shows a response in 88% of xenograft tumors in an MDA-1986 head and neck human tumor animal model.[160]

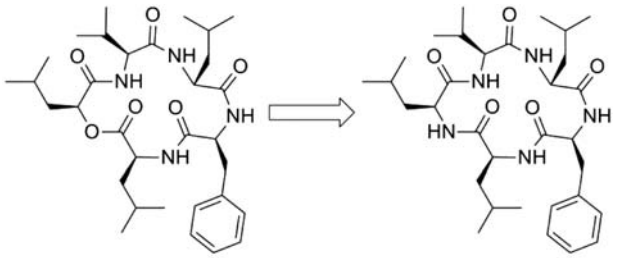

Fig. 51 Chemical structures of San A **86** and San A amide derivative **87**.

5.07.3.3.1.1.4 Other natural product inhibitors of HSP90

Sansalvamide A (San A, **86**) is a cyclic pentapeptide (depsipeptide) isolated from a marine fungus and known to have antitumor activity (Fig. 51). The lactone link in San A is readily hydrolysed leading to ring-opening and was replaced with the more stable amide link to give San A amide derivatives.[161] Out of some 86 derivatives, San A amide **87** (Fig. 51) showed potent antiproliferative activity against a human colon cancer cell line, HCT-116 ($GI_{50} = 700$ nM). The target of San A was investigated in a pull-down experiment using biotinylated San A amide.[162] This suggested HSP90 as the specific binding target and the site of binding was investigated by exploring the effect of San A amide on binding partners of HSP90 known to bind in different regions. This led to the conclusion that San A amide does not bind to the N-terminal domain and subsequent biochemical experiments using different HSP90 constructs showed that San A amide binds to the middle domain. This leads to San A amide possessing a different inhibition profile to not only the N-terminal binders such as geldanamycin but also novobiocin. San A amide does not inhibit the ATPase activity of HSP90, but unlike novobiocin and its analogs, it blocks the binding of FKBP and HOP. Additionally, San A amide is c.100-fold more potent in its inhibition of C-terminal client proteins. This opens up further opportunities for selective inhibition of HSP90 function.

Gambogic acid **88** was identified as an inhibitor of HSP90-mediated luciferase refolding from a screen of natural product libraries (Fig. 52).[163] It had been known for some time to possess a wide range of biological effects including anticancer activity and there is a mention of a Phase I trial in China involving **88** as an anticancer compound.[164] Gambogic acid was shown to demonstrate the classic client depletion signature of an HSP90 inhibitor along with disruption of HSP70 and CDC37 binding to HSP90. Surface plasmon resonance (SPR) was used to show that **88** binds to both full-length and N-terminal domain HSP90 with K_d in the single digit micromolar range but is not competitive with geldanamycin, suggesting an alternative site of binding on the N-terminal domain. There is much interest in gambogic acid as an anticancer agent although its complexity does not render it amenable to the usual medicinal chemistry approaches. A recent report demonstrated in vivo activity in a NSCLC tumor xenograft (NCI-H1993 cells) at doses of 10, 20, and 30 mg kg^{-1} ip once daily without any effect on mouse body weight.[164]

5.07.3.3.1.2 Purine-based inhibitors

As the natural ligand ATP contains an adenine group that is directly involved in the binding to HSP90, it is not surprising that purine-scaffold inhibitors were among the earliest synthetic, small-molecule inhibitors of HSP90 identified. The early work in this area has been reviewed by Taldone and Chiosis[165] and only key points will be presented here. The first purine inhibitor was PU3, **89** (Fig. 54), arrived at by a consideration of the unusual shape of the HSP90 ATP-binding pocket and the bound conformation of ATP itself.[166] Substitution at C-8 of the purine ring was identified as a key site and features in several of the purine-scaffold

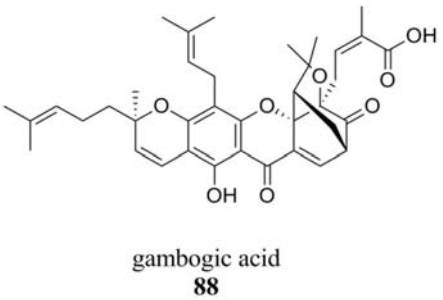

Fig. 52 Chemical structure of gambogic acid **88**.

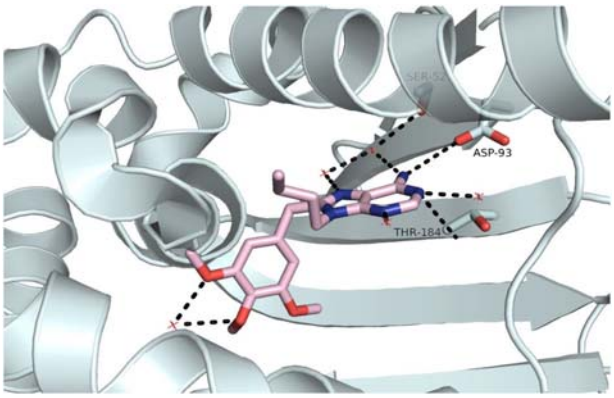

Fig. 53 X-ray crystal structure of the HSP90 NTD (*cyan*) in complex with PU3, **89** (*light pink*), PDB: 1UY6. The structure of the ligand, and the key binding site residues are shown as sticks. Selected interactions are shown in *black-dashed lines*.

inhibitors. PU3, **89**, is significantly less potent than geldanamycin with an EC_{50} value of about 20 μM for binding to purified HSP90 and it exhibited the HSP90 client protein depletion profile at concentrations below 50 μM. The crystal structure of PU3 bound to HSP90 N-terminal domain shows the key role of the C-6 amino group binding to Asp93 and there is the typical water-mediated array of interactions involving other nitrogen atoms of the purine ring[167] (Fig. 53).

The first phase of exploration of SAR around PU3 involved changes to the N-9 alkyl chain, the C-8 linker to the trimethoxyphenyl group, and substitution at C-2 of the purine. Combining the best of all these changes led to PU24FCl, **90**.[168] A key change was introduction of fluorine at C-2 which not only enhanced potency but also led to increased solubility in a chemical series with relatively poor physicochemical properties. PU24FCl showed improved binding to HSP90 with an $EC_{50} = 0.45$ μM and an $IC_{50} = 2$ μM for HER2 depletion in MCF7 human breast cancer cells. More importantly, PU24FCl showed in vivo efficacy in a human breast cancer xenograft (MCF7) model. At 200 mg kg^{-1} iv dosed on alternate days for 30 days, a 72% reduction in tumor volume compared to controls was observed.

The next advance in this area was to change to a sulfur-linker at C-8 and introduce a basic amine in the N-9 alkyl chain to aid solubility. Out of these studies emerged PUH71, **91**, which possessed an EC_{50} for HSP90 binding of 10–55 nM, a GI_{50} in various human cancer cell lines of 50–90 nM, and an IC_{50} for HER2 depletion of 50–80 nM. Interestingly, the 2′-iodo compound is significantly more potent than the 2′-bromo derivative. This has been rationalized by the presence of a lipophilic pocket large enough to accommodate the iodine substituent (PDB: 2FWZ). Salt forms of PUH71 showed good solubility in PBS buffer and improved pharmacokinetic properties including passive permeability as measured in a PAMPA assay. The only cytochrome inhibition found was CYP2D6 ($IC_{50} = 0.89$ μM) and 37% of PUH71 was metabolized to the inactive diphenol after 30 min exposure to human liver microsomes. Extensive in vivo data is available concerning the efficacy of PUH71 in human tumor xenograft experiments across a wide range of tumor types. One of the most compelling involved the treatment of a triple negative breast cancer (TNBC) xenograft in which alternate day dosing of PUH71 at 75 mg kg^{-1} iv led to a complete response in all the mice. In Jul. 2011, PUH71 entered a Phase I clinical trial sponsored by Memorial Sloan Kettering Cancer Centre. Preliminary results were presented at the American Society of Clinical Oncology (ASCO) meeting in 2015[169] and showed PUH71 to be well-tolerated with some signs of activity in a range of cancers.

A team at Myrexis further developed the basic skeleton of PUH71 leading to the clinical candidate MPC-3100,[170] **92**. They focused on optimizing the N-9 alkyl and the C-8 arylsulfide substituents for both potency and pharmacokinetic properties. They discovered that the bromo-version of the halo-methylenedioxyaryl group at C-8 offered the best overall properties at that position and that a pendant piperidine ring in the alkyl chain at N-9 was optimal. A large number of substituents on the piperidine nitrogen were explored leading to MPC-3100. The synthetic chemistry is noteworthy for a novel synthesis of the sulfide by nucleophilic displacement of a C-8 bromide on the adenine unit using in situ deprotection and reaction of a propanoyl ester-protected aryl thiol, thus preventing disulfide formation. In addition to good HSP90 binding in an FP assay ($IC_{50} = 140$ nM), MPC-3100 potently inhibited HER2 expression ($IC_{50} = 60$ nM) and caused growth inhibition in HCT116 human colon cancer cells ($GI_{50} = 540$ nM). It showed good stability in in vitro microsome assays and of the derivatives explored, showed the best C_{max} (c.23 μM), AUC (81,800 h ng mL^{-1}), and oral bioavailability ($F = 37\%$) along with an impressive 53-fold induction of HSP72 expression. Following oral administration of MPC-3100 in a human tumor xenograft model at 200 mg kg^{-1} for 22 days, an average of 48% reduction in tumor volume was observed. MPC-3100 was progressed to a Phase I trial where it demonstrated safety and tolerability with side effects including diarrhea, nausea, and vomiting.

Subsequent exploration of the purine scaffold as HSP90 inhibitors moved away from the C-8 aryl substituent by shifting this benzyl group to N-9 in place of the alkyl chain found in previous inhibitors. It was found that this led to inactive compounds until the C-6 amino group was also moved to become a C-2 amino substituent. The culmination of this work by Biogen Idec/Conforma led to BIIB021, **93**, in which the aryl substituent at N-9 has been changed to a pyridyl unit and a chloro-substituent added at C-2

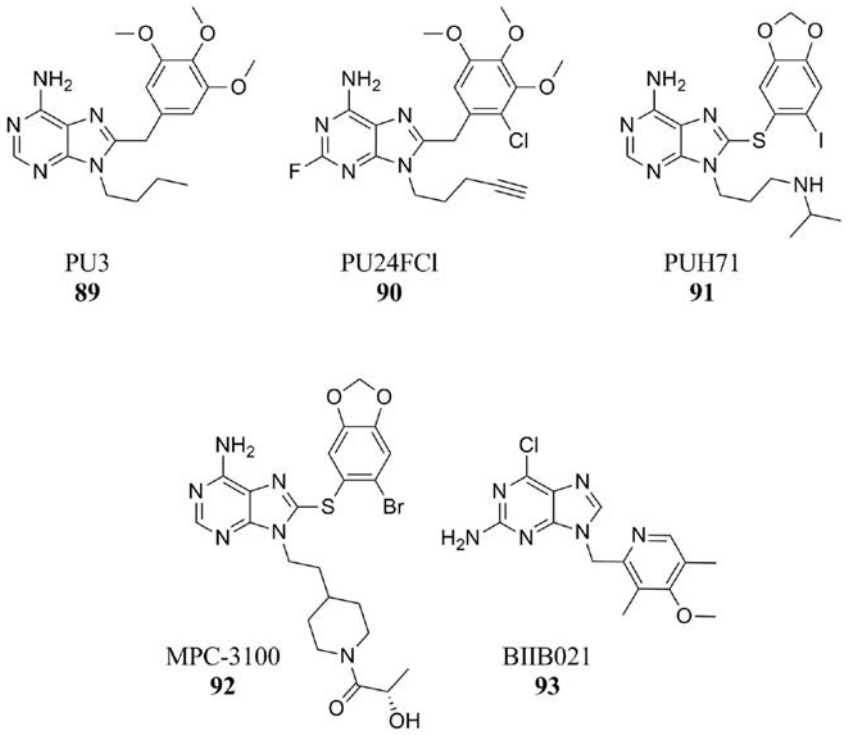

Fig. 54 Chemical structures of compounds **89**, **90**, **91**, **92**, and **93**.

(Fig. 54). BIIB021 displayed good solubility and good oral exposure in mice; its EC_{50} for HSP90 binding is 20 nM and its GI_{50} in various cancer cell lines was 50–150 nM. An in vivo efficacy study using N87 human tumor xenografts gave 87% tumor growth inhibition on dosing at 125 mg kg^{-1} orally 5 days per week for 5 weeks. The observation of oral efficacy in a xenograft study was a clear advance. BIIB021 has entered clinical trials and has shown partial responses as determined by FDG-PET in a Phase II trial in gastrointestinal stromal tumors (GIST).[171]

5.07.3.3.1.3 Resorcinol-based inhibitors

As discussed in "**Radicicol-based inhibitors**" section, the resorcinol motif of radicicol binds deeply in the ATP-binding pocket of the N-terminal domain of HSP90, anchored by water-mediated hydrogen bonds via conserved waters. The drug discovery program to realize the potential of the resorcinol unit arose from a high-throughput screen at The Institute of Cancer Research which identified pyrazole **94** (Fig. 55). This showed an $IC_{50} = 280$ nM for HSP90 binding in a fluorescence polarization assay and a cellular $GI_{50} = 6$ μM. This compound was advanced in a collaboration with Vernalis through addition of an amide at the 5-position of the pyrazole to pick up a binding interaction with Lys58, and gave pyrazole amide **95** with considerably enhanced biochemical and cellular potency. Introduction of a solubilizing group to the 4-aryl substituent and a change to the isoxazole ring to reduce the hydrogen bond donor count gave compound **96** with significantly improved cellular potency. Finally, fine-tuning of the lipophilic group on the resorcinol ring and selection based on pharmacokinetics and pharmacodynamics gave the clinical candidate **97** which was licensed to Novartis and became NVP-AUY922.[172]

NVP-AUY922, **97**, shows significant growth inhibition and/or regressions in both orthotopic and subcutaneous human tumor xenograft experiments in nude mice across a range of cancer types. It is dosed intravenously as it has poor oral bioavailability owing to glucuronidation of the resorcinol. It shows the classic molecular signature of an HSP90 inhibitor with depletion of key oncogenic client proteins and an increase in expression of HSP70. Unlike tanespimycin, activity was independent of NQO1 expression and liver toxicity was avoided.[173] It is entered over 25 clinical trials (www.clinicaltrials.gov) both as a single agent and in combination with other cancer therapeutics. A highlight of these trials so far include a Phase II trial in combination with trastuzumab in ERBB2-positive metastatic breast cancer which achieved a partial response rate of 23% and was well-tolerated with diarrhea and reversible visual disturbance being the main side effects.[174] A Phase II trial is underway in patients with NSCLC carrying an exon 20 insertion mutation in EGFR; which tumors are resistant to EGFR inhibitors such as erlotinib.

A different approach to a resorcinol-based HSP90 inhibitor was taken by the team at Astex. Using the fragment-based approach they have helped pioneer, they uncovered two fragments that bound (by ITC) with a $K_d < 1$ mM. One of these fragments was phenolic benzamide **98** ($K_d = 790$ μM, $LE = 0.26$) and the other was an aminopyrimidine **99** ($K_d = 250$ μM, $LE = 0.38$) (Fig. 56).[175] They pursued both series using protein/ligand structures but although not the most ligand efficient, the phenol series

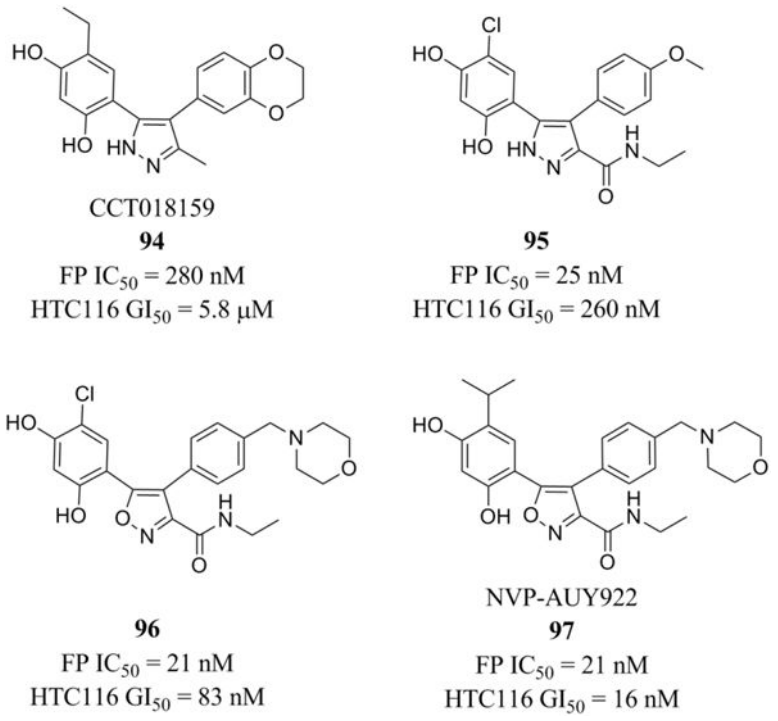

Fig. 55 Chemical structures of compounds **94**, **95**, **96**, and **97**.

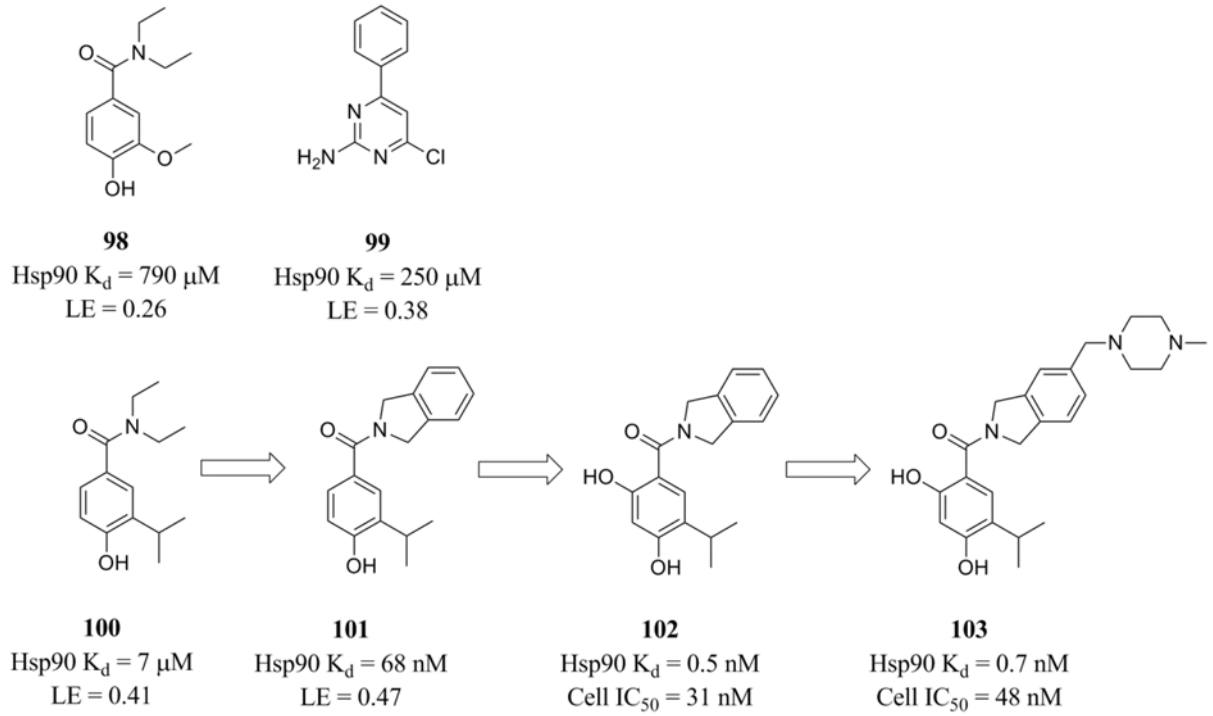

Fig. 56 Fragment-based discovery of AT13387, **103**.

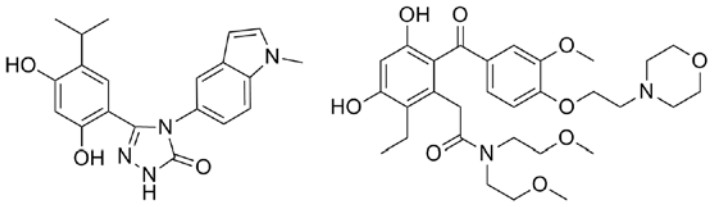

Fig. 57 Chemical structures of compounds **104** and **105**.

led to a clinical candidate. Introduction of an alkyl group to replace the methoxy group and fit into the lipophilic pocket gave compound **100** with a large increase in potency and ligand efficiency (Fig. 56). Replacing the diethylamide with a larger isoindoline group (**101**) moved the Lys58 sidechain and allowed lipophilic interactions with the protein, further enhancing binding. Based on the resorcinol motif, the Astex team then introduced a 2-hydroxy group to **101** to give resorcinol **102** which showed subnanomolar binding and low nanomolar cellular activity. Subsequent exploration of substituents on the isoindoline to enhance the solubility led to the clinical candidate AT13387 (**103**) which retained the binding and growth inhibitory properties of **102** but possessed good pharmacokinetic properties suitable for IV and intraperitoneal administration.[176] In a human colon cancer xenograft experiment in nude mice, compound **103** dosed at 60 mg kg^{-1} ip 3 days on and 3 days off led to 78% tumor growth inhibition. AT13387, **103**, is in some 12 clinical trials covering a range of cancers, as both a single agent and in combinations.

Two further resorcinol-based HSP90 inhibitors have been developed and are in the clinic but much less information has been revealed about their discovery. Ganetespib, **104**, has been developed by Synta and has been shown to be a potent HSP90 inhibitor (Fig. 57).[177] It is currently in some 38 clinical trials as both a single agent and in combination with other cancer therapeutics in a range of cancers. In common with other resorcinols, the mode of administration is iv. The final example of a resorcinol that has reached the clinic is KW-2478, **105**, developed by Kyowa Hakko Kirin Pharma. This compound has entered clinical trials in hematological cancers.[178]

5.07.3.3.1.4 Miscellaneous N-terminal inhibitors

Serenex employed a unique chemoproteomics approach to discover their HSP90 inhibitor SNX-5422.[179] Targeting ATP-binding proteins, they treated immobilized purine-based affinity media with cell lysate and then used a small library of compounds to elute various proteins. They identified proteins eluted by each compound and hence discovered hits to the eluted proteins. The 4-substituted benzamide **106** was discovered in this way and elaborated using structure-based design to give the clinical candidate SNX-5422, **107**, which is a glycine ester prodrug to improve solubility (Fig. 58). This compound was licensed to Pfizer and showed low nanomolar growth inhibition of a wide range of human cancer cell lines in vitro. In a human breast cancer (BT-474) xenograft experiment in nude mice, SNX-5422 was dosed at 40 mg kg^{-1} orally three times per week and led to tumor regressions. This is unlike the previous HSP90 inhibitors described earlier in having orally efficacy in the animal model. SNX-5422 has been in a number of Phase I and Phase I/II trials for both solid and hematological malignancies.[180]

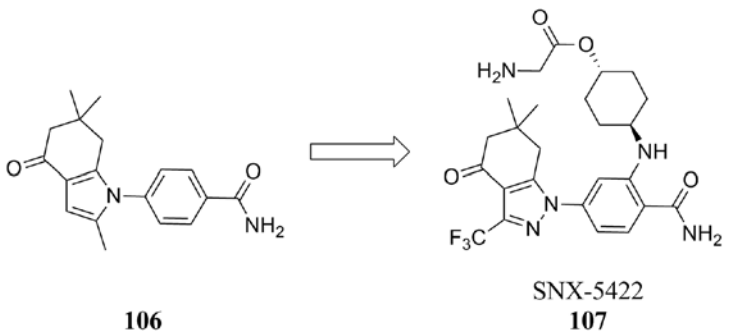

Fig. 58 Development of compound SNX-5422, **107**.

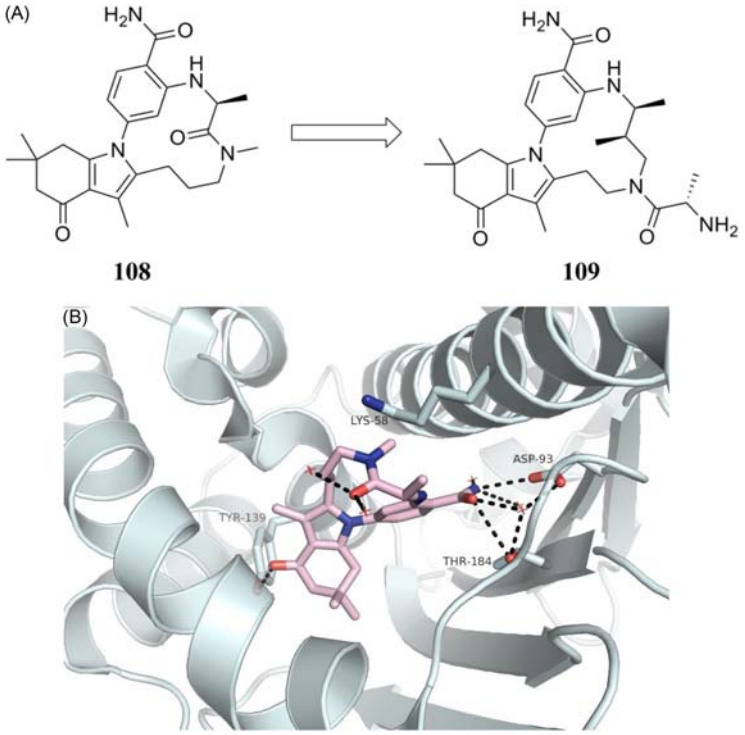

Fig. 59 (A) Chemical structures of **108**, **109**. (B) X-ray crystal structure of the HSP90 NTD (*cyan*) in complex with **108** (*light pink*), PDB: 3R91. The structure of the ligand, and the key binding site residues are shown as sticks. Selected interactions are shown in *black-dashed lines*.

Starting with the structure of SNX-5422, a group at Pfizer used a macrocyclic motif to constrain the conformation leading to compound **108** which showed an $IC_{50} = 92$ nM against the ATPase function of HSP90.[181] A crystal structure showed that the benzamide formed hydrogen bonds with the key Asp93 in the ATP-binding pocket (Fig. 59). This series was progressed to macrocycle **108** (Fig. 59) which showed good in vitro and in vivo pharmacokinetic properties with significant accumulation in the tumor but low oral bioavailability.[182] In a H1975 human lung cancer xenograft in nude mice, **108** dosed daily at 25 mg kg^{-1} iv showed regressions.

Another macrocyclic HSP90 inhibitor, this time based on a 2-aminopyrimidine core, has been disclosed by a group from Chugai.[183] Starting from triazine **110** which was a potent HSP90 inhibitor but with poor pharmacokinetic properties, they developed macrocycle **111** by mimicking the interactions seen in the geldanamycin/HSP90 crystal structure (Fig. 59). Macrocycle **111** showed excellent in vivo pharmacokinetic properties including a high oral bioavailability (71%). In a HCT116 human colon cancer xenograft model, **111** showed tumor growth inhibition of 83% when dosed at 25 mg kg^{-1} po once daily.

A further benzamide-derived HSP90 inhibitor has been discovered and developed by a team at Exelixis.[184] Starting with a high-throughput screen against HSP90 using a fluorescence polarization assay, they screened over 4 million compounds to find two tropane-containing benzamides exemplified by compound **112** (Fig. 61). After a medicinal chemistry campaign in which initially potency was increased followed by a focus on permeability and pharmacokinetics, XL888, **113** (Fig. 61), was obtained with low nanomolar potency in both biochemical and cell-based experiments. Although not the most permeable compound as measured

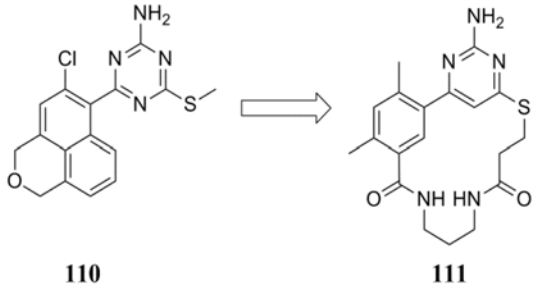

Fig. 60 Chugai compounds: hit **110** and clinical candidate **111**.

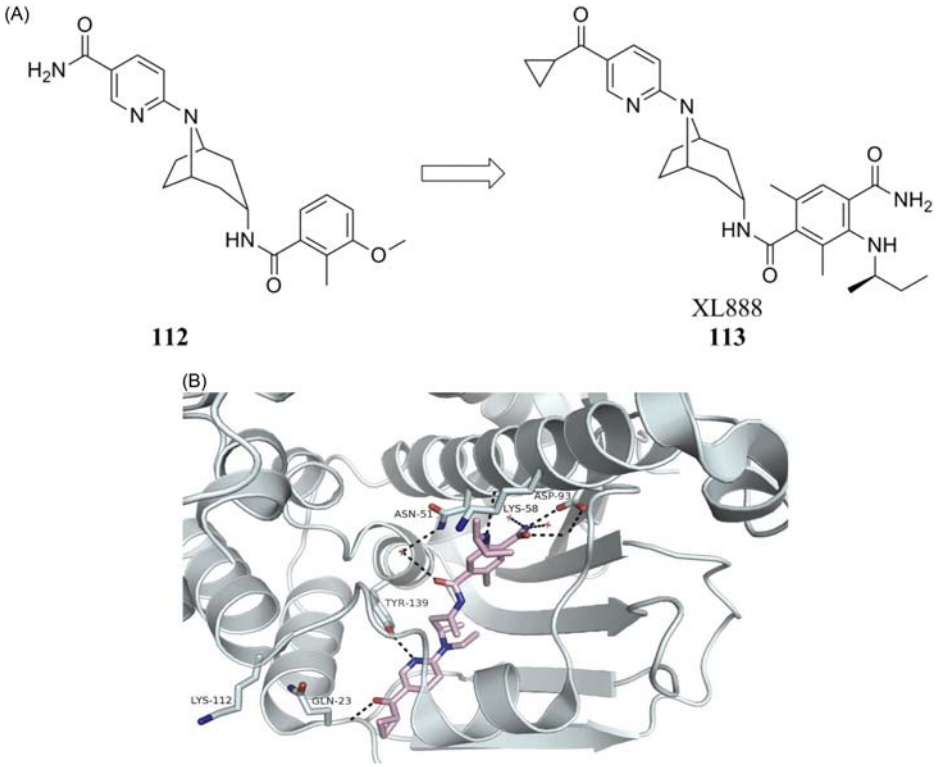

Fig. 61 (A) Structures of Exelixis compounds: hit **112** and clinical candidate **106**. (B) X-ray crystal structure of the HSP90 NTD (*cyan*) in complex with **113** (*light pink*), PDB: 4AWO. by the MDCK assay, **113** possessed relatively low clearance and 30% oral bioavailability in mice and was chosen for progression to efficacy experiments. Treatment of a NCI-N87 human stomach cancer xenograft in nude mice at 60 mg kg^{-1} orally once a day led to 100% tumor growth inhibition. Interestingly, dosing at 100 mg kg^{-1} once a day on the 3 days out of 7 schedule led to enhanced efficacy with tumor growth inhibition exceeding 100% (21% tumor regression) demonstrating the balance in scheduling between a toxic dose and a therapeutically efficacious dose. XL888 (**113**) has entered clinical trials in solid tumors.

A high-throughput screening effort at Novartis yielded the dihydroquinazolinone **114** with a potency of about 1 μM versus HSP90.[185] With good ligand efficiency ($LE = 0.42$) and good aqueous solubility, a protein/ligand crystal structure for **114** with HSP90 was obtained which enabled structure-based drug design (Fig. 62). A key early step in this work involved a scaffold hop from the carbocyclic ring to a lactam which eased the issue of chiral resolution to obtain the active *R*-series by enabling an enantiospecific synthesis utilizing Ellman chemistry. Exploration mainly focused on the aryl substituent leading to NVP-HSP990 (**115**) which showed an IC_{50} against full-length HSP90 of 1 nM. NVP-HSP990 was found to have a half-life of 146 min in mouse pharmacokinetic experiments with an oral bioavailability of 76%. In a PK–PD experiment following depletion of c-Met as the biomarker, NVP-HSP990 led to prolonged suppression after a single dose. In a GTL-16 human gastrointestinal cancer xenograft, NVP-HSP990 dosed at 5 mg kg^{-1} orally once every 3 days led to 76% tumor growth inhibition. Consequently, NVP-HSP990 (**115**) was chosen for clinical evaluation. A Phase I dose-escalation trial has reported[186] that 50 mg per week is the MTD as a single agent with neurological toxicity being dose limiting. No objective responses were reported although 25/64 patients showed stable disease.

A team at Pfizer has also reported the discovery of a clinical candidate based on a different chemical structure.[187] They started from the hit compound **116**, discovered by a high-throughput screen, and widely explored the structural space using extensive ligand/HSP90 crystal structures to direct the synthetic chemistry (Fig. 63). The hit compound **116** showed a K_i of 1.2 μM against HSP90 but no cellular activity. After multiple rounds of optimization they nominated compound **117** as a clinical candidate. Key drivers of the optimization were decreasing hERG affinity and enhancing in vitro ADME properties. In vivo pharmacokinetics showed an oral bioavailability that corresponded to clearance across species suggesting near complete absorption and also a high volume of distribution leading to a long half-life. Cellular potency was in the low nanomolar range and a xenograft experiment using the A2058 human melanoma cancer cell line with dosing at 25 mg kg^{-1} po once daily gave 96% tumor growth inhibition.

An isolated publication by a team at Sanofi-Aventis reported the design and synthesis of polycyclic HSP90 inhibitor **118** (Fig. 63).[188] This was reported to have arisen from a much simpler resorcinol-containing compound that X-ray crystallography found bound to an induced lipophilic pocket near the ATP-binding site. Compound **118** showed potent cellular activity in terms of both growth inhibition and biomarker modulation and activity in a murine leukemia model.

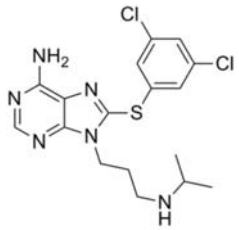
5.07.3.3.2 Isoform selectivity

As HSP90 consists of four isoforms distributed differentially (see "HSP90 Family" section), it might be expected that isoform selective inhibitors may display different biology compared to the pan-HSP90 inhibitors. Some insights into this have been reported.[122] Taldone, Chiosis et al. have reported a comprehensive exploration of the binding of a wide variety of inhibitors with all four HSP90 isoforms using a fluorescence polarization assay based on a purine probe compound.[189] They have coupled this with a structural analysis of each of the proteins and the binding modes of the inhibitors using protein/ligand structures where available or modeling if structures were not available. They postulate three binding pockets; pocket A is the ATP-binding region,



119

Fig. 64 GRP94 selective inhibitor.

pocket B is an adjacent lipophilic region, and pocket C is the exit vector to solvent. Their data suggests that selectivity is achieved via pockets B and C and explain the lower binding of several inhibitors to Trap-1 as being caused by a clash of substituents on the ligands with Lys126 and Phe201 in this pocket of Trap-1. Evidence that selectivity can affect the biology observed has been demonstrated for a purine-based inhibitor **119** (Fig. 64) which is 140-fold selective for GRP94 over HSP90.[190] GRP94 specifically associates with HER2 in SkBr3 cell membranes and compound **119** destabilizes HER2 but does not lead to induction of HSP70. Further recent work exemplifying these principles has recently been reported and the profile of compound **119** investigated in detail.[191] The possibility for further tuning of the pan-HSP90 response by developing selective inhibitors is an exciting area.

5.07.4 Targeting Protein Degradation

5.07.4.1 Introduction

The UPS represents the major quality control pathway for newly synthesized proteins and is a crucial element for maintaining intracellular protein homeostasis and normal cellular functions. The UPS governs proteolytic degradation and other essential cellular processes, such as cell cycle progression, signaling, and antigen processing; therefore, its malfunction is often connected to the development of diseases, including cancer, immune disorders, and neurodegeneration. Thus, targeting the UPS with small-molecule inhibitors represents a viable approach in drug discovery. In particular, the great value of the UPS as a cancer therapeutic target was revealed in 2003 with the FDA approval of the proteasome inhibitor bortezomib, which has become the standard of care for the treatment of relapsed and refractory MM and MCL.[192] Further corroboration arrived the following year as the discovery of the ubiquitin-mediated protein degradation was awarded the Nobel Prize in chemistry.[193]

However, despite the undeniable potential, only a limited number of drugs targeting the UPS have reached FDA approval to date. The main reason for such slow progress is perhaps the difficulty in targeting with small molecules a system that lacks a well-defined enzymatic function and mostly relies on multiple protein–protein interactions. Nevertheless, despite these challenges, improved proteasome inhibitors have been developed and other promising targets within the UPS cascade upstream of the proteasome have emerged with potential for more targeted therapies. These are designed to improve the therapeutic index of the pioneer proteasome inhibitors.[194]

5.07.4.2 The Ubiquitin–Proteasome System

The UPS comprises a series of enzymes, whose aim is to achieve protein ubiquitylation and degradation (Fig. 65). As a whole the cascade includes 2 E1 enzymes, around 40 E2 enzymes, 700 E3 ligases and the proteasome, providing opportunities for both broad and targeted therapeutic approaches.[195]

The process consists of five main steps:

(1) *Activation*: the protagonists in this first step are the E1 activating enzymes, which use the energy derived from ATP hydrolysis to form a thioester bond with the carboxyl terminus of ubiquitin and initiate the cycle.
(2) *Conjugation*: the E2 conjugating enzymes receive the ubiquitin molecule from the E1 enzymes via transthiolation reactions.
(3) *Ubiquitin-conjugate recognition*: the E2-ubiquitin complex is recognized by the E3 ligase enzymes, interacting to transfer the ubiquitin to an acceptor lysine residue present on the substrate protein of E3. This process of ubiquitin-tagging of the target protein is repeated several times and is linked to various physiological processes. The linkage can happen to any of the seven lysine residues of ubiquitin (K6, K11, K27, K29, K33, K48, and K63). Generally, if the polyubiquitin chain is K48-linked, it represents the label which marks the substrate for proteasomal degradation. On the other hand, if poly-ubiquitylation happens at the K63 site, modifications of signal transduction pathways occur.
(4) *Ubiquitin removal*: at this point, the ubiquitylated protein can have two distinct destinies: it can be rescued via deubiquitylation through specific deubiquitylating enzymes (DUBs) or it can proceed toward the final step of degradation.
(5) *Substrate degradation by the proteasome*: the substrates bearing the K48-linked ubiquitin chain are delivered to the 26S proteasome. When the proteasome interacts with the tagged proteins, they are degraded into small peptides, while ubiquitin is released and recycled.

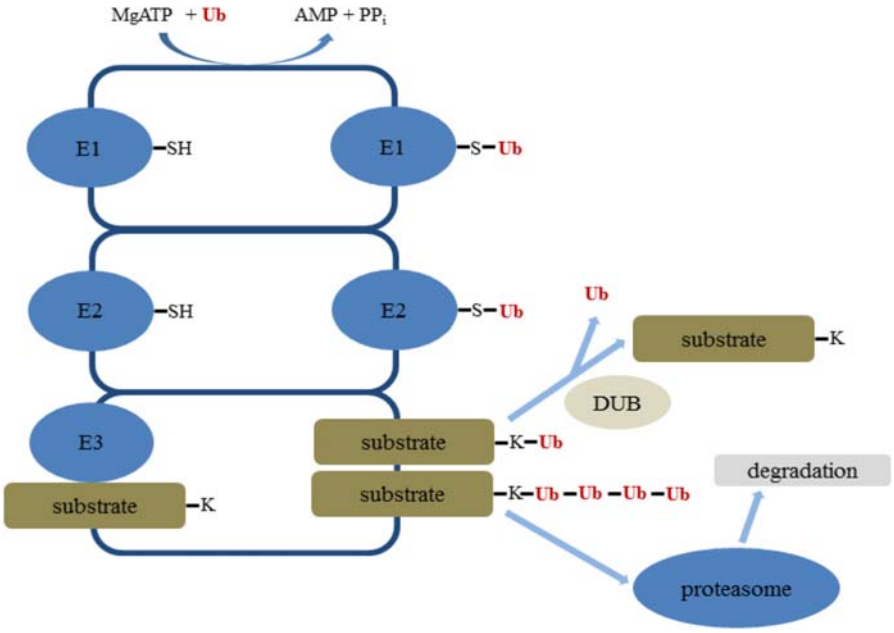


Fig. 65 Schematic representation of the ubiquitination–proteasome degradation cascade. E1: ubiquitin activating enzyme; E2: conjugating enzyme; E3: ligase; Ub: ubiquitin; DUB: deubiquitylating enzyme; –K: lysine residue; –SH: thiol moiety.

It is important to highlight that, although being the first identified and most thoroughly studied, ubiquitin is not the only tag for protein degradation. Subsequently, other tags, called UBLs (ubiquitin-like proteins), have been identified, adding complexity to the proteolytic system.[196,197]

5.07.4.3 Targeting the E1 Activating Enzymes in Cancer Therapy

The E1 (ubiquitin activating enzymes) are at the top of the UPS cascade. Only two different isoforms have been identified in humans, UBA1 and UBA6 (of which UBA1 predominates), which control ubiquitylation of all downstream targets. Due to the low number of isoforms, E1 enzymes are considered challenging broad targets as their lack of specificity could lead to toxic side effects. However, they are also the only enzymes within the UPS cascade with an ATP-dependent mechanism, a feature which may be exploited for the development of selective inhibitors.[192,198]

In their mechanism of action, ATP and ubiquitin interact to form a ubiquitin–AMP intermediate which then reacts with the catalytic cysteine residue of E1 to form a thioester adduct. Another molecule of ATP and ubiquitin bind the enzyme to form a ternary complex from which, via transthiolation, E1 transfers ubiquitin to E2. There are different points of the process in which a small-molecule inhibitor could interfere and the interest in targeting E1 enzymes is increasing.[194,199] To date, there have been mainly two strategies under development: the first strategy focuses on targeting the cysteine residue at the active site of E1 in order to inhibit the transthiolation reaction; the second approach exploits small molecules as AMP mimetics in order to stop the formation of the ubiquitin–AMP complex.

Although delivering early stage irreversible E1 inhibitors, such as the synthetic cell permeable 2-nitro-furan-based inhibitors, PYR41 and PYZD4409,[192] or the natural products himeic acid A and panepophenanthrin[199,200] (Fig. 66), the first approach was unsuccessful for the development of clinical candidates, mainly as a result of selectivity issues, undefined mechanistic characterization, suboptimal potencies, and a lack of drug-like properties, which prevented further progression.

More fruitful, on the other hand, has been the second approach, which led to the development of the clinical candidate pevonedistat.

5.07.4.3.1 Pevonedistat (MLN4924)

Pevonedistat, **125**, is a first-in-class NAE inhibitor with a unique mechanism of substrate-assisted enzymatic inhibition.[195] It targets a specific subclass of E1 enzymes, called NAE (NEDD8-Activating Enzyme, where NEDD8 is an ubiquitin-like protein). In contrast to E1 pan-inhibitors, which were found to be unsuitable for clinical development due to toxicities associated with the broad spectrum E1 inhibition, the great advantage of pevonedistat is its superior selectivity.[201] Importantly, this highlighted that it is possible to target a single UBL pathway without affecting the bulk protein turnover.[202]

Pevonedistat was discovered via a HTS campaign,[201,203,204] and it is an analog of AMP, **126**, a tight binding product of NAE. There are some key structural differences: pevonedistat bears a deazapurine base instead of the adenine base; a carbocycle moiety replaces the ribose sugar and the phosphate group is replaced with a sulfamate, particularly important for its mechanism of action.

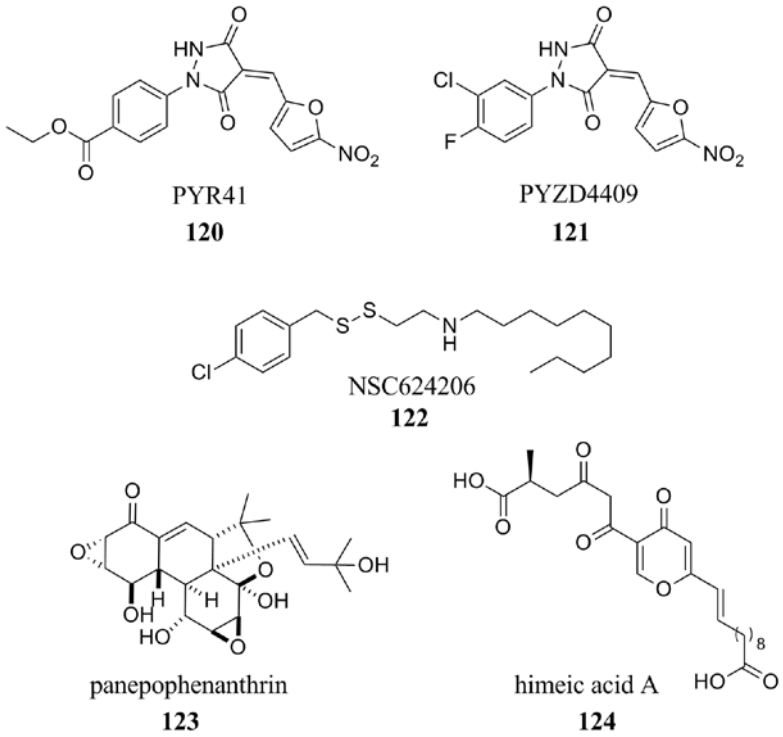

Fig. 66 Chemical structures of some reported synthetic and natural E1 inhibitors.

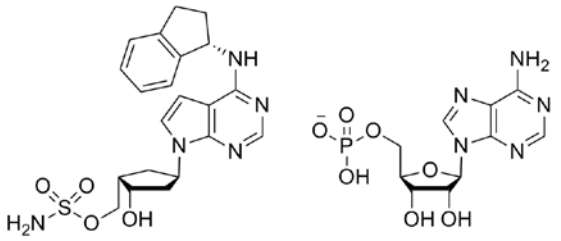
The stereochemistry, too, is different, with pevonedistat bearing a nonnatural antirelationship between the deazapurine and the sulfamate groups[205] (Fig. 67).

Under normal conditions, the enzyme NAE controls the activity of the E3 Cullin-RING ubiquitin ligases (CRLs) by promoting modification of the NEDD8 protein. ATP and NEDD8 bind to NAE and react to form a covalent complex, NEDD8-AMP. The adduct then reacts with a cysteine residue at the active site of the NAEβ subunit to form a thioester bond between NAE and NEDD8, releasing AMP. Finally, a second NEDD8 molecule is added to form the ternary complex, NEDD8–NAE–NEDD8 (probably more favorable in terms of energy and conformation), which transfers the NEDD8 to specific E2 conjugating enzymes by transthiolation.[206] In turn, the E2 enzymes will transfer NEDD8 to a specific lysine residue at the active site of the E3 ligase. This neddylation reaction is an important posttranslational modification necessary to activate the CRLs. Pevonedistat can exploit the amino group of the sulfamate moiety to perform nucleophilic attack on the thioester bond between NEDD8 and the NAEβ subunit, and form



NAE IC50 = 0.004 μM
UAE IC50 = 1.5 μM
SAE IC50 = 18 μM
UBA6 IC50 = 8.2 μM
ATG7 IC50 >10 μM

Fig. 67 Structural features and selectivity profile of pevonedistat/MLN4924, **125**.

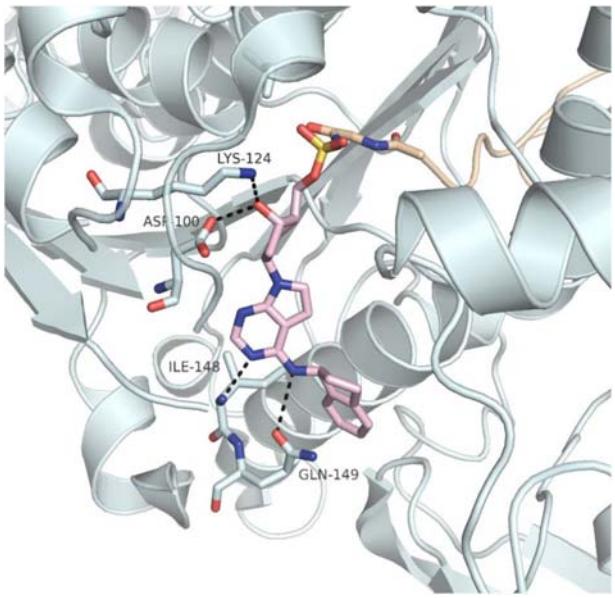


Fig. 68 X-ray crystal structure of NAE (*light cyan*) complexed with NEDD8-MLN4924 (NEDD8 shown in wheat and pevonedistat/MLN4924, **125** shown in *light pink*), PDB: 3GZN. The structure of the ligands NEDD8-MLN4924, and the key binding site residues are shown as sticks. Selected interactions are shown in *black-dashed lines*.

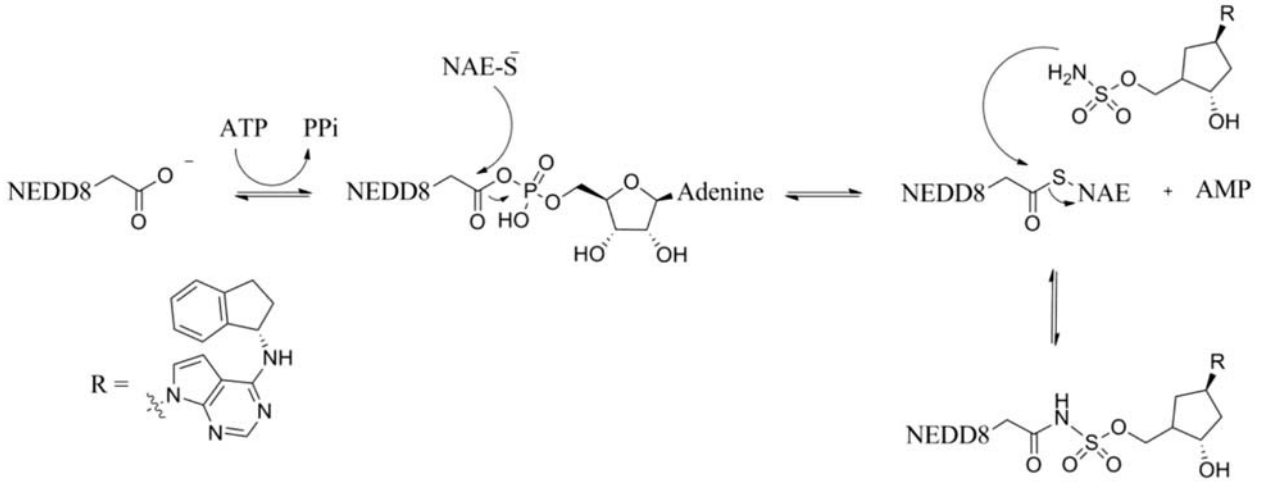
a covalent bond with the C-terminal glycine of NEDD8. This adduct inhibits the cascade. Crystallographic analysis of MLN4924 in complex with the NAEβ subunit has highlighted key interactions which mimic the contacts between the enzyme and ATP. In particular, Asp100 and Lys124 interact with the 3′-OH of the cyclopentane moiety and Ile148 and Gln149 interact with the deazapurine ring. Finally, the sulfamate oxygens interact with Gly79 mimicking the interaction with the α-phosphate oxygens of ATP (Fig. 68). This final interaction is proposed to be responsible for lowering the pK_a of the sulfamate moiety (pK_a 9.35) and promoting nucleophilic attack at the thioester bond of the NEDD8–NAE complex[201] (Scheme 2).

Pevonedistat showed potent inhibition of NAE, with an IC_{50} of 4 nM, and good selectivity with respect to other related enzymes in biochemical assays monitoring the formation of E2-UBL thioester complexes (Fig. 67). The selective NAE inhibitory effect was reconfirmed in cell-based assays that showed apoptosis and selective deregulation of the DNA synthesis (S) phase in cancer cells.[201] This translated in vivo; indeed, pevonedistat displayed high efficacy (growth inhibition and regression) at tolerated doses in multiple human cancer xenograft models when administered daily or at set dosing schedules.[201]

This exciting preliminary data supported the transition of pevonedistat in clinical development.[201] In Phase I studies, pevonedistat displayed a reasonable safety profile with only limited myelosuppression, rendering it suitable for combination therapy with cytotoxic agents. To date, several clinical trials of **125** in multiple solid tumors and hematological cancers have been completed,



Scheme 2 Mechanism of the NEDD8-MLN4924 complex formation.

with some still ongoing, where pevonedistat is used as a single agent or in combination with cytotoxic agents (gemcitabine, paclitaxel, docetaxel, and carboplatin).[207]

5.07.4.3.2 Targeting the E2 conjugating enzymes in cancer therapy

The E2 conjugating enzymes are not only "ubiquitin-carriers," responsible for the transfer of ubiquitin-tags to the target proteins, but they are also considered key mediators in the chain assembly process and in substrate selectivity.[192,208,209] As the E2 enzymes have been connected to several malignancies including ovarian carcinoma, breast cancer, melanoma, and lung cancer, they may represent an alternative target for cancer therapy.[210] In addition, E2 enzymes are more diverse (there are around 40 isoforms in humans) thus this class might provide the required specificity which is lacking in the E1 enzyme-focused therapies. However, there are some caveats associated with the drugability of E2 enzymes. Firstly, their enzymatic core is highly conserved and possess a reactive cysteine residue, therefore development of selective drugs can be challenging. Secondly, they possess a shallow active site, difficult to target with small molecules.[195]

In theory, as the E2 enzymes function as intermediates between E1 and E3 proteins, and as they bind E1, E3, and ubiquitin, inhibitors could be targeted to different interfaces.[211] Unfortunately, possibly due to the complexity behind the dynamics of the interactions, no potent and selective E2 small-molecule inhibitors have been developed to date. However, some advances have recently been published.[209,212–214] The compound CC0651,[215] **127** (Fig. 69), has been reported as an allosteric inhibitor of the E2 enzyme CDC34, with consequent inhibition of ubiquitination of $p27^{KIP1}$. Also, BAY11-7082, **128**, has been reported as an inhibitor of UBE2N via covalent modification of a cysteine residue in the active site.[216] Another reported small molecule is the NFkB inhibitor, NSC697923, **129**, which specifically targets the E2 enzyme UBE2N and inhibits transfer of ubiquitin to target proteins by blocking the formation of the UBE2N-ubiquitin thioester conjugate.[217] The specificity is related to binding to a cleft in the active pocket not accessible in other E2 enzymes.[209] Also recently reported are selective Rad6 inhibitors, such as TZ8, **130**, and TZ9,[213] **131** (Fig. 69).

5.07.4.3.3 Targeting E3 ligases

More focus has been put on the discovery and development of E3 ligase inhibitors. Probably the main reason for this is that the E3 ligases represent the least promiscuous class of enzymes within the whole ubiquitination–proteasome degradation pathway, thus they are considered safer targets to exploit in cancer therapy. Selective targeting of the E3 ligases with small-molecule inhibitors has been seen as a promising approach in the quest for less toxic anticancer therapies.

The human genome contains around 700 E3 ligases, which are responsible for substrate selectivity in the ubiquitin–proteasome cascade. They are generally divided into four classes: HECT (homology to E6AP C-terminus) domain E3 ligases; U-box E3 ligases; RING (Really Interesting New Gene) finger E3 ligases; multisubunit E3 complexes.[192,218] The E3 ligases are responsible for the ubiquitin–protein conjugation step necessary to obtain targeted proteasomal degradation. As E3 ligases possess specific regions

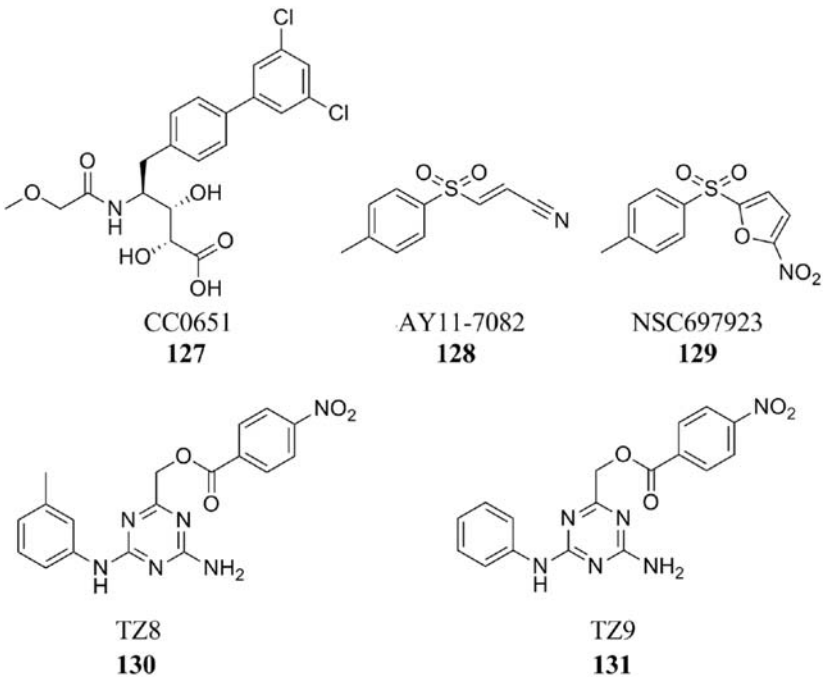


Fig. 69 Chemical structures of recently reported E2 enzyme inhibitors.

for recognition and binding of the target proteins, they determine the substrate specificity and so the selectivity of the proteasome machinery.

Although the principle of targeted E3 ligase cancer therapies is extremely appealing, drug discovery for these proteins is technically challenging as it involves inhibition of protein/protein interactions.[195] The main limitations concern the lack of catalytic activity or recognizable active sites which lead to targeting large protein interfaces with small-molecule inhibitors in order to disrupt the E3 complexes or to achieve allosteric inhibition. Another caveat around inhibition of E3 ligases is the abrogation of auto-ubiquitylation, which would lead to accumulation of a pool of E3 ligases. This excess pool would still bind their substrates without ubiquitylating them, and could result in the possible impairment of the substrate functions.

Nevertheless, several E3 ligase inhibitors[194,219] have been developed and have undergone or are undergoing clinical trials (some examples are: JNJ26854165, LCL161, AEG 35156, AEG 40826, YM155).[192,220]

So far the most druggable E3 ligases appeared to be MDM2 (mouse double minute 2 homolog) and IAPs (inhibitor of apoptosis proteins).[218] More recently, also SCF^{SKP2} (Skp1–Cul1–F-box-protein) is emerging as a possible selective anticancer target. Small molecules capable of binding SCF^{SKP2} and disrupting the interaction between SKP1 and SKP2 have revealed antitumor activity in several animal models and demonstrated synergistic activities with other anticancer agents.[221]

5.07.4.3.3.1 MDM2

MDM2 is an E3 ubiquitin ligase which fulfills the criteria of an ideal cancer target, with low expression in physiological conditions and significant overexpression in a wide variety of tumors including breast, lung, esophageal carcinomas, sarcomas, melanomas, and glioblastomas.[222] MDM2 acts as an E3 ligase and promotes degradation of the oncosuppressor p53. Inhibition of MDM2 is a valid strategy to reactivate p53.[223]

However, protein–protein interactions are one of the most challenging target classes in medicinal chemistry due to the large interfacial area between the two proteins and successful antagonism of these interactions often require small-molecule "hot spots" to be present on the protein surface, where high affinity interactions can be achieved.[224]

Despite the caveats associated with the development of small molecules targeting protein–protein interactions, crystallographic analysis of the MDM2/p53 complex was encouraging as it revealed a deep and well-defined hydrophobic pocket at the N-terminus of MDM2 which is capable of accommodating p53. The N-terminus of the p53 peptide uses three key amino acids (Phe19, Trp23, and Leu26) to interact with MDM2 (**Fig. 70**).[225,226]

It was reasoned that small molecules could insert into this defined cleft, mimic the three key amino acids of p53, and disrupt the protein–protein interaction.

Several MDM2 ligase inhibitors have been reported to date, including compounds identified by in vitro HTS screens (i.e., HL198,[227] TDP521252, and TDP665759[228]), in cell screens (Mel 23[229]), or structure-based design (MI-63[230]).

Through a biochemical high-throughput screen, Roche screened a diverse library of small molecules, from which numerous hits were optimized for potency and selectivity. In particular, one chemical series of *cis*-imidazolines, also termed the nutlins, has been progressed to the clinic.[231]

5.07.4.3.3.1.1 Nutlins

These unusual *cis*-dihydroimidazole compounds bind to the surface of MDM2 by mimicking an alpha-helical segment of p53 in which three key lipophilic residues, Leu26, Trp23, and Phe19, project into lipophilic pockets on the surface of MDM2.[232] The first lead compound, nutlin-3a, **132** (**Fig. 71**), contains two 4-chlorophenyl moieties that perfectly occupy the Leu26 and Trp23 pockets and an isopropoxy substituent which is deeply buried in the Phe19 pocket (**Fig. 70**). Interestingly, only one enantiomer displayed high binding potency ($IC_{50} = 0.09\ \mu M$ vs. $IC_{50} = 13.6\ \mu M$ by SPR).

Nutlin-3a, **132**, exhibits good potency in biochemical HTRF (homogeneous time resolved fluorescence) assay with an IC_{50} of 88 nM, promising IC_{50} of 1.5 μM in a cell viability MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay against a series of wild-type p53 cancer cell lines (HCT-116, SJSA-1, RKO), and selectivity (defined as ratio between IC_{50} for mutant and WT p53 cell lines) of 15-fold.[225,231] This potency translated in vivo, where in human osteosarcoma SJSA-1 xenograft mouse model nutlin-3a dosed at MTD (200 mg kg^{-1}, po, twice daily) afforded 90% tumor growth inhibition. Albeit a useful chemical tool for the study of the p53/MDM2 complex, nutlin-3a had a suboptimal pharmacological profile which needed to be improved for clinical development.[233]

A second-generation nutlin, RG7112, **133**, was designed (**Fig. 71**). This compound retains the most important structural features of nutlin-3a necessary to bind MDM2, such as the two 4-chlorophenyl groups where the chlorine substituents are crucial to maintain activity, and the third aromatic ring which inserts its alkoxy substituent into the Phe19 pocket. In an effort to reduce the molecular weight, the isopropoxy group was changed to the slightly smaller ethoxy group, without detriment to the interactions with the Phe19 pocket.

In order to prevent oxidation of the imidazoline core, which inactivates the compound, the hydrogens in the 4- and 5-positions of the ring were masked with two methyl groups, whose steric bulk was well-tolerated in terms of binding. Furthermore, the 4-methoxy group on the aromatic ring, which represented another metabolic soft spot, was replaced by a bulkier and more stable *tert*-butyl group. Finally, a solvent-exposed vector was exploited for attachment of a polar sulfone lateral chain. This afforded RG7112, which had improved biochemical activity (HTRF $IC_{50} = 18$ nM), cellular activity (MTT $IC_{50} = 0.4\ \mu M$), and selectivity (33-fold) (**Fig. 71**).

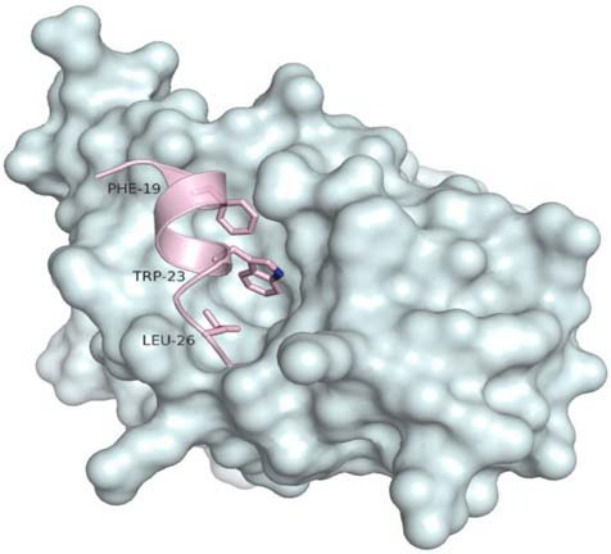

Fig. 70 X-ray crystal structure of the MDM2/p53 complex (PDB: 4HFZ). The structure of MDM2 is shown as surface (*cyan*), p53 is shown as cartoon (*light pink*), and the key binding site residues are shown as sticks.

Comparison of the crystal structures of nutlin-3a, **132**, and RG7112, **133**, bound to MDM2 revealed a very similar binding mode for the two analogs (Fig. 72). The improvement in affinity and consequent antiproliferative activity was attributed to the methyl sulfone substituent on the piperazine ring. Introduction of a polar lateral chain and removal of the metabolic soft spots resulted in a better in vivo PK performance, with high exposure and long half-life (~9 h) in mice.

RG7112 was considered suitable for in vivo efficacy studies in the human osteosarcoma SJSA-1 cell line xenograft mouse model. The compound achieved 74% tumor growth inhibition at a daily oral dose of 50 mg kg^{-1} and tumor regression at 100 mg kg^{-1}. Similar results were obtained in other osteosarcoma cell lines.[233] In addition, RG7112 displayed a good safety profile in preclinical toxicology studies and it was progressed to human clinical trials. To date, RG7112 has undergone six clinical trials, with one still ongoing, for the treatment of both solid and blood cancers.[234]

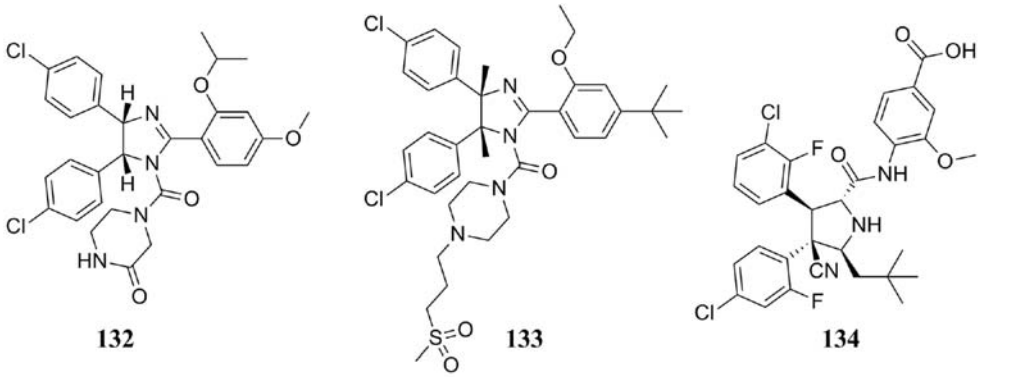

Fig. 71 Evolution of the nutlins from the tool compound, **132**, to the clinical candidates, **133** and **134**.

Unfortunately, some Phase I clinical trials of RG7112 have been rather disappointing due to a lack of response and quite severe side effects, including neutropenia and thrombocytopenia.[235] This highlights the difficulty surrounding a p53 stabilizing therapy which would not affect normal cells. Despite the improvement afforded with the second-generation nutlin, better potency and selectivity were desirable. In order to achieve efficacy in the treatment of AML, RG7112 is administered at the MTD (1500 mg twice daily) which results in some toxicity, such as hematological and gastrointestinal side effects and delirium.[223] For such reasons, Roche continued further optimization of this series, which led to the development of a third generation of nutlins, with increased potency and selectivity.[236]

The key structural feature of this new chemical subseries is a pyrrolidine ring with a "*trans-trans*" configuration, which allows the 3-chlorophenyl and neopentyl substituents to adopt an equatorial position and maintain optimal binding with the hydrophobic pockets (**Fig. 72**).

Structure–property relationship exploration identified introduction of fluorine atoms on the aromatic rings together with the *para*-benzoic acid side chain, as a useful tool to improve the pharmacokinetic profile, leading to compound RG7388, **134**. Interestingly, while lying in proximity to a rather flat region of the protein surface, the *para*-benzoic acid substituent also improved the potency (HTRF $IC_{50} = 6$ nM; MTT $IC_{50} = 30$ nM) and selectivity (344-fold), together with an improvement in the PK profile (mouse $CL = 11\%$ HBF, $F = 80\%$).

Superior potency and pharmacokinetics translated into better efficacy in xenograft models at reduced dose and exposure. Indeed, in human osteosarcoma SJSA1 xenograft mouse model RG7338 displayed tumor regression with TGI > 100% at 25 mg kg^{-1}, while the precursor RG7112, at double dose of 50 mg kg^{-1}, reached a TGI of 74%.

Currently, RG7338 has completed two Phase I clinical trials for the treatment of advanced malignancies and is now undergoing new trials (**Fig. 73**).[237]

5.07.4.3.3.1.2 Other MDM2/p53 inhibitors

The serendipitous discovery of the nutlins established an alpha-helical mimicking pharmacophore as the key design feature for future inhibitors. To mimic the helical conformation of the p53 peptide, a spirooxindole core was designed with similar lipophilic substituents as the original nutlins. This led to the clinical candidate MI77301, **136** (**Fig. 74**), displaying subnanomolar biochemical affinity, $GI_{50} = 70$ nM in wild-type p53 cancer cell lines and regression in human xenograft tumors.[238]

Other small-molecule MDM2/p53 inhibitors have been developed over the past two decades, such as RITA,[239] **137**, MI-63,[230] **138**, and MI-219,[240] **139** (**Fig. 75**), which act on MDM2 E3 ligase by promoting p53 stabilization, or the natural product parthenolide (PN) and its dimethylamino derivative DMAPT,[241] **140**, which induce ubiquitylation and proteasomal degradation of MDM2 with consequent activation of p53. Serdemetan (JNJ-26854165), **141**, is a tryptamine-derived compound which binds to MDM2 and prevents the ubiquitylation and degradation of p53.[194] This compound has undergone Phase I clinical studies in patients with advanced stage or refractory solid tumors.[242]

However, despite the undeniable therapeutic potential, each aforementioned MDM2/p53 inhibitor is only active against WT p53, while p53 mutants are stabilized and remain unaffected by MDM2 ubiquitylation. It might be more efficacious to use small molecules aiming to restore p53 to its native form. In this context, PRIMA-1 and APR-246[243] exploit the covalent alkylation of thiols in mutant p53 in order to restore the wild-type conformation and activity. APR-246, **142**, is currently being evaluated in combination therapy with carboplatin against high-grade serous ovarian cancer[244] (**Fig. 75**).

5.07.4.3.3.2 Inhibitor of apoptosis proteins (IAPs)

The Inhibitor of Apoptosis Protein (IAP) E3 ubiquitin ligases are another broad family of ligases of interest for cancer therapy as they are overexpressed in many cancer cells and it has been demonstrated that they contribute to tumor survival, chemoresistance, and disease progression.[194,245,246] Eight IAP isoforms have been identified in humans, among which XIAP, cIAP1, and cIAP2 have been the focus of several drug discovery programs. Their mechanism of action is based on the exploitation of three specific domains (BIR1, BIR2, and BIR3) to bind, ubiquitylate, and degrade caspases 3, 7, and 9.[194] The majority of the small-molecule inhibitors of IAPs developed to date are termed "Smac-mimetics" as they mimic the natural inhibitor of IAP proteins, Smac/DIABLO.[247] The latter is a proapoptotic protein that binds IAP and blocks the interaction with the caspases. Several Smac-mimetics have undergone, or are currently undergoing, Phase I/II clinical trials.[192]

5.07.4.3.3.2.1 AT-406 (SM-406)

AT-406/SM-406, **143**, is a potent and orally bioavailable compound (Fig. 76) discovered by Ascenta Therapeutics as an antagonist of multiple IAP proteins (XIAP, cIAP1, and cIAP2).[248]

The compound was designed using structure-based drug design on the crystal structure of Smac in complex with the XIAP BIR3 domain, with the aim to mimic the interactions between the endogenous Smac AVPI tetrapeptide, **144**, and XIAP BIR3 domain (Fig. 77).

As there are numerous caveats associated to the use of Smac peptides, such as poor permeability, lack of oral bioavailability and metabolic stability, the SAR exploration was focused on nonpeptide analogs. In particular, based on the finding that the isopropyl group of the valine residue of AVPI can be replaced and cyclized in a bicyclic lactam without distorting the binding conformation, constrained lactam analogs were evaluated.[249]

In addition, as the isoleucine residue only exploits the hydrophobic side chain to interact with the protein while the carbonyl moiety is not involved in any specific interaction, this terminal amino acid could be replaced by aromatic substituents with great gain in binding affinity. This led to SM-122, **145**, a highly potent analog. An unfavorable PK profile in rats prevented its further progression. Exploitation of a more polar diazabicyclic core had a dramatic effect on the physicochemical balance of the compound, leading to the candidate compound, SM-406, **143**, characterized by good aqueous solubility (>50 mg mL^{-1}) and adequate oral exposure, consistent across the species (F: mouse = 38%; rat = 45%; NHP = 42%; dog = 55%).[248]

Computational docking simulations revealed that AT-406 can form similar hydrophobic and hydrogen bonding interactions with respect to AVPI (Fig. 77)[250]; however it engages a further hydrophobic interaction with Trp323 of XIAP and exploits its terminal methylamino moiety to insert into a small hydrophobic binding pocket created by Trp310 in XIAP BIR3.[248] Replacement of the methylamino substituent with a bulky 3-methyl-1H-indole motif disrupts the interaction of AT-406 and XIAP BIR3, leading to an inactive compound (SM-428, **146**) used as a negative control. The FP assay revealed that AT-406 has 50- to 100-fold higher

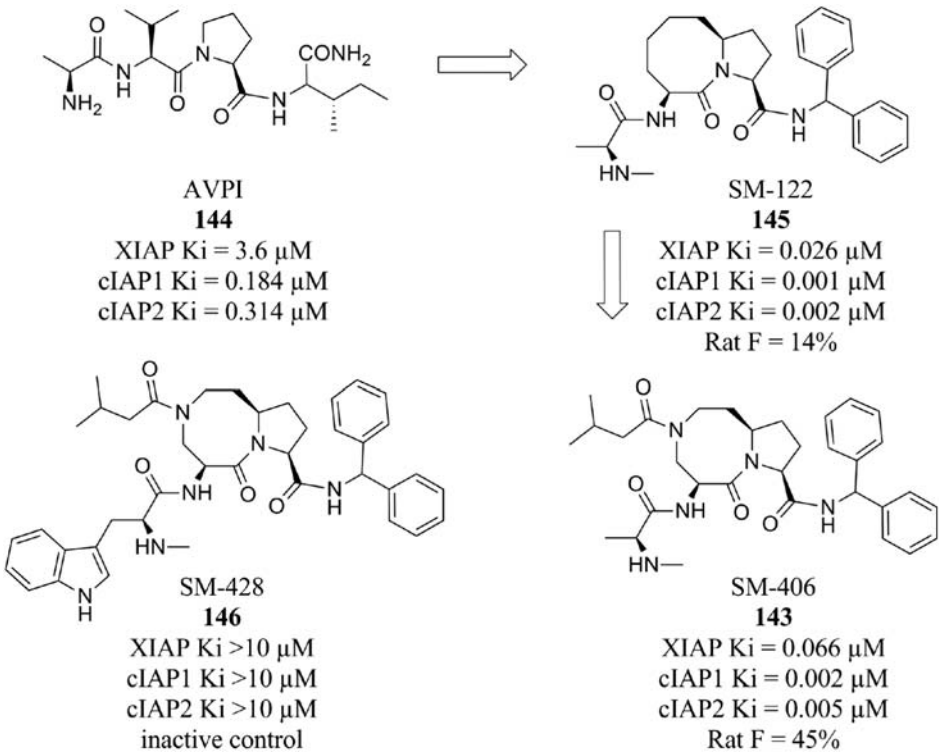

Fig. 76 Structure-based design from the Smac tetrapeptide, **144**, AVPI to the clinical candidate SM-406, **143**. The matched pair negative control SM-428 is also highlighted.

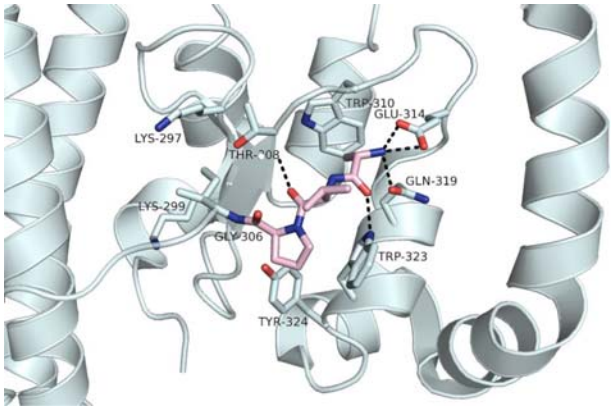

Fig. 77 X-ray crystal structure of XIAP BIR3 (*cyan*) complexed with Smac AVPI, **144** (*light pink*), PDB: 1G73. The structure of the ligand, and the key binding site residues are shown as sticks. Selected interactions are shown in *black-dashed lines*.

affinity than Smac AVPI and binds to XIAP, cIAP1, and cIAP2 with K_i of 66.4, 1.9, and 5.1 nM, respectively. The negative control, as expected, lost affinity for the IAPs (FP IC_{50}s > 10 μM) (Fig. 76).[248] Subsequently, AT-406 and its inactive matched pair were tested in a cell-free functional assay for caspase 9 activity; at 1 μM AT-406 completely antagonized XIAP and reactivated caspase 9 function. The inactive control, on the other hand, showed no activity even at > 100 μM.

AT-406 was screened against more than 100 human cancer cell lines and showed potent growth inhibition for the ovarian SK-OV-3 (IC_{50} = 142 nM) and breast MDA-MB-231 (IC_{50} = 144 nM) by 4-day WT assay, with minimal toxicity toward normal human epithelial cell lines (IC_{50} > 10 μM). In addition, AT-406 displayed high efficacy in MDA-MB-231 breast cancer xenografts, causing tumor growth inhibition after oral dosing at 100 mg kg^{-1} (T/C = 0.30 on day 50) with no toxic effects. A good in vitro safety profile with no hERG ion channel inhibition (IC_{50} > 30 μM) and minimal cytochrome P450 inhibition, coupled to favorable tolerability in dogs, allowed progression of this compound to Phase I clinical trials against ovarian cancer as a single agent, and in combination with carboplatin.[251]

5.07.4.3.3.2.2 GDC-0152

GDC-0152, **147**, is another analog of the endogenous AVPI tetrapeptide (Fig. 78) which was developed as a pan-IAP antagonist, capable of inhibiting cIAP1/2, ML-IAP, and XIAP.[252]

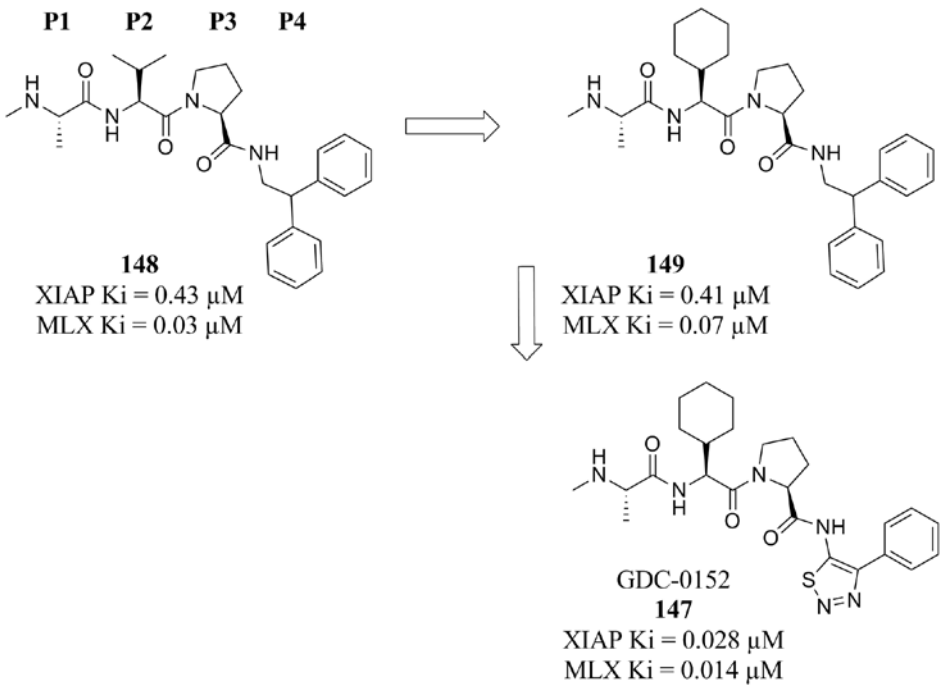

Fig. 78 Development of the clinical candidate GD-0152, **147**, by peptidomimetic approach.

After several unsuccessful large HTS small-molecule screening campaigns (>2,000,000 compounds) which did not deliver any viable hits, a more fruitful peptidomimetic approach was utilized; with the Ala-Val-Pro-2,2-diphenethylamine analog (compound **148**) as a starting point, a systematic approach was undertaken in order to explore different substitutions in the P1–P4 positions with the aim to reduce the peptide character of the compound.[253]

Crystallographic studies revealed that the methyl group of the alanine residue in P1 was deeply inserted into a hydrophobic pocket composed of Leu131, Trp134, and Glu143. As this is a key interaction, it is difficult to replace. At the P2 position, on the other hand, the SAR was broad, with different substitutions being tolerated. The endogenous valine residue only gives weak van der Waals interactions with Ser133 of ML-IAP and it can be easily modified. Substitution with larger, hydrophobic substituents, such as cyclohexyl moieties, provided no differences in binding affinities (compound **149**).

In the P3 position, substitution on the proline ring has been reported as a strategy to tailor selectivity toward specific classes of IAPs, and therefore it would not be suited for a pan-IAP inhibitor approach.[254] As such, the proline residue was left unmodified. Finally, for the P4 position, several aromatic moieties were screened as replacements of the endogenous AVPI isoleucine to occupy the hydrophobic pocket created by Thr116, Gly130, and Glu132 (Fig. 79). Among these substituents, thiadiazole proved to be the moiety of choice.

The resultant candidate, GDC-0152, **147**, binds XIAP-BIR3, cIAP1-BIR3, cIAP2-BIR3, and ML-IAP with $K_i < 50$ nM. This potency translated into cells where the compound was found to activate caspases 3 and 7 in a dose- and time-dependent manner. When tested in a 3-day cell viability assay in the MDA-MB-231 breast cancer cell line, GDC-0152 produced a decrease in viability, with no effect on normal human mammary epithelial cells.

The compound also displayed good kinetic solubility (40 mg mL^{-1} at pH 5.5, 2.0 mg mL^{-1} at pH 6.7, and 4.6 mg mL^{-1} at pH 7.7) and a favorable PK profile with good predictions to man (predicted human $CL = 9.6$ mL min^{-1} kg^{-1}; $V_{ss} = 1.2$ L kg^{-1}) based on allometric scaling from mouse, rat, dog, and monkey. In xenografts of MDA-MB-231 human breast cancer cells, it showed effective tumor reduction when dosed at 100 mg kg^{-1} once per week, with 95% tumor growth inhibition. Such overall promise, combined with a favorable safety profile in preclinical species, led to the selection of GDC-0152 for clinical trials. It has currently undergone Phase I studies with advanced or metastatic solid tumors.[255]

5.07.4.3.3.2.3 Birinapant (TL32711)

Birinapant, **150** (Fig. 80), is another Smac-mimetic IAP-antagonist, developed by Tetralogic Pharmaceuticals.[256] This compound is a bivalent Smac-mimetic, a symmetrical molecule containing two Smac-mimetic monomers tethered by a linker. Dimerization is common among proapoptotic proteins and small-molecule dimers are considered a useful strategy to enhance potency and selectivity with respect to the monovalent counterparts as the dimers can bind multiple BIR3 domains of IAPs.

In contrast to the aforementioned monomeric IAP antagonists, which were developed aiming toward a pan-IAP inhibition as a means to increase efficacy, birinapant was designed to be more selective as part of a strategy to improve tolerability.

SAR exploration around the P2 residue highlighted how the increase in steric bulk at this position increases the selectivity against XIAP; this is detrimental as a strong inhibitory effect on the XIAP pathway is connected to NOD-dependent NFkB activation, inflammatory responses, and lower tolerability.[256] By carefully tailoring the steric bulk around P2, it was possible to achieve strong cIAP1 inhibition with milder effects on cIAP2 and XIAP functional activity, as demonstrated by NOD-dependent NFkB luciferase assay (Fig. 80).

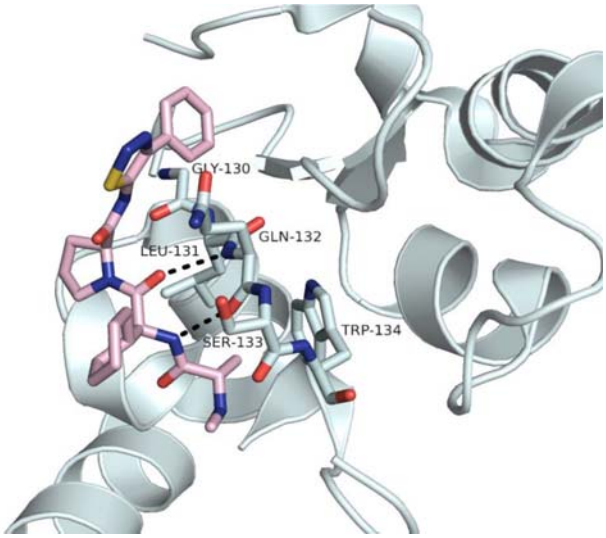

Fig. 79 X-ray crystal structure of the ML-IAP/XIAP chimeric binding domain (*cyan*) complexed with GDC-0152, **147** (*light pink*), PDB: 3UW5. The structure of the ligand, and the key binding site residues are shown as sticks. Selected interactions are shown in *black-dashed lines*.

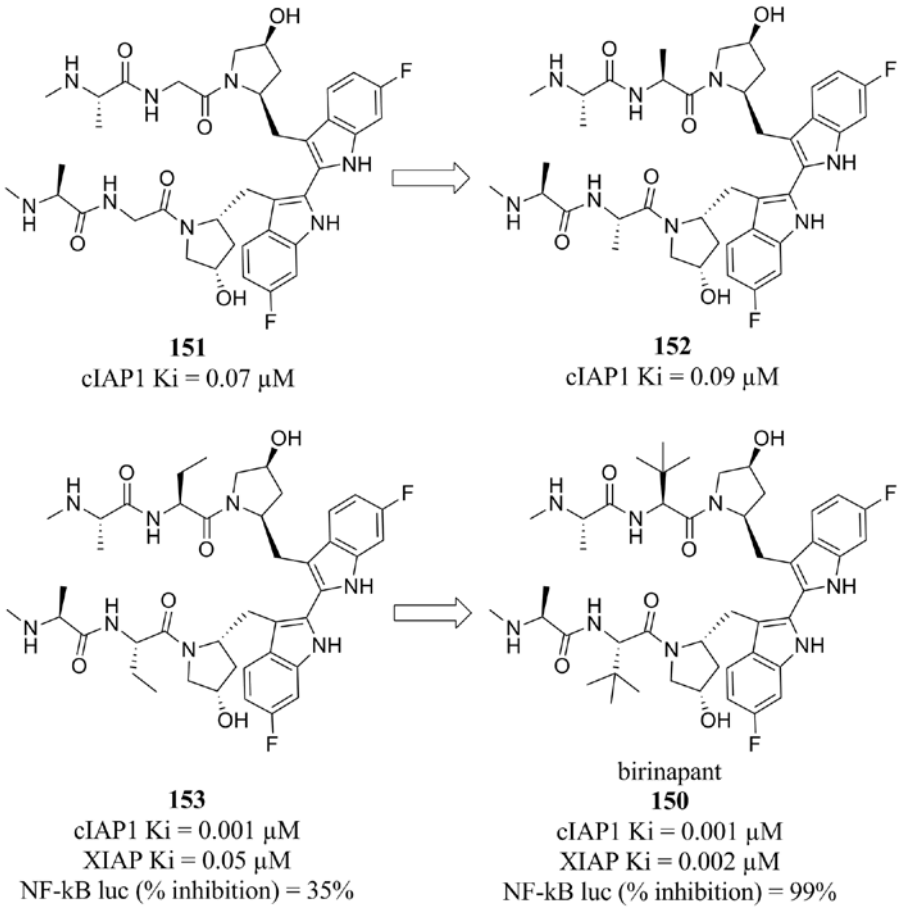

Fig. 80 SAR exploration around the P2 position of the dimeric Smac-mimetics.

Overall the compound maintains the N(Me)Ala at the N-terminal P1 position, common to many Smac-mimetics, an α-aminobutyric acid (Abu) at the P2 position, and a 4(*S*)-hydroxypyrrolidine moiety at P3. A 6-fluoroindole moiety was utilized to occupy the hydrophobic pocket in P4 (Fig. 81). In cell lysate assays the compound gave caspase 3 activation, and treatment of MDA-MB-231 breast cancer cells with TL32711 caused caspase-dependent apoptosis and cell death within 72 h. Efficacy studies conducted in vivo on MDA-MB-231 human xenografts in mice showed dose-dependent tumor regression at well-tolerated doses

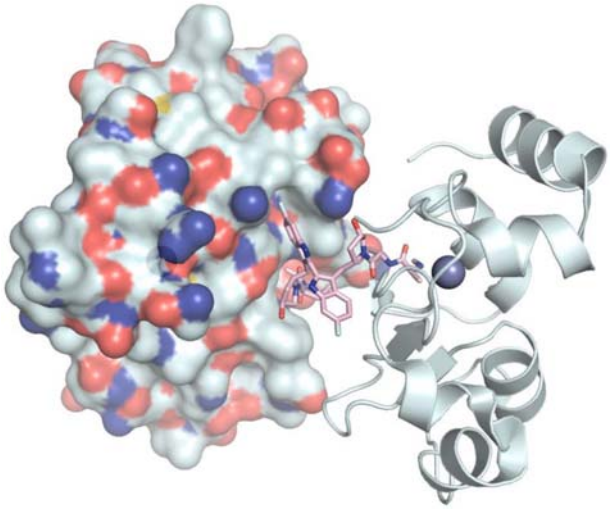

Fig. 81 X-ray crystal structure of birinapant, **150**, (*light pink*, shown as sticks) complexed with two XIAP BIR3 domains (*cyan*, one domain shown as surface, atomic coloring, the other domain is shown as cartoon), PDB: 4KMP.

(5 mg kg^{-1}, iv). Due to the positive profile in a preclinical setting, the compound was advanced to clinical trials. Initial Phase I trials have shown that this compound is well-tolerated without dose-limiting toxicity issues and can lead to anticancer effects both in advanced solid tumors and lymphomas. Further Phase I and Phase II clinical studies are ongoing for solid and hematological tumors.[257]

5.07.4.4 Targeting the Proteasome in Cancer Therapy

The proteasome is involved in the final common step for all the degradative pathways, and therefore is not characterized by high specificity as a therapeutic target.[258] Nevertheless, it remains, to date, the target within the UPS that has afforded the most successful results in anticancer therapy. In fact, the proteasome represents the only UPS target to yield FDA-approved anticancer drugs, namely: bortezomib, carfilzomib, and ixazomib for the treatment of MM. Following the success of bortezomib, a plethora of new promising inhibitors of the proteasome appeared in the literature over the last two decades.[259] In theory, as the proteasome is essential for the physiological homeostasis of cells, it would seem very difficult to succeed in exclusively targeting the proteasome of cancer cells without disrupting normal cellular functions. However, cancer cells possess accelerated proliferation and aberrant cell cycle checkpoints and, as such, can rapidly accumulate a large amount of defective proteins, increasing their susceptibility to proteasome inhibition.[260]

5.07.4.4.1 Structure and function of the proteasome

The 26S proteasome is a 2.4 MDa ATP-dependent multienzyme complex belonging to the Ntn (N-terminal nucleophilic) hydrolase family.[261] The proteasome consists of two subcomplexes: a barrel-shaped 20S core domain containing the protease active site and two 19S regulatory domains which cap the barrel at each end and act as gatekeepers. These domains have the function to recognize, unfold, and translocate the substrates into the cavity of the 20S proteasome[262] (Fig. 82).

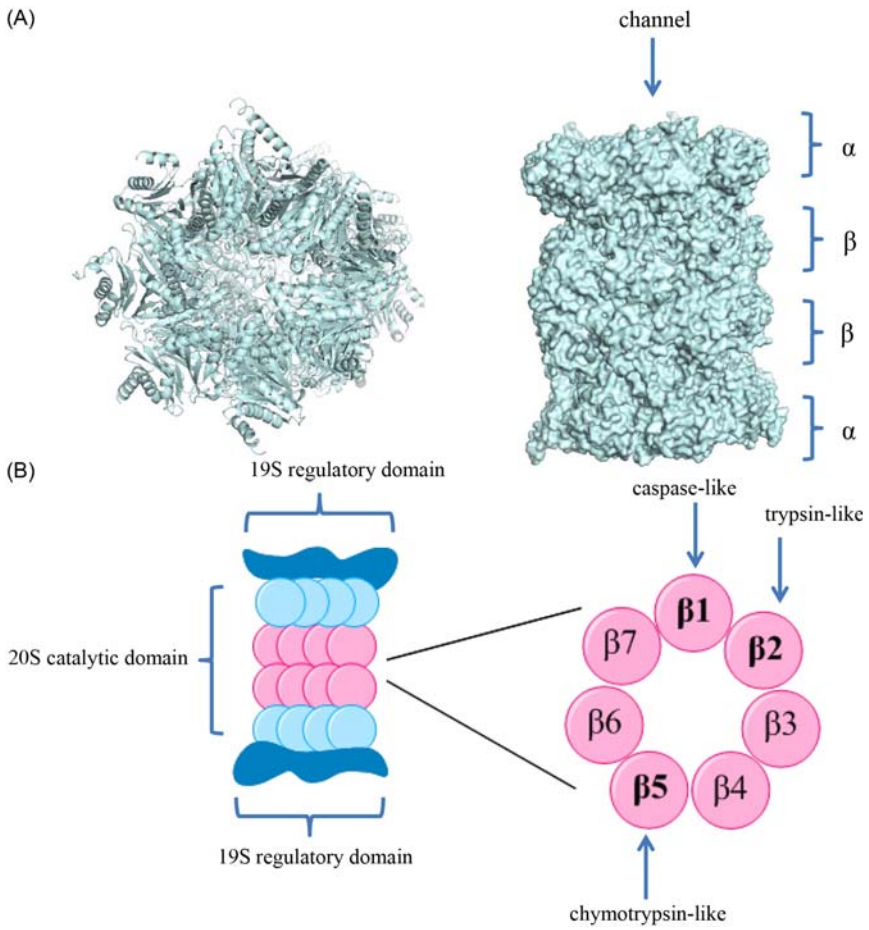

Fig. 82 (A) Crystal structure of the human 20S proteasome (PDB: 4R3O). (B) Schematic representation of the components of the 26S proteasome: the two 19S regulatory domains, the 20S catalytic domain and highlighting the subunits which form the proteolytic active site (β1, β2, and β5).

The central core 20S proteasome is formed by 28 subunits organized into 4 stacked rings, which create the cylindrical structure. The two external rings are formed by seven polypeptides called α-subunits; the two internal rings are composed of seven β-subunits which form the internal core of the complex among which subunits β1 (caspase-like), β2 (trypsin-like), and β5 (chymotrypsin-like) form the proteolytic active site. The proteolytic specificity is determined by the specific (S) pockets of the proteasome, which accommodate side chains (called P sites) of the protein substrate, among which the P1 residue appears to be crucial[263] (**Fig. 83**).

The three proteolytic subunits possess N-terminal threonine residues which act as catalytic nucleophiles in the proteolytic cycle. Nucleophilic Thr1 residues of the proteolytically active β subunits attack the carbonyl carbon of the target peptide bonds affording an acyl-enzyme intermediate which is finally hydrolyzed to release degradation products and restore the active site (**Scheme 3**). Single site mutation studies have identified the β5 subunits as the most important targets for proteasome inhibition and in fact the different classes of proteasome inhibitors mainly act around the chymotrypsin-like proteolytic activity.[265]

Aside from the constitutive proteasome, it is worth also highlighting the importance of the immune proteasome, whose catalytic core 20Si is responsible for the generation of peptides essential in the antigen processing phase of the immune response. Selective immunoproteasome inhibitors are emerging as promising leads for bortezomib-resistant MM therapies.[266]

5.07.4.4.2 Proteasome inhibitors

Proteasome inhibitors can be natural products or synthetic compounds which interact reversibly or irreversibly with Thr1 residues of the proteasome catalytic sites. They are mostly peptidomimetic compounds which mimic the binding mode of natural substrates in the active site channel of the proteasome. Proteasome inhibitors have pleiotropic effects; they stabilize IKB which binds to NFkB

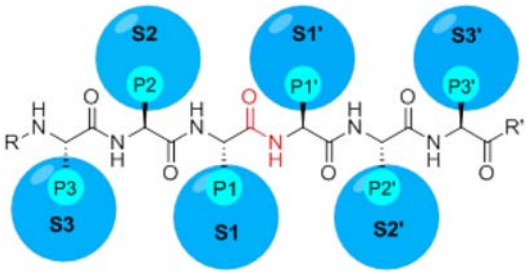

Fig. 83 Specificity pockets of the catalytic site of the proteasome. The scissile bond is highlighted in *red*.

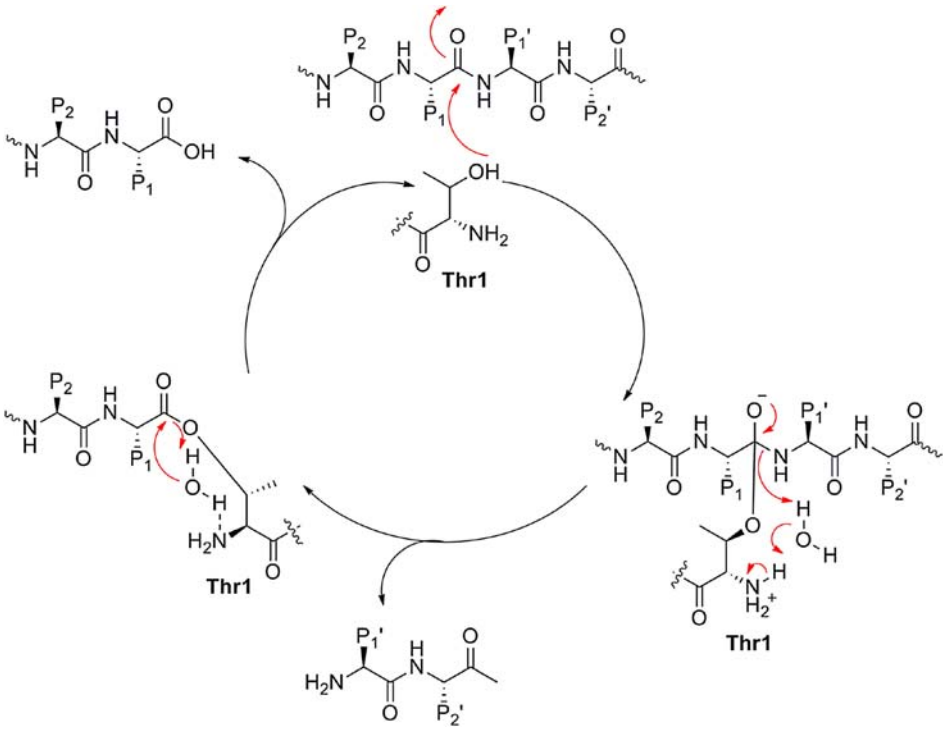

Scheme 3 Catalytic mechanism of the proteasome.[264]

and prevents its activation and nuclear translocation. As a result, the NFkB pathway is repressed with positive consequences on angiogenesis, cell invasion, oncogenesis, proliferation, and suppression of apoptosis. They also stabilize proapoptotic proteins such as p53 and Bax, induce endoplasmic reticulum stress, and activate antiapoptotic cascades.

Proteasome inhibition has proven to be a rational therapeutic approach in single agent therapies and also in combination therapies, being capable of inducing chemosensitization and addressing chemoresistance. Proteasome inhibitors are generally grouped into seven main classes on the basis of the structural properties of their pharmacophore.[192,266]

5.07.4.4.2.1 Peptide aldehydes

Peptide aldehydes (Fig. 84) represented the first class of proteasome inhibitors. They exploit the electrophilic carbonyl carbon atom of the aldehyde to react with the Thr1O$^{\gamma}$ residue of the proteasome and reversibly form a hemiacetal (Scheme 4). Despite being useful tools to study the cellular biochemistry and the mode of action of the proteasome, peptide aldehydes were unsuccessful in clinical development. The highly reactive head groups were successful in achieving high inhibitory potency, but were also detrimental in terms of selectivity. In fact, peptide aldehydes can also target serine and cysteine proteases such as catepsin B and calpains, leading to toxicity issues.

Also, peptide aldehydes display stability concerns: firstly, substituents in the α-position with respect to the aldehyde moiety are not stereochemically stable, due to the acidity of the α-proton; secondly, aldehydes can be rapidly oxidized to inactive carboxylic acids which are effluxed from the cells by multidrug resistance transporters. The consequent poor pharmacokinetic profile, with high clearance and low oral bioavailability, significantly limited the therapeutic potential of this class of inhibitors. As an example, MG132, **154** (Fig. 84), despite being the most widely used proteasome inhibitor tool, was never tested in the clinic due to rapid oxidative metabolism.

5.07.4.4.2.2 Peptide vinyl sulfones

In an attempt to overcome the issues related to the peptide aldehydes, vinyl sulfones were explored as alternative, less reactive head groups. Vinyl sulfones react in a Michael-type 1,4-addition with the Thr1O$^{\gamma}$ to give irreversible formation of an ether bond (Scheme 5 and Fig. 85). This led to a partial improvement in selectivity with respect to aldehydes as the vinyl sulfone head groups act as a Michael acceptor for soft nucleophiles only, and as such do not affect serine proteases. However, the high affinity for cysteine proteases still remained unsolved and this, similar to the peptide aldehydes, prevented in vivo development.

5.07.4.4.2.3 Syrbactins

As with the synthetic peptide vinyl sulfones, the syrbactins were also evaluated as proteasome inhibitors. They are natural products bearing a 12-membered macrolactam ring system in which the vinylamide moiety can undergo 1,4-addition from the Thr1O$^{\gamma}$ residue of the proteasome. Due to the similarity in the mechanism of action, the syrbactins share the same limitations as the vinyl sulfones, which prevented their therapeutic application (Scheme 6 and Fig. 86).

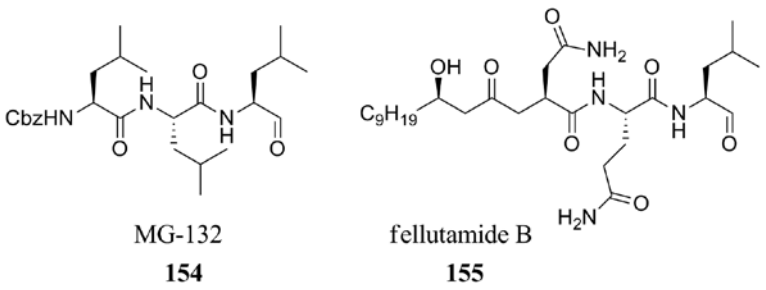

Fig. 84 Examples of peptide aldehydes: MG-132, **154**, and fellutamide B, **155**.

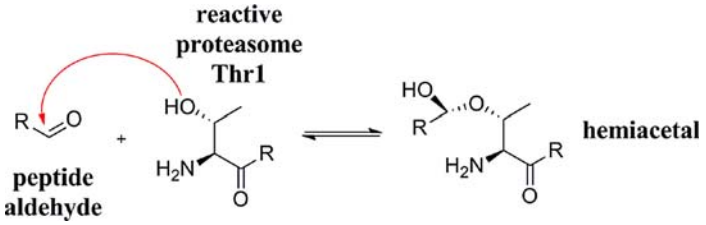
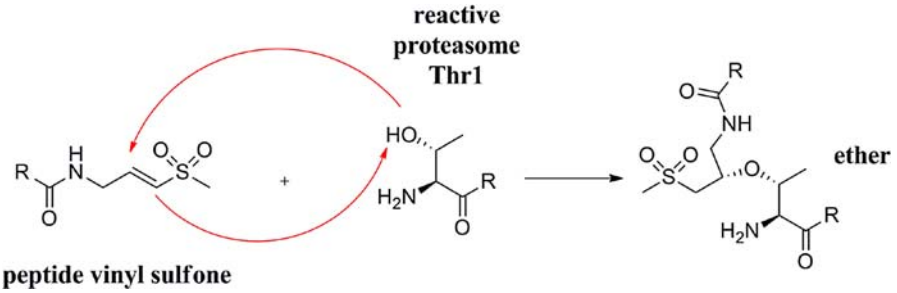


Scheme 4 Reaction mechanism highlighting the interaction between the warhead of the peptide aldehyde and the active site of the proteasome.



Scheme 5 Reaction mechanism highlighting the interaction between the warhead of the peptide vinyl sulfone and the active site Thr1 of the proteasome.[261,267]

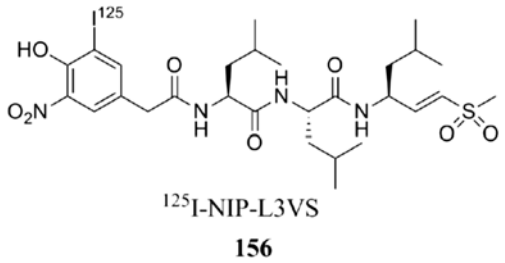


Fig. 85 Example of a peptide vinyl sulfone proteasome inhibitor.

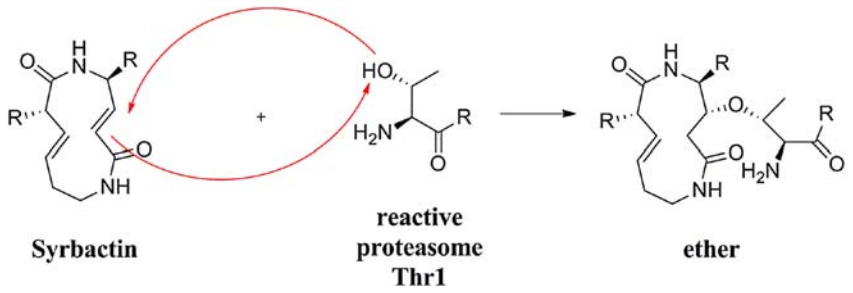
5.07.4.4.2.4 Peptide boronates

The real breakthrough in the development of proteasome inhibitors arrived with the synthesis of boronic acid derivatives, which represent the most important class of proteasome inhibitors to date for several reasons. Firstly, boronate derivatives are more potent inhibitors with respect to the aldehyde precursors as they have significantly slower dissociation rates. Secondly, boronates are highly selective thanks to the nature of their warhead; the boronic acid moiety guarantees high affinity for hard oxygen nucleophiles, rendering the boronate derivatives less prone to interaction with the soft nucleophiles of cysteine proteases. Peptidyl boronic acids were already recognized in the drug discovery scenario as efficient serine protease inhibitors, due to the presence of an empty p-orbital on boron which can accept the lone pair from the serine oxygen residue in the catalytic site. It was reasoned by analogy



Scheme 6 Reaction mechanism of the syrbactins.[268]

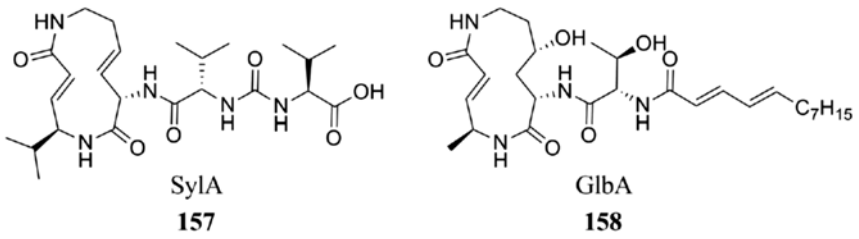


Fig. 86 Examples of Syrbactins, SylA, **157**, and GlbA, **158**.

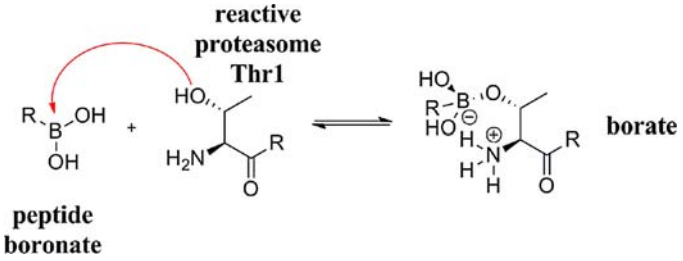


Scheme 7 Reaction mechanism highlighting the interaction between the warhead of the peptide boronate and the active site of the proteasome.

that boronic acid derivatives could form similar interactions with the N-terminal threonine residue present at the β5 subunit of the proteasome active site.

Pleasingly, the peptide boronates displayed higher affinity for the proteasome with limited affinity for the serine proteases and this can be explained by their mode of action. The boron atom forms a covalent bond with the lone pair of the Thr1O$^{\gamma}$ residue of the proteasome, while one hydroxyl of the boronate group forms a hydrogen bond with Gly47N stabilizing the oxyanion hole. The resultant tetrahedral adduct is further stabilized by the second hydroxyl group of the boronate moiety which forms a hydrogen bond with Thr1N (Scheme 7). This extra bond with the active site explains the high selectivity of boronate derivatives for the proteasome with respect to serine proteases.

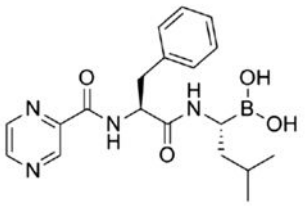
A third reason for the importance of this compound class is that the peptide boronate inhibitors possess suitable properties for in vivo development due to their higher stability in the physiological environment compared to the previous scaffolds.

5.07.4.4.2.4.1 Bortezomib (MG-341)

The boronic acid derivative bortezomib, **159**, represents the first approved drug targeting the UPS pathway. Structurally, it is a dipeptide boronic acid derivative composed of four main parts: the pyrazinoic acid substituent, the phenylalanine and leucine residues, and the boronic acid warhead (Fig. 87). Mechanistically, bortezomib acts as a reversible inhibitor of the 26S proteasome. In its bound form, the compound adopts an antiparallel β-sheet conformation and the boronic acid head group leads to the tetrahedral adduct formation characteristic of the boronate class.

It was introduced in 1995 with the name MG-341 by Myogenics Company, in an attempt to improve the peptidyl aldehyde inhibitors by finding a good aldehyde surrogate. Preliminary SAR exploration around the tripeptide aldehydes had revealed that leucine was the optimal residue to occupy the P1 position. Starting from this idea and using the common template Cbz-Leu-Leu-R, several R moieties were screened in order to replace the unstable aldehyde motif (Table 2).[269] Trifluoromethyl- and chloromethyl-ketones (compounds **163** and **164**) did not inhibit the proteasome, while the diketo ester and the ketobenzoxazole (compounds **161** and **162**) displayed only modest activity. On the contrary, using a boronic acid as the head group gave 100-fold increase in potency with respect to the aldehyde inhibitor (compound **160**).

As this first tripeptidyl boronate derivative displayed picomolar potency, it was possible to simplify the structure to a truncated version and still maintain good inhibitory activity. Hydrophobic residues were inserted in the P2 and P3 positions and this contributed to the increased potency, leading to the optimized bortezomib, a compound with lower molecular weight, good biochemical activity ($K_i = 0.62$ nM), and very high selectivity for the proteasome with respect to serine proteases.



bortezomib

159

20S proteasome K_i = 0.62 nM
thrombin K_i = 13,000 nM

[a]Assay performed using the procedures described by Stein et al. Inhibition of Chymotrypsin-Like Proteolytic Activity of Rabbit Muscle 20S Proteasome. *Biochemistry* **1996**, *35*, 3899.

Bortezomib selectively targets the chymotrypsin-like activity of the proteasome by binding at the β5 subunit active site. Thanks to the P1 leucine side chain, bortezomib creates a shift in the Met45 residue of the β5 subunit affording an induced fit. This structural rearrangement enlarges the S1 specificity pocket allowing further hydrophobic interactions between the P1 leucine side chain and the S1 pocket. The boron atom interacts with the Thr1O$^{\gamma}$, while the remaining two hydroxyl groups of the boronate interact via hydrogen bonds with Thr1N and the Gly47N, respectively. The carbonyl oxygen of Gly47, on the other hand, interacts with the NH of one of the amide moieties, while the second amide interacts with Thr21O. Thr21N, in turn, interacts with a carbonyl of the bortezomib peptide backbone. In addition, one nitrogen atom of the P3 pyrazyl moiety forms a hydrogen bond with the hydroxyl group of Asp114 in the adjacent β6 subunit, further stabilizing the complex. Finally, a series of water-mediated interactions are established with Ala49N and Ala50N and the backbone of bortezomib (Fig. 88).

The anticancer effect of bortezomib is mainly attributed to NOXA upregulation and NFkB suppression. In preclinical studies, bortezomib showed a strong inhibitory effect against a panel of both drug-resistant and drug-sensitive human MM cell lines, with IC_{50}s in the range of 3–40 nM. As this compound showed promising in vitro and in vivo preclinical results, with a strong apoptotic effect in a broad range of cancer types, it entered a Phase I clinical trial in patients with MM under the name PS-341. In clinical setting, patients with refractory MM were treated with bortezomib and showed dose- and time-dependent proteasome inhibition (from 36% to 74% inhibition within 1 h at doses from 0.40 to 1.38 mg m^{-2}).

In 1999, Millennium Pharmaceuticals acquired this promising compound and subjected it to thorough clinical trials. In Phase II trials bortezomib displayed 27% of overall response against MM when administered as an IV bolus at 1.3 mg m^{-2}, with a median duration of response of 12.7 months. In Phase III trials, bortezomib displayed better overall response rate with respect to dexamethasone (43% vs. 18%). Such outcomes led to the approval of **159** in 2003 by the FDA and in 2004 by EMEA under the name bortezomib (Velcade) for the treatment of relapsed and refractory MM as a first-in-class proteasome inhibitor and in 2008 it became the first-line treatment.[270]

The human PK profile showed that after IV dosing the compound has rapid distribution from plasma to tissues (10 min) and has a half-life of 40 h. It can distribute broadly in the body with the exception of the brain and adipose tissue. Metabolism is mostly due to intracellular oxidative deboronation by cytochrome P450 enzymes. Proteasome inhibition induced by bortezomib is reversible and disappears within 72 h of administration.

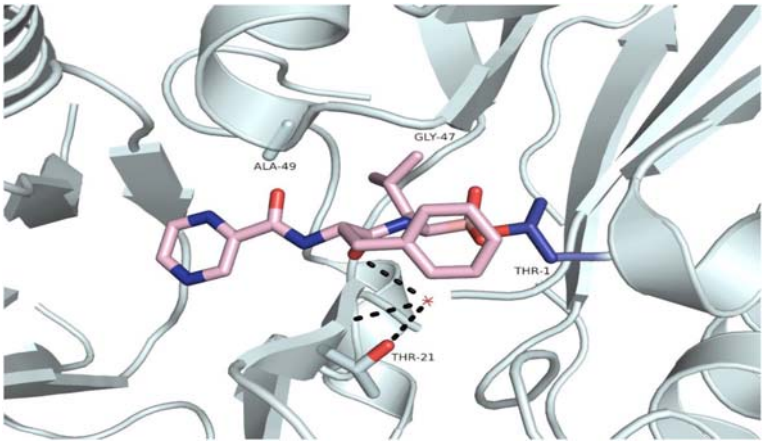

Fig. 88 X-ray crystal structure of the 20S proteasome (*cyan*) complexed with bortezomib, **159** (*light pink*), PDB: 2F16. The structure of the ligand, and the key binding site residues are shown as sticks. Thr-1 is represented in *blue*. Selected interactions are shown in *black-dashed lines*.

Bortezomib also proved advantageous in combination therapy with cytotoxic anticancer drugs (carboplatin, doxorubicin, docetaxel, and prednisone). Bortezomib has a chemosensitizing effect and, as a result, causes increased sensitivity of cancer cells to conventional drugs, allowing dose reduction with respect to monotherapy. However, despite the great success of bortezomib for the treatment of relapsed and refractory MM and for the treatment of MCL, and despite the fact that this drug has given improved response rates and survival compared to other treatments, such as dexamethasone, some limitations have been identified. Bortezomib therapy displayed some disadvantages: IV administration, which reduces patient compliance and dosing flexibility; side effects (thrombocytopenia, neutropenia, gastrointestinal disorders); dose-limiting toxicities, such as tremors, neurotoxicity, fatigue, hypokalemia, hyponatremia, nausea, and especially peripheral neuropathy. This last side effect has been associated with the inhibition of serine (HtrA2) which protects neurons from apoptosis.[195] Another caveat is that bortezomib therapy is hampered by both intrinsic resistance (only 35% of the MM patients treated with bortezomib were sensitive) and acquired resistance (due to β5 mutations and overexpression, together with multidrug resistance).[271]

Although bortezomib displayed great efficacy in the treatment of hematological diseases, the results have been less satisfactory for solid tumors. The issues around bortezomib therapy highlighted the need to develop a second generation of peptide boronates capable of addressing these limitations.

5.07.4.4.2.4.2 Ixazomib (MLN9708)

In an attempt to improve the pharmacokinetic profile and the route of administration, Millennium Pharmaceuticals developed a boronic ester prodrug called Ixazomib, **165**, that in vivo rapidly converts via hydrolysis into its biologically active form MLN2238, **166** (Fig. 89). Ixazomib (Ninlaro, Takeda) was approved by the FDA in 2015 for the treatment of MM in combination with lenalidomide and dexamethasone. The main advantage introduced by ixazomib over bortezomib is that it represents the first orally bioavailable proteasome inhibitor.[272]

While one of the limitations of bortezomib is the lack of efficacy in solid tumors, which has been connected to its inability to penetrate into tissues due to a slow off-rate and high partitioning in red blood cells, ixazomib although slightly less potent than bortezomib in a cellular luciferase assay (MDA-MB-231 4xUb-Luc $EC_{50} = 525$ vs. 310 nM) possesses a shorter 20S proteasome dissociation half-life (18 vs. 110 min) leading to a wider tissue distribution, with a sixfold larger volume of distribution (20 L kg^{-1} vs. 4 L kg^{-1}) in preclinical species (Fig. 90).

Ixazomib possesses an improved pharmacokinetic profile, with an oral bioavailability of 60% in mouse, and stronger antitumor activity than bortezomib in xenograft tumor models in both blood tumors (T/C = 0.2 vs. T/C = 0.8 in lymphoma WSU-DLCL2 for **165** and **159**, respectively) and solid tumors (T/C = 0.4 vs. T/C = 0.8 in prostate CWR22 cancer cell line for **165** and **159**, respectively).

The faster off-rate in blood contributed to a more than 10-fold higher MTD with respect to bortezomib (14 mg kg^{-1} iv vs. 0.8 mg kg^{-1} iv). This improvement was confirmed in human clinical trials, where ixazomib showed superior antitumor activity

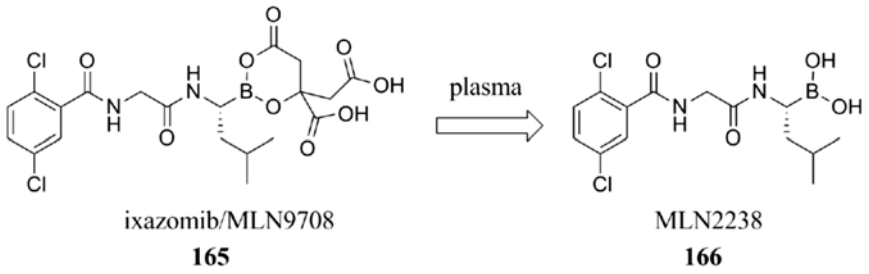

Fig. 89 Conversion of the prodrug ixazomib/MLN9708, **165**, into its active form MLN2238, **166**.

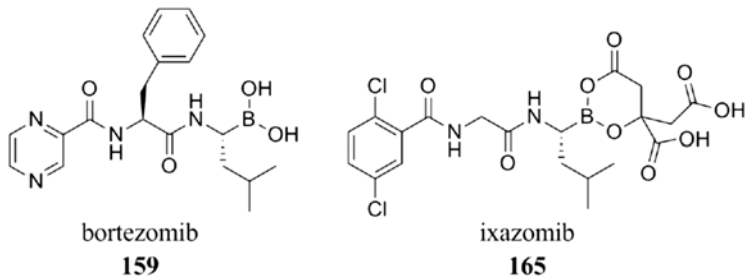

Fig. 90 Comparison between the in vitro and in vivo profiles of bortezomib, **159**, and ixazomib, **165**, in preclinical species.

in hematological malignancies, efficacy in solid tumors and reduced dose-limiting toxicities such as peripheral neuropathy. The lower neurotoxicity has been attributed to lack of inhibition of the serine protease HtrA2.[195] The compound is now undergoing Phase III clinical trials.[273]

5.07.4.4.2.4.3 Delanzomib (CEP-18770)

Delanzomib/CEP18-770, **167**, is another second-generation boronate analog revealing promising results in clinical trials. By leaving untouched the leucine residue in position P1, as crucial for selectivity, the medicinal chemistry efforts focused on amino acid scanning at the P2 position and SAR exploration around the P3 position. A threonine and an aromatic motif, respectively, emerged as the optimal combination in order to improve potency (Fig. 91).[274]

To improve the physicochemical properties of this series, the phenylalanine in the P2 position was replaced by a more polar threonine residue. The consequent loss in potency (see compound **168**; 11-fold loss in enzyme potency and >50-fold loss in cellular activity) was compensated by introduction of a biaryl substituent at the P3 position. Introduction of the 6-phenylpyridin-2-yl motif afforded high potency in biochemical assay (human 20S erythrocyte proteasome fluorimetric kinetic assay of CT-L proteasome activity, HEP $IC_{50}=3.8$ nM), low cross-reactivity (human pancreas α-chymotrypsin activity CHY = 1.5 μM), and high cellular activity (ovarian carcinoma cell line A2780 $IC_{50}=13.7$ nM).

This exploration led to the clinical candidate, called delanzomib or CEP-18770, **167** (Figs. 91 and 92). The compound showed a minimal difference in potency from enzyme to cell-based assay, demonstrating high permeability and potency in antiproliferation assays. In a broad panel of 42 proteases representing all mechanistic classes of these enzymes, the compound displayed high selectivity for the proteasome with no significant inhibition of serine, cysteine, or aspartyl proteases, or metalloproteases. Most importantly, despite being equivalent to bortezomib, **159**, in terms of potency and selectivity, delanzomib also possesses a very good PK profile in rodent species (Fig. 93). In both mouse (CD-1 mouse) and rat (Sprague–Dawley rat), the compound displayed long half-life, large volume of distribution, low clearance, and especially improved oral bioavailability in mice with respect to bortezomib (39% vs. 11%), which translated to improved in vivo efficacy in different human MM xenograft models. At its MTD, delanzomib gave 86% inhibition of proteasome binding compared to 48% given by bortezomib. Also, the safety profile of delanzomib, unlike bortezomib, is not hampered by neuropathy as a dose-limiting toxicity issue. With the improvement demonstrated in preclinical studies, delanzomib has undergone Phase I/II clinical trials for the treatment of myeloma, lymphoma, and solid tumors.[275] Delanzomib yielded an improvement in MM resistant to standard treatment; when used in IV combination with bortezomib, delanzomib afforded complete regression of bortezomib-sensitive tumors and markedly delayed progression of bortezomib-resistant tumors.

5.07.4.4.2.5 α′,β′-Epoxyketones

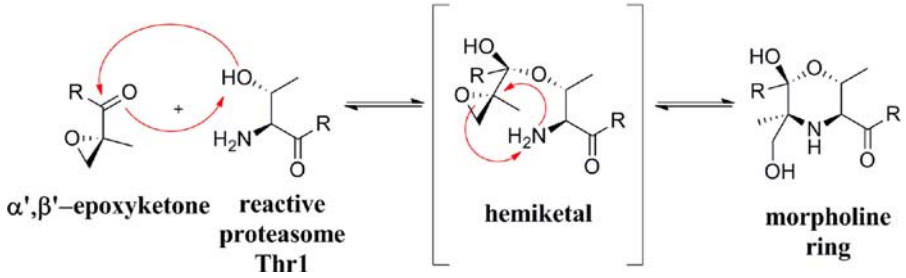
Due to the bivalent mode of action involving both Thr1O and Thr1N, α′,β′-epoxyketones are considered the most specific functional groups among the proteasome inhibitors. These inhibitors act through a mechanism very similar to the α-ketoaldehydes. Initial reversible formation of the hemiketal involving the ketone and the Thr1O is followed by nucleophilic attack of Thr1N on the epoxide moiety with irreversible formation of a morpholine ring system (**Scheme 8**). The class of α′,β′-epoxyketones has been particularly fruitful as it has yielded a third marketed proteasome inhibitor named carfilzomib.

5.07.4.4.2.5.1 Carfilzomib

Carfilzomib, **169** (PR-171, Kyprolis), was developed by Proteolix as a more potent proteasome inhibitor. It is a modified peptide related to the family of the natural product epoxomicin. It possesses two key structural features: a peptide portion responsible for selective binding to the proteasome pocket, and an epoxyketone pharmacophore that interacts stereospecifically with the catalytic threonine residue, giving irreversible inhibition of the enzyme. Once carfilzomib is bound to the proteasome, protein turnover is necessary to reestablish proteasomal activity, which explains why carfilzomib has higher potency than bortezomib.[277]

Starting from the natural product epoxomicin, **170**, which showed antitumoral activity, a series of nonnatural α′,β′-epoxyketones was developed. Several residue sequences and lengths were explored as they deeply influence the potency and selectivity for the three main catalytic functions of the proteasome. For example, hydrophobic residues such as leucine and phenylalanine usually give high selectivity for chymotrypsin-like activity, while basic amino acids such as lysine and arginine shift the selectivity toward trypsin-like activity. In order to obtain selective inhibitors of chymotrypsin-like activity, the first round of optimization led to YU-101, **171**, a tetrapeptide epoxyketone bearing a phenylalanine and a leucine at the P2 and P3 positions, respectively. Also, as large hydrophobic side chains have been reported to improve selectivity, an aromatic group was utilized in the P4 position (**Fig. 94**). This compound was a potent and selective inhibitor of the proteasome, however it was flawed by very low aqueous solubility ($<1\ \mu g\ mL^{-1}$) which limited its applicability in vivo.

Carfilzomib, **169**, was developed as an improvement on YU-101, where, thanks to the N-terminal morpholine, the aqueous solubility was greatly increased (>1000-fold). Crystallographic analysis of the human 20S proteasome in complex with carfilzomib revealed a series of key interactions. Thr1O and Thr1N give a dual covalent adduct with the epoxyketone motif to create



Scheme 8 Reaction mechanism of the α′,β′-epoxyketones.[276]

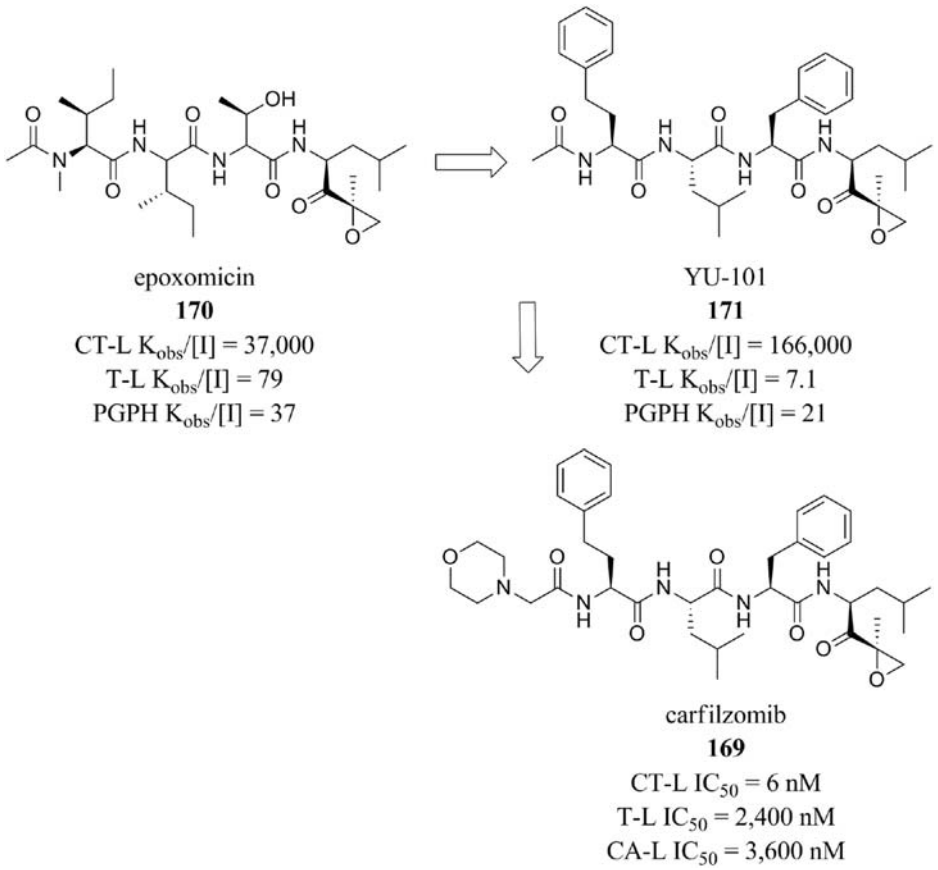


Fig. 94 Evolution of α′,β′-epoxyketones from the natural product epoxomicin, **170**, to the marketed drug PR-171, **169** (Carfilzomib, Proteolix, Inc.).

a morpholine ring. Gly47O, Thr21O, and Thr21N are involved in hydrogen bonds with the peptide backbone of carfilzomib. Finally, water-mediated hydrogen bonds take place with Ala49N and Ala50N (Fig. 95).

Although carfilzomib possesses similar potency to bortezomib, it displayed greater selectivity toward chymotrypsin-like activity over trypsin- and caspase-like activities. Also, because nonproteasomal serine and cysteine proteases do not possess the free α-amino group necessary to form the dual adduct with carfilzomib, this compound displayed higher specificity, giving hope for greater tolerability in vivo.

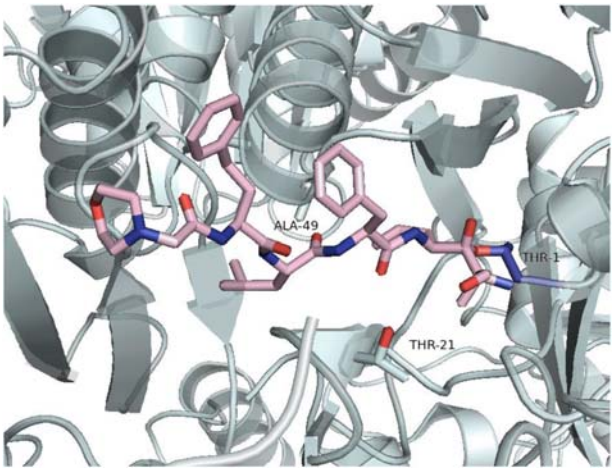

Fig. 95 X-ray crystal structure of the 20S proteasome (*cyan*) complexed with carfilzomib, **169** (*light pink*), PDB: 4R67. The structure of the ligand, and the key binding site residues are shown as sticks. Thr-1 is represented in *blue*.

In animal models, carfilzomib led to a dose-dependent inhibition of chymotrypsin-like activity of the proteasome in a wide range of tissues, with exception of the brain. Carfilzomib is well-tolerated after 2 or 5 days treatment with >80% proteasome inhibition seen in blood and tissues. Due to its potential, Onyx Pharmaceuticals, after acquisition of Proteolix, advanced carfilzomib into several Phase I/II clinical trials. In MM patients treated with 20 mg m^{-2} of carfilzomib, a 47% response rate was obtained with less serious side effects with respect to bortezomib, such as fatigue and cytopenia, but importantly not neuropathy, attributed to the higher selectivity with respect to HtrA2 and other serine proteases. In 2012, the FDA-approved carfilzomib for the treatment of MM in patients not responsive to bortezomib and immunomodulatory therapy.

5.07.4.4.2.5.2 Oprozomib (ONX0912, PR047)

Oprozomib, **172**, was discovered during an effort to find improved analogs of carfilzomib, as orally bioavailable alternatives, with superior patient compliance and dosing flexibility. This work began with the exploration of truncated versions of carfilzomib, **169**. As carfilzomib is a tetrapeptide epoxyketone characterized by poor oral bioavailability and low metabolic stability, the rationale was that truncated forms of carfilzomib would maintain biological activity while improving oral exposure.[278]

Initially, di- and tripeptide analogs (compounds **173** and **174**) were prepared (Fig. 96). In contrast to the dipeptide, the tripeptide epoxyketone proved to be very active both in biochemical and cellular assays (20S proteasome CT-L activity inhibition, $IC_{50}=57$ nM; Molt-4 CT-L $IC_{50}=45$ nM) and represented the starting point for a broad SAR exploration around the tripeptide scaffold. The exploration was performed through a systematic screening of different N-cap groups, coupled with sequential modifications at the P1, P2, and P3 positions, respectively. The first N-cap screening identified five-membered heterocycles as viable substituents for potency optimization. In particular the 5-methyl-isoxazol-3-yl derivative provided good activity (compound **175**, Fig. 97). However, solubility needed to be improved in order to achieve oral exposure. Thus, in a second round of optimization the more polar O-methylserine was identified as the most promising residue for the P3 position with a >12-fold improvement in solubility (compound **176**). In order to increase metabolic stability reduction of lipophilicity through the introduction of a second polar O-methylserine residue was carried out at the P2 position, leading to a twofold improvement in microsomal stability (compound **177**). Finally, by keeping P2 and P3 unchanged, several N-cap groups were screened in combination with leucine or phenylalanine at the P1 position. The best combination was provided by phenylalanine in P1 and 2-methyl-thiazol-5-yl at the N-terminus, giving the final candidate oprozomib/PR047, **172** (Fig. 97).

The candidate showed a favorable profile, with good solubility (1.86 mg mL^{-1} in oral dosing vehicle), metabolic stability in simulated intestinal fluids (90% of parent compound unchanged at 15 min), liver microsomal stability (R_e=liver extraction ratio; mouse $R_e=0.51$; human $R_e=0.60$), and oral bioactivity (mice PO PD=94% inhibition of CT-L activity at 10 mg kg^{-1}).

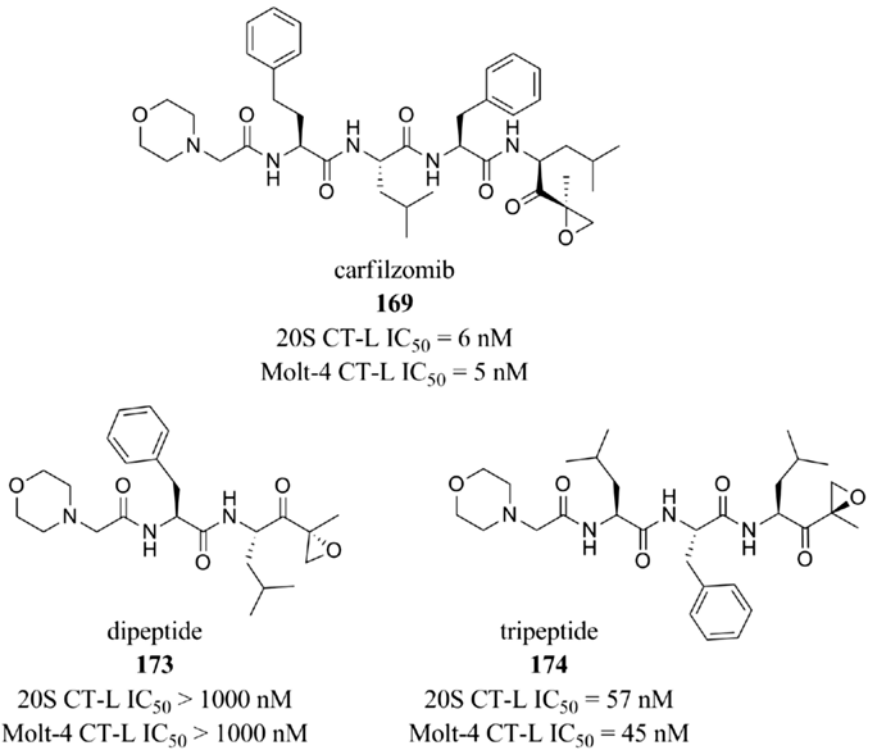

Fig. 96 Structure of carfilzomib, **169**, (PR-171) and its truncated forms. As highlighted in the figure, the dipeptide analog, **173**, lost inhibitory activity against the 20S proteasome chymotrypsin-like activity, while the tripeptide, **174**, represented an encouraging starting point. (From Zhou et al. *J. Med. Chem.* **2009**, *52*, 3028.)

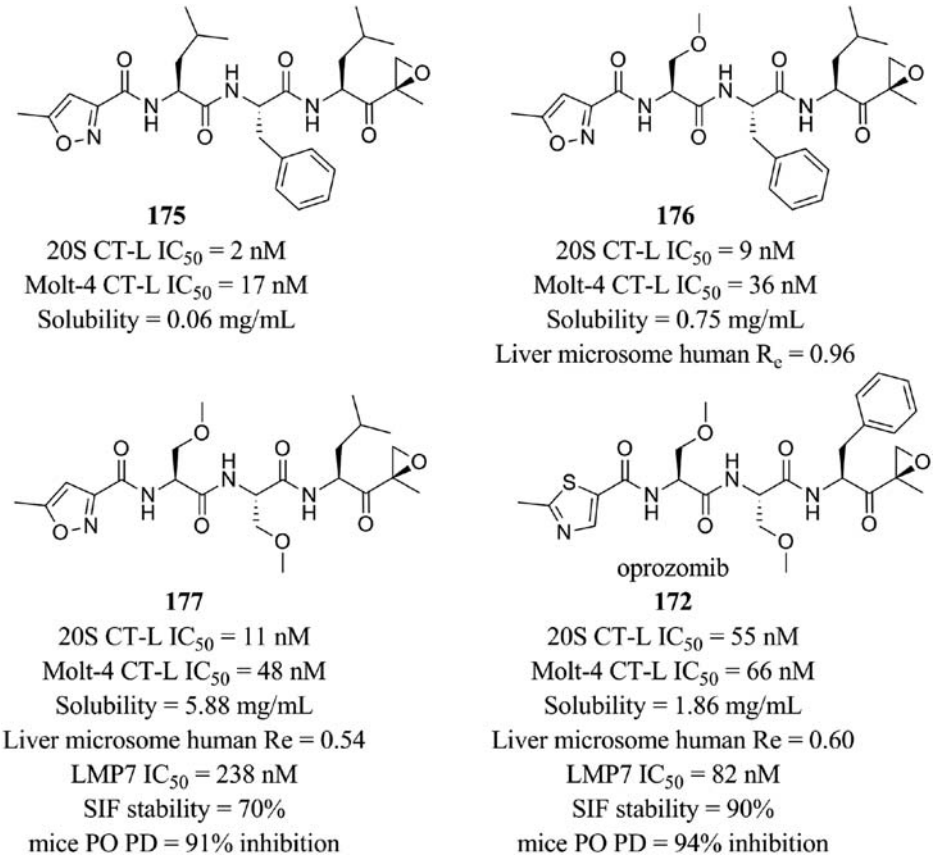

Fig. 97 Development of the clinical candidate PR-047, **172**.

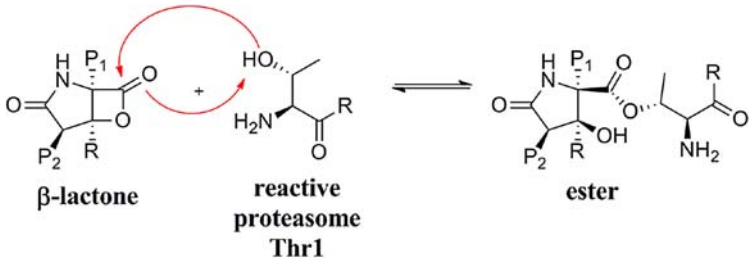
Oprozomib also possessed adequate oral bioavailability across the preclinical species (mouse $F = 17\%$ at 40 mg kg^{-1}; rat $F = 21\%$ at 40 mg kg^{-1}; dog $F = 39\%$, at 19 mg kg^{-1} dose) and enhanced inhibition of the immunoproteasome (LMP7 $IC_{50} = 82$ nM) together with the constitutive proteasome.

Oprozomib was evaluated for antitumor activity in human tumor xenografts (lymphoma and colorectal tumor cell lines) and proved to be very effective. In contrast to carfilzomib, it was administered at a lower dose than its MTD and orally rather than IV, producing the same response in terms of anticancer efficacy. The compound is currently undergoing Phase I/II clinical trials.[279]

5.07.4.4.2.6 β-Lactones

β-Lactones are derivatives of the natural product omuralide (lactacystin) and represent a promising alternative pharmacophore to overcome the limitations associated with bortezomib therapies, especially resistance. The mechanism of action involves nucleophilic attack of the proteasome Thr1O$^{\gamma}$ on the carbonyl which opens the β-lactone ring of the drug to afford an ester product (**Scheme 9**).



Scheme 9 Reaction mechanism of the β-lactones.[280]

5.07.4.4.2.7 Marizomib (salinosporamide A/NPI-0052)

In contrast to the previously described proteasome inhibitors, the β-lactones are nonpeptide-based compounds. They are natural products of microbial origin among which omuralide, **178**, and salinosporamide A (marizomib), **179**, are the most well-known examples (Fig. 98). Salinosporamide A is a marine natural product extracted from the actinomycete *Salinispora tropica*, which showed high potency as a 20S proteasome inhibitor (IC_{50} in the nanomolar range).[281] In particular, omuralide and salinosporamide A share the β-lactone-γ-lactam bicyclic ring system, but with different substitutions. The common β-lactone unit represents the key pharmacophore. Salinosporamide A, **179**, possesses higher potency with respect to omuralide, **178**, likely deriving from the substituents on the ring (cyclohexene ring and halogenated lateral chain substituents). The necessity of the β-lactone moiety for potency was proven by hydrolysis of the ring which led to complete loss of potency in all assays ($IC_{50} > 20$ μM).

Salinosporamide A exerts its inhibitory activity on the proteasome with a unique two-step mechanism of action. In the first step, the nucleophilic Thr1 residue attacks and opens the lactone ring, then there is cyclization to a tetrahydrofuran ring due to nucleophilic displacement of the chlorine atom.

Salinosporamide A represents a potential replacement therapy to traditional bortezomib as it is able to overcome bortezomib resistance in MM cells. Salinosporamide A has a fairly broad effect as it inhibits all the three catalytic functions of the proteasome (chymotrypsin-like, trypsin-like, and caspase-like) in addition to inhibition of NFkB activation and growth inhibition of human cancer cells. The compound is dosed intravenously twice per week and displays wide tissue distribution (including crossing the BBB). The compound possesses a different toxicology profile to bortezomib and the dose-limiting toxicities are hallucinations, cognitive problems, and loss of balance, probably connected to brain penetration. It is currently undergoing Phase I/II clinical trials as a single agent or in combination therapy in patients with advanced solid and blood cancers.[282]

5.07.4.4.3 Immunoproteasome inhibitors

Selective inhibition of the immunoproteasome is also under evaluation in bortezomib-resistant MM therapies. The aldehyde IPSI-001, **180**, and the epoxyketones ONX0914, **181**, and PR-924, **182** (Fig. 99), are compounds which selectively inhibit the 20Si activity with respect to the competitive proteasome, overcoming bortezomib resistance in a preclinical setting and are therefore appealing as alternative therapeutic approach.

5.07.4.5 Targeting the Deubiquitylating Enzymes in Cancer Therapy

The deubiquitylating enzymes (DUBs) or deubiquitinases share the ability to deconjugate ubiquitin from proteins and provide a regulatory step within the UPS cascade.[192,283] These enzymes specifically cleave the bond between the C-terminal group of ubiquitin and the ε-amino group of lysine side chains or between the α-amino groups of the target proteins.[284] The DUBs are appealing as cancer targets as they are involved in various biological processes essential for cellular homeostasis (protein turnover rate, activation, recycling, and localization). They are less promiscuous than other members of the UPS with around 100 DUBs having already been identified in the human genome.[192,285]

All of this encouraged the development of a series of DUB inhibitors[286] (i.e., HBX 19,818,[287] **183**; P5091,[288] **184**; b-AP15,[289] **185**; IU1,[290] **186**; Fig. 100), however to date no DUB inhibitors have been developed into successful clinical candidates. Perhaps this can be attributed to the fact that, except for JAMMs (JAB1/MPN/MOV34 metalloproteases), all other deubiquitinases are cysteine proteases, known to be more challenging to drug with small-molecule inhibitors due to a lack of specificity and poor pharmacokinetics.[291]

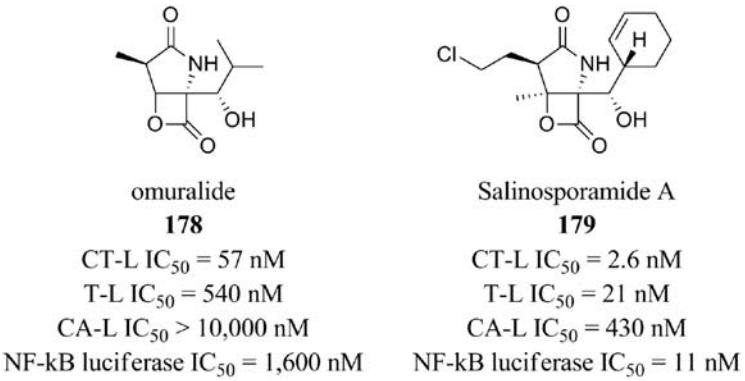


Fig. 98 Chemical structures and in vitro activity/selectivity profiles of omuralide, **178**, and Salinosporamide A, **179**.

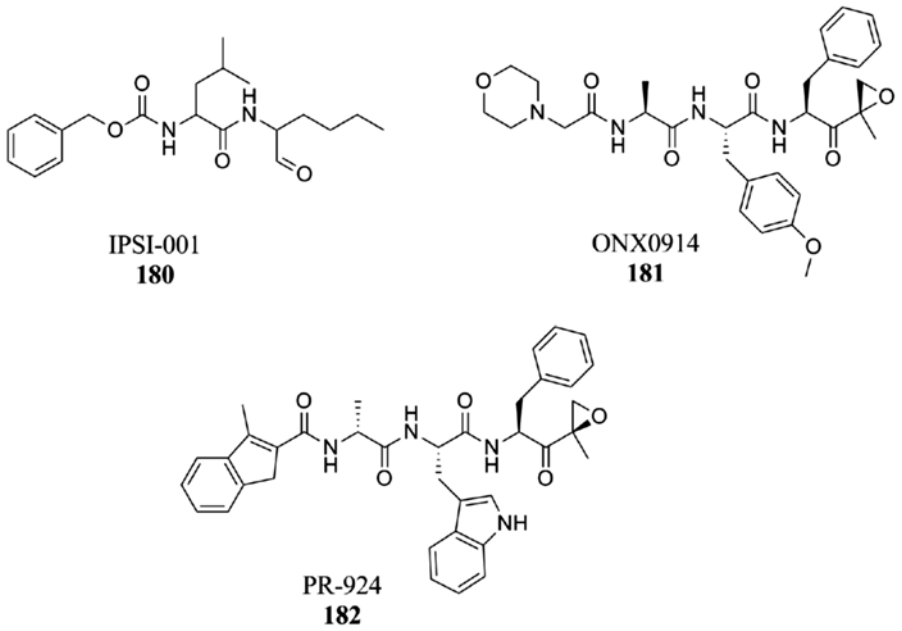

Fig. 99 Chemical structure of selective immunoproteasome inhibitors.

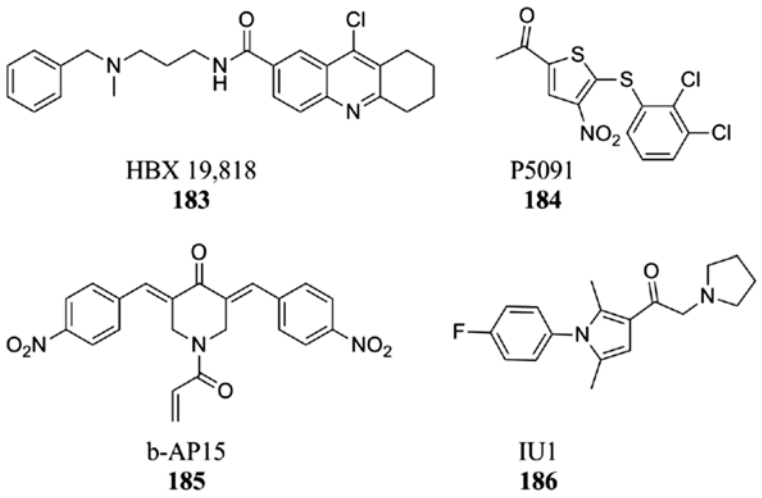

Fig. 100 Chemical structure of some recently reported DUB inhibitors.

5.07.4.6 Degradation of Undruggable Targets in Cancer Therapy

Another emerging strategy focuses on the exploitation of ubiquitination as a tool to enhance degradation of currently undruggable targets, such as MYC, β-catenin, and MCL1.[192] Enhancing the degradation of these targets, for which proteasome degradation is generally impaired in cancer cells, might represent a useful approach to block tumorigenesis.[292] In this context, a series of different classes of small molecules have been explored, such as molecular switches[293] (RNF146 and PAR[294]), PROTACs (protein-targeting chimeric molecules[295]), HyT (hydrophobic tagging[296]), and SERDs (selective estrogen receptor degraders[297]). However, to date, the best results in this field have been achieved with the IMIDs (immunomodulatory drugs).

5.07.4.6.1 Thalidomide and immunomodulatory drugs

The first-in-class compound was thalidomide (Fig. 101), previously known for sedative and antiemetic therapeutic effects, but also for teratogenic side effects. Through high-performance affinity FG beads (FG = ferrite-glycidyl methacrylate), it was demonstrated that thalidomide, **187**, can bind to cereblon (CRBN),[298] a component of the E3 ligase complex $CRL4^{CRBN}$, preventing its ubiquitylation and consequent proteasomal degradation. The interaction between thalidomide and cereblon was deemed responsible for the teratogenicity of the drug.

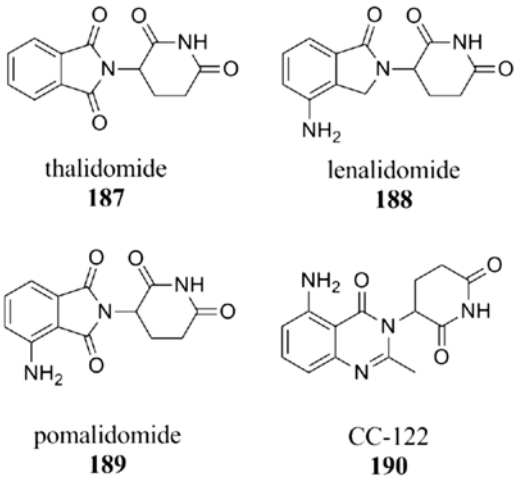

Fig. 101 Chemical structure of thalidomide, **187**, and immunomodulatory drugs.

Subsequently, this interaction has also been connected to the immunomodulatory and antiproliferative effects of thalidomide and of the second-generation immunomodulatory drugs, called IMIDs. The targeting of CRBN and the modulation of its ubiquitylation targets by IMIDs lead to selective degradation of the Ikaros and Aiolos TFs, with consequent strong antiproliferative activity.

This E3 ligase-mediated selective degradation of TF has been exploited in anticancer therapy. In particular, thalidomide displayed good results in the treatment of MM, both as a single agent or in combination therapies with cyclophosphamide or dexamethasone. Thalidomide has also been evaluated in clinical trials for solid malignancies, such as renal cancer, prostate cancer, glioma, and melanoma.[299] While thalidomide showed efficacy in patients with advanced cancer, its use was limited by severe toxic effects, especially teratogenesis. To address the toxicity issues related to thalidomide, second-generation IMIDs analogs were developed. IMIDs proved to be effective against MM[300] and particularly successful were the 4-aminophthalate analogs, developed by Celgene aiming to improve the inhibition of TNF-α. This strategy leads to a 50,000-fold increase in potency against TNF-α, with respect to thalidomide. The best compounds in this series were lenalidomide, **188**, (CC-5013, Remivid) and pomalidomide, **189**, (CC-4047, Actimid). Newer generations of IMIDs, such as CC-122, **190** (Fig. 101), were developed by shifting the focus from TNF-α inhibition to the antiangiogenic and immunomodulatory effect. CC-122 is a nonphthalimide, pleiotropic pathway modifier drug (PPM) with immunomodulatory, antiangiogenic, and antiproliferative effects and was particularly effective in chronic lymphocytic leukemia (CLL) primary cells. CC-122 showed superior performance to lenalidomide, having a broader spectrum of action and efficacy, even in patients nonresponsive to lenalidomide, likely due to CC-122 targeting a new and distinct CLL pathway. CC-122 is currently undergoing Phase I clinical trials.[301]

5.07.4.7 Summary

Protein degradation is an essential process for intracellular homeostasis, being linked to cell cycle progression, signaling, and other vital processes. As cancer cells are highly susceptible to the impairment of the UPS cascade, targeting the UPS system with small-molecule inhibitors is considered a viable strategy for anticancer therapy.

The FDA approval of bortezomib over a decade ago as a first-in-class proteasome inhibitor was welcomed as a sign that the proteasome inhibitors could have undergone a similar fate to kinase inhibitors in anticancer therapy. However, in contrast to the kinase phenomenon, where FDA approval of imatinib initiated an exponential increase in the number of kinase inhibitor candidates reaching the clinic, targeting the UPS cascade has proven more difficult, yielding only three marketed drugs to date. Resistance, dose-limiting toxicities, and selectivity issues are the main limitations challenging this therapeutic area. These caveats highlight that there remains a large window for improvement. In particular, targeting upstream from the proteasome has emerged as a more elegant and useful approach with numerous candidates now reaching the clinic. The UPS pathway is still an open field, with great unexploited potential, and new opportunities may lie just around the corner.

5.07.5 Conclusion

Research to find small-molecule drugs that directly affect protein synthesis, folding, and degradation has proven successful over the last 5–10 years and a wide range of compounds have entered the clinic to treat various cancers along with some significant drug approvals. The underpinning medicinal chemistry has been wide-ranging. Natural products and semisynthetic compounds have featured prominently, in particular as proof of concept compounds that have been taken all the way to the clinic, but also as starting

points for medicinal chemistry. Potent protein/protein interaction inhibitors have been discovered and progressed to the clinic. Selectivity in kinase inhibition has been important as this area matures. Targeting ATPases has been undertaken and considerable success has been achieved in selected cases with challenges remaining in other cases. The recent cereblon-mediated approach provides a potentially new approach to selective degradation of desired proteins in a manner similar to the biological approach of RNAi but using small molecules. In summary, there have been significant advances in the discovery of new molecularly targeted anticancer drugs but there are many remaining challenges. It is clear there will be further exciting advances in the discovery of new cancer therapeutics in this area over the next period.

5.08.1 Introduction

The medical community has been working to understand and treat cancer since before the disease was identified as such. As the field of medicine has advanced so has our understanding of cancer, not as a single uniform disease but as a collection of malignancies united by common hallmarks of aberrant cell growth.[1] In the last decade, the role posttranslational modifications (PTMs) play in driving cancer has been an area of burgeoning research. This article will review how recent advances in our understanding of a subset of the mechanisms by which these modifications drive cancers have led to drug discovery programs, clinical trials, and marketed therapies.

5.08.2 Epigenetic Modifications

5.08.2.1 Histone Structure

Cells store an immense amount of genetic information in the form of deoxyribonucleic acids (DNA). To fit this information into the cell nucleus, the DNA is wound around proteins called histones, of which there are five major families: H1/H5, H2A, H2B, H3, and H4, which come together to form a cylinder shape. Together, the DNA and the histones form the nucleosome which resembles beads on a string. The nucleosomes are further compacted into chromatin which can exist in the open euchromatin form or the highly condensed heterochromatin form (Fig. 1). Utilizing histones in this manner enables 1.8 m of DNA to be compacted into 90 μm of chromatin. Due to the compacted structure of heterochromatin, genes are largely inaccessible to the transcriptional machinery, thus rendering heterochromatin transcriptionally inactive. To initiate protein synthesis, the heterochromatin structure must loosen in a highly controlled manner to reveal specific promoter regions. The relaxing of heterochromatin into euchromatin, and the reverse process, is called chromatin remodeling and is controlled by changes to the structure of the nucleosomes.[2]

The structural changes to the nucleosome are effected through PTMs to the ~30-amino acid tail portion of the histone proteins (Fig. 2). The PTMs include phosphorylation, methylation, and acetylation among others. The enzymes that control the methyl and acetylation states of the lysine residues, and in the case of methylation, arginine residues as well, in histone tails have been the most widely studied to date and will be the subject of this article.[3]

5.08.2.2 Role of Chromatin Modifications in Cancer

It is known that epigenetic regulation is often dysregulated in cancer; however, the precise role chromatin modifying proteins (CMPs) play in driving cancer is postulated for only a small subset of cancers.[3,4] For example, mutations to enhancer of zeste homolog 2 (*EZH2*), which acts as part of a larger complex, can result in an aberrant increase in histone 3 lysine 27 (H3K27) trimethylation activity. Overexpression of EZH2 is also observed in several leukemias and other solid tumors.[2c,3] Methylation of H3K79 by disrupter of telomeric silencing like protein (DOT1L) at ectopic gene locations has also been implicated in leukemia, in which wild-type DOT1L is recruited to mixed lineage lymphoma (MLL) target genes by MLL-fusion proteins. The resulting ectopic methylation at H3K79 leads to overexpression of several genes known to drive leukemogenesis.[5]

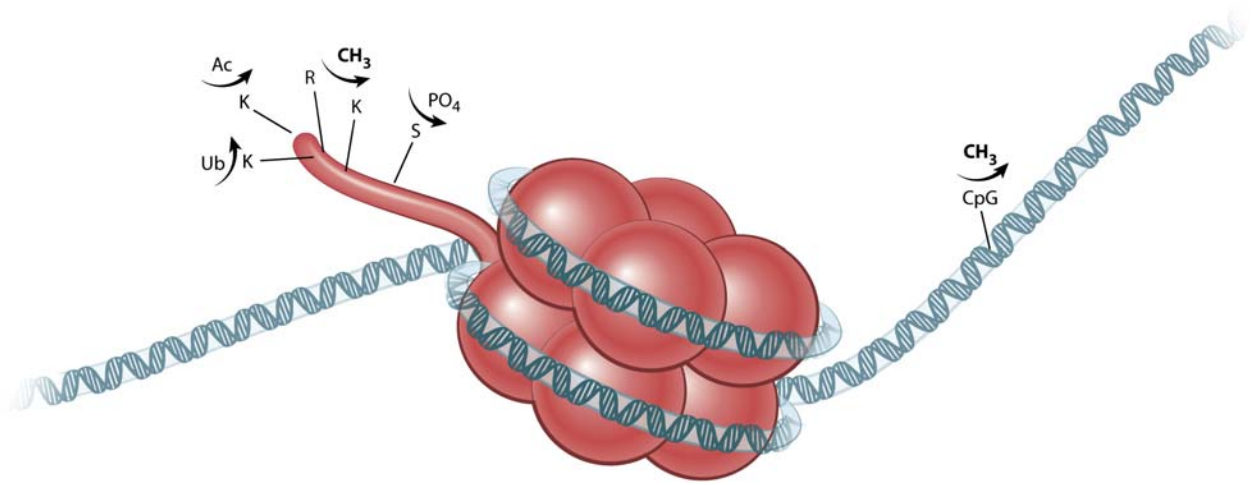

Fig. 2 Representation of the types of PTMs possible on the tail portion of histone proteins: *CH_3*, methylation; *PO_4*, phosphorylation; *Ac*, acetylation; *Ub*, ubiquitination; *K*, lysine; *R*, arginine; *S*, serine; *CpG*, 5′-C-phosphate-G-3′ with permission from Epizyme.

5.08.2.3 Methyl Modifications to Lysine and Arginine

Histone residues can undergo multiple posttranslational modifications. This article will address posttranslational methylation. With respect to methylation, histone-lysine residues can exist in multiple states including the unmodified residue, mono-, di-, or trimethylated (KMe1–3). Likewise, histone arginines can exist in multiple states; they can be mono- or dimethylated and the dimethylation state can either be symmetric or asymmetric (RMe, RMe2sym, and RMe2asym, respectively). The enzymes responsible for these transformations are collectively called writers. There are also reader proteins for both lysine and arginine that recognize the various PTMs and eraser proteins that remove the methyl groups from lysines.[3,4]

5.08.2.4 Writer Enzymes

5.08.2.4.1 Histone methyl transferases

Methyl modifications to histones are catalyzed by histone methyltransferases (HMTs) sometimes more generally referred to as protein methyltransferases. The HMT enzyme class consists of over 50 members and can be divided by target residue into lysine methyltransferases (KMTs) and arginine methyltransferases (RMTs). HMTs use *S*-adenosylmethionine (SAM) as a methyl donor substrate and the methyl group is transferred via an S_N2 mechanism to the side chain nitrogen of the lysine or arginine acceptor substrate.[4] The HMTs vary in substrate specificity; for example, DOT1L is only known to methylate histone H3 lysine 79 (H3K79).[4] On the other hand, H3K9 can be dimethylated by euchromatic histone-lysine *N*-methyltransferase 2 (EHMT2) and trimethylated by SET domain bifurcated 1 enzyme. Protein arginine methyltransferase 5 (PRMT5) is known to methylate H4R3 and H3R8 along with other proteins (http://www.thesgc.org/epigenetics). At the time of writing this article, there are four inhibitors targeted toward two KMTs undergoing clinical trials; tazemetostat, GSK2816126 and CPI-1205 for EZH2, and pinometostat for DOT1L.

5.08.2.4.2 Histone acetyl transferases

In addition to methylation, histone lysines can undergo acetylation mediated by a family of enzymes called histone acetyltransferases (HATs). This 18-member family of enzymes transfers an acetate moiety from acetyl-CoA to the amino group of lysine residues on histones and other proteins. The HATs have not been studied as extensively as some of the other epigenetic regulator families and no HAT inhibitors have advanced to the clinic to date (http://www.thesgc.org/epigenetics).

5.08.2.5 Reader Domains

Histone methyl and acetyl marks are read by proteins containing one of several reader domains. The tudor domain-containing proteins interact with di- and trimethylated lysine, whereas the malignant brain tumor domain-containing proteins bind mono- and dimethylated proteins. Tudor domains are also able to interact with methylated arginine. In contrast, plant homeodomains recognize lysine acetylation and all three methylation states but are specific to H3K4 location for methylation and acetylation and H3K14 for acetylation. H3K4 methylation can also be read by chromodomains. To date, there are no small-molecule inhibitors of methyl reader domains in the clinic (http://www.thesgc.org/epigenetics).

In addition to the proteins mentioned in the previous paragraph, the histone acetyl marks are also read by a family of proteins known as bromodomains. There are over 60 bromodomains encoded in the human genome and 40 bromodomain-containing

proteins.[6] There are currently two compounds in the clinic that target the bromodomain and extra C-terminal domain (BET) subfamily of bromodomains.

5.08.2.6 Eraser Enzymes

5.08.2.6.1 Lysine demethylases

Lysine methyl marks are removed by the lysine demethylase (KDM) family of enzymes in a sequence-dependent manner. The KDMs are divided into two subfamilies, the lysine-specific demethylases (LSD1/KDM1) and the Jumonji C (JmjC)-domain-containing demethylases (KDMs2–7). The lysine-specific demethylase family of enzymes is flavin dependent whereas the JmjC domain-containing enzymes are Fe(II) and 2-oxoglutarate dependent. Jumonji domain-containing 6 (JmjD6) has been reported to have arginine demethylation activity; however, this activity is subject to conflicting reports.[7] Currently, there are three KDM1 inhibitors undergoing clinical trials (Table 1).

5.08.2.6.2 Histone deacetylases

Lysine acetyl marks are removed by a family of enzymes known as histone deacetylases (HDACs). HDACs remove acetyl groups from the lysine residues of histones and other proteins. The HDACs are divided into five broad classes. Class 1 (HDAC 1, 2, 3, and 8), Class IIa (HDAC 4, 5, 7, and 9), Class IIb (HDAC 6 and 10), and Class IV (HDAC 11) are zinc-containing enzymes, whereas Class III are nonzinc-dependent enzymes called sirtuins. The HDACs have historically been the most studied family of histone-modifying proteins to date and as a result there are four approved HDAC inhibitors and numerous others are undergoing clinical trials (Table 1).

5.08.3 Comparison to Kinases

KMTs and RMTs are both members of the broader family of HMTs and both utilize the same methyl donating cofactor (SAM). One can draw an instructive analogy to protein kinases, which also employ a common cofactor, adenosine triphosphate (ATP) to

Table 1 Summary of epigenetic regulators approved and in clinical trials

Drug name	*Target class/enzyme*	*Status*	*Indication*
Belinostat	HDAC/pan-HDAC	Approved	Peripheral T cell lymphoma
Panobinostat	HDAC/pan-HDAC	Approved	Multiple myeloma
Pracinostat	HDAC/class I, II, IV	Approved	AML, T cell lymphoma
Romidepsin	HDAC/Zn dependent HDACS	Approved	Cutaneous T cell lymphoma
Vorinostat	HDAC/pan-HDAC	Approved	Cutaneous T cell lymphoma
Entinostat	HDAC/class I, III	Phase II/III	Multiple cancers
Givinostat	HDAC/class I, II	Phase II	
Mocetinostat	HDAC/pan-HDAC	Phase II	Lymphoma, leukemia
Quisinostat	HDAC/pan-HDAC	Phase II	Leukemia, MLL, lymphoma, solid malignancies
Resminostat	HDAC	Phase II	HCC
Tacedinaline	HDAC/HDAC1, HDAC2	Phase II	Multiple myeloma
Tazemetostat	HMT/EZH2	Phase II	Lymphoma, solid tumors
Valproic acid	HDAC/pan-HDAC	Phase II	Multiple cancers
ACY-1215	HDAC/HDAC6	Phase I/II	Multiple myeloma
AR-42	HDAC/pan-HDAC	Phase I/II	MLL, lymphoma, leukemia
ORY-1001	KDM/KDM1A	Phase I/II	AML
OTX015	Bromodomain/BET	Phase I/II	Glioblastoma
Tranylcypromine	KDM/KDM1A	Phase I/II	AML
ABBV-075	Bromodomain	Phase I	Advanced cancers
Abexinostat	HDAC/pan-HDAC	Phase I	B-cell lymphoma
BAY-1238097	Bromodomain/BET	Phase I	Neoplasms
BMS-986158	Bromodomain/BET	Phase I	Solid tumors
CPI-0610	Bromodomain/BET	Phase I	Lymphoma
CPI-1205	HMT/EZH2	Phase I	B-cell lymphoma
CUDC-907	HDAC/class I, IIB	Phase I	Lymphoma, multiple myeloma, solid tumors
GSK525762	Bromodomain/BDR4	Phase 1	Hematological malignancy, NUT midline carcinoma
GSK2816126	HMT/EZH2	Phase I	B-cell lymphoma, follicular lymphoma
GSK2879552	KDM/KDM1A	Phase I	AML
Pinometostat	HMT/DOT1L	Phase I	Leukemia
TEN-010	Bromodomain/BET	Phase I	AML and solid tumors

accomplish their function. Kinases transfer the terminal phosphoryl group from ATP to a serine, threonine, tyrosine, or histidine residue on the target protein and in doing so generate adenosine diphosphate as a byproduct. Protein kinases have been a vigorous area of pharmaceutical research for the past decade and there are >25 approved kinase inhibitors on the market and a further >50 kinase inhibitors currently in clinical trials. The vast majority of kinase inhibitors that have been clinically examined are ATP competitive and are targeted toward a single kinase. Therefore, kinase specificity is often a challenge for this target class. There is however sufficient structural diversity within the ATP-binding pockets of kinases to enable selective inhibitors to be designed and generated as exemplified by tarceva[8] and imatinib.[9] One could take a parallel approach with HMTs by designing inhibitors that compete with SAM and engender specificity for the HMT of choice by taking advantage of any structural uniqueness within the SAM-binding site (Fig. 3). This has been successfully demonstrated at Epizyme by the production of two selective SAM-competitive HMT inhibitors: tazemetostat,[10] an EZH2 inhibitor, and pinometostat,[11] a DOT1L inhibitor (see Fig. 3).

There are, however, some alternative potential modes of inhibition that can be targeted when drugging HMTs. It is possible to target the protein substrate pocket, interfering where the lysine or arginine residues would bind prior to being methylated. This approach offers certain advantages over SAM competition as proteins with a low K_m for SAM will result in large potential cell shifts when moving from a biochemical assay run under balanced conditions into a cellular context where there may be high intracellular SAM concentration. This is analogous to targeting a kinase with a low K_m for ATP, such as Janus Kinase 3 (JAK3). JAK3 has a reported K_m for ATP of 6 μM,[12] using the Cheng–Prusoff equation and a cellular [ATP] of 1 mM, one would predict that an inhibitor run under balanced condition would see a fold-loss of ~170× when run in a cellular assay. That is a large potency gap that a medicinal chemist would have to anticipate and account for when establishing a desired drug profile. Thus, should the target HMT have a low K_m for SAM relative to the cellular concentrations of SAM, it may be preferable to optimize a noncompetitive SAM inhibitor over a SAM-competitive inhibitor. The screening paradigm would need to be designed, such that it could identify and differentiate a competitive versus noncompetitive profile.

5.08.4 Challenges in Screening

The discovery of small-molecule inhibitors of CMPs is a relatively recent phenomenon. HDAC inhibitors were the first to be discovered but as mentioned in the previous section there are many enzyme classes for which tool compounds are not yet known. Discovering starting points for medicinal chemistry programs has been challenging for a number of reasons.

5.08.4.1 Enzyme Selection

The first step in setting up a screening strategy is determining the protein or protein complex to use in the screen. Even in isolated enzyme screens selecting the enzyme form, full length or truncated, is a crucial step and may influence the hits obtained in the screen. In their SET and MYND domain-containing 2 (SMYD2) program, Eli Lilly used full-length SMYD2 enzyme,[13] in contrast the Structural Genomics Consortium (SGC) used a truncated EHMT2 (913–1193) enzyme in the development of their EHMT2

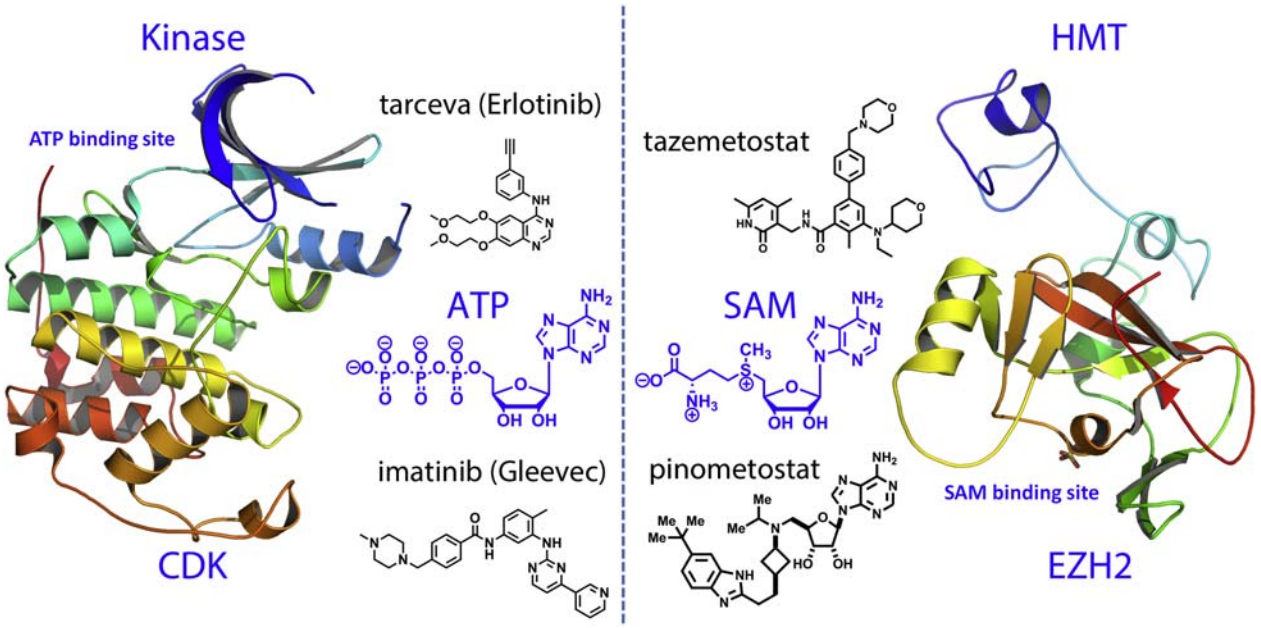

Fig. 3 X-ray representation of CDK and EZH2 and their associated cofactors and published inhibitors.

tool compound.[14] The EZH2 enzyme exists as part of the larger polycomb repressive complex 2 (PCR2) and screening has been carried out using recombinant PCR2 complexes. Constellation (SUZ12, EED, RBBP4, RBBP7, and either wt EZH1, wt EZH2, or Y641N mutated EZH2),[15] Epizyme (EED, SUZ12, RbAP48, and wt EZH2 or Y641C mutant EZH2),[16] GSK (EZH2, EED, SUZ12, AEBP2, and RbAp48),[17] and Novartis[18] (Ezh2, Suz12, EED, RbAP48, and AEBP2) all used a recombinant PRC2 complex in their EZH2 programs.

5.08.4.2 Substrate Identification

Once a protein or protein complex is selected, the substrate for the assay must be identified and validated. The endogenous substrates for these enzymes are the histone proteins that have been compacted into nucleosomes. In their DOT1L program, Epizyme used chicken oligonucleosome as the methylation substrate.[19] However, in their PRMT5 program, Epizyme used an H4 histone tail peptide.[20] Eli Lilly developed both a histone tail (residues 1–24 of H4) assay and a tumor protein p53 (p53) peptide (residues 361–380) assay for their SMYD2 program.[5,13]

5.08.4.3 Assay Conditions

Assay conditions can have a profound influence on the types of hits found during the screening process. For enzymes that have a cofactor, such as the HMTs, HATs, and KDMs, inhibitors can be substrate or cofactor competitive. Running an HMT assay at high SAM concentration, for example, will bias the results toward SAM uncompetitive hits. Boehringer Ingelheim took this approach during their EHMT2 screening campaign.[21] Running an assay under balanced conditions enables the identification of both substrate and cofactor competitive inhibitors.[22]

5.08.4.4 Hit Validation

Both Epizyme and Constellation reported low micromolar potency hits from their PRMT5[20] and EZH2[15] screens, respectively. In this potency range compounds can exhibit a number of behaviors that lead to false positives. For this reason, both companies employed additional assays to identify compounds that were truly inhibitors of the enzymes in question. Epizyme ran the initial screen using a fluorescence assay. Pan-assay interference structures (PAINS)[23] were removed and the remaining compounds were subjected to an orthogonal radiometric PRMT5 assay using ^{3}H SAM followed by a redox assay. These triage steps narrowed the original hit list down to a single prioritized series with potencies ranging from 0.4 to 7 μM. This series was further validated using biophysical methods and X-ray crystallography. Constellation reported 288 confirmed hits in an EZH2 screen, the majority of which were >20 μM in potency. After subjecting these compounds to a number of assays further described in the "**Enhancer of zeste homolog 2**" section, a single weak inhibitor was selected as a starting point for medicinal chemistry optimization.

5.08.4.5 Cellular Assays

Cellular assays are also complicated by the fact that several days of compound treatment can be necessary before effects on histone methyl marks or target genes are observable. Additionally, there is currently a lack of commercially available antibodies for detecting a broad spectrum of specific acylation or methylation events.[5]

5.08.5 Approved and Clinical Stage Epigenetic Regulators

See **Table 1**.

5.08.6 Case Studies

5.08.6.1 Histone Deacetylases

The HDACs have been an area of active research for a number of years and there are currently four approved HDAC inhibitors on the market.[1] Vorinostat, also known as suberoylanilide hydroxamic acid (SAHA), panobinostat, and belinostat are pan-HDAC inhibitors, whereas romidepsin primarily inhibits Class I HDACs (**Fig. 4**).[3] With the exception of romidepsin and valproic acid, both of which are natural product derived, the most advanced HDAC inhibitors can be divided into two different structural classes. Vorinostat, belinostat, panobinostat, and a number of others contain hydroxamides, whereas mocetinostat[24] and entinostat are 2-aminoanilides.

Vorinostat was the first approved HDAC inhibitor, although at the time of discovery the mechanism of action was unknown.[25] Vorinostat evolved from the discovery that murine erythroleukemia cells (MELC) turned red upon treatment with high concentrations of dimethylsulfoxide. A similar result was seen with other highly polar solvents, with amide containing solvents being the most potent. This observation led to the design and synthesis of hexamethylene bisacetamide which inhibited the MELC growth with an IC_{50} of 5 mM (**Fig. 5**). The bisacetamide compound entered clinical trials but was not well-tolerated and it became clear

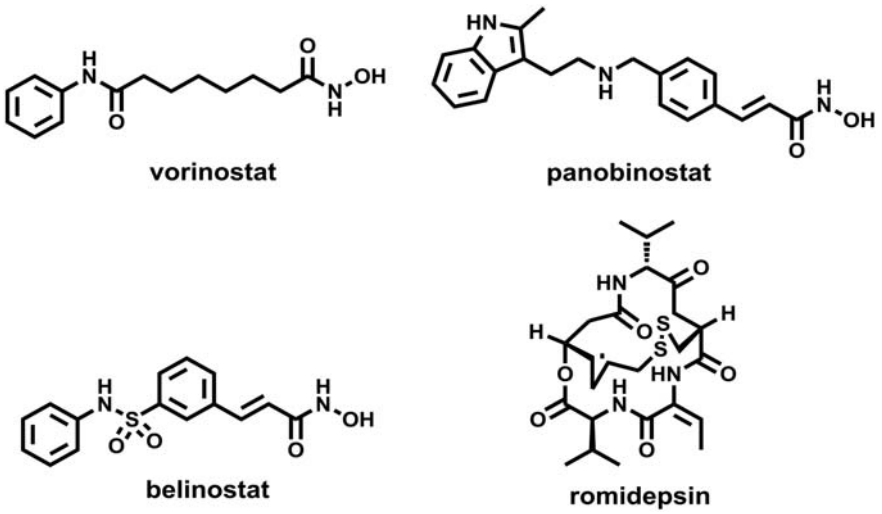

Fig. 4 Structures of approved HDAC inhibitors.

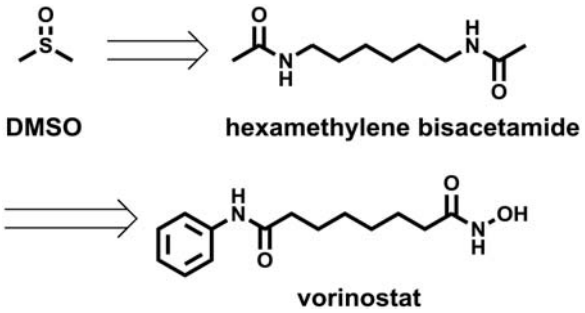

Fig. 5 Chemical iterations toward vorinostat.

that a more potent compound was necessary. Speculating that the amides were binding to a metal containing site on an enzyme, a series of hydroxamide containing compounds were prepared. Vorinostat is not the most potent analog in this series but does strike a balance between efficacy and toxicity. Vorinostat was approved for the treatment of cutaneous T cell lymphoma but due to undesirable side effects has not been approved in other indications.[2a]

Due to the dose limiting toxicity seen with some of the pan-HDAC inhibitors, the next generation of inhibitors has aimed to be more selective, targeting a single HDAC isozyme, or a small subset of isozymes. There are currently several HDAC inhibitor compounds undergoing clinical trials in lymphoma and other indications (**Table 1**).

5.08.6.2 Histone Methyltransferases

5.08.6.2.1 Arginine methyltransferases

5.08.6.2.1.1 Protein arginine methyltransferase 5

PRMT5 is reported to have roles in diverse cellular processes, including tumorigenesis. Overexpression of PRMT5 is observed in cell lines and primary patient samples derived from lymphomas, particularly mantle cell lymphoma (MCL). Epizyme conducted a homogeneous time-resolved fluorescence (HTRF) assay-based HTS campaign monitoring the mono methylation of an H4R3 peptide. A library of 370,000 compounds was profiled and generated a hit rate of 0.7%.[20] A triage funnel was applied (cherry pick retest, PAINS filters, and removal of additional proprietary frequent hitter substructures). This furnished 800 compounds for further follow up. Compounds making it through this preliminary triage were then further culled by utilizing additional screens looking for HTRF artifacts. Examples of these assays were an orthogonal biochemical assay and a redox assay. This further winnowed down the list to a single interesting series, which was further characterized by enzymology experiments, biophysical methods, and X-ray crystallography. EPZ007345 (**Fig. 6**) was an example of a series of 17 compounds with activity against PRMT5 ranging from 0.4 to 7 μM.[26]

The tetrahydroisoquinoline (THIQ) is believed to participate in a π–cation interaction with the charged methyl group of SAM. Altering the electronic properties or the positioning of the aryl ring of the THIQ resulted in compounds with a reduced inhibitory

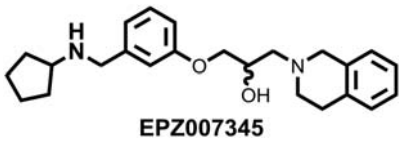

Fig. 6 Structure of EPZ007345.

potency. Initial structure activity relationships (SAR) demonstrated that structural changes distal to the THIQ moiety were well-tolerated and able to show improvements in potency and absorption, distribution, metabolism, and excretion (ADME) properties. Compounds **1** and **2** (Fig. 7) were both active in the cellular methylation assay but compound **2** showed a threefold improvement in cellular antiproliferative assays when compared to **1**. While these compounds represent an improvement in cellular potency, these compounds and others in the chemical series were not stable in human and mouse liver microsome assays.

To address the high clearance in liver microsomes, efforts were directed toward less lipophilic compounds with lower clogD values. Additional attention was paid to compounds with human liver microsome scaled clearance values $\leq$50% of hepatic blood flow. The authors propose that this parameter was likely to lead to chemical space from which a candidate quality compound could be identified. Further assessment of compounds in mouse pharmacokinetic (PK) studies led to the identification of EPZ015666, a 22 nM PRMT5 inhibitor with a favorable in vivo profile (Fig. 8).

EPZ015666 was shown to be competitive with substrate and uncompetitive with SAM. EPZ015666 was also selective versus a panel of 20 other protein methyltransferases, where no inhibition was seen up to 50 μM. The mouse PK profile was also favorable with a plasma clearance of 30 mL $min^{-1} kg^{-1}$ and a volume of distribution of 1.7 L kg^{-1} after intravenous dosing at 2 mg kg^{-1}, and oral bioavailability of 69% following oral administration of 10 mg kg^{-1}. Thus EPZ015666 was used for both in vitro and in vivo studies to explore the biology of PRMT5.

A quaternary crystal structure of PRMT5:MEP50 in complex with EPZ015666 and SAM was obtained (Fig. 9). The THIQ moiety was shown to be involved in a cation–π interaction with the charged methyl group of SAM. The THIQ also made a π–π stacking interaction with Phe327.

EPZ015666 was then profiled in a cellular context. A panel of five MCL cell lines (Z-138, Maver-1, Mino, Granta-519, and Jeko-1) was utilized to characterize target engagement and subsequent effects on cell proliferation upon treatment with a PRMT5 inhibitor. The effects of EPZ015666 treatment on cellular symmetric arginine demethylation in Z-138 cells were tested by immunoblotting using a pan-dimethyl symmetric arginine antibody. A concentration-dependent decrease in the intensity of multiple bands, including one that colocalized with the previously reported PRMT5 substrate small nuclear ribonucleoprotein D3 polypeptide was observed. This effect was further validated using short hairpin ribonucleic acid (RNA). Antiproliferative effects of EPZ015666 were evident after several days of exposure, thus a long-term proliferation assay was established (12 days). EPZ015666 demonstrated potent concentration-dependent antiproliferative effects, with IC_{50} values of 96 and 450 nM for Z-138 and Maver-1 cells, respectively. EPZ015666 is bioavailable and thus suitable for in vivo studies. EPZ015666 was dosed twice-daily to severe combined immune deficiency mice bearing Z-138 or Maver-1 xenografts at doses of 25, 50, 100, and 200 mg kg^{-1} for 21 days. EPZ015666 demonstrated dose-dependent exposure and tumor growth inhibition (TGI) in both models. The 200 mg kg^{-1} cohort induced tumor stasis in Z-138 cells with 93% TGI. In comparison the 200 mg kg^{-1} cohort induced >70% TGI in the Maver-1 study. EPZ015666 was well-tolerated in all models with minimal weights loss in the 200 mg kg^{-1} groups and no other toxicity observations.

5.08.6.2.1.2 Protein arginine methyltransferase-6

Protein arginine methyltransferase-6 (PRMT6) is a member of the 45-enzyme RMT family. PRMT6 is found in the nucleus and can generate mono and asymmetric, dimethyl omega-*N*(G)-arginine derivatives on histones possessing a GAR motif. PRMT6 is the only

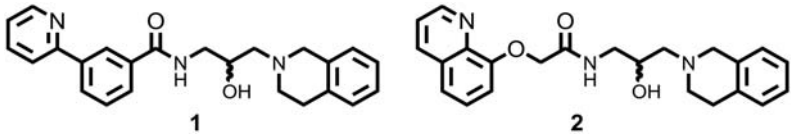

Fig. 7 Published PRMT5 inhibitors from Epizyme.

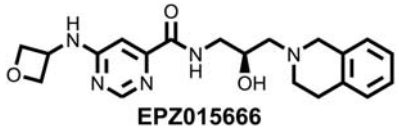

Fig. 8 Structure of EPZ015666.

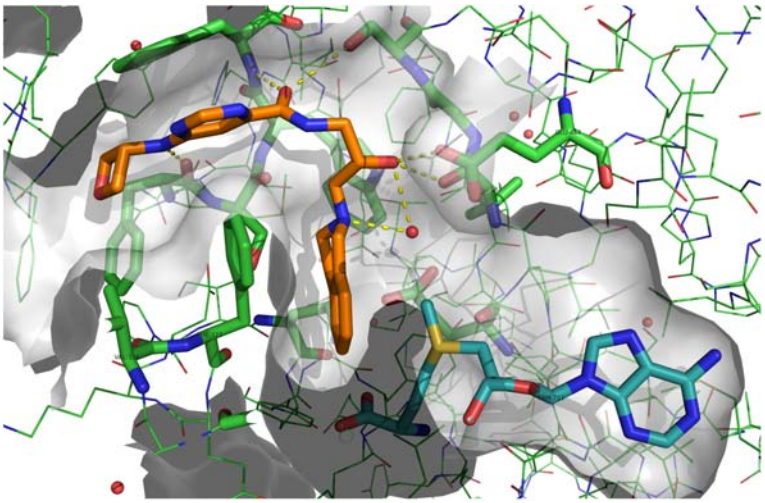

Fig. 9 X-ray pose of PRMT5:MEP50 in complex with EPZ015666 and SAM.

RMT known to methylate the H3R2 mark. Overexpression of PRMT6 has been reported in several cancer types including melanoma, lung, and prostate.[27] The hope is that small-molecule inhibitors of PRMT6 could have utility against these cancer types.

Through screening of its internal compound collection against protein methyltransferase 1 (PRMT1), PRMT6, and protein methyltransferase 8 (PRMT8), Epizyme identified aryl pyrazoles bearing diamine side chains as having inhibitory activity (**3**, Fig. 10).[27]

A ternary crystal structure of compound **3**, *S*-adenosylhomocysteine (SAH) and PRMT6 was generated. The diamine side chain portion of the molecule occupies the putative substrate site. The terminal nitrogen atom gets close to the sulfur atom of SAH and makes multiple direct hydrogen bonds to Glu155 and water-mediated hydrogen bond interaction to Trp156 and Glu164. The X-ray pose of **3** also suggested that there was space in the pocket for further expansion beyond the para-position of the aryl group.

Several analogs of **3** were generated. Analog generation was facilitated by replacement of the *para*-fluorine with an oxygen atom and a series of compounds was prepared. Larger ethers retained activity against PRMT6, PRMT8, and PRMT1. Metachlorination was also tolerated. A different pyrazole isomer and N-methylation of the terminal nitrogen were also well-tolerated. Incorporation of two metasubstituents eroded PRMT6 activity. Epizyme was able to generate some PRMT6 selective compounds by extending further from the phenyl para-position. Various linkers were tolerated such as nitrogen, oxygen, and carbon. After further ADME characterization and in vitro and in vivo studies, EPZ020411 (Fig. 11) was selected as a viable tool compound with a biochemical potency of 10 nM against PRMT6. EPZ020411 demonstrated 10- to 20-fold selectivity for PRMT6 over PRMT8 and PRMT1 and over 100-fold selectivity compared to other HMTs.

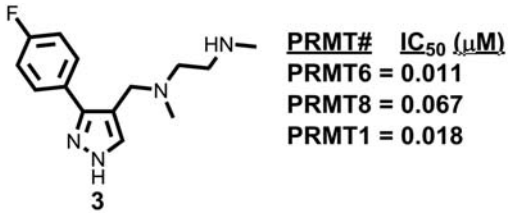

Fig. 10 Published PRMT6 inhibitor from Epizyme.

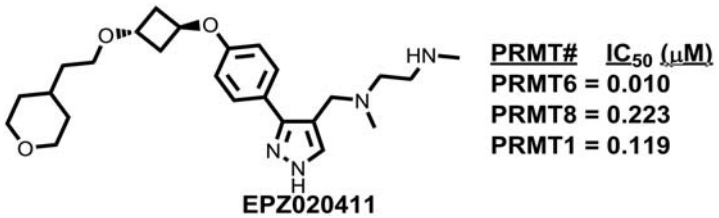

Fig. 11 Structure of EPZ020411.

A ternary crystal structure of EPZ020411, SAH, and PRMT6 was obtained (Fig. 12). The gross topology of the binding pose was similar to that of the previously described compound. The entirety of the oxygen-linked para-substitution was not well-ordered in the structure with electron density not observed for the terminal tetrahydropyran moiety.

The cellular activity of EPZ020411 was investigated in an engineered model in which PRMT6 was transiently expressed in an A375 cell line background. EPZ020411 did not affect levels of PRMT6 expression, but did dose-dependently reduce cellular H3R2 methylation with an $IC_{50} = 0.64\ \mu M$. EPZ020411 was ~10-fold less potent against PRMT1. EPZ020411 demonstrated ~50% free fraction in both human and rat plasma and was poorly permeable in the parallel artificial membrane assay. Subcutaneous dosing of 5 mg kg^{-1} in rats afforded 66% bioavailability with the unbound blood concentration remaining above the PRMT6 biochemical IC_{50} value for >12 h. This suggests that EPZ020411 could be a viable in vivo tool compound with which to explore PRMT6 biology.

5.08.6.2.2 Lysine methyltransferases

5.08.6.2.1.3 Enhancer of zeste homolog 2

HMT EZH2 demonstrates prevalent overexpression in several cancers making it a potential target for drug intervention.[15,17,18,28–32] EZH2 acts as a part of a multiprotein PRC2 complex where it catalyzes the methylation of histone H3 on lysine 27 (H3K27). Increases in H3K27 methylation have been correlated with disease stage and poorer prognosis. Change of function mutations of EZH2 have also been identified in patients with germinal center B-cell diffuse large B-cell lymphoma (DLBCL) and follicular lymphoma. These mutations result in increased levels of H3K27Me3, further implicating EZH2 as an interesting drug target.

Several companies have been active in the area of EZH2 inhibitor design and pyridone-methyl-acetamides have been a dominant chemotype employed (Fig. 13):

Several compounds have advanced into the clinic. Epizyme's inhibitor tazemetostat was the first in Jun. of 2013, followed by GSK with 2816126 and Constellation Pharmaceuticals with CPI-1205 (structure not published).

Epizyme has described the story of the discovery of their clinical candidate tazemetostat.[10] They conducted high-throughput diversity screens against the four-component PRC2 complex containing EZH2, EED, SUZ12, and RbAp48 using chicken oligonucleosomes as the substrate. Epizyme chose to run the screen under balanced conditions (at K_m for SAM and nucleosome) to ensure inhibitors acting via diverse mechanisms of action could be identified, such as competitive with SAM or with nucleosome. Any identified matter was triaged through a rigorous hit validation procedure. Compounds that were redox active, had solubility issues, formed micelles as determined by differential light-scattering, or were known PAINS compounds were removed. This enabled identification of compound **4** as a validated hit (Fig. 14).

Compound **4** contained a 4,6-dimethyl pyridone and demonstrated an EZH2 biochemical IC_{50} of 3.4 μM. Acquisition of commercially available analogs enabled rapid exploration of the chemical space around the initial hit. This effort identified compound **5** as a sub-μM inhibitor of EZH2 (Fig. 15).

Resynthesized compound **5** retained activity and passed a battery of "bad actor" counter screens. Mechanism of action studies demonstrated that compound **2** was SAM-competitive and nucleosome noncompetitive. These data enabled the conclusion that the inhibition mechanism was via direct interaction with the enzyme. Using compound **5** as a starting point, a lead optimization campaign was initiated. Initial modifications were focused on improving the poor ADME profile of compound **5**. Attempts to increase the solubility by incorporation of basic amine moieties were well-tolerated on the 6-position of the 7-azaindazole and improved solubility without substantial loss of potency. After extensive exploration, a benzyl morpholine encompassed the best balance of properties. Epizyme now chose to focus on finding the best central core components. Several 6,5-fused heterocycles

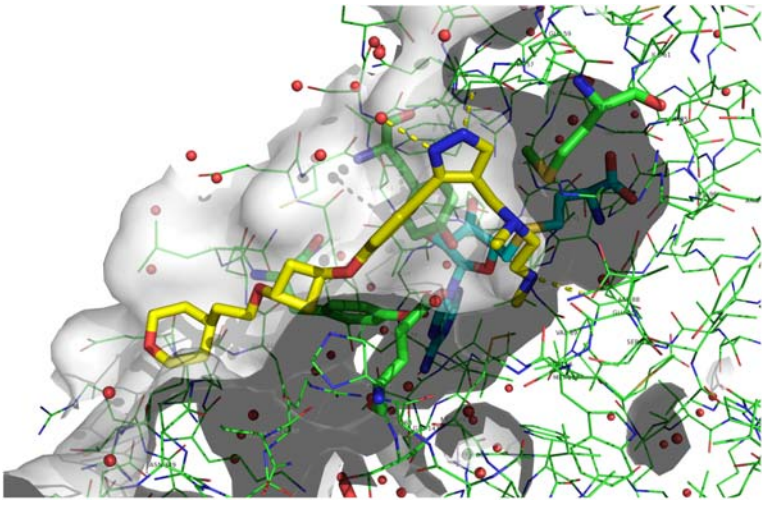

Fig. 12 X-ray pose of PRMT6 in complex with EPZ020411 and SAH.

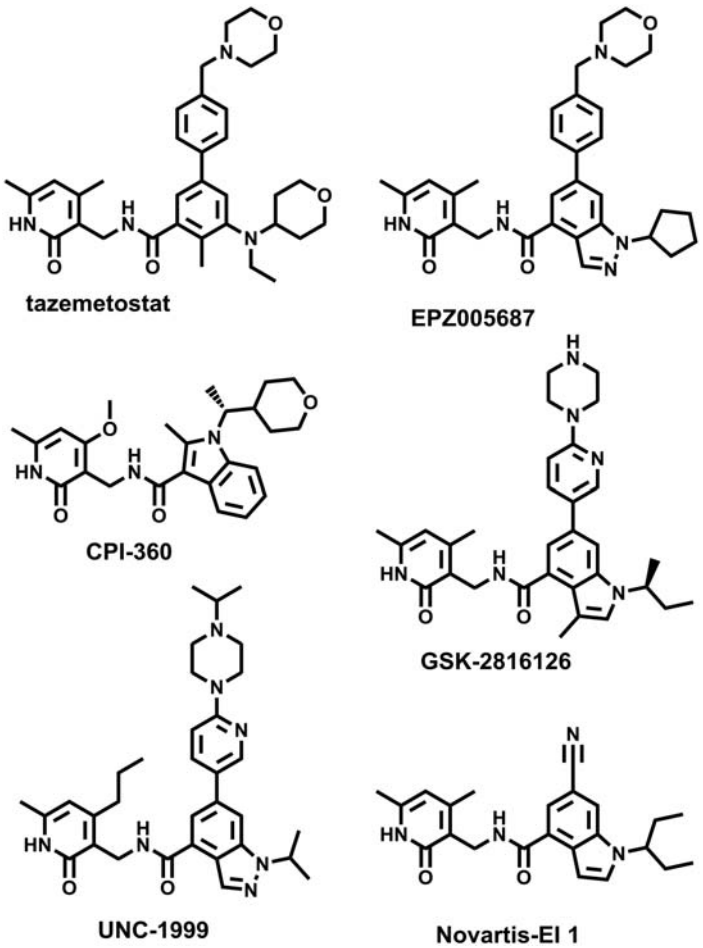

Fig. 13 Published EZH2 inhibitors.

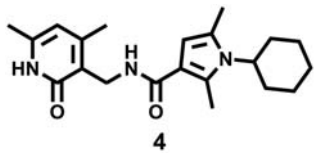

Fig. 14 Published EZH2 inhibitor from Epizyme.

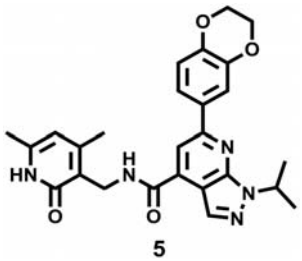

Fig. 15 Published EZH2 inhibitor from Epizyme.

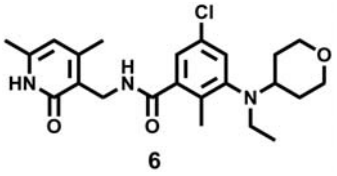
were investigated furnishing the 4-substituted indazole. N1-Alkylation of the indazole with small branched chain alkyl groups was found to be superior for potency, where an *iso*-propyl group was 10× more potent than the ethyl group, which was 10× more potent than the simple methyl group. The team then decided to take a step back and spend some time examining the core ring structure again. Epizyme then "disconnected" the 5,6-bicycle to afford a substituted aniline which enabled access to different vector displacement opportunities. It was then demonstrated that maintaining a substituent on the equivalent position to the carbon of the five-membered ring in the indazole was necessary for potency. This was postulated to be due to a conformational preference for the 6,5-fused hetereocycle systems forcing the amide out of plane relative to the core into a position optimal for binding. The methyl substitution in the ring opened versions was suggested to then mimic that same effect. Other SAR demonstrated a preference for the aniline to be disubstituted. This again was proposed to be due to a conformational effect, where the second substitution would force the aniline to be twisted out of plane relative to the aryl ring. The combination of these two effects enabled Epizyme to reach single digit nM potent compounds for the first time. These efforts culminated in a series exemplified by compound **6** (Fig. 16).[10]

Compound **6** demonstrated acceptable mouse IV clearance, but suffered from poor bioavailability. To optimize the bioavailability, Epizyme considered whether the highly polar benzamidomethyl pyridone could be deleteriously affecting absorption. However, all attempts to further modify or replace the benzamidomethyl pyridone failed to be tolerated for potency. Thus optimization of PK properties remote to the benzamidomethyl pyridone moiety afforded tazemetostat, which had the best balance of potency, clearance, and bioavailability. Tazemetostat was able to show reduction of H3K27Me3 in both tumor and surrogate tissue in mouse xenograft experiments.[33]

Epizyme also disclosed EPZ011989 as a potent, orally available EZH2 inhibitor with robust in vivo activity for the purposes of expanding the known biology of EZH2 (Fig. 17).[28] EPZ011989 was discovered through modification of the pyran substituent of tazemetostat (Fig. 13). The *trans*-*N*,*N*-dimethylcyclohexylamine replacement is able to maintain biochemical activity, but when combined with the morpholine sidechain, the cellular activity of the resulting di-basic compound is negatively impacted. Modulating the pK_a of the amines was proposed as a solution and the resulting SAR validated this approach when adding a methoxyethyl group and replacing the second benzene ring with an acetylene linker to generate EPZ011989.

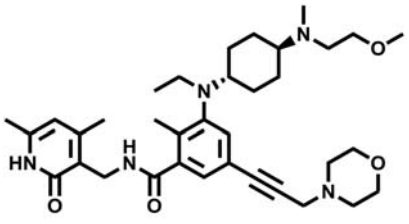
EPZ011989 was shown to be a very potent EZH2 inhibitor with a biochemical K_i of <3 nM on both mutant and wild-type EZH2. EPZ011989 was also shown to be selective for EZH2, with >15-fold selectivity over EZH1 and with >3000-fold selectivity against a panel of 20 other HMTs. The cellular potency, measured by suppression of the H3K27 methyl mark in an Y641F mutant bearing human lymphoma cell line, WSU-DLCL2, was <100 nM. Further, in vitro characterization suggested that EZP011989 would have reasonable rodent PK, which was then verified when a 1000 mg kg^{-1} oral dose provided target coverage for 24 h. A 7-day pharmacodynamic (PD) study looking at H3K27 methylation in bone marrow showed that a 500 mg kg^{-1} BID dose caused complete ablation of the methyl mark by the end of the seventh day of dosing. EPZ011989 was then reformulated and explored in a 21-day subcutaneous EZH2 mutant KARPAS-422 human DLBCL xenograft TGI study. Both doses, 250 and 500 mg kg^{-1} BID, of EPZ011989 afforded significant tumor regression with nominal effects on body weight. Efficacy at the lower dose was in part due to the superior exposure achieved with the new formulation. Thus EPZ011989 is an excellent tool for both in vitro and in vivo work to further explore EZH2 pathobiology.

Constellation Pharmaceuticals reported a series of EZH2 inhibitors obtained from a conventional high-throughput screen employing a PRC2 enzymatic assay monitoring ^{3}H-labeled methyl group transfer from SAM to oligonucleosome substrate.[32] The HTS assay was run under balanced conditions (i.e., SAM and substrate at K_m) in order to find inhibitors that operate via competitive, noncompetitive, or uncompetitive modes. A total of 150,000 compounds were screened and yielded an initial 288 confirmed



6

Fig. 16 Published EZH2 inhibitor from Epizyme.



EPZ011989

Fig. 17 Structure of EPZ011989.

hits with potencies generally >20 μM. These were triaged down through several filters (frequent hitters, reactive/toxic moieties, and problem structural features by visual inspection) and then retested in the IC_{50} assay. Any compounds displaying Hill slopes outside a range of 0.7–1.5 were omitted and then several shift assays[32] were employed to remove additional "bad actors" and classify compounds by potential mechanism of action. At this point in the triage funnel, only several weak inhibitors remained (>20 μM) and one of these was the starting point for their optimization campaign (Fig. 17). Shift assay data suggested that the new chemotype was SAM competitive and selective when assayed against other HMTs. Constellation's initial plans were to rapidly explore the inhibitor topology to gauge the quality of the matter. The hit was sectioned into four areas for exploration (Fig. 18).

Initial linker SAR identified that the ether could be replaced by a sulfide. The sulfoxide and sulfone were both inactive, suggesting a preference for a linker that can accept a hydrogen bond. Homologation by methylene insertion next to the central phenyl ring was tolerated, although conversely methylene homologation next to the terminal phenyl ring was not. This was rationalized to be due to a preference for a twist conformation of the bi-aryl system. For the right-hand side SAR, the 2-position was identified as amenable to substitution with cyano being the preferred moiety conveying a 15-fold boost in potency (3.5 μM). The central core was tackled next and while substitution next to the amide of the left-hand side was tolerated, substitution next to the linker ether provided potency enhancements with chlorine providing the best balance of potency and physiochemical effects. Moving back to the right-hand side of the molecule, a para hetero-aromatic ring, specifically a pyridazine, demonstrated an improvement in potency down to 24 nM. This compound **7** (Fig. 19) was poorly permeable in a Caco-2 assay and had a high efflux ratio, which would predict poor oral bioavailability. Attempts to attenuate the pK_a of the piperidine nitrogen were not tolerated nor were any significant modifications to the left-hand side of the molecule. Ultimately compound **7** was selected for further evaluation of EZH2 biology. Compound **7** was evaluated in KARPAS-422 cells and afforded a suppression of global H3K23Me3 levels and growth arrest consistent with previously reported EZH2 inhibitors.

In a follow-up communication to the one described earlier, Constellation Pharmaceuticals reported a class of indole-based EZH2 inhibitors for in vivo dosing.[29] As part of their on-going EZH2 inhibitor program, Constellation also developed a pyridone chemotype, exemplified by compound **9** (Fig. 20). Compound **9** was shown to be SAM competitive and inhibit the PRC2 methyltransferase activity at 39 μM. Due to the structural similarity between the new chemotype (**9**) and the previous series (**8**), Constellation tested the interchangeability of the tetramethyl-piperidine and the dimethylpyridone groups making compound **10**. While **10** was much less potent than the optimized compound from the previous series, it did demonstrate improved potency relative to **7**. Truncation of the chloro, cyano, and pyridazine substituents showed improved potency (**11**).

A scan of various linkers between the two phenyl rings concluded that a carbon linker was the most potent. To maintain the chemical matter in a more drug-like space, Constellation wished to introduce some more polarity into the molecules. This was achieved by swapping the central phenyl group for various heterocycles. The introduction of a 2-methyl group onto an indole linker resulted in a 126-fold increase in potency relative to the des-methyl equivalent (**12** and **13**, Fig. 21). The increase in potency was attributed to an impact on rotational flexibility of the amide, such that the 2-methyl group biases the amide toward a single rotamer.

Replacing the terminal phenyl group with a piperidine ethyl sulfonamide afforded a lower cLogP and good biochemical and cellular potency, but maintained the high microsomal clearance. When this was combined with a change of the dimethylpyridone to a methoxypyridone (Fig. 22), the resulting compound **14** demonstrated a better microsomal stability profile, while retaining its biochemical and cellular potency.

Compound **14** was selected for in vivo profiling. Mouse IV PK showed a clearance of 2.74 $L\,h^{-1}kg^{-1}$, reasonable volume (0.795 $L\,kg^{-1}$), and a short half-life of 0.37 h. Subcutaneous dosing at 200 $mg\,kg^{-1}$ afforded an improved half-life and AUC with plasma adjusted free fraction above the cellular EC_{50} out to 16 h. Constellation was then able to demonstrate a PD response in a KARPAS-422 model. After 17 days of dosing 200 $mg\,kg^{-1}$ BID compound **14** demonstrated an 84% reduction in H3K27Me3

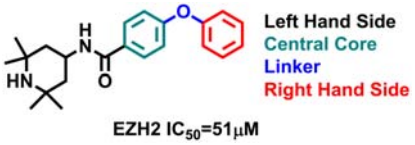


Fig. 18 Published Constellation EZH2 screening hit.

mark relative to vehicle control. Compound **14** was then tested in an efficacy model where the 200 mg kg^{-1} dose showed a TGI of $>100\%$. The compound was well-tolerated, suggesting that compound **14** may be a useful tool compound for studying the effect of EZH2 inhibition, both in vitro and in vivo.

5.08.6.2.1.4 Disrupter of telomeric silencing-like 1

DOT1L methylates histone H3 lysine 79 (H3K79) and has been implicated in leukemias bearing MLL rearrangements (MLL-r). MLL is an HMT responsible for the methylation of H3K4. Chromosomal translocations involving the MLL gene result in the expression

of MLL-fusion proteins which lack catalytic activity. It is thought that these fusion proteins are able to recruit DOT1L to a larger MLL containing multiprotein complex which then aberrantly methylates H3K79 leading to enhanced expression of leukemogenic genes.[19,34]

Epizyme initiated a structure-guided approach to discovering a small-molecule, DOT1L inhibitor based on the structure of SAM, and the product of the enzymatic reaction SAH. The initial aim of replacing the polarizable sulfur atom, removing the charged amino acid side chain, and establishing the minimum pharmacophore resulted in EPZ00004 ($K_i = 38$ μM) (Fig. 23). X-ray crystal analysis showed that EPZ0004 bound in the active site with the same configuration as SAM. From this starting point, the program used structure-based design to increase potency by engaging further with the SAM-binding pocket and the adjacent lysine-binding pocket. Systematic modifications to the alkyl side chains appended to the 5′ amine lead to EPZ003696 ($K_i = 13$ nM) (Fig. 23). Changes to the nucleoside portion of the compound were less well-tolerated; however, the nitrogen at position 7 could be replaced with a carbon to give tool compound EPZ004777 ($K_i = 0.3$ nM) (Fig. 23). EPZ004777 demonstrated selectivity over other HMTs, inhibition of intracellular methylation of H3K79, and selective killing of MLL-r leukemia cell lines.[34b] However, poor PK properties, specifically high clearance and low bioavailability, precluded further development. To address these shortfalls, a strategy of reducing the conformational flexibility of the molecule along with the number of hydrogen bond donors was employed.[11] This lead to the discovery of pinometostat (EPZ005676, $K_i = 0.07$ nM), a selective DOT1L inhibitor that demonstrated complete and sustained tumor regression in a nude rat subcutaneous xenograft model of MLL-r leukemia. Pinometostat improved upon EPZ004777; however, both were not orally bioavailable necessitating the use of an IV infusion dosing strategy in the in vivo efficacy studies.[35] Despite the dosing limitations, the preclinical data was compelling and pinometostat has advanced to Phase I clinical trials in pediatric and adult patients.

Initially, it was expected that the extended side chain in EPZ003696 would reach into the proximal lysine-binding channel; however, X-ray crystal structures revealed that the side chain in EPZ003696,[34b] EPZ004777,[34b] and pinometostat[11] accesses a novel subpocket that is not present in structures of the enzyme with SAM, SAH, or EPZ00004. The inhibitors with the extended side chain are able to simultaneously interact with recognition elements in both the SAM pocket and the induced hydrophobic subpocket. This conformational change is unique to DOT1L and thus these compounds demonstrate remarkable selectivity against other HMTs.[34b]

5.08.6.2.1.5 Set and MYND domain-containing protein 2

AstraZeneca reported the discovery and characterization of a SMYD2 inhibitor AZ505 (Fig. 24). The molecule was found as part of an HTS campaign and was then crystallized with the SMYD2 protein (Fig. 25). To establish the optimized HTS assay conditions, AstraZeneca profiled the enzymatic activity of the SMYD2 protein across a panel of standard buffers using peptides derived from two

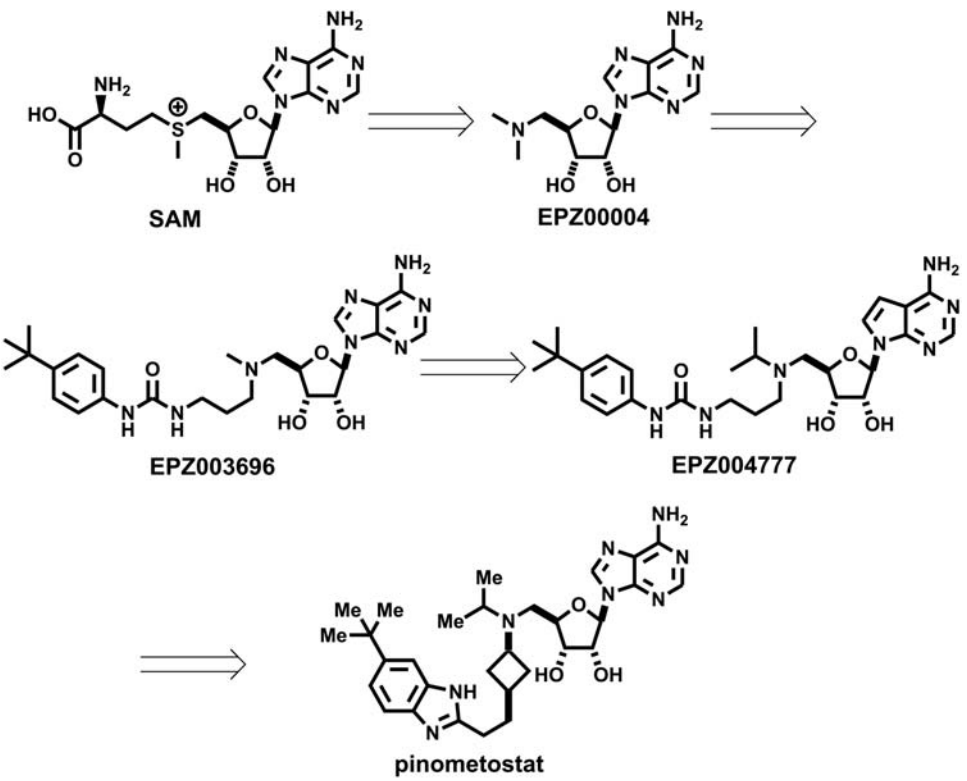

Fig. 23 Chemical developments toward pinometostat.

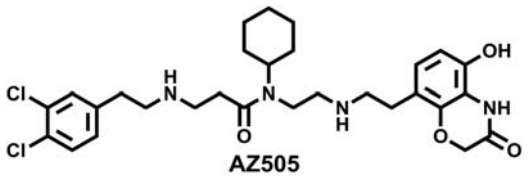

Fig. 24 Structure of AZ505.

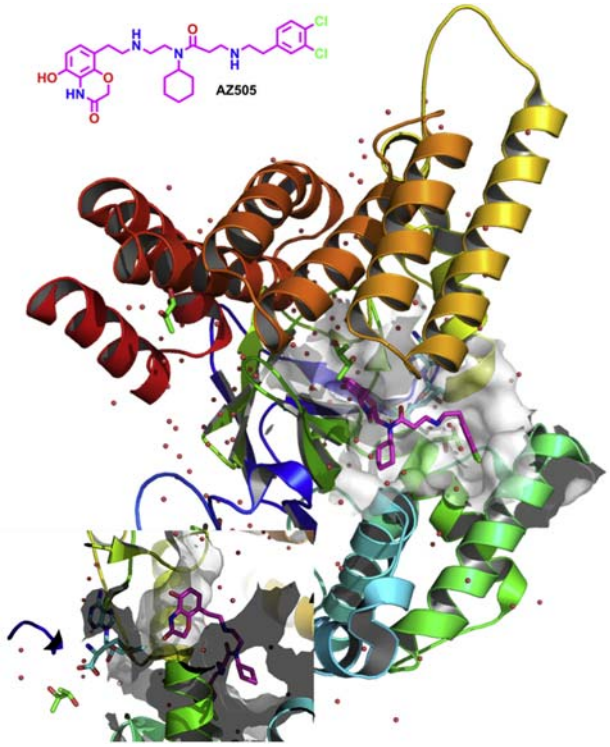

Fig. 25 X-ray representation AZ505 bound to SMYD2.

published substrates (K36 of histone H3 and K370 of transcription factor p53). Tris–HCl with low ionic strength buffer was selected utilizing a p53 substrate peptide as under these conditions SMYD2 demonstrated maximal activity. A small amount of detergent was also utilized to increase protein stability and decrease compound-facilitated protein aggregation.

An AlphaScreen HTS campaign of 1.23 million compounds was completed furnishing a hit rate of 1.2%. As AlphaScreen technology can afford a high false-positive hit rate, a validation cascade was configured. This included an artifact counter screen to invalidate any hits coming from compound interference. A five-point radiometric scintillation proximity assay (SPA) was also employed. A total of 1200 follow-up compounds were then condensed to 25 chemically distinct series along with singletons. Preliminary medicinal chemistry efforts were initiated through purchase of commercially available compounds.

One of the hits, designated AZ505 [*N*-cyclohexyl-3-oxo-3,4-dihydro-2*H*-benzo[b][1,4]oxazin-8-yl)ethylamino)ethyl)propanamide] showed an IC_{50} of 0.12 μM. AZ505 was also shown to be selective over a small panel of KMTs; SET and MYND domain-containing 3 (SMYD3), DOT1L, EZH2, euchromatic histone-lysine *N*-methyltransferase 1 (EHMT1), EHMT2, SET domain-containing (lysine methyltransferase) 7, and SET domain-containing (lysine methyltransferase) 9 having IC_{50}s > 83.3 μM. AZ505 performed well in an isothermal calorimetry assay with a calculated K_d of 0.5 μM. An analysis of the binding kinetics also demonstrated that AZ505 was competitive with substrate and uncompetitive with cofactor (SAM).

AZ505 was also cocrystallized in SMYD2 affording a structure with a resolution of 2.42 Å (Fig. 24). The ternary complex (SMYD2, AZ505, and SAM) showed a single molecule of AZ505 bound in the peptide binding groove. This supported the kinetic evidence that AZ505 is competitive with substrate. The benzoxazinone portion of AZ505 was positioned deep within the lysine-binding channel and showed a series of electronic and hydrophobic packing interactions with the donor methyl group of SAM and surrounding main chain and side chain atoms of SMYD2. The cyclohexyl group of AZ505 binds to a hydrophobic pocket formed at the interface of the core SET and I-SET domains. The terminal dichlorophenethyl moiety slots into another hydrophobic pocket adjacent to the cofactor binding site.

AbbVie also described the identification of a SMYD2 inhibitor, A-893 (Fig. 26). A-893 was developed via a rational design approach based on the, as then, only described small-molecule inhibitor of SMYD2, AZ505. AbbVie described the potency optimizations of the three regions of AZ505 mentioned previously (benzoxazinone, cyclohexylamine, and dichlorophenyl subunits). The SAR was enabled by the utilization of a SPA that measured the SMYD2-mediated methylation of the p53 peptide. The initial premise was that the two moieties occupying the hydrophobic pockets were not significantly contributing to the overall binding efficiency of the molecule (cyclohexylamine and dichlorophenyl subunits). Thus the first targeted analogs were designed to investigate the effects of changes or omissions of these groups. As it turned out, these two regions were sensitive to subtle changes. The initial SAR demonstrated that reducing the size of the cyclohexylamine and dichlorophenyl subunits was generally deleterious to activity. Therefore the team changed focus to the benzoxazinone portion of the molecule. The team wanted to understand the relative importance of each hetero atom in the benzoxazinone lysine channel binding group. They chose to first remove the hydroxyl group. While attempting to synthesize the des-hydroxyl analog, there was a challenge with a reduction reaction resulting in generation of a racemic benzyl hydroxyl compound (Fig. 26). This compound was separated by chiral chromatography to furnish two enantiomers. The measured potencies of the two enantiomers were 2.8 nM (A893) for one enantiomer and 5.8 nM for the other. The mechanism of action was shown to be competitive with peptide, the same as AZ505.

An X-ray structure of A893 in SMYD2 was obtained and showed that the binding mode was very similar to that of AZ505. In the lysine channel, the modified benzyl alcohol accesses a hydrogen bond with the backbone carbonyl of Y240, helping to explain the potency enhancement over AZ505. A893 was shown to be selective for SMYD2 over a panel of 31 other methyltransferases. A893 was also profiled in a human lung carcinoma cell line where incubation at 10 μm for 18 h afforded reduction in the ratio of P53 K370Me1 to overall P53 levels.

Lilly disclosed LLY-507, a potent, cell permeable, and selective small-molecule inhibitor of SMDY2 (Fig. 27).[13] The SMYD2 inhibitory potency of LLY-507 was measured via SPA and found to be <15 nM.[36] LLY-507 binding to SMYD2 was also confirmed by differential scanning fluorometry where 100 μM levels of LLY-507 increased the thermal stability of SMYD2 ($T_m = 49°C$) by 5°C ($T_m = 54°C$). LLY-507 selectively inhibited SMYD2 in a panel of 25 methyltransferases, 454 kinases, 36 G protein-coupled receptors, 14 nuclear hormone receptors, and 3 cytochrome P450 enzyme targets. A high-resolution X-ray structure of LLY-507 in SYMD2 was also generated at 1.63 Å where the binding mode was very similar to that of AZ-505. LLY-507 was examined in a cellular context, where it was demonstrated under three separate sets of conditions and formats that LLY-507 inhibit SMYD2-mediated methylation of p53 with potencies <1 μM.

5.08.6.2.1.6 Set and MYND domain-containing protein 3

SMYD3 is a lysine methyltransferase (KMT) related to SMYD2. Epizyme recently reported the first description of a SMYD3 inhibitor, EPZ031686, that demonstrated good bioavailability in mice upon oral dosing.[37] Epizyme described that SMYD3 is expressed at high levels in several cancer histologies and is associated with a poor clinical prognosis. Epizyme identified compound **15** (Fig. 28) as a micromolar inhibitor of SMYD3 while screening their internal HMT-biased compound library. Compound **15** was able to be crystallized in a ternary complex with SMDY3 and SAM.

The X-ray structure revealed that the oxindole carbonyl formed a hydrogen bond to the side chain Ser202 and was within 2.9 Å of the SAM methyl group. The aromatic ring system formed a π-stacking interaction with Phe183 as well as the oxindole nitrogen making a water-mediated bridge to the protein. The central amide linker made two hydrogen bonds that mimicked a protein substrate interaction. The terminal piperidine was placed into a large solvent-filled peptide binding site and engaged a water-mediated interaction with the side chain reside Glu192. The second molecule of compound **15** present on the periphery of the

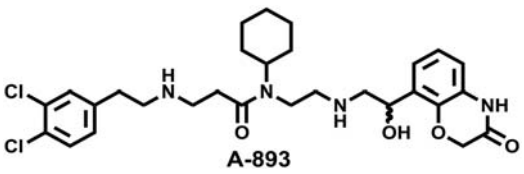

Fig. 26 Structure of A-893.

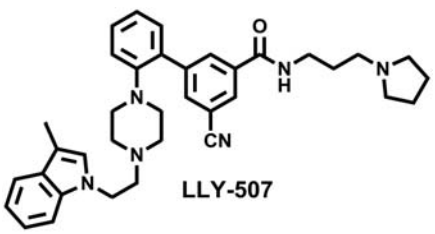

Fig. 27 Structure of LLY-507.

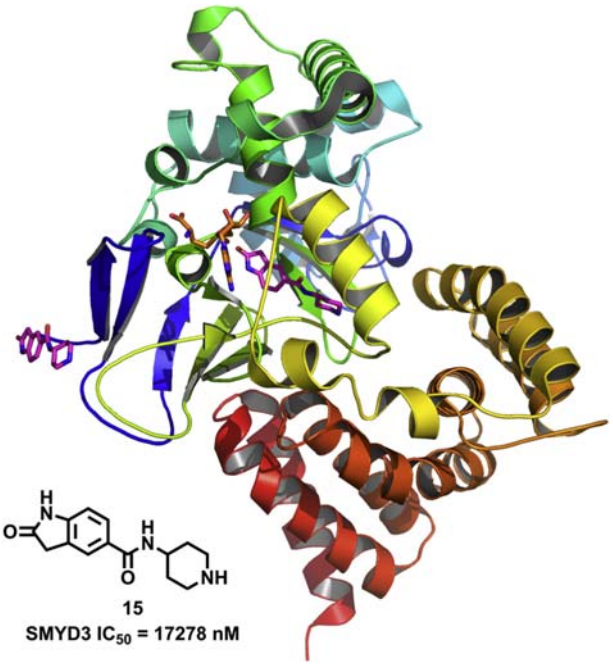

Fig. 28 X-ray representation of SYMD3 inhibitor bound to SMYD3.

structure is a crystal packing artifact. Initial medicinal chemistry efforts were aimed toward exploiting two potential new interactions with Glu192 and Asp241, which were within 3.5 Å of compound **15**'s basic nitrogen. When compound **15** was alkylated on the piperidine nitrogen with a propylamino-sulfonamide moiety, a 10-fold potency boost was observed. Conformational restriction of the terminal amine into a piperidine and the central piperidine core afforded compound **16** (Fig. 29) with a 40-fold potency boost.

However, even though compound **16** had single digit nM potency against SMYD3 in a biochemical assay, the cell potency was still in the single digit micromolar range. This was attributed to poor cell penetration, due to high polarity and too many hydrogen bond donors. Removing hydrogen bond donors successfully increase cell penetration and lowered the biochemical-to-cellular shift, as exemplified by EPZ031686 (Fig. 30), which had an IC_{50} of 36 nM in cell assays. EPZ031686 was profiled against 13 KMTs (including SMYD2), at 10 μM and demonstrated no inhibition >30%. EPZ031686 was examined in mouse oral PKs where a 50 mg kg^{-1} dose was 69% orally bioavailable and the unbound blood concentration remained above the SMYD3 cellular potency

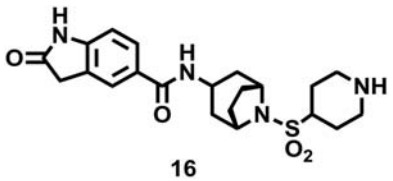

Fig. 29 Published SMYD3 inhibitors from Epizyme.

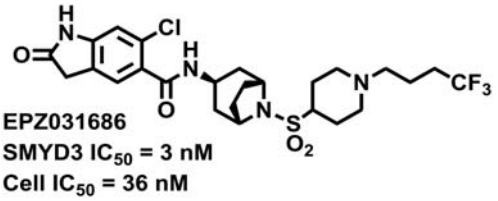

Fig. 30 Structure of EPZ031686.

value for more than 12 h. These data led Mitchell et al. to conclude that EPZ031686 is a suitable tool compound for potential in vivo target validation studies.

5.08.6.2.1.7 Euchromatic histone-lysine-N-methyltransferase 2

EHMT2, also known as G9a, is primarily responsible for the mono and dimethylation of histone 3 lysine 9 (H3K9Me2). Upregulation of EHMT2 is linked to several cancer types[38] and is correlated with a poor prognosis in aggressive lung cancer.[39] At the time of writing, there are no clinical-phase or marketed inhibitors of EHMT2 but several tool compounds have been developed. Boehringer Ingelheim conducted a screen against EHMT2 using a fluoroimmunoassay and a glutathione *S*-transferase-tagged fusion product.[21] The library used in the screen was preselected using an internal algorithm developed using data from publically available HMT inhibitor structures. The resulting ~125,000 compounds were screened at high SAM concentration to bias the results toward substrate competitive hits. Seven potential hits were identified and following additional screening BIX-01294 emerged as the single selective hit (**Fig. 31**). Additional studies showed that BIX-01294 was noncompetitive with SAM, selective against other HMTs, and reduced H3K9Me2 levels in mouse embryonic stem cells and fibroblasts.

In 2009, Chang et al. published an X-ray crystal structure of BIX-01294 bound to the catalytic SET domain of EHMT1.[40] During the course of this work, BIX-01294 was retested against both EHTM1 and EHTM2 using linear conditions for both assays and it was found that BIX-01294 was slightly more potent against EHTM1 (0.7 and 1.9 μM, respectively). The previous EHTM1 assay had been run under saturated conditions resulting in the production of H3K9Me3 rather than the assay end point of H3K9Me2, highlighting that judicious selection of assay conditions is a critical component of a successful program.

In an effort to develop further tool compounds for EHMT2 and to expand the, at the time, sparse knowledge around HMT inhibitors in general, Lui at the University of North Carolina initiated an SAR campaign around the 2,4-diamino-6,7-dimethoxyquinazoline scaffold.[14,41] Replacement of the benzyl group with a simple methyl afforded compound **17** (**Fig. 31**) which was equipotent to BIX01294 in the AlphaScreen assay. This finding is consistent with the X-ray structure of BIX-01294 in EHMT1 which shows the compound bound in the substrate binding groove with the benzyl moiety projecting away from the protein into solvent.

Modifications to the 2-amino moiety of the scaffold were well-tolerated with **17** remaining the most potent. Using the aforementioned X-ray crystal structure as a guide, the 7-methoxy group was replaced with a lysine mimic to generate UNC0224 (**Fig. 31**). The X-ray crystal structure of an EHMT2–UNC0224 complex shows that the 7-dimethylamino side chain is occupying the lysine channel as expected. Compound UNC0224 was found to be significantly more potent than BIX-01294 against EHMT2 in the ThioGlo assay (15 and 109 nM, respectively) but was equipotent to BIX-01294 in the AlphaScreen (298 and 290 nM, respectively). The authors attribute the similar potencies to the compounds reaching the IC_{50} limit of this assay. Using the crystal structure as a guide, compound UNC0224 was then further optimized to UNC0321 (**Fig. 32**).[14] While UNC0321 had single digit nM activity in the in vitro assay, the compound was much less active than BIX-01294 in the cellular assays.

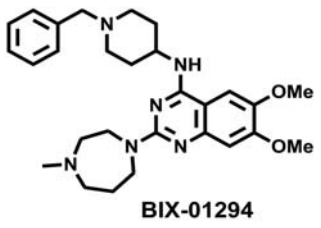

Fig. 31 Structure of BIX-01294.

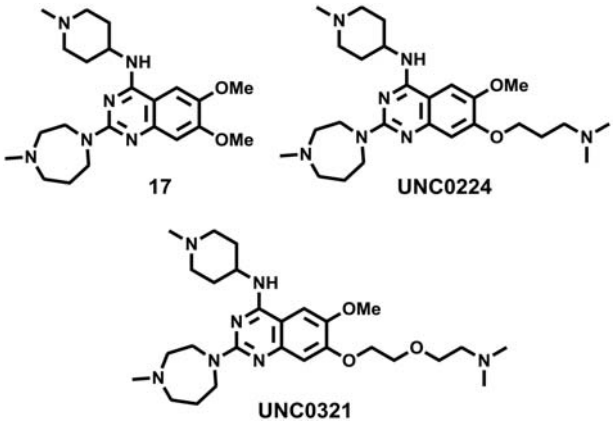

Fig. 32 Published EHMT2 inhibitors.

Extensive SAR exploration around the 2-, 4-, and 7-positions of the quinazoline core led to compound UNC0638 (Fig. 33).[42] The compound bound in a reversible manner and was found to be substrate competitive and SAM uncompetitive. Unlike compound UNC0321, UNC0638 showed activity in a number of cell assays but due to poor in vivo PK properties is not a suitable tool compound for animal studies. Further efforts to improve the properties of the compound resulted in UNC0642 (Fig. 32).[43] The in vitro and cellular potency is similar to UNC0638, but the half-life and clearance in mice is improved.

Following the publication of UNC0638 AbbVie published a structurally distinct inhibitor of EHMT2.[44] A diversity screen using an AlphaLISA assay identified **18** ($IC_{50}=153$ nM) (Fig. 34). The dimethoxy moiety was reminiscent of BIX-01294 and as such the authors postulated that **18** could be binding in a similar fashion. Several lysine mimetic replacements for the 6-methoxy group were prepared. Gratifyingly the pyrrolidine side chain showed a significant improvement in potency (A-366, $IC_{50}=3.3$ nM). A-366 was cell active, showing a reduction in H3K9Me2 at concentrations similar to UNC0638. A-366 represents an alternative chemotype for further exploration of EHMT2 biology. A summary of the SAR around these two chemotypes is presented in Table 2.

5.08.6.3 Lysine (K)-Specific Demethylases

5.08.6.3.1 Lysine (K)-specific demethylase 1A

The first report of a histone demethylase, lysine (K)-specific demethylase 1A (KDM1A), was published in 2004.[45] KDM1A demethylates H3K4Me2 and H3K4Me1 via a flavin adenine dinucleotide (FAD)-dependent oxidative reaction.[46] KDM1A has been of interest as a target for treating a variety of cancers including acute myeloid leukemia and small cell lung cancer.[47]

KDM1A belongs to the monoamine oxidase family and as such known MAO inhibitors were evaluated for KDM1A activity.[48] The antidepressant *trans*-2-phenylcyclopropylamine (tranylcypromine, Parnate) was found to inhibit KDM1A in an irreversible manner (Fig. 35). While promising, tranylcypromine was not selective and was expected to show broad toxicity at the dose necessary for efficacy in a cancer setting.[47a]

Promisingly, crystallographic[49] studies among others suggested that tranylcypromine inhibits the KDM1A–CoREST complex through formation of bridged adduct with FAD. This finding is particularly notable in that the FAD adduct formed in the presence of KDM1A is quite different from the adduct formed in the context of MAO B, suggesting that there is an opportunity to design selective inhibitors of KDM1A.

GlaxoSmithKline screened 2.5 million compounds in a KDM1A biochemical assay and identified a series of molecules containing a cyclopropylamine.[47c] The series was progressed to compound GSK287955 which is currently undergoing Phase I trials in myelocytic leukemia and small cell lung cancer (Fig. 36). A number of other groups have used tranylcypromine as a starting point for developing a KDM1A inhibitor.[50] Oryzon has filed a number of patent applications around tranylcypromine derivatives and has also started clinical trials in Europe in acute leukemia with ORY-1001 (structure not disclosed).

Efforts to identify a reversible KDM1A inhibitor have also been initiated.[47a,b] However, the H3 tail binding site is quite large making identification of a reversible inhibitor particularly challenging. The majority of reversible inhibitors have shown low to mid μM range activity in biochemical assays.

5.08.6.4 Bromodomains

5.08.6.4.1 Bromodomain and extra C-terminal domain

Histone acetylation marks are read by a diverse set of proteins that contain a bromodomain. The bromodomains are structurally diverse, but all share a conserved fold in the vicinity of the acetylated lysine-binding area and the lysine-binding pocket is largely

hydrophobic with a conserved asparagine residue.[51] A subclass of bromodomains, known as BET, simultaneously recognizes two acetylated lysine residues. The BET subclass includes bromodomain 2, bromodomain 3, bromodomain 4, and bromodomain testis-specific (BRD2, BRD3, BRD4, and BRDT).

In 2010, Filippakopoulos et al. and GSK disclosed the structures of diazapine containing, selective BET inhibitors (+)-JQ1[52] and GSK525762A,[53] respectively (Fig. 37). In 2001 GSK launched an effort to identify small molecules that could upregulate Apolipoprotein A-1 (ApoA1) expression. GW841819X was identified through a screening campaign using an ApoA1 luciferase reporter assay and further optimization led to GSK525762A. To determine the mechanism of inhibition of these compounds, GSK screened a large number of structurally related compounds against panels of known drug-target protein classes including kinases, ion channels, and GPCRs. However, the compounds were not active in any of the GSK panels, suggesting they acted on a class of targets not

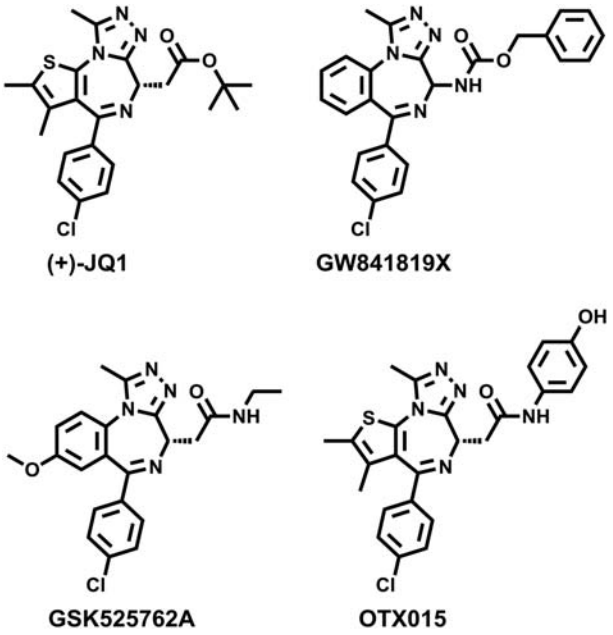

Fig. 37 Published bromodomain inhibitors.

represented in the panels. A chemoproteomics approach revealed that GSK525762A bound to three proteins, BRD2, BRD3, and BRD4. Further biophysical studies demonstrated that the compound could bind simultaneously to each bromodomain of the BET proteins to give an overall 2:1 stoichiometry. The X-ray crystal structure of GSK525762A bound to BRD4 showed the compound positioned at the acetylated lysine pocket with the triazoyl moiety mimicking the key hydrogen bonds made between the AcK substrate and Asp140 and Tyr97. GSK has advanced GSK525762 and the compound is currently undergoing Phase I clinical trials. Oncoethix also has a diazapine containing compound in Phase I/II (OTX015) (Fig. 37).

Additional related tool compounds include CPI-3[54] and CPI203[55] from Constellation (Fig. 38). CPI-3, a close analog of (+)-JQ1, has a short half-life in vivo and was not ideal for animal studies. Efforts to improve the tool compound began with

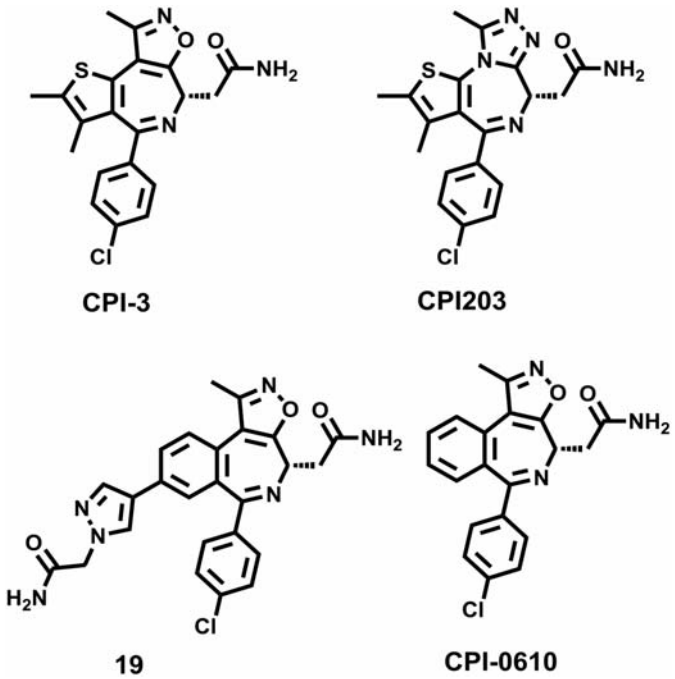

Fig. 38 Published bromodomain inhibitors from Constellation.

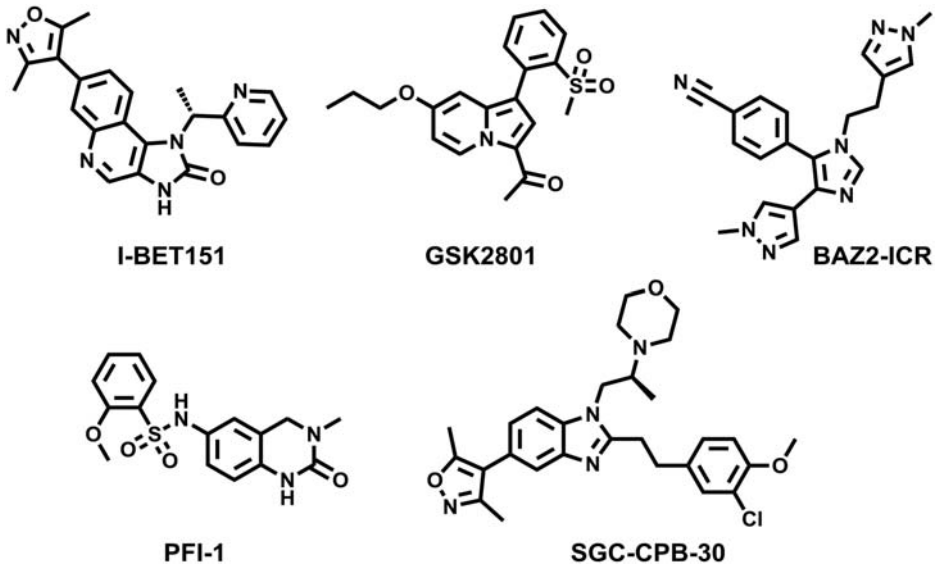

Fig. 39 Published bromodomain inhibitors.

replacement of the thiophene with a phenyl ring. This reduced metabolic liabilities and created a handle for additional substitution. Addition of a pyrazole at the para-position of the new phenyl ring provided a boost in potency and X-ray crystal structures of compounds bound to BRD4 indicated that the pyrazole was making a desired stacking interaction with W81. Compound **19** has an improved PK profile compared with CPI-3 and was selected for further study. The compound is a pan BET inhibitor but did not inhibit other bromodomains. Constellation compound CPI-0610 is currently in a Phase 1 trial for leukemia and other blood disorders.[56]

Much work has also been done to identify nondiazapine and nondiazapine-like bromodomain inhibitors. As part of their ApoA1 program GSK identified I-BET151,[53b] a BET inhibitor that is distinct from GSK525762 (Fig. 39). Additionally, in conjunction with the SGC, GSK has released tool compound GSK2801 which is selective for bromodomain next to zinc finger domain 2A (BAZ2A) and bromodomain next to zinc finger domain 2B (BAZ2B) over the BET proteins (Fig. 39).[57] The SGS in collaboration with Cancer Research UK and the University of Oxford have also published an inhibitor of the BAZ2A and BAZ2B bromodomains (BAZ2-ICR, Fig. 39).[58] Pfizer has also partnered with the SGC to identify PFI-1, a BET domain selective inhibitor.[59] The SGC has released a tool inhibitor for the CREB binding protein and E1A binding protein 300 bromodomains[60](Fig. 39). Abbvie (ABBV-075), BMS (BMS-986158), and Roche (TEN-010) each have inhibitors in the clinic for oncology indications (structures not disclosed).

Recently, Schonbrunn et al. reported that kinase inhibitors BI2536 and TG101209 are potent inhibitors of BET protein BRD4 with high selectivity for the BET family of bromodomains.[6] Building on an earlier discovery that the cyclin-dependent kinase inhibitor dinaciclib bound to BRDT1,[61] a set of 581 kinase inhibitors was screened against BRD4-1 using a high-throughput cocrystallization campaign. Of the 194 crystal structures obtained, 14 showed ligand bound to the KAc site of BRD4-1. The compounds were classified into four groups based on the interactions between BRD4-1 and the kinase hinge binding region of the ligand, Type N (Asn140), Type PZA (Pro82 and ZA channel), Type ZA (ZA channel), and Type I (not involved). The most potent compound, polo-like kinase 1 inhibitor BI2536 (BRDT-4 $IC_{50}=25$ nM), interacts with Asn140 through a carbonyl moiety and the hinge binding region interacts with the ZA channel and Pro82. JAK2 inhibitors TG101209 and TG101348 were the next most potent compounds and are both classified as Type N inhibitors. In addition, these compounds interact with Pro82 via a second aniline group. Taken together, these data suggest that the kinase hinge binding group can interact with the KAc binding area of BET proteins in at least two ways. The new scaffolds identified in this study provide additional starting points for the structure-based design of new BET inhibitors.

5.08.7 Conclusion

Posttranslational modifications of histones have developed into a burgeoning area of research yielding several approved drugs and clinical candidates. HDACs were the first of the histone-modifying enzymes to yield a clinical candidate and there are now more than four HDAC inhibitors on the market and several more in clinical trials. Despite early success, HDAC inhibitors are still an active area of research as, in efforts to reduce toxicity, investigators aim to develop inhibitors that are specific to a single HDAC or class of HDACs.

As the field advanced beyond HDACs toward the discovery of HMT inhibitors, it became clear that each class of enzymes would require new assays and screening paradigms. The collective EHMT2 programs, for example, used a number of different biochemical assays and results were dependent on assay conditions. Pinometostat, a SAM-competitive DOT1L inhibitor, was the first HMT inhibitor to enter clinical trials followed closely by several peptide competitive EZH2 inhibitors. With the exception of EZH2, structure-aided design has played a large role in the development of HMT inhibitors.

Bromodomain and KDMs inhibitors quickly followed the HMT inhibitors with compounds in the clinic from several companies. To date bromodomains, specifically BET domains, are the only reader protein with inhibitors in the clinic. Despite the recent successes, there is much still to understand around histone modifications and the role these changes play in cancer. New tools for discovering key histone-modifying enzymes are being developed and new tool compounds for HATs and other histone-modifying enzymes are emerging in the patent literature.

With the potential for intervention in both methyl and acetyl marks and targets that affect readers, writers and erasers there remain a rich landscape for further investigation. As the science continues to move forward we will see the full fruition of modulating the posttranslational modifications of histones.

5.09.1 Introduction

Polynucleotides comprising ribo- or deoxyribo-guanidylic acid repeats have long been known to readily form unusual aggregated structures, especially in the presence of potassium or sodium ions. Fiber diffraction and biophysical studies have established that these are in the form of four-stranded right-handed helical arrangements.[1–4] Analogous arrangements can be formed by specialized sequences comprising several short guanine(G) tracts, which can be found in many eukaryotic and prokaryotic genomes, notably at the ends of chromosomes in telomeric regions.[5,6] Typically such sequences contain four such G-tracts and are of the form $G_{3-5}\ X_n\ G_{3-5}\ X_o\ G_{3-5}\ X_p\ G_{3-5}$ where X_n, X_o, and X_p are loops with one to seven nucleotides. These sequences can readily fold into stable discrete four-stranded structures, termed quadruplexes, with close analogy to the polynucleotide four-stranded helices, although it cannot be assumed that all putative quadruplex-forming sequences actually form stable structures.[7]

*Corresponding author.

Telomeric DNA, the sequences at the ends of eukaryotic chromosomes, comprise tandem repeats of quadruplex-forming sequence—in the case of *homo sapiens*, the telomeric repeat[8] is the hexanucleotide d(TTAGGG), which can form (i) intramolecular quadruplexes with four repeats, and (ii) intermolecular quadruplexes with either one, two, or rarely three repeats.[9–12] Their properties have been extensively characterized by structural (X-ray crystallography and high-field NMR) and biophysical methods [especially UV and fluorescence spectroscopy and circular dichroism (CD)],[13–20] and serve as a paradigm for quadruplexes found in other genomic locations. These methodologies have also been extensively used in the biophysical characterization of quadruplex-small molecule complexes.

The quadruplex field has been well-served by a number of authoritative reviews on various aspects—structural,[16–18] biology,[21–26] and small-molecule binding.[27–37] This article provides a general background to the small-molecule quadruplex field, together with key references. It focuses on the small molecules that have been reported to selectively affect quadruplex function at the level of individual gene promoters, with a view to their potential as anticancer drug candidates, emphasizing those that have promise by virtue of their ability to target particular cancer-selective genes (i.e., oncogenes). It does not aim to catalog all such compounds, but illustrates the main organic compound classes and their known functions. We have for the most part excluded the literature on metallo-containing compounds since although a number of compounds show high potency,[29] their development as potential clinical agents is at present considerably less advanced. Human cancers continue to be the principal area of focus in the therapeutic quadruplex field, but a few studies have indicated the potential of the approach in other therapeutic areas, notably as antibacterial, antiviral, and antiparasitic targets.[38–43]

5.09.1.1 Quadruplex Occurrence and Biological Function

Quadruplex-forming sequences have for some while been identified in a variety of biological contexts in the human genome, notably in immunoglobin switch regions and in the nuclease hypersensitive region of the c-*MYC* oncogene. The availability of the sequence of the human genome has enabled systematic searches of their occurrence to be made using algorithms which employed the general quadruplex-forming sequence shown earlier. Two distinct bioinformatics approaches provided very similar numbers, with a total of c. 350,000 putative occurrences.[44,45] Many of these were found in regions of high G density, with unequal length G-tracts, and multiple overlapping potential quadruplexes. This suggests that some quadruplexes are in dynamic equilibrium, with multiple overlapping species being possible. Validation of actual quadruplex formation is usually made for a particular sequence using data from CD, UV fluorescence melting, and NMR methods[17,19,20]; all need to individually and unequivocally point to quadruplex formation in order for an unambiguous conclusion of quadruplex formation to be made and distinguished from, for example, formation of a stable hairpin structure. To date, this has only been done for a modest number of sequences. There is currently only a limited ability to reliably predict quadruplex folds directly from primary sequence, especially for more complex arrangements since ab initio quadruplex structure prediction approaches are still in their infancy. A recent direct approach to the problem of even predicting validated putative quadruplex-forming sequences, using next-generation DNA sequencing, has not used the assumption of a maximum loop length, of seven nucleotides, inherent in the earlier bioinformatics studies. Instead over 700,000 occurrences have been mapped, with over 450,000 not having been previously predicted.[46] These more recently located occurrences tend to have longer loops and/or sequences that do not conform to the canonical quadruplex sequence shown earlier. Bioinformatics searches in other organisms, notably in prokaryotics such as *Escherichia coli* and in viruses such as HIV, have shown the wide-spread existence of quadruplex sequences,[38–43] although almost all medicinal chemistry effort to date has focussed on quadruplex occurrences in the human genome, especially as potential anticancer targets.
