Objectives in the LO phase are to improve a variety of critical parameters relating to drug properties: functional activity, selectivity against antitargets, cellular activity, physicochemical properties, in vitro and in vivo pharmacokinetic properties, in vivo efficacy, safety and tolerability, and drug substance properties such as chemical stability and crystallizability. Only affinity and selectivity optimization can be directly impacted by structural biology. However, knowledge about the binding mode of a lead series will have a strong impact on the optimization of the other properties, mainly by clarifying to the medicinal chemist which changes to the molecular structure, planned to optimize these other properties, will be neutral or even beneficial to affinity. For instance, the costructure will instruct the chemist how to tackle problems of solubility by indicating positions on the molecule to which solubilizing groups can be attached without interfering with target interaction.

The multiparameter LO is an iterative process (the "design-make-test-analyse" DMTA cycle). Even if the structural changes to the lead structure are small in each cycle, it is strongly recommended to check by costructure determination if the binding mode is preserved. Especially, when SAR cannot be readily explained by existing structural information, it may turn out that the binding mode has changed.

If it turns out that a lead class has intrinsic issues with any of the optimization parameters that cannot be overcome applying structural information can be extremely powerful, for example, by suggesting modifications to the core chemical structure of a lead that changes the basic compound properties but leaves the binding mode unaltered.

The following paragraphs will illustrate the interplay of crystallography, medicinal chemistry, and biological testing with two case stories. Our fist example will focus on the design of potency and selectivity, while the second example will illustrate *lead hopping* to generate novel chemical matter.

2.06.4.4.1 Isoform selective PI3Kγ inhibitors

Signaling via phosphoinositide 3-kinases (PI3K) has been shown to be a key pathway in the regulation of the immune response[130] and is in the focus of many research programs in inflammatory diseases and cancer.[131] In an internal project, we attempted to generate isoform selective PI3Kγ inhibitors to block the underlying inflammation in chronic obstructive pulmonary disease (COPD).[132] PI3Kγ is one member of the class I PI3Ks, which phosphorylate PI(4,5)P2 to produce the critical second messenger PI(3,4,5)P3. The project was initiated under the hypothesis that PI3Kγ was the predominant isoform responsible for leucocyte migration (which is unwanted in COPD) and thus should be inhibited. Other PI3K isoforms should not be targeted in a chronic indication as COPD, to avoid potential toxicity issues. Due to its ubiquitous expression and central role in insulin signaling, the PI3Kα isoform in particular was closely monitored. Following a HTS campaign we identified lead structure BI-1 with an attractive MW and good initial potency. An early crystal structure of BI-1 bound to PI3Kγ was helpful to guide initial synthesis (Fig. 7). On the one hand, growth vectors for chemical exploration were identified; on the other hand, two hydrogen bonds were revealed to be critical for establishing the binding mode. These were not modified to maintain molecular recognition.

While BI-1 was already in the desired potency range (IC_{50}(PI3Kγ) < 50 nM) it showed no selectivity to PI3Kα and other isoforms (target values were IC_{50}(PI3Kα) > 200 nM absolute and > 100 × relative selectivity). In the absence of other PI3K isoform structures, similarity was assessed by mapping a PI3K family sequence alignment on the structure (Fig. 8A). It was immediately evident that, due to its small size, BI-1 was exclusively in contact to residues conserved throughout the family. We therefore designed a small series of modifications that were directed toward less conserved regions to engage residues unique to PI3Kγ (Fig. 8B) and thus held promise to improve selectivity. Compound BI-2 was identified with a tendency toward the right direction (ratio $\alpha/\gamma = 28$), but was still far from having the ideal selectivity range. A crystal structure of BI-2 confirmed our design hypothesis and revealed that the compound engages its basic pyrrolidine moiety in a salt bridge to nonconserved aspartic acid D950, which is a serine in PI3Kα. In a parallel exercise, we had discovered that modifications of the tri-cyclic core structure also resulted in a slight improvement in selectivity (ratio $\alpha/\gamma = 15$) for BI-3. We were initially puzzled by this observation, since BI-3 is not appreciably larger than BI-1 and was not predicted to contact nonconserved regions. A costructure of BI-3 (Fig. 8C) revealed that the exit vector of BI-3's phenyl ring had a slightly modified direction and could only be accommodated through a concomitant conformational change of the active site lid-region. Interestingly, this conformational adaptation propagated to a second shell of residues that is not conserved between isoforms. Although the ligand-induced conformational change came along with a slight loss in PI3Kγ-potency, we assumed based on the observed selectivity data that other isoforms were even less tolerant to these conformational changes. To combine both observations, we attached the previously identified c-hexyl-pyrrolidine fragment on BI-3 to obtain BI-4 (Fig. 8D). As expected, the new compound featured largely improved potency and selectivity (IC_{50}(PI3Kγ) = 6.5 nM; ratio $\alpha/\gamma = 55$) and made the desired interaction with PI3Kγ D950 (Fig. 8E). In a final step we "recycled" our initial exploration of *linker-selectivity probe*

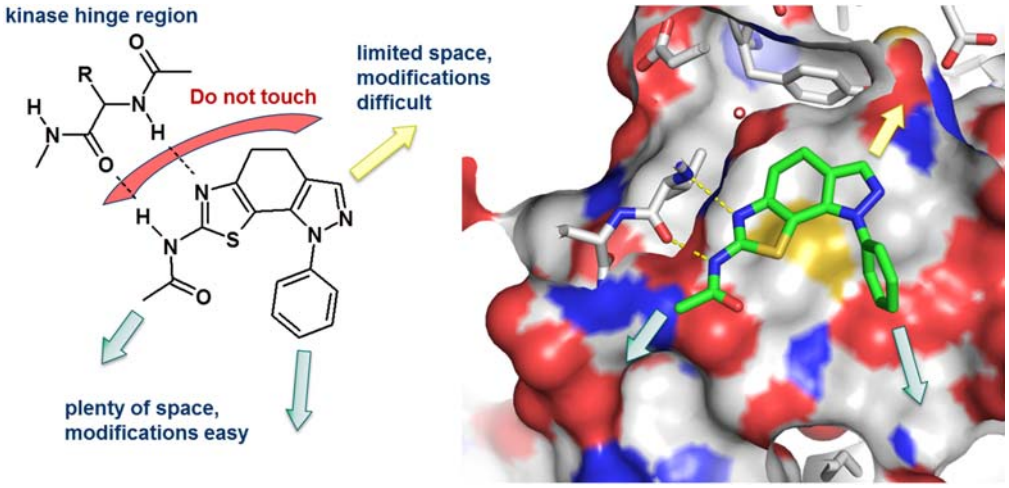

Fig. 7 Structure of lead BI-1 and potential growth vectors.

	PI3Kγ IC_{50} (nM)	PI3Kα IC_{50} (nM)	α/γ
BI-1	32	94	3
BI-2	14	390	28
BI-3	75	1100	15
BI-4	6.5	360	55
BI-5	0.6	420	700

Fig. 8 Iterative optimization of potency and selectivity. (A) Active site of PI3Kγ color coded according to sequence conservation between isoforms (α, β, γ, δ) with compound BI-1 (purple). (B) As in (A) and with superimposed compound BI-2 (blue). The insert shows the nonconserved selectivity-pocket. (C) Complex between BI-3 (cyan) and PI3Kγ (cyan ribbon) superimposed on the PI3Kγ BI-2 complex (color coded as in (B)). (D) As in (C) and with superimposed compound BI-4 (blue). (E) Schematic of the combinatorial library and final molecule BI-5. (F) Activity data and selectivity ratios.

combinations in a biased combinatorial library. The best compound, BI-5, bound to PI3Kγ in the predicted manner (Fig. 8F) and with ~10-fold improved potency and selectivity.

The presented case is a good example for the iterative nature of structure-based design: It usually takes multiple cycles of chemical synthesis, biological testing, structure analysis, and hypothesis generation to arrive at a molecule with the desired properties. More often than not, there is a need of an element of serendipity (in our case deliberately introduced through combinatorial chemistry) to succeed. We should be poised not to miss it!

2.06.4.4.2 Lead hopping in fXa

Focus of this endeavor was on direct inhibitors of factor Xa (fXa), a highly validated protease target to treat thromboembolic disorders such as stroke.[133,134] From the early days of research on thrombin (fIIa) and fXa inhibitors, conventional thinking was that a strong interaction of basic P1 groups with Asp-189 in the S1 specificity pockets of these trypsin-like serine proteases (Fig. 9A) was indispensable for potent inhibitors. However, by the late 1990s focus was shifting from strongly basic to less basic and, eventually to neutral compounds (Fig. 9B) that would provide a better chance of oral bioavailability without the need to resort to prodrug approaches.[135,136]

Characteristic for benzamidine containing compounds, such as the direct fIIa inhibitor dabigatran, the first novel oral anticoagulant (NOAC) to be brought to the market in 50 years,[137] is a bidentate salt bridge interaction with Asp-189 at the bottom of the pocket. A conserved, structural water molecule in a hydrophobic subpocket is hydrogen bonded between the amidine moiety and the Phe-227 carbonyl oxygen. Fig. 9B illustrates the binding of neutral compounds into the S1 pocket. Rivaroxaban, a fXa inhibitor and the second marketed NOAC, as an example of a compound with a nonbasic character binds with its chlorothiophene carboxamide into the fXa S1 pocket. It does not bind to Asp-189 but instead utilizes aryl halogen interaction with Tyr-228 and a hydrogen bond to Gly-219. Water displacement and an energetically favorable (Ar)C–Cl π interaction compensate for the loss of interaction with Asp-189.

At Boehringer Ingelheim, information on this distinct type of interaction in the S1 pocket was used early on to convert highly active benzamidine leads into equally potent nonbasic chloro-benzimidazoles.[138] Superposition of the crystal structures of a benzamidine lead class representative with a neutral chloropyridyl-diaminophenol (Fig. 9D) suggested a way to replace the m-substituted benzamidine by a chloro-substituted bicyclic ring system with the aim of generating an alternative neutral equipotent

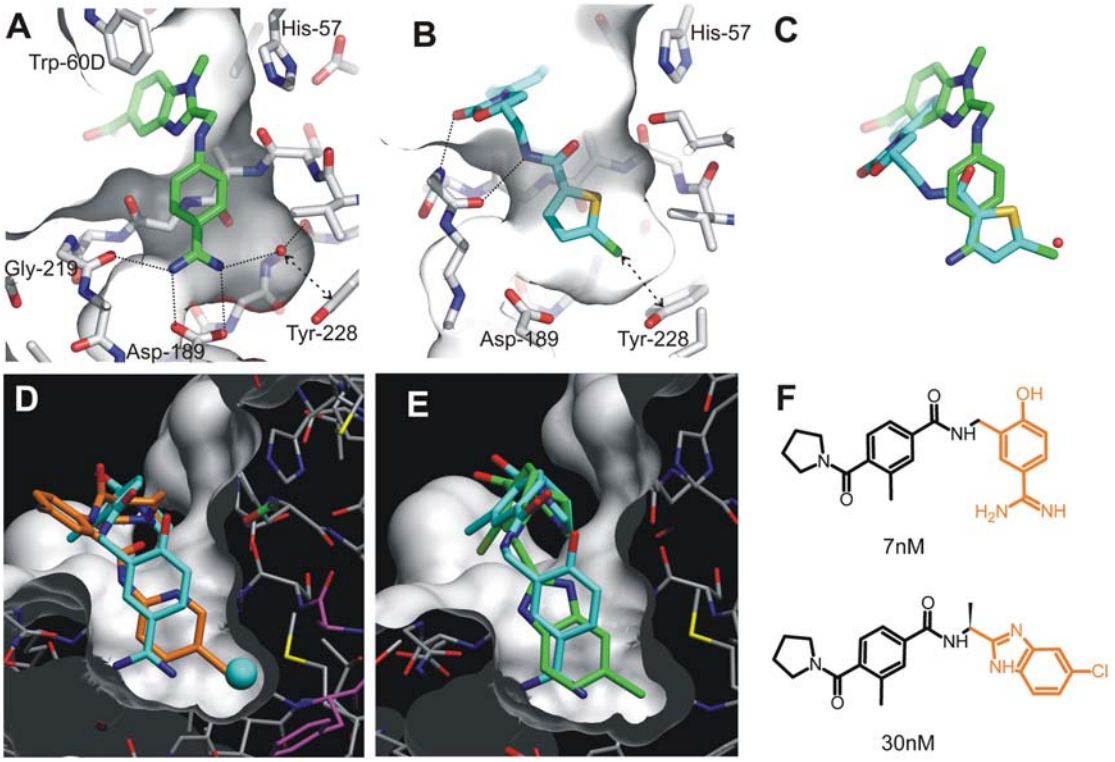

Fig. 9 Blood coagulation serine proteinase S1 pocket interaction principles and structure-based lead hopping. (A) The S1 pocket of fIIa in the dabigatran complex. (B) The S1 pocket of fXa in the rivaroxaban complex (PDB code 2w26). (C) Superposition of the two compounds as bound to the structurally aligned proteins. (D–F) Hybridization of an aryl halogen motif onto the benzamidine lead class. Benzamidine lead compound: blue carbon atoms in (D) and top molecule in (F). Chloropyridyl-diaminophenol competitor compound: orange carbon atoms in (D). New chlorobenzimidazole lead: green carbon atoms in E and bottom molecule in (F). Figure reproduced with permission from Trends in Pharmacological Sciences.

lead. A chlorobenzimidazole (Fig. 9E) was made that retains the left-hand side of the benzamidine compound with only a marginal loss of affinity (Fig. 9F).

The presented case is a good example for the need to look beyond one's own nose. It is always advisable to investigate binding modes of competitor molecules (or any other available chemical matter) to obtain new design inspirations, hybrid ideas, etc. Many of our ideas may fail, but the one that survives might be the next lead structure!

2.06.4.5 Biologics Discovery

Biopharmaceuticals made up around one-fourth of the 200 top selling drugs in 2013. Many different types of biological drugs (or NBEs) are on the market, the most prominent are antibodies, hormones, and vaccines. Among the 20 top selling drugs in 2013, 9 were proteins.[139] The antibody adalimumab (Humira®) was number one on the list and had worldwide sales of more than 10 billion dollars. This illustrates the growing role of biopharmaceuticals in drug discovery.

As for new chemical entity discovery, the knowledge about the 3D structures (of target molecules and the NBE itself) can be of great help for research and development. For many protein classes, representative structures can be found in the PDB. Especially for antibodies, SBDD can be applied readily because their structures are well understood. As of Nov. 2015, more than 2200 structures of Fab-parts have been deposited to the PDB.[140] Around 460 structures have been determined in complex with a (poly)peptidic antigen. This huge amount of information enables modeling of newly discovered antibody sequences and can help on the way of optimizing different properties of these drug candidates. 3D structures can, for example, be used to aid the humanization of antibodies from animal sources like rodents or camelids[141–147] or guide the optimization of affinity and efficacy.[148] Framework engineering, the optimization of the constant parts of an antibody, is a means to tailor a molecule for its purpose. This region is responsible for binding to effector molecules like Fcγ-receptors,[149,150] complement factor C1q,[151] or neonatal Fc-receptor FcRn.[152,153] Modifications in this region can alter antibody-dependent cell-mediated cytotoxicity, complement activation, and cell-dependent cytotoxicity. The half-life of an antibody can be modulated by altering its affinity to the FcRn-receptor.

Despite the already known structures of antibody fragments and their interaction with effector molecules, there is added value in the crystallization of an individual NBE-candidate alone and in complex with its antigen. Modeling of Fabs has its limitations, especially for the highly variable CDR-H3 loop. The detailed knowledge of the paratope region and structure is the starting point for the above-mentioned strategies for humanization and affinity maturation. Another advantage of antibody:antigen structures is the fact that apart from the paratope, one also gains insight into the nature of the epitope. This can be useful for patenting reasons or for a rational design to overcome species selectivity. The structure of a complete antibody or antibody fragments has also been shown to be of help in overcoming solubility issues for a certain antibody.[154,155] In these studies, the crystal structure of the Fab alone revealed a tetrameric arrangement of the molecules. The contacts between the molecule also involve parts of the paratope. The structure was used to guide the design of mutants that have 10 times higher solubility while retaining the activity of the antibody (Fig. 10).

The molecular properties of the antigen have a strong influence on the probability of a successful Fab:antigen crystallization. Therefore it is of high importance that SR is involved in NBE discovery from the very start of a new project. The knowledge of the structure of the antigen can be of help in the design of the optimal protein for immunization. This has been demonstrated in the design of several vaccines, where a structure-based design of the antigen leads to a higher immune response or a broader immunization against several isotypes of the pathogen.

2.06.5 Outlook—Industrial structural biology of the future

The generation of 3D structural information for use in drug discovery for the past 4 decades has been dominated by X-ray crystallography. While some target structures with limited MW (<50 kDa) have been determined by NMR methodology, the vast majority of structures were derived with crystallographic methods. Moreover, in contrast to NMR-based methods, the determination of multiple structures of target–ligand complexes is easily facilitated by either cocrystallization or soaking protocols and thus enables the essential domain of HTX in drug research. Recently, with the rising number of elucidated IMP structures, most notably GPCRs, this large group of pharmacologically relevant targets have finally become accessible to SBDD.

2.06.5.1 X-ray free electron lasers and cryo-electron microscopy

There are two relatively new developments in structural biology that promise to have a major impact to the field.

During the last ~3–4 years, the technology of XFELs has become accessible at several synchrotron facilities around the world. These generate ultrashort pulses of coherent and extremely intense X-radiation that exceed the brilliance of third-generation synchrotron sources by ~11 orders of magnitude.[156,157] The enormous energy input through femtosecond X-radiation pulses allows for rapid collection of diffraction information, but the samples are irreversibly destroyed ("diffraction before destruction"). Therefore, for collection of complete diffraction data sets, a large number of diffraction patterns have to be collected from either series of small crystals traversing the X-ray beam in a liquid carrier matrix supplied by injection devices or by irradiating multiple spots on crystals traditionally mounted on goniometers. With XFELs it is now possible to obtain structural information for notoriously difficult targets for which either only very small crystals can be obtained (which are not suitable for diffraction experiments

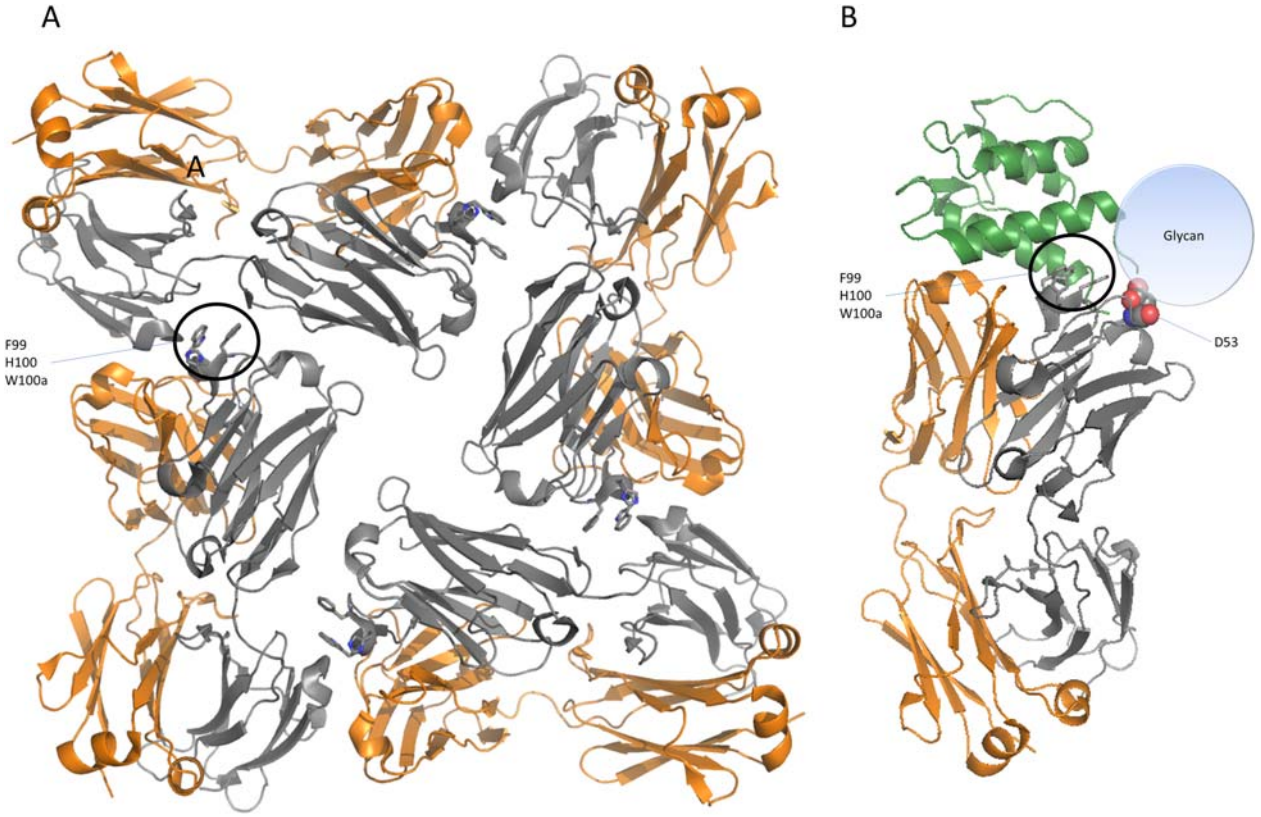

Fig. 10 Design of soluble versions of an anti IL13 antibody. (A) Tetrameric arrangement in the structure of the Fab, residues responsible for the packing (F99, H100, W100a) are shown as sticks. (B) Structure of the Fab in complex with the antigen IL13 (green), same orientation as in (A). The mutation D53N introduces a glycosylation site that prevents the formation of the tetramers but retains the antigen binding capacity of the antibody. Residue number annotations were determined according to Chothia's structure-based numbering scheme.[195]

on regular synchrotron beamlines) or radiation damage is a serious problem (eg, for metalloproteins[158]). Examples include the structure determination of GPCRs which were crystallized in lipidic cubic phase[159] and of recombinantly expressed proteins which, under conditions of overexpression, form nanocrystals within the expression host cells.[160] Further, XFELs offer opportunities that exceed those of traditional X-ray crystallography. For instance, it is now conceivable to derive details of molecular dynamics given the picosecond temporal resolution of XFELs.[161] In the context of drug discovery, the enhanced access to novel structures in particular of tough targets is of great value. Whether the XFEL technology will significantly impact the "productive" cocrystallography stage has to be seen. Currently, the very high effort involved to determine a structure by serial femtosecond crystallography (SFX) and, compared to traditional crystallography, the poorer data quality and resolution limit applications to nonroutine, low throughput, and high value projects.

Secondly, on the basis of revolutionary developments in the field of direct electron detectors and image processing algorithms,[162] with single-particle Cryo-EM 3D structures of biomolecules can now be determined at near-atomic resolution.[163] Study objects currently are mainly large macromolecular complexes (~500–4000 kDa size) some of which reside in membrane, can adopt multiple conformational states, and/or have been refractive to crystallization.[164] Recent examples of pharmacological targets studied by cryo-EM include TRPV1[165] and γ-secretase.[166] For β-galactosidase, a 2.2 Å resolution structure was obtained allowing for the resolution of atomic details of a ligand interaction site.[167] No crystals and only little amounts of sample are needed and sample heterogeneity can be dealt with at the image processing stage of a structure determination. Conformational heterogeneity, often detrimental to crystallization efforts, can even be used to ones favor in cryo-EM, because it can be analyzed after data collection and yields most valuable information pertaining to the mode-of-action of proteins for which structural dynamics is required for function.[168] All these circumstances define the great attractiveness and potential of the technology and explain why many people believe that cryo-EM will be the dominating technology in the structural biology of the future. Concerning applications in the field of pharmaceutical research it appears that currently, in favorable cases, cryo-EM is able to achieve the resolution needed to elucidate details of protein–ligand interactions thus enabling structure-based design. However, current applications are restricted to biomolecules with a minimal molecular size of about 100 kDa[169,170] so that for the time being a large set of relevant drug targets appears too small to be amenable to cryo-EM studies. Possibly, this limitation can be overcome by future methodological developments or circumvented by studying molecular targets in the context of larger, functional protein complexes.

2.06.5.2 Structural biology of integral membrane proteins (IMP)

Membrane proteins constitute a highly important target class. Most prominently, GPCR targeting molecules account for many of best-selling drugs and 30–40% of all prescribed pharmaceuticals.[92] Compounds modulating the function of channels and transporters—two other larger membrane protein classes—account for another ~10% of the pharmaceutical market.

X-ray crystallography of IMPs has been lagging behind that of soluble proteins[171] due to the large technical difficulties associated with overexpression, purification, stabilization, and crystallization. Illustrating that point, only 2.3% of the 114,080 entries in the PDB (as of Dec. 7, 2015) were annotated as IMPs. Consequently—despite its huge relevance—drug discovery for this target space was until recently only sparsely supported by experimental structures. A comprehensive discussion of SR and SBDD for membrane proteins is beyond the scope of this paragraph and instead we briefly touch on the three most important target classes: GPCRs, ion channels, and transporters.

The last decade has brought a game change to the field which has probably been most remarkable in the area of GPCR structural biology.[172,173] First crystal structures of beta-adrenergic receptors (bAR) bound to inverse agonists were reported in 2007[174] and 2008.[175] Already in 2011 the complex of activated bAR2 with G protein[176] contributed to another landmark in the field leading to the 2012 Nobel Prize in Chemistry. Meanwhile the PDB lists ~30 different GPCRs, many of them crystallized in various signaling states and with multiple ligands (**Fig. 11**). Many of the available structures are in complex with established drugs or drug candidates and are invaluable to better explain their molecular mechanism of action.[177] The remarkable progress in GPCR structure determination has come about by the combination of a number of techniques and a better understanding of factors influencing membrane protein stability (**Table 2**). Naturally, the main focus of this first wave of structures has been on obtaining structures "at all," allowing for a retrospective understanding of binding modes. As the field is maturing we are now starting to see examples where GPCR structures were determined in pharma companies to drive ongoing programs.[178–180] Moreover, the first companies are now pioneering FBS on GPCRs.[181–183] Despite the significant advances made, GPCR crystallography is still far from being routine and both timelines as well as throughput of ligand costructure delivery might be prohibitive for many internal drug discovery programs.

Similar to GPCRs, ion channel structural biology benefits from a rich and well explored pharmacology that provides tools to stabilize the protein of interest.[184–186] Several families, as for example the NMDA synaptic receptors, carry large extracellular domains for ligand or modulator binding, which can be separately expressed to facilitate structural studies.[187–189]

Membrane transporters are a large and heterogeneous superfamily,[190] but are still to large extents unexplored as a target space.[191] While initial progress in crystallography was made on simpler model systems from bacteria or thermophiles,[192] we now increasingly see structures from higher species being solved[193,194] making it likely that the field will soon experience first success stories of SBDD.

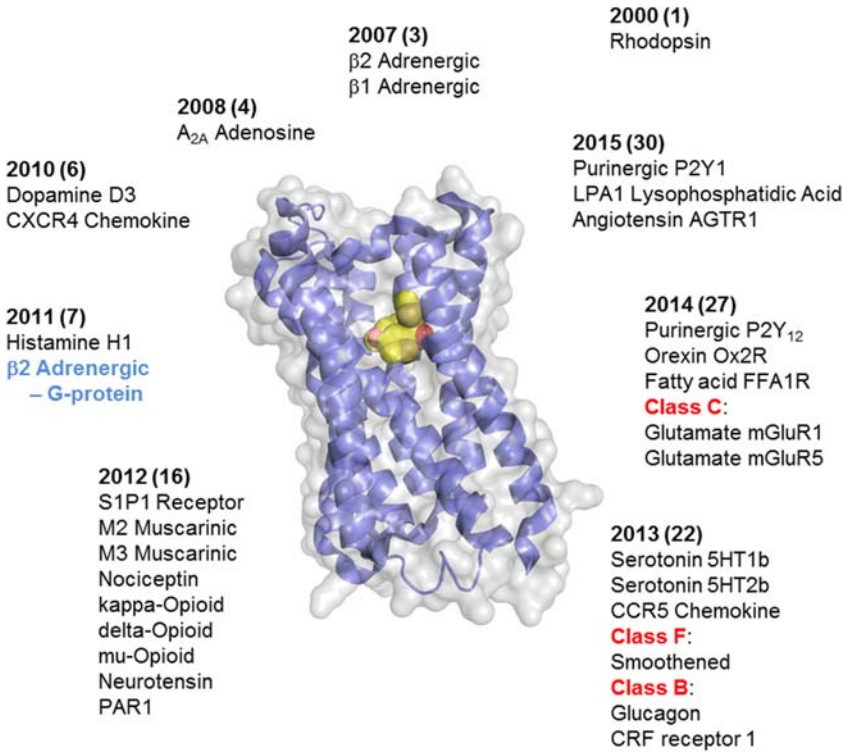

Fig. 11 Advances in GPCR structural biology. Only unique new GPCR structures are listed with the exception of the β2 adrenergic receptor–G-protein complex (blue). Orthologues and other ligand or effector complexes are not listed. The total number of GPCR structures in the PDB was ~150 by the end of 2015.

Table 2 Strategies and technological advances for membrane protein expression

Technology/strategy	*Explanation*	*Reference*
Thermophilic/bacterial protein	Use "easier" more stable surrogate targets to model human system. Not suitable for GPCRs	Indiveri (2013)[192] Baker (2010)[196]
Novel detergents	Milder detergents to solubilize and purify protein in functional state	Kang (2013)[172]
Thermostabilization mutants	Screen for mutations that stabilize protein, but do not affect function/ligand binding	Tate (2012)[197]
Fusion proteins	Replace flexible loops by fusion partner to reduce conformational heterogeneity and expand extracellular surface for crystal contacts	Chun (2012)[198]
Ligands	Ligands to stabilize desired conformation, preferably highly potent	Alexandrov (2008)[199] Andrews (2014)[183]
Crystallization chaperones	Fab fragments, nanobodies, or other binding partners to stabilize conformation and expand extracellular surface	Rasmussen (2011)[200] Lawson (2012)[201]
In meso crystallization	Specialized crystallization system in lipidic cubic phase	Caffrey (2015)[202]
SFX	Serial femto second crystallography	Liu (2014)[159]

2.06.6 Summary

HTX was established in the 1995–2005 decade and has found a precious application in structure-based drug discovery. The initial promises that using structural information combined with computational approaches would lead to superior quality drugs has not fully materialized. However, in our view the major contributions are that it leads to an increase of the probability to find new leads and to accelerate their optimization into drugs. Thereby, it has greatly contributed to major successes in drug discovery during the last decade and contributed to a large enhancement in process efficiency of industrial medicinal chemistry activities. Since computational approaches are suffering from still poor quality of protein structure and ligand pose predictions, for the foreseeable future the science of protein crystallography will continue to be a key success factor in drug discovery.

2.07.1 Introduction

Drug discovery is a long and complex process, requiring multiparametric optimization. Detecting, characterizing, and optimizing molecular interactions lie at the heart of successful drug discovery, and these processes may be facilitated by understanding the kinetics and thermodynamics of ligand binding. Formation of a protein–ligand complex is driven by the change in free energy of binding, which itself is composed of enthalpic and entropic components, and so, the free energy change upon binding may be increased by improving the contributions from either or both components, providing different options for optimizing binding interactions. Of course, equilibrium considerations alone are not sufficient to fully describe a binding response, as the binding affinity is also composed of association and dissociation kinetic contributions. In fact, these contributions may be more important in the drug discovery setting, where the introduction of a drug to the body is more realistically represented by nonequilibrium considerations representative of an open system, where responses are not directly related to concentration. Hence, a greater understanding of the kinetic contribution to binding may offer further opportunity to optimize molecular interactions for greater efficacy under these nonequilibrium conditions.

The challenge for medicinal chemists is to understand both the thermodynamic and kinetic contributions and to exploit opportunities for modifying these contributions in order to make more effective and safer medicines. As a tool to help guide this process, various different measures of the efficiency of compound binding, termed ligand efficiency metrics (LEM), have been proposed that help to relate different binding parameters to various physicochemical properties of the compounds studied (such as molecular weight or hydrophobicity).

By employing rigorous experimental procedures to determine the thermodynamic and kinetic contributions to binding interactions and by applying simple tools and guidelines that help to identify compounds that outperform the trend in terms of the desired biological response, medicinal chemists will be able to use these principles to further optimize compounds toward improved clinical properties. Ultimately, this will decrease clinical attrition and help to make drug discovery more successful.

2.07.2 Kinetics in Drug Discovery

2.07.2.1 Biophysical Methods for Measuring Binding Kinetics

There are several different methods that allow binding kinetics to be measured and individual rate constants for association and dissociation derived. These include both biochemical and biophysical assays, which have different requirements for instrumentation and assay design. Of course, binding kinetics can be determined by any technique that is capable of measuring a change in bound or free analyte concentration with time. Ultimately, the choice of method will depend upon the desired information, the reagents available, and the access to specific instrumentation. Over the last few years, however, surface plasmon resonance (SPR) experiments have become particularly popular for determining both affinities and kinetics.

2.07.2.2 Principle of SPR

Optical biosensors measure changes in a particular characteristic of light, coupled to changes linked to binding at the sensor surface by making use of the electromagnetic evanescent wave formed at the gold interface of the sensor chip surface. Biosensors employing SPR are the most well-known optical biosensors, utilizing this phenomenon to enable detection of protein–ligand interactions in real time.

When total internal reflection occurs, the electromagnetic field component of the incident light (the evanescent wave) penetrates into the gold film on the sensor surface and interacts with free electrons, termed plasmons. Photons of the incident light are absorbed, the evanescent field strength is increased, and the light is no longer reflected. This decrease in the reflected light intensity occurs at an angle that is dependent upon the refractive index of the material in the flow cell and is called the SPR angle. The

refractive index of the flow cell changes with increased mass on the surface and thus allows detection of ligand binding. In a typical direct binding SPR experiment, the gold surface is coated with a carboxymethylated dextran matrix to which the target of interest can be immobilized. Test compounds or other binding partners are then flowed across the sensor chip surface, where binding during the association phase results in an increase in mass, a change in refractive index, and a measurable signal. Ligand dissociation can then be observed by simply flowing buffer, instead of ligand, across the protein surface.

Thus, these instruments potentially allow the kinetic rate constants and the equilibrium dissociation constant for an interaction to be measured, depending upon the experimental setup, the most common of which will be described in the succeeding text.

2.07.2.3 Experimental Considerations

The process employed in SPR experiments can be described by several key steps, which are required to generate useful data. Firstly, one binding partner must be immobilized; the association kinetics can then be monitored by injecting the other partner over this ligand surface; during the steady-state period, a kinetically independent affinity may be determined; subsequently, the dissociation of the analyte may be monitored, and finally, regeneration of the ligand surface must be achieved before the next analyte can be studied. These different stages of the SPR experiment will be briefly described in the succeeding text.

2.07.2.4 Ligand Immobilization

A requirement of SPR experiments is that one binding partner, termed the ligand, is attached to the biosensor surface. There are several options by which this capture may be achieved, including either covalent or noncovalent methods. Typically, it is the protein that is attached to the hydrogel matrix, and this must be achieved in a manner that retains authentic binding activity and capacity. Many factors contribute to the decision on which partner to immobilize, including the potential immobilization density required to produce a reasonable signal upon complexation, the routes for immobilization, and the type of assay required.

The successful immobilization of proteins requires consideration of the size/molecular weight of the protein, the amino acid composition, isoelectric point (pI), pH stability, and potential tagging sites for directional, homogeneous coupling. When possible, methods that minimize the possibility of heterogeneous coupling through different parts of the molecule should be prioritized. As with other biophysical methods, the quality of the protein is also important, and information about the quality and behavior of the protein can help to reduce problems with immobilization and subsequent affinity and kinetic measurements.

2.07.2.5 Ligand Size/Molecular Weight Considerations

Binding signals in SPR rely upon changes in refractive index caused by changes in mass on the sensor surface, with larger molecules producing correspondingly larger signal changes upon binding than smaller analytes. Sometimes, it can be advantageous to immobilize the smaller binding partner, as this will lead to larger responses during the experiment. Immobilization densities will need to be considered so that mass transfer does not limit the measurement of binding kinetics. This may be especially important if high densities of low-molecular-weight ligands are captured.

2.07.2.6 Choice of Coupling Methods

There are two general types of capture methods: covalent attachment and affinity capture. However, in order to capture the ligand onto the biosensor surface using either method, there must be a location at which either a chemical attachment (usually allowing complementary reaction with a surface bound group) or a capture tag can be placed without affecting binding functionality. Covalent attachment is often accomplished using amine, thiol, or aldehyde groups on the ligand, with complementary chemistry on the sensor surface allowing the formation of the covalent bond. These three coupling methods have been used extensively and are well understood and established. The immobilization density is relatively easily controlled, and reagent consumption is low. Disadvantages with this approach lie with the number or position of the reactive groups on the ligand: orientation of ligands containing more than one reactive group may be heterogeneous; coupling through a reactive group close to the analyte binding site may obscure the binding site resulting in reduced or abolished binding affinity.

Affinity capture of the ligand can often be achieved by initially introducing a high-affinity binding partner onto a site on the ligand, for a complementary partner that can be covalently attached to the sensor surface. Immobilization is then achieved via the high-affinity recognition between the two partners. Often, affinity capture approaches make use of the high-affinity interactions between antibodies and antigens or between biotin and streptavidin, for example, by capturing a biotinylated analog of the ligand onto a streptavidin-coated surface. High-affinity interactions such as these, although not irreversible, often provide stable enough surfaces that allow kinetic measurements to be made.

In the antibody capture approach, usually, the antibody can be covalently immobilized using amine capture, as described earlier, as often coupling occurs via the Fc region leaving the Fab region free to bind the antigen, which may be attached to the ligand, or the ligand itself (providing the antibody recognition site is distal to the analyte binding site).

It is also possible to combine both affinity capture and covalent approaches; for example, the weak affinity Ni-NTA–6His tag interaction may be used to directionally orient the ligand to the surface, allowing subsequent chemical interaction with groups in proximity to the surface.

The process involves activating the Ni-NTA chip with NHS/EDC in the standard manner for amine coupling (as the chip retains a significant proportion of nonderivatized carboxyl groups), followed by the introduction of the His-tagged ligand. The ligand is weakly but directionally noncovalently captured to the surface via the His–Ni-NTA interaction, but once it is close enough to the reactive esters on the chip, proximal free amines on the ligand can react to yield covalent coupling. The advantage of this method is twofold: It avoids the need for the low pH usually required for amine capture; it results in a more functional and robust immobilization, based upon the directionality of the capture. The chosen immobilization procedure often depends upon the type of ligand (protein, carbohydrate, nucleic acid, small molecule, etc.), the partner analyte to be used (small or large molecule), and the data required.

2.07.2.7 Ligand Quality Control Considerations

Purity of test compounds is seen as a key factor in screening and follow-up characterization, yet often, the purity and other quality control factors associated with the target protein have a lower profile. In fact, this should be a prioritized consideration, as the target protein is the key reagent used to identify and characterize all potential hits and leads. Before beginning immobilization procedures, it is good practice to verify the identity, purity, concentration, functionality, and stability of the target protein, using a combination of biochemical and biophysical methods. This can help to avoid problems associated with heterogeneous immobilization, which could result from impurities being coupled to the surface; it also helps to identify buffer conditions that are compatible for maintaining folded and active protein during both capture and subsequent kinetic binding experiments. Another factor not directly related to ligand quality is the availability of the ligand, as the requirements for this are often lower, in an individual experiment, than the analyte, which has to be injected at several different concentrations. However, the amount of ligand required to thoroughly analyze many different analytes may be considerable.

2.07.2.8 Consideration of Buffers

The choice of immobilization buffer, controlling the pH relative to the pI, and the ionic strength and the presence of other additives required for stability can make a considerable difference to both the attraction of the ligand to the surface and the final immobilization density. Buffers should be chosen carefully to achieve a reasonable preconcentration at the carboxymethyldextran sensor surface, as an initial high local ligand concentration promotes efficient coupling. Electrostatic preconcentration is accomplished by introducing a positive charge on the ligand while maintaining a negative charge on the hydrogel matrix by using a pH lower than the pI of the ligand and by having a low ionic strength. The pK_a of the typical carboxymethyldextran surface is around 3.5, and so, ligand preconcentration is not successful at pH values below this. Usually, the buffer with the highest pH, giving a reasonable preconcentration response, is used for the immobilization process.

A key consideration, especially when running kinetics experiments, is the ligand immobilization density. Kinetic measurements are best achieved with the lowest ligand immobilization density that gives a measurable response. This is because secondary effects including mass transfer and steric hindrance are reduced at lower immobilization densities.

The theoretical maximal binding capacity for the analyte is given by the Eq. (1):

$$R_{max} = \frac{MW_{\text{analyte}}}{MW_{\text{ligand}}} \text{x} R_{\text{ligand}} \text{x}\, n \tag{1}$$

where R_{max} is the maximum analyte binding capacity in RU, MW is the molecular weight of the indicated species, R_{ligand} is the amount of immobilized ligand in RU, and n is the stoichiometry of analyte binding to ligand.

This formula assumes that all the immobilized ligand molecules are accessible and fully functional, which may not always be the case. In order to characterize the surface before undertaking binding kinetics studies on test compounds, it is useful to employ a control or tool analyte that may be used to probe the ligand functionality and to test the sensor surface for stability over time and cycles of regeneration.

It is also beneficial for a reference ligand, which lacks the ability to bind analytes, to be immobilized to the same density as the target ligand. This surface provides a suitable reference allowing for changes in refractive index occurring from analyte injections or other injection artifacts to be corrected.

2.07.2.9 Association Phase

Once a suitable ligand surface has been prepared, the next step is the injection of the analyte over the ligand in order to monitor binding. Binding occurs when the injected analyte collides with the immobilized ligand, following the diffusion of the analyte from bulk flow to the sensor surface. Recognition occurs and a binding signal detected if the analyte has the correct direction of approach and sufficient energy. The binding response at any time, t, during the association phase is given by Eq. (2):

$$R = \frac{k_a.C.R_{\text{max}}}{k_a.C + k_d}\left(1 - e^{-(k_a.C+k_d).t}\right) + R_i \tag{2}$$

where R is the signal in RU, C is the concentration of injected analyte, R_{max} is the maximum signal, k_a is the association rate constant, k_d is the dissociation rate constant, and R_i is a curve-fitting parameter that allows for a nonzero signal at the start of the injection (often reflecting bulk refractive index changes).

As the association rate constant becomes larger, it becomes more difficult to reliably measure. Two factors contribute to this: the effect of mass transfer becomes more important and the assumption that the concentration of analyte in the flow remains constant at its injected value. Thus, the upper limit to reliable values lies in the range 10^7 $M^{-1}s^{-1}$.

As Eq. (2) shows, the association phase contains information about not only the association rate constant but also the dissociation rate constant, as dissociation events will also occur during analyte injection.

2.07.2.10 Steady-State Phase

As dissociation events occur during the injection of analyte, if the injection of analyte continues for long enough, then the net binding rate observed will fall to zero (shown when the binding response becomes parallel to the baseline), as the rate of dissociation becomes equal to the rate of association. This situation is called steady state (not equilibrium since there is continuous addition and removal of the analyte) and reflects the fact that the concentration of ligand–analyte complex is not changing. The responses at steady state, obtained for different concentrations of analyte, may then be used to calculate the steady-state affinity or equilibrium dissociation constant, K_D, as shown in Eq. (3):

$$K_D = \frac{[L][A]}{[LA]} = \frac{[A](R_{max} - R_{ss})}{R_{ss}} = \frac{k_d}{k_a} \tag{3}$$

where [L] is the free concentration of ligand, [A] is the free concentration of analyte, [LA] is the concentration of the ligand–analyte complex, and R_{ss} is the response at steady state for the injected analyte concentration. Often in SPR experiments, the ligand is the immobilized protein, and the analyte is the injected small-molecule ligand, so care should be used with the nomenclature.

Plotting the steady-state response, R_{ss}, versus the injected analyte concentration yields a rectangular hyperbola described by the Langmuir binding isotherm, and the K_D value is determined as the concentration of analyte producing a half maximal response (rearrangement of Eq. (3) in the preceding text). Since steady-state measurements of K_D are not affected by mass transport limitations or potential analyte rebinding, often affecting rate constants, this offers an internally consistent approach to check the validity of the kinetic rate constants by comparing the steady-state K_D with that calculated from k_d/k_a.

2.07.2.11 Dissociation Phase

After binding has taken place, the ligand and analyte remain bound in the complex until dissociation takes place. Dissociation is the process by which the analyte is released from the complex and is removed from the sensor surface of the SPR instrument by buffer flow. As stated previously, dissociation events occur during the association and steady-state phases of the sensorgram, but during these phases, any dissociated ligand is replaced by new analyte from the injection. However, when the flow of analyte is stopped and replaced with buffer, the concentration of the free analyte falls to zero, and the dissociation events are easily detected as a decrease in signal (in the absence of rebinding further along the flow cell, there are no further binding events to obscure the measurement).

The response at any time, t, during the dissociation phase is given by Eq. (4) in the succeeding text:

$$R = R_0.e^{-k_d t} + R_{(t \to \infty)} \tag{4}$$

where R_0 is the initial signal at the start of the dissociation phase (at the time the analyte injection is stopped and buffer flow started), k_d is the dissociation rate constant, and $R_{(t \to \infty)}$ is the response after infinite time (essentially a background term).

Dissociation rates that are very fast ($k_d > 1$ s^{-1}) or very slow ($k_d < 10^{-4}$ s^{-1}) are difficult to measure reliably. In the rapid case, the data sampling rate (even at 10 Hz) does not allow the collection of sufficient data for accurate data fitting (90% of the signal is lost in 2.3 s for a k_d of 1 s^{-1}). Conversely for the slow rate situation, data collection takes too long for enough dissociation phase to be collected to be reliable (10% reduction in starting signal for a $k_d = 10^{-4}$ s^{-1} takes 17.6 min). In the slow dissociation example, it is important that control experiments are carried out to account for any baseline drift during the long data collection times.

A typical example of multicycle kinetic data is shown in Fig. 1, top panel.

2.07.2.12 Regeneration Procedures

In SPR instruments with a single channel or flow cell for target immobilization or for higher throughput in multichannel instruments, when the aim is to characterize large numbers of interactions, it is important to remove any remaining analyte from the ligand following the monitored dissociation phase, without affecting the ligand functionality. This process is known as regeneration, as the aim is to regenerate the starting condition of free ligand so that a further cycle of analyte testing can take place. Conditions leading to regeneration have to be evaluated empirically since the physical forces driving the binding interaction usually are not known. Hence, a series of different regeneration conditions must be sampled for their ability to disturb the binding interaction without negatively affecting the binding competence of the ligand. Sometimes, regeneration occurs by partially unfolding the

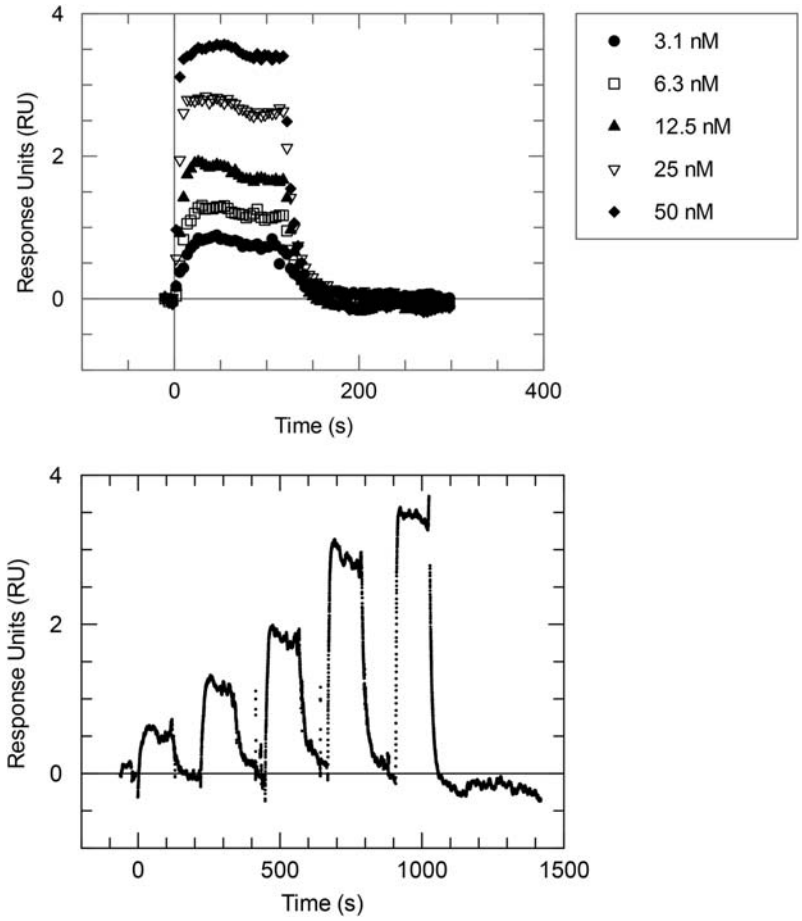

Fig. 1 Typical sensorgrams from a Biacore instrument, showing multicycle kinetics (top panel) and single-cycle kinetics (bottom panel).

protein ligand or by using pH, ionic strength, or chemicals to remove the analyte. Guidelines for regeneration suggest that the chosen conditions should be the mildest solution that completely disrupts the complex, producing free ligand.

Sometimes, it is possible to avoid the need for regeneration by employing single-cycle kinetics measurements. As the name suggests, this involves a series of injections of analyte at increasing concentrations in a single cycle, with no regeneration in between, Fig. 1, bottom panel. This effectively allows the monitoring of the increasing concentration of complex formation and can potentially be advantageous when working with slowly dissociating compounds.

Direct binding assays are dependent upon the MW and K_D of the test compound in order to produce a large enough signal, which potentially represents a challenge when working with fragments, where both the compound size and affinity are low.

However, problems in sensitivity due to ligand molecular size may be overcome by the use of alternative assay formats such as the surface competition assay (SCA) or inhibition in solution assay (ISA). In the SCA format, an analyte competes with a higher-molecular-weight analog for binding to a common partner immobilized on the sensor surface; for example, a peptide and protein could compete for binding to a second immobilized protein partner.

The ISA overcomes the size issue by measuring the binding of the macromolecule, whereby increasing test compound concentration results in a decrease in the observed signal due to competition.

The ISA format requires immobilization of a tool compound or so-called target definition compound (TDC) to the sensor surface, which then serves as a probe for the binding site. The binding interaction between the TDC and the target protein results in a control signal, which is reduced in the presence of competing test compounds. Only those test compounds demonstrating kinetic competition with the immobilized TDC will reduce the amount of free protein available at equilibrium to bind to the TDC. This approach allows affinity information for test compounds to be derived, although kinetic information is not easily obtained.

2.07.2.13 Biolayer Interferometry

Biolayer interferometry (BLI) is another optical technique that may also be used to measure binding kinetics. The BLI method is based on the interference wave pattern created from the reflection of white light as a function of the thickness of the biosensor

tip surface. Ligand (here used in its more traditional sense, compared with the SPR section in the preceding text), binding to the immobilized protein attached to the sensor surface, causes a change in the optical layer thickness. This results in a change in the interference pattern between this and the reference reflection that can be measured in overtime. This change is brought about because some of the wavelengths of light are subject to a change in path length during reflection, as a result of alteration in the surface thickness. Thus, the interference patterns for all wavelengths are changed, due to differences in the constructive and destructive interference patterns. The resulting interferometric profile is wavelength-shifted, by an amount that is proportional to the change in thickness, compared with the original sensor surface. Only molecules associating with or dissociating from the biosensor surface result in a change in thickness, generating a change in signal. This method is insensitive to changes in the refractive index of the surrounding solution and so may be used with complex mixtures without adverse effect.

2.07.2.14 Optical Waveguide Grating

Biosensor instruments employing optical waveguides may also allow direct measurements of binding interactions and are suitable for high-throughput measurements.

Similar to SPR, the instruments exploit evanescent waves generated when light traveling through a boundary of different refractive indices undergoes total internal reflection. Waveguides situated adjacent to each other allow coupling and propagation of the wave from one element to the next. Broadband light is used to illuminate the surface, which then reflects a specific wavelength dependent upon the refractive index close to the sensor surface. Ligand binding causes a change in refractive index, leading to a wavelength change in the reflected light. This measurement correlates with the change in mass on the sensor surface.

The largest difference between both BLI and optical waveguide grating (OWG) instruments and SPR-based instruments is the absence of a flow system. This means that BLI and OWG systems measure an approach to a new equilibrium during dissociation experiments, rather than a true dissociation rate constant. However, in practice, the large dilution of dissociating analyte means that the errors are often insignificant.

2.07.2.15 Biochemical Methods to Determine Binding Kinetics

2.07.2.15.1 Radioligand binding

Radioligand binding is an approach that makes use of a radioactively labeled compound, which binds at the target binding site. These long-established assays are potentially suitable for purified protein, tissue homogenates, cell lysates, and also even whole cells. The radioligand tool compound should have a specific activity high enough to allow detection of the protein–ligand complex (usually by a scintillation counting method) in the binding assay and should demonstrate a high degree of selectivity and being pure and stable. The kinetics of the binding interaction are measured by detecting the incorporation of the radioactivity into the protein over time. Most radioligand binding assays need a separation step (typically filtration or washout) to separate bound from free radioligand before the measurement of the incorporated radioactivity is undertaken.

An alternative radiolabeled approach is using scintillation proximity assays (SPA), where the protein of interest is captured onto a scintillant-containing solid support (usually beads or microtiter plates). SPA typically involves isotopes whose decay particles have only a short path length in aqueous solution (e.g., β-particle emitters such as tritium). This means that only a radioligand bound to the immobilized protein is close enough to excite the scintillant, which results in signal generation.

Competition experiments between the tool ligand and test compounds may be employed, as long as the tool compound is known to interact at the same binding site as the test compounds. This method allows determination of test compound binding kinetics without the need to label each individual compound.

Radioligand binding experiments may be used to determine both association and dissociation rate constants, depending upon the experimental design, discussed in the succeeding text. As with other methods, the direct binding experiment analysis assumes that binding follows the law of mass action so that at any time, the rate at which the protein–ligand complex is formed is proportional to the radioligand concentration and the number of binding sites unoccupied. In the dissociation experiment, the rate of dissociation is proportional to the concentration of protein–ligand complexes.

2.07.2.15.2 Measurement of dissociation rate constant: Direct dissociation of radiolabeled compound

Dissociation experiments, following dissociation of the radiolabeled molecule itself, directly measure the dissociation rate constant for radioligand dissociating from the protein. The setup involves allowing the ligand and receptor to bind, usually until equilibrium is reached, at which point, further binding of radioligand to the protein is prevented, for example, by adding unlabeled compound or by large dilution. The addition of a saturating level of a competitor compound in order to prevent rebinding of the dissociated ligand, especially in the case of fast association kinetics, may also be considered. The rate of dissociation can be described by a single exponential decay with a rate constant equal to the k_d for the ligand.

2.07.2.15.3 Measurement of association rate constant

Measurement of the association rate constant is achieved by adding radioligand to protein and measuring the specific binding component at various times. The binding signal increases with time until a plateau is reached. As described in the SPR section in the preceding text, this plateau is not the maximum binding signal, as the value of the plateau in this experiment depends upon the concentration of radioligand used, and so represents the steady state under the conditions used. The maximum binding

signal is given by extrapolation to an infinite concentration of radioligand or in practical terms a concentration that is much greater than K_D.

As shown in Eq. (2) for SPR in the preceding text, the rate with which the binding signal increases is controlled by three factors: the association rate constant itself, k_a, which needs to be determined in the experiment; the concentration of radioligand used (higher concentrations of radioligand result in faster equilibration times); and the dissociation rate constant, k_d. At first, it may be unexpected that the measured rate of association depends partially on the dissociation rate constant. However, consideration of the binding process reveals that during the association experiment, radioligand both binds to and may also dissociate from the protein. The system reaches steady state when the rates of the association and dissociation events are equal. Thus, the observed rate of association indicates the time to reach steady state, and it is not possible to fit a simple equation to association data to determine the association rate constant, unless the value of the dissociation rate constant is already known. It is possible to resolve the values if two or more concentrations of radioligand are used.

2.07.2.15.4 Fluorescence approaches

Fluorescence-based methodologies, such as fluorescence polarization (FP), Förster resonance energy transfer (FRET) or fluorescence intensity (FLINT), see Fig. 2, offer an alternative approach to radioactivity-based assays, along with potentially higher throughput.

In FP assays, the ligand, containing the fluorophore, is excited by linearly polarized light. The degree of polarization of the fluorescence emission is proportional to the rate of tumbling in solution of the fluorophore. The rate of tumbling is proportional to the size of the species to which the fluorophore is attached, with higher-molecular-weight species tumbling at lower frequencies. Hence protein-bound ligands retain more of the polarization of the excitation light. FP assays are applicable to both isolated protein assays but have also found application in cell-based methods, enabling the detection and kinetic characterization of ligand–cell surface receptor interactions.

The FRET method involves the nonradiative transfer of energy between a donor (usually a fluorescently labeled ligand) and an acceptor (often a fluorescently labeled protein). The FRET signal is dependent upon ligand since the FRET phenomenon is distance-dependent, with the maximal donor/acceptor distance being around 5–10 nm. Only when bound to the protein will the donor fluorophore be positioned close enough to be able to excite the acceptor fluorophore attached to the protein.

FLINT experiments rely upon the change in fluorescence signal brought about by a change in polarity of the environment experienced by the fluorophore. This may be the relocation from solvent to the protein-bound state for the (labeled) fluorescent ligand or due to conformational changes induce within the protein by ligand binding that alter the intrinsic protein fluorescence or that of a protein-bound fluorophore.

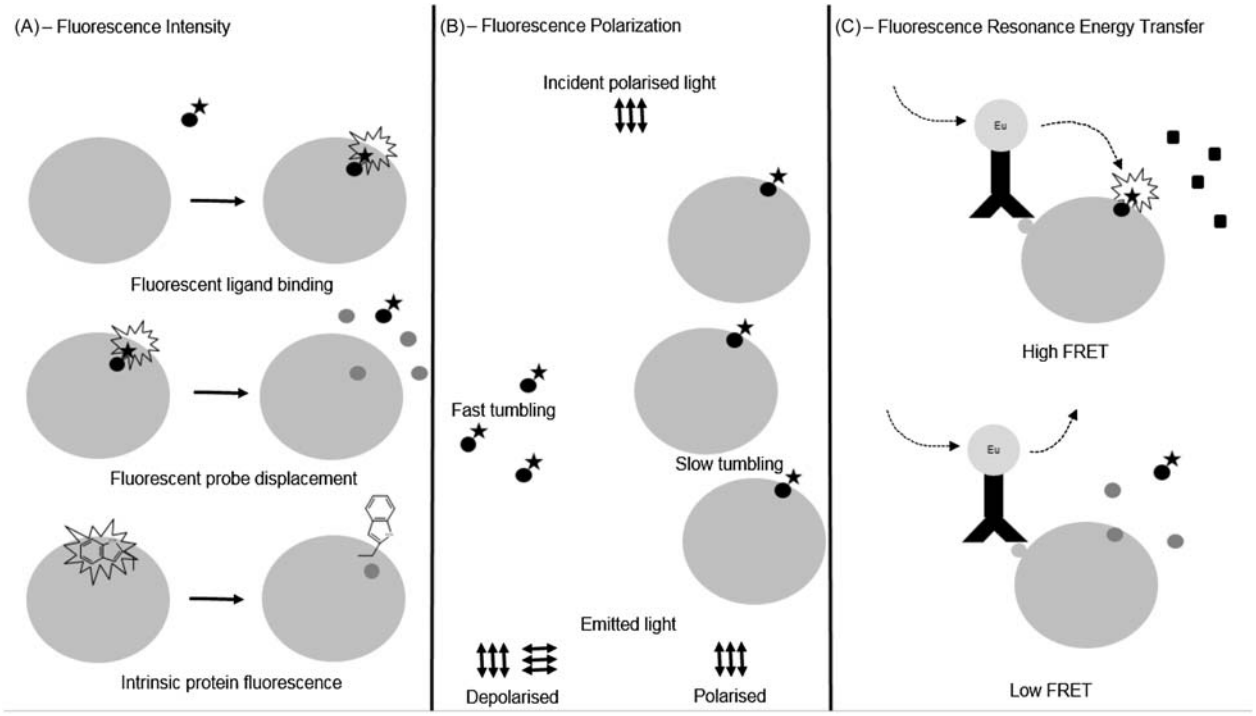

Fig. 2 Principles of fluorescence-based methodologies—(A) fluorescence intensity; (B) fluorescence polarization; and (C) fluorescence resonance energy transfer.

2.07.2.15.5 Competition methods

As mentioned earlier for radiolabeled methods, competition experiments are also useful in fluorescent approaches, as they preclude the need to label every compound. Such indirect, competition methodologies are suitable for use with both radioligand and fluorescence-based assays, making use of the kinetic competition between the test compound and the (radio)labeled tool ligand. In this type of experiment, the binding kinetics of the test compound are derived by the affect upon the kinetics of a labeled reporter molecule. Usually, it is desired for the labeled molecule to have rapid association/dissociation kinetics, such that these kinetics do not affect the kinetics of the test compound. Complications arise when the labeled ligand has its own, resolvable binding kinetics. In these cases, knowledge of the mechanism of inhibition/binding and knowledge of the binding kinetics of the labeled ligand are required in order to resolve the kinetics of the test compound. For the simple 1:1 binding situation, following the law of mass action, the method of Motulsky and Mahan, which has seen an increase in use again recently, can be employed.[1] Extending this, a model including an isomerization step upon compound binding, for example, as described for muscarinic receptors, has also been described.[2]

It should be noted that a potential problem when employing some label-based approaches (especially where the labels are large molecular entities, as can be the case for fluorescent labels) is the possibility that the incorporation of the label into the ligand may potentially affect its binding kinetics and affinity. Of course, label-free methods offer the opportunity to avoid this issue, and the use of biosensors to measure binding kinetics has increased dramatically over the last decade. While strictly not truly label-free (as the protein has to be coupled to the sensor surface), the use of these technologies does not require the use of small-molecule labels.

2.07.2.16 Enzyme Kinetics

Enzyme assays, which often can be followed using biophysical readouts, for example, quantification of the amount of a fluorescent product, can also be used to measure binding kinetics. However, knowledge of the inhibitor mechanism of action (MoA) is required in order to access the relevant parameters. An example is the derivation of the kinetic parameters for inhibitors of the enoyl-acyl carrier protein reductase, FabI, from forward reaction progress curves (enzyme assay time courses) through a detailed understanding of the MoA of the inhibitors coupled with computational methods.[3]

Jump dilution methods offer a more direct way to estimate inhibitor dissociation rate constants. In a similar way to the large dilution experiments described earlier, the enzyme is incubated with a saturating concentration of test compound, and this mixture is rapidly diluted into a large excess of substrate. Product accumulation is then again measured as a function of time, and the observed rate of enzyme activity recovery fits to a single exponential in order to derive the inhibitor dissociation rate constant. Two important factors in conducting this type of experiment are that the inhibitor concentration falls well below its apparent inhibition constant, K_i', upon dilution and that the final enzyme concentration, following the dilution, is sufficient to generate enough product for reliable detection.

2.07.2.17 Residence Times

The exploration of the use of residence times has gained popularity recently, with several authors proposing advantages over equilibrium-based affinity measurements[4–7] and describing applications of medium to high throughput in drug discovery.[8] Residence time, τ, is proportional to the half-life for dissociation and describes the time the protein is occupied by the ligand, and methods such as those described earlier have allowed more routine application of the measurement of the kinetics of biomolecular association and dissociation within drug discovery projects. Biophysical methods especially tend to play a larger role in the characterization of hits and leads, allowing kinetic data to be considered during the optimization of lead molecules.

In order for residence times to be compared and utilized, it is important to consider the mechanism of the binding interaction. Three simple mechanisms of single compound binding to target proteins have been described, with and without protein isomerization steps. An overview of these different mechanisms, along with the parameters describing them, are shown in **Table 1**.

Table 1 Parameters and their relationships to individual rate constants associated with the three common models of ligand binding

Parameter	*Model*		
	Single step	Induced fit	Conformational selection
	$R + L \underset{k_2}{\overset{k_1}{\rightleftharpoons}} RL$	$R + L \underset{k_2}{\overset{k_1}{\rightleftharpoons}} RL \underset{k_4}{\overset{k_3}{\rightleftharpoons}} R^*L$	$R + L \underset{k_4}{\overset{k_3}{\rightleftharpoons}} R^* + L \underset{k_2}{\overset{k_1}{\rightleftharpoons}} R^*L$
k_{obs}	$k_1[L] + k_2$	$k_4 + \left(k_3/\left(1 + K_D'/[L]\right)\right)$	$k_3 + \left(k_4/\left(1 + [L]/K_D''\right)\right)$
τ	$1/k_2$	$(k_2 + k_3 + k_4)/k_2k_4$	$1/k_2$
K_D	k_2/k_1	k_2/k_1	–
$K_D{}^*$	–	$k_2k_4/(k_1(k_3 + k_4))$	k_2/k_1

Note that for the one-step binding mechanism, k_1 is k_a, and k_2 is k_d.

k_{obs} is the observed rate constant for association. K_D and K_D^* are the equilibrium dissociation constants for the relevant bimolecular complexes (RL and R*L, respectively), and K_D' and $K_D^{*\prime}$ are their apparent values. These may be related to the true values, by the usual Cheng–Prusoff relationships, according to the mode of inhibition.

For a simple one-step reversible interaction, the residence time, τ, is the reciprocal of the dissociation rate constant and is correlated to the amount of time the protein is occupied by the ligand. The value of comparison of residence times really comes from the discrimination between hits and leads in terms of the dissection of the affinity into the component association and dissociation rate constants. Compounds with similar binding affinities may have very different kinetic contributions. The increased application of biophysical and biochemical methods to dissect the kinetics of ligand binding from affinity values will potentially lead to the development of more refined structure–kinetic relationships. The ultimate goal is a set of guidelines that may help to steer medicinal chemistry efforts in the modification of the kinetic behavior of compounds in order to achieve the desired kinetic profile required for the specific intervention at the protein target in the disease state.

2.07.2.18 Effect of Binding Kinetics on Fractional Occupancy and IC_{50}

The association and dissociation rate constants are important factors in determining the fractional occupancy and the correct inhibitor potency, as these may change according to time at which the fractional occupancy or IC_{50} is measured, dependent upon the value of the individual rate constants. This is because, where slow kinetics are involved and/or the time of the assay is short relative to the required equilibration times, then a lower fractional occupancy will be observed according to Eq. (5) in the succeeding text:

$$\text{Fractional occupancy} = \left(\frac{[\text{L}].k_a}{[\text{L}].k_a + k_d}\right).\left(1 - e^{-([\text{L}].+k_d).t}\right) \tag{5}$$

Usually, this is not a problem during the initial screening activities, as the potencies of initial hits are usually relatively low, test compound concentrations are usually high, and often assays are long enough, or contain preincubation periods that ensure that equilibration occurs, so that even very slowly, equilibrating compounds are still identified with the correct potency. For example, for 1 μM potency with an incubation time of 30 min, the true potency is observed for compounds with association rate constants ranging from 1×10^3 to 1×10^8 M^{-1} s^{-1}, and all the fractional occupancy versus concentration curves overlay, see **Fig. 3**.

However, for more potent compounds and lower assay times, then, differences between true and observed potencies become more problematic for compounds displaying slower kinetics, and now, the difference in the fractional occupancy versus concentration plots is easily observable for the slower association rate constants, **Fig. 4**.

It can be seen that as the association rate constant (and correspondingly the dissociation rate constant) decreases, for this time point (here 15 min), then, the concentration of compound required for 50% fractional occupancy increases significantly. Although for very rapid rate constants ($k_a = 1 \times 10^8$ M^{-1} s^{-1} and $k_d = 0.1$ s^{-1}), the observed affinity is similar to the true affinity; for the slowest rate constants depicted here ($k_a = 1 \times 10^3$ M^{-1} s^{-1} and $k_d = 1 \times 10^{-6}$ s^{-1}), the observed affinity is almost three orders of magnitude lower than the true affinity at this time point (top panel). It can also be seen that the slope of the curves increases as the rate constants become slower, with slope factors increasing from 1 to around 1.4 from the fastest to the slowest values of rate constants (bottom panel). This highlights the need to understand the potential for binding kinetics to vary during the hit to lead process in order to ensure that assays are conducted suitably so that compound ranking may be correctly assessed in terms of equilibrium affinity values and also to allow follow-up on interesting kinetic profiles.

Of course, binding kinetics and residence times will not be the only decisive factor considered during lead selection and the consequent optimization process. But together with approaches suggested by Lipinksi and Leeson[9,10] and the potential application

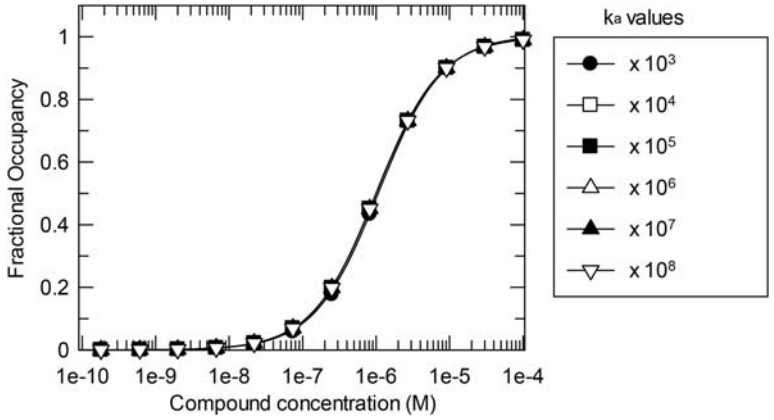

Fig. 3 Effect of various combinations of rate constants on the fractional occupancy for compounds of 1 μM potency, tested at a range of concentrations in an assay lasting 30 min. Even for a wide range of rate constants, varying by over five orders of magnitude, there is little difference in the plot of fractional occupancy versus concentration.

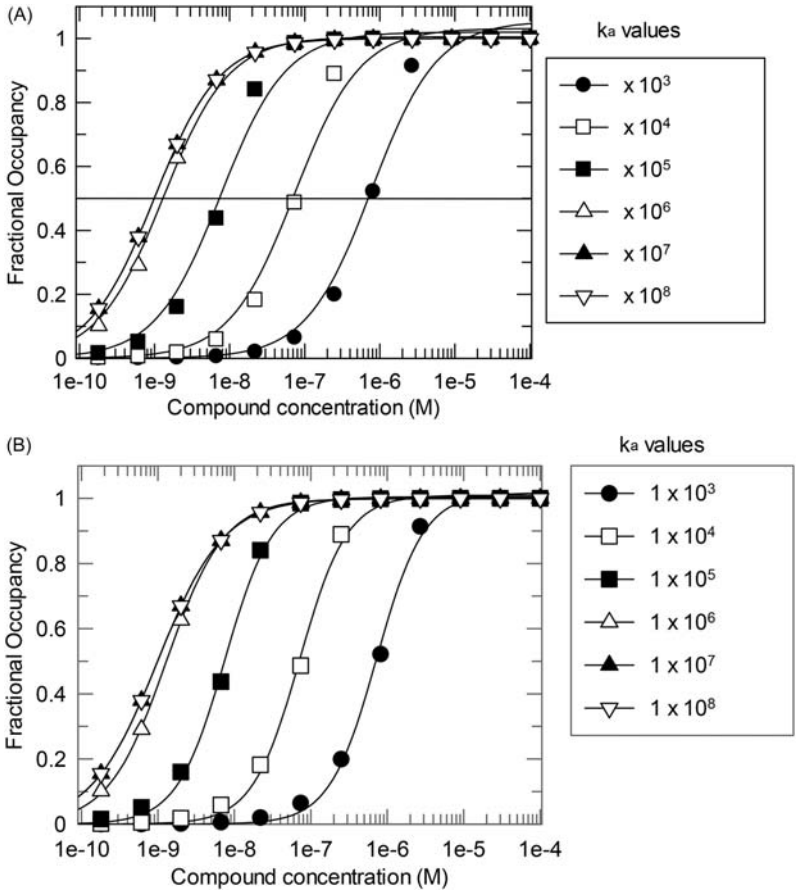

Fig. 4 Effect of various combinations of rate constants on the fractional occupancy for compounds of 1 nM potency, tested at a range of concentrations in an assay lasting 15 min. In this case, there may be a marked difference in the fractional occupancy achieved at each concentration, depending upon the kinetics of the interaction. Fits are shown to a simple 1:1 binding model (top panel) and to a binding model including a slope factor (bottom panel), representative of models that may be fitted to the data during the lead optimization phase of drug discovery.

of some recent LEM, for example, those suggested by Hopkins and Ladbury,[11,12] they form part of a collection of features that are accessible for the medicinal chemist to examine in order to construct a comprehensive and efficient strategy for optimization. This allows the optimization process to be based on the inclusion of a thorough overview of a range of different compound properties.

2.07.2.19 Mechanistic Aspects to Binding Kinetics

Ligand binding can be viewed most simply as the molecular collision between two molecules, described by the **Scheme 1**.

This simplistic view of ligand binding overlooks potential conformational effects and assumes that the complex results from ligand collisions with the binding site. The association rate constant is proportional to the frequency of productive encounters, and the dissociation rate constant, which is a measure of stability of the resulting complex, is inversely proportional to the residence time of the inhibitor.

The dissociation rate constant is directly accessible experimentally, as described earlier, and can be measured by dilution of the preformed complex. The association rate constant is measured only indirectly, because it is difficult to separate the formation of new complexes from the dissociation of complexes previously formed. Consequently, upon addition of ligand to the target protein, the concentration of the complex accumulates with rate constant k_{obs}, where the magnitude of k_{obs} is governed by both the production of the receptor–ligand complex and its simultaneous breakdown by dissociation back to the free partners, Eq. (6):

$$k_{obs} = k_a.[L] + k_d \tag{6}$$

$$R + L \underset{k_{diss}}{\overset{k_{ass}}{\rightleftharpoons}} RL$$

Scheme 1

The equilibrium dissociation constant, K_D, is given by

$$K_D = \frac{k_d}{k_a} \tag{7}$$

From Eq. (6) and **Scheme 1** in the preceding text, it can be seen that for a single-step mechanism, a simple plot of k_{obs} versus ligand concentration is linear with slope and intercept equal to k_a and k_d, respectively.

Sometimes, this simple model is insufficient to describe the interaction process, as often the free partners must undergo adjustments in shape in order to bind successfully, and the structures of the unbound and bound states differ significantly. Two different theories have been established that describe the potential mechanisms of these necessary conformational rearrangements. These are termed the induced fit and conformational selection models.

While these types of conformational rearrangements are often discussed from the perspective of the protein target, it should be remembered that ligands may also undergo rearrangement, and so, binding may occur via conformational selection or induced fit-type processes, which reflect ligand shape and the changes required to form high-affinity interactions.

The induced fit theory (**Scheme 2** and **Fig. 4**) describes the formation of a weak initial complex, which proceeds via intermediates that gradually rearrange to establish further interactions, until the final high-affinity state is reached.

The conformational selection model (**Scheme 3** and **Fig. 4**) suggests that the bound conformation of the protein preexists in the absence of ligand as a small population of different substructures available in conformational space. When ligand is added, complexes are only formed with that subset of protein molecules in the correct conformation to support binding.

The observed binding kinetics reflect the molecular processes that occur during the binding event, and so, the dependence of k_{obs} on [L] can be used to select the most appropriate model from the conformational selection and induced fit models. The induced fit model (**Scheme 2**) produces a hyperbolic plot of k_{obs} versus [L], which reflects the situation at high ligand concentrations, where initial complexes are formed rapidly, driven by the high ligand concentration, with the second step being rate-limiting. Addition of further ligand does not increase the rate of final complex formation, see Eq. (8):

$$k_{obs} = k_3 . \frac{[L]}{K_d + [L]} + k_4 \tag{8}$$

where K_d is given by

$$K_D = \frac{k_2}{k_1} \tag{9}$$

and $K_D{}^*$ is given by

$$K_D^* = \frac{k_2 . k_4}{k_1 (k_3 + k_4)} \tag{10}$$

A modified induced fit model may be applied to describe the binding of specific irreversible covalent inhibitors, where the second reversible step in **Scheme 2** is replaced by the irreversible covalent reaction process.

Conversely, for the conformational selection model (**Scheme 3**), the plot of k_{obs} versus [L] shows a hyperbolic decrease with increasing ligand concentration, Eq. (11). This can be understood since the concentration of binding competent protein decreases as these molecules become bound with ligand. Thus, at high ligand concentrations, all of the binding competent protein is rapidly complexed, and the formation of new binding competent conformations becomes rate-limiting:

$$k_{obs} = k_3 + k_4 . \frac{K_D^*}{K_D^* + [L]} \tag{11}$$

where $K_D{}^*$ is now given by

$$K_D^* = \frac{k_2}{k_1} \tag{12}$$

Of course, these two models rely on a number of assumptions, and often, the binding process may be more complicated, with both mechanisms potentially occurring at the same time. It is possible for both pathways to be followed simultaneously where the concentration of R* and R*L will determine which mechanism tends to dominate the observed kinetics. It is also possible for both

$$R + L \underset{k_2}{\overset{k_1}{\rightleftharpoons}} RL \underset{k_{-1}}{\overset{k_3}{\rightleftharpoons}} R^*L$$

Scheme 2

$$R + L \underset{k_4}{\overset{k_3}{\rightleftharpoons}} R^* + L \underset{k_2}{\overset{k_1}{\rightleftharpoons}} R^*L$$

Scheme 3

pathways to occur sequentially; for instance, binding may occur following a conformational selection step, with subsequent optimization of side chain and/or backbone interactions occurring via an induced fit.[13]

Clearly, medicinal chemistry applied during the lead optimization process can only impact the initial conformation of the ligand and not the target protein. This process often results in a decrease in conformational entropy as a result of ligand rigidification, aimed at minimizing entropic penalties upon binding.[14]

This approach, whether deliberate or serendipitous, may be considered as the advantageous exploitation of conformational selection.

There are examples in the literature describing systems that appear to conform to these models. The induced fit model has been proposed to occur for the binding of compounds such as imatinib to protein tyrosine kinases. Binding has been shown to occur in two different binding modes: a low-affinity, ATP-competitive form known as Type I, (where the aspartate–phenylalanine–glutamate motif (DFG motif) is in the DFG-in conformation)[15] and the high-affinity form, Type II form where the kinase adopts an inactive conformation (DFG-out).[16]

The conformational change between these two modes requires substantial rearrangement of the protein, where the DFG motif at the beginning of the activation loop moves to reposition the catalytic machinery into an inactive conformation.

Almost 40% of the imatinib–Abl kinase binding free energy appears to come from the DFG-in to DFG-out transition. Interestingly for imatinib binding to Src kinase, the DFG-out conformation contributes much lower free energy, which results in a high selectivity for binding to Abl compared with Src.[17,18] The DFG conformational change has been targeted in the development of other Type II Abl inhibitors such as nilotinib and ponatinib[19,20] and for inhibitors of other kinases.

The conformational selection model is exemplified by the mechanism of ligand recognition by ubiquitin. Lange et al.[21] used both NMR studies and computational approaches to identify the ensemble of conformations populated by free ubiquitin in solution. The group of conformations was demonstrated to contain all of the crystallographically observed structural changes in ubiquitin bound to different ligands, leading to the conformational selection mechanism being established as the preferred model to describe binding in this system.

2.07.2.20 Kinetic Selectivity

The kinetics of ligand binding are dictated by the energy barriers for the association and dissociation processes, which are themselves governed by the nature of the forces controlling the interactions between a ligand and its target. In a simplistic manner, we can consider these interactions to be dependent upon four primary aspects: binding site accessibility, the electrostatic nature of the interaction, the nature of hydrophobic interactions, and conformational dynamics.

The accessibility to and from the binding site plays a key role in controlling the observed binding kinetics of a ligand. Intuitively, the entry and exit of a ligand to and from a narrow binding cleft would be expected to produce slower kinetics than that of a ligand binding to a shallow, flat area of the protein. In a study of prostaglandin H2 synthase, slow-binding kinetics are observed due to restricted access to the binding site.[22] Although both slow tight-binding and rapidly reversible inhibitors bind in identical binding modes, the kinetic divergence of prostaglandin H2 synthase inhibitors is explained by the rate and effectiveness with which the compounds open the narrow channel and gain entrance to the binding site, and it is proposed that the kinetic differences may reflect differences in the efficiency with which the inhibitors perturb the hydrogen-bonding network in the vicinity of Arg-120 and Tyr-355.

Electrostatic interactions between charged ligands and charged binding site will influence both association and dissociation rates. This may be demonstrated by varying the solution ionic strength, which will greatly affect association rates (increasing ionic strength decreases the on-rate) but hardly affects off-rates. These effects are due to ions screening the electrostatic interactions between the associating partners during the association process, but the dissociation shows less dependence due to similar geometries in the bound and transition states, leading to relatively little difference in the electrostatic interaction energy between the transition state and the bound state.

Ligand binding to the charged binding site of acetylcholinesterase demonstrates the influence of electrostatics on binding kinetics.[23] Neutralization of the net positive charge of the m-trimethylammonium trifluoroacetophenone ligands leads to around 30-fold decrease in the association rate constant and greater than 10-fold increase in dissociation rate constant.

The hydrophobic effect and the role of water in stabilizing protein–ligand complexes have been well studied from a thermodynamic perspective, but the influence on ligand binding kinetics is less clear. However, it is thought that the kinetic consequences may be related to the distance from the binding location. Schmidtke et al.[24] investigated the role of hydrophobicity in determining binding kinetics by employing both experimental and computation methods in the model Hsp90 system. This study suggested that protein–ligand interactions that contain hydrogen bonds that are shielded from bulk water by hydrophobic residues may result in a kinetically more stable complex than when hydrogen-bonded waters are solvent exposed.

The role of conformational dynamics and the mechanisms of the induced fit and conformational selection models have been illustrated earlier.

2.07.2.21 Role of Kinetics in Selectivity and Efficacy

The principle of kinetic selectivity is relatively simple—potentially, the binding kinetics rather than the binding affinity may allow discrimination between the temporal occupancy of target versus secondary, off-target binding sites. It has been understood for many years that the relative difference between the activity of a drug at its primary and secondary (off-) targets is important in determining

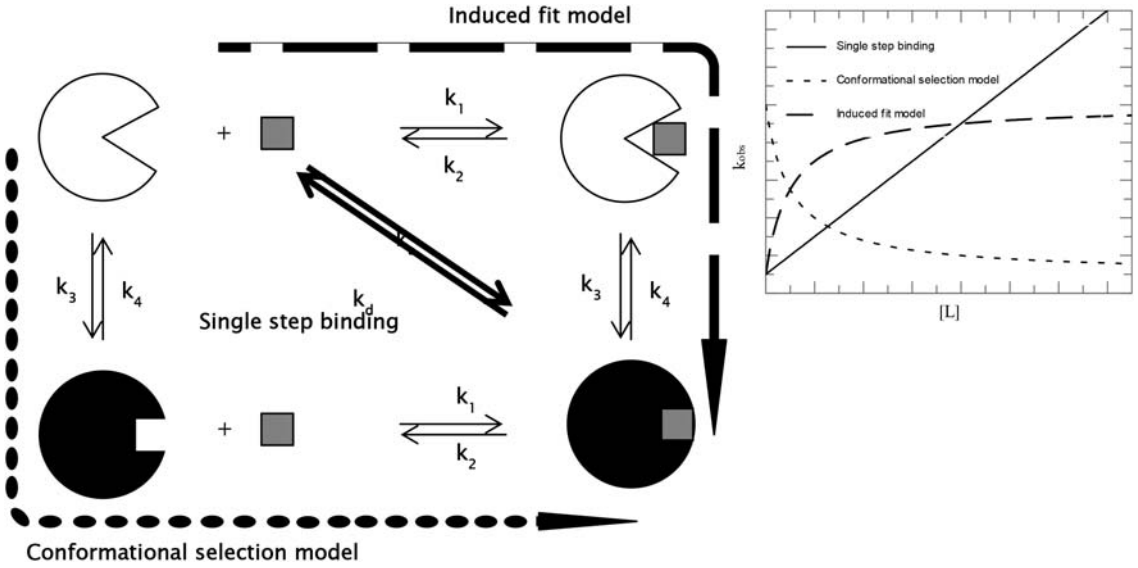

Fig. 5 Scheme showing the processes for single-step, induced fit, and conformational selection binding models. Rate constants relate to the parameters given in **Table 1**. Inset shows the variation of the observed rate constant, k_{obs}, with varying ligand concentration.

the therapeutic window of drug action (which is the difference in concentrations required for efficacy at the primary target and that leading to adverse effects in vivo). Most often, selectivity is characterized from thermodynamic values, such IC_{50} or K_d, measured in enzyme assays or ligand binding assays at equilibrium. However, since the affinity of a ligand for its protein target is also determined by the ratio of the dissociation and association rates (and the free ligand concentration at equilibrium), it is possible, at least theoretically, to obtain differences in kinetic selectivity via differences in association rate or residence time (**Fig. 5**). This figure shows that the binding kinetics may allow a higher fractional occupancy over time even at a target for which the compound binds 100-fold less tightly (according to the equilibrium K_D value). The fractional occupancy for the slower kinetic profile remains at 88% after 3 h, whereas the fractional occupancy for the faster kinetic profile has dropped to around 0.01%.

The concept of kinetic or temporal selectivity was promoted by Copeland et al.,[4] and it was suggested that a prolonged residence time for the primary target could provide beneficial selectivity against secondary, off-targets in vivo.

For a hypothetical drug binding to the primary target by a two-step mechanism that includes a second-step isomerization to form a tight-binding complex (see **Scheme 2**), the fractional occupancy for a primary target, with a 25-fold increased residence time compared with a 30-fold weaker secondary target, is shown in **Fig. 6**. The fractional occupancy remains above 95% after 10 h,

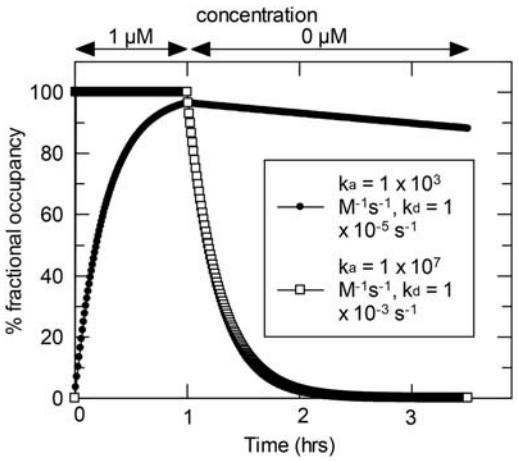

Fig. 6 Effects of kinetics on the fractional occupancy for compounds with different potencies. Prolonged occupancy is demonstrated even for a 100-fold weaker binding compound ($K_D = 10$ nM (filled circles) versus $K_D = 100$ pM (open squares)), following removal of free compound, due to its lower dissociation rate constant. This demonstrates that fractional occupancy at a particular time may be dictated by the binding kinetics of the interaction and is not just a consideration of the binding affinity.

even after the plasma concentration has dropped to almost zero, due to drug elimination. For the secondary target, the fractional occupancy falls to 40% for the 30-fold weaker affinity target.

In another well-known example, drugs binding to the angiotensin II type 1 receptor and displaying extended residence times, for example, candesartan, are more efficacious than compounds with faster off-rates, such as losartan. The two compounds bind in the same pocket, although with very different binding kinetics (residence times 174 and 4 min, respectively). This difference in residence time is assumed to account for the clinical differentiation between the compounds, allowing PD to outlast pharmacokinetics (PK) and to provide improved efficacy for candesartan.[25] However, the prolonged blood pressure lowering effect of candesartan is attributed not only to its long residence time but also to the rebinding of the drug to the receptor.[26]

Slow-binding inhibition of the acyl carrier protein enoyl reductase (FabI) in *Mycobacterium tuberculosis and Francisella tularensis* has been exemplified for drugs such as triclosan and isoniazid. An examination of the *F. tularensis* compounds demonstrated that there was poor correlation connecting affinity (K_i) or minimum inhibitory concentration values and in vivo efficacy. However, a much stronger linear correlation was revealed between residence time and efficacy (percent survival).[27]

The use of kinetic selectivity is exemplified by the development of subtype-selective muscarinic receptor antagonists. Tiotropium bromide, glycopyrronium bromide, and aclidinium bromide are inhaled long-acting muscarinic antagonist drugs for treatment of COPD.[28,29] It appears that the dissociation rate constant may be important for providing kinetic selectivity and may partly explain their therapeutic indices.[30] Glycopyrronium is slightly selective for the M3 receptor over the M2 receptor, whereas aclidinium and tiotropium show no selectivity in terms of binding affinity between the two receptors. All three drugs, however, dissociate more rapidly from the M2 receptor than the M3 receptor, giving them kinetic selectivity for the M3 receptor and so reducing side effects associated with M2 binding. The largest kinetic selectivity ratio of the three drugs is shown by glycopyrronium, which has a greater cardiovascular therapeutic index for hypotension and bradycardia compared with tiotropium in preclinical models.[31,32]

2.07.2.22 Irreversible Inhibitors

Understanding kinetic SAR should enable inhibitors with the desired kinetic profiles to be developed more effectively. Optimizing compound structures to give very slow dissociation rate constants has led to what has been termed ultimate physiological efficacy,[33] which indicates that inhibition is persistent until replacement of the inhibited target is accomplished by fresh protein synthesis. It would seem sensible for the most effective way to develop an ultimate physiological inhibitor being to optimize the binding kinetics (ideally increasing the association rate to enhance rebinding and decreasing the dissociation rate to prolong residence time). However, focusing on residence time optimization, without deliberately trying to optimize association kinetics (as this would seem a more difficult task), with the systematic application of SAR-driven medicinal chemistry effort seems the most practical way forward. The insights gained from taking the time to understand structure–kinetic relationships can be very valuable, and deriving empirical relationships can lead to improved PD effects.[34]

Clearly, the ultimate endpoint for the development of inhibitors with progressively longer residence times is the development of irreversible covalent inhibitors. Covalent compound development can be a successful strategy for targets where a suitable residue allowing covalent attachment is present in the binding site, where on-target toxicity is not a risk and target protein turnover is slow. The molecular recognition by and covalent reaction to related proteins must be scrutinized during the optimization process, particularly for proteins that share the residue for covalent attachment. Having a rapid clearance rate is also ideal for irreversible compounds, because this will tend to restrict off-target side effects.

Targeting kinases with irreversible compounds has been reviewed[35] and reveals an additional benefit—overcoming competition by high concentrations of natural substrates—demonstrating reduced ATP competition, which may be a problem for reversible competitive inhibitors, given that the cellular concentration of ATP is usually much higher than the K_m for ATP. This is due to the fact that covalent inhibition for kinases follows a modified induced fit model, where only the first step is competitive with respect to ATP.

The application of covalent inhibition is not restricted to kinases.

2.07.2.23 Optimizing Residence Time

To design new ligands with longer residence times, it would be useful to understand which molecular interactions contribute to increases in residence times so that this could be applied to any particular target. Cusack et al.[17] summarized the rationale for long residence time for a large number of ligand–target interactions. In these examples, prolonged residence time was attributed to a variety of different features including an increase in the kinetic barrier to dissociation, hydrophobic interactions, stabilization of the drug–target complex from multiple contacts, and the induction of conformational changes. Given that the contributions to increased residence time may be quite diverse and vary from target to target, it appears difficult to develop a generic approach for increasing residence times and to prospectively design slow dissociation kinetics into a given ligand.

Conversely, the principles underpinning the rational improvement of binding affinity during the lead optimization phase are relatively well understood. However, as described in the preceding text, the rational modulation of binding kinetics is not nearly as well characterized or understood. Whereas the magnitude of the equilibrium binding constant is directly associated with the structures and energies of the free and bound states, the kinetics of moving between these states is determined by the structure and corresponding energy of the transition state. Since the transition state is a low-abundance and highly unstable state, which often is difficult to characterize, understanding the kinetic constants associated with passing through this state is also difficult.

Although there are structural methods that facilitate the study of low-abundance conformations (e.g., Carr-Purcell-Meiboom-Gill pulse train sequences used for dynamic NMR measurements) and room-temperature and time-resolved Laue crystallography approaches,[36,37] the predetermined manipulation of compound binding kinetics remains intractable, and it is often only retrospectively that structure–kinetics relationships are revealed.

As a result, there is a current lack of detailed guidelines for kinetic-based ligand optimization, and the structural rationalization for differences in binding kinetics can really only be attempted for situations involving highly similar chemotypes or targets.

If kinetic modulation is to be undertaken, it is clear that in general, increasing residence time is more a realistic goal than modulation of the association rate constant. This can be realized by inspection of the simple free energy diagram describing a single-step binding mechanism following **Scheme 1**. The residence time (k_d^{-1}) can be increased by raising the energy barrier for dissociation, which can be accomplished either by increasing the energy of the transition state, by decreasing the energy of the complex, or by a combination of both effects, **Fig. 7**. Optimization of the binding energy is usually one of the main approaches taken during drug discovery, and the residence times of compounds may often increase in parallel with increases in affinity during lead optimization. An example of such a correlation was shown by Chang et al.[3] for inhibitors of enoyl-ACP reductase from *Staphylococcus aureus* (Fabl). The structure–affinity–kinetics relationships demonstrated that within the same chemical series, there was a strong relationship between K_i and k_d, whereas the corresponding k_a values remained similar for all of inhibitors within the chemical series.

By inspection of **Fig. 7**, it can be seen that increasing the energy of the transition state is another approach for kinetic modulation, as this will slow both the association and dissociation rates. As a general approach, restricting the accessibility to the binding site by increasing the molecular size of the compound often results in increasing the energy barrier, leading to slower rates.[38] Increasing the rigidity of compounds during lead optimization, as a means of reducing conformational entropy losses upon binding, also often leads to longer residence times, as a result of the concomitant increase in transition state energy.

Where the induced fit model best describes the binding process, it may be advantageous to retain a degree of flexibility in lead compounds in order to allow conformational rearrangements within the initial complex, which permit access to conformations that ultimately are more stable, and demonstrate higher affinity and slower dissociation.

It should be noted, however, that at least for some proteins, restricting the flexibility of the test compound may also have a corresponding effect on the association rate. An illustration of this point is provided by Fleck et al.[39] where it was shown that for a series of corticotropin-releasing factor type 1 receptor antagonists, constraining the active ligand conformation by ring substitution resulted in an increase in the association rate of around 33-fold. No effect on the dissociation rate was observed, suggesting a conformational selection mechanism.

Clearly, the logical extension of long residence time compounds is to move to irreversible complexes via covalent bond formation between the test compound and the protein target, as discussed earlier. There is renewed interest in covalent compounds, and as long as safety concerns stemming from the lack of specificity can be addressed, then approaches targeting nucleophilic cysteines with reactive warheads may be a useful approach. This strategy has been employed to target proteins such as EGFR[40] and the Ras G12C mutant.[41]

Covalent binding can often be described by a mechanism similar to the induced fit model, which involves initial molecular recognition, driven by noncovalent interactions, followed by the slower covalent chemical reaction. Gradually, an understanding of how to combine the fine-tuning of warhead reactivity, together with factors that modulate initial recognition, is developing,

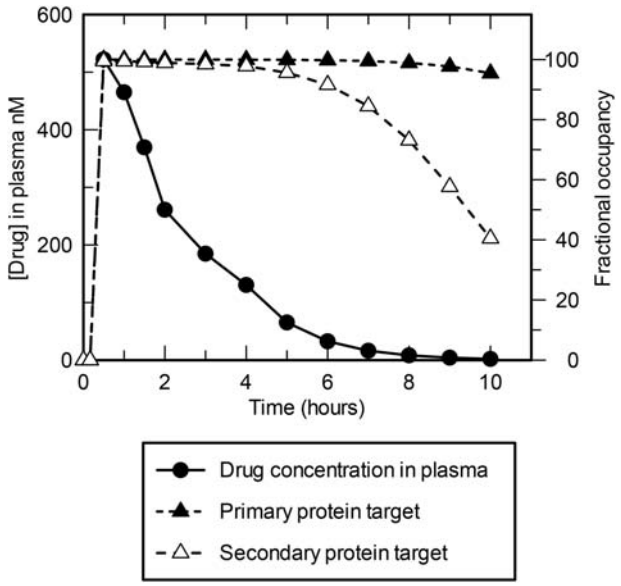

Fig. 7 Effect of kinetics and affinity on fractional occupancy for a primary target and a secondary target following a single-step binding mechanism.

which will eventually allow covalent inhibitors to be designed with the desired kinetic profiles. The utility of the covalent approach has been exemplified nicely by Bradshaw et al.[42] where the use of inverted cyanoacrylamides targeted to noncatalytic cysteines in kinases demonstrated the possibility of increasing residence times by chemical design.

2.07.2.24 Binding Kinetics and PK/PD

The interaction between a drug and the target protein, controlled by the relevant kinetic rate constants for association and dissociation, establishes the link between PK and PD effects. Clearly, a drug can only generate a biological response when it is bound to its target protein, and so, understanding the individual contributions that control the duration of target occupation is critical when trying to optimize these interactions for the particular target in the disease setting. The simplest model describing the relationship between binding kinetics and PK is shown in Fig. 8, although more complex models, for example, including the extra rate constants required to describe the induced fit and conformational selection models may be envisaged.

The free concentration of the drug in the location around the target protein governs the formation of the drug–protein complex. As can be seen from Fig. 8, this is controlled by the target protein concentration and a combination of rate constants, including the rate constants for distribution and clearance, which control the delivery and removal of drug to the target location, and the rate constants for association and dissociation, which control the formation of complex between the two partners, while the drug is in the vicinity of the target.

As long as binding reaction occurs more rapidly than the clearance of drug from the target location, then the drug will accumulate in the target vicinity and target occupation will be driven by mass action.

For different drugs with fixed affinity, since $K_D = k_d/k_a$, slower dissociation is coupled with slower association, and so, equilibrium may not be reached before significant clearance occurs. In these cases, frequent and multiple dosing may be required for slow associating drugs to reach equilibrium.

In the case of slow dissociating compounds, the limit to the value of increasing residence time even further is reached when the dissociation half-lives extend beyond that of protein turnover. In this case and also for the case of irreversible inhibitors, the rate of fresh protein synthesis dictates the ultimate limitation for the duration of effect, when the entire free compound pool has been eliminated.

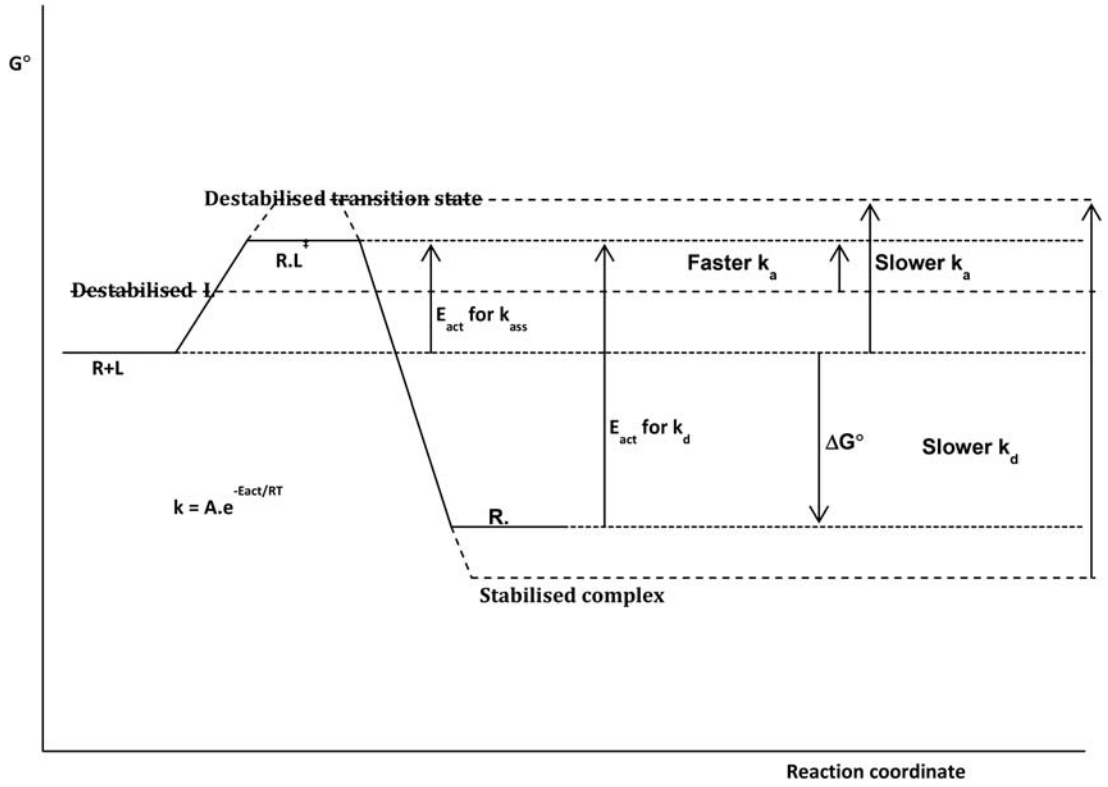

Fig. 8 Free energy diagram showing the effect of destabilizing the ligand or the transition state or stabilizing the protein–ligand complex on the observed rate constants. R.L‡ indicates the transition state between the free partners and the complex. E_{act} represents the activation energy barrier between the ground state and the transition state, controlling the magnitude of the rate constant for the binding or dissociation process as indicated—the larger the activation energy barrier, the slower the kinetics. ΔG° represents the change in free energy G° between the free partners and the bound complex. Slower dissociation rates may be achieved if the bound complex can be stabilized and/or the transition state destabilized. Faster association would require stabilization of the transition state (which opposes slow dissociation) or destabilization of the ligand.

When this situation occurs, a sustained pharmacological effect can only be achieved via PK exposure, when additional free compound is available to bind to newly produced protein. Thus, increasing residence time, by decreasing the dissociation rate constant, has a benefit only up to this limit, when PK effects are not considered. Fig. 8 demonstrates that there will be certain combinations of PK and BK rate constant profiles that will allow optimization of coverage but that conversely there will be some combinations that will not produce enough of a benefit to merit attempts to increase residence time further. In the induced fit case, exemplified in Scheme 2, if clearance is rapid, a decrease in the rate constant k_4 of over three orders of magnitude will be required in order to extend the time for which the fractional occupancy remains above 0.5 by only a factor of 10 (where the other parameters are $k_1 = 1 \times 10^6\ M^{-1}\ s^{-1}$, $k_2 = 1\ s^1$, $k_3 = 1 \times 10^{-3}\ s^{-1}$, clearance $t_{½} = 1$ h, $C_{max} = 500$ nM, and t_R varies from 2.8 to 2780 days with $k_4 = 1 \times 10^{-4}\ s^{-1}$ and $1 \times 10^{-7}\ s^{-1}$, respectively).

On the other hand, if clearance is slow, then there may be not a considerable advantage to efforts aimed at increasing the residence time. As an example, if we consider the same two-step binding mechanism where the clearance $t_{½}$ is now increased 24-fold to 24 h, a fractional occupancy of over 0.5 is maintained for 2.5 days when k_4 is left unchanged at $1 \times 10^{-4}\ s^{-1}$ ($t_R = 2.8$ days). Decreasing k_4 will extend this, but it is clear that once-daily dosing is sufficient to maintain the pharmacological effect with no requirement for any further chemical optimization.

Dahl and Akerud[43] have investigated the range of suitable kinetic values that permit high-target occupancy for a period of time after elimination. Their calculations suggest that k_a for a drug-like molecule should be in the range 2×10^3–$1 \times 10^8\ M^{-1}\ s^{-1}$, with a potency greater than a lower level of about 30 nM. Assuming there is a single-step binding process, this gives a range of equivalent k_d values of between $6\ s^{-1}$ and $6 \times 10^{-5}\ s^{-1}$. However, inspection reveals that not all of these combinations of rate constants allow the required occupancy, and so, optimization of k_d toward a maximum value of around $1 \times 10^{-4}\ s^{-1}$ is desirable if the fast k_a can be preserved. However, if as a result of chemistry efforts to decrease k_d, k_a is also reduced toward the lower values given earlier; then, k_d may need to be decreased further, by even another two orders of magnitude. This highlights the difficulties faced in kinetically optimizing test compounds, starting from initial hits, which may have affinities of the order of 1 μM, and assuming a reasonable value of k_a of $5 \times 10^5\ M^{-1}\ s^{-1}$, where the corresponding k_d would be of the order of $0.5\ s^{-1}$. This signifies that around a 5000-fold decrease in residence time is necessary to reach the suggested upper limit, with even additional improvement required to give the desired BK profile. Assuming there is no change in the corresponding association rate constant, the end result of the chemistry design efforts would be with a compound with 10 pM affinity.

2.07.2.25 Future Trends for Kinetic Characterization

Currently, designing a particular binding kinetics profile into a compound remains challenging but clearly remains a strategic goal for the medicinal chemist, as kinetics provides an opportunity to optimize compounds to gain a therapeutic advantage. Modifying binding kinetics can lead to improved therapeutic index and improve coverage via changes in PK/PD relationships.

Modifying binding kinetics will ultimately require changes to the energy levels of either the transition state or the protein–ligand complex, and understanding how to achieve these will be key. The increased measurement of binding kinetics, together with both structural information and computational approaches such as molecular modeling and molecular dynamics simulations, will help to provide a better understanding of both protein dynamics and the factors influencing binding kinetics.

Currently, we often think about lead optimization from an equilibrium perspective, since the interactions that are introduced relate to the two ends of an equilibrium, and we understand little of what happens in between. We may consider the modification of a compound structure and the result on residence times in two simplistic ways: Firstly, the structural change leads to a conformational change in the protein, leading to altered binding kinetics; secondly, the structural change changes the balance of interactions to favor the slowly dissociating ones. In this simplistic view, it would appear that the former would be very target-specific and understanding the effect on protein conformation might be challenging to accomplish in order to have impact in medicinal chemistry projects in a timescale that would be useful. The second approach seems more tractable, and we would hope that there may be some simple guidelines that could be established to promote rational design.

And even if this cannot be done directly, the strategy for optimizing long residence times can focus on optimizing affinity or by exploring additional binding interactions that are associated with larger kinetic barriers.

As our understanding of the implication of binding kinetics grows, the opportunity to impact projects will improve as we begin to implement kinetic optimization in order to decrease the number of iterations to move from lead to candidate drug or from first-in-class to best-in-class molecule.

Several recent articles have reviewed the current status of the use of binding kinetics in drug discovery for improved drug effects,[44] focusing on optimizing on rates,[45] and for GPCR kinetic optimization.[46]

2.07.3 Thermodynamics in Drug Discovery

2.07.3.1 Methods for Measuring Binding Thermodynamics

Thermodynamic data may be generated in two main ways, either directly employing ITC or indirectly utilizing the Van't Hoff approach and any method that can determine K_D as a function of temperature, for example, SPR or fluorescence.

2.07.3.2 Direct Calorimetric Methods

2.07.3.2.1 Principle of ITC

Isothermal titration calorimeters quantify the heat change that results when two molecules interact. Heat is almost always generated or absorbed as a result of the redistribution of noncovalent bonds when the interacting partners proceed from the initial free to the final bound state. Commercially available power compensation-based calorimeters detect these heat changes by monitoring the differential power required to preserve a zero temperature difference between the reference and sample cells as the binding partners are mixed and the binding reaction takes place.

The reference cell typically contains only the matched experimental buffer used for the individual interactants, while the sample cell contains one of the binding partners (often the macromolecule), and the injection syringe holds the other binding partner (often the ligand). In a typical injection protocol, aliquots of between 0.5 and 2 μL are injected, separated by enough time to allow equilibration between injections, until the final total ligand concentration attained is around two- to threefold greater than the total protein concentration. Each injection of ligand generates a heat pulse, and the power that is applied to maintain the temperature difference between the sample and reference cells close to zero is monitored. The power versus time plot shows a peak (for exothermic reactions, the peak represents a drop in applied power) that returns to the baseline level during the restoration of the thermal equilibrium. Each peak in the power versus time plot is subsequently integrated with respect to time and may be normalized versus concentration to produce a titration curve or binding isotherm, where enthalpy (kcal/mol) is plotted versus molar ratio (ligand/sample). In typical experiments, most of the injected ligand becomes bound in the early injections, since there is a large excess of free protein, and the differential ligand concentration is greatest. These initial injections therefore produce the largest heat changes, allowing estimation of the binding enthalpy. During subsequent injections, the heat changes are reduced as the titration proceeds. This is because the concentration of free protein decreases, due to complex formation, and some of the total added ligand remains free in solution.

During a typical experiment, the measured heat change is composed of at least three contributions: the heat of complex formation (which is the desired parameter), the heat of dilution of both binding partners, and the heat of mixing. In order to determine the heat of complex formation, a number of control experiments are required, in order to dissect this contribution from the total measured signal.[47] The heat of dilution of the protein can be measured by injecting buffer into fresh protein solution or may be estimated from the injection peaks near the end of the titration, after saturation is reached, as this dilution is often relatively modest. The dilution heat for the ligand can be measured by identical titration of ligand into buffer in the absence of protein. The heat of mixing is usually small and may sometimes be neglected, or it can be measured by titrating buffer into buffer. Identically matched buffers should be used throughout these experiments to contain components in the sample cell and the titration syringe, because differences in buffer composition may lead to additional heat signals during the titration, which will introduce additional complexity to the measurement of the heat of binding. In order to avoid this, the protein usually is dialyzed or buffer exchanged into the experimental buffer and the test compound dissolved in the stock buffer or that recovered from the dialysis.

A relevant binding model may then be fitted by nonlinear regression analysis to the data to obtain the affinity (K_D), stoichiometry (N), and enthalpy of interaction (ΔH) potentially from a single experiment. The binding enthalpy is estimated from the heat change per mole of added ligand during the early injections. The K_D is measured as the free ligand concentration at the midpoint of the cumulative heat change during the titration. The stoichiometry is calculated from the depletion of total ligand, giving a lower free ligand concentration, in a similar manner to tight-binding inhibition in concentration–response analysis of enzyme kinetic data. Further thermodynamic parameters including the Gibb's free energy change upon binding (ΔG) and the change in the entropy (ΔS) can be calculated from the equation in the succeeding text:

$$\Delta G = RT \ln K_d = \Delta H - T\Delta S \tag{13}$$

where R is the universal gas constant and T is the experimental temperature in Kelvin.

A typical thermogram, showing the raw power data, collected over time (top panel) and the integrated heat signals from each injection (bottom panel) are shown in Fig. 9. Using additional experiments, it is also possible to determine the change in heat capacity for the binding interaction (ΔC_p) by measuring the change in enthalpy at several different temperatures (T) and utilizing the relationship shown in the succeeding text:

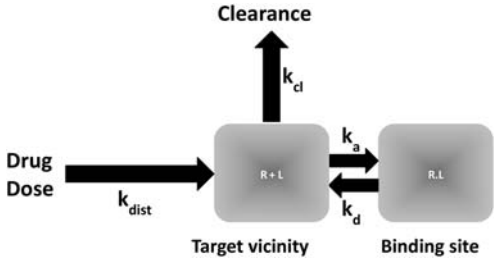

Fig. 9 Simplest scheme relating binding kinetics and PK.

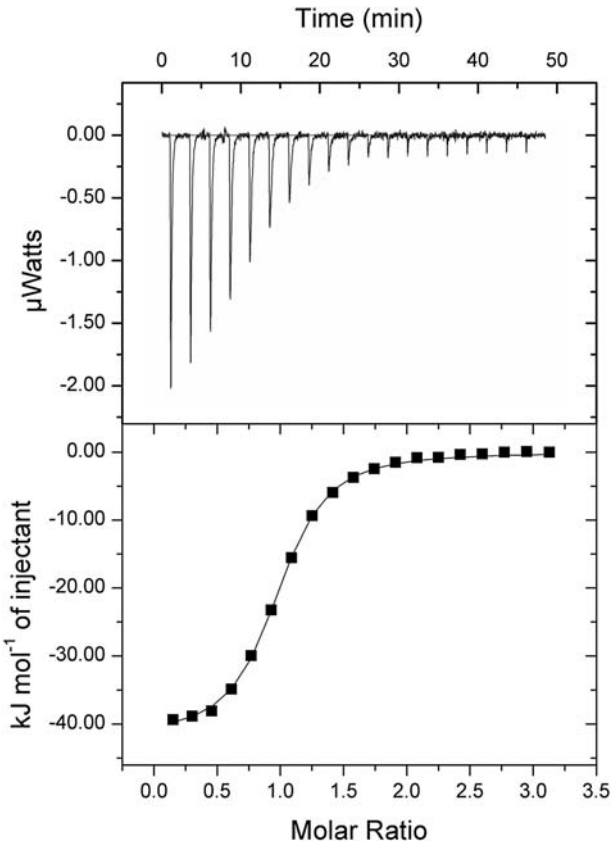

Fig. 10 A typical thermogram from an ITC instrument, showing raw data (top panel) and the integrated heats fitted to a simple 1:1 binding model (bottom panel).

$$\Delta C_p = \delta \Delta H / \delta T \tag{14}$$

The range of binding parameters that can be measured depends upon the concentration of protein required to give a measurable heat signal and the binding affinity of the ligand (Fig. 10). The nature of the thermogram is governed by the unitless parameter, c, whose value is given by the concentration of protein binding sites divided by the dissociation constant.[48] For high-affinity interactions ($c \rightarrow \infty$), all of the injected ligand becomes bound to the target protein until saturation is reached, and the resulting binding isotherm resembles a step shape and so only allows estimation of ΔH° and the binding stoichiometry. Conversely, for low-affinity interactions ($c \leq 0.1$), the thermogram resembles a horizontal trace. In both of these situations, little information is accessible on the value of K_d. In order to obtain reliable estimates of K_d, values of c in the range 1–1000 are suitable to allow nonlinear regression analysis to approximate the magnitude of K_d. In order to adjust the c-value, the protein concentration should be adjusted in order to produce an appropriate value of c. The injection protocol (injection number, injection volume, ligand concentration, and injection timing) often may be created to allow the estimation of ΔH°, K_d, and the heats of dilution in a single experiment.

2.07.3.2.2 Van't Hoff analysis

In the absence of calorimetric data, it is still possible to assess the enthalpic and entropic contributions to the binding affinity. These thermodynamic values may be elucidated using indirect methods, which involve the determination of the temperature dependence of the binding affinity, by analysis using the Van't Hoff equation. This approach allows estimates of entropy and enthalpy to be determined using any method that permits the determination of the binding affinity over a range of experimental temperatures. Eq. (15) shows an integrated version of the Van't Hoff equation, which demonstrates that the enthalpy can be calculated from temperature-dependent changes in the binding affinity, so as long as the constant pressure heat capacity change associated with the binding event (ΔC_p) is known or can be fitted by nonlinear regression. The entropic contribution can then be determined from the Gibbs–Helmholtz equation in the standard manner. In this way, a number of standard laboratory methods to measure K_d, including SPR, microscale thermophoresis, fluorescence, and radioligand binding assays, can be employed to measure the effects of temperature on K_d to determine Van't Hoff enthalpies. For Van't Hoff analysis, the experimental protocol should be designed so that individual binding affinities are measured over a broad enough temperature range (ensuring that the protein does not become unfolded), so that the enthalpy change associated with the binding interaction can subsequently be calculated from the Van't Hoff relationship shown in Eq. (15):

$$ln\, K_1/K_2 = \left(\Delta H_1 - T_1 \cdot \Delta C_p\right)/R \cdot (1/T_1 - - 1/T_2) + \Delta C_p/R \ln T_2/T_1 \tag{15}$$

where K_1 and K_2 are the dissociation constants at different temperatures, T_1 and T_2. R is the universal gas constant and ΔC_p the constant pressure heat capacity change for the binding interaction.

Although the use of the Van't Hoff approach can provide thermodynamic information without the need for a calorimeter, it is not without potential problems. Since the enthalpy is temperature-dependent, the inclusion of the ΔC_p term is required, necessitating the use of the more complex form of the Van't Hoff equation. Obtaining ΔC_p without calorimetric data is difficult since the estimation of ΔC_p from Eq. (14) requires the significant curvature in the Van't Hoff plot to be discernible from apparent curvature resulting from errors in the K_d values. Consequently, this indirect method requires both accurate and precise K_d measurements. Additionally, the temperature-dependent variation of ΔG often is comparatively small, making the derivation of two correlated parameters from the data rather difficult. Often, this results in a relatively large uncertainty in the fitted enthalpy in comparison with the direct, calorimetric approach.

2.07.3.2.3 The thermodynamics of T_m shifting assays

Thermal stability assays have become widespread for both screening and hit characterization over the last few years. In a manner similar to the Van't Hoff approach in the preceding text, it is possible to access affinity measurements from these assays, using the stabilization observed due to ligand binding during protein unfolding. When a ligand binds to the folded state of a target protein, this leads to a stabilization of the folded state. The degree of stabilization may be measured as an increase in the midpoint of the thermal melting transition, T_m. From the observed increase in the measured T_m values obtained in the presence of ligand, compared with control, it is possible to derive an equilibrium dissociation constant for the ligand binding event. The unfolding experiments may be carried out using differential scanning calorimetry or other noncalorimetric methods, where the degree of unfolding may, for example, be measured by fluorescence, circular dichroism, or some other biophysical method.

The equilibrium describing a simple, two-state, reversible unfolding reaction is described by Scheme 4.

Where the equilibrium constant for unfolding, in the absence of ligand, K_0, at any temperature can be described as the relative concentrations of unfolded and folded protein, Eq. (16):

$$K_0 = [U]/[N] \tag{16}$$

The Gibbs free energy of unfolding, ΔG_{unf}, is related to the equilibrium constant for unfolding, K_0, by modification to Eq. (13). It can also be written as difference in free energy between the unfolded and folded state, shown by Eq. (17):

$$\Delta G_{unf} = G_U - G_N \tag{17}$$

Similarly, the equilibrium association constant for ligand binding, K_A, is given by Eq. (18):

$$K_A = [NL]/[N][L] \tag{18}$$

Eqs. (16) and (18) can be combined to yield an equation for K_A at the melting temperature, $K_{A(Tm)}$; see Eq. (19) in the succeeding text:

$$K_{A(Tm)} = \left[K_{0(Tm)} - 1\right]/[L]_{(Tm)} \tag{19}$$

However, Eq.(19) must be modified to account for the transposition of K_A from T_m (the affinity at the melting temperature) to a more relevant temperature for ligand binding, T_{rel}, and hence to calculate binding affinity at a more relevant temperature, such as 25°C or 37°C. This produces Eq. (20):

$$K_{A(Trel)} = K_{A(Tm)} \exp\left[\left(-\Delta H_{L(Trel)}/R\right)(1/T_{rel} - 1/T_m) + \left(\Delta C_{pL}/R\right)(\ln(T_{rel}/T_m) + 1 - (T_{rel}/T_m))\right] \tag{20}$$

where $K_{A(Trel)}$ is the equilibrium association constant at a relevant temperature and $\Delta H_{L(Trel)}$ and ΔC_{PL} represent the ligand binding enthalpy at a relevant temperature and the heat capacity change on ligand binding, respectively.

It is also possible to determine K_D for ligand binding directly from fluorescence-based thermal shift assays using a two-stage process. Firstly, the fluorescence thermal shift data are analyzed to produce the T_m for each ligand concentration. Secondly, the T_m value at each ligand concentration is related to the expected effect for a given K_D, using Eqs. (21) and (22) in the succeeding text:

$$y(T) = y_{F,T_m} + m_F(T - T_m) + \frac{\left(y_{U,T_m} - y_{F,T_m}\right) + (m_U - m_F)(T - T_m)}{1 + e^{\frac{\Delta_U H_{T_m} + \Delta_U C_p (T - T_m) - T\left(\Delta_U S_{T_m} + \Delta_U C_p \ln\left(\frac{T}{T_m}\right)\right)}{RT}}} \tag{21}$$

where y is fluorescence, dependent upon temperature T; $y_{F,Tm}$ is the fluorescence of the probe bound to native protein; $y_{U,Tm}$ is the fluorescence bound to the unfolded protein; m_F is the slope of fluorescence when the probe is bound to the folded protein; m_U is the

$$N \Leftrightarrow U$$

Scheme 4

slope of fluorescence when the probe is bound to the unfolded protein; $\Delta_U H_{Tm}$ is the enthalpy of unfolding; $\Delta_U S_{Tm}$ is the entropy of unfolding; and $\Delta_U C_p$ is the change in heat capacity on unfolding.

$$L_t = \left(e^{\frac{-(\Delta_U H_{T_r} + \Delta_U C_p (T_m - T_r) - T_m \left(\Delta_U S_{T_r} + \Delta_U C_p \ln\left(\frac{T_m}{T_r}\right)\right)}{RT_m}} - 1 \right) \times \left[\frac{P_t}{2} \cdot \frac{1}{e^{\frac{-(\Delta_U H_{T_r} + \Delta_U C_p (T_m - T_r) - T_m \left(\Delta_U S_{T_r} + \Delta_U C_p \ln\left(\frac{T_m}{T_r}\right)\right)}{RT_m}}} + \frac{1}{e^{\frac{-(\Delta_b H_{T_0} + \Delta_b C_p (T_m - T_0) - T_m \left(\Delta_b S_{T_0} + \Delta_b C_p \ln\left(\frac{T_m}{T_0}\right)\right)}{RT_m}}} \right] \quad (22)$$

where P_t is the total protein concentration and T_0 is a reference temperature.

2.07.3.3 Mechanistic Aspects to Binding Thermodynamics

2.07.3.3.1 Enthalpy–entropy compensation

Enthalpy–entropy compensation (EEC) is a widely observed phenomenon that often has been examined in the thermodynamic literature over several years. It appears that EEC is a real and observable effect that has been experienced in many systems and by many groups, but its origin may be due to multiple effects occurring across and within experimental measurements.[49] The fundamental principle is reasonably simple. The binding event between a ligand and a target protein is the result of the disruption of interactions that each free partner has with the solvent and the concomitant formation of new interactions with each other in the complex. In the lead optimization process, the structure of the ligand is changed with the aim of increasing optimal bonding interactions with the target binding site. Generally, this often makes ΔH° more negative. By introducing further or more optimal points of interaction, this will tend to introduce increased order into the complex as a consequence of the alteration, which will generally lead to a more negative component to ΔS°. Frequently, the two opposing contributions to ΔG° have a tendency to be of similar size, in many instances in a number of biological systems. As a result, the conventional medicinal chemistry process of building new chemical functionality into a lead compound to optimize the interactions within the binding site (leading to favorable enthalpy) tends to establish restrictions to movement of the compound and also even the protein (leading to unfavorable entropy). Given that these two contributions to the free energy oppose each other, the overall change in ΔG° of binding often is fairly small, potentially thwarting the intention to increase affinity. Conceivably, this cause of EEC is not unexpected, given that both ΔH° and ΔS° themselves are dependent upon the change in heat capacity, ΔC_p. On the other hand, there are other reasons that may lead to the observation of real or apparent compensation. For instance, errors in the measurement of the enthalpy value can give rise to similar and opposite errors in the calculated entropy. This source of error may initiate from errors in the ligand concentration, which has a larger effect on the estimated ΔH° than on ΔG° or also from the error in the estimated parameter values due to the uncertainty in the nonlinear regression fit. Additionally, there is a moderately narrow window, both in terms of the quantifiable binding affinities that can be determined by ITC and also in terms of the affinity values that are actually physiologically relevant. This narrow window restricts the measurable range of ΔG°, but not ΔH° or ΔS°, and so leads to apparent compensation in plots of ΔH° versus $T\Delta S^\circ$.

The phenomenon of EEC, real or apparent, means that modifying the structure of a test compound often has a larger effect on ΔH° than on ΔG° (usually measured from K_D or IC_{50} values). This has significant repercussions for medicinal chemistry, as there may be variation in ΔH°, but not ΔG°, for structurally related compounds that may form diverse interactions with the protein. In the extreme case, a difference in binding mode, resulting from modifications to the compound leading to different thermodynamic profiles, but with modest change in affinity may be observed using ITC measurements. This is vital so that SAR may be understood correctly in the context of the changed interactions within a common binding mode, rather than being masked by the complicating effects of trying to understand changes across a completely different set of interactions in a switched binding mode.

The role of EEC and how to overcome or exploit it remain a key challenge for the medicinal chemist, when the objective is to make alterations to lead compounds in order to increase the binding affinity for the target protein.

It has been recommended that exploiting both enthalpic and entropic optimization options should be employed to direct lead optimization,[50] and clearly, this seems to be the most efficient approach to improve affinity. Clearly, in order to achieve this, the individual enthalpic and entropic components must first be dissected. Different thermodynamic profiles have often been attributed to different types of molecular interactions, and some simple guidelines have been proposed that chemists may apply; for instance, hydrogen bonds associated with favorable enthalpy, hydrophobic interactions tend to be entropically driven, release of water trapped in the binding sites is entropically favored, and increasing ligand rigidity reduces the entropy loss upon binding. However, even if these simple guidelines always held, there is also no constraint for these different types of interaction to contribute to the binding free energy in a simple and additive manner. This means that it is often complex for the chemist to interpret and utilize these signatures in straightforward prospective design setting.

Moreover, the general rule of thumb illustrated earlier often does not hold up to detailed scrutiny themselves, which adds to the difficulty in attempting to make alterations to lead series by employing enthalpic and entropic signatures, as numerous different contributions may give rise to the observed values.

So, if we expect that EEC, at least to some extent, may occur throughout lead optimization, how can the medicinal chemist make the best use of this accessible information?

The most powerful approach would still be to use a combination of thermodynamic data coupled with high-resolution crystal structures in attempting to decide upon a strategy to attempt to overcome this propensity toward compensation. Some of these strategies have been highlighted previously, for example, directing hydrogen bonds to previously structured regions of the protein or by introducing multiple hydrogen bonds from a single group so that the entropic penalty for constraining the test compound has already been paid.[51]

The existence of EEC suggests that even when specific interactions with likely enthalpic signatures are introduced, it will not be certain that these modifications will result in an increase in binding affinity. This highlights the advantage of having an excellent understanding of the structural features of the binding site and an appreciation of the flexibility and dynamics of the protein both within the binding site vicinity and beyond. Undoubtedly, in the absence of this detailed understanding, designing for improvements in affinity directly utilizing traditional SAR approaches may be more successful.

EEC thus represents a global phenomenon, as it reveals properties of the entire molecules associating or perturbed during the binding event. This includes the water molecules that may be relocated or reorganized during the interaction.

Of course, local increases in entropy upon binding are still possible. Zidek et al.[52] exemplified this via NMR studies on the binding interaction between mouse major urinary binding protein I and the ligand 2-sec-butyl-4,5-dihydrothiazole.

Recognition of the compensatory effects of the contribution of delicate changes in the network of water molecules surrounding a ligand and the resulting thermodynamic fingerprints have been highlighted recently.[53] These are not the water molecules displaced by the ligand upon binding (which also have been previously discussed in detail) but those on the protein surface that encounter the ligand on the exterior.

2.07.3.3.2 Enthalpy–entropy transduction

As described earlier, the measured values of binding enthalpy and entropy often can be complicated to interpret, especially in terms of the fundamental physical forces controlling the binding interaction. Alongside the problem of entropy–enthalpy compensation, another potential reason this can be complex includes understanding the correct binding equilibrium, as there may be other unknown linked equilibria that may confuse the interpretation of the observed thermodynamic data. Of course, errors in the experimentally determined values should also be handled cautiously, in order to avoid overinterpretation.

Another perplexing relationship between enthalpy and entropy that may hinder the use of these values in chemical design has been proposed recently, termed enthalpy–entropy transduction. A statistical thermodynamic examination of the primary conformations of the 1 ms MD simulation for the small trypsin inhibitor, BPTI, showed that three conformation clusters were carefully balanced in free energy. This delicate balance between conformations meant that even fairly small perturbations in the system could alter their probabilities.[54] In this situation, small adjustments to a test compound could, theoretically at least, lead to significant changes in enthalpy and entropy values for the binding interactions but only minor differences in free energy.

Selection for one of these three major conformational clusters may consequently influence the magnitude of the global enthalpy and entropy terms. So the thermodynamic nature of the local driving forces controlling the binding event need not be the same as the global thermodynamic results of complex formation. Hence, there may be a transduction of the local driving force into a different global thermodynamic profile, which leads to the term entropy–enthalpy transduction (EET). This expression basically arises because the protein may be able to switch conformational states upon binding allowing the conversion or transduction of binding enthalpy into entropy or vice versa.

Given that this phenomenon may occur for a small, comparatively rigid protein, such as BPTI, the trend may be even more common in larger, more flexible proteins often encountered in drug discovery. As a result, ligand binding events, even within a chemical series with relatively small modifications, such as generally experienced during lead optimization, may sometimes be expected to display large changes in entropy and enthalpy of binding if alternative conformational states are populated, particularly if the free energy difference between these states is small.

Since EET may be responsible for changes in entropy and enthalpy arising from global effects that may not be predicted from local considerations alone, it may be prudent to explore relevant possible conformational changes by undertaking structural- and dynamics-based studies, in an integrative structural biology approach that may be crucial in really interpreting experimental calorimetric data.

EET also may add to the difficulties in interpreting the measured thermodynamic signatures in the presence of substantial solvent reorganization and also even in systems where prominent EEC occurs.

In the case of solvent reorganization, it is believed that conformational rearrangement from one state to another of comparable free energy results in water release at sites away from the binding site, which may be overlooked when predicting or analyzing the experimental thermodynamic contributions.

In the example of combination with EEC, a series of related compounds binding to the same target protein could access a number of alternative protein conformations of similar free energy but with different enthalpic and entropic contributions. This would then produce the linear compensation plots typically observed during the lead optimization process.

2.07.3.3.3 The complex role of water

The hydrophobic effect may partly explain the binding of test compounds to protein target binding sites, as burial of hydrophobic surfaces on both partners occurs. Medicinal chemists increase the hydrophobicity of compounds as a common approach to improve binding affinity, since this leads to an increase in the total amount of hydrophobic surface area burial. The hydrophobic effect occurs via displacement of water molecules from around the hydrophobic surfaces of both the protein target and the test compound. The

ligand binding interaction can therefore be described by two steps—desolvation and association. Water is present in all biological systems, often at high concentration, but is often not considered in ligand binding experiments, although protein structures often reveal that water molecules are regularly present in binding sites and the role of water in modulating interactions is often discussed in the literature. Understanding the nature of the solvation state of the target protein, especially at the binding interface, is advantageous during lead optimization.[55] Water molecules occupying hydrophilic pockets tend to have the strongest binding affinities as they make optimal hydrogen-bonding interactions with charged amino acids. Hydrophobic cavities tend to contain more weakly bound water molecules. Often, binding interactions dislodge water from the binding surface, with a small gain in free energy (around 2 kcal mol^{-1}) resulting from the favorable entropy associated with this water release.[56] Numerous waters within protein pockets are disordered and exchange rapidly with bulk solvent, and so, these waters may be readily expelled from the pocket. However, some tightly bound water molecules may be more difficult to displace. Displacing these tightly bound waters incurs an enthalpic penalty, which often offsets any entropic gain. These tightly associated water molecules often can be identified from numerous X-ray structures of the same target protein as their positions are preserved and they usually have lower crystallographic temperature factors (*B* factors—which reflect the displacement of atomic positions from a mean value, identifying flexible regions as those with larger displacement from the mean and greater *B* factors) than the mean temperature factor for all waters in the structure. Temperature factors are related to the relative vibrational motion of atoms within the X-ray structure and so may be applied to help identify the reduced movement of these tightly bound waters. Identification of tightly associated water molecules allows them to be dealt with differently to weakly bound waters, during compound design. Tightly bound waters can in effect be considered as part of the protein structure, and often, these water molecules are even called "structural" waters. Design strategies would then not aim to displace these waters, but potentially even look for compounds to form interactions with them. Although the hydrophobic effect has been studied for many years, the full extent and the true role of water in binding interactions are still not fully understood. Several studies have established that hydrophobic interactions can be dominated by either enthalpy or entropy, signifying that simple explanations are not sufficient to fully explain the underlying driving forces.[57,58] Various computational approaches[59] including specialized software such as WaterMap[60] or protocols using freely available software[61] have been used to try to incorporate the effects of the water network into drug design. Additionally, studies using D_2O and osmolytes at a range of concentrations have been used to try to explain binding behavior in cell, where the effects of water are also complicated by molecular crowding effects.[62]

2.07.3.4 Role of Binding Thermodynamics in Selectivity and Efficacy

Several examples have been used to exemplify the role of thermodynamics in selectivity and efficacy, and some of these case studies will be briefly described in the succeeding text.

2.07.3.4.1 HIV-1 protease

Kawasaki and Freire studied the thermodynamic profile for two similar compounds binding to HIV-1 protease and two antitargets, cathepsin D and pepsin.[63] Even a relatively subtle change like the introduction of two methyl groups into a phenyl moiety produced a gain of around 11 kJ/mol in binding free energy, resulting from the favorable enthalpy component for the methylated derivative. This arises due to the optimal filling of the small cavity around the aryl moiety allowing the methyl groups to form advantageous contacts. Alongside the improvement in affinity, the selectivity over pepsin and cathepsin D increased by 13- and 34-fold, respectively. In a second example, the thioether group was substituted by a sulfonylmethyl moiety resulting in a decrease in binding free energy of about 1 kJ mol^{-1}. Although the binding free energy was less favorable, the binding enthalpy increased by approximately 16 kJ mol^{-1}, alongside an almost completely compensating decrease in entropy. X-ray structures show that the added sulfonyl group forms a strong hydrogen bond with Asp30 of the protease, which reflects the increase in enthalpy. The selectivity over pepsin and cathepsin D increased by seven- and ninefold, respectively. It was suggested that maximal selectivity could be achieved by establishing few but strong hydrogen bonds in the interaction with the target protein.

It was reasoned that suboptimal H-bonds formed with antitarget proteins are penalized resulting in a larger decrease in the binding free energy for the off-target proteins. This example suggests that as the enthalpic contribution to binding free energy is increased, the compounds are more specific for the primary target. Supporting this view is the fact that of the four compounds, it is the one with the most favorable binding enthalpy that is the most selective.

2.07.3.4.2 Matrix metalloproteinase 12

Another example demonstrating matrix metalloproteinase 12 (MMP12) inhibitor optimization, with a focus on selectivity over MMP13, shows a similar effect.[64] Highest selectivity was observed for the compound with the largest enthalpic component (around -40 kJ mol^{-1}) although this was not the highest affinity compound for the MMP12 target. Although these observations were on a limited congeneric compound set, the results further reinforce the hypothesis that the binding enthalpy has higher contribution to off-target selectivity.

2.07.3.4.3 Thrombin

Optimization of sulphonamide inhibitors of thrombin containing triazole and tetrazole moieties, with selectivity over trypsin, may also fit with the hypothesis of binding enthalpy being important for selectivity.[65] The lead compound showed over 800-fold selectivity versus trypsin, and selectivity over tryptase and chymase was also favorable. The lead compound was found to bind to

thrombin with binding enthalpy of around $-38\ \mathrm{kJ\ mol^{-1}}$ and a slightly unfavorable entropy. In this study, only the lead compound was characterized in terms of the thermodynamic components, but the high-selectivity and enthalpy-driven nature of binding to the target fits with the proposed relationship between these properties.

2.07.3.4.4 HMGCoA reductase

A retrospective analysis of the binding thermodynamic profiles of marketed statins inhibiting 3-hydroxy-3-methylglutaryl coenzyme A (HMGCoA) reductase suggested there may be advantages to enthalpically driven binding.[63] The study showed a correlation between market entry time and the enthalpic contribution of the binding affinity for the statins, a trend that has also been observed for HIV protease inhibitors[63] and inhibitors of farnesyl pyrophosphate synthase.[66] First-in-class drugs were entropically driven, with unfavorable or very low enthalpic components in each of these systems.

New drugs acting on the same target for the same biological effect must show advantages over existing therapies. In these cases, new drugs showed successively increased binding enthalpy. Of course, binding enthalpy alone may not explain the success of the later compounds, as other factors shown by the more enthalpic compounds may contribute to improved physicochemical properties, such as lipophilicity and solubility. These later drugs were all optimized without a focus on binding thermodynamics, and a large number of other parameters may have influenced the success, but the increased enthalpy contribution during drug evolution for each of these systems is still significant and certainly merits further investigation.

The contribution of enthalpy to selectivity may also be prevalent in the statin example, as hepatoselectivity is desired for statin drugs to avoid myalgia, which has been suggested to be linked to myocyte HMGCoA inhibition. Consistent with this, the most enthalpic binder, rosuvastatin has the highest hydrophilicity and hepatoselectivity, with almost 1000-fold selectivity over the myocyte. The hepatoselectivity of the less enthalpic binding compounds (e.g., pravastatin, atorvastatin, and cerivastatin) is lower than that of rosuvastatin, showing around 400-, 100-, and fourfold hepatoselectivity, respectively.

2.07.3.4.5 Aldose reductase

A further example suggesting a link between binding enthalpy and selectivity may be from work on aldose reductase (ALR2) and selectivity of inhibitors over aldehyde reductase (ALR1).[65] X-ray crystallography grouped the six studied compounds into those protruding into the specificity pocket and others leaving the pocket closed. The X-ray structures suggested that the favorable enthalpy displayed by IDD393 might result from specific polar contacts between the nitro moiety of the compound and Ser302 in the protein. Sorbinil was shown to form a strong H-bond with the backbone NH of Leu300. In both of these examples, the increased selectivity over ALR1 is suggested to come from the specific enthalpic engagement with the primary target that may be suboptimal for binding to ALR1.

Although the correlations between selectivity and binding enthalpy are not completely consistent across the entire dataset, this may arise from the differences in physicochemical profiles for the two types of ligand classes. Those compounds penetrating into the selectivity pocket are carboxylic acids, sharing similar pharmacophoric features, while those binding outside the pocket are small, weak NH acids, showing less pharmacophoric elements compared with compounds in the first cluster.

The correlation between enthalpy and selectivity may not always be clear, and obtaining thermodynamic profiles may not always enable the development of selective compounds. Undoubtedly, there will be a variety of factors that contribute toward selectivity and efficacy, and optimizing enthalpy alone will not be sufficient. However, the hypothesis first presented by Freire[67] provides a framework for attempting to increase ligand selectivity by improving protein–ligand complementarity. Precisely oriented interactions, accomplished from enthalpic binding, tend to result in a higher bias toward the primary target, leading to potentially less promiscuous compounds. It seems that there is already some evidence across a number of diverse ligands for several different validated drug targets (including HIV protease and HMGCoA reductase) showing selectivity profiles that support this concept. Only by exploiting this observation in compound optimization will the strength of this hypothesis be truly tested.

2.07.3.5 Optimizing Enthalpy

Observations by Freire[67] that for two important drug classes, the statins and the HIV protease inhibitors suggested that the best-in-class drugs tended to have the most favorable binding enthalpy. Although there are a large number of other factors that lead to a best-in-class molecule, this focus on thermodynamics initiated a drive by many pharmaceutical companies to begin to include thermodynamic data in some early-phase drug discovery decision-making.

Potentially, thermodynamic signatures could be used to identify compounds optimized in a number of different ways, including flexibility, helping to minimize drug resistance due to mutation occurring at the compound binding site[68]; specificity, reducing off-target effects caused by nonspecific binding interactions;[69] and water solubility, maximizing the ligand efficiency of polar interactions.[70]

These thermodynamic signatures have been used to produce guidelines that have been suggested may help to exploit thermodynamic data for advancing lead optimization.[67,69] Simplistically, hydrogen bonds tend to produce favorable enthalpy changes, hydrophobic interactions yield favorable entropic contributions, and conformational changes are often entropically unfavorable.

Although simplistic, these signatures and guidelines can be used during lead optimization to formulate strategies for new chemical design and to monitor the success of these strategies. For instance, the successful introduction of hydrogen-bonding interactions should lead to increases in potency potentially driven by favorable enthalpy gains, whereas ligand rigidification should reduce

entropic losses. Thus, the expected thermodynamic changes suggest that the strategy was successful, and differences from the profile expected suggest that structural information on the complex may be informative in understanding unexpected SAR.

Although the combination of ITC and X-ray structure with medicinal chemistry design is clearly a powerful tool, examples have emerged recently that suggest that thermodynamic-guided lead optimization is difficult to implement in prospective compound design.[71] Complicating factors such as EEC and transduction and the role of water have been highlighted in the preceding text, and it is important that these aspects should be considered carefully when trying to optimize binding enthalpy.

2.07.3.6 Role of Binding Thermodynamics in Fragment-Based Drug Design

Since fragment-based lead generation has become a successful paradigm for drug discovery, biophysical methods have established an even wider influence, since they are frequently used as the basis for primary fragment screens, due to their sensitivity in detecting small, weak compound binding. The foundation of fragment-based drug discovery (FBDD) is that small fragments sample chemical space more effectively than large molecules and therefore provide more effective and potentially more diverse start points for lead generation. However, since fragments often lack the substituents required for high affinity, the link with biophysical detection methods is ideal, as these methods are often preferred over biochemical assays to discover and quantify the weak binding that these fragments often demonstrate.

Some studies suggest that fragments bind to a target binding site with an average of two hydrogen bonds, which display close to optimal geometry.[72] Sites within a protein that permit optimal hydrogen-bonding interactions in a hydrophobic environment are frequently described as hot spots. From estimation of the free energy increase of hydrogen bond formation (around 1–2 kcal per mol per H-bond), as opposed to apolar desolvation, which is usually smaller (usually less than 0.25 kcal per mol per heavy atom), comes the suggestion that fragments require optimal hydrogen bonds in order to attain measurable binding affinities. This may be the basis of a benefit frequently asserted in fragment-based drug discovery—that fragment binding is inherently enthalpically driven—arising from the formation of these few but optimized polar interactions within the hot spot of the protein binding site.

Understandably, the effects of ligand size on the underlying thermodynamic contributions to the binding free energy change have been studied, and it has been demonstrated that these contributions show different effects when considered in the context of compound size, molecular weight, or heavy atom count. The entropic component becomes progressively more dominant with increased size of compounds, whereas enthalpy seems to lack a correlation with compound molecular weight. So what are the reasons for this behavior? There may be several explanations that may help explain these observations. As compound molecular weight rises, the probability for a corresponding group of H-bond donors and acceptors declines, thus lowering the likelihood for forming polar interactions. Another possible cause for the number of hydrogen bonds to remain essentially unchanged with compound size may be the constrained motion of the protein and compound with increasing numbers of polar interactions. The contribution from the unfavorable entropic penalty thus limits any enthalpic advantage of added polar interactions.

Additionally, larger compounds are likely to have increased amounts of apolar surface area, which means that the involvement of apolar desolvation in the contributing to the binding affinity becomes more significant.

These observed effects and the potential reasons behind them help to formulate a possible strategy for the use of thermodynamic data in fragment optimization. For example, suppose the most enthalpically driven, small polar fragments that often bind to protein hot spots could be identified, from the considerations in the preceding text, these compounds might be preferred start points for further optimization than fragments that may be entropy-driven. Starting from these interaction-rich fragments should theoretically be an advantage because affinity may be gained straightforwardly via typical structure-based expansion of these fragment cores, where the increase in affinity is brought about by an entropically favorable component, which is usually easier to incorporate. Analysis of 39 fragment to lead campaigns undertaken by the fragment-focussed company Astex showed that the positions of atoms in a starting fragment core are frequently well preserved in the final, larger, and optimized leads. This highlights that the original polar interactions, responsible for the enthalpy-driven nature of the fragment binding, are conserved during lead optimization.[72]

There are additional benefits to examining fragment thermodynamic profiles during the optimization process; for example, the ability to detect conformational changes that might occur as fragments is grown and also in assisting in identifying the most appropriate strategy for extracting a contribution to the binding free energy from water molecules in the binding site. Fragment growing might result in ligand-induced protein conformational changes as additional substituents are added that may contact the protein and constrain it to adopt alternative conformations. Should these differences in conformation or binding mode occur, then the thermodynamic signatures related to these different binding modes may be detected using ITC. This is an advantage of ITC over other affinity only techniques, since these methods for measuring binding affinity may, in the absence of structures, lead to misleading SAR, as changes in binding mode may be missed if there is no concomitant change in binding free energy change.[73]

The presence of high-energy water molecules located within a protein hot spot signifies that large desolvation energy may potentially be available if displacement of these waters can be achieved. Since it may be rather complicated to achieve displacement of these water molecules, which have large entropic terms, by standard fragment optimization design strategies, prioritizing fragments that previously displace these waters would seem an attractive approach. However, it can be difficult to categorize these water molecules and to identify those fragments that displace them, but the use of structural B factors and the simple enthalpy–entropy compensation plot can give some insight into which fragments achieve this displacement and should be prioritized for optimization.[74]

2.07.3.6.1 Experimental considerations for fragment ITC

Due to the weak affinity of fragment binding and potentially low solubility relative to achievable aqueous concentrations and sometimes even low-enthalpy values, characterizing the thermodynamic contributions to fragment binding can often be challenging. As a result, direct titrations with fragments often lead to low *c*-value (where *c* is the unitless parameter that governs the shape of the binding isotherm, whose value equals the stoichiometry of the interaction × the macromolecule concentration in the cell divided by the K_D value) situations, because the binding affinity is frequently only in the low mM to high μM range and often the achievable protein concentration only around tens of μM. This results in *c*-values potentially around 1 or lower (whereas values between 5 and 100 are ideal), which means that in order to resolve reliable binding parameter values, necessitates final test fragment concentrations that are significantly in excess of the K_D value. The ability to reach these concentrations so that a significant degree of saturation is reached depends upon the aqueous solubility of the fragment being used. In the low *c*-value regime, the ITC method resembles other traditional binding techniques, which do not permit differential measurements. Another disadvantage of experiments conducted under low *c*-value conditions is that the stoichiometry value must be arbitrarily fixed, and so, information about the number of binding sites from other sources should be used if possible.[75]

Thus, low *c*-value experiments with fragments may be challenging, but there are some modifications that can be made to standard ITC experimental methods that can be used to access some of the individual binding parameters, either directly or indirectly, to allow full characterization of the binding interaction.

Competition or displacement experiments may be carried out, if a suitable tool compound is accessible, which is known to compete for the binding site, and for which the binding affinity is measurable and is in the range of around 10–100 nM. This reference ligand is first characterized in a traditional direct titration in order to obtain its thermodynamic parameters. Next, the tool ligand titration is repeated but this time in the presence of a known, fixed concentration of the test fragment. This methodology allows the measurement of the degree of competition caused by the presence of the fixed concentration of fragment, and so consequently, the fragment binding parameters may be indirectly determined. Thorough descriptions and applications of the technique and the associated data analysis procedures are available.[76,77]

As mentioned earlier, there are certain requirements that the reference compound must satisfy in order to get reliable, accurate, and precise results. Obviously, the reference ligand has to compete with the binding of the fragment, and ideally, the enthalpy of the binding interaction should be significantly different to that of the fragment. Consideration should also be given to the fact that errors in the binding parameter values of the tool compound will be compounded during the calculation of the parameter values for fragment binding. Despite these issues, however, when carried out cautiously, both the low *c*-value methods and displacement experiments can provide comparable results, indicating the robustness of both methods.[78]

Finally, an adaptation to the typical displacement method has been described, termed single-injection thermal extinction (SITE), whereby it is feasible to determine relative enthalpies for fragments, compared with a reference ligand using only a single injection. Even though this does not give exact enthalpy values and the binding affinity must be measured separately, it offers a rapid method for identifying those fragments with a favorable enthalpic binding profile.[79]

2.07.3.7 Future Trends for Thermodynamic Characterization

Theoretically at least, it would appear that thermodynamic signatures are valuable in guiding compound selection and lead optimization. However, due to the many different contributing factors to both the enthalpic and entropic components, it has proved difficult to use these fingerprints effectively in prospective drug design. Rather, the combination of thermodynamic data with structural information has been used to postrationalize the optimization process. So the role of thermodynamics may be more subtle than previously believed. Certainly, ITC still has a major role to play in early lead identification and optimization. It is still regarded as one of the most powerful methods for characterizing both target proteins and tool ligands in terms of functionality, concentration, and affinity. It can also highlight important changes in the binding interactions that other affinity only methods may miss. The additional measure of the binding enthalpy is therefore useful in identifying unexpected changes in enthalpy that may indicate potential changes in binding mode that could lead to comparisons across different structure–activity relationships, which will ultimately confound optimization. So, ITC will remain useful during the early stages of drug discovery. But what of the future for thermodynamic-guided lead optimization? By combining thermodynamic data, especially for systems that show unexpected or unusual profiles, with structural information and computational methods that may enable the underlying intermolecular interactions to be better understood, we may begin to implement approaches where manipulation of enthalpic or entropic contributions to produce more favorable molecules may be successful.

2.07.4 Use and Misuse of Efficiency Measures in Drug Discovery

LEMs are used in drug discovery to normalize affinity or activity with respect to various physicochemical properties, and there has been debate in the literature recently over the value of using such metrics. In the succeeding text, we will provide an overview of the different metrics and will comment on the application in prioritizing and optimizing lead compounds.

The principle for employing LEMs is based around a potentially more relevant comparison of compounds than by considering affinity alone. This is because affinity is often linked to molecular size and so introduces a bias for the selection of larger compounds during lead optimization. Of course, affinity is not the only factor that has to be considered during lead optimization, and the

physicochemical properties of leads are also important. For example, it is usually considered that excess molecular weight or lipophilicity is associated with poor PK and toxicity, associated with off-target binding, and so should be constrained during ligand optimization. However, affinity for the primary target also increases with these factors, and so, modifying these variables should be carried out in the most efficient manner.

The role of different physicochemical properties for leads and drug-like compounds was highlighted some time ago by Lipinski,[80] and since this seminal paper, the "rule of five" has been a valuable guide for establishing the physicochemical boundaries associated with reduced attrition at the later drug discovery stages. A recent article by Gleeson emphasized the importance of selecting the most appropriate hits and for tracking increases in molecular weight and lipophilicity alongside affinity during lead optimization, as almost all ADMET parameters were shown to worsen with increasing compound size and lipophilicity.[81]

However, the use of LEMs should be employed in the knowledge that it is free concentration and affinity that determines the extent of target engagement, not the ligand efficiency value itself.

2.07.4.1 Common LEM

2.07.4.1.1 Ligand efficiency

Ligand efficiency (LE), the concept for which was first described in 1999,[82] is one of the most commonly used LEMs and is defined as the affinity of the ligand divided by the number of heavy (nonhydrogen) atoms,[83] given by the expression

$$\mathrm{LE} = -\Delta G/n_{\mathrm{HA}} \approx 1.4^{*}\mathrm{pIC}_{50}/N_{\mathrm{HA}} \tag{23}$$

where N_{HA} is the number of heavy (non-H) atoms and pIC_{50} is the negative logarithm of IC_{50}.

Its use and popularity was linked to the growth of fragment-based drug discovery and the desire to bring forward compounds into the optimization process that are smaller and with lower lipophilicity.

2.07.4.1.2 Other size-based metrics

Table 2 shows a number of other LEM that are dependent upon heavy atom count

As is evident from Table 2, efficiency metrics are mathematical functions that attempt to describe how efficiently potency is achieved relative to some other variable. Also evident from the table, which does not list all LEMs, is that there are many composite metrics that have been proposed to help medicinal chemists improve success rates by moving away from simple potency optimization. The premise of LEMs is that they encourage multiparametric optimization as they include other parameters that may be important to consider during compound optimization.

2.07.4.1.3 Ligand lipophilicity efficiency

Another frequently used LEM is ligand lipophilicity efficiency (or lipophilic ligand efficiency) (LLE) or lipophilic efficiency (LipE):

$$\mathrm{LLE} = (\mathrm{pIC}_{50} \text{ or } pK_i) - (\log \Delta \text{ or } C\log P) \tag{24}$$

$$\mathrm{LipE} = (\mathrm{pIC}_{50} \text{or } pK_i) - C\log P \tag{25}$$

where $C\log P$ is the calculated octanol–water partition coefficient and $\log D$ is the measured distribution coefficient.

These LEMs attempt to account for the lipophilicity of the compound rather than the molecular size and may be considered more useful than size-based metrics when trying to achieve optimal ADMET properties. Compounds with high LLE therefore are suggested to gain affinity through direct specific interactions, minimizing the probability for nonspecific interactions. In order to combine the effects of molecular size and lipophilicity into a single efficiency metric, lipophilicity measurements have been combined with potency and molecular size in two further LEMs: the Astex ligand lipophilic efficiency ($\mathrm{LLE}_{\mathrm{AT}}$) and the lipophilicity-dependent ligand efficiency (LELP):

$$\mathrm{LLE}_{\mathrm{AT}} = 0.11 - \left[\ln(10).RT(\log P - \mathrm{pIC}_{50})/N_{\mathrm{HA}}\right] \tag{26}$$

$$\mathrm{LELP} = C\log P/LE \tag{27}$$

Table 2 Selected commonly used LEM, with their abbreviations and definitions. HAC is heavy atom count (=N_{HA}), MW is molecular weight, and Δ represents a change in the associated parameter

Name	*Abbreviation*	*Definition*
Maximal ligand efficiency	%LE	(LE/max LE) × 100
Size-independent ligand efficiency	SILE	$1.4 \times \mathrm{pIC}_{50}/\mathrm{HAC}^{0.3}$
Scaled ligand efficiency	LE_scale	$0.0715 + 7.5328/\mathrm{HAC} + 25.7079/\mathrm{HAC}^2 + 361.4722/\mathrm{HAC}^3$
Fit quality	FQ	LE/LE_scale
Binding efficiency index	BEI	pIC_{50}/MW
Group efficiency	GE	$-\Delta\mathrm{pIC}_{50}/\Delta HAC$

The uptake of LEMs into the considerations of the medicinal chemist was driven by both the established use of the rule of five guidelines and the increasing application of fragment-based lead generation and its equivalent rule of three.[84] Ligand efficiency became a convenient way to track and prevent property inflation during optimization programs, as it offered a simple calculation to avoid making compounds unacceptably large.

2.07.4.1.4 Enthalpic efficiency

As described earlier, the measurement of ΔH potentially offers a direct estimate of the heat change associated changes in noncovalent bonding upon formation of the protein–ligand complex. Therefore, taken in its most simplistic form, a favorable enthalpy for ligand binding suggests that stronger or an increased number of bonds are formed when moving from the free to the bound state. As we have seen, it is very difficult to design compounds that are able to form new noncovalent bonds in the complex. If we take the example of hydrogen bonds, then there are relatively few examples where new bonds have been introduced in a rational and expected way in order to increase affinity. This is due to the precise orientation and distance constraints on both donor and acceptor moieties, which dictate the geometry of optimal hydrogen-bonding interactions introduced in the binding site. Since modification of small molecules to maintain existing interactions while introducing new ones is difficult to achieve from a rational design perspective, often, new hydrogen bonds arise by chance, as the medicinal chemist often is focussed upon increasing the entropic contribution to the binding free energy change. This may, however, suggest that the greatest value from ITC is in the measurement of the ΔH term, as this allows the monitoring of increasing bonding interactions.

Clearly, the exploitation of the binding enthalpy is most important when comparing and contrasting molecules of similar structure binding to the same target binding site, and so, it is the difference in enthalpy values, $\Delta\Delta H$, which is most informative. This is due to the fact that the effects of solvent removal from the surfaces buried during the formation of the complex will mostly cancel for compounds that are closely related structurally. Hence, a potential criterion for guiding subsequent optimization would be to prioritize those compounds with the most favorable comparative enthalpic contribution.

In fact, the use of the enthalpic component has been expressed as comparable to the use of other LEM to prioritize ligands for further optimization, and enthalpic efficiency, EE (defined in Eq. (28)), was introduced in order to compare compounds according to their net bond forming capability:[85]

$$\mathrm{EE} = \Delta H/N_{\mathrm{HA}} \tag{28}$$

So, it may be advantageous to calculate the enthalpic efficiency or break this down further to provide a measure of the specific enthalpic efficiency of polar groups, $\Delta H/N_{\mathrm{polar}}$, since it is the favorable interactions from the polar groups with the target protein that contribute to affinity, not the mere presence of a polar group in the ligand. Similar to many of the described LEMs, enthalpic efficiency can be corrected for molecular size to produce a size-independent enthalpic efficiency, SIHE, $(\mathrm{p}K_{\mathrm{H}}/40)\cdot {H_{\mathrm{A}}}^{0.3}$, where $\mathrm{p}K_{\mathrm{H}}$ is $-\Delta H/2.303 \bullet RT$.[86]

The maximum potential binding enthalpy has been suggested to decrease with molecular size, leading to the hypothesis that enthalpy-driven binding may be applicable only to smaller compounds. From this analysis, it seems that enthalpic optimization may represent a suitable strategy only while the molecular size of the compounds requiring optimization remains below around 30 heavy atoms.[87] After this size, it appears that affinity improvement may only be possible by predominantly increasing entropy, until solubility limits, protein binding and clearance limits, and other physicochemical property issues prevent further entropic gains from being achievable.

Clearly, EE has not replaced other more established LEMs, and it would not be appropriate to switch from one metric to another without understanding the thermodynamic basis of the metrics and the information they provide, but EE was proposed to add to the toolbox for facilitating the decision-making process.

2.07.4.1.5 Kinetic efficiency

In 2011, we proposed[88] that the kinetic parameters for the binding interaction per atom or kinetic efficiency (KE) could be used to complement ligand and enthalpic efficiencies:

$$\mathrm{KE} = \tau/N_{\mathrm{HA}} = \tau_{½}/(0.693N_{\mathrm{HA}}) \tag{29}$$

The application of kinetic data and the KE metric may be best applied later during lead optimization as rapid kinetics are often exhibited by low-molecular-weight compounds, which demonstrate low-affinity compounds, and so, there is often little discrimination in residence times. Once differences in residence time become apparent, for compounds from different chemical series where differences in molecular weight may still be significant, KE may be used to rank them in order of potential later-stage optimization and developability. Use in this way may be compared with the similar use of enthalpic efficiency, as it is often difficult to determine the binding enthalpy for small, weak binding hits.

In terms of binding kinetics, it may also be possible to dissect the ligand efficiency into an association efficiency and an alternative expression for a dissociation rate-based efficiency metric, for example, from Eq. (23) in the preceding text:

$$\mathrm{LE} = -\Delta G/nHA = RT\ln(k_{\mathrm{d}}/k_{\mathrm{a}})/nHA = RT\ln k_{\mathrm{d}}/nHA - RT\ln k_{\mathrm{a}}/nHA \tag{30}$$

However, we believe there is more value in utilizing dissociation rate measures as medicinal chemistry efforts can only modify the ligand in an effort to alter association kinetics, and usually, there is a more limited range of accessible values (typically spanning

three to four orders of magnitude), whereas it may be easier to modify the interactions formed by the ligand in the complex (and the accessible rate constant values often cover a wider dynamic range (often over six orders of magnitude)).

LEMs have been used increasingly to guide the hit to lead and lead optimization processes as they relate changes in certain measured parameters to changes in compound molecular weight and so may offer an advantage over the absolute parameters. The use of these metrics has been supported by retrospective analysis suggesting that many recently approved drugs have high ligand efficiency values for their targets, often due to the fact that the metrics have been used to restrict the previous tendency for uncontrolled property inflation.

However, there have been a number of publications that have questioned the use and even the validity of certain LEM.[89,90]

Some of the concerns may well be at least partially justified; for example, some drugs have low ligand efficiencies, LEMs have no power to resolve between different atom types or functional groups, and the increase in the number of different metrics may have introduced more complexity than the metrics themselves may be able to reduce.

Of course, these metrics should be applied cautiously and should not be employed as fixed rules, but as simple guidelines that may help to frame the optimization process in terms of kinetic or thermodynamic parameters, with a view to restricting the inflation of molecular weight and lipophilicity. They should be viewed as pragmatic tools that can offer insights into the evaluation of hits and leads, beyond affinity alone. What should be avoided is an excessive reliance on metrics, without also undertaking a thorough analysis of the available data.

In defense of LEM, they have been compared with fuel economy (miles/gallon), which allows comparison of the efficiency of motor vehicles. Of course, fuel efficiency is not the only criterion used when choosing a car, but it is one factor that helps the decision-making process when there are a large number of different factors to consider. LEM should be viewed in the same manner and the limitations and the application of the different metrics understood. For example, size-independent metrics should be preferred when comparing compounds of contrasting sizes, and consideration of the target binding site should also be kept in mind when thinking about LEMs, as lead compounds binding to large binding sites will naturally tend to have lower ligand efficiency than lead compounds binding to smaller binding sites. The short article by Reynolds[91] and the references contained within are recommended for a thorough appreciation of the role of LEM.

2.07.4.2 Future Trends for Application of LEM

LEMs will continue to be used as a tool for optimizing fragments and small molecules and applied by medicinal chemists during the optimization process. It is hoped that the recent debate in the literature around the validity and usefulness of these metrics will help to further the understanding of the physical basis of the various LEM calculations and the scaling or offsetting applied to the measured activity. Ultimately, the role of LEMs is to help to identify compounds that outperform the observed trend in the data, with respect to a chosen risk factor, so that these compounds can be prioritized for further optimization. It may be that there will be a move toward a least square-based approach for identifying these compounds as our understanding of the limitations of LEMs is increased, as suggested by Kenny et al.[89] But regardless of how lead compounds are actually identified, the general guiding principle that drugs should be as hydrophilic as possible while maintaining efficacy remains a key strategic objective in drug design.[92]

2.07.5 Summary

Ligand binding thermodynamics describes the differences in free energy between the two ends of an equilibrium, while binding kinetics are dependent upon the free energy barriers between those two states. Clearly, an appreciation of both is important to fully understand binding interactions and to maximize the opportunities for modifying compounds for improved activity and desired thermodynamic and kinetic profiles.

We are beginning to appreciate how these properties might be connected to both binding affinity, efficacy, and selectivity, and studies have been presented where attempts have been made to explain postrationally or utilize prospectively the kinetic and thermodynamic components to improved compound properties. Optimizing compounds via improved kinetics and/or thermodynamics remains a difficult task, and tools and guidelines for helping to do this are attractive and increasingly used. Some of the most widely used LEM have been discussed and some potential pitfalls with their application.

By increasing our understanding of protein–ligand interactions from a kinetic and thermodynamic perspective and by applying this learning throughout the optimization process, with a view to control undesired properties such as increasing hydrophobicity and molecular weight, we will become more successful in designing safe and effective medicines.

2.08.1 Introduction

The identification of new chemical leads is a key step for the innovation and success in small-molecule drug design in drug discovery programs.[1] Over the past two decades, the pharmaceutical industry has committed to high-throughput screening (HTS) approaches through screening large libraries of compounds (up to 10^6) for lead discovery.[2–4] However, most HTS libraries tend to have a limited coverage of chemical space and structural diversity, leading to the difficulty in discovering ideal hit leads for drug development in this "finding a needle in a haystack" game.[5,6] Moreover, unfavorable ADMET (absorption, distribution, metabolism, excretion, and toxicity) drug properties and potential ambiguity about how best to increase potency are also obstacles for subsequent hit-to-lead development.[7] Obviously, the inherent limitations of HTS result in high attrition rates in drug discovery. Hence, there is an urgent need for new lead generation strategies to address such issues.[8]

With the scientific and technological advances in screening fragments, fragment-based drug discovery (FBDD) has emerged as an alternative to HTS in hit identification and hit-to-lead discovery.[9,10] Taking advantages of both random screening and structure-based drug design, FBDD constructs novel lead structures from weak-affinity fragments. Fragments are typically "rule of three" (RO3) compliant: MW $\leq$ 300 Da, LogP $\leq$ 3, and hydrogen bond acceptors/donors $\leq$ 3.[11] These properties allow a wider exploration of chemical space compared with larger lead-like compounds and this FBDD strategy has demonstrated a higher binding efficiency, higher hit rate, and more effective optimization capability relative to HTS. Notably, this approach has already yielded one marketed drug (ie, vemurafenib) within 6 years from concept to FDA approval, and a dozen of preclinical and clinical drug candidates in development to date.[12]

2.08.2 Fragment-Based Screening (FBS)

To date, an increasing number of commercial companies, such as ChemBridge, ChemDiv, Emerald Bio, and Enamine, provide a variety of well-defined fragment libraries for screening of new hits. Since the identification of fragments is the starting point for FBDD, selection of a suitable fragment-based screening assay is particularly critical.[13] However, fragments inherently have relatively weak binding affinities (medium μM to low mM range), thereby requiring highly sensitive techniques. The past decade has witnessed a huge development of FBS techniques, providing us with a wide range of screening methods for hit and hit-to-lead identification.[14] Therefore, the ability to choose the most suitable FBS techniques for a specific drug discovery program is especially important. To this end, it is imperative to understand the characteristics of each FBS approach, including its advantages and disadvantages.[15] Herein, the biophysical techniques, including nuclear magnetic resonance (NMR), X-ray crystallography (XRC), surface plasmon resonance (SPR), mass spectrometry (MS), thermal shift assay (TSA), and isothermal titration calorimetry (ITC), as well as other screening methods such as high concentration screening (HCS) and virtual screening (VS), are enumerated further; While their advantages and disadvantages are also discussed.

2.08.2.1 Nuclear Magnetic Resonance

NMR is one of the widely used approaches for FBS, which is able to detect very weak interactions (mM range) between a target and a fragment with unmatched sensitivity.[16–18] The various NMR techniques currently available for FBDD can be divided into two major groups: target-based and ligand-based approaches.[19] Target-based NMR monitors signal changes (mainly chemical shift) in isotopically (^{15}N or ^{13}C) labeled target protein upon ligand binding.[20] Other than the high-affinity fragments identified, the binding site can also be precisely localized and partially characterized with this method.[21] However, it is only applicable for proteins with high purity, suitable solubility, and modest molecular weight (typically smaller than 30–40 kDa).[22,23] In addition, it also requires large amounts of protein and a relatively long acquisition time.[24] Ligand-based NMR detects NMR parameters' changes in ligand upon binding to a target using relatively little protein. Moreover, ligand-based NMR allows rapid fragment identification, with target protein not isotopically labeled and its molecular mass practically unlimited.[25] However, ligand-based NMR is not able to provide the detailed information about the actual binding pocket. Foremost, once the fragment binds tightly with the target protein, there exist false negatives.[26]

2.08.2.2 X-ray Crystallography

As a primary screening method in construction of fragment library, XRC can provide detailed information regarding protein–ligand interactions like NMR spectroscopy.[27–29] This approach includes the following steps: The soaking of crystals in a solution containing fragments; X-ray data collection and processing; ligand identification by analyzing electron density maps. While XRC possesses a lot

of advantages compared to other FBS approaches, such as avoiding false positives, applicability to large proteins, and more importantly, providing detailed binding information with high resolution, there are also some disadvantages. Firstly, false negatives may occur because of crystal packing that would hamper fragments from entering into the protein crystal. Secondly, the throughput is low, mainly owning to the requirement for a crystallized protein. Thirdly, it is not feasible to quantitatively assess the binding affinity, due to the lack of inhibition data. Fourthly, despite recent several techniques and tools are available to improve crystallizability, crystallization of difficult targets remains a challenge, making screening by XRC sometimes impractical. Fifthly, due to poor crystallizability, resolution may be a significant problem in structural determination. In addition to the aforementioned shortcomings, low affinity requires high fragment concentrations, thereby leading to potential solubility issues.

2.08.2.3 Surface Plasmon Resonance

SPR, once known as a powerful and versatile tool investigating biomolecular interactions, is now emerging as a popular method for primary screening in FBDD.[30–32] In general, fragments are allowed to flow past a biosensor (usually a thin gold film) onto which a target protein is immobilized. Then the changes in the refractive index of the biosensor are observed upon ligand binding. Intrinsic advantages and recent technical advances, such as multiple biosensor channels, have made SPR a rapid, efficient, high-throughput, and cost-effective methodology for FBS. Compared to other biophysical and biochemical FBS methods, SPR has the following merits: Consuming less protein (as little as 25–50 μg) while keeping a high sensitivity to fragments with molecular weight as low as 100 Da; capable of providing kinetic and thermodynamic information of ligand binding, which is useful for later hit-to-lead optimization.[33] Despite these advantages, more attention should be paid to implementing all necessary steps, including assay design, data analysis, and interpretation to avoid false negatives.

2.08.2.4 Mass Spectrometry

More recently, MS has extended its application in fragment identification as a highly sensitive and accurate screening tool.[34–36] The fragments are detected with MS mainly in two approaches: Electrospray ionization MS and tethering, which detects noncovalent and covalent (disulfide bond) binding between fragments and target protein, respectively.[37,38] Based on the mass-to-charge ratio and abundance of a protein–ligand complex, it is possible to directly determine the fragment as well as its binding affinity and stoichiometry. In addition, MS requires small amounts of protein and fragments with significantly reduced constraints on purity, and there is no need to label them. Meanwhile, MS approach is rapid and automatable, indicating a very high screening capacity. These combined features provide significant advantages over other fragment screening methods.[39] However, it is worth noting that MS is unable to provide information concerning ligand-binding mode, which constitutes a major disadvantage of MS.

2.08.2.5 Thermal Shift Assay (TSA)

TSA is a thermal-denaturation assay to measure the thermal stability of proteins. It is a relatively high-throughput, inexpensive, and rapid method for fragment identification.[40] As binding to protein can enhance the stability of the protein, the unfolding temperature (also called melting temperature, T_m) of ligand-binding protein is higher than the nonligand binding, which may cause a temperature shift (ΔT_m) between them. Moreover, only those ligands with $\Delta T_m \geq 0.5°C$ are considered to be hits.[41] Based on this simple principle, TSA is able to distinguish hits from fragments requiring significantly reduced degree of technical expertise compared to previously described FS approaches. Meanwhile, TSA consumes small quantities of proteins, there is no need to know the function of the target protein, and it does not involve any target modification and separation step.[42] However, there also exist limitations and drawbacks with this method. Firstly, problems regarding fragment solubility and aggregation may be caused due to the high concentrations of fragments required for screening. In addition, it is difficult to detect very weakly binding fragments by TSA.[43] Moreover, the screening results may be false negatives or positives. Multiple binding events may occur and thereby generate either false increases or false decreases in T_m, indicating that the screening results determined by ΔT_m might be incorrect.

2.08.2.6 Isothermal Titration Calorimetry

ITC has been applied for FBS by directly measuring the heat change when a ligand binds to a target protein.[44] From these precise measurements, the binding affinity (K_a), stoichiometry (n), as well as the enthalpy ($\triangle H$) and entropy ($\triangle S$) changes of the intermolecular interaction can be calculated or determined. The parameters acquired can provide information about both binding events and structural features, which is quite useful for fragment identification and lead optimization.[45] Nonetheless, there exist some severe limitations with ITC, such as low throughput and resolution, high protein and ligand consumption. ITC is thus more suitable for secondary screening instead of primary screening, particularly for screening of large compound libraries.

2.08.2.7 High Concentration Screening

As a simple and rapid method, HCS with biochemical assays has been used for identifying fragments by measuring changes in the activity of a target upon fragment binding.[46] In addition to high-throughput, there are several major advantages with HCS: Various

available techniques for detection, small amounts of protein requirement, and upfront knowledge of biochemical activity. However, drawbacks still exist mainly due to the high concentration of fragment (250–1000 vs. 10–30 μM in HTS) and subsequent large quantities of organic solvents required. These drawbacks include false positives (compound aggregation induced), false negatives (caused by poor solubility of fragments), cell toxicity (induced by large amounts of organic solvents), and target denaturation (ditto). Hence, in order to minimize these potential artifacts, it is necessary to carefully design the screening cascade and preferably apply more sensitive biophysical and biochemical methods especially as initial screenings. The frequently conducted initial biochemical assays include needle screening, MULBITS (Multiple BITS), substrate activity screening, the cell-based functional assay, and combinatorial target-guided ligand assembly. Meanwhile, initial bioassay screens in combination with virtual fragment screening followed by fragment validation using other sensitive biological and biophysical screenings may be an effective approach to the identification of novel starting points for further fragment elaboration.

2.08.2.8 Virtual Screening

VS is a computational technique which uses computer programs to search potential hits from virtual fragment libraries.[47,48] There are two widely used approaches for VS: Structure-based methods (docking) and ligand-based methods.[49] In contrast to experimental methods, VS, on the one hand, is fast and cost-effective, but on the other hand, has relatively low accuracy of predictions and rapid accumulation of errors.[50,51] Notably, ZINC as one of the big free databases offers various fragment-like libraries including target-orientated libraries for VS.

2.08.2.9 Combination Approaches

Nothing is perfect, and FBS approach is no exception. Each FBS approach has its limitations, such as low throughput, high protein consumption, long time-consuming, and so on. Therefore, the combination of two or more screening methods might compensate the limitations of each method and fulfill a win–win situation.[52–54] Generally, the combination of FBS by biophysical screening approaches together with XRC offers more benefits. Several successful drug discovery campaigns, which are discussed here, provide the detailed examples for such combinations. VS may also assist other approaches to yield the potential fragments for further biophysical screening, and the predicted binding modes have attracted more and more interests, especially for the targets which are very difficult to crystallize. In short, experimental or computational predicted structural information about fragments binding to the target enables a more efficient chemical space exploration for further fragment elaboration to establish structure–activity relationships and explore potential drug candidates.

2.08.3 From Fragments to Clinical Drug Candidates

Once the potential fragment hits have been identified and validated, the next step is to improve potency through transforming these fragments into a drug-like lead compound without losing their original binding modes. A broad range of metrics, strategies, and methodologies have been developed to guide the fragment-based hit-to-lead generation.

2.08.3.1 Ligand Efficiency

Ligand efficiency (LE) as a widely applied metric was first proposed for selecting favorable fragments through comparing the values of average binding energy per atom.[55–57] It is simply the free binding energy divided by the number of heavy atoms, $LE = -\Delta G/N = -RT\ln(K_d)/N \approx -RT\ln(IC_{50})/N$. Fragments with higher LE values indicate more potential improvement in binding affinity through structural information guided drug design. Another extending metric based on LE is lipophilic LE, also known as LLE or LiPE ($LLE = pIC_{50}$ – CLogP).[58] Note that utilization of these metrics including the derivation of LE metrics during the overall drug design process to control the balance of molecular size and potency will significantly improve success rates.[59] The derivation of LE metrics is also discussed in more detail by Leeson.[60]

2.08.3.2 Fragment Elaboration

Despite recent numerous biophysical techniques that have benefited FBS and resulted in higher hit rates and more available chemical space, the subsequent chemical optimization of identified fragments toward high-affinity lead compounds remains a crucial aspect for the FBDD approach.[61] In general, as depicted in **Fig. 1**, there are four main strategies for converting low-affinity fragments into a fledged lead structure: (1) Fragment growing (a.k.a. fragment evolution), (2) fragment optimization, (3) fragment linking or merging, and (4) fragment self-assembly.[62,63] The increasing number of candidates progressing into clinical trials has demonstrated that available target structure is beneficial for elaboration of the fragments through utilizing the X-ray crystallographic and/or NMR spectral data.[64] Structural information about the binding mode of the initial fragment is very useful to know how to build up more complex compounds possessing additional interactions with the target. This "evolution" results in development of some tighter binding molecules, which can be used as the second starting points for further chemical optimization.[65]

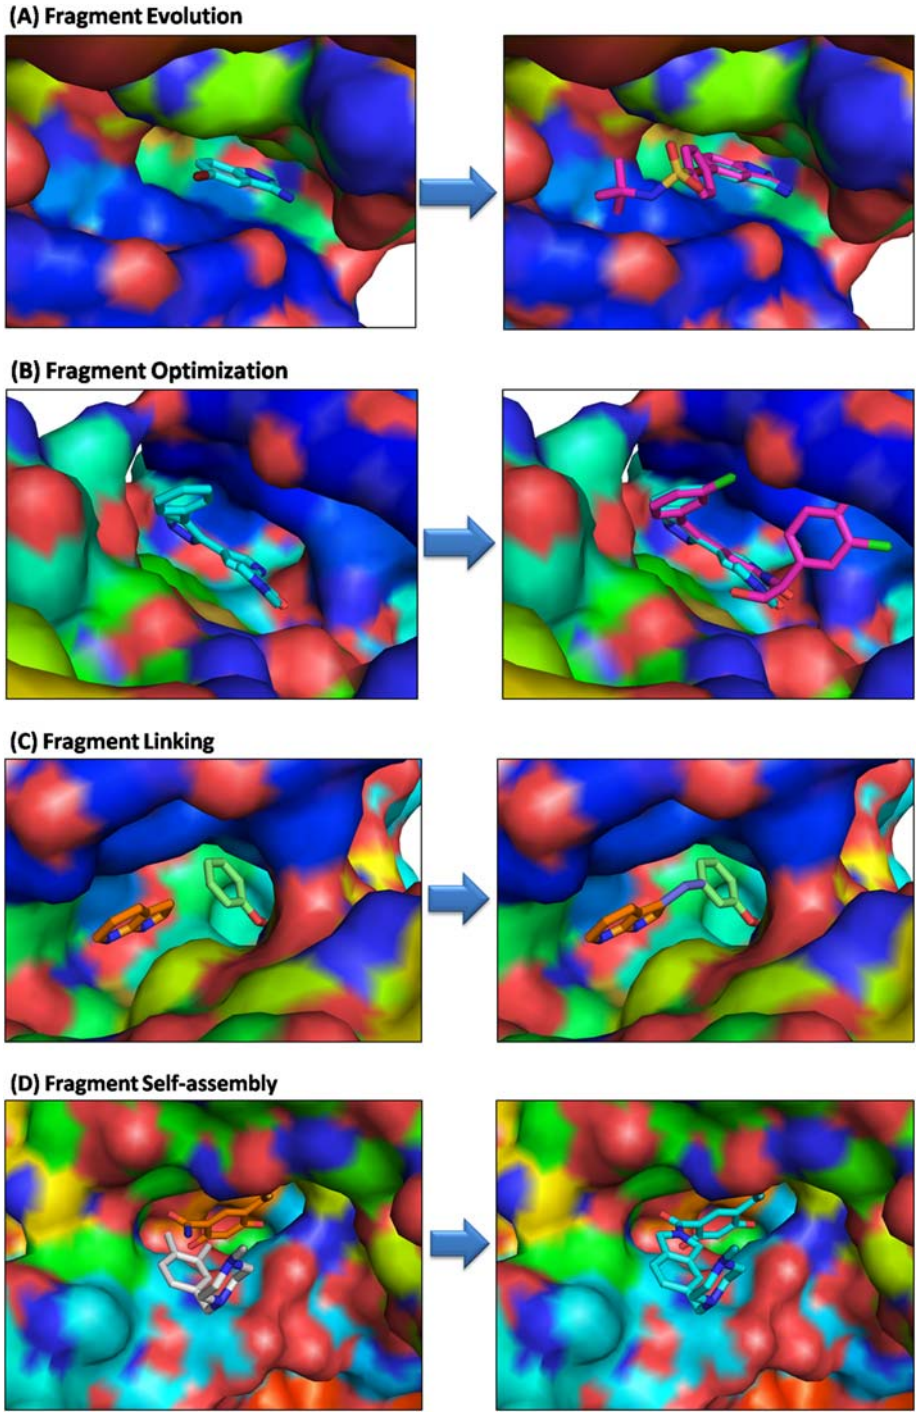

Fig. 1 Four different approaches for converting low-affinity fragments into a fledged lead structure: (A) Fragment evolution; (B) fragment optimization; (C) fragment linking or fragment merging; and (D) fragment self-assembly.

Iterative fragment growing (Fig. 1A) closely resembles traditional medicinal chemistry, and it is thus the most straightforward and preferred strategy in fragment optimization. Generally, functional features are added to adjacent regions of the initial fragment core for access to additional pockets at each chemical modification step during iterative cycles, eventually leading to a desired compound with enhanced potency and favorable pharmacological properties. As mentioned earlier, structural biology is crucial to guide the chemical optimization of initial fragment toward clinical candidate drugs. Fragment optimization (Fig. 1B) is similar to the traditional HTS campaign to maintain the initial scaffold without big chemical modification. Fragment linking (Fig. 1C) involves two identified privileged fragments binding to separate and adjacent pockets are chemically connected via an appropriate

linker in an ideal fashion, resulting in development of a hybrid molecule with significantly improved binding affinity and pharmacokinetic (PK) properties.[66] However, this strategy consumes more experimental time and effort to explore the right linker.[67] Fragment self-assembly (Fig. 1D) is the complementary functional groups of advancing fragments "automatically" assembled in the right places.[68] It should be noted that fragment self-assembly appears not to be the widely applied approach.[69]

2.08.3.3 Medicinal & Synthetic Chemistry Rules

The aforementioned four different approaches for converting identified fragments into potential drug candidates appear to be straightforward. Nevertheless, how to find the correct positions and select reasonable chemical reactions for further successive generations of structural modifications becomes an extremely challenging task. To address this issue, several computer-assisted drug design software programs have been developed to improve drug discovery process. Drug Guru™ as the first web-based software program was established to apply a set of medicinal chemical transformation rules for drug design.[70] AutoGrow, another computational method, combined the strengths of fragment growing and docking algorithms to explore new chemical space more efficiently.[71,72] MedChem Transformations (MCT) is a new algorithm for automatically generating new compounds guided by the set of 206 transformations including functional group addition, linker modification, atom removal, ring addition/modification/removal, and terminal group exchange.[73] Notably, Roughley et al. summarized the most commonly applied reaction types in the pursuit of drug candidates and classified them into 10 major categories.[74] No matter which software programs and reaction types are chosen, medicinal chemistry knowledge on the balance between pharmacological and pharmaceutical properties together with synthetic chemistry knowledge on the large diversity of reactions and functionalities will be beneficial for increasing drug design efficiency and clinical approval success rate.

2.08.4 Success Stories in FBDD

Recently, accumulating evidence indicates that FBDD approaches are widespread in both academia and industry settings, and the aforementioned four predominant strategies have been successfully utilized to generate the optimized drug candidates with enhanced potency as well as improved physicochemical or ADMET properties. A number of successful examples are provided below with more detailed information as to how the starting fragments have been advanced to the optimized drug candidates for human clinical trials or even reaching the market.

2.08.4.1 Case 1: Vemurafenib (PLX-4032), FDA Approved Drug

Vemurafenib (**PLX4032**, Zelboraf) was the first approved fragment-derived drug for the treatment of BRAF-mutant melanoma in Aug. 2011 in the United States.[75,76] Vemurafenib was discovered by Plexxikon Company through utilizing a combination of scaffold- and structure-based drug discovery.[77] Firstly, a library of 20,000 "scaffolds" with molecular mass of 150–350 Daltons was selected and screened at 200 μM against various kinases. Numerous weak and nonselective fragments were identified despite the fact that these small fragments would have been overlooked in a traditional HTS. In order to avoid potential false positives which were apt to occur in early drug screening at high concentrations, cocrystallographic screening was performed as secondary validation at next step. The cocrystals confirmed the binding between initial identified fragments and provided atomic-level details of the binding interactions. Combined with the structural information and criteria for scaffold selection, a nonselective 7-azaindole (initial fragment **1**, Fig. 2A) was selected for further chemical optimization. To address its multiple binding mode within the ATP-binding site and thus weak affinity ($IC_{50} > 200$ μM for Pim-1), additional hydrogen bonding interactions were introduced as shown in Fig. 2B, resulting in an enhanced potency with a single binding mode. Subsequently, a group of 7-azaindole derivatives were synthesized and screened against 17 kinases, such as wild-type and mutated B-RAF, which are present in most of melanomas. Derivatives bearing a difluorophenylsulfonamide motif displayed excellent potency and high selectivity toward mutated B-RAF. Their selectivity was confirmed in a panel assay of 70 kinases, while the anti-B-RAF activity was validated in different melanoma cell lines, including several drug-resistant cell lines. Structure-guided optimization led to the development of **PLX4720**, which exhibits good selectivity in both of enzyme- and cell-based assays ($IC_{50} = 13$ nM for B-RAF V600E, $IC_{50} = 160$ nM for wild-type B-RAF, $IC_{50} > 1$ mM for several other kinases).[77] Addition of a phenyl group afforded **PLX4032** (MW 490; clogP = 4.2), which was chosen over **PLX4720** due to its superior PK properties.[78] Clinical trials confirmed the excellent efficacy of **PLX4032** in patients with metastatic melanoma harboring the V600 B-RAF mutation, consistent with the notion of **PLX4032** as a personalized medicine.[78] The PK properties of vemurafenib prompted its progression into clinical studies that culminated in its approval in 2011.

2.08.4.2 Case 2: ABT-199 (Venetoclax), Phase III

The inhibition of a protein–protein interaction (PPI) is an extremely difficult challenge for medicinal chemists due to general large and flat PPI interfaces.[79] Given the fact that few molecules in existing compound libraries were designed for other PPIs, in contrast to enzyme inhibitors/receptor ligands, etc., traditional HTS fails to offer validated hits for further chemical discovery process.[80] To circumvent this challenge, FBS by the NMR method provides a particularly successful strategy to afford various small-size ligands for further chemical optimization.[81] Abbott Laboratories applied their pioneering developed technology of SAR by NMR[18] to

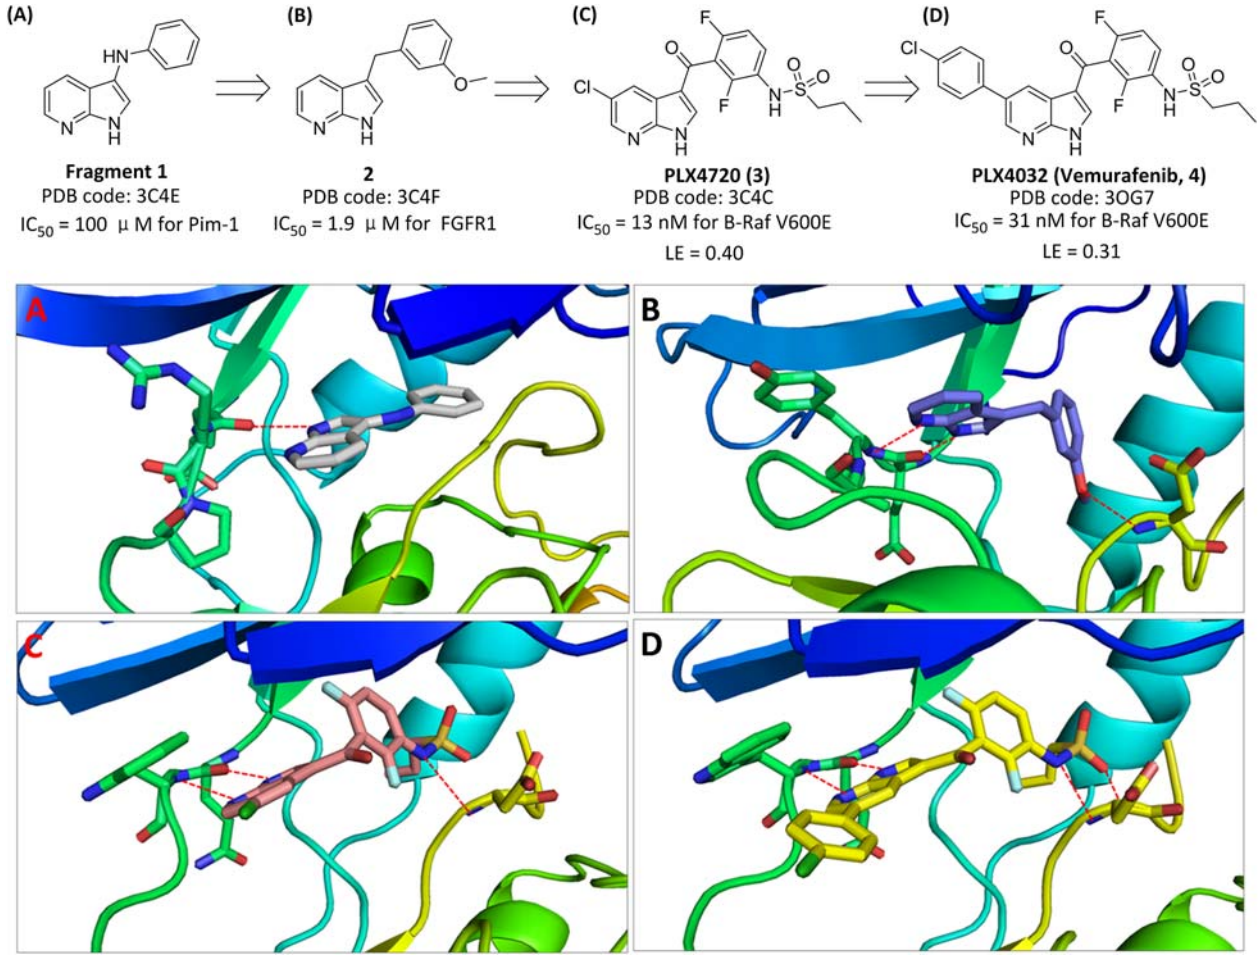

Fig. 2 Progression from initial fragment **1** to the approved drug **PLX-4032** (Vemurafenib). (A) The chemical structure of 3-aminophenyl-7-azaindole (fragment **1**) and its X-ray costructure with Pim-1 kinase. (B) The chemical structure of 3-(3-methoxybenzyl)-7-azaindole (compound **2**) and its X-ray costructure with the kinase domain of FGFR1. discover potent and selective inhibitors targeting the intracellular Bcl-2 family PPI for the treatment of Bcl-2-dependent hematological cancers. Fig. 3 illustrates the long-lasting drug discovery effort of **ABT-199** as a new orally bioavailable therapeutic agent that is currently being evaluated in clinical trials for the treatment of chronic lymphocytic leukemia patients. Fragment **5**, with a dissociation constant (K_d) of about 300 μM, was identified from a screen of 10,000-compound small fragment library (average MW = 210 Da).[82] NMR-based structural investigation revealed that fragment **5** occupies the center of the hydrophobic pocket of Bcl-x_L, which is the same position as the BAK-binding site. In order to search for molecules binding into the proximal groove, the second screening was performed in the presence of excess fragment **5**. From this second-site ligand screen, fragment **6** with a K_d value of 6000 μM was identified by using a 3500-compound library (average MW = 125 Da).[82] The detailed structural interaction of fragment **5** and fragment **6** with the ternary complex of Bcl-x_L for FBDD was calculated using NMR data for structure-guided design and synthesis. Fragment linking strategy was utilized to merge these two fragments, and parallel chemistry ultimately resulted in development of compound **7** containing a trans-olefin moiety as an appropriate linker.[82] Despite this compound displayed a significant enhancement in potency with an inhibition constant (K_i) of 1.4 μM, further structural characterization from the NMR-based model revealed that the trans-olefin is not the ideal linker for the biaryl fragment and cannot fit effectively into the hydrophobic groove. To overcome this shortcoming, replacement of the carboxylic acid with an acylsulfonamide demonstrated that the sulfonamide represented as a suitable linker to bridge two initial fragments in an optimal fashion. This strategy eventually led to lead compound **8** with 8300-fold improvement in potency ($K_i = 36$ nM).[82] Due to its relatively low solubility and high binding to human serum albumin, further medicinal chemistry resulted in discovery of **ABT-737**, which binds to Bcl-2, Bcl-x_L, and Bcl-w with subnanomolar affinity ($K_i = 0.8$ nM) and exhibits impressive single-agent activity in several murine cancer xenograft models.[83] However, due to low aqueous solubility, it is not orally bioavailable. In order to improve flexible application in the clinical setting, Abbott eventually discovered an orally bioavailable Bcl-2/Bcl-x_L/Bcl-W inhibitor **ABT-263** (navitoclax) with improved pharmacodynamics, which finally entered Phase II clinical trials in patients with lung cancer and hematological

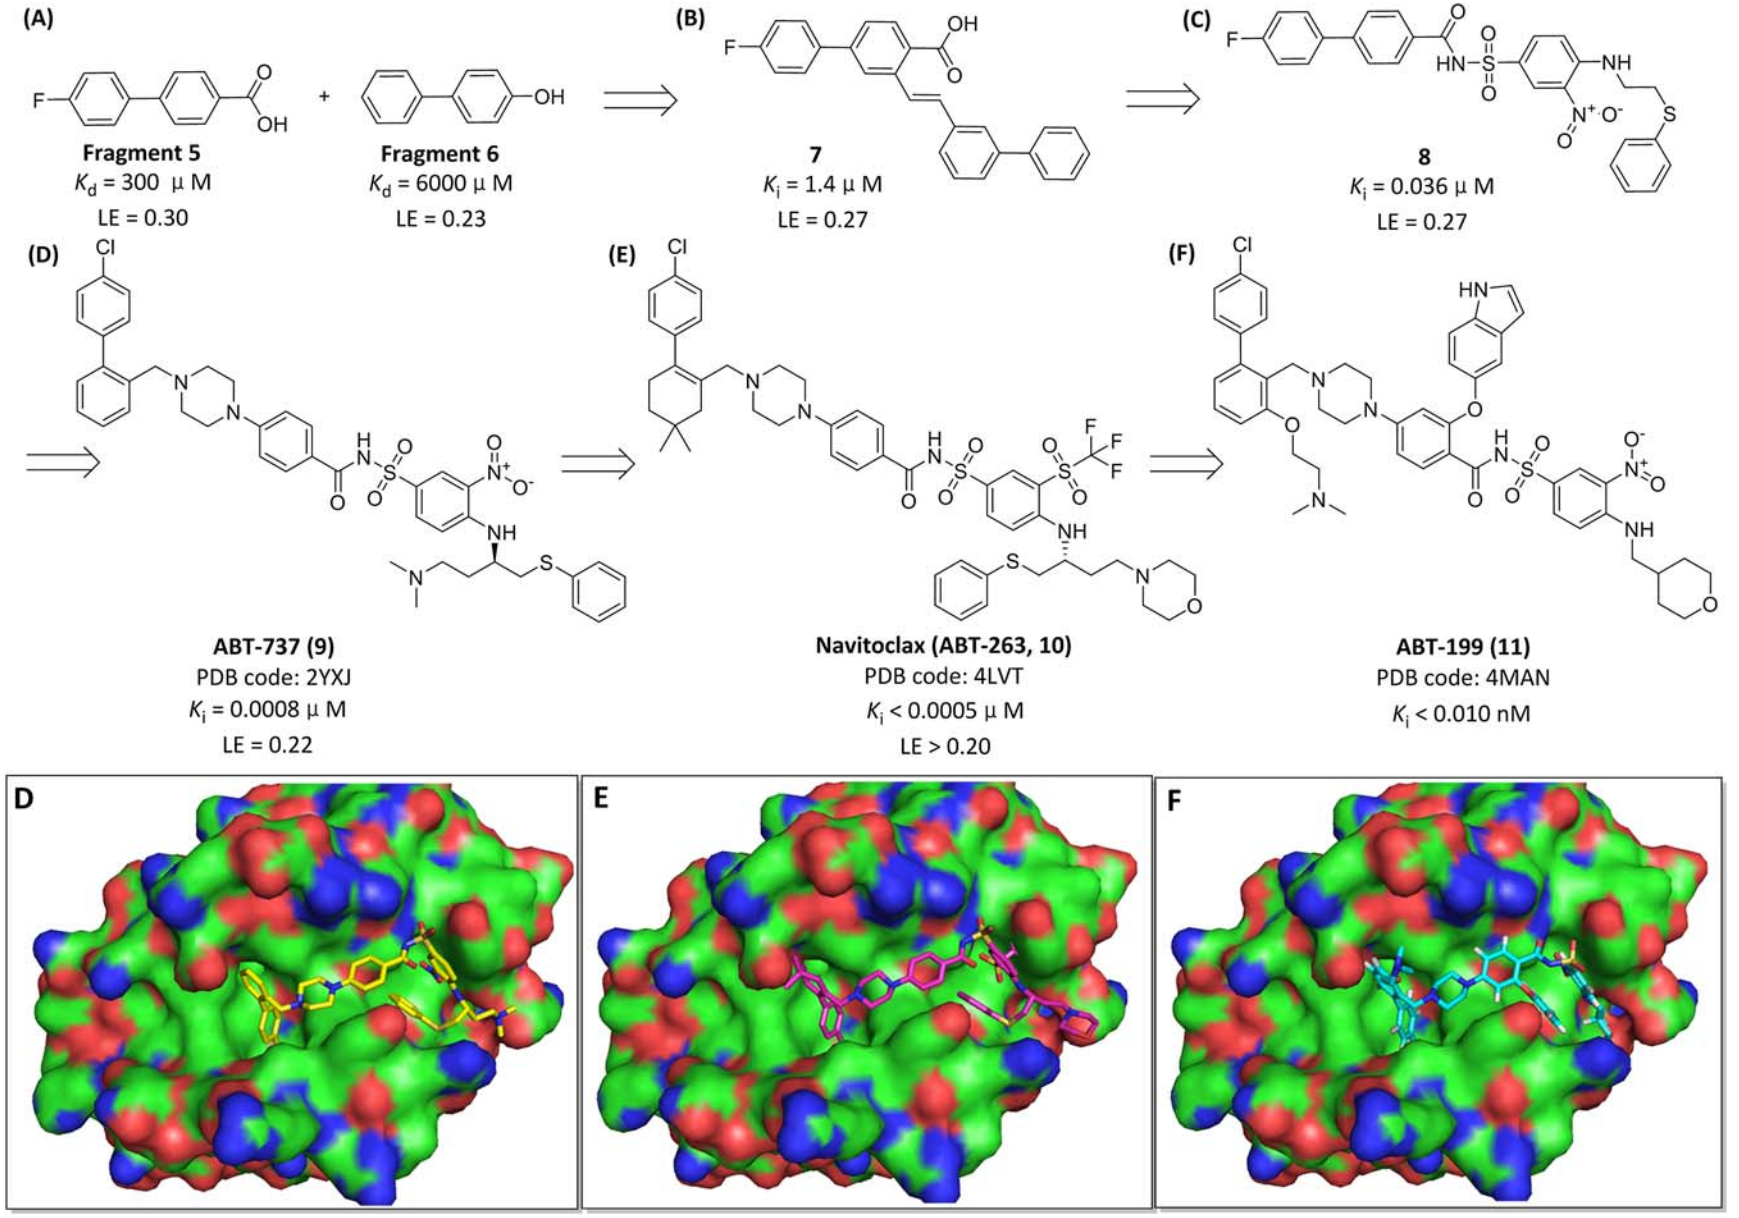

Fig. 3 Progression from initial fragment **5** and fragment **6** to the clinical candidate **ABT-199**. (A) The chemical structures of initial fragment **5** and fragment **6**. (B) The chemical structure of compound **7**. (C) The chemical structure of compound **8**. (D) The chemical structure of **ABT-737** and its X-ray costructure with Bcl-2. (E) The chemical structure of **ABT-263** and its X-ray costructure with Bcl-2. (F) The chemical structure of **ABT-199** and its X-ray costructure with Bcl-2.

malignancies.[84] During clinical investigation, the efficacy of **ABT-263** is limited by thrombocytopenia (platelet loss) caused by inhibition of Bcl-x_L.[85] In order to design a Bcl-2-selective inhibitor to avoid thrombocytopenia, **ABT-263** was cocrystalized with Bcl-2. The binding mode revealed that a tryptophan residue from a neighboring Bcl-2 sat very nearby to **ABT-263**. Addition of an indole near this position led to the discovery of **ABT-199** (venetoclax), which binds Bcl-2 about 10-fold more tightly than **ABT-263** and displays 5000-fold selectivity for Bcl-2 compared to Bcl-x_L.[85]**ABT-199** accesses the BAK-binding pockets without possessing the peptide backbone structure. It is noteworthy that **ABT-199** is more ligand efficient than **ABT-737** and **ABT-263**. Excitingly, **ABT-199** has been advanced into Phase III clinical trials, and very recently, granted breakthrough therapy designation by FDA as an investigational Bcl-2 inhibitor for the treatment of 17p deletion relapsed-refractory CCL (http://www.roche.com).

2.08.4.3 Case 3: AT13387, Phase II

The heat-shock protein 90 (Hsp90) as a popular oncology target is involved in cancer progression and has quickly captured the attention of medicinal chemists. Accumulating clinical advancement of Hsp90 inhibitors also demonstrated the potential therapeutic opportunities for human cancers and neurodegenerative disorders.[86] One of the most impressive drug candidates is **AT13387**, which was discovered by Astex Pharmaceuticals through a successful application of the FBDD approach. The whole drug discovery campaign is very useful for us to learn how to use different techniques and biological data to achieve the final structure with improved pharmaceutical properties. Approximately 1600 selected fragments spanning various chemotypes were firstly screened via water LOGSY (Water-**L**igand **O**bserved via **G**radient **S**pectroscop**Y**) as a primary method for NMR screening.[87] Fragments displaying obvious LOGSY signal were further characterized through competition experiments and high-throughput XRC assay. From this process, 26 cocrystal structures of fragments with Hsp90 were solved and the binding affinities (K_d) were determined by ITC. Among them, fragment **12** with the K_d value of 790 μM and LE of 0.26 was chosen as the starting point for further fragment optimization campaign (Fig. 4). The binding mode revealed that the carbonyl moiety forms an H-bond with the side chain of Thr184 and the methoxy group does not properly fill the proximal lipophilic groove around Met98, Leu107, Phe138,

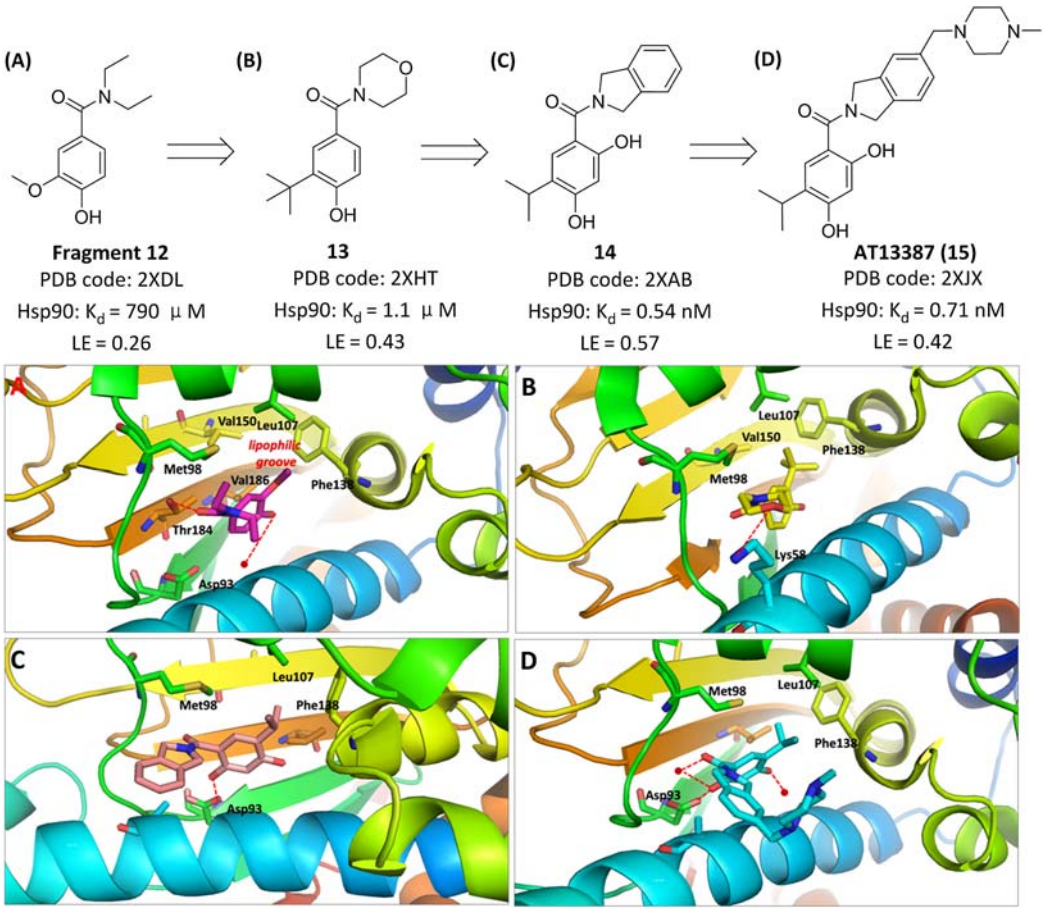

Fig. 4 Progression from initial fragment **12** to the clinical candidate **AT13387**. (A) The chemical structure of fragment **12** and its X-ray costructure with Hsp90. (B) The chemical structure of compound **13** and its X-ray costructure with Hsp90. (C) The chemical structure of compound **14** and its X-ray costructure with Hsp90. (D) The chemical structure of **AT13387** and its X-ray costructure with Hsp90.

Val150, and Val186, indicating that replacement with other substituents might be beneficial for rapid improvement in potency. Replacement of the methoxy group with a more lipophilic moiety provided compound **13** with significantly enhanced potency and improvement in LE. The crystal structure of compound **13**/Hsp90 confirmed that the *tert*-butyl moiety effectively fits into the lipophilic pocket and the H-bond forms between the morpholine oxygen and the side chain Lys58. However, Lys58 might also form the lipophilic interactions with the surrounding side chains including Ala55 and Ile96, indicating that morpholine moiety should be a potential position for further structural modification. Overlay analysis of cocrystal structures (the natural product radicicol/Hsp90, PDB code: 1BGQ) and fragment **12** revealed that the group of 2-OH in radicicol forms the direct H-bond with Asp93, suggesting that the additional hydroxyl moiety might bring additional benefit for affinity improvement.[88] Further synthetic manipulation resulted in isoindoline resorcinol **14** with subnanomolar affinity as well as excellent LE. The additional hydroxyl moiety as a polar positively charged group significantly improved potency and the distribution properties. The binding mode of compound **14** in Hsp90 also confirmed that the additional hydroxyl moiety forms H-bonds with Asp93. Further optimization of compound **14** was focused on the 2,4-dihydroxybenzamide moiety and the bicyclic isoindoline ring. In an attempt to block potential sites of oxidative metabolism and increase the p*K*a of the basic center, as well as reduce lipophilicity, **AT13387** was prepared containing the *N*-methylpiperazine group, exhibited favorable physicochemical and PK properties, and was selected as the drug candidate for further clinical investigation.[89] It is worth mentioning that LE was used as one of the criteria to guide the whole optimization campaign for controlling the molecular size. The superimposition with fragment **12** demonstrated that the binding mode was maintained during the process of fragment elaboration. As the advanced drug candidate, **AT13387** possesses the excellent balance of properties including potency, in vivo PK, acceptable risk profiles, as well as suboptimal physicochemical properties (p*K*a, $\log D_{7.4}$, and aqueous solubility).

2.08.4.4 Case 4: AT9283, Phase II

AT9283 is a novel multitargeted kinase inhibitor with potent Aurora kinase activity, which was also identified and developed by Astex Therapeutics.[90]**AT9283** displays potent antiproliferative and apoptotic properties in vitro, and the in vivo anticancer activity has been demonstrated in several human tumor xenograft models. Recently, clinical trials are ongoing to verify the effects of this fragment-derived compound. Unlike the previous fragments, fragment **16** was firstly identified as a starting point to explore CDK inhibitors (Fig. 5). Subsequently, FBDD resulted in identification of benzamide analogue **17** as a potent CDK2 inhibitor with an affinity of 0.052 μM. During the fragment optimization campaign, Astex researchers found that fragment **16** also exhibited superior inhibition for Aurora A with an IC_{50} value of 0.91 μM (LE = 0.59). Further characterization of fragment **16** and compound **17** through XRC revealed that fragment **16** fits deeply in the active site of Aurora A. The ligand H-bonds to backbone carbonyl of Glu211 and to the carbonyl and backbone NH of Ala213 of hinge region, the benzimidazole motif binds in the cleft around Ala213, Pro214, Leu215, and Gly216. This cleft has significant differences compared to the comparable region in CDK2. The binding mode of compound **17** also revealed the same three H-bonds to the hinge region. An intramolecular H-bond exists between the benzimidazole and the amide NH, holding the molecule in a planar conformation. The region of the ATP pocket occupied by the benzamide motif also displays significant differences between Aurora A and CDK2. With the aim to identify compounds with improvement on cellular potency via inhibition of Aurora kinases A and B, Astex researchers decided to add a basic motif on 5- or 6-position of the benzimidazole without causing any clashes. Weakly basic morpholine moiety ($pK_a \approx 7$) was selected with the aim to minimize the increase in effective H-bond donors since compound **17** has already possessed three H-bond donors. During this hit-to-lead phase, *p*-fluorophenyl analogue **18** displayed enhanced cellular potency and encouraging PK properties in mouse, while the plasma protein binding was found to be high (PPB = 99.5%). The X-ray cocrystal structure of compound **18**/Aurora A revealed that the motif of pyrazole–benzimidazole fills the narrow region of the ATP pocket, while the *p*-fluorophenyl fragment partially fills the surrounding region, indicating that the chemical space in this region needs further modification. The synthetic effects resulted in providing **AT9283** as a highly potent Aurora A inhibitor ($IC_{50} \approx 3$ nM, LE ≈ 0.42). The crystal structure of **AT9283**/Aurora A revealed that the urea linker allows a folded conformation, while the key H-bonds between initial fragment **16** and Aurora A are retained during the process of fragment elaboration. The high LE of the pyrazole–benzimidazole motif resulted in development of **AT9283** as the clinical drug candidate with low nanomolar potency and favorable pharmacological properties.

2.08.4.5 Case 5: AT7519, Phase II

AT7519 as a novel multi-CDK inhibitor is another example that was developed by Astex Therapeutics through utilization of fragment-based X-ray crystallographic screening and structure-based drug design (Fig. 6).[91] They began their drug discovery campaign by soaking crystals of CDK2 with a library of focused fragments. Approximately 30 low-affinity and small-size fragments binding to the active site of CDK2 were solved and identified with high LE and limited functionality. Despite indazole **20** displayed relative low binding affinity (>100 μM), the detailed binding mode revealed that this fragment with comparative higher LE (LE = 0.57) forms two classical H-bonds with CDK2 and it does not access the surrounding pocket, indicating that fragment indazole is suitable for potential substitution to occupy deep pocket of ATP-binding site. Structural analysis also suggested that addition of an aryl amide to the 3-position of indazole might form another hydrogen bonding interaction to Leu83. An alternative design strategy was pursued to decrease molecular weight through simplification by removal of the fused benzene ring without the significant loss in LE. The above-mentioned effects afforded the pyrazole **21** with the IC_{50} value of 97 μM and LE of 0.39. CDK2 cocrystal structure of compound **21** confirmed the additional hydrogen bonding interaction with Phe82. It is noteworthy to mention that the

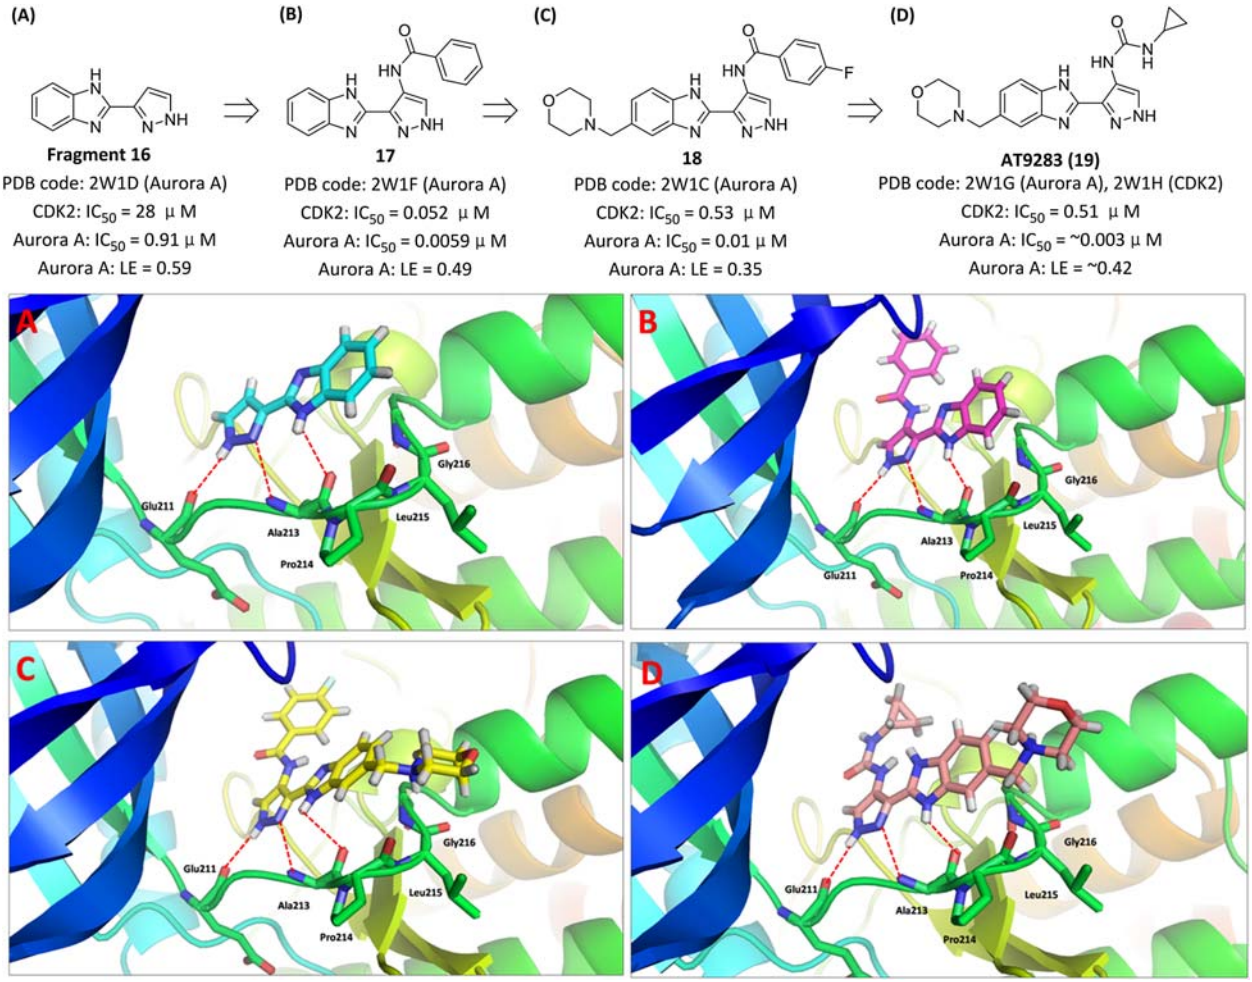

Fig. 5 Progression from initial fragment **16** to the clinical candidate **AT9283**. (A) The chemical structure of fragment **16** and its X-ray costructure with Aurora A. (B) The chemical structure of compound **17** and its X-ray costructure with Aurora A. (C) The chemical structure of compound **18** and its X-ray costructure with Aurora A. (D) The chemical structure of **AT9283** and its X-ray costructure with Aurora A and CDK2.

binding mode of pyrazole **21** remained identical to that of the starting fragment **20**, further indicating that the strategy applied herein is suitable for fragment optimization. The X-ray crystal structure also revealed that functionalizing the pyrazole moiety at the 4-position provided an opportunity to accommodate more space. Introduction of a 4-amino moiety gave compound **22**, resulting in a significant improvement in potency and enhanced LE ($IC_{50} = 0.003$ μM; LE = 0.45). The X-ray structure of **22**/CDK2 revealed that water-mediated H-bond from the amide carbonyl oxygen to the backbone NH of Asp145 benefits for improvement in affinity, while diortho substitution of the phenyl ring might be beneficial for stabilization of the twist. Although compound **22** exhibited potent kinase activity, due to its low cell permeability, this compound displayed moderate antiproliferative cell activity. Further optimization by replacement of the lipophilic 4-fluorophenyl moiety and modifications of the 2,6-difluorophenyl group ultimately led to the 2,6-dichlorophenyl derivative **AT7519**, which exhibited promising in vitro kinase, antiproliferative cell activity as well as low PPB and reasonable tumor distribution. The crystal structure of **AT7519** complexed with CDK2 reveals that the two chlorine atoms fill the lipophilic pocket more effectively than fluorine. **AT7519** demonstrated significant in vivo efficacy and is currently under evaluation in Phase II clinical development for multiple myeloma.

2.08.4.6 Case 6: NVP-AUY922, Phase II

NVP-AUY922 is one of small molecules targeting Hsp90 currently under Phase II clinical trials. Previous screening resulted in identification of small-molecular size 4,5-diarylpyrazoles including **CCT018159** as a new class of Hsp90 inhibitors (Fig. 7).[92] X-ray determination of **CCT018159**/Hsp90 cocrystal structure indicated that chemical modification on pyrazole ring especially methyl group might be beneficial for improvement in potency, and the resorcinol moiety seems to be important for two phenolic hydroxyls form two critical H-bonds with Hsp90. The structure-based drug design for the optimization of **CCT018159** led to the discovery of the amide-substituted pyrazole **VER-49009** that exhibited significant potency ($IC_{50} = 25$ nM). However, **VER-49009** did not show

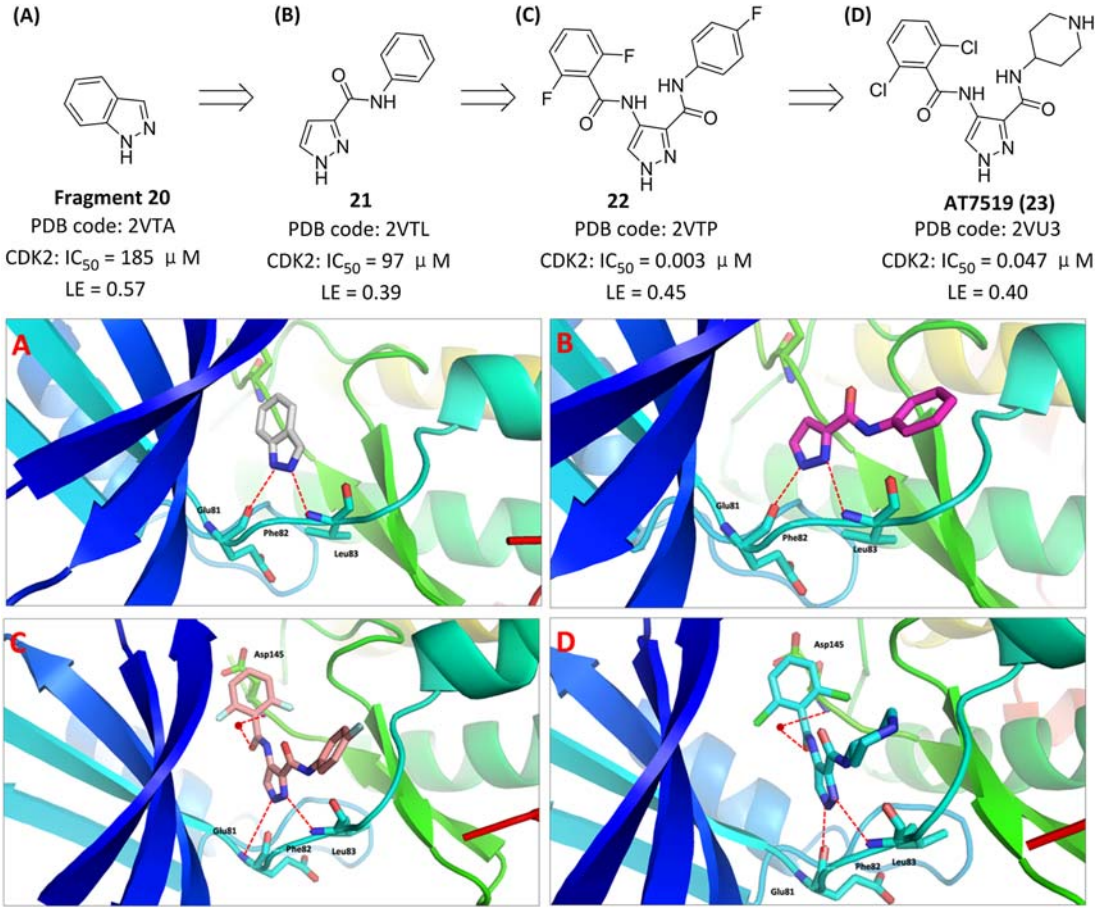

Fig. 6 Progression from initial fragment **20** to the clinical candidate **AT7519**. (A) The chemical structure of fragment **20** and its X-ray costructure with CDK2. (B) The chemical structure of compound **21** and its X-ray costructure with CDK2. (C) The chemical structure of compound **22** and its X-ray costructure with CDK2. (D) The chemical structure of **AT7519** and its X-ray costructure with CDK2.

ideal antiproliferative effects (HCT116 colon cancer cell line: $GI_{50} = 0.26$ μM). Subsequent structural analysis of Hsp90/**VER-49009** revealed that there is limited space for chemical modification around resorcinol group and pyrazole ring, while various substituents can be placed on the 5′-position of the resorcinol ring and incorporation of one solubilizing moiety on the 4-arylpyrazole substituents is recommended.[93] Additionally, modification of the pyrazole heterocycle provides another option to maintain the binding mode without changing the key scaffold core. Replacement of the pyrazole core with the isoxazole scaffold and the solubilizing group incorporation on the para position of the 4-aryl ring provided the isoxazole analogue **VER-50589** which showed significantly improved inhibition of cell proliferation against HCT116 cells with a GI_{50} value of 0.083 μM. Further replacement of the chlorine by an isopropyl group afforded **NVP-AUY922** as the desired drug candidate which exhibited excellent potency ($IC_{50} = 21$ nM) and inhibited proliferation in a wide range of human cancer cell lines with an average GI_{50} of 9 nM. X-ray crystal structure of Hsp90/**NVP-AUY922** confirmed an additional hydrophobic interaction with Leu107 in the flexible lipophilic pocket. **NVP-AUY922** exhibited excellent efficacy in a range of human tumor xenograft models covering major cancer types and diverse oncogenic profiles.

2.08.4.7 Case 7: Bruton's Tyrosine Kinase Inhibitor

Smith et al. sought to identify novel inhibitors of Bruton's tyrosine kinase (Btk) for the treatment of rheumatoid arthritis.[94] They began their drug discovery campaign by using a Caliper mobility shift assay to screen a library of 11,098 fragments. Small potential fragments were selected for XRC based on the novelty of fragment structure, LE, and the confirmation of binding data derived by NMR. Fragment **28** was selected for further structural optimization due to its high LE value (LE = 0.53) and the synthetic tractability (Fig. 8).[94] The binding mode of fragment **28** revealed that several potential accessible vectors can be modified for fragment evolution toward the floor pocket, P-loop, and the gatekeeper around the side chain residue Thr474. Of all possible vectors for fragment growth, 8-position of the cinnoline ring was selected to modify in order to enhance potency, selectivity, and ADME properties for this vector pointed to the center of ATP-binding site and might provide a great opportunity to grow the fragment toward the floor pocket and P-loop. The synthesis efforts resulted in the discovery of compound **29** with improved Btk potency. Further X-ray

cocrystal structure revealed that the pyridine moiety of compound **29** makes a bifurcated water-mediated H-bond with P-loop. Therefore, with the goal to displace this water, a series of bicyclic heterocycles were designed and synthesized. 5-Methyl-indazol-6-yl analogue **30** was found to be a good lead compound with significant improved affinity, higher selectivity over Lck, and favorable cellular potency. The X-ray cocrystal structure revealed that the indazole moiety of the lead compound **30** forms two H-bonds with two strands of the P-loop and stabilizes the P-loop conformation, while the 4-amino and 3-carboxamide motifs make three H-bond interactions with the hinge, conserving the binding mode of the initial fragment **28**.

2.08.4.8 Case 8: RSK2 Inhibitor RMM-46

Recently, Taunton et al. used a fragment-based approach to develop the first reported inhibitor targeting RSK2 (ribosomal S6 kinase) C-terminal kinase domain.[95] They screened several heteroaryl-susbstituted cyanoacrylamides against three human kinases (RSK2, NEK2, and PLK1). Fragment indazole **31** and fragment azaindole **32** (Fig. 9) were found to inhibit RSK2 with submicromolar IC_{50} values and suitable ligand efficiencies (LE = 0.54 and 0.39, respectively). In order to gain detailed structural insight into the extraordinary LE, the cocrystals of these fragments with RSK2 were determined. The results revealed that the moiety of indazole forms two H-bonds with the side chains of Leu495 and Met496. However, this group does not properly fit into the ATP pocket around Ile428, Met496, and Leu546, indicating the potential position for further chemical optimization. The cocrystal structure of azaindole **32** revealed that the group of ketone formed an H-bond with the hinge residue Met496 and the azaindole moiety filled the entrance of the ATP pocket. Overlaying these two cocrystals revealed that aromatic substituents appended to the 3-position of indazole **31** might fill the hydrophobic cleft occupied by the azaindole moiety of **32**. Therefore, a series of analogues with 3-substituents on indazole and substituents on the primary amide were designed and synthesized. This provided the optimized inhibitor PMM-46 with significant improvement in potency toward RSK2 and higher selectivity over NEK2 and PLK1. The overlay of the cocrystals of PMM-46 and **31** revealed that the indazole cores of both compounds were aligned perfectly. Similar to compound **32**, trimethoxyphenyl moiety of PMM-46 was nestled around Ile428, Met496, and Leu546, while the fragment of 1,1-dimethyl-2-hydroxyethyl amide extended beneath the glycine-rich loop.

2.08.4.9 Case 9: HCV NS3 Protein Modulator

Astex Pharmaceuticals identified a series of fragments by high sensitive fragment screening using crystals of the HCV NS3-NS4a protein.[96] Some crystal structures revealed a new allosteric binding pocket at the interface between the protease and helicase domains. Fragment **34** bound to this relatively hydrophobic pocket with a fairly low potency and a high LE ($IC_{50} = \sim 500$ μM, LE = 0.3; Fig. 10). Examination of the crystal structures suggested that modification on the ring A and the side chain might lead

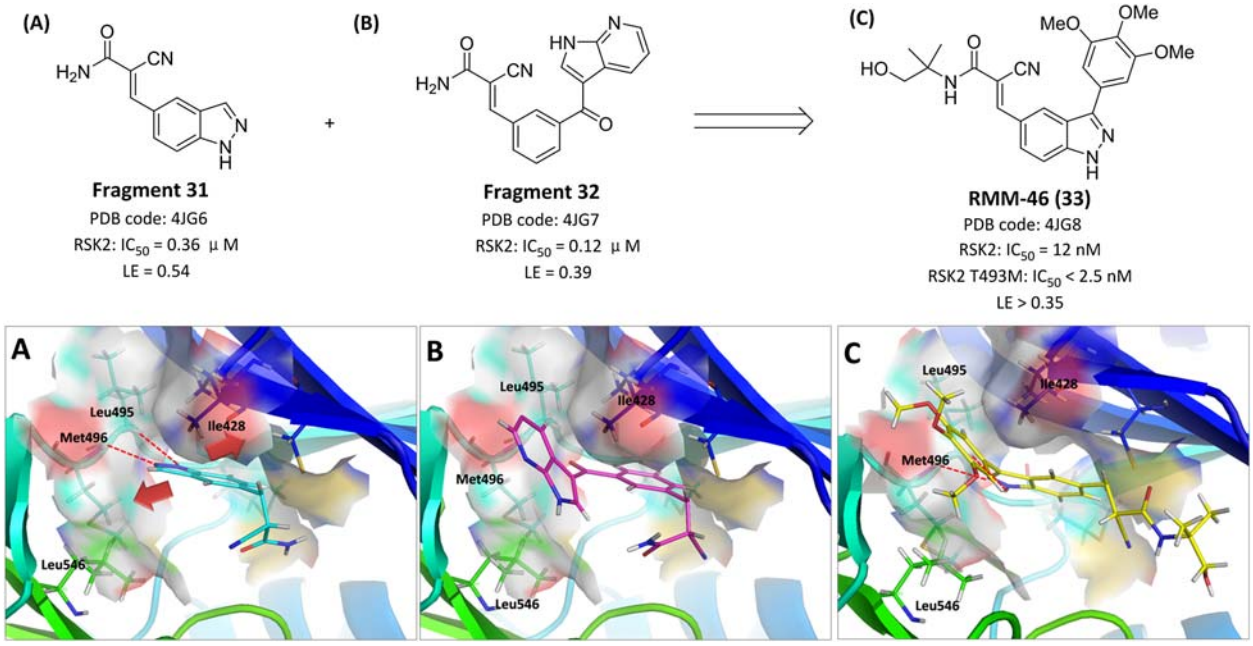

Fig. 9 Progression from initial fragment **31** to the lead compound **RMM-46** (**33**). (A) The chemical structure of fragment **31** and its X-ray costructure with RSK2. Fig. 10 Progression from initial fragment **34** to the lead compound **37**. (A) The chemical structure of fragment **34** and its X-ray costructure with HCV NS3 protein. (B) The chemical structure of compound **35** and its X-ray costructure with HCV NS3 protein. (C) The chemical structure of compound **36** and its X-ray costructure with HCV NS3 protein. (D) The chemical structure of the lead compound **37** and its X-ray costructure with HCV NS3 protein.

to afford more potent lead compound to efficiently fill the hydrophobic binding site, maximize van der Waals interactions, and stabilize the bound conformation. Initial effects resulted in a conformationally constrained compound **35** with a significant increase in binding affinity and a considerable improvement in LE ($IC_{50} = 1.3$ μM, LE = 0.42). Introduction of an ethyl group at the benzylic position restricted the rotation of the side chain. Modification on the side chain provided an excellent vector to identify more additional specific hydrogen bonding interactions. This effect led to the discovery of compound **36** which forms two key interactions with residues from both the protease and helicase domains. Addition of an ethylamino side chain led to the identification of the lead compound **37** with great improvement in potency ($IC_{50} < 0.01$ μM, LE ~0.39). Cocrystal structure revealed that the lead compound **37** forms further interactions with the pocket around the residues of Asp79, Thr519, and Leu522.

2.08.4.10 Case 10: Dual pan-RET/VEGFR2 Kinase Inhibitors

Li et al. recently identified a dual pan-RET/VEGFR2 kinase inhibitor **Pz-1** through successful application of the computational modeling-guided fragment-based approach (Fig. 11).[97] From a library of kinase-directed fragments, one benzimidazole scaffold **38** was identified as a promising starting point for a tyrosine kinase inhibitor targeting RET. This fragment was found to inhibit RET effectively at 20.0 μM. Molecular modeling of **38** in the RET kinase "DFG-in" (native active fold, the active DFG-in conformation) indicated that the chemical space around the position of bromine is solvent-exposed and the substitution at this region might be tolerated. The resulted compound **39** exhibited slightly enhanced potency against the RET kinase with an IC_{50} value of 18.2 μM. Further computational modeling revealed that the DFG pocket of RET could be accessed with the addition of a hydrophobic moiety connecting to the allosteric pocket. The optimized compound **40** displayed improved RET potency with an IC_{50} value of 2.1 μM. The combination of SAR information from both compounds **39** and **40** indicated that further optimization at the position of bromine and the allosteric region might lead to some promising compounds. The chemical synthesis and biological evaluation efforts resulted in identification of a significant potent lead compound **Pz-1** (**41**) containing a pyrazole at the solvent region

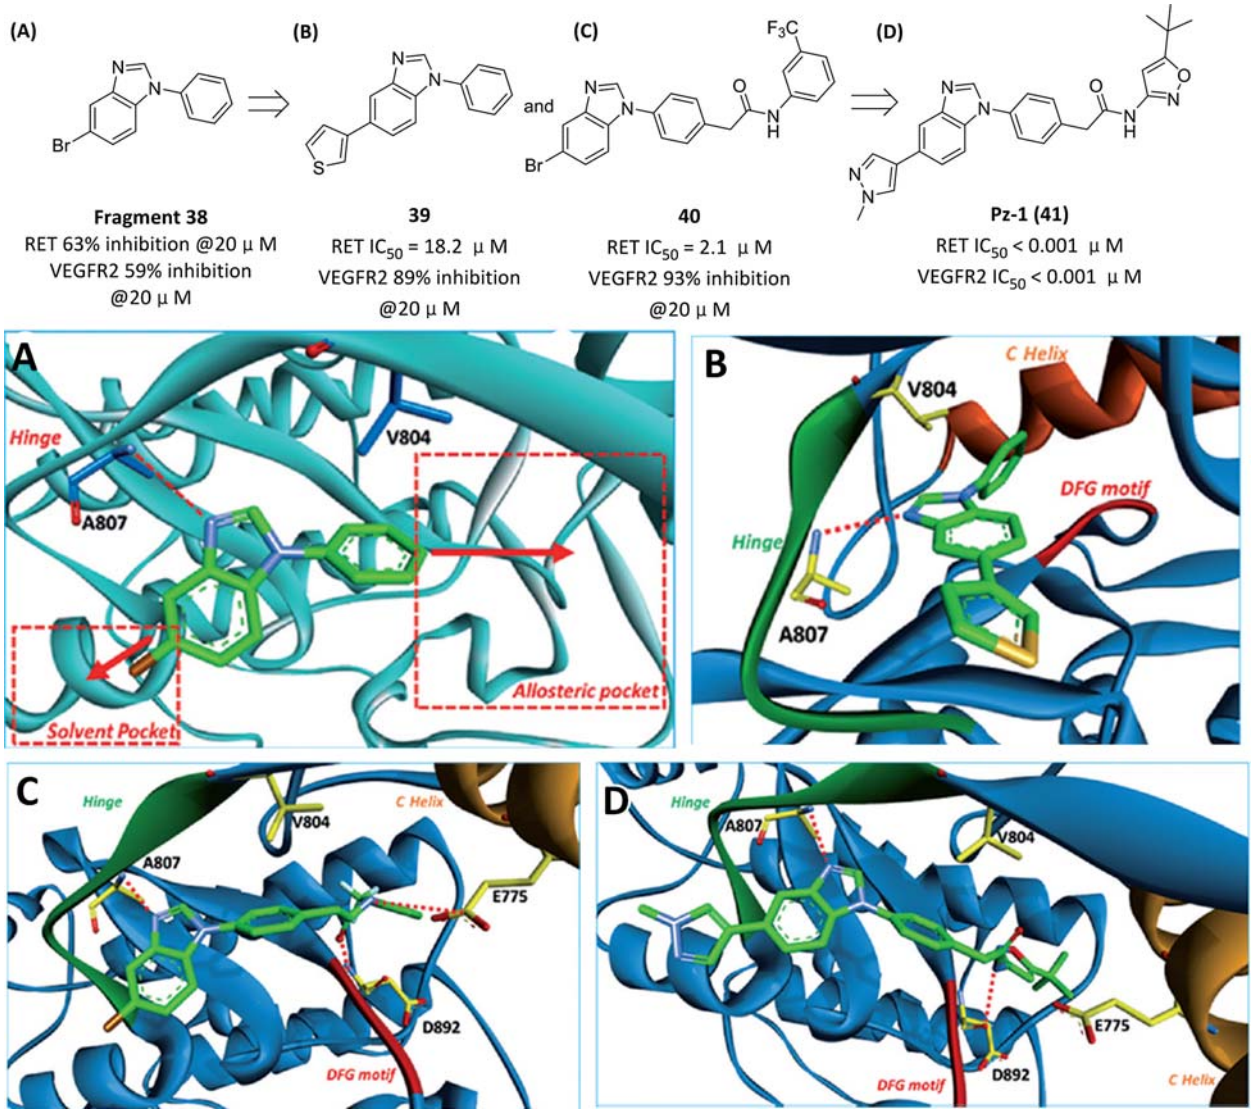

Fig. 11 Progression from initial fragment **38** to the clinical candidate **Pz-1** (**41**). (A) The chemical structure of fragment **38** and its computational modeling in the RET DFG-in crystal structure. (B) The chemical structure of compound **39** and its computational modeling in the RET DFG-out homology model. (C) The chemical structure of compound **40** and its computational modeling in the RET DFG-in crystal structure. (D) The chemical structure of **Pz-1** (**41**) and its computational modeling in the RET DFG-out homology model. Reproduced with permission from Frett, B.; Carlomagno, F.; Moccia, M. L.; Brescia, A.; Federico, G.; De Falco, V.; Admire, B.; Chen, Z.; Qi, W.; Santoro, M.; Li, H.Y. Fragment-based discovery of a dual pan-RET/VEGFR2 kinase inhibitor optimized for single-agent polypharmacology. *Angew. Chem. Int. Ed. Engl.***2015,** 54, 8717–8721.

and an isoxazole in the allosteric pocket. This clinical candidate **Pz-1** was found to be active against RET, RET mutants, and VEGFR2 with IC_{50} values at the subnanomolar level. Pz-1 can strongly block VEGFR2-mediated nutrient accumulation and inhibited RET/RET-mutant cell proliferation. Computational modeling of **Pz-1** within the RET kinase indicated that binding occurred >3.5 Å away from the side chain V804 of the gatekeeper region. Due to the large binding distance from the gatekeeper, **Pz-1** exhibits an improved binding affinity for the gatekeeper mutant RETV804M. It is worth noting that the clinical development of **Pz-1** represents a successful application of a computational modeling-guided FBDD.

2.08.5 Lessons Learned From Success Stories in FBDD

As we discussed, FBDD became a widespread applied approach throughout both the academia and industry settings over the past two decades. There are several key lessons that we can learn from the successful cases. Several areas with more attention should be considered so that future drug discovery opportunities may increase the impact and success of FBDD approaches even further.

2.08.5.1 Fragment Identification

As aforementioned, various techniques have been developed for FBS.[98] Therefore, more options are available to select one suitable assay for the first-round fragment screening to identify valuable fragments for further chemical modification.[99–101] As we mentioned earlier, combination of different methods to confirm the right fragments is critically important for the entire drug discovery campaign.[27] Utilization of XRC is the first choice to confirm the right fragments through achieving the detailed structural information about the binding mode with high resolution.[102–104] However, it requires high-purity protein, the automated infrastructures, and professional knowledge.[105] NMR spectroscopy also consumes large quantities of purified proteins and the expensive equipment, while target-based NMR needs ^{15}N-labeled protein to identify binding sites.[23] Other assays including several biochemical and functional assays that are rapid and cost-effective, while the detailed information about the localization of fragment binding is missing. Different from the FBS assays mentioned earlier, the appropriate deconstruction of reported ligands may also provide potential privileged fragments for further reconstruction of novel scaffolds with favorable drug-likeness.[106–108] Despite a number of methods are capable of identifying interesting fragments for further fragment elaboration, the quality of fragments with real potential is one crucial factor that should be taken into account to validate the effective fragment identification.[109] Ideally, these fragments are metabolically stable, pure, and unreactive with fewer off-target effects. Special attention should be paid to recognize the pan-assay interference compounds issues with many hits identified from HTS and FBS that are artifacts and promiscuous binders to a variety of biological targets.[110] Such hits should be eliminated early from the FBDD approaches to avoid a "garbage in, garbage out" process.

2.08.5.2 Fragment Elaboration

During fragment elaboration cycle, utilization of LE is very important to control the balance of molecular size and potency.[111,112] Structural information about the binding mode is useful to guide drug design. Such information may provide the potential structural sites that are tolerable for modification to increase the binding affinity, and identify which chemical sites are available for incorporating additional fragments to improve selectivity and PK properties. Several assays may be conducted to figure out the detailed structural information including XRC, target-based NMR, and molecular docking.[113] Even though molecular docking only predicts the potential binding mode, the suitable algorithms are widely applied to guide drug design, and several successful examples demonstrated their potential applications in rational drug design.[97,114,115] It is worth mentioning that retaining the binding mode of the initial fragments is critical in the course of fragment elaboration and structural optimization.[116] While there are relatively few approaches emerging as reliable and efficient methods for rapidly exploring chemical space for lead compound development, the aforementioned successful cases may provide some useful insights for utilizing the FBDD strategy.

2.08.5.3 Drug Candidate Selection

The initial fragments must be structurally optimized to yield favorable PK properties.[117] Therefore, how to select potential drug candidates for further clinical evaluation is challenging, especially when couple of ideal compounds are available with favorable drug ADMET properties and suitable aqueous solubility.[118] Oral bioavailability and the pharmacological efficacy have the top priority for drug candidate selection. The ease of chemical synthesis and the source of the starting materials are also important factors to be considered. In addition, some useful programs such as pkCSM for predicting small-molecule PK properties using graph-based signatures may facilitate a more effective drug-candidate selection in FBDD for further development.[119]

2.08.6 Conclusion and Outlook

With an increasing number of FBDD-derived drugs progressing into clinical trials, more and more attention from both industry and academia have been and will continue to be paid to FBDD.[120–122] As an alternative strategy to HTS in drug discovery, FBDD increases the hit rates via screening low MW fragments covering a relatively broader chemical space. However, initial fragment tends to display a weak binding affinity, thereby requiring highly sensitive screening methods to identify such weak interactions between fragments and the target protein. Fragment screening requires appropriate selection and integration of various techniques based on the available technology for identification and validation of right fragments. Each fragment screening technique has its advantages: XRC provides detailed structural information, NMR offers binding affinity and binding site, while other bioassays afford functionally relevant activity data for larger collections of fragments.[123] However, these experimental screening approaches require large quantities of purified proteins. The strength of biochemical screening is that the throughput allows large fragment collections to be screened in a short time period. This ensures that the most ligand efficient diverse starting points are available for medicinal chemists to select for subsequent optimization. The most effective way to perform fragment screening is not to rely on a single method but to use orthogonal methods in concert.

Regardless of the screening method, developing low-affinity fragment hits into a lead by fragment evolution, fragment optimization, fragment linking, or fragment self-assembly is challenging.[124] Of all cases described earlier, structural information played a profound role in both discovering fragments and advancing them into the clinic.[125] Both NMR and XRC are capable of providing detailed structural information, but recently tremendous progress in computational structure-based drug design leads to

development of novel therapeutic agents with promising pharmacological efficacy. This further demonstrates that the combination of different sophisticated and reproducible molecular modeling tools may also advance fragments to drug candidates, especially in case some membrane proteins are challenging to characterize using experimental structural methods.[126–129] With the experimental or predicted structural information in hand, how to effectively select the potential chemical sites for further structural optimization becomes crucial to improve potency and selectivity. Recently, several tools and software programs such as Drug Guru™, AutoGrow, and MCT are available to explore chemical space more efficiently as we discussed earlier. The optimal balance of properties including molecular weight, potency, selectivity, amphiphilicity, and druggability is quite sensitive in the fragment elaboration campaign. Notably, the adoption of early stage PK and PD studies has also contributed greatly to a significantly reduced late-stage attrition rate of clinical candidates.[130,131] Taken together, it is our hope that the strategic advances and lessons learned will continue to enable and expand the efficient applications of FBDD in the discovery and development of new drugs in the years to come.

2.09.1 Introduction

Over the past few years, computational models have positioned themselves quite significantly within the pharmaceutical industry, particularly in the earlier phases of drug discovery, not only for the prediction of efficacy or affinity to specific pharmacological targets, but also for the optimization of safety and pharmacokinetics profile. The transition from a promising compound to a successful drug that can ultimately benefit patients is the result of a fine balance of a daunting number of favorable properties, including target potency, selectivity, ADME (absorption, distribution, metabolism, excretion), and (pre)-clinical safety profiles.[1,2]

As a clinical candidate needs to undergo rigorous preclinical optimization in various domains, multidimensional optimization (MDO) is a term often used to describe the intensive investigations during the first 3 to 4 years of drug development from the identification and validation of the target to the selection of the molecule most suitable for clinical development. The current MDO process comprises the use of in silico, in vitro, as well as in vivo models. In general, in silico tools have the intrinsic advantages to be fast and not to need the physical presence of the test compounds and can therefore be applied very early in drug development. Theoretically, in silico models can be developed for all endpoints and organisms, but the availability of large enough, balanced, and high-quality datasets are the main drawbacks for reliable predictions. An excellent correlation with the in vitro/in vivo data, that is, high sensitivity, as well as high specificity, an easy to use and easy to interpret in silico model are key requirements for its usefulness. In the past few years, computational toxicology prediction systems tremendously increased their predictive power for endpoints like

genotoxicity, carcinogenicity, phototoxicity, phospholipidosis, GSH adduct formation, hERG inhibition, CYP inductions, and DILI (drug-induced liver injury), but still have not achieved the major breakthrough due to lack of sufficiently large datasets covering more complex and broader toxicological endpoints (e.g., liver-, kidney-, cardio-toxicity). These are the critical toxicity endpoints, which needs to be further investigated in the next years to weed out potential safety issues in the clinics. Recent initiatives and consortia (e.g., IMI/eTOX, ToxCast, and ToxBank) dealing with data sharing of preclinical in vivo toxicology studies and development of computational approaches have the potential of significantly improving these endpoint predictions and filling the most data gaps.[3]

This article will outline general considerations on the mainly applied expert systems—rule-based and statistical-based models—in toxicology and ADME for pharmaceuticals and their application in the early drug discovery and optimization process as well as their regulatory impact on the assessment of potential impurities arising in the manufacturing process. Recent improvements and future perspectives on the main challenges of predicting complex in vivo endpoints will be summarized and discussed.

2.09.2 Methods for the Prediction of Toxicity

The thorough assessment of the safety profile of drug candidates is of great importance to ensure that no harm is posed to healthy volunteers and patients during and after clinical development throughout the entire lifecycle of the drug product. Drug toxicity can manifest itself in a number of ways and may interest one or more target organs or biological processes.

In particular, carcinogenicity, liver, renal, cardiovascular, reproductive, and genetic toxicities are among the most significant safety issues that can prevent drug candidates from progressing through clinical development or can cause the withdrawal of already marketed products. Overall, between 20% and 30% of failures can be attributed to safety reasons.[4–6]

In recent years, predictive computational approaches have gained more importance within industry, helping discovery teams to rank compound classes according to specified criteria and prioritize follow-up experiments, either in vitro or in vivo, with the most promising molecules. Few factors have been instrumental in the increased popularity of in silico approaches in drug discovery, among them:

(a) Broader availability of high quality datasets either via the public domain route or through focused data sharing initiatives;[7,8]
(b) More robust computational models that can provide more reliable predictions;[9]
(c) General pressure to reduce animal testing (e.g., ban on animal testing in the EU for the cosmetic sector);[10]
(d) Increased unmet medical needs calling for bringing innovative drugs to patients faster;
(e) Legislation on the assessment of potential genotoxic impurities;[11]
(f) Software and technology progress, both at a commercial and open source levels.

The most widely used platform-based computational methods specifically designed and developed for the prediction of toxicity endpoints can be roughly divided into two main categories, rule-based and statistical-based systems, depending on what type of methods they use to make their classifications.[3]

2.09.2.1 Rule-Based Systems

Computational tools included in this category store and manipulate knowledge to interpret information. They are often referred to as expert systems, which make use of a set of explicit rules (i.e., not implicitly embedded in a code) to make deductions and classifications. Such systems have the advantage that rules can be easily represented and developed by experts in the field of toxicology (or of any discipline the systems are applied to), rather than by information technology (IT) specialists. In addition, solid expert rules can be derived from limited amounts of data, as long as they are sufficiently representative of specific chemical and biological spaces. Both commercial and open source systems are available within the rule-based methodologies and they include, among others, Derek Nexus,[12–15] ToxTree,[16] CASE Ultra Expert Rules,[17] and Leadscope Expert Alert system.[18]

2.09.2.1.1 Derek Nexus

It is an expert, knowledge-based system which contains structural alerts (SAs) and expert knowledge rules (derived from both public and proprietary data by scientists at Lhasa Ltd.) for a wide range of toxicological endpoints and applies these to make in silico predictions about the toxicity of chemical entities. The knowledge-based expert rules represent knowledge from the literature, academic, industrial, and Lhasa Ltd. scientific experts and are regularly updated according to the newly available experimental data and publications. In making predictions, the expert rules, which take into account not only the presence or absence of a structural alert but also the species and a few calculated physicochemical parameters (where applicable) in a process akin to the human-based logic of argumentation. Proprietary data donated, by Lhasa Ltd. members, has been used in the development of approximately 25% of the bacterial in vitro (the Ames test) mutagenicity alerts in Derek Nexus and proprietary data sets are used to validate the performance of alerts for this, and other endpoints, to provide an indication of predictive performance within the chemical space of highest interest to users. In addition, proprietary and customized alerts can be defined by users and implemented through the Derek Knowledge Editor.

The most recent version of Derek Nexus contains expert-derived functionality to provide negative predictions for bacterial in vitro mutagenicity in order to give more confidence on nonpositive predictions. If a query compound does not match a structural

alert for mutagenicity, then it is compared to a Lhasa reference set of Ames test data and a negative prediction is provided based on the features within the query compound.[19] In case of absence of alerts for endpoints other than mutagenicity, negative calls should be made with caution as alerts that are not part of the rule base, hence unknown to the system, can still be relevant in the induction of certain toxicities.

Since Derek is an expert system, it has no training set in a strict sense as in QSAR-based systems, but there are example compounds for the alerts stored in its knowledge base.

2.09.2.1.2 ToxTree

It is a Java-based, freely available, open-source application for toxicity prediction. It was developed by Ideaconsult Ltd. (Sofia, Bulgaria) under the terms of a contract with the European Commission Joint Research Centre. The program is mainly based on structural alerts but also provides QSAR models for distinct chemical classes to refine the predictions. For mutagenicity, ToxTree implements the Benigni–Bossa rulebase[20] for carcinogenicity and mutagenicity. The alerts are only differentiated into genotoxic and a small number of nongenotoxic ones, without distinction between carcinogenicity and mutagenicity. Additionally, this module offers QSAR models for aromatic amines and α,β-unsaturated aldehydes, which should improve the predictivity for these specific chemical classes. However, the mutagenicity QSARs refer to Salmonella typhimurium TA100 only. With regards to structures that do not trigger any alert, the same considerations on negative predictions made for nonmutagenic endpoints for Derek Nexus apply.

2.09.2.1.3 CASE Ultra expert rules

As of version 1.5.2.0 of CASE Ultra, an *expert rule system* is built using rules from expert knowledge or scientific literature for the prediction of bacterial mutagenicity.[17] A detailed description of the software is given in the related section describing the statistically based systems.

2.09.2.1.4 Leadscope expert alert system

Leadscope Inc. produces several software modules applicable in the context of toxicological forecasting, particularly in the field of QSAR models. Recently, Leadscope developed a rule-based expert system for the prediction of mutagenicity, using an extensive high quality genetic toxicity database containing the results of the bacterial mutagenesis assay along with chemical structures.[21] Firstly, the chemical structures were merged using a chemical registration system to assign a unique identifier to each chemical and merging entries on the basis of this identifier. Next, the graded endpoints for *Salmonella* and *E. coli* were combined from the different sources, resulting in a database of over 7000 chemicals each with a positive/negative overall bacterial mutation call. The reference set also covers a diverse collection of compounds since they have been derived from many different sources, including pharmaceuticals, pesticides, industrial chemicals, and food additives. Clustering led to 1220 clusters with two or more examples, and 1049 singletons (clusters with one example). Once substructures are identified for alert definitions, the selected alerts are consolidated and organized hierarchically (i.e., parent/child). This helps in establishing a mechanistic explanation particularly where any child alert is lacking or has limited mechanistic information, as it may be inherited from the parent alert. When the expert alerts are used to make prediction, a score is calculated reflecting the precision of the alert.[21] In addition to the primary alert, it is also important to define any factors that would deactivate the alerts as a result of electronic or steric effects or by blocking an important metabolic step. In this context, the Leadscope software identified and quantitatively assessed deactivating factors using the 27,000 predefined structural features in Leadscope and generated new chemical scaffolds associated with negative bacterial mutagenicity. Any deactivating fragments identified were quantitatively evaluated using the reference set.

2.09.2.2 Statistical-Based Systems

Quantitative structure–activity relationship (QSAR) models are regression or classification models used in the chemical and biological sciences and other disciplines. Like other regression models, QSAR regression models relate a set of "predictor" variables (X) to the potency of the response variable (Y), while classification QSAR models correlate the predictor variables to a category value of the response variable.

The QSAR approach can be generally described as an application of data analysis methods and statistics to models development that could accurately predict biological activities or properties of compounds based on their structures. Any QSAR method can be generally defined as an application of mathematical and statistical methods to the problem of finding empirical relationships (QSAR models) in the form $P_i = k'(D1, D2,\ldots,Dn)$, where P_i are biological activities (or other properties) of molecules; $D1$, $D2,\ldots,Dn$ are calculated (or, sometimes, experimentally measured) structural properties (or molecular descriptors) of compounds; k' is some empirically established mathematical transformation that should be applied to descriptors to calculate the property values for all molecules. The goal of QSAR modeling is to establish a trend in the descriptor values, which parallels the trend in biological activity.[22]

Both commercial and open source systems are available within the QSAR-based methodologies and they include, among others, Sarah Nexus,[23] CASE Ultra,[17] Leadscope Model Applier,[24] OECD Toolbox,[25] Bioclipse,[26] admetSAR, and Prous Institute Symmetry.[27]

2.09.2.2.1 Sarah Nexus

It is a statistical system which utilizes a self-organising hypothesis network (SOHN) model to generate predictions for mutagenicity.[28] This hierarchical model not only retrieves matching fragments, it also further refines these results by considering the structure's similarity to the query structure. The methodology retains those fragments that are perceived to be of greater value; fragments may be of various sizes and can even overlap, ensuring greater accuracy in predictions. Fragments are generated from the provided training set of molecules and not selected from lists of predetermined fragments. Both global (broad coverage, not adequately sensitive to local variations) and local (more accurate for fragments that fall inside their chemical space, narrower in scope) models are available in Sarah Nexus. If the query structure is not an exact match to a compound within the training set (for which a prediction of 100% confidence is generated), the structure is fragmented and the software will select the most appropriate model for each fragment.

The structural explanation for the prediction provided by Sarah Nexus is conveyed by highlighting those fragment(s) that the model considers meaningful. Sarah Nexus provides a confidence score and a structural explanation for each prediction alongside direct access to supporting data to aid expert analysis.[29] The results of the validation of the system using 14 different in vitro mutagenicity data sets provided by nine pharmaceutical companies have been recently published by Barber et al.[30]

2.09.2.2.2 CASE Ultra

CASE Ultra's algorithm is mainly influenced by the original MCASE methodology,[31,32] a traditional QSAR system, which can automatically generate a predictive model from a training set of noncongeneric compounds with associated biological or toxicity data. The training set ideally should contain examples of both active and inactive chemicals in a nonoverly skewed ratio.

CASE Ultra can identify alerts that are not limited to linear paths of limited size or limited branching pattern and the training sets could be larger than 8000 molecules.[33] To build a model, CASE Ultra picks up one active chemical at a time from the training set and systematically generates a list of fragments for that chemical. Each fragment's relevance for activity is then determined using a two-objective criteria comprised of Shannon's entropy[34] as a fitness measure and the number of the active training set molecules containing this fragment (fragments that are optimal based on the two objectives, i.e., the ones that cannot be replaced by any other fragment without degrading one or both objectives, are selected and then sorted in descending order of the number of their active chemicals). A top few fragments (based on the aforementioned two-objective criteria, e.g., fragments that have low entropy as well as supported by higher number of active training chemicals) are selected. These fragments are considered as potential positive alerts. The fragment generation procedure produces simple linear chains of varying lengths and branched fragments as well as complex substructures generated by combining simple fragments. When the algorithm has finished scanning all the active chemicals, a search is made in the accumulated list of the potential positive alerts to find the alert that covers the highest number of active chemicals, and it is added to the final list of positive alerts. This step is repeated until enough positive alerts were identified to cover all the active chemicals in the training set. Once a final set of positive alerts is identified, CASE Ultra attempts to build separate local QSARs for each positive alert in order to explain the variation in activity within the training set chemicals covered by that alert. In addition, deactivating alerts are found using a very similar process but by scanning inactive chemicals and finding fragments that occur mainly in inactive chemicals. This collection of positive and deactivating alerts constitutes a model for a particular endpoint and can be used for predicting activity in test chemicals. During prediction, a test chemical is scanned against the list of the model's positive and deactivating alerts, and if no positive alerts could be identified in it, the chemical is considered inactive. In general, if the test chemical contains one or more positive alerts, it is predicted as "active." However, this active prediction call can be changed if the local QSAR of the positive alert modifies the prediction. The presence of a deactivating alert alongside a positive alert renders the prediction call as "inactive." If more than one positive alert is present, then the one with the highest number of active chemicals is used, and in the case of more than one deactivating alert, the one with the highest number of inactive chemicals is used. If a test chemical contains a positive alert that has been seen in just one or two active training set chemicals, the prediction result is considered "inconclusive" because of the alert low statistical confidence. CASE Ultra recognizes unusual features/fragments in test chemicals that do not match training data (unknown structural fragments). The presence of more than three unknown structural fragments in the test chemical results in an "out of domain" call.

2.09.2.2.3 Leadscope model applier

The Leadscope software employs a fragment-based QSAR paradigm; however, the fragments are not paths of distinct lengths but are predefined in a hierarchically organized dictionary that is closely related to common organic/medicinal chemistry building blocks. For binary classification problems, such as the Ames test results, the algorithm identifies toxicity modulating fragments using a χ^2-test. Furthermore, the software is able to build superstructures from smaller fragments if they improve predictivity. Together with eight global molecular properties, the set of fragments is then used as a descriptor set in a partial least squares (PLS) logistic regression model of the activity class. Therefore, the predictions from this algorithm are continuous probabilities of class membership rather than binary outputs. The program also assesses the applicability domain by measuring the distance to training set molecules. Typically, probabilities greater than 0.5 as can be used to give an "active" prediction and probabilities smaller than 0.5 an "inactive" prediction, which is the standard procedure used by the Model Applier for pretrained models. The system can also annotate compounds as "out of domain" or with "missing descriptors" when a conclusive prediction cannot be made.[24]

2.09.2.2.4 OECD toolbox

The OECD Toolbox (http://www.oecd.org/chemicalsafety/risk-assessment/theoecdqsartoolbox.htm)[25,35] represents a free source of various models. The Toolbox is a software application intended to the use of governments, chemical industry, and other stakeholders in filling gaps in (eco)toxicity data needed for assessing the hazards of chemicals. The Toolbox incorporates information and tools from various sources into a logical workflow. Crucial to this workflow is grouping chemicals into chemical categories. The seminal features of the Toolbox are: (i) identification of relevant structural characteristics and potential mechanism or mode of action of a target chemical; (ii) identification of other chemicals that have the same structural characteristics and/or mechanism or mode of action; (iii) use of existing experimental data to fill the data gap(s). The Toolbox includes a number of models predicting several toxicological endpoints, such as skin sensitization, Ames mutagenicity, acute and repeat-dose toxicity, aquatic toxicity, and others.[36]

2.09.2.2.5 Bioclipse

Bioclipse[26] is an open source cheminformatics toolkit with a wide array of toxicity models integrated, such as carcinogenicity, mutagenicity (Ames), hERG, aquatic tox (daphnia), and a wide array of models from OpenTox.[37] The Ames mutagenicity model in Bioclipse is built using the dataset published by Kazius et al. in 2005[38] containing 4337 chemical structures of which 2401 were classified as mutagen and 1936 nonmutagen. The datasets can be downloaded and the software can be used to generate many molecule descriptors (using the CDK)[39,40] and then QSAR models (through integration with the R-statistical software). The software is considered not as user friendly as some other commercial tools.[41]

2.09.2.2.6 admetSAR

admetSAR[42] is a free website (http://lmmd.ecust.edu.cn:8000/)[43] that enables a single input SMILES structure to be used to rapidly predict scores against a wide range of ADME/Tox models (at the time of writing, 26 qualitative classification and 5 quantitative regression models). These datasets can also be downloaded as most are based on other publications. Each model has some statistics describing the model as well as a probability to provide more confidence in the result. The software is simple to use and drawbacks appear to be the lack of batch processing operation, the "black box" nature of the models, and the lack of capability to build or update the models on the website.[41]

2.09.2.2.7 Symmetry

Symmetry[27] is a platform that applies advanced machine-learning techniques to a variety of structural features and physicochemical properties of small molecules to provide predictions about biological effects. Available Symmetry algorithms include binary classification for active/inactive data sets, meta-classifiers to achieve consensus predictions for sets of binary models, and multilabel learning that yields ranking and probabilistic estimates of the possible outcomes. Symmetry offers a wide range of predictive models (http://symmetry.prousresearch.com/symmetry-models/), including mechanism of action and phenotypic models, toxicity,[44] and human adverse effects.

2.09.3 Assessment of Genotoxic Impurities

2.09.3.1 Regulatory Requirements

The European Medicines Agency Committee for Medicinal Products for Human Use (CHMP) released in 2006[45] a "Guideline on the Limits of Genotoxic Impurities," which describes an approach for assessing genotoxic impurities of unknown carcinogenic potential based on the Threshold of Toxicological Concern (TTC) concept.

The TTC bases its rationale on the fact that it is possible to identify "safe levels of exposure" for chemicals with known toxicological profiles. TTC is a pragmatic risk assessment approach that aims at establishing a human exposure threshold value below which there is a very low probability of an appreciable risk to human health.[46]

Genotoxicity is a broad term that typically describes a deleterious action on cellular genetic material. Chemicals may induce DNA damage by directly interacting with it (e.g., alkylating agents) or by acting on non-DNA targets (e.g., mitotic spindle poisons, inhibitors of topoisomerase). For DNA-reactive genotoxins, the mechanism by which they induce genetic damage is assumed to follow a linear no-threshold model; on the other hand, for molecules not interacting directly with DNA, the existence of a threshold concentration required to induce the damage is accepted.[46] Impurities that belong to the second category of substances can be regulated according to the ICH Quality Guideline Q3C[47] which includes Class 2 Solvents. The thresholds or permissible daily exposures are calculated from the no-observed-effect Level (NOEL) obtained in the most relevant animal studies with the use of conservative conversion factors used to extrapolate the animal data to humans.

In terms of regulatory guidelines on this specific aspect of risk assessment, the European Medicines Agency Committee for Medicinal Products for Human Use (CHMP) released in 2006[45] a "Guideline on the Limits of Genotoxic Impurities," which describes an approach for assessing genotoxic impurities of unknown carcinogenic potential based on the TTC concept. The CHMP guideline suggests that the TTC concept should be applied to those genotoxic impurities that do not have sufficient evidence of a threshold-related mechanism of action. The reference values are taken from Kroes et al.,[48] where a TTC of 0.15 μg/day is proposed for impurities presenting a structural alert for genotoxicity, corresponding to a 10^{-6} lifetime risk of cancer. In the case of pharmaceuticals, the guideline suggests a 1 in 100,000 risk be applied, resulting in a TTC of 1.5 μg/day.[3,46]

Also in 2006, a task force established under the umbrella of the US Pharmaceutical Research and Manufacturing Association (PhRMA) for the first time proposed the ″staged TTC″ concept to be applied to pharmaceuticals.[49] The task force was established as a response to various clinical holds imposed by the FDA on investigational drugs in clinical trial phases based on suspicions to contain genotoxic impurities at levels potentially associated with a risk for the volunteers or patients involved in these trials.[50] The staged approach allows levels of daily intake of mutagenic impurities higher than 1.5 μg as defined by the lifetime TTC, namely 10 μg (for a 6-to-12-month duration), 20 μg (3–6 months), 40 μg (1–3 months), and 120 μg for not more than 1 month. The EMA adopted the staged TTC approach for limits of genotoxic impurities in clinical trials in the 2007 Q&A document (EMA 2010,[51]), but to be more conservative it reduced the staged TTC limits proposed in the PhRMA paper by a factor of 2.

In 2008, the FDA issued a draft "guidance for Industry on Genotoxic and Carcinogenic Impurities in Drug Substances and Products: Recommended Approaches" (FDA 2008) which was largely similar to the EU guidance. However, this document has not been finalized because in 2009 the topic "genotoxic impurities" was adopted by ICH for development of a new internationally harmonized guideline. Since the topic was considered to include both safety and quality aspects the projected guideline was assigned to the M (multidisciplinary) series of the ICH process and designated as ICH M7 with the title "Assessment and Control of DNA-Reactive (Mutagenic) Impurities in Pharmaceuticals to Limit Potential Carcinogenic Risk."[52] The document was adopted as a step 4 ICH Harmonised Tripartite Guideline in June 2014 (ICH 2014) and is currently on step 5, adopted by CHMP on 25 Sep. 2014 and issued as EMA/CHMP/ICH/83812/2013.

2.09.3.2 The ICH M7 Guideline

The ICH M7 guideline combines many of the principles set by the EU- and the draft FDA Guidelines on genotoxic impurities. Some aspects, though, have been updated and clear recommendations can be identified. A thorough description of all key aspects of the ICH M7 guideline, is beyond the scope of the present contribution.[50] It is nonetheless worthwhile mentioning few of the critical aspects that the ICH M7 guideline does enforce:

1. Structure-based assessment of potentially mutagenic impurities has to be carried out using two in silico systems that complement each other: one should be a rule-based and one a statistics-based method;
2. The impurities classification system proposed by the ICH M7 guideline has been derived from the scheme proposed by Müller et al. in 2006,[49] with five classes of impurities assigned according to data availability for the characterization of their mutagenicity and carcinogenicity potential;
3. ICH M7 replaced the term "genotoxic impurities" as applied by the EU Guideline on the Limits of Genotoxic Impurities with the term "DNA-reactive impurities" in order to specify that DNA reactive compounds (i.e., that typically covalently bind to DNA generating adducts, which, if unrepaired, can lead to point mutations and/or strand-breakage) are those that fall within the scope of the Guideline. There is also the assumption that DNA-reactive (Ames-positive) compounds are likely carcinogens with no threshold mechanism;
4. For DNA-reactive (Ames-positive) compounds lacking rodent carcinogenicity data, a generic TTC value would be applied as an acceptable intake level that poses a negligible risk of carcinogenicity;
5. If rodent carcinogenicity data is available for a (potentially) mutagenic impurity, the application of the TTC concept is not warranted and a compound-specific calculation of acceptable levels of impurity intake is recommended;[52]
6. Compound-specific calculations for acceptable intakes can be applied case-by-case for impurities which are chemically similar to a known carcinogen compound class (class-specific acceptable intakes) provided that a rationale for chemical similarity and supporting data can be demonstrated (Note 5);[46,52]
7. The acceptable intakes derived from compound-specific risk assessments can be adjusted for shorter duration of exposure. The TTC-based acceptable intake of 1.5 μg/day is considered to be protective for a lifetime of daily exposure (**Table 1**,[11]). To address Less Than Lifetime (LTL) exposures to mutagenic impurities in pharmaceuticals, a formula is applied in which the acceptable cumulative lifetime dose (1.5 μg/day × 25,550 days = 38.3 mg) is uniformly distributed over the total number of exposure days during LTL exposure. This allows higher daily intakes of mutagenic impurities than would be the case for lifetime exposure and still maintain comparable risk levels for daily and nondaily treatment regimens;
8. As far as multiple impurities are concerned, when there are more than two mutagenic (i.e., Ames positive) or alerting impurities, total mutagenic impurities should be limited as described in **Table 2** for clinical development and marketed products.

2.09.3.3 Prediction of Mutagenicity With Commercial In Silico Systems

In silico methods for the prediction of mutagenic activity have been available for many years and they have undergone continuous updates and improvements driven by advancements in technology and greater availability of high quality data.

Table 1 Acceptable Intakes for an Individual Impurity

Duration of treatment	*≤ 1 month*	*> 1–12 months*	*> 1–10 years*	*> 10 years*
Daily intake (μg/day)	120	20	10	1.5

Table 2 Acceptable intakes for an individual impurity

Duration of treatment	*≤ 1 month*	*> 1–12 months*	*> 1–10 years*	*> 10 years*
Daily intake (μg/day)	120	60	30	5

The specific use of such in silico tools in the pharmaceutical industry, in the context of the evaluation of genotoxic impurities, has been summarized and reviewed by Sutter et al.[53] The authors, representing a total of 14 pharmaceutical companies, compared the predictive value of the different methodologies analyzed in two surveys conveyed in the US and European pharmaceutical industry: most pharmaceutical companies used a rule-based expert system as their primary methodology, yielding negative predictivity values of ⩾78% in all participating companies. A further increase (>90%) was often achieved by an additional expert review and/or a second statistics-based methodology. Also in the latter case, an expert review was encouraged, especially when conflicting results were obtained. The conclusion was that a rule-based expert system complemented by either expert knowledge or a second (Q)SAR model is appropriate.

More recently, still using ICH M7 as binding guidance, Amberg and coworkers went deeper in elucidating scenarios where additional expert knowledge may be beneficial (on top of the in silico classification), what such an expert review may contain, and how the results and accompanying considerations may be documented.[54]

In order to comply with the ICH M7 guideline specifications, mandating the use two different methodologies, one expert-rule based and one statistical based, additional commercial in silico tools and novel models have been made available to the scientific community. Brigo and Muster[55] evaluated three expert-rule systems (*Derek Nexus v.4.0.5*,[12] *ToxTree v.2.6.6*,[16] *Leadscope Expert Alert v.3.2.4-1*[18]) and three statistical systems (*Sarah v.1.2.0*,[23] *Leadscope Model Applier v.3.2.4-1*,[24] *three models of CASE Ultra v.1.5.1.8*[17]—*GT1_7B; SALM2013; SALM2013PHARMA*) in an individual and combined fashion. All the examined programs (see **Table 3**) have been applied as commercially available, without internal customization or any follow-up expert knowledge driving the final classifications.

The evaluation was carried out using a large validation set of Ames mutagenicity data comprising over 10,000 compounds, 30% of which are Roche proprietary data (**Table 4**). The Roche datasets include the vast majority of compounds (not only impurities) tested in the Ames standard[57] and Microsuspension[58] protocols over the past 30 years.

The application of individual systems showed, as expected, adequate performance statistics with public domain datasets (concordance: 74–95%; sensitivity: 58–99%; specificity: 51–96%; **Fig. 1**), however there was a significant drop in sensitivity with the Roche data sets, down, in one case, to single digit (concordance: 66–88%; sensitivity: 8–54%; specificity: 69–95%; **Fig. 2**). The assessment of the overlap between training and validation data sets showed high values (up to 91% for Sarah) for the "public validation sets," which obviously contributed to good performance of the systems with these specific sets.[3,55]

Expert-rule based tools showed lower specificity with public domain datasets versus the statistical-based programs. Statistical tools showed a much higher number of compounds (up to 39% in one case) outside of their applicability domains and, hence, not predicted (**Fig. 2**).

Table 3 Software tools assessed in the validation experiments and main features

Software tool	*Methodology*	*Availability*	*Vendor*
Derek Nexus v.4.0.5	Rule-based	Commercial	Lhasa Limited

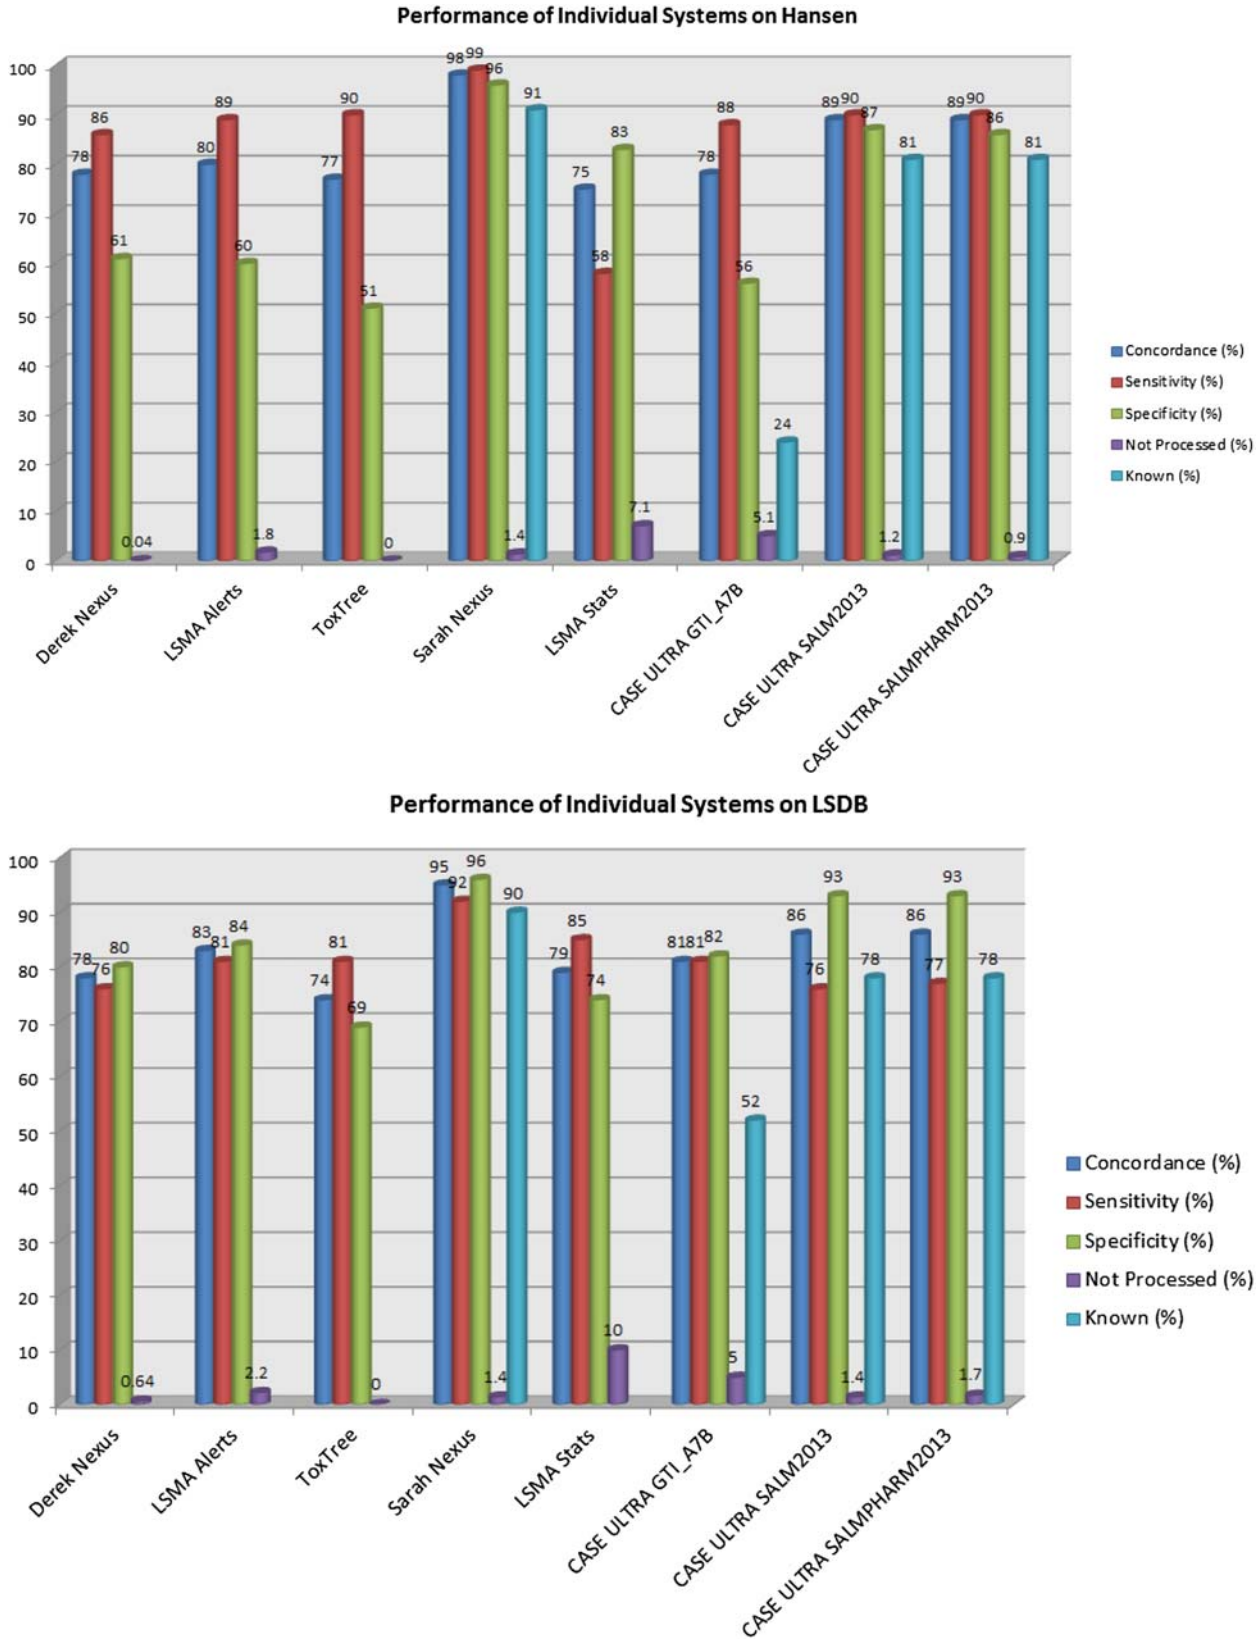

Fig. 1 Performance of individual systems on public datasets Hansen and LSDB.

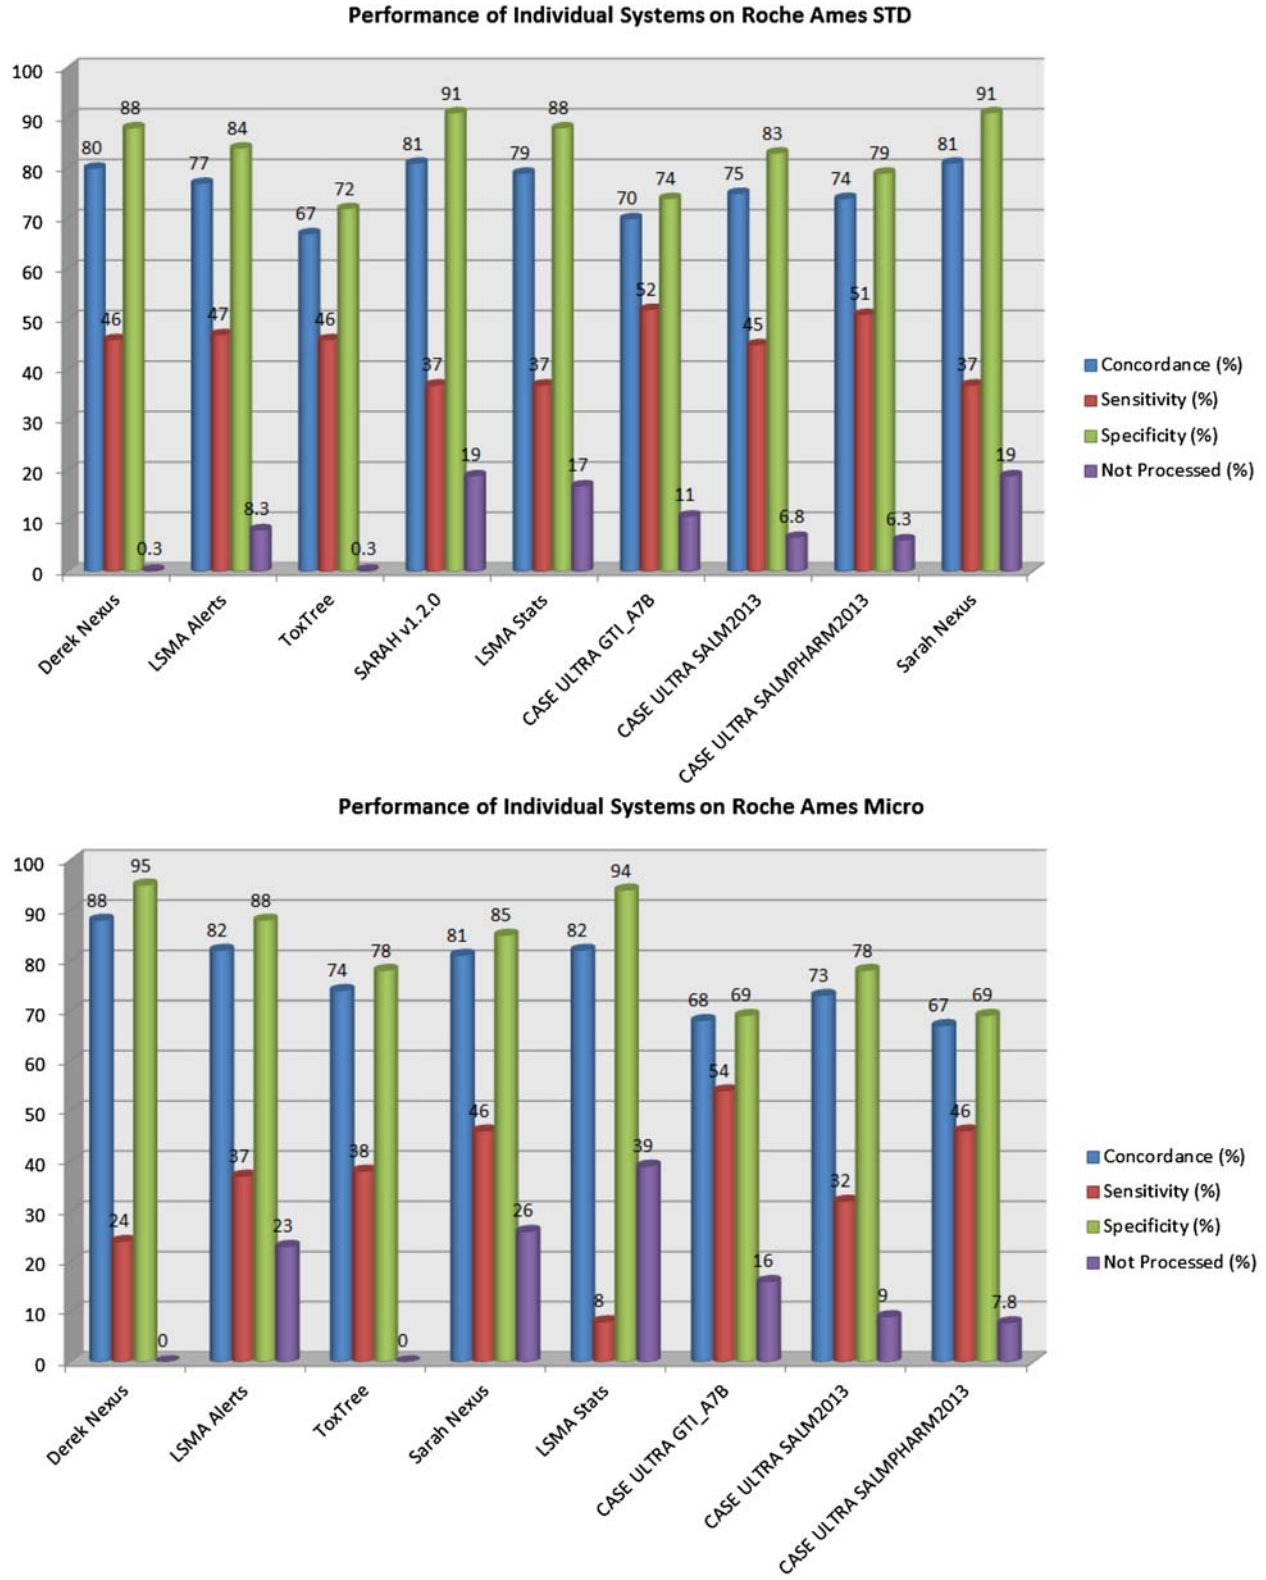

Fig. 2 Performance of individual systems on proprietary Roche datasets.

As previously mentioned, the ICH M7 requires the use of a single combination of one rule-based and one statistical-based tool for the assessment of potential genotoxic impurities. In order to evaluate how such a combined approach changes the overall prediction performance in comparison to the use of individual systems, the Roche validation data sets were submitted to all possible systems permutations (Figs. 3 and 4).

The combinations of all systems, compared to their individual performance with both Roche validation sets, improves the sensitivity to consistently above 50%, up to 71% for the combination "LSMA Alerts + SALM2013." As expected from a consistent increase in sensitivity, specificity is generally lower than with individual systems, but its reduction is limited for the majority of combinations with deltas lower than 20%.

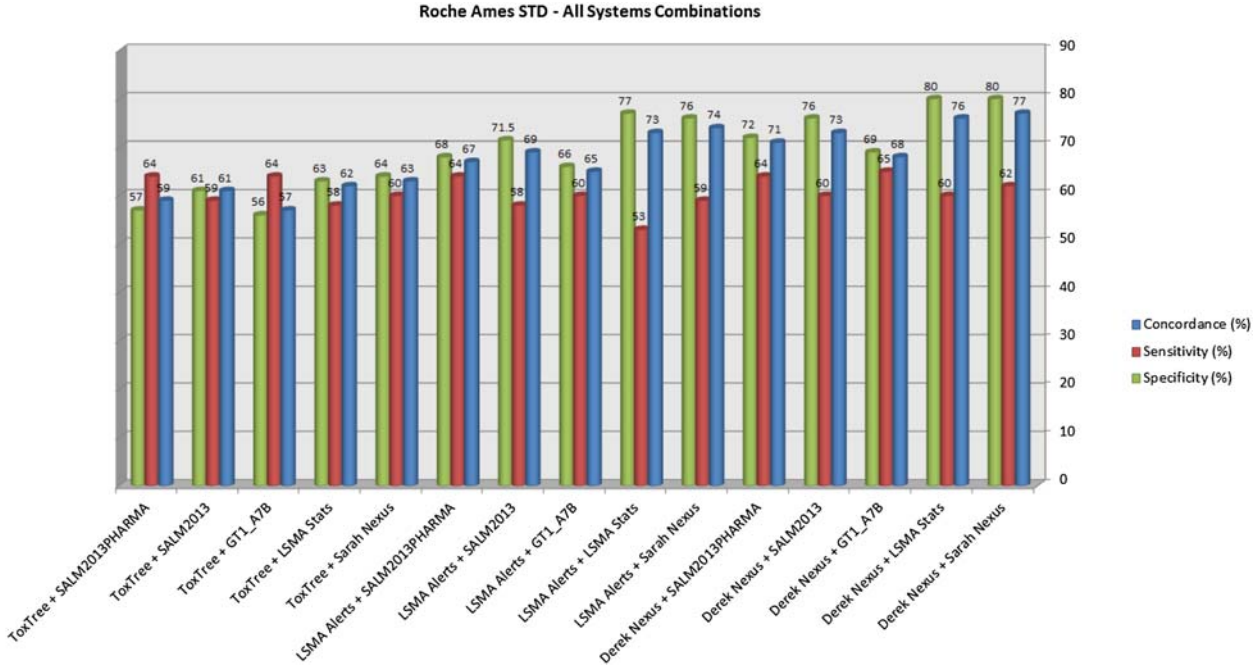

Fig. 3 Performance of individually combined systems on the Roche Ames Standard dataset.

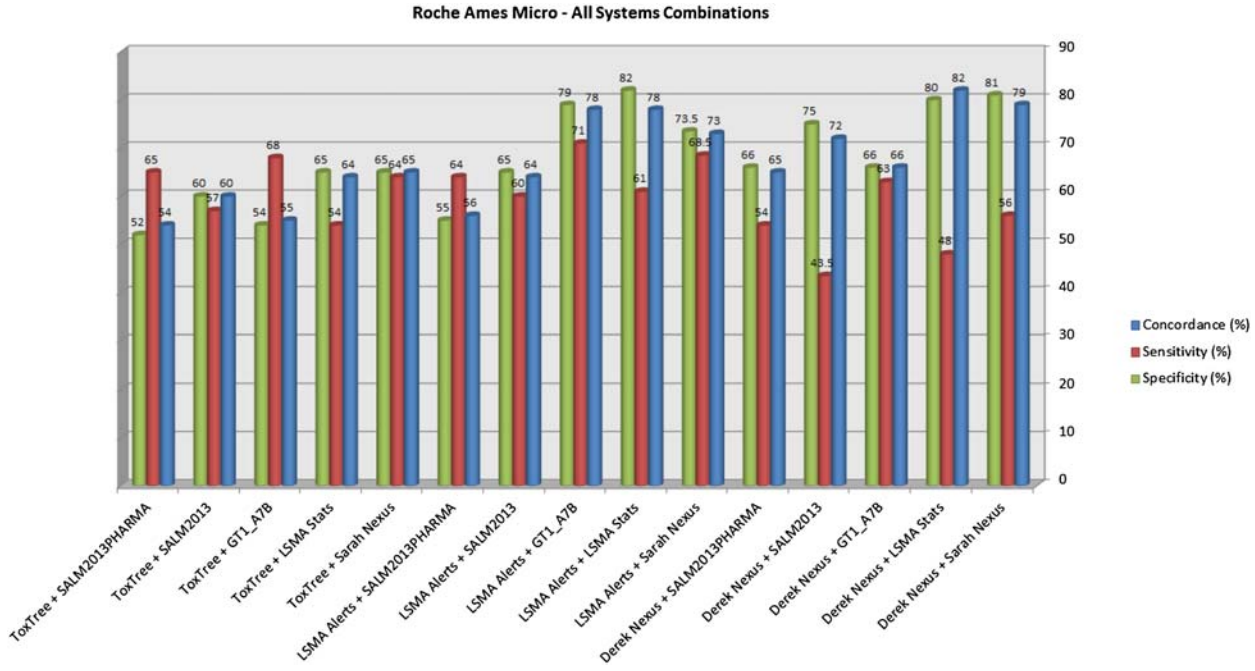

Fig. 4 Performance of individually combined systems on the Roche Ames Microsuspension dataset.

The Roche datasets used in this validation exercise include a rather broad proprietary chemical space not restricted to the usual potential genotoxic impurities domain. A rather quick way to focus the analysis specifically to impurities was the generation from both Roche validation sets of four subsets with molecular weights (MW) ≤ 400, ≤ 350, ≤ 300, and ≤ 250, respectively. Such subsets cover the chemical space of the large majority of the potential genotoxic impurities tested in Roche over the past 10 years.

All in silico programs have been tested against these subsets individually (Figs. 5 and 6) and in all possible permutations (Figs. 7 and 8).[3,55]

With individual systems, sensitivity shows a clear trend to increase proportionally to the decrease of MW. For example, in the Roche Ames Microsuspension set, sensitivity improves as follows: Derek from 27% to 64%; Sarah from 51% to 76%; ToxTree from 42% to 85%; CASE Ultra SALMPHARM2013 from 45% to 71%; LSMA Alerts and LSMA Stats show an increase in sensitivity to 60% up to MW ≤ 300, but there is a flection down to $\sim 55\%$ for both programs for MW ≤ 250. In general, sensitivity increases significantly with low-MW subsets with almost all programs and models (Figs. 5 and 6). The only exception is the CASE Ultra SALM2013 model, which keeps the same sensitivity values throughout all subsets (between 29% and 33%).[3,55] Changes in MW from ≤ 300 to ≤ 250 show overall a rather stable trend in sensitivity with rather small variations. In general, the specificity is affected but to a lesser than expected extent by the decrease in MW, with strong dependency on the system. Looking at the two MW extremes in the Ames Microsuspension subsets (i.e., MW ≤ 400 and MW ≤ 250), Derek Nexus sees a decrease in specificity from 94% to 87%, LSMA alerts from 83% to 61%, ToxTree from 76% to 54%, Sarah from 74% to 53%, and LSMA Stats from 91% to 72%.

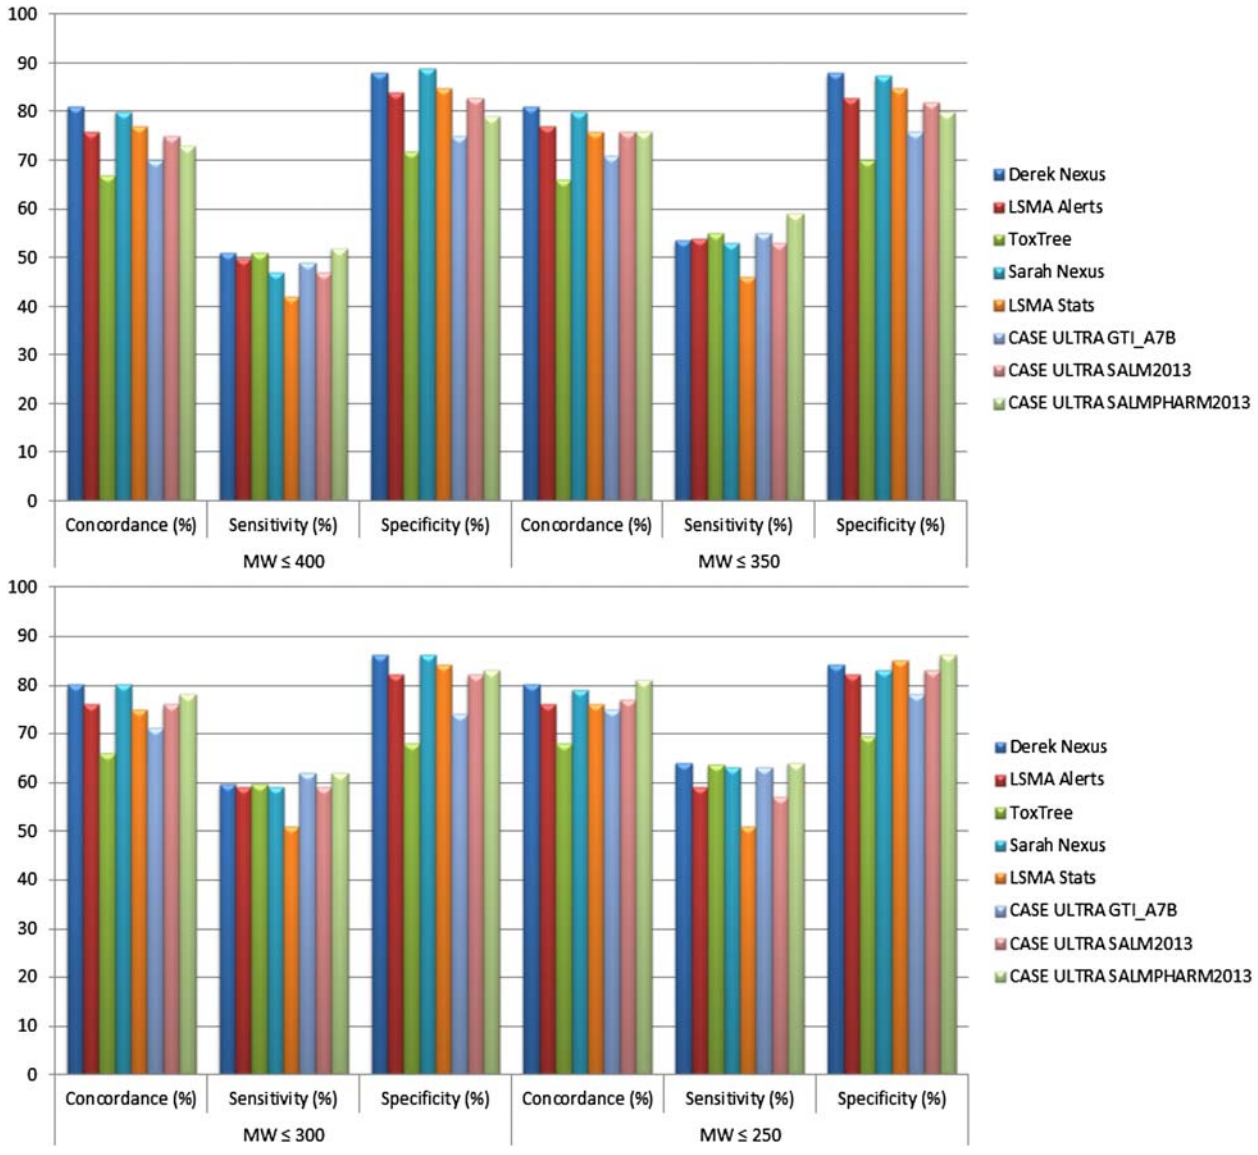

Fig. 5 Performance of individual systems on the Roche Ames Standard dataset filtered by MW.

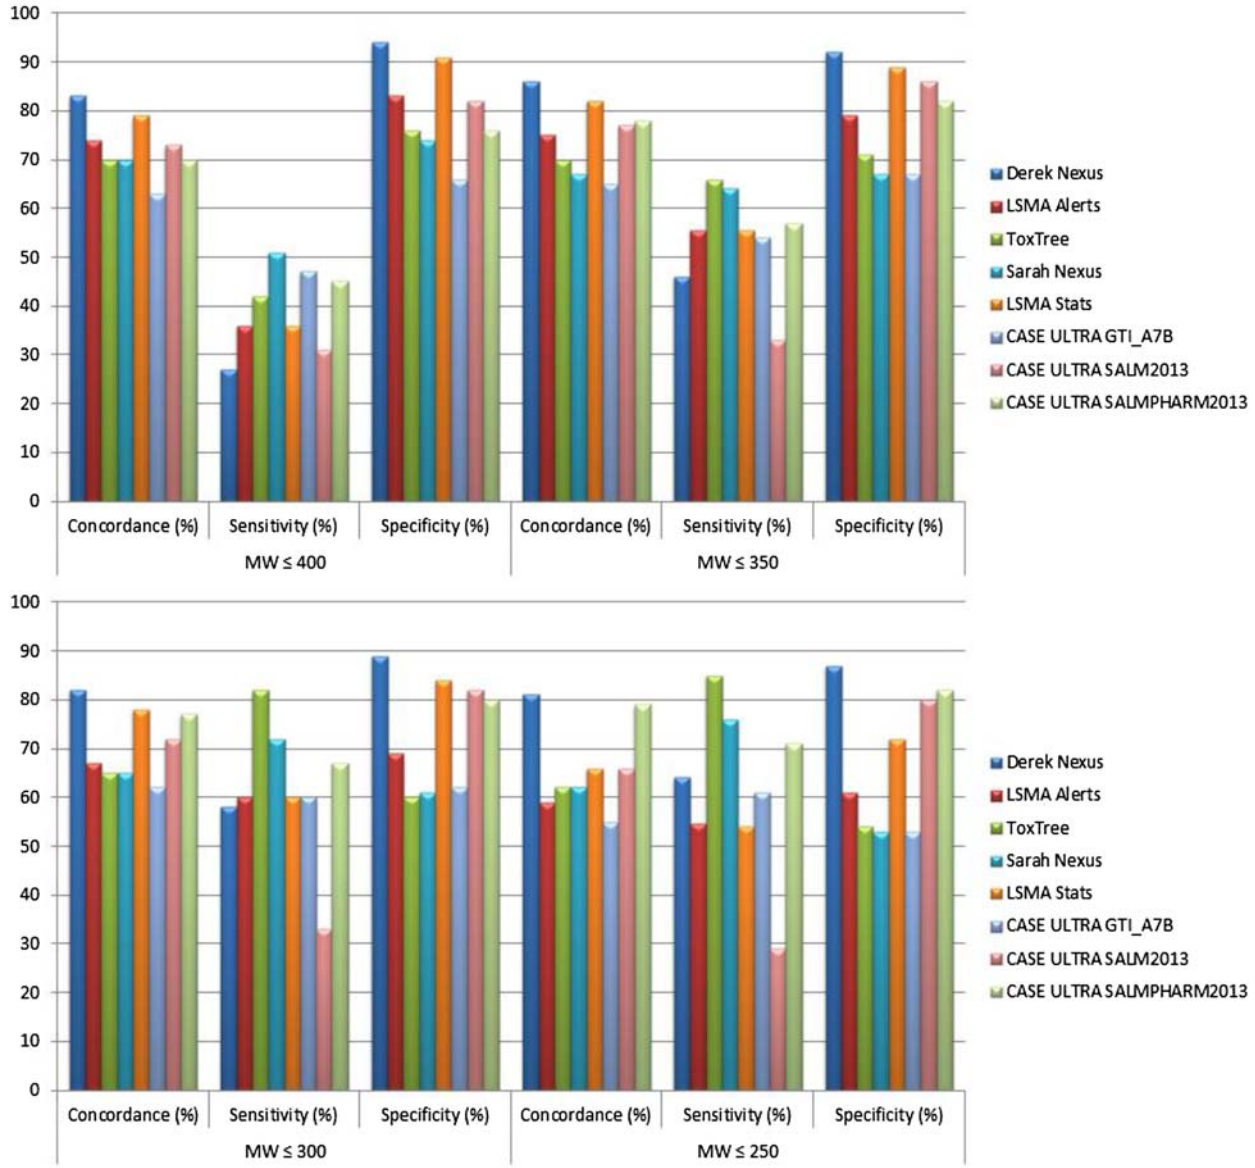

Fig. 6 Performance of individual systems on the Roche Microsuspension dataset filtered by MW.

The evaluation of combined systems with lower MW Roche subsets shows a significant increase in sensitivity, up to over 90% for sets with MW $\leq$300 and $\leq$250 with several combinations (Figs. 7 and 8). The increase in sensitivity is proportional to the decrease in MW; at the same time, there is a considerable decrease in specificity ($\sim$30% in some cases). Such deltas are generally more pronounced in the Ames Micro dataset (Fig. 8) compared to the Roche Ames Standard dataset (Fig. 7). Such effect on the specificity is in general more pronounced compared to single systems. In the Ames Standard subsets, specificity and sensitivity values are consistently comprised between 70% and 80% in nearly all Derek Nexus and LSMA Alerts combinations. In the latter combinations, values are a bit lower than 70% at higher MW. ToxTree combinations show lower sensitivity and specificity values at higher molecular weights and greater gaps between sensitivity and specificity within the subsets MW $\leq$300 and MW $\leq$250.[3,55]

As far as the Roche Ames Micro set is concerned, the sensitivity is in the range of 90% in the subset with MW $\leq$250 with several combinations, such as Derek Nexus + Sarah and Derek Nexus + GT1_A7B; LSMA Alerts + Sarah; LSMA Alerts + CASE Ultra models. Nearly all combinations with ToxTree gave sensitivity in the range of 90%. Nearly all combinations of LSMA Alerts showed high sensitivity also in the subset with MW $\leq$300.

Looking at the plots in Fig. 8, it is evident that more balanced results are obtained with all Derek Nexus combinations: in other words, the sensitivity increases proportionally to the decrease of the MW at a moderate expense of specificity. Compared to this, LSMA Alerts combinations have overall lower specificity than Derek combinations.

At the same time, ToxTree combinations, despite showing good sensitivity, have a greater corresponding decrease in specificity, down to approximately 50% and lower.

The aim of the earlier described in silico systems analysis is not to identify the best performing in silico tools, or combinations thereof, but rather to identify trends and assess their behavior specific to the test sets used. The performance metrics used in the present contribution (namely, sensitivity, specificity, and concordance) is known to be strictly dependent to the test sets used. Some software tools may perform rather poorly with one test set or very well with a different one. This observation is confirmed by the present analysis as well, since most tools performed very satisfactorily with the public domain datasets but their performance got worse with the Roche proprietary datasets.

Our study showed that the use of two systems does indeed improve the overall sensitivity values, meaning that they gain a higher ability to identify mutagenic compounds at a relatively minor increase of the rate of false positive calls.

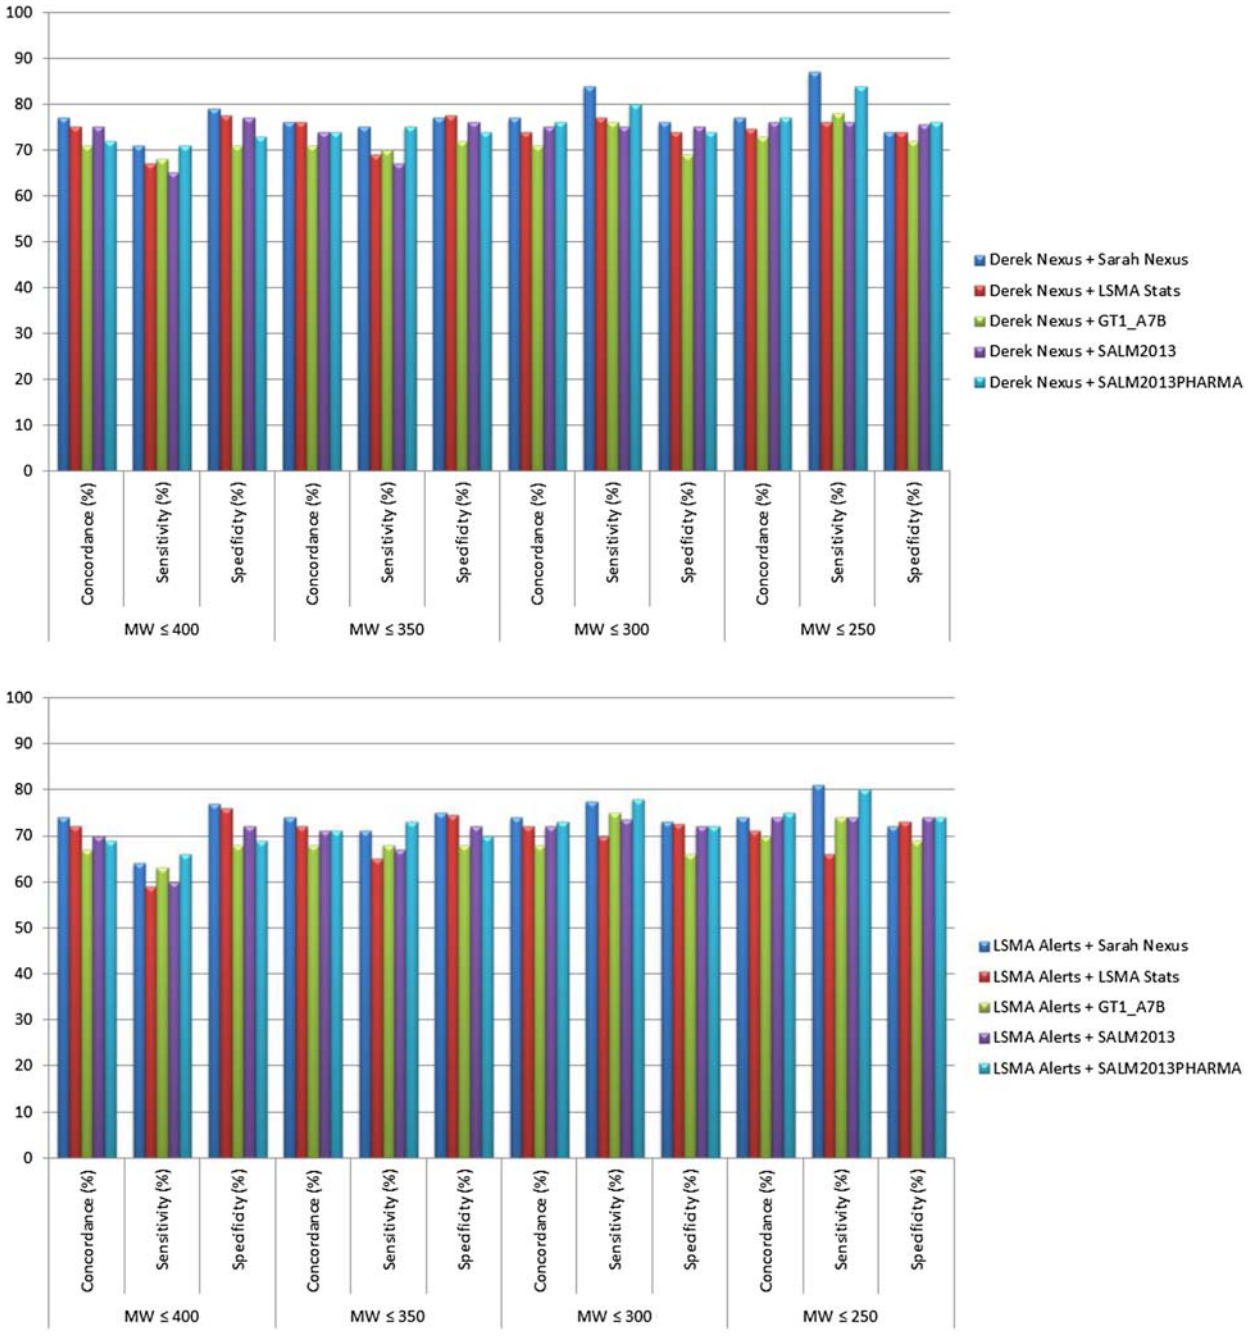

Fig. 7 Performance of individually combined systems on the Roche Ames Standard dataset filtered by MW.

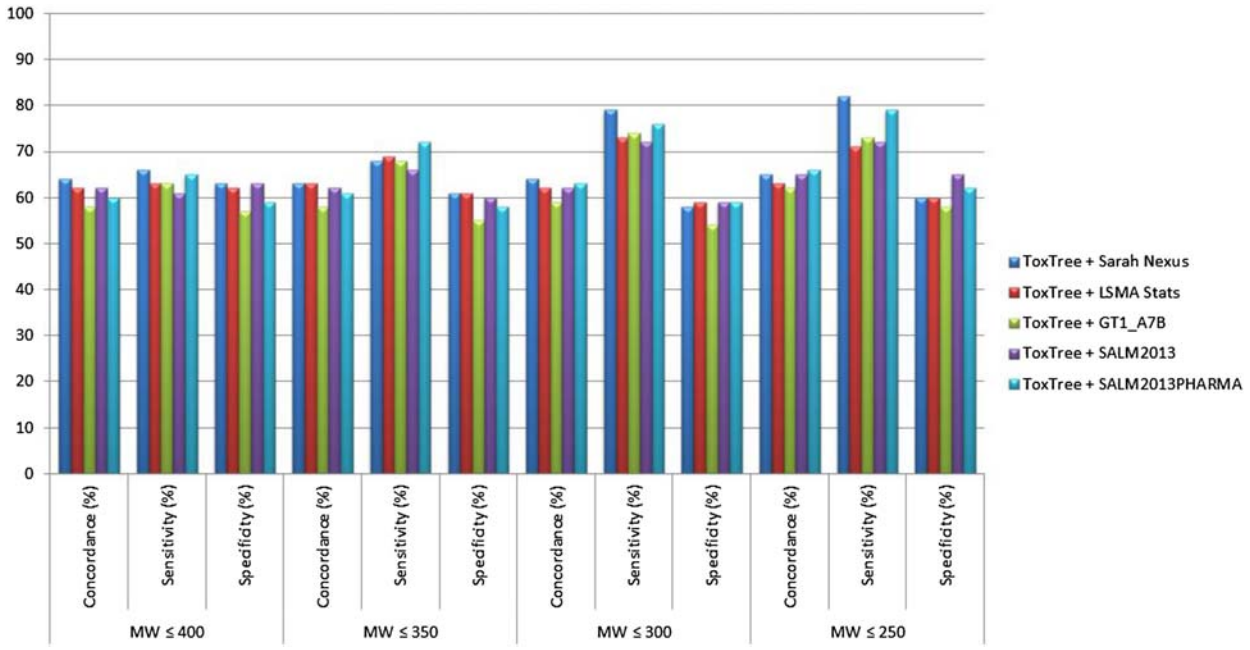

Fig. 7 (*continued*).

In general terms, the most obvious room for improvement lies within the expansion of the chemical space known by the in silico systems via the addition of new data, particularly within the proprietary domain. This goal can be achieved via cross-industry data sharing initiatives (some of them are already active) aiming at filling the gaps of specific chemical classes providing that there are no competitive conflicts.

Another area where some efforts should be directed to is the investigation and establishment of significant correlations between specific chemical properties (e.g., log *P*, PSA, MW), metabolic pathways, and the final biological (or toxic) effects. This would allow complementing the classic fragment-based or substructure-based approach with other parameters that in some cases are critical for the explanation of specific biological activities.

2.09.4 In Silico Models for the Prediction of Toxicity in Drug Discovery

In silico approaches to predict potential toxicities and drug metabolism on the basis of the chemical structure are of particular interest to the pharmaceutical industry as having the potential to impact the early drug discovery process as well as in the candidate selection phase. Prediction models for the identification of metabolic soft spots and potentially toxic substructures can be easily applied to a large number of chemical structures and are therefore integrated already during HTS (high-throughput screening) or even earlier as an automatically attributed alert for all new chemical entities. At this early stage, only a basic in silico profiling can be done, as only the most well validated endpoints can be reliably applied automatically and generated on-the-fly without an expert intervention. Later in the development, at the latest before the final candidate is selected, a more detailed in silico profiling also considering the whole profile of the compound is thoroughly conducted. According to the development scheme provided in Fig. 9, the further in silico tools and in vitro downstream activities are conducted.

2.09.4.1 Target Identification (TI), Target Assessment, and Exploratory Work

The first step after the target has been identified as potential development opportunity is a target assessment (TA) conducted by nonclinical safety experts, using appropriate databases and public sources. A proper target/functionality assessment in healthy and diseased status contains pathway mapping, information from knock-out and transgenic models, a target expression profile in relevant species, as well as a critical evaluation of potential off-target safety alerts (selectivity). Various software systems are available to assist the experts in these assessments (e.g., MetaCore,[59] Symmetry[27]).

Modern in silico prediction software is able to calculate thousands of chemical structures on-the-fly and can be therefore applied very early in the drug development process. Immediately after the chemical structure is known, meaning chemical libraries are added to the company's chemical database, a basic in silico prediction panel is applied using reliably validated toxicological endpoints like genotoxicity and carcinogenicity. As always, a large, homogeneous, and high-quality database is the prerequisite

for reliable predictions. Therefore, in vitro screens which have been used within pharmaceutical companies for years containing data generated often in one single lab are the best sources for the development of highly predictive models. For example, an in silico model predicting the potential of drug-induced phospholipidosis (a reversible storage disorder characterized by accumulation of phospholipids within cells) has been developed. Based on more than 600 in vitro assay, an accuracy of 86% led to a replacement of the in vitro by the in silico method. The model is calculating the free energy of amphiphilicity ($\Delta\Delta G_{AM}$) and log P value[60] of cationic amphiphilic drugs and can be applied in a high-throughput mode. Further endpoints that can be used for on-the-fly predictions are teratogenicity, GSH adduct formation, irritation, and skin sensitization.

At this early stage of development, the potential safety hazards identified by the application of an expert system in combination with a set of statistical models contribute to the overall compound profile (in silico default), but are not used as a decision pathway (see Fig. 10).

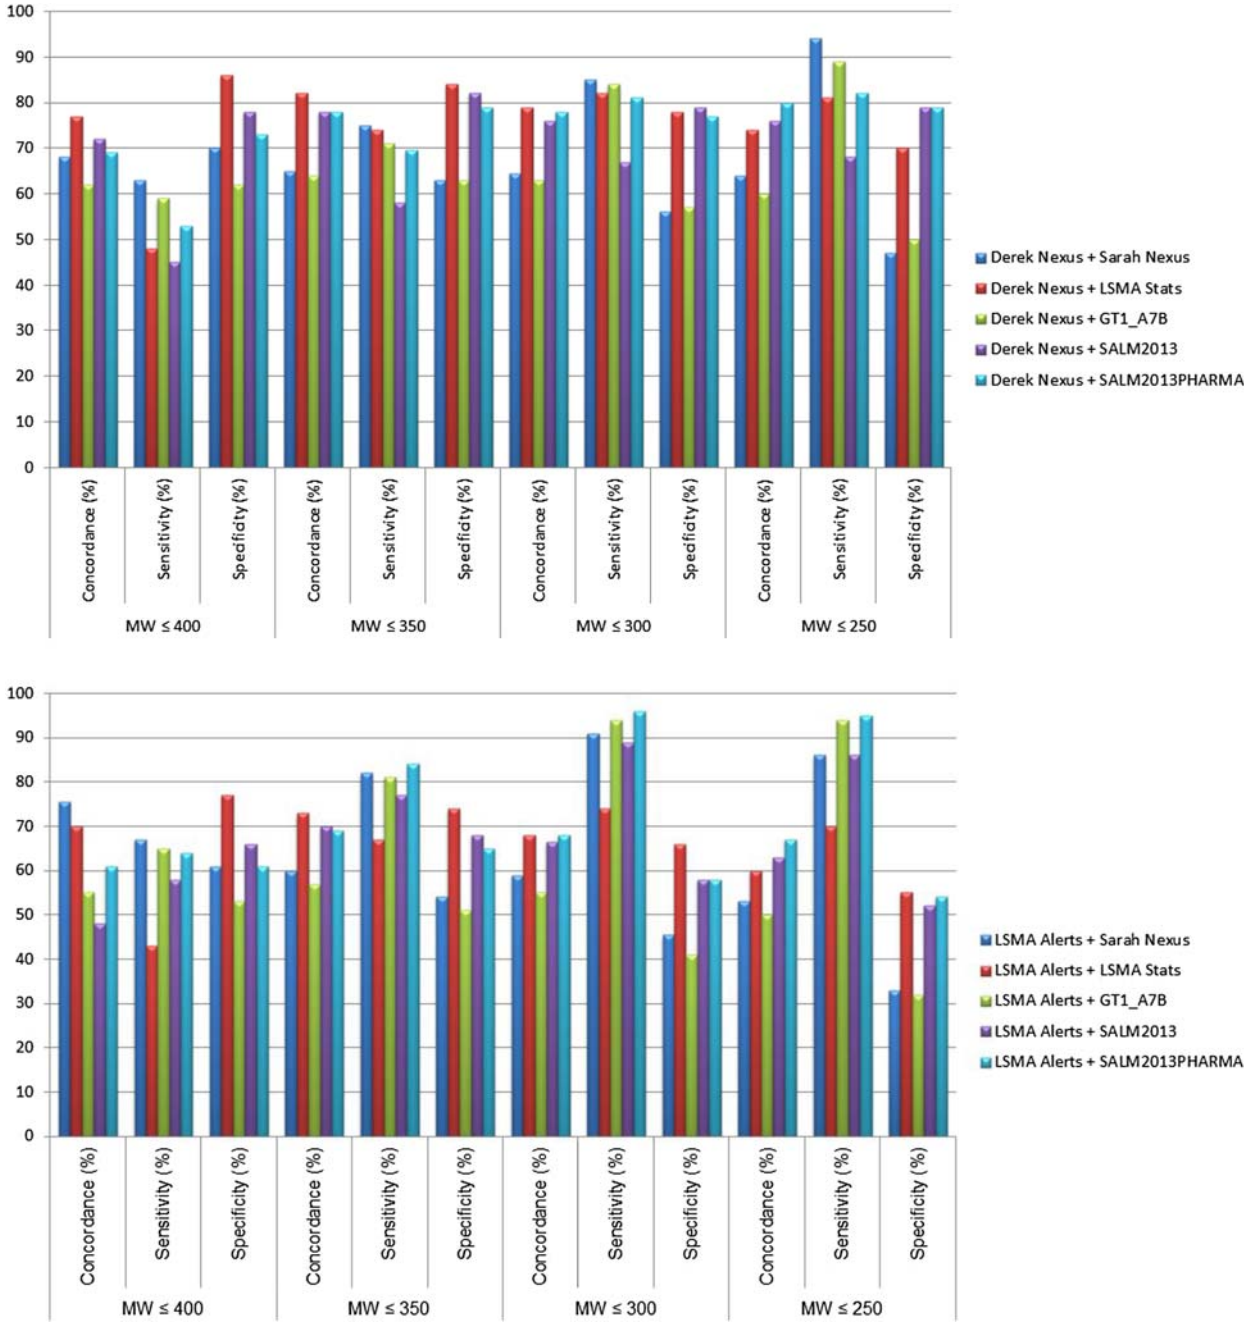

Fig. 8 Performance of individually combined systems on the Roche Ames Microsuspension dataset filtered by MW.

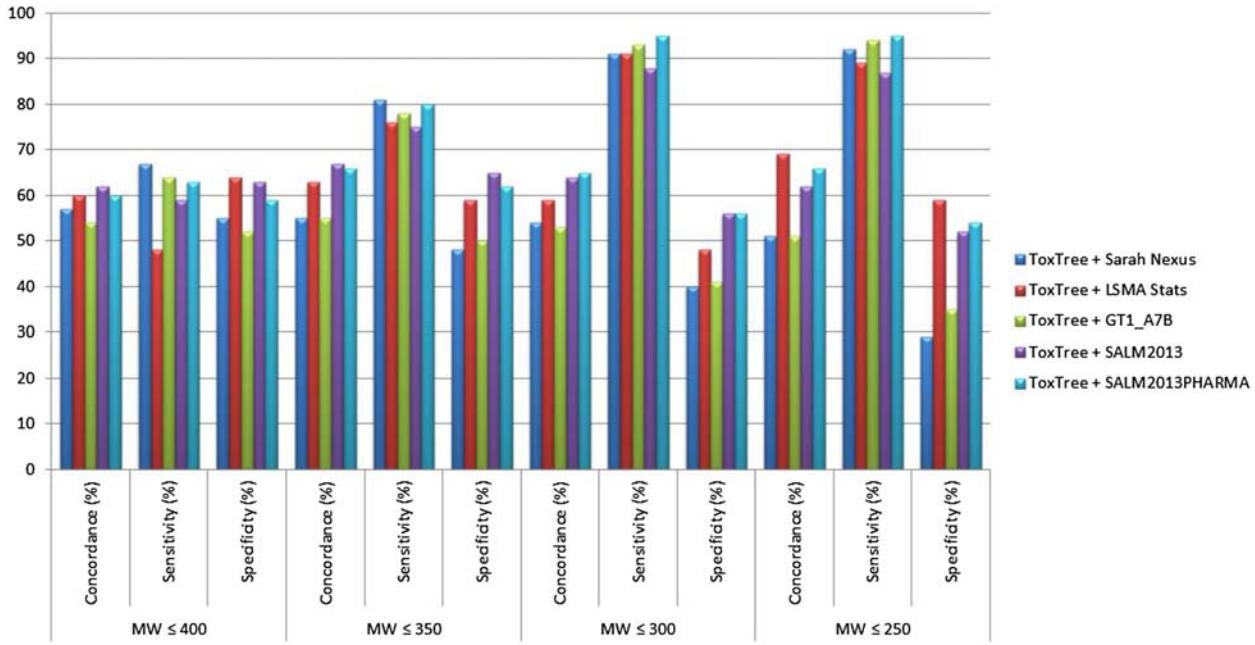

Fig. 8 (*continued*).

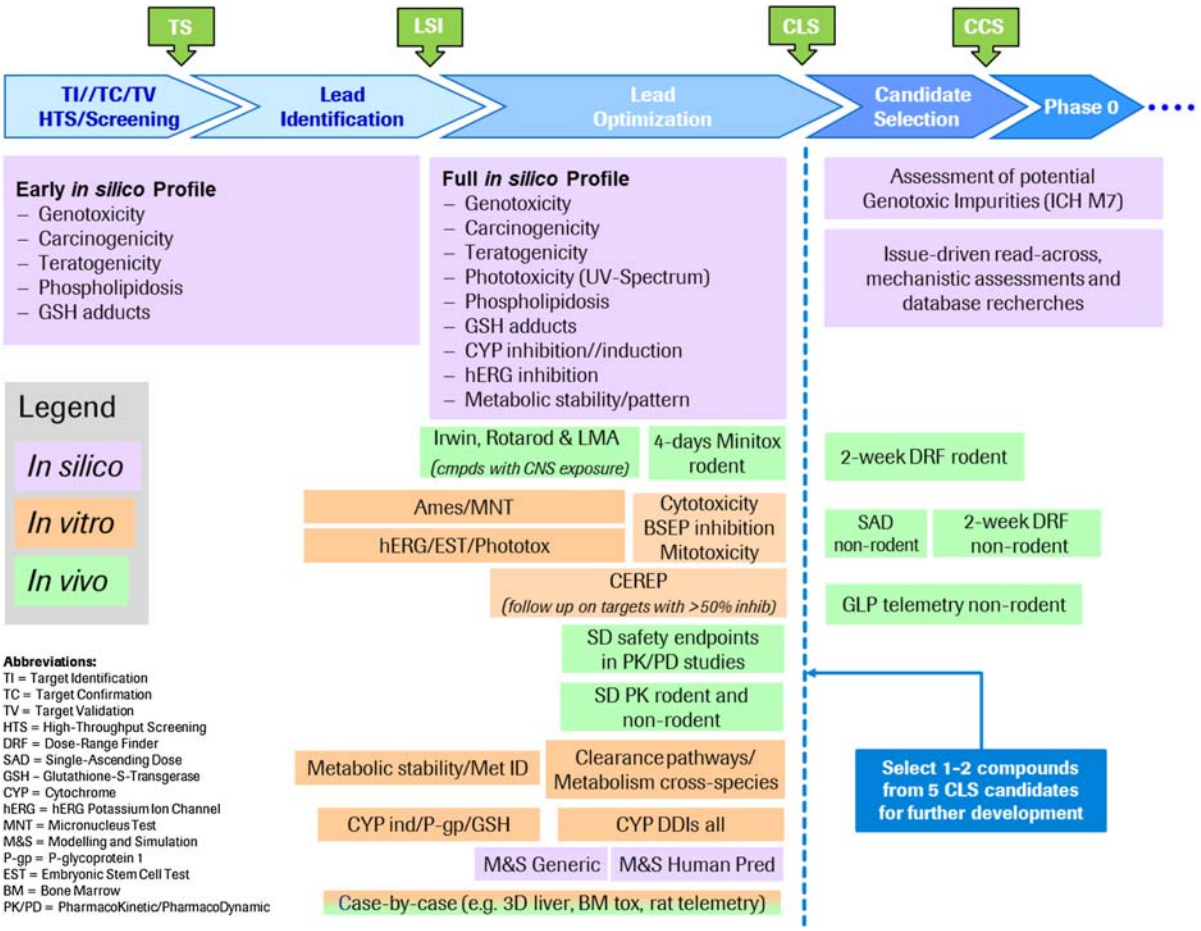

Fig. 9 Use of in silico tools and safety screening during the early drug development process.

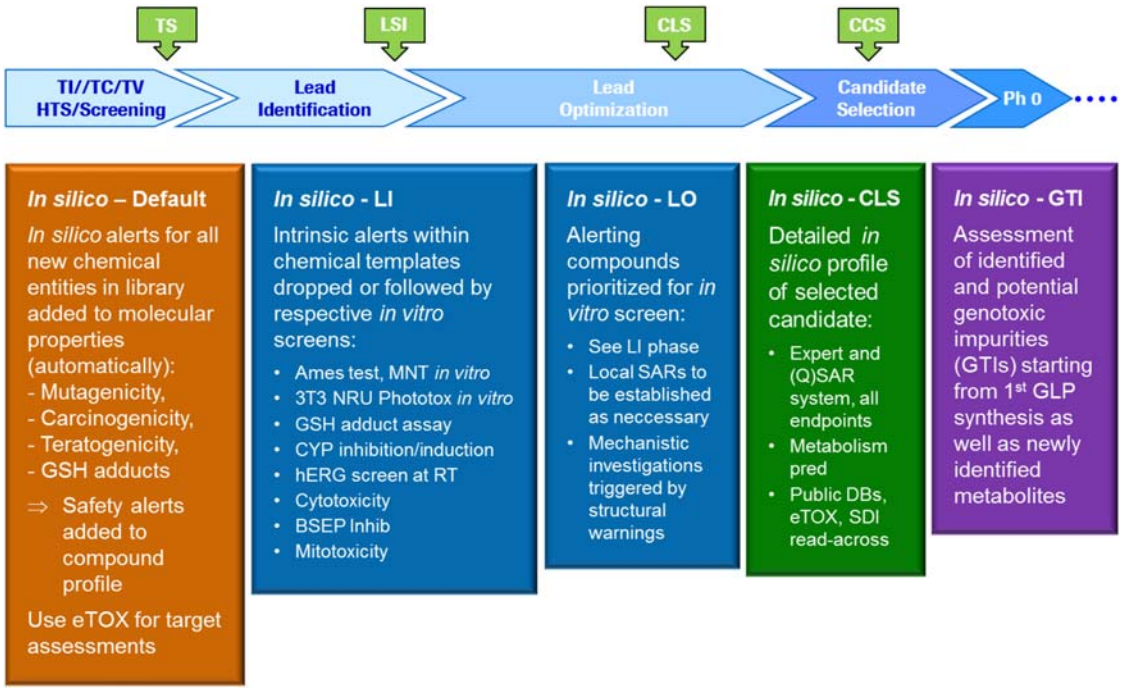

Fig. 10 Downstream activities following in silico alerts in the drug development process.

2.09.4.2 Lead Identification Phase: Target Selected (TS) to Lead Series Identified (LSI)

The main goal during lead identification (LI) is to identify valid chemical templates for further optimizing the efficacy and selectivity on the target, ideally multiple discrete series. Besides computational chemistry tools to calculate physicochemical properties, virtual screening, structure-based design, QSAR analysis of both the desired target but also off-target activities, chemical structures are analyzed continuously in silico for possible structure-related safety concerns to identify major issues with the templates (in silico LI). Insights into the toxicological potential of a scaffold or series of structures early in the drug discovery process could help medicinal chemists to prioritize particular scaffolds. Components of early avoidance of chemical structure safety liabilities include predictions for genotoxicity, carcinogenicity, hERG channel blockade, reactive metabolite formation, phospholipidosis, structural similarity to problematic molecules, CYP inductions, GSH adduct formation, and DMPK properties (cell penetration, microsomal stability, CYP3A inhibition). The in silico tools offer good guidance on what additional tests may be necessary or whether further characterization is warranted; however, they also have limitations.[61]

Drug, metabolism, and pharmacokinetics (DMPK) properties play a major role during lead identification. Numerous commercially available tools for the prediction of metabolites exist, such as METEOR,[13,19] MetabolExpert,[62] and MetaSite.[63] Most software packages correctly predict metabolites that are detected experimentally. However, a relatively high incidence of false predictions of metabolites is common to most unspecified computerized systems. In the hand of drug metabolism experts, these software packages have a certain value for hypothesis generation and guiding to experimental approaches for the identification of drug metabolites. However, the generation of additional new local rules, intended to predict the activity of a single enzyme (and often only within a chemical series), can significantly improve the prediction accuracy.

Experimental follow up of potential issues is conducted to build/refine safety plans moving forward. Even if in vitro assays clearly disprove identified in silico alerts further spot-checking of the distinctive endpoint will be conducted to avoid creeping in of a structural liability. The in vitro results always overrule the in silico warnings provided that the corresponding assays could have been conducted under reliable conditions (e.g., solubility, stability). Chemical templates with identified and confirmed intrinsic metabolic and/or safety concerns will be eliminated (see **Fig. 10**).

2.09.4.3 Lead Optimization (LO) Phase: LSI to Clinical Candidate Selected (CLS)

The task of the LO phase is to take a lead and convert it into a candidate for preclinical evaluation. This phase is intensively accompanied by early safety in vitro screening in various areas: genotoxicity, hERG and other ion channels, cytotoxicity, hepatic toxicity, bone marrow toxicity, transporters, metabolites identification, metabolic stability, CYP induction/inhibition, reactive metabolites, off-target pharmacology/secondary pharmacology, and cross-species comparisons, where applicable. Further screens might be applied based on the target liabilities or already identified potential safety issues. If adverse in vitro activities appear, specified

structure-activity relationships (SARs), the so-called local SARs, will be established to support the discovery projects in optimizing the clinical candidates toward safety/DMPK in parallel to efficacy (in silico LO).

At this stage, first, fit for purpose in vivo studies are conducted to address early target or chemistry-related safety concerns. The first general toxicology studies are maximal tolerated dose (MTD) and dose-range finding (DRF) studies generally performed in rodents and nonrodents. The value of performing exploratory drug safety studies before candidate nomination is to identify unwanted toxicities evident in a study of up to 14 days duration, as well as any potential toxicities anticipated based on a known cause for concern. In the absence of findings or the presence of findings that are judged manageable, these studies provide a greater comfort in the selection of a molecule for advancement into development with higher likelihood of success. Additional benefits of these studies are the identification of target organs to monitor in development and the selection of doses for the GLP toxicology studies. In addition, identification of the toxicity profile of a lead compound can be useful for the backup program where the goal is often an improved safety margin. In silico safety concerns might be included as part of pharmacokinetic/pharmacodynamics (PK/PD) characterization in vivo (disease) models to extract safety-relevant information and to build confidence in safety before expanding into larger regulatory animal studies (in silico CLS).

During LO, every in silico alert is immediately followed up by the corresponding in vitro screen, in case, even in vivo studies might be frontloaded. To avoid late failures of optimized candidates, spot-checking of the potential development candidates without alerts is conducted if the resources and throughput of the assay allow. In case of screening alerts, creation of local SARs can result in significant acceleration of project by optimizing the chemical improvement rounds. Specific and tailor-made local models normally have a significantly higher accuracy, if continuously updated with new incoming screening results. Learnings and newly identified alerting substructures should be implemented in general rules and models (customized systems) to continuously improve the performance of the computational tools used for drug optimization (see **Fig. 10**).

2.09.4.4 Phase 0: After CLS to Entry Into Humans (EIH)

The main usage of in silico tools after the final candidate has been selected encompasses the assessment of potentially genotoxic impurities according to the ICH M7 guideline as well as cross-reading and pathway analysis following an unexpected event in preclinical studies (in silico GTI). Furthermore, a backup or fast-follower program will trigger dedicated in silico profiling and screening of the new molecules, based on experiences and identified issues of the frontrunner compound.

Apart from the use of in silico tools to assess genotoxic impurities, there are no computational assessments which are mandatory requirements from regulatory agencies, but in case in silico models have been applied during drug development and influenced the testing strategy or triggered addition investigations, the information should be included in regulatory documents and adequately described.

2.09.5 Prediction of Complex Toxicity Endpoints

2.09.5.1 Outcome of In Vivo Safety Studies: A Challenging Prediction

Certain assays like the Ames assay,[57] present their outcome in what can be considered a binary way, in which the answer is a "yes" or "no" type. In such cases, in silico models have a higher chance to give a better predictive performance if compared to more complex assays and studies, where multiple parameters need to be brought together and analysed in relation to doses, time, and other factors to reach a final result or classification.

The mechanism of action of a molecule leading to a specific readout plays a critical role in the predictive performance of in silico models as it is one of the biggest challenges of, for instance, QSAR models. "Do the descriptors have any physicochemical interpretation that is consistent with a known biological mechanism?"[64] is often a very difficult question to answer. In vitro chromosome damage (an assay used to establish the clastogenicity potential of test compounds) can also be considered binary (i.e., the test item is "clastogenic" or "not clastogenic"). However, the mechanisms of action that may lead to clastogenicity are manifold and may involve the interaction of the compound with a number of proteins or enzymes, the disruption of one or more biological pathways that ultimately lead to a clastogenicity outcome. Such scenarios are quite difficult to be consistently accounted for within an in silico prediction system or model since the actual targets leading to the final assay outcome are mostly unknown. Even when using large proprietary datasets to improve the performance of existing models, the risk is to obtain better prediction metrics specific to the training set and not much broader than that since minor structural changes within a chemical class can have a large impact on the mechanism of action (e.g., the interaction with one or more proteins may be hampered, hence changing the final outcome of the assay).[3]

Even greater challenges are offered to the prediction of the outcome of single dose and repeat-dose toxicity in vivo studies. In the pharmaceutical industry, such studies are typically used to identify a Maximum Tolerated dose (MTD) and the NOAEL (Non-Observed Adverse Effect Level) for a test compound, in addition to the identification of a general toxicity profile and significant target organs that may show toxicity upon exposure to the compound tested.

Since animal models are very complex and the number of readouts collected in such studies is extremely wide, the development of in silico models that can reliably predict such outcomes is extremely challenging. If we reason in terms of dimensionality, if an Ames assay can be considered 2D, in vivo studies are multidimensional, making their accurate representation in a comprehensive model rather difficult. For example, a typical repeat-dose study requires the use of a control group plus 3 dose groups: each animal is

then carefully examined for clinical observations throughout the in-life part, including body weight and food consumption measurements as well as some behavioural evaluations; clinical pathology values are collected at different time points; urine analysis is performed; macroscopic and microscopic examinations are carried out on selected organs; toxicokinetics values are then calculated using the test item concentrations measured in blood from the samples collected throughout the study, which could be of different durations, from 5 days till 39 weeks (up to 2 years for the rodent bioassays for the evaluation of carcinogenicity) and in different species.

The variations, permanent or transient, of the parameters and values briefly described earlier may depend on the pharmacological target, on the chemical structure of the test item and related physico-chemical properties, on background incidences due to adaptations or other factors, such as major differences in plasma exposures. Because of this variability, building an in silico model capable of predicting all these different "degrees of freedom" is extremely challenging, in particular due to the fact that the identification of unequivocal mechanisms of action for whatever findings has been identified is not trivial. In addition, the development of robust SARs using the outcome of such studies is made more difficult by the very limited amount of publicly available data and, even within large pharmaceutical companies, the number of chemically similar compounds tested in such long and expensive studies for each investigated pharmacological target is often small (less than 5). This, of course, hampers the possibility to even develop local models since the number of similar compounds, designed for the same target, undergoing the same type of complex and expensive studies is rather limited.

Sophisticated in silico models may indeed become available for the prediction of the potential findings identified in, for example, repeat-dose studies, however all the limitations described earlier and the difficulties to conduct a proper validation with external data sets would make debatable, within the pharmaceutical industry, whether or not to accept them for decision making on compounds prioritization or as guidance for chemical optimization.

2.09.5.2 Drug-Induced Liver Injury

Drug-induced liver injury (DILI) is a major clinical and pharmaceutical concern and has remained one of the top two causes of drug attrition in the last decades.[65] DILI is responsible for about 30–50% of acute liver failure cases in the developed world and accounts for the withdrawal of a significant number of approved drugs from the market.[66–68] Hence, the early and reliable detection of hepatotoxicity during the drug discovery process is a must and would go a long way in reducing the drug development costs by decreasing the attrition rate. Nonetheless, DILI is complex and encompasses a wide range of effects, like liver enzymes elevation in serum, acute liver failure, and chronic liver dysfunction. In addition, patient-related factors play a significant role in liver injuries,[68,69] among them, age, race, co-medication, genetic polymorphism, and diet/nutritional state. Given the complexity of DILI and often the lack of understanding of its etiology, its prediction, using in vitro, in vivo, and in silico tools, has been very challenging with sporadic success. In the present contribution, we will give on overview of some of the in silico models that have been proposed and used for the prediction of DILI[70]; other in vitro and in vivo methods will not be illustrated.[65]

A variety of computational models have been developed with the aim to predict global hepatotoxicity, from nonspecific to idiosyncratic using several training set combinations.[70] Two models used in vitro data only,[71,72] one model used a combination of in vitro and in vivo data,[73] while the remaining one used only in vivo data, being human[74–79] or animal data.[80,81] The ideal situation for the prediction of hepatotoxicity is to have models with high sensitivity, that is, capable of identifying with high confidence compounds with high likelihood of being hepatotoxic. The reason is that excluding hepatotoxicants early from further development will have a much higher impact on patients' health and costs for pharmaceutical companies than excluding a false positive molecule (e.g., as a result of a low specificity of the model).

Clark and coworkers[71] applied Idiotropic Field Orientation for Comparative Molecular Field Analysis (IFO-CoMFA) as structural descriptors and Soft Independent Modeling of Class Analogy (SIMCA) to make a classification of hepatotoxicity from 654 drugs. Measurement of hepatotoxicity was done using four different in vitro assays assessing cell proliferation, lactate dehydrogenase (LDH), intracellular ATP, and levels of caspases 3 and 7. Greatest accuracy of 52% was achieved for a hierarchical ranking model combining all four assays. The global IFO-SIMCA approach showed poor predictivity for a large dataset of biologically active compounds, but significant improvements were achieved when the model was built for nonsteroidal antiinflammatory drugs (NSAIDs) as a single pharmacological class of chemicals. Such models, built on specific cytotoxicity indicators, may have the limitation to be performant only on individual chemical classes, which may share a similar mechanism of action. This aspect is deemed to limit the applicability domain of the model.

Fourches and coworkers[81] developed a QSAR model from mining published literature data for hepatotoxicity descriptors derived from in vitro and in vivo (animal and human) data. The model used hierarchical cluster analysis and QSAR with Support Vector Machines (SVM) using different types of descriptors to predict whether a compound would be hepatotoxic in humans. The predictivity of the models was assessed via internal and external fivefold cross-validation, which returned accuracies ranging from 61.9% to 67.5% and 55.7% and 72.6% for internal and external validations, respectively. The models were also applied to external test sets of 18 and 246 chemicals, respectively; the prediction accuracy for 78% for the former set and 67.5% for the latter set. Overall, the described approach showed reasonably good predictivity considering that the training sets were coming from an automated text mining technique with limited manual intervention.

In general terms, the availability of in vivo liver toxicity data is higher than in vitro data. In vivo liver toxicity can be divided into intrinsic, often linked to the presence of specific structural moieties within the molecules, and idiosyncratic, which is rare and dose-independent.

Cheng and Dixon[74] compiled a data set of liver toxicity data for drug and drug-like compounds from the literature collecting 149 toxicants and 233 nontoxicants. Recursive partitioning (RP)[82,83] with an ensemble approach was used to generate the models, from training set subsets, that will be then averaged into one single model. RP uses a number of decision trees to split the training set into mainly toxic and nontoxic compounds based on 1D and 2D descriptors selected by a Monte Carlo linear regression. A total of 151 trees were created and used to predict each compound as toxic or nontoxic and then averaged to make a final prediction. Leave-one-out (LOO) validation and leave-10%-out methods were used for internal validation with sensitivity of 78% and 76% and specificity of 90% and 75%, respectively. Overall concordance was 85% and 76%, respectively. External validation conducted on 54 compounds showed that the model could correctly predict 81% of the test set. The overall good accuracy suggests that this model could be applied to diverse classes of chemicals for the prediction of hepatotoxicity risk.

The prediction of idiosyncratic hepatotoxicity presents even more challenges as it is the product of the probability of each individual contributing factor, such as chemical properties of the drug, genetic polymorphism, and environmental aspects (i.e., tobacco, alcohol, age, gender, health status, and use of additional drugs).[70]

A model for the prediction of idiosyncratic hepatotoxicity implementing linear discriminant analysis (LDA), ANN, and machine learning algorithms (OneR) have been described in 2008.[79] Literature data was used to collect a set of 74 drugs, 33 with idiosyncratic hepatotoxicity and 41 without it. The models constructed with 3D radial distribution descriptors showed an accuracy of 84%, sensitivity of 78%, and specificity of 90% for the training set. The LDA model correctly predicted 86% of the compounds. Two external sets were also used for models validation. A first set consisted of six chemicals, which were similar in pharmacology and chemical structures, but with opposite toxicity profiles: LDA and OneR showed the same predictive accuracy of 83%. The second external test set consisted of 13 hepatotoxic drugs, 9 of which were correctly classified by the LDA model. These results may suggest that these computational approaches may find some applications in the lead selection or lead optimization stages to filter out some compounds with the potential to induce idiosyncratic hepatotoxicity.

On the regulatory side, the US FDA conducted a broad investigation aimed at setting up a health effect database and develop QSAR models to predict hepatobiliary adverse effects of drugs.[71,78,84] The effort resulted in a set of about 1660 chemical structures[85] with five hepatobiliary endpoints considered: liver enzyme disorders, cytotoxic injury, cholestasis and jaundice, bile duct, and gall bladder disorders. Four QSAR programs (MC4PC,[17] MDL-QSAR, Bioepisteme,[27] and Leadscope Predictive Data Miner (LPDM)[24]) were selected to build predictive models using the same training set. Leave-many-out validation methods showed an average sensitivity of 39% and a specificity of 86% for all four programs. A pairwise consensus approach was also tested giving an average sensitivity of 56% and specificity of 78%. An external validation set consisting of 18 compounds withdrawn from the market because of unacceptable hepatotoxicity was tested and almost 90% of the drugs were predicted to be hepatotoxic by at least one of the four programs. When applying a consensus scheme, 67%, 44%, and 11% of the external set were correctly predicted by two, three, and four programs, respectively. This analysis showed that carefully built QSAR models using robust data can provide valuable support in the early profiling of candidate leads.

Ekins et al.[76] used a 295-compound training set (including 158 DILI-positive molecules) to build a liver toxicity prediction model using a Bayesian classification approach. A test set of 237 compounds (114 DILI drugs) was also used for the model evaluation. 2D descriptors were used to differentiate the activities and highlight chemical substructures known to be critical for DILI. The Bayesian model correctly classified 56% of active chemicals and 67% of the inactive. Despite the performance metrics can be considered disappointing, the fact that a broad and diverse training set was used for the model development suggests that the approach may be applied early on in the drug discovery process.

Rodgers and coworkers[77] applied the *k*-nearest neighbor (*k*-NN) method to build a model for binary classification of drugs, inducing liver toxicity based on the chemical structure. A 200-compound subset of the HLEAD database (containing five different serum enzyme markers for liver toxicity: ALP, ALT, AST, LDH, and GGT) was used to construct the model using two types of descriptors. Models were built for the five endpoints and for a composite liver endpoint showing sensitivity greater than 73% and specificity greater than 94% in external validation settings. The applicability domain of the models was tested using the WDI, PCL, and the Biowisdom Liver Intelligence Module chemical databases. The exercise showed a rather poor coverage of the composite model, with 80% of the WDI database being out of domain. This study pointed out the general challenges of in silico methods to achieve an acceptable applicability domain as well as their inner limitations in identifying the correct mechanisms of action or biological pathways leading to liver toxicity.

Zhu et al.[86] constructed in silico models for human hepatotoxicity using both the chemical structure and in vitro assay data. The in vitro data were from human hepatocyte imaging assay technology (HIAT) that measured the intensity of biochemical indicators (e.g., lipids and glutathione) after the exposure of human hepatocytes to a single test compound. Models combining chemical descriptors and in vitro assay data were compared alongside the conventional QSAR, as well as models based on pure in vitro assay data. A dataset of 156 DILI positive and 136 DILI negative compounds were selected for model development. First, models based on chemical descriptors (CDK, Dragon, and MOE) and in vitro cell-imaging endpoints (HIAT) descriptors were built using random forest (RF) and fivefold cross-validation procedure. Then, three hybrid models were built using HIAT and a single type of chemical descriptors. Generally, the models based only on chemical descriptors were poor, with a correct classification rate (CCR) around 0.60 when threshold value of 0.50 was used. The hybrid models afforded a CCR of 0.73 with a specificity of 0.74 and a better true positive rate (sensitivity of 0.71). Stricter classification thresholds showed higher benefits of the hybrid models.

Egan and coworkers reported the development of structural alerts for hepatotoxicity as implemented in VERDI.[75] A series of 244 molecules was compiled, including 54 drugs that were withdrawn from the market due to liver toxicity. Based the dataset the authors developed 74 alerts, most of them related to functional groups converted to reactive metabolites. Predictive performance

of the alerts pool was not provided as according to the authors, liver toxicity prediction is not possible due to the wide variety of factors and mechanisms involved in such endpoint.

Greene et al.[87] described a four-stage approach for the development of structural alerts. In step 1, 1266 chemical structures were selected from the literature. Step 2 looked into the relationship between compounds and reported toxicity in order to derive specific structural classes. Subsequently, structure–activity relationships (SARs) were built for 38 classes and finally implemented in Derek Nexus[12] and the predictive performance was evaluated using an external validation set consisting of 626 compounds developed by Pfizer. Each validation compound was assigned to one of the four identified activity classes: (i) no evidence for hepatotoxicity; (ii) weak evidence for hepatotoxicity; (iii) animal hepatotoxicity; (iv) human hepatotoxicity. The four activity classes, for the purpose of validation, were combined into two classes (first two into one negative set and the last two into one positive set). Derek Nexus showed a sensitivity of 46%, a specificity of 73% with an overall concordance of 56%. Poor sensitivity was attributed to the limited mechanistic evidence for some classes of compounds and to the lack of good predictions for the pool of compounds hepatotoxic in preclinical studies and not tested in clinical trials.

2.09.5.3 Data Integration of In Vivo Toxicity Studies

Despite the obvious challenges described earlier and the disappointments given by some of the models attempting to predict DILI, a lot of efforts have been recently directed toward leveraging the information coming from complex in vivo models. Promises have been shown by some in silico methods that can be considered as a valuable support for the early selection of compounds with the potential of inducing hepatotoxicity. An obvious strategy aiming at the further improvement of prediction models is to keep adding new, high quality data, to existing (or totally new) models to (re)train them and expand their applicability domain. Another key aspect is to get the data classification right for the generation of more robust correlations with the most significant molecular properties or substructures.

Within the industry, it has been recognized that the consolidation of the results of in vivo toxicity within appropriate tools making use of the right technology would allow the full exploitation of the knowledge that such data can provide.

Large Pharma organizations can typically count on many years of drug discovery and research conducted across several sites on a significant number of therapeutic areas, pharmacological targets, and molecules. This consists of a large amount of complex datasets, stored in different repositories or Laboratory Information Management Systems (LIMS) each designed specifically to accommodate the data type of interest (e.g., Histopathology, Clinical Observation, Clinical Pathology, PK, Urinalysis). The organization of such wealth of information to generate specific knowledge from the integration of all of these data types has been considered several times in the past by many pharmaceutical companies. However, due to limited resources or inadequate technology, the outcome of such initiatives has often been disappointing or only partially successful.

In more recent years, there has been a tremendous focus across industries, not only pharma, to extract knowledge and identify patterns or trends from large amounts of data, being either omics, market research, customer purchase preferences in retail stores, people's favourite digital movies rental,[88] airplane estimated times of arrivals, and others. A lot of these initiatives often fall under the term "Big Data," generally underlying the intention of many organizations to look deeper into their databases and assess whether an improvement in the way such data are organized, stored, made accessible, and mined may provide any advantage for the business in terms of saving resources or increasing efficiency via surfacing hidden value. Another angle is to collect more data in a targeted way in order to ensure that critical information is promptly made available by analysing such data to identify or anticipate specific trends or make better, more informed decisions.

Along this line, Roche has been working on a number of "Big Data" projects across several areas of research and IT. One of them had the goal to integrate all in vivo nonclinical safety data generated by the company over the past 30 years across three research sites, two in the United States and one in Switzerland. The goal was to ensure that all different data types that are part of in vivo studies (i.e., histopathology, clinical observations, PK, clinical pathology, etc.) were brought together electronically in such a way that they could all be searched and made available at the same time to the users community. The scope for such a platform, internally called SDI (i.e., Safety Data Integration), is to allow scientists to identify specific patterns of findings across species and their historical relevance, correlations between molecular structures and toxicological effects, and, eventually, use the data to generate more reliable prediction algorithms. The application of a semantic data integration approach[89] for the harmonization of terms, formats, units, and taxonomy, allowed the implementation of a Non-Clinical study warehouse including more than 5000 studies of different types which can be interrogated with very complex queries such as: "Which compounds showed Spleen Hyperplasia AND Liver Necrosis AND Lung Leukocytosis AND an AST increase $>50\%$?" returning an answer in a matter of seconds. The identification of studies and compound matching the query above, in the absence of properly designed data integration efforts, would have been extremely labour intensive and time consuming, if possible at all.[3] Further integration efforts have seen the SDI platform being interfaced with other internal databases, such as the chemical structures and the in vitro biology data repositories to further expand the data integration beyond toxicology allowing the users to assess the compound profile in almost its entirety.

2.09.5.4 Development of Prediction Models

As far as models development is concerned, one of the advantages of the platform described earlier is the high data granularity available, down to the single animal level.

One of the challenges in the development of predictive models for complex endpoints, such as, for example, hepatotoxicity, is that the modeller is forced to make a generic binary classification (hepatotoxic vs. nonhepatotoxic), often neglecting safety margins (vs. pharmacological activity), doses at which specific toxicity is seen and ignoring the specific findings and whether it is transient or not. This is because, more often than not, all these elements are not easily available. All these factors make such classification relatively inaccurate: for example, paracetamol (or acetaminophen) an over-the-counter mild analgesic, commonly used to relieve headaches and reduce fever, is commonly classified as hepatotoxic (as its overdose can cause fatal liver damage[90]). However, at doses as high as up to 4 grams per day in adults, paracetamol is regarded as totally safe and can comfortably be used (at lower doses, of course) even in infants. This example explains how critical and challenging a correct classification is: it is correct to classify paracetamol as hepatotoxic, since an overdose would likely cause a fatal liver failure, however, in drug development settings, what type of decision can be made on a compound predicted to be hepatotoxic by a model based on the information gathered, among others, from paracetamol? Should this molecule be discontinued and any further investigation stopped before knowing what safety margins might there be with regards to its intended therapeutic indication? Disregarding this molecule immediately after a positive prediction bears the risk of losing a potentially valuable compound. Continuing the investigations to further profile the molecule for future clinical development may be the best option to get to a more solid data-driven decision on its potential to become a drug. The bottom line is that, in this context, the prediction model will have a negligible impact on the decision. The same can be said in relation to other potential liabilities beyond hepatotoxicity, such as cardiotoxicity.

In order to strengthen the reliability of in silico models for the prediction of complex endpoints, all information generated by in vivo single- and repeat-dose studies should be made available in a clear and searchable way at the highest possible level of details. This is the most critical starting point for experts to generate very specific models based on the correct compounds classifications for very specific findings engaging into a careful data analysis. For example, it will be possible to have models for AST and ALT increases above 50% versus control groups, or for the prediction of bilirubinemia, moving away from a nonspecific, for example, "hepatotoxicity" classification. Even better, it would allow correlating certain parameters changes in the blood with very specific organ microscopic findings. This approach would, in principle, also make the identification of sound mechanisms of action for the specific observed toxicities a bit easier to address.

2.09.6 Data Sharing Initiatives and Data Exchange for Regulatory Purposes

2.09.6.1 IMI eTox and NextGets Initiatives: Data Sharing and Modeling Approaches

Analysis of reasons for previous failures and exploitation of them should help in improving the efficiency of clinical development of new drugs and their safety profiles. So far, preclinical study reports have been rarely stored in a format that supports data mining or statistical analysis. Some pharmaceutical companies have realized these hidden treasures in their archives and started internal work to improve retrievability of their report data. It would clearly be of benefit to the whole industry to analyze these data across multiple companies in order to expand the chemical and biological space. However, extracting these data from the reports and building such a database requires considerable investment. Recent advances achieved in international initiatives, including IMI's eTOX project, have shown that sharing of preclinical data, both private and public, is achievable through the combination of legal (IP), IT, and honest broker concepts[91,92] (see **Fig. 11**).

The eTOX project aims to collect, extract, and organize preclinical safety data from pharmaceutical industry legacy study reports and publically available toxicology data into a searchable database to facilitate data mining and the development of innovative in silico models and software tools to predict potential safety liabilities of small molecules. The eTOX-consortium consists of 13 pharmaceutical companies, 11 academic institutions, and 6 SMEs working together under the sponsorship of the Innovative Medicines Initiative (IMI) since 2010. The participating partners embrace expert knowledge in computational modelling, toxicology, pathology, and database design, liaising within the project in an integrative working environment.

After establishing an effective data sharing intellectual property (IP) protection within an "honest broker" approach (see **Fig. 11**), the project was able to compile a unique, well-curated dataset of currently more than 7000 study reports, corresponding to c.2000 test compounds. The concept to divide the results from the legacy reports of the pharmaceutical companies in different "confidentiality classes" was fundamental to facilitate data sharing and overcome IP and legal hurdles. Public data (class 1) are accessible to the public on request, nonconfidential data (class 2) are open for eTOX consortium members, confidential data (class 3) are only accessible within the consortium with an additional secrecy agreement, and private date (class 4) are only for EFPIA data owners, but can be shared for model generation on request.

Treatment-related findings have been classified within the database, reflecting the interpreted study outcome of every report. A suite of ontologies, built through OntoBrowser now released by eTOX to the public domain, enables the user to directly compare observed effects or toxicities of chemically similar structures (read-across).

A new in silico tool—eTOXsys—has been developed with a single user interface, which manages search queries on the high-quality preclinical database and organizes requests to a steadily growing collection of independent prediction models. Aspects of IP rights for data sharing, definition of ontologies, design of database structure, development of in silico models, data analysis, validation, and sustainability are key aspects of the eTOX project.

The recent advances achieved in several international initiatives, including the beforehand described IMI eTOX project, have shown that sharing of preclinical data, both private and public, is achievable, ontology development has been fostered in the area, and systems to handle, mine, and exploit these data across studies, compounds, pharmacology, side effects, and other criteria

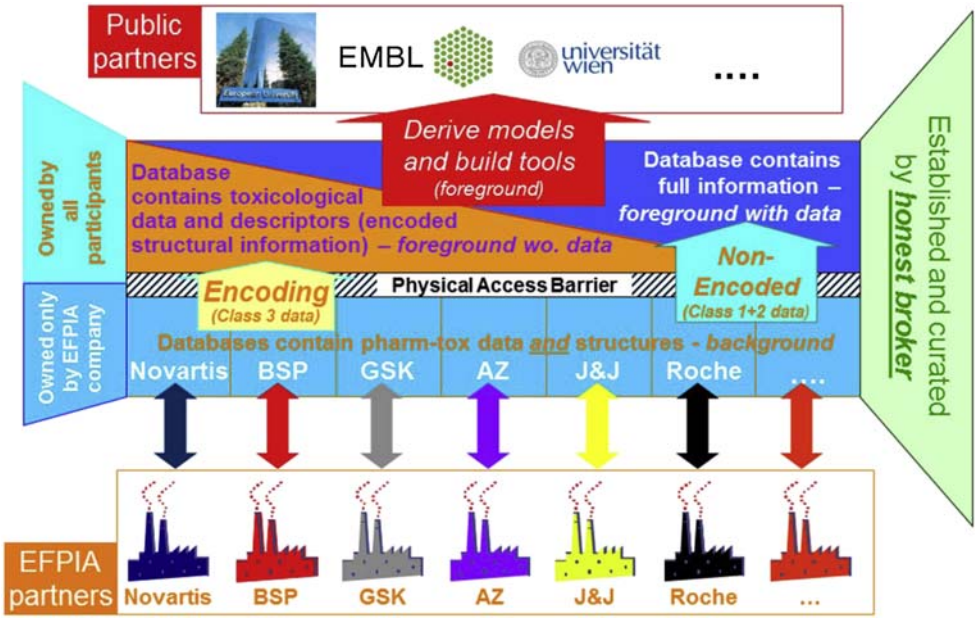

Fig. 11 The overall setup of the eTOX Project.

have been created and partly implemented within industry. In parallel, the electronic CDISC-SEND format has been chosen for file submission in IND/NDA/ANDA/BLA to FDA. This offers an opportunity for automatic collection of data, and sharing those into a common platform for reasons of data transparency, but also to obtain more powerful predictive data analyses. Existing initiatives in the field offer a relevant basis for an expanded IMI-based effort that leverages database and the data sharing. The so-called NexGETS initiative (*Nex*t Generation of *E*lectronic *T*ranslational *S*afety) is intended to provide a cost-efficient ideal environment for incorporating these data, optimizing tools, and providing linkage to human safety information to support the described regulatory-compliant, holistic perspective. In addition, tools for multivariate and multilevel data analysis and modelling, comparative data display across studies and compounds shall be developed within this proposed IMI2 project to enable meaningful exploitation of the accrued data.[93]

Beyond data sharing and mining, prediction of potential toxicity events both in preclinical species and in humans is key. The in-depth assessment of the preclinical species predictivity to human can only be achieved by analyzing as large an amount of organized data as possible. The linking of preclinical databases to chemical and biological knowledge, and to human clinical data probably represents the most powerful approach to achieve this endeavor and offers a unique opportunity. Such a translational approach will greatly advance the assessment of the relevance of animal findings for humans. In addition, it will contribute to the public discussion regarding the necessity of animal studies during drug development.

2.09.6.2 SEND Data Model and Electronic Submission to FDA

On Dec. 18th 2014 FDA issued the binding guidance titled "Providing Regulatory Submissions In Electronic Format—Standardized Study Data"[94] that requires Investigational New Drug (IND), New Drug Application (NDA), Abbreviated New Drug Application (ANDA), and Biologics License Application (BLA) submissions to be made in a standardized electronic format. The Clinical Data Interchange Standards Consortium (CDISC) Standard for Exchange of Nonclinical Data (SEND) is intended to guide the structure and format of standard nonclinical datasets for interchange between sponsors and Contract Research Organizations (CROs) and for submission to the US FDA.

SEND, or the *S*tandard for *E*xchange of *N*onclinical *D*ata, is an implementation of the CDISC Standard Data Tabulation Model (SDTM) which specifies a way to present nonclinical data in a consistent format.[95]

The current production version of the SEND Implementation Guide (SENDIG v.3.0) is designed to support single-dose general toxicology, repeat-dose general toxicology, and carcinogenicity studies.

The guidance requires submission of nonclinical safety studies in SEND format for the study types currently supported. In the near future, the standard will be expanded to include additional study types, such as Safety Pharmacology (cardiovascular and respiratory) and Developmental and Reproductive toxicology, which will also be required.

The guidance further stipulates that published FDA Specific SEND Validation Rules will be enforced for all submitted data sets. The Agency may refuse to file (for NDAs and BLAs) or refuse to receive (for ANDAs) an electronic submission that does not have study data in conformance to the required standards.

Under the guidance, supported studies (included in NDA, ANDA, and certain BLA submissions) starting after Dec. 18th, 2016 must be submitted in SEND.

For IND submissions supported studies starting after Dec. 18th, 2017 must be submitted in SEND.

Currently nonclinical safety data is provided as tabulated data within PDF Study Reports, Original electronic data, generated in-house, is normally stored on the originating LIMS systems until it is archived. In the case of CRO studies, original electronic data is typically not made available unless explicitly requested by the sponsor. The FDA now requires that, in addition to the PDF reports, the original electronic data also be submitted in SEND format. This is a new requirement that is currently unsupported at Roche.

While it is possible to build a SEND data set manually, the process is labor intensive, error prone, and very difficult to validate. Given the fact that data comprising a study may come from multiple data sources the challenge becomes unworkable.

An automated or semi-automated computerized system that can accurately and consistently transform original non-SEND data from multiple sources to the SEND standard and validate SEND data following published rules is required. Oversight, tools and processes for ensuring that source data sets are collected, curated, transformed to SEND, and made available for submission in an effective manner are also required. A number of vendors offer SEND solutions, among them: Instem;[96] Integrated Nonclinical Development Solutions, Inc.;[97] PDS;[98] PointCross LifeSciences;[89] Xybion;[99] Zifo RnD Solutions.[100] The vendors offer a number of features in their solutions to make it easy to handle the numerous aspects of data management and production, including the ability to define and maintain mappings from company-specific lexicons to SEND controlled terminologies.

Currently, FDA pharm/tox reviewers analyze the submitted study reports by manually extracting the tabulated data contained in the appendices of the PDF documents and loading them into any number of tools they see fit for visualizing and reviewing it. This first step is labor intensive and time consuming.

With the recently issued guidance for e-submissions, FDA reviewers have the opportunity to receive the study data directly in the appropriate format into one single platform called Non Clinical Information Management System (NIMS). FDA will use NIMS also to visualize the data, run their analyses, and draw their conclusions on the studies under review.

This approach will allow FDA reviewers to save time on data curation and formatting aspects and free resources for more in-depth scientific analyses, also leveraging the large amount of information and knowledge that NIMS will be capturing over the coming years.

Since clinical data is also electronically exchanged via standardized models (www.cdisc.org), it can be expected that one day, clinical and nonclinical data will be integrated under one single platform intra- and intercompany, which would represent a significant milestone in Translational Medicine arena.

2.10.1 Introduction

2.10.1.1 The Concept of Polypharmacology

In the past decades, the predominant paradigm of drug discovery and development has been the rational design of maximally selective drugs for a certain target.[1,2] Great success has been achieved in pharmaceutical industry using this method, especially regarding diseases with well-defined mechanisms.[3,4] Nevertheless, the pathology of many diseases is much more complex and it would be very unlikely to cure these diseases through hitting only one target.[5,6] Increasing evidence acquired from genomics studies have shown that many biological systems are insensitive to a single attacker.[7,8] Interestingly, it is also found that over 40% of these targets are involved in more than one disease through molecular network analysis.[9] Indeed, single gene-knockout studies have shown little effect on phenotype in many cases. Of all the "druggable" genes and targets in mice,[10] the number of models with knockdown of one gene that are valuable in target validation can be as little as 10%.[7,11,12]

The substantial and robust nature of these observations can be understood by considering redundancy inherent in the vital system such as the alternative, complementary, or compensatory signaling pathways. These biological networks are characterized by their high resilience to mutations of a random node, but high instability when the highly connected (or significant) hubs are deleted.[13,14] The studies suggest that organisms tend to develop compensatory signaling pathways in order to counteract the acquired mutation/deletion of a single node.[15] Such findings encourage new thinking of drug discovery: in order to modify a phenotype, modulation of several targets is often required.[13] The burgeoning molecular networks predict that deletion of a single node will not affect many disease states; modulation of multiple proteins in the network is required to alter functions and restore the normal phenotypes.[13,16] Even if perfectly selective drugs were developed toward specific targets, those targets are also likely to be involved in multiple pathways, and thus target specificity does not guarantee a real "functional" specificity.

To bring a new drug onto the market, the cost was proximately $800 million in 2003. However, current estimates place the value ranging from $900 million to $1.7 billion (USD).[17–19] The average success rate from first-in-man to registration has been reported by big pharmaceutical companies from 1991 to 2000 at around 11%, with oncology and central nervous system (CNS) disorder treatments showing ~5% and ~8% success, respectively.[20] However, the attrition rate increases in the later stages of clinical development (Phases IIb and III) with the highest cumulative investment to that point. Even more worrisome is that compounds with novel mechanisms of action (MOA) experience higher attrition than those with well-defined mechanisms (defined as hitting a known target or showing proof of concept in clinical trials).[20,21] For instance, during 2011–15 Food and Drug Administration (FDA) approved 19 kinase inhibitors,[22] and in 2015 only ~36% of the approved drugs are targeting novel mechanisms[23]

One may argue that the bleak outlook for the pharmaceutical industry is due to the social climate or the corporate structure; regulatory authorities now are stricter with drug safety than ever before, and the standard of health care is higher than ever. The true reason for the depressing outlook, however, could be more fundamental than those mentioned; the most critical manner in which drug development is executed might be flawed. It is difficult to ignore the growing rate of failures and attrition in drug development over the last two decades based on the "one drug for one target for one disease" model. This philosophy was in harmonious combination with genetic reductionism and classification of one disease-causing gene.[24] The goal of drug discovery at that time was to produce "clean" drugs that minimized toxic side effects by making ligands as selective as possible for their respective targets. However, the current efficiency of drug development cannot achieve this goal and a new paradigm is required to boost the progress of drug development. Polypharmacology, defined as "the specific binding of single or multiple ligands to two or more molecular targets,"[25] then was a property that was considered undesirable in rational drug design, now, becomes a new paradigm to develop more effective and less toxic agents. It is worthy of note that polypharmacology design is still a very challenging task in its infancy. Many of the drugs were found to be active against multiple targets only after introduced to the market. For example Gleevec was introduced as one of the most selective kinase inhibitors and later was found to be targeting multiple receptors.[26,27]

2.10.1.2 Overview of the Current Status of Polypharmacology

As a new concept, the goal of polypharmacology is to design compounds specifically binding to more than one molecular target.[6,25] On the one side, interaction with multiple targets is one of the major reasons that cause drug side effects and toxicities. For instance, terfenadine, an H1 receptor antagonist that entered the market in 1982, was later withdrawn due to its side effects including life-threatening ventricular tachyarrhythmia, torsades de pointes. Such toxicity is caused by the blockade of the human ether-à-go-go-related gene, which is a common reason of failure in early drug safety assessment.[28] Another example is propoxyphene, which is a *mu* opioid receptor agonist and noncompetitive $\alpha 3\beta 4$ neuronal nicotinic acetylcholine receptor antagonist used as analgesic. After 55 years, the drug was withdrawn from the market due to its fatal side effects.

However, on the other side, drug polypharmacology could be beneficial. It has been recurrently used to identify novel indications of existing drugs, also known as drug repurposing. Sildenafil (Viagra), for instance, is an inhibitor of the cyclic guanosine monophosphate (cGMP)-specific phosphodiesterase type 5 (PDE5), initially developed to treat ischemic heart disease and hypertension by Pfizer in 1980s. Its side effect of stimulating penile erections was reported during Phase I clinical trials. Soon after Phase II clinical trials failure for treating angina, sildenafil was repurposed for the treatment of erectile dysfunctions[29] and successfully approved by FDA in 1998. After that, sildenafil quickly became a blockbuster. Recently, the promiscuous nature of a variety of FDA approved drugs has led to redirection of their use in different diseases, and this helps pharmaceutical companies to cut down their drug development cost, since the toxicity and side effect data is available from previous clinical trial studies.

In recent years, polypharmacology has gained significant interest in drug discovery.[30] Using "polypharmacology" as the keyword to search in Google Scholar generated 3840 results as of Mar. 16, 2016. Out of these literatures, more than half reports (about 2810) were published within the last 5 years. In particular, kinase inhibitors are well-known examples for their polypharmacology profiles. For instance, imatinib is a tyrosine kinase inhibitor approved by FDA for treatment of multiple cancers. Initially, it was designed to selectively inhibit the breakpoint cluster region protein–ABL complex (BCR–ABL) for the treatment of chronic myelogenous leukemia (CML).[27] Later it was found also to inhibit CD117 and platelet-derived growth factor receptor (PDGFR) and improve conditions of the patients with gastrointestinal stromal tumors.[31] Currently it is known that imatinib inhibits many other targets to exert its pharmacological effects, and its polypharmacology profile is illustrated in **Fig. 1**. One of the advantages of such multitargeted drugs is that they are compatible with a larger population of patients and would show better overall efficacies in treatment.[32]

Although most of the current multitargeting drugs are serendipitous discoveries, understanding of molecular polypharmacology may also contribute to rational design of new compounds with better efficacy and less side effects.[33] For instance, Knapp and colleagues designed several compounds with dual inhibition of kinases and bromodomains.[34] Bromodomains play an important role in multiple diseases where kinase inhibitors are used as therapeutic drugs.[35–37] In order to rationally obtain dual kinase-bromodomain inhibitors, the team tested 628 kinase inhibitors against the first bromodomain of bromodomain-containing protein 4 (BRD4).[34] They identified PLK1 inhibitor BI2536 as the potent inhibitor of BRD1 receptor. To further understand the mechanism, analysis of crystal structures of Polo like kinase 1 (PLK1) and BRD4 was carried out for rational design and further optimization of novel multitargeting drugs.

In 2005, Murphy et al. published a comprehensive review article focused on rational design of multitargeted ligands.[38] In this article they described the main strategies and applications in this field reported from 1990 to 2004. Over the past years, more methods have been developed. For instance, Apsel et al. identified compounds that inhibit both tyrosine kinases and phosphatidylinositol-3-OH kinases (PI3K).[39] These kinase subfamilies are characterized by low overall sequence identity but share a similar fold (two-lobed structure) with conserved residue motifs in the ATP site. Using iterative chemical synthesis, X-ray crystallography and biochemical profiling, the authors discovered some compounds with promising dual target activity. Structural features were also examined to rationalize the selectivity toward their targets. More recently, Besnard and team members devised an automated approach to design ligands with desirable polypharmacological profiles.[40] Bayesian models were built to prioritize the compounds, and 800 ligand–target predictions were tested experimentally, of which 75% were confirmed as true. In particular, starting with the drug donepezil, an acetylcholine esterase inhibitor initially for Alzheimer's disease (AD) therapy, they predicted and confirmed weak polypharmacological activity on dopamine receptors D4 and D2. A recent review study by Katselau et al. focused on successful

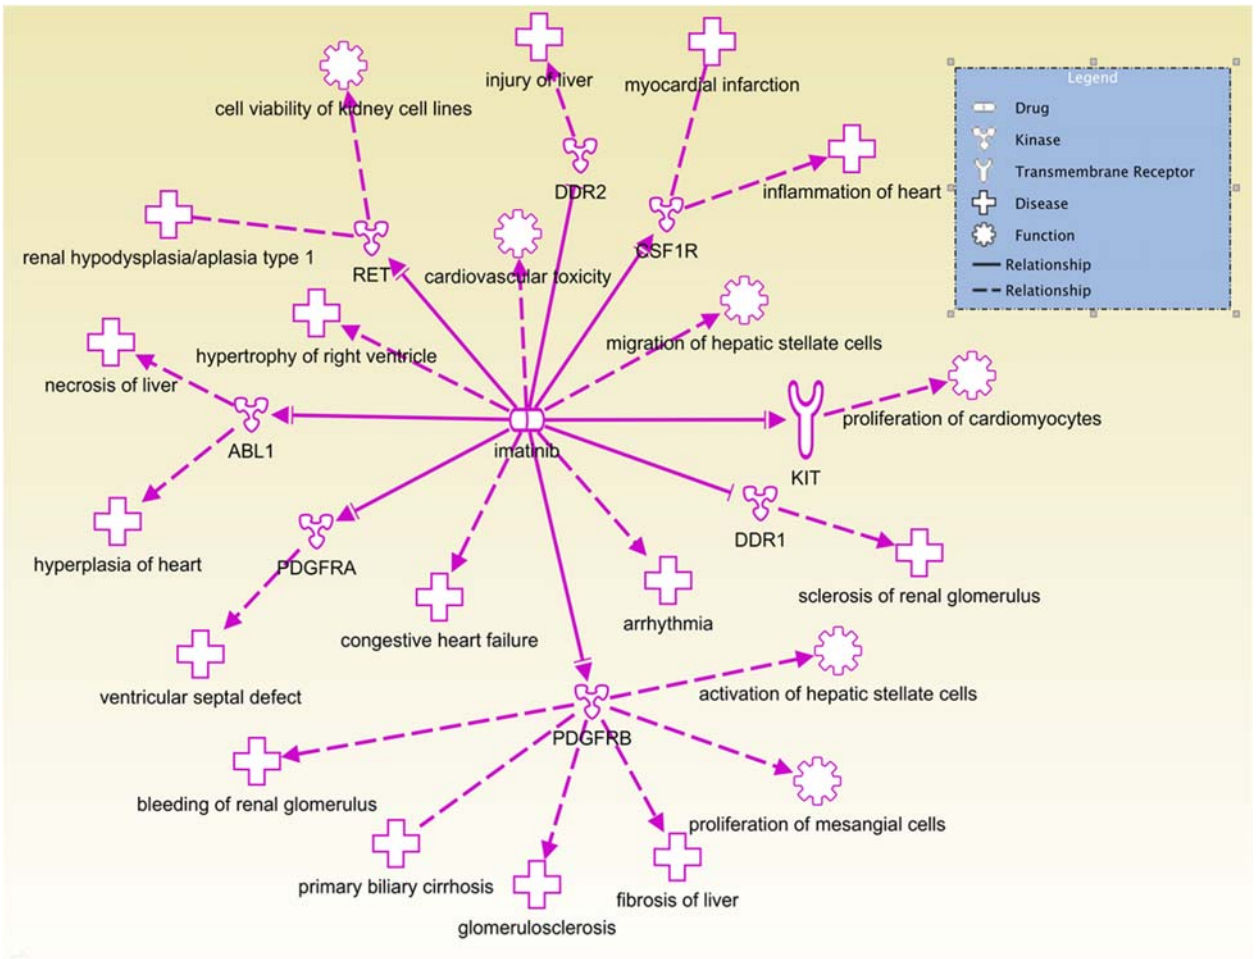

Fig. 1 Polypharmacology profile of imatinib. Generated using the QIAGEN's Ingenuity Pathway Analysis (IPA, QIAGEN Redwood City).

applications of multitargeted strategies for the treatment of chronic diseases like AD, Parkinson's disease, and cardiovascular and inflammatory diseases.[41]

2.10.1.3 Comparison of Polypharmacology With Monotherapy and Combination Therapy

In the last few decades, considerable research efforts have been made in the discovery and development of therapeutics that modulate individual disease-modifying targets. Based on different MOAs, there are many drugs in the market to treat disease conditions ranging from the simplest one to the most complicated one. These drugs can be classified as: (1) Drug acting on single targets, (2) Combinations of drugs acting on single or multiple targets, and (3) Single drug acting on multiple targets. The comparison of these therapies and some respective examples are shown in Fig. 2. These drugs have their own pros and cons and the limitation varies with the complexity of diseases.

Monotherapy is the preferred choice of medicine for most of the conditions. In most cases it is able to get the desired response and it also reduces potential drug adverse effects due to drug–drug interactions. The major disadvantage of this class of drugs is that the drug off-target activities are poorly known and lead to the consequences of reduced drug efficacy, increased drug resistance, and poor quality of life of the patients. Complex diseases such as cancer or those that affect multiple tissues such as diabetes and immune-inflammatory disorders are caused by multiple pathogenic mechanisms. Drugs designed to act against individual molecular targets usually are insufficient to combat multigenic diseases.[42] Attempts to develop more effective treatments by discovering highly selective single drugs have been largely unsuccessful in case of such complex diseases.

In comparison to single-target drugs, combinations of specific drugs that impact multiple targets simultaneously are found to be more effective at controlling complex diseases.[34,43,44] They are designed either in a way that one of the drugs facilitates the action of others, that is providing synergistic effect, or in the way that they exhibit a combined additive effect. A good combination of drugs is the one in which the drugs are individually active, are able to elicit a synergistic effect, have different MOA, have nonoverlapping mechanisms of resistance, and demonstrate distinct toxicities. In some cases, the risks of drug–drug interactions associated with combination therapies could be mitigated, resulting in a simplified therapeutic regimen. Many drug combination therapies have

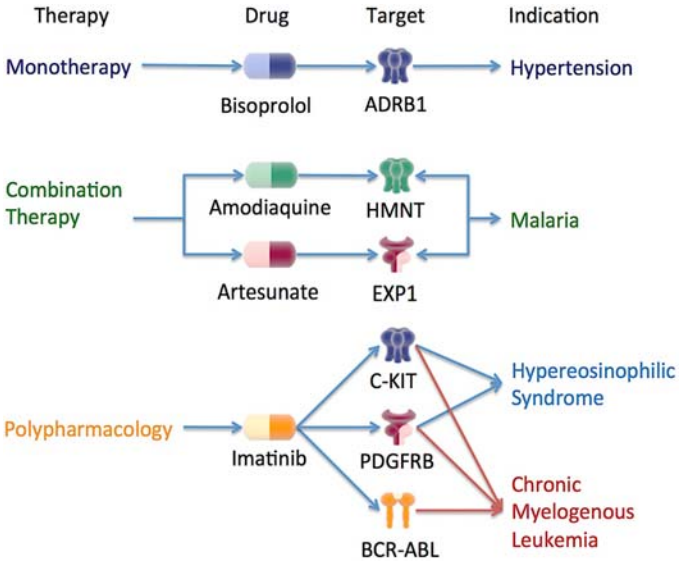

Fig. 2 Comparison of monotherapy, combination therapy, and polypharmacological agents.

been investigated in different disease conditions. For example, the implementation of artemisinin-based combination therapy was carried out to treat chloroquine-resistant and sulfadoxine–pyrimethamine-resistant malaria,[45] although it is not used as the preferred first-line antimalarial drug. Combination therapy is also explored in multiple sclerosis, a complex CNS inflammatory disease process that comprises multiple potential therapeutic targets. For example, one drug can be used to reduce the inflammation while another is able to augment neuroprotection or reduce side effects.

Though combination therapies have proved to be highly significant and therapeutically relevant, they have some disadvantages. Adverse effects of individual drugs can be additive or even synergistic, and drugs might interfere with each other, thereby reducing efficacy and exacerbating potential drug–drug interactions. If the combinatorial drugs are not highly selective, they could lead to a higher chance of acute or delayed toxicities. The use of drug cocktails often complicates dosing schedules and negatively impacts patient adherence to the treatment. Moreover, developing combination drugs is a time-consuming and arduous process, as it requires demonstration of the activity and safety of combination to regulatory agencies. In addition, problems may also arise if different pharmaceutical companies are developing two drugs selected for the combination therapy. In this case regulatory and intellectual property issues may delay clinical trials of these investigational drug combinations. To resolve this, the FDA recently expanded their patent portfolio. It is now possible to patent combination drugs in cocrystal format which could minimize some of the above combination therapy issues in the future.

On the other side, single drug acting on multiple targets have many advantages over drug acting on single targets or combination of drugs. They can act on multiple targets simultaneously; hence they show excellent efficacy compared to a compound with high specificity for a single target. They often show superior efficacy against advanced stage diseases. A single molecule with dual activity may have a more predictable pharmacokinetic (PK) profile compared to multiple molecules administered in combination. Therefore, it may display a superior PK and safety profile. This is particularly true if the adverse effects are molecule-based because a single molecule would be administered instead of combination. On the other hand, no clear advantage is obtained if the adverse effects are target-based. In this case two adverse effects will be independent of each other. The chance of developing target-based resistance to multitarget drugs is statistically lower than that of single-target drugs. Administering a single drug modulating multitarget guarantees the simultaneous presence of the molecule in tissues where the active principle is required to work such that the compound interacts with its multiple targets. Although it is arguable, developing a single agent binding to multiple targets might be easier compared to developing combination drugs. More detailed comparisons have been described by Anighoro et al.[30]

2.10.2 Methods to Study Polypharmacology

In polypharmacology, the ideal goal is to identify/develop compounds that act on multiple key targets involved in a given disease with increased efficacy and decreased side effects. Systematic method integration and data visualization is required to facilitate such studies. Significant efforts have been put forth to develop polypharmacology databases and computational methods. Some of the representative databases include STITCH,[46] Polypharma,[47] SuperTarget,[48] IBIS,[49] and SIDER.[50] Tools such as PyMine bring relevant data from databases and facilitate hypothesis generation for polypharmacology studies.[51] Various computational methods have been developed to predict on/off target activities for small molecules. One can use these methods to predict novel targets of known drugs and repurpose them to treat new indications. For example, Keiser et al. applied the similarity ensemble approach

(SEA) method and predicted new targets for methadone, emetine, and loperamide.[52] They found that these drugs might act as antagonist of muscarinic M3, α2 adrenergic, and neurokinin NK2 receptors, respectively. Experimental studies validated their prediction results. Recently, Kumar and Jasrai published a study in which they identified seven targets of kinetin using idTarget, a structure-based target prediction web server. Four of the seven predicted targets were experimentally validated in the subsequent literature search.[53] Although there have been a few successes, more accurate and robust approaches are still needed. Current methods can be divided into four categories: ligand-based, structure-based, network-based, and bioinformatics methods. In the rest of the article, we will review these methods (**Table 1**) and expect that a better understanding of their algorithms will greatly help to improve and develop novel technologies for polypharmacology studies. It is worth mentioning that since it is not realistic to cover all reported methods, herein we arbitrarily select and discuss some of them as examples in each category. We also provide an overview of the polypharmacological agents that have been discussed in this Chapter, including their 2D structures, mode of action, and indications to use (**Table 2**).

2.10.2.1 Ligand-Based Methods

A general assumption behind target identification using ligand-based methods is that similar compounds share similar targets. Many similarity-based methods and machine learning algorithms have been developed to predict targets of small molecule

Table 2 Drug formulas, mode of action, and indications to use

Structure	*Name*	*Targets/mode of action*	*Indications*
	Imatinib	Tyrosine kinase inhibitor	Multiple cancers
	Terfenadine	H1 receptor antagonist	Withdrawn
	Propoxyphene	*Mu* receptor agonist and noncompetitive nAChR antagonist	Withdrawn
	Sildenafil	cGMP–PDE5 inhibitor	Hypertension and erectile dysfunction
	Aspirin	Suppression of prostaglandins and thromboxane, COX1 and COX2 inhibitors	Pain, cancer, and arthritis
	Mebendazole	Microtubule synthesis inhibitor	Nematode infestation, advanced colon cancer
	Sunitinib	VEGFR, PDGFR, KIT, FLT3 modulator	Renal cell carcinoma, GIST tumors
	Memantine	Uncompetitive glutamatergic NMDA receptor antagonist	Alzheimer's disease
	Clozapine	5HT1A partial agonist	Schizophrenia
	Gefitinib	EGFR inhibitor	Breast, lung, and other types of cancer

Table 2 Drug formulas, mode of action, and indications to use—cont'd

Structure	*Name*	*Targets/mode of action*	*Indications*
	Sorafenib	Multiple kinase inhibitor including VEGFR, PDGFR and Raf family proteins	Kidney cancer and thyroid carcinoma
	Nelfinavir	Inhibits angiogenesis, HSP90, HER2, and AKT signaling pathway	HIV and cancer

compounds (**Table 1**). SEA is one of the earliest similarity-based methods that generates similarity maps for targets based on their ligand topological similarities.[52] The statistical method of SEA is similar to the one used in basic local alignment search tool.[83] The dataset consists of 246 sets of targets acquired from MDL Drug Data Report with a unique set of ligands. In the first step, the 2D topological Daylight fingerprints are calculated for each ligand, and a pair-wise similarity metric is generated for each element of the two sets by calculating the Tanimoto coefficient (T_c).

$$T_c = \frac{A \cap B}{A \cup B}$$

Then the linear least square optimizer is used to predict raw scores of the two sets. These raw scores are then converted into z scores using the following formula:

$$z\text{score} = \frac{\text{raw score} - \text{random raw score at that set sizes}\,(\mu)}{\text{random standard deviation}\,(\sigma)}$$

The z scores are then converted to the E-value as a probability of score being achieved by random chance, as follows:

$$E(z) = P(z)N_{\text{db}}$$

where N_{db} is the number of set comparisons made in the database and $P(z)$ or $P(Z>z)$ is the probability of obtaining the same z score or better z score by random. In this case it was found that the background z scores have an extreme value distribution. Therefore, $P(Z>z)$ is calculated as follows:

$$P(Z > z) = 1 - exp(-e^x)$$

where $x = -\frac{z\pi}{\sqrt{6}} - \Gamma'(1)$ and $\Gamma'(1)$ is the Euler Mascheroni constant (≈ 0.577215665).

For numerical precision, when z score > 28, $P(Z>z)$ is approximated as:

$$P(Z > z) = -(x + (x2)/2 + (x3)/6)$$

A matrix of SEA E-values is then constructed for all pair of sets in the database. Using the Kruskal's algorithm, a minimum spanning tree is built as similarity map. Although the similarity map is calculated based on ligand similarities, it generates clusters of targets that are biologically related.

Another example is Shape Signature developed by Zauhar et al. It is a novel fragment-based ligand similarity search method that uses smooth molecular surface triangulator algorithm to generate surface of the ligand.[84] Along with the ligand similarity, it can also compare the shape of the ligand with the shape of the binding sites. This shape-based similarity function can be further explored for polypharmacology applications.

The structure–activity relationship (SAR) data has also enabled application of various machine-learning algorithms to derive relationship between small molecules and targets. Most of the similarity-based polypharmacology methods use Tanimoto coefficients whereas machine-learning algorithms include support vector machine (SVM), artificial neural networks, and Bayesian classifiers. In machine learning-based target prediction methods, similarity matrices between drug–drug and target–target are generated. A variety of machine learning methods such as Gaussian interaction profile,[85] pairwise kernel method (PKM),[86] Laplacian regularized least squares,[87] kernel regression,[88] bipartite local method,[89] and kernelized Bayesian matrix factorization with twin kernels (KBMF2K)[90] have been developed. For instance, Ding et al. carried out comparison studies on these methods and concluded that PKM and KBMF2K performed better than any other methods.[91] The PKM method was adopted by Jacob et al.,[86] and it is an

SVM-based method that precomputes drug–drug and target–target similarities and uses drug–target interaction as instances. The similarity of drug–target pairs from the drug similarity score and the target similarity score is computed by the following formula:

$$S((d,t),(d',t')) = S_{\mathrm{d}}(d,d')\cdot S_{\mathrm{t}}(t,t')$$

The generated similarity matrix (kernel) of drug–target pairs is then used to train SVM classifier for prediction of drug–target interactions. The authors tested this algorithm on three classes of receptors (enzymes, GPCRs, and ion channels) and reported that the methods did exceptionally well compared to traditional ligand-based methods, especially when target receptors did not have a set of known ligands.

2.10.2.2 Structure-Based Methods

Traditionally, structure-based methods such as molecular docking are used to screen small molecule libraries against targets of interest. In recent years, the significant increase of the number of unique 3D protein structures in Protein Data Bank (PDB) has paved the way for development of inverse docking methods. The primary goal of inverse docking is to dock the small ligand into active sites of multiple targets and rank those targets. Though available docking algorithms are capable of carrying out inverse docking, major challenge is to handle large amount of structural data and ranking of targets instead of small molecules. Multiple studies have suggested that energy scores used in traditional docking algorithms are not sufficient for ranking targets.[92–94] For example, Wang et al. reported limitations of Glide score in ranking targets.[92] They found that Glide score performed better when a correction term related to binding site description was added. Kellenberger et al. published a study on ranking of targets using Gold fitness score and topological molecular interaction fingerprint (IFP) and concluded that traditional single scoring function is not enough to rank targets accurately.[94] Their combination of gold fitness score with topological molecular IFPs performed better than any single scoring function. From these studies, it is clear that target-specific scoring functions are required to rank targets accurately for polypharmacology studies.

In recent years, various inverse docking methods such as INVDOCK,[58] TarFisDock,[61] and idTarget[59] were developed by using traditional docking algorithms with slightly modified parameters. For example, in 2001 Chen et al. developed the first automated inverse docking method INVDOCK.[58] It scores the protein targets based on ligand–protein interaction energy function (ΔE_{LP}) through calculation of two threshold values $\Delta E_{\mathrm{Threshold}}$ and $\Delta E_{\mathrm{competitor}}$ to screen potential targets. The first one is calculated from the analysis of PDB receptor–ligand complex analysis:

$$\Delta E_{\mathrm{Threshold}} = -\alpha N$$

where α is calculated by fitting above linear equation to the calculated ΔE_{LP} values of all receptor–ligand complexes in PDB database and N is the number of atoms in ligand. Based on the observed relation, targets are considered as binders if calculated $\Delta E_{\mathrm{LP}} < \Delta E_{\mathrm{Threshold}}$ kcal/mol.

The second threshold value $\Delta E_{\mathrm{competitor}}$ is applied to detect if the given small molecule is better competitor as compared to the ligand present in PDB structure of that receptor target. The threshold value is calculated from original receptor–ligand complex found in PDB database.

$$\Delta E_{\mathrm{competitor}} = \beta \Delta E_{(\mathrm{pdbcomplex})}$$

From computed energies of multiple compounds, it was suggested to use a value of 0.8 for β to produce statistically significant results. Targets are considered as binders if $\Delta E_{\mathrm{LP}} < \Delta E_{\mathrm{competitor}}$. Multiple studies have applied INVDOCK method for multitarget identification of small molecules.[95–98] For example, Zhao et al. identified multiple targets for Astragaloside IV.[98] Out of 32 predicted targets they experimentally validated three targets, namely calcineurin, angiotensin-converting enzyme, and c-Jun N-terminal kinase.

Later, Wang et al. developed idTarget, a web server for target fishing.[59] It employs a target scoring function based on binding pocket affinity profile modeled by a Gaussian function. A range of predicted binding affinities of multiple ligands for a given receptor determines the width of the Gaussian function. From this profile, a z score can be calculated where target prediction is considered significant if large negative Z value is observed. For ligand j to a given binding pocket i, the Z value can be calculated using the following equations:

$$Z_{ij} = \frac{E_{ij} - E_i}{sd_i}$$

$$E_i = \sum_{k=1}^{N_{\mathrm{c}}} E_k^{\mathrm{c}} / N_{\mathrm{c}}$$

$$sd_i = \sqrt{\frac{\left(E_k^{\mathrm{c}} - E_i\right)^2}{N_{\mathrm{c}} - 1}}$$

where E_{ij} is the dock energy of ligand j and binding pocket i; E^{c} is the dock energy from crystal pose; E_i is the center of the affinity profile for pocket I; and sd_i is the width of the affinity profile for pocket i.

Another widely used approach for target prediction is binding site similarity search. Based on the "lock & key model" postulated by Emil Fisher in 1894, it could be assumed that structurally similar proteins have similar molecular functions and therefore may

bind to structurally similar compounds. However it is worth to mention that many proteins do not share overall sequence similarity or structural similarity but they still have local similarities in form of binding sites and thus bind similar ligands. This is also an active area of research and a number of tools have been developed to identify similar binding sites (Table 1). Most of these methods use some variation of geometric pattern comparison, in which the 3D coordinates of the proteins are converted into simplified patterns such as pharmacophoric features or geometric triplets. Such patterns are then aligned using various search algorithms. Most commonly used strategies include geometric matching of triplets, where triplets are aligned based on measurements of distances between two points of the triplets.

Recently, the Fingerprints for Ligands And Proteins (FLAP) algorithm were developed by combining the GRID molecular interaction fields (GRID-MIFs) and pharmacophoric features.[99] First, MIFs are generated using various chemical probes covering all types of chemical interactions. The weighted energy-based and space-coverage function is then used to convert these MIFs into pharmacophoric features. All possible combinations of pharmacophoric features are used to generate four-point pharmacophore fingerprints, and they are used to find ligand–ligand, ligand–receptor, and receptor–receptor similarities. BioGPS is an automated method that calculates binding site similarities using FLAP algorithm.[100] It uses Fixpdb algorithm for automatic protein structure preparation and employs FLAPsite algorithm for binding site detection using 16 different GRID probes. Then with the FLAP protocol, MIFs are generated for the binding sites, and they are then superposed against all binding site MIFs in the database. For each solution, the algorithm calculates a set of Tanimoto coefficients.

Also, inverse pharmacophore methods have been implemented to map small molecule pharmacophoric features on structure-based pharmacophore models of the targets.[71,99] Traditionally, pharmacophore modeling is used as ligand-based virtual screening to identify compounds that match similar pharmacophoric features of known ligand. Liu et al. developed PharmMapper, a web server that can predict targets for a given small molecule by reverse mapping of pharmacophore to the receptor structure. The PharmMapper algorithm generates a triangle-hashing table from triplets of feature points, which resembles to the widely used geometric hashing method in pharmacophore modeling. These triangles from ligands are matched with precomputed library of triangles from receptor. The Kabsch algorithm is then used to optimize the alignment of these triangles. An evaluation of the alignment is carried out using distance-dependent scores.

$$\text{PointScore} = \sum_{i=1}^{n} w_i F(p)_i = \begin{cases} 1 - \left[\dfrac{d(p)_i}{T(p)_i}\right]^2, & d(p)_i \le T(p)_i \\ 0, & d(p)_i \le T(p)_i \end{cases}$$

$$\text{VectorScore} = \sum_{i=1}^{n} w_i F(v)_i \times cos\theta$$

where $d(p)_i$ is the distance between ligand point feature p and corresponding one in pharmacophore; $T(p)_i$ is the matching tolerance value; and θ is the angle between the two vectors from the matching pair of vector features in the ligand and pharmacophore. The final fit score is calculated using the following equation:

$$\text{FinalFitScore} = \text{PointScore} + \text{VectorScore} - \text{PenaltyScore}$$

where PenaltyScore is the PointScore calculated between ligand heavy atoms and pharmacophore excluded volumes. PharmMapper method was used to predict targets for a series of acenaphtho[1,2]pyrrole derivatives,[101] tyrosine kinases were identified as putative targets and then validated experimentally.

2.10.2.3 Network-Based Methods

High-throughput techniques in genomics, proteomics, and metabolomics are generating enormous amounts of data, which increases our understanding of complex diseases. Large efforts are being made to annotate and integrate such data to understand system-wide effects of small molecules. The Connectivity Map Project is the largest collection of gene-expression profiles for diseases, genetic mutations, and drug activities. One way to represent such data is by creating networks of various biological entities, and the graph algorithms can be used to deduce relation between biological entities, in this case the off-targets of small molecules. Recently, Vitali et al. developed a network-based method that builds a protein–protein interaction network in order to increase the number of possible associations retrieved, that is, the physical interaction between proteins and their binding type. It was then used to rank targets for polypharmacology studies.[102]

STITCH is an example that utilizes network-based methods and curated databases to predict protein–inhibitor interactions.[103,104] The authors extracted the interactions from literature using natural language processing text-mining techniques, and then used this data to predict interactions of query compounds. In the latest version, the authors added a new function to predict the protein–ligand interaction based on compound structures. They curated ligands with more than 100 binding proteins in ChEMBL database and utilized random forest to predict the binding proteins for query compounds. During the past several years, our group has embarked the development of using molecular networks that allows users to visually and efficiently navigate publicly available information on drug properties (biological targets, pharmacology, etc.) and can show relationships among drugs and their receptors based on their function annotation (biological targets, toxicity, side effects, metabolism, etc.) or chemical similarity.[105] Currently, this platform has been expanded to the analysis of more than 5000 drugs and 10 million virtual library compounds, along with 56,000 biological

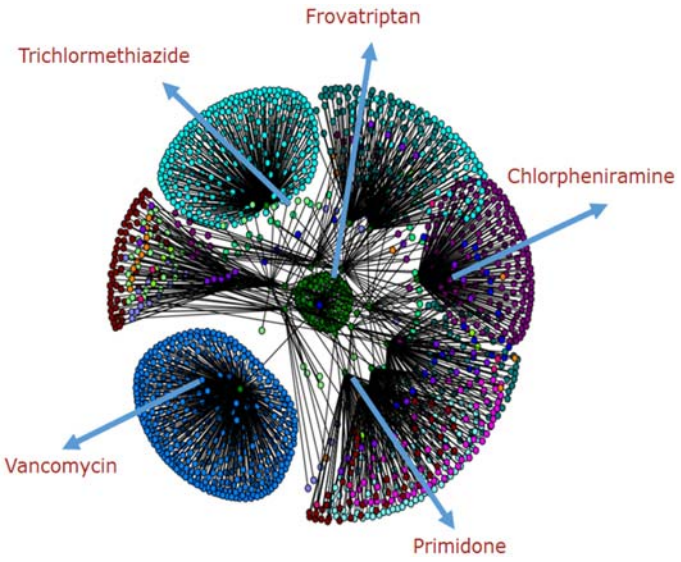

Fig. 3 *Drug network for butalbital*, generated based on shared targets with other approved drugs. Targets have been hidden in order to reduce the complexity, and drugs related to butalbital are shown in three levels with different colors. Butalbital is placed in the center of the graph; Frovatriptan is an example of innermost cluster *(dark green)*; Vancomycin, Trichlormethiazide, Chlorpheniramine, and Primidone are situated in blue, cyan, purple, and magenta clusters, respectively.

macromolecules with available high-resolution 3D structures. To fully explore the huge and complex molecular networks among ligand–ligand, ligand–receptor, and receptor–receptor molecules, integration of a diverse set of tools including chemical similarity searches, text mining, cheminformatics mapping, and high-throughput docking approaches are being implemented for in silico polypharmacology prediction and design. Fig. 3 demonstrates the drug network for Butalbital using our tools. Along this line, *Polypharma* is another database of multitargeted small molecules developed by our group recently.[47] In this database, we curated all drug-like ligands (953) that bind to more than two distinct proteins in PDB. Further analysis has shown that compared to single target-specific ligands, the multitargeted ligands have different chemical characteristics such as molecular weight and hydrophobicity. As a consequence, Polypharma provides a collection of confirmed multitargeted compounds that are very useful in the polypharmacology research such as novel target predictions and identification of new multitargeted compounds. The analyses of these multitargeted compounds provide insights of difference between multitargeted and single-targeted compounds.

2.10.2.4 Bioinformatics Methods

High-throughput methods, such as RNA-Seq, next generation sequencing, and reverse protein phase array, have generated large amount of gene expression data. With the help of genome-wide expression data from treated and untreated samples, one can study the overall functional effects of a small molecule and generate gene expression signatures that could be used for training data sets for polypharmacology studies. Sirota et al. developed a drug repositioning method that can predict novel therapeutic effect of the drugs based on gene expression pattern of 100 diseases and 164 drug treatments collected from public databases.[106] They demonstrated the capability of their method by recovering known drug–disease relationships. They also experimentally validated probable use of Cimetidine, an antiulcer drug in lung adenocarcinoma.

Currently, the NIH Library of Integrated Network-based Cellular Signatures Program (LINCS) (http://www.lincsproject.org) aims to collect and disseminate data and analytical tools needed to understand how human cells respond to perturbation by drugs, environment, and mutation. The database contains more than 1 million drug-induced gene expression profiles that can be explored to study drug polypharmacology. Another well-known tool for such studies is Ingenuity Pathway Analysis (IPA). It is developed by Qiagen with a significant amount of curated and annotated data of genes, chemicals, diseases, pathways, and toxicity studies. It helps in analyzing and visualizing gene expression data by mapping onto various canonical and novel pathways. Of note, bioinformatics-based polypharmacology applications can also be developed with Cytoscape, which is an open source molecular interaction network visualizer.[107] Other bioinformatics approaches that can be used for polypharmacology studies are summarized in Table 1.

2.10.3 Advantages of Polypharmacological Drugs

As already mentioned above, polypharmacological drugs have a number of advantages over single target drugs or combination. Generally, the therapeutic efficiency of the multitargeted drugs is increased as the result of their ability to target multiple cellular

pathways at the same time. More obviously, it is much easier to alter the physical and chemical properties of a single agent than combinations for better bioavailability. In addition, due to their promiscuous nature, multitargeted drugs may have multiple routes of elimination, thus less accumulation in the body and making them safer. Another advantage of multitargeted drugs is that they may be suitable for a larger population of patients and produce much better overall effects by targeting multiple signaling pathways as compared to selective drugs. This also creates incentives for pharmaceutical industry to invest more financial and research efforts in term of profitability. For instance due to its multitargeting activity, imatinib is effective in a more broad population while gefitinib as a selective EGFR inhibitor is shown to be effective only in patients with EGFR mutations.[32]

The multitargeted behavior of these drugs has proved to be a great asset in drug development. One of the most renowned examples is aspirin. This drug has not only been employed for pain relief, but frequently used for decreasing platelet aggregation, prevention of cancer and preeclampsia, and treating arthritis.[108–110] Its actions on several pain-related pathways have been well studied in depth and more MOA have been elucidated. Drugs like sorafenib and sunitinib have also shown favorable results with their multitargeted behavior. Especially sorafenib, which impedes the activity of several of kinase receptors such as platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), also triggers the RAF/MEF/ERK signaling pathway (inhibition of cell proliferation) and the VEGFR-2/PDGFR-β signaling cascade (curbing tumor angiogenesis).[111–113] On the other hand, sunitinib, a small molecule with inhibition of tyrosine kinase activities, acts on VEGF, PDGF, and FLT3 receptor tyrosine kinases.[114,115] They both are used as frontline drugs for treatment of a variety of cancers.

In many cases it is observed that the polypharmacological agents present relatively low binding affinity to their targets, as compared to the single targeted, selective drugs. However, such feature does not diminish their therapeutic effects. For example, memantine (a drug used to treat AD) and other multitargeted, noncompetitive NMDA receptor antagonists display minimal side effects and prevalence.[116] More encouraging, the low affinity binding molecules have been employed to inhibit unconventional targets such as unstructured proteins, where the weak binding properties prove to be very useful in modulating the signaling and regulation.[117] The low affinity binding also involves fleeting interactions with the targets, which may manifest in greater off-rate as compared to on-rate actions. Interestingly, the low affinity binding does not necessarily reduce the efficiency. It is observed that most of the signaling pathways and transcriptional networks involve weak linkage protein interactions, which are transient in nature,[118] and these reactions have low flux energy consumption. The polypharmacological drugs usually have transitory interactions with their targets in cells and such binding is adequate to modulate the required modifications needed to trigger the next step in the pathway.

The multitarget effects of these drugs not only aid in developing new strategies for rational drug design but also help understand the promiscuous binding, even in processes such as drug delivery and excretion. This has presented a new challenge for drug development across the disciplines, where further research will be needed for designing the next generation of therapeutics.

2.10.4 Challenges in Polypharmacology Design

Though multitargeted drug design is suitable for complex diseases, there are many challenging tasks that need to be overcome.

2.10.4.1 Avoiding the Off-Target Activity

By understanding the mechanisms behind off-target activities, we can devise strategies to avoid unintended effects, which may cause side effects or toxicities. For example, when the RNA-induced silencing complex processes siRNAs, it also downregulates unintended targets that result in measurable false-positive phenotypes.[119] This problem can be mitigated by understanding the basic mechanism, selecting appropriate relevant targets, and including phenotypic screening experiments. Additionally we can also optimize the chemical structure and carry out siRNA pooling to decrease potential side effects.[120,121] Again with the multikinase inhibitor sorafenib as the example, it was found to be also active against 5-HT receptors in the range of nanomolar concentrations.[122] Such issues could be addressed by developing more accurate computational methods to predict the promiscuous nature of drugs and their targets in the earlier stage of drug discovery.

2.10.4.2 Optimizing the Potency of Multitargeted Agents

With the help of combinatorial chemistry and SAR studies, it is feasible to optimize the compound potency for a particular target. For combination therapy targeting multiple receptors, it can be achieved by simply optimizing the ratio of the individual drug doses. It is rather difficult to optimize potencies at multiple receptors while optimizing the single chemical structure. However, multitargeted single drugs avoid drug–drug interactions and simplify the process of clinical trial development for new drug approval. To outweigh the advantages of monotherapy and combination therapy, computational methods can be used to optimize drug potencies against multiple targets. Recently, Besnard and Hopkins developed an automated and adaptive design method to develop drugs targeting multiple specific receptors also with potency optimization strategies.[40] Using the algorithm, the team was able to develop highly potent donepezil derivatives against the D4 dopamine receptor ($K_i = 8.9$ nM) as compared to donepezil ($K_i = 614$ nM).[40] Wermuth et al. in a recent publication described a novel approach termed as selective optimization of side effect (SOSA) which was used for optimization to increase affinity to the new target for a known drug, while reducing affinity to the primary target.[123] In the first step, screening is carried out to identify hits from carefully selected, structurally diverse compounds with known toxicity and bioavailability data. In the second step, the selected hits are optimized for their potency against the new target using traditional approaches such as

parallel or combinatorial chemistry. These studies have demonstrated that the potency of the multitarget agents can be optimized through rational design.

2.10.4.3 Achieving Multitargeting Without Becoming Nonselective

Again sunitinib was one of the first multikinase inhibitors used to selectively block VEGFR2 signaling to achieve antitumor efficacy that is by regulating both tumor proliferation and angiogenesis.[115] But one study found that the off-target effects of the RTK inhibitor might disturb the homeostatic barrier function of the host vasculature, leading to metastasis promotion.[124] Later, sunitinib was also found to be a nonselective drug that promotes some cancer towards the aggressive stage in animal models. The proposed mechanism behind this action is that the Akt/β-catenin pathway gets activated in response to drug-induced hypoxia and then it stimulates the growth of the distinct aggressive tumor cells.[125] To overcome this problem, combination therapy of this drug with agents that can block the Akt/β-catenin pathway was suggested.[126] This demonstrates that complete understanding of pathways and protein networks is required to treat complex diseases, and it is crucial to derive multitargeted, but still selective agents.

2.10.4.4 Selecting the Best Multitargeted Strategies

Information obtained from in vitro assays in developing multikinase inhibitors cannot be solely relied on, but rather additional cell-based studies are required to assess system-wide effects including membrane permeability, intracellular ATP concentrations, and the relative concentrations of the kinase targets and their substrates. In some cases such as relapsed or refractory lymphomas or Hodgkin disease after DHAP induction, clinicians need to prescribe a series of drugs with maximum tolerable doses to achieve sequenced action as the molecular target. Such highly potent and multiple targeted therapies are very difficult with multitargeted single drug therapy. Thus, combination therapies have to be used as complementary approaches to the multitargeted drug therapy in these cases.

2.10.5 Applications of Polypharmacology

2.10.5.1 Targeting Complex Diseases

The "one drug–one target" approach is beneficial when the underlying etiology of a disease is well studied and it produces the maximum efficacy by targeting a single receptor or enzyme. Unfortunately this does not hold true for complex diseases. Diseases such as cancer and AD arise from multiple factors including biological and environmental. In most of the cases the underlying mechanisms of these diseases are poorly known. Despite the large amount of money invested and recent success in target identification, the single drug approach and the combination therapy have failed to show expected results. On the other hand, multitargeted drugs indeed have been shown with significant advantages in treating cancer and AD. Next we briefly discuss some application of polypharmacology to the therapy of these diseases.

2.10.5.1.1 Polypharmacology in cancer

Utilization of molecular networks has been pivotal to have next big breakthroughs for treatment of this seemingly unstoppable disease. Cancer is poised to surpass heart disease to become the most common cause of death in the United States.[127] It is no surprise that, when compared to other diseases afflicting the current population, cancer is described as a malady "at best, minimally controlled by modern medicine."[128] While the mortality rates of cardiac, cerebrovascular, and infectious diseases have been brought down about two-thirds in the last 50 years, the mortality rates from cancer have remained largely the same.[127] The global market for cancer drugs has hit $100 billion in annual sales, and could reach $147 billion by 2018, even with numerous recent discoveries in many diverse fields of cancer studies.[129] Also, the active cancer patient population demands the latest aggressive chemotherapy regimens that can easily command high prices due to unmet need. Patients whose survival is limited are desperate for treatments in order to extend their livelihood. These factors allow drug prices to reach record high, and the demand for the next cancer breakthroughs has reached an unprecedented level.

Multitargeted kinase inhibitors are a specific subset of drugs that hold the promise of overcoming the woes of the current attrition rate, and rational design approaches can bring the pipe dream of cancer cure closer to reality. It should come as no surprise that because tyrosine kinases are involved in cell growth, survival, and proliferation, many model systems show that a perturbation of tyrosine kinase signaling results in malignant transformation and oncogenic mutations in tumors.[130–132] Tyrosine kinase inhibitors with impressive clinical efficacy have been attributed to a selectivity profile that incorporates multiple targets.[132,133] Examples include imatinib (Gleevec), used for CML and gastrointestinal stromal tumors (GIST), sunitinib (Sutent) for treatment of imatinib-resistant GIST and renal cell carcinoma (RCC), sorafenib (Nexavar) for RCC and hepatocellular carcinoma. Analysis of 974 anticancer agents from 1995 to 2007 in the area of oncology demonstrates an attrition rate from Phase I to registration of 82% as a whole, but in the subset of multitargeted kinase inhibitors, the observed attrition rate drops to 53%.[134]

Along with tyrosine kinases, the PI3K class of kinases are commonly mutated and activated in human cancers. While the two types of kinases lack a primary sequence homology, they share a kinase domain structure and a crucial function of tyrosine kinases is to activate the lipid kinases of the PI3K family.[135] PI3Ks are validated targets for drug development, and the isoform p110α is the most frequently mutated kinase in human cancer.[136,137] In an effort to generate molecules that preferentially inhibit both PI3Ks and tyrosine kinases, Apsel et al.[39] used kinome-wide biochemical profiling of compounds sharing a pyrazolopyrimidine (PP) core,

combined with X-ray crystallography and iterative chemical synthesis, to discover the small molecule PP121. The compound forms the same hydrogen bonds to kinases as the adenine of ATP, exploiting the conserved region in both tyrosine kinases and PI3Ks. The authors then showed that the selectivity of PP121 toward the PI3K/tyrosine kinases relative to serine/threonine kinases is due to a "gatekeeper residue" that is bulkier in serine/threonine. Given that PP121 can inhibit both tyrosine kinases and PI3Ks at nanomolar efficacy, they next examined its use in imatinib-resistant CML. PP121 was able to block proliferation by inducing G_0/G_1 cell cycle arrest, and the authors attribute this effect to PI3K pathway inhibition. The results show that consideration of potential inherent polypharmacological effects against two signaling pathways provides promising new anticancer agents with advantages over other treatments.

2.10.5.1.2 Polypharmacology in CNS disorders

Another area that has seen the first-hand benefits of polypharmacological drugs are the antipsychotic and anti-dementia medications. Profitability and demand from this new market have exploded, with over 45 million annual prescriptions as of 2007, and worldwide sales are over $17 billion.[138,139] While the profitability is large, the success rate of CNS drugs, as stated above, is significantly low from first-in-man trials to registrations. It has been well established that many mental illnesses are polygenic in origin and the embodiment of complexity, with substantial environmental and possibly even epigenetic components.[140,141] Although neurological disorders display deregulation of multiple signaling pathways, drug mechanistic studies of these diseases have only focused on specific targets, such as dopamine transmission for psychosis and acetylcholine and glutamate transmission for Alzheimer's dementia.[142]

Atypical antipsychotics, also known as the second-generation antipsychotics, differentiate themselves from typical antipsychotics by their ability to bind to both serotonin and dopamine receptors and their decreased extrapyramidal side effects. The first atypical antipsychotic is Clozapine, which remains the "gold standard" of atypical antipsychotic treatments. Interestingly, it was discovered through phenotypic screening/optimization and not originally designed to hit any one individual protein target. However, the pharmacological profile of Clozapine shows binding (with affinity values $K_i < 100$ nM) to at least 26 receptors.[139] Even more interesting, almost all attempts to target a single "magic receptor" thought to be involved in schizophrenia have resulted in much lower efficacy than multitarget drugs like Clozapine.[139] The pleiotypic nature of Clozapine is most likely accountable for its efficacy in treating schizophrenia and related disorders.[143,144] Examination of functional electrophysiology data demonstrated that antipsychotic and anti-dementia medications directly modulated multiple ligand- and voltage- gated ion channels.[142] A logical expansion of this fact is that enhanced understanding of the polypharmacological effects of these drugs can coincide with progress in disease subtyping, leading to personalized drugs toward patients with unique polymorphisms of ion channels.

Antidepressants are also trending toward polypharmacological effects. Genetic studies have shown that depression displays a complexity that spans many diverse genes.[145] Results show that dual-action antidepressants (serotonin and noradrenaline reuptake inhibitors, or SNRIs), which inhibit both 5-HT and dopamine and/or noradrenaline reuptake, are more effective than single-action antidepressants (selective serotonin reuptake inhibitors, SSRIs).[146,147] Clearly, the most clinically effective treatments for depression, schizophrenia, and possibly other mood disorders display multiple MOA, working as nonspecific "magic shotguns" rather than "magic bullets" on the CNS.[139]

2.10.5.2 Targeting Drug Resistance

Polypharmacology can also be applied to overcome drug resistance problem. As known with a long history, one of the common methods to deal with bacterial drug resistance is to use broad spectrum antibiotics. In cancer, a general drawback of target-specific monotherapy therefore derives from the fact that a single genetic alteration conferring target resistance to an individual tumor cell can eventually lead to relapse, as exemplified by the clonal selection for drug-resistant *BCR–ABL* alleles during imatinib therapy. Therefore, the ability of kinases to mutate in response to the selective pressure created by drug treatment provides a strong rationale for hitting more than one essential target at the same time in the tumor cells.[148] Alternatively, simultaneous targeted inhibition of multiple essential protein components in the cancer cells aims not only at increased therapeutic potency but also at reduction in the risk of molecular resistance formation by reducing the tumor cell population.[149]

The success of such efforts can be illustrated by a series of indolinone inhibitors. The first is SU5416 originally developed as a monospecific inhibitor of VEGFR involved in angiogenesis.[150] The follow-up compound SU6668 improved both pharmacological properties and potency due to its simultaneous inhibition of three RTKs (VEGFR2, PDGFRβ, and FGFR174). However, FGFR signaling was hardly affected by SU6668 and VEGFR2 seemed to be only partially blocked.[151,152] SU11248, later marketed as sunitinib, shows comparable potency against multiple RTKs including PDGFRα, PDGFRβ, VEGFR2, Kit, and FLT3.[153–155] Its balanced activity profile was well translated into simultaneous inhibition of disease-relevant RTKs in vivo and has resulted in therapeutic efficacy in neoplasias such as renal cell carcinoma.[149] In addition, sunitinib showed promising results in GIST tumors with acquired resistance to imatinib. In addition to Kit in tumor cells, sunitinib targets both VEGFR and PDGFR tyrosine kinases in endothelial and perivascular cells and interferes with tumor vascularization.[156] This explains why efficacious multitargeted kinase inhibitors such as sunitinib could potently thwart resistance formation.

2.10.5.3 Drug Repositioning/Repurposing

As already discussed, another beneficial aspect of polypharmacology is drug repositioning/repurposing (i.e., identifying new medical use for approved, discontinued, shelved, and experimental drugs). It has gained enormous attention during the last

10 years,[157] and there have been numerous examples of success in drug repurposing, including the aforementioned sildenafil repurposed from treating angina to erectile dysfunctions therapy,[29] imatinib from the initial CML treatment expanded to treat GIST,[31] aspirin for pain relief and then for treating cancer and cardiovascular diseases,[108–110] etc. Most of these successful efforts of drug repositioning have been serendipitous to date or through exploitation of the original drug mechanism of action for new indications. Currently, systematic approaches are being carried out to find novel use of marketed drugs. For instance, Liu et al. reviewed recent advances in drug repositioning for the discovery of new anticancer drugs.[158] They discussed many currently marketed drugs that are in clinical trials for their novel anticancer activity including Nelfinavir. Nelfinavir inhibits angiogenesis and this led to systematic studies of its anticancer activities. In addition further studies showed that the drug also inhibits HSP90, HER2, and AKT signaling pathways.[159–161]

The complexity of the problem clearly needs novel multimodal approaches for better solutions. To this end, our group developed an integrative computational framework based on classical structure-based drug design, chemical-genomic similarity, and molecular graph theories.[162] Briefly, we used pharmacophore modeling to guide docking pose selection resulting from our high-throughput virtual screening. Using a novel chemo-genomic similarity approach, we evaluated if any hits missed by docking can be obtained. We also developed drug–target bipartite graph to assess similarity of different inhibitors based on their connections to other compounds and targets. The approaches were applied to the repurposing of existing drugs against ACK1 through screening of 1447 marketed drugs. We identified 10 hits and 4 drugs were experimentally confirmed as potent ACK1 inhibitors. In particular dasatinib could inhibit ACK1 with $IC_{50} = 1$ nM. Currently we have also expanded our novel, integrative strategy to the screening of other biological targets with a more comprehensive coverage of known bio-chemical space for repurposing studies. Recently, Corbett and colleagues identified some drugs that are effective toward distinct pathological conditions such as hypertension, type 2 diabetes mellitus, and retinoid therapy, and these agents can be used to treat AD.[163] In a phenotypic screening study, Nygren et al. found novel use of mebendazole, an anthelmintic drug, in advanced colon cancer treatment,[164] and this has been confirmed by our own recent studies elucidating the novel mechanism of action through inhibiting the Wnt signaling pathway. All of these studies suggest that multitargeted agents are natural candidates for more innovative drug repositioning and advancement in computational modeling will significantly facilitate such efforts.

2.10.6 Conclusions

During the past decades, pharmaceutical companies have successfully carried out their drug discovery programs using reductionist approach. The increase of drug development cost has demanded for alternative strategies, and recent successes in discovering novel use of well-studied FDA approved drugs provide a great impetus for such efforts. The assumption that similar compounds share similar targets remains the basic principle behind most of the ligand-based and structured-based methods developed for polypharmacology studies. Although some computational methods can be used to calculate similarity, a major challenge is to develop scoring functions that can accurately and robustly rank targets instead of small molecules. In addition, novel approaches such as rational design of multitargeting small molecules are being explored. Apart from chemogenomics-based methods, interests in network-based and bioinformatics-based methods have been increased. These methods are not only able to predict new targets for small molecules but also help understand the complex dynamics of the diseases and molecular interaction pathways. Recently NIH and FDA initiated programs to identify new indications of existing drugs. These programs have been enhanced through collaborations with major pharmaceutical companies. Such efforts will boost the interests of general public as well as improve collaborations among government, industry, and academia for drug repurposing. In the near future we expect that, taking the advantages of the current big data studies and more advanced deep learning technologies, we will be able to develop robust computational approaches for modeling multitargeted drugs with optimal efficacies but minimum side effects. Of course significant challenges still lie ahead.

2.11.1 Introduction

Drugs on the market can be divided into orthosteric or allosteric drugs according to their molecular mechanism of action. Orthosteric drugs compete with the endogenous substrates or ligands to occupy the active site. By contrast, allosteric drugs bind to sites distinct from the active site, also referred to as allosteric sites. As such, allosteric drugs are resistant to orthosteric competition. Rather, they typically exert their effects in concert with the endogenous substrates or ligands in the active site. Allostery takes place when proteins propagate the perturbation signal from an allosteric site to an orthosteric site, giving rising to regulation of a protein's functional activity.[1–4] Allosteric regulation allows for exquisite control of numerous normal processes of cells, including signal transduction, metabolism, enzymatic catalysis, and gene regulation.[5–11]

Since the concept of allostery was introduced by Monod and Jacob in the 1960s,[12] the repertoire of allostery has undergone profound development.[13] In the theoretical aspect, many, if not all, allosteric models, such as Monod–Wyman–Changeux,[14] Koshland–Nemethy–Filmer,[15] population shift model,[16] morpheein model,[17–19] and dynamics-driven models,[20–23] have been formulated to elucidate the underpinnings of allosteric regulation (**Fig. 1** and **Table 1**). Several allosteric network methods, such as SPACER[24] and MCPath,[25] have been developed to predict likely allosteric pathways (communication) between orthosteric and allosteric sites. In addition, a gamut of computational approaches, encompassing AlloSite,[26] ASbench,[27] molecular dynamics (MD) simulations,[10,28–31] two-state Gō model,[32–34] normal mode analysis (NMA),[35–37] binding leverage,[38,39] graph theory,[40] and statistical coupling analysis (SCA),[41–45] have been developed to predict as-yet-unknown allosteric sites in proteins. Experimental methods to identify potential allosteric sites have also made great improvements currently. These methods include disulfide trapping,[46–48] high-throughput screening,[49,50] fragment-based screening,[51–53] alanine-scanning mutagenesis,[54,55] and photoaffinity labeling.[56–58] Significantly, the improvement of biophysical technologies such as X-ray crystallography and NMR,[59–66] together with several other novel methods including fluorescent labeling,[67] electrophysiology,[68] and patch clamp,[69] provides valuable avenues to detect allosteric protein binding sites and to design and develop novel efficient therapeutics aiming at allosteric sites. Therefore, the repertoire of allostery has been experiencing an upsurge, evidenced by an explosive growth in the number of allosteric proteins and allosteric modulators in recent years.[70–72] These lay the foundation for allosteric discoveries and applications.

2.11.2 Advantages and Disadvantages of Allosteric Protein Regulation

There are several features of allosteric regulation that offer considerable advantages for allosteric modulators as preferred therapeutic agents compared to classic orthosteric ligands. First, unlike the highly conserved orthosteric binding sites, allosteric binding sites are less well conserved. In theory, any evident cavities on protein surfaces distinct from the active site can potentially serve as

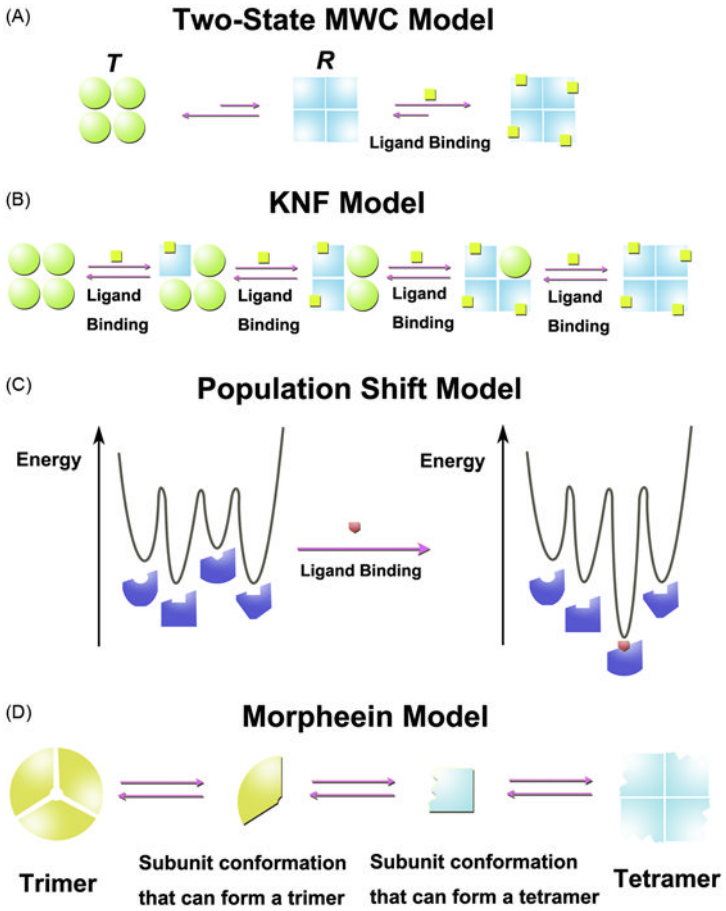

Fig. 1 Models of allostery. (A) The two-state concerted model of Monod–Wyman–Changeux (MWC). (B) The sequential model of Koshland–Nemethy–Filmer (KNF). (C) The population shift model of allostery. (D) The morpheein model of allostery.

Table 1 Models of allostery and their characteristics

Two-state concerted model of Monod–Wyman–Changeux (MWC)	(1) Regulatory proteins are symmetrical homooligomers (2) Conformation of the subunits (tertiary structure) of multimeric proteins changes in a concerted manner (3) Ligand-free oligomers spontaneously exist under two discrete and symmetrical conformations. Upon ligand binding, the equilibrium of the preexisting oligomer between two states (quaternary structure) is merely shifted
Sequential model of Koshland–Nemethy–Filmer (KNF)	The KNF model assumes that a ligand binding to one subunit of a multimeric protein can induce the conformational change of that subunit, thereby remodeling the conformation of the binding site to completely accommodate the ligand
Population shift model	In the unligand forms, proteins exist in an ensemble of conformations. When an allosteric effector is accessed to a specific protein, the conformer (substate) of the dynamically fluctuating protein whose binding site is most complementary to the effector conformation will be selected for binding. Following binding, the ensemble of dynamic conformations undergoes a population shift, redistributing the conformational states toward the conformation favored by the effector
Morpheein model	Two or more homooligomers (morpheein forms) with distinct functionality comprise a protein and is pertinent to homooligomeric proteins. The interchange of morpheein forms requires the obligatory dissociation of higher-order multimers into a lower-order multimer, and a conformational change occurs in the lower-order state prior to assembly into the alternate higher-order multimer
Dynamic-driven model	Allosteric effects are elicited by changes in protein dynamics, without changes in the shape of protein structure

allosteric sites that can be targeted by allosteric modulators. In this context, allosteric modulators can exploit a structurally diverse feature of an allosteric site that may distinguish the target protein from other homologous proteins, in particular in protein kinases and G-protein coupled receptors (GPCRs; also known as seven-transmembrane receptors).[73–77] In fact, a vast majority of small-molecule kinase inhibitors bound to the conserved ATP-binding sites interact with multiple members of the protein kinase family.[78] Davis et al. performed a comprehensive analysis of kinase inhibitor selectivity based on 72 kinase inhibitors and 442 protein kinases;[79] the latter covers >80% of the human catalytic protein kinome. The results showed that, in general, the selectivity of an orthosteric inhibitor to its primary target is fairly poor, with 10–40% of the tested inhibitors at a concentration of 3 μM interacting with >60% of kinases. Polypharmacology is referred to a single drug molecule able to simultaneously and specifically interact with multiple targets.[80–82] For instance, because of the highly conserved ATP-binding sites in the kinome, a designed inhibitor is able to modulate the activity of additional targets beyond the primary target. In contrast, a designed allosteric modulator bound to the less conserved allosteric site can reduce the possibility of polypharmacology, which facilitates the design of more specific drugs. In addition, the low evolutionary conservation of allosteric sites guarantees the high specificity of a designed allosteric modulator to the primary target, which has promise for application to personalized medicine.[83,84] For example, an orthosteric drug, zolmitriptan, was developed to treat migraine targeting serotonin receptors 5-HT-1B and 5-HT-1D.[85] The side effects such as increased pain sensitivity (hyperesthesia) occurred in response to the treatment of zolmitriptan. This effect is owing to the binding of zolmitriptan to the off-target (antitarget) 5-HT-7 (26% sequence identity between 5-HT-7 and 5-HT-1B, 5-HT-1D). However, the low evolutionary conservation of allosteric sites has the potential to cause significant *species differences*.[86,87] For instance, the allosteric effects of allosteric modulators are effective in recombinant human receptors in vitro. However, drug screening using rodent receptors or the investigation of drug effects in vivo using rodent models may disqualify them as effective allosteric modulators.

Second, allosteric modulators have the potential to achieve fewer side effects and lower toxicity compared to orthosteric ligands. Here, we define the allosteric modulators as that ligands bind to an allosteric site and modulate the binding and/or signaling efficacy of orthosteric ligands, while we define the allosteric agonists/antagonists as that ligands binds to an allosteric site and activate/inactivate proteins in the absence of "traditional" orthosteric ligands. The specific function of a protein depends on the extent that a macromolecule populates its active conformation.[20,88] The outcome of binding of an orthosteric ligand to the orthosteric site constrains the ensemble of the protein conformation to one predominant active or inactive conformation. As such, orthosteric ligands can immoderately shut off or turn on native protein function. In contrast, binding of an allosteric modulator to the allosteric site alters the population of the conformation at the orthosteric site, coupled with the occupation of orthosteric site by an orthosteric ligand simultaneously. As a result, allosteric regulation merely modulates the protein's function. In this context, an allosteric modulator can selectively tune cellular responses in tissues, while the endogenous orthosteric ligand exerts its normal physiological effects, thereby maintaining both the temporal and spatial aspects of endogenous physiological signaling.

Third, some proteins are amenable to allosteric regulation by allosteric modulators, whereas they are resistant to orthosteric activation or inhibition by orthosteric ligands. As in the case of class B GPCRs, a small family of peptide-binding receptors, although they are able to be orthosterically interacted with peptides, this cannot be achieved with small-molecule CNS drug space. This is due to the natural polypeptide ligands with varying lengths (ranging from 30 to 40 residues) outside classic oral drug-like space.[89] The fact that orthosteric sites in the class B GPCRs are relatively flat and narrow renders design of orthosteric ligands bound to these sites refractory. However, allosteric modulators can hit class B GPCRs through binding to their allosteric sites. In addition, allosteric GPCR modulators have good pharmacokinetic properties. In the case of metabotropic glutamate (mGlu) receptors, the endogenous ligand, glutamate, bound to the orthosteric site of mGlu receptors underscores the necessity of designing agonists or antagonists with amino acid-like structures for binding. Such polar, charged molecules are closely related to poor bioavailability and blood–brain barrier permeability. In contrast, allosteric sites of mGlu receptors are located in the seven-transmembrane (7TM) domain where they commonly are neutral and lipophilic, which allows for the design of hydrophobic allosteric modulators with favorable pharmacokinetic properties such as good brain permeability. However, allosteric GPCR modulators usually have micromolar affinities to receptors and frequently encounter "*flat*," *nontractable structure–activity relationships* (SAR).[86,87] This deficiency leads to the difficulty in improving allosteric GPCR modulators into bona fide lead compounds. Moreover, allosteric modulation in many cases of mGlu receptors has not achieved for clinical signals, suggesting that allosteric modulation of mGlu receptors may be less effective than orthosteric modulation.

Fourth, allosteric modulators, in combination with orthosteric ligands, can overcome drug-resistant mutations. Combination of both allosteric modulators and orthosteric ligands in the treatment of diseases has a potential advantage because of targeting allosteric sites alone where resistance escapes for nonfunctional site would be easier. For instance, the gatekeeper T315I mutation in the breakpoint cluster region/Abelson (Bcr/Abl) tyrosine kinase fusion protein is resistant to ATP-competitive drugs imatinib (STI-571/Gleevec) and nilotinib (AMN-107/Tasigna). The advent of drug resistance is resulting from the stabilization of active Abl conformation induced by the mutation.[90,91] GNF-5 is a selective allosteric inhibitor targeting the myristoyl-binding pocket of Abl in the C-terminal lobe.[92] The combination of imatinib with the allosteric inhibitor GNF-5 can repress the emergence of resistance mutations by shifting conformational equilibrium of Abl to the closed, inactive state.[93] In addition, combining allosteric modulators and orthosteric ligands can synergistically help to surmounting the diseases, which cannot be achieved by either agent alone. As in the case of mGlu4, a selective, brain-penetrant mGlu4-positive allosteric modulator, (1*S*, 2*R*)-N^1-(3,4-dichlorophenyl)-cyclohexane-1,2-dicarboxamide (Lu AF21934) (**Fig. 2**), in tandem with the dopamine precursor L-3,4-dihydroxyphenylalanine (L-DOPA), allows reducing the effective dose of L-DOPA and preventing the development of L-DOPA-induced dyskinesia.[94]

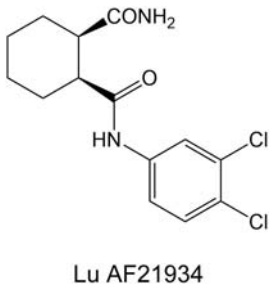

Fig. 2 Chemical structure of Lu AF21934.

Despite the existence of challenging in the design of allosteric modulators, however, owing to unparalleled advantages shared by allosteric modulators as mentioned earlier, current drug discovery efforts in pharmaceutical regimes have increasingly invested in the development of allosteric drugs.

2.11.3 Allosteric Proteins

2.11.3.1 Target Distribution

We have constructed a large dataset of known allosteric proteins and allosteric modulators deposited into the allosteric database (ASD),[70–72] which provides a comprehensive allosteric resource depicting the specific structure, function, and mechanism of allosteric proteins and allosteric modulators. The most direct evidence to determine whether a protein is an allosteric protein is to solve the cocrystal structures between the target protein and its allosteric modulators. In this case, the definite allosteric proteins in complex with their allosteric modulators were annotated. Otherwise, if cocrystal structures are currently unavailable, the indirect biochemical evidences must be satisfied with one of the three following cases, such as inactive mutation of allosteric residues, cooperativity of kinetic effect from two ligands, and uncompetitive binding assay with chromatography. These cases of proteins would also be identified as allosteric proteins. The first version of ASD was released in Aug. 2010, which contains only 316 allosteric proteins. The current ASD (Aug. 2015) is the third version, which contains 1930 allosteric proteins. Thus, in the past five years, the number of allosteric proteins was significantly increased owing to that a great deal of effort that has been focused on the detection of allosteric proteins.

As shown in Fig. 3A, systematic investigation of known allosteric proteins in the ASD exhibits that allosteric phenomena can be widely observed in the vast majority of proteins, such as GPCRs, protein kinases, ion channels, peptidases, phosphatases, transcription factors, nuclear receptors, and E-proteins. This observation reflects that in principle, in addition to orthosteric modulation, any protein has the ability to take advantage of additional allosteric modulation. As of yet, the number of allosteric proteins is mainly observed in the three categories, that is, GPCRs, kinases, and ion channels, which are three largest human drug targets. This phenomenon is ascribed to the fact that these therapeutic targets are amenable to allosteric (and orthosteric) regulation and have therefore gained more attention by academia and the pharmaceutical industry in modern drug discovery. Because of the remarkable structural conservation of orthosteric sites in the kinome and homologous GPCRs, it has been a long-standing conundrum in the discovery of highly specific kinase and GPCR orthosteric inhibitors or activators. Thus, targeting the structural diversity of allosteric sites in

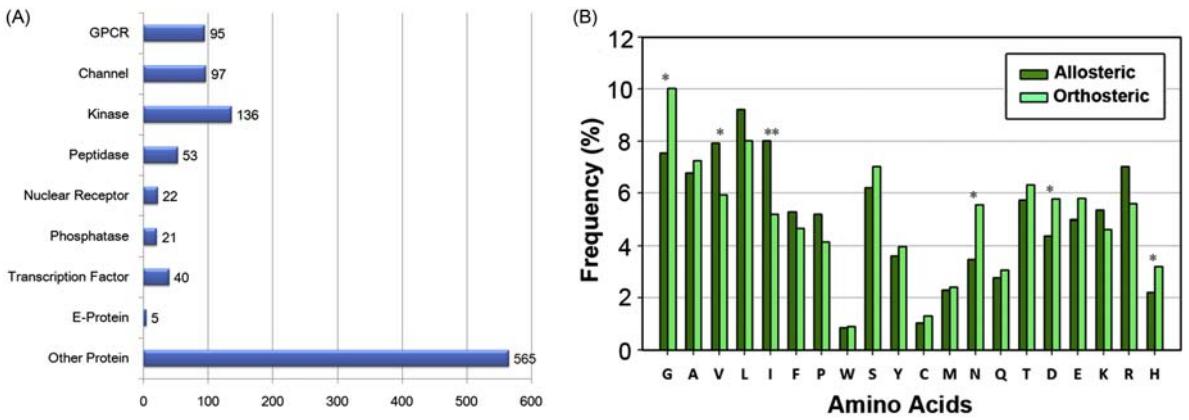

Fig. 3 (A) The distribution of allosteric drug targets. (B) Amino acid compositions of orthosteric and allosteric sites. The fraction of each amino acid of orthosteric and allosteric is shown.

protein kinases and GPCRs provides a promising new paradigm for the design of potent modulators with improved protein subtype selectivity, adverse effects, and pathway-biased signaling.[95] For instance, in class C GPCRs, allosteric modulators are capable of selectively activating these targets. Conversely, the discovery of selective orthosteric ligands against this subtype of GPCRs remains a daunting task because of a paucity of feasible modification positions in these small ligands.[96] In the case of protein kinases, allosteric modulators by targeting the less conserved allosteric sites outside the highly conserved ATP-binding site can achieve greater selectivity for a target kinase against others. For example, allosteric activators, 2-(3-Oxo-1,3-diphenylpropyl)malonic acids, highly selectively activate 3-phosphoinositide-dependent kinase-1 (PDK1) via binding to the interacting fragment (PIF) pocket compared to a panel of AGC kinases, including PKA, PKB/Akt, PKC, p70 S6 kinase (S6K), serum- and glucocorticoid-induced protein kinase (SGK), p90 ribosomal S6 kinase (RSK), and protein kinase C-related kinase 2 (PRK2), which all share a homologous PIF pocket with PDK1.[97] However, allosteric modulators may be easier to acquire resistance compared to orthosteric ligands because allosteric sites are not be conserved in wider population.

2.11.3.2 Target Properties

Traditionally, multimeric proteins are considered to be the prototypes of allosteric proteins, such as hemoglobin, SAM domain- and HD domain-containing protein 1 (SAMHD1), and *N*-methyl-D-aspartate receptor.[98,99] In the multimeric allosteric proteins, cooperativity can be achieved by conformational changes caused by ligand binding to one of the equivalent sites that propagate to the other clefts and facilitate or impair binding of other ligand molecules. Now, the observation of the allosteric phenomenon has expanded from multimeric proteins to monomeric proteins by means of crystallography and electron microscopy studies of signaling molecules, including regulatory enzymes, membrane receptors, and nuclear receptors.[3,100] For example, in the Bcr/Abl kinase, binding of allosteric inhibitor GNF-2 to the C-terminal myristate pocket of Abl resulted in changes in the structural dynamics of the ATP-binding site, facilitating the stabilization of an inactive conformation of Abl.[92] In the human δ-opioid GPCR, Fenalti et al. revealed the presence and fundamental role of a sodium ion in mediating allosteric control of receptor functional selectivity and constitutive activity.[101,102]

Recent experimental observations have suggested that intrinsically disordered proteins (IDPs) can also be allosterically regulated.[103,104] An IDP is a protein that lacks a fixed or ordered three-dimensional (3-D) structure, but in some cases, it has the ability to adopt a fixed 3-D structure after binding to other ligands or macromolecules.[105,106] As in the case of the intrinsically disordered segment of protein tyrosine phosphatase 1B (PTP1B), Krishman et al. demonstrated that binding of small-molecule inhibitor MSI-1436 to the intrinsically disordered segment close to the catalytic domain, with cooperative effects between the two sites, locked PTP1B in an inactive state.[107]

2.11.3.3 Allosteric Site Properties

Over the past few years, the rapid growth in the number of allosteric proteins determined by X-ray crystallography and NMR spectroscopy provides unparalleled insight into the structural properties of allosteric proteins.[70–72] A comprehensive analysis of sequence differences between allosteric sites in the allosteric proteins and orthosteric sites in the nonallosteric proteins using the relatively small allosteric protein set from ASD v1.0[70] was performed. Li et al.[108] and Yang et al.[109] revealed that allosteric sites bear more hydrophobic residues than orthosteric sites, with the emergence of a high frequency of hydrophobic residues in allosteric sites, such as isoleucine, proline, tryptophan, leucine, valine, phenylalanine, methionine, and tyrosine. Similarly, based on the analysis of intramolecular interactions between the allosteric protein set and the randomly generated protein set, Namboodiri et al.[110] demonstrated that hydrophobicity patterning assessed by recurrence quantification analysis descriptors, representative of allosteric hotspots signatures, plays a pivotal role in determining the allostery of proteins. On the basis of relatively large allosteric protein set from ASD v3.0,[72] we also investigated the physicochemical properties of allosteric sites and their corresponding orthosteric sites by comparing their amino acid compositions. As shown in **Fig. 3B**, the hydrophobic residues such as valine and isoleucine are highly enriched in allosteric sites, where polar residues glutamine, aspartic acid, histidine, and glycine are highly enriched in orthosteric sites. These differences in amino acid composition for the allosteric and orthosteric sites are attributed to the different functional roles of the sites. Yang et al.[109] explained that in orthosteric (catalytic) sites, ligands are subject to the heterolytic breakage and formation of covalent bonds, yet such bond breakage and formation do not occur in allosteric sites. In contrast, hydrophobic residues are enriched in allosteric sites to provide a binding pocket for a specific ligand, with only a small fraction of charged residues that are present to facilitate specific interactions during ligand binding.

Yang et al.[109] investigated sequence conservation of allosteric and orthosteric sites in 56 enzyme structures and found that residues of allosteric sites are significantly less conserved than residues of orthosteric sites. Consistently, previous comparative analysis of sequence conservation of ATP-binding sites between allosteric and substrate ATP-binding sites uncovered that residues in the allosteric ATP-binding sites, with the average conservation score of 0.63, were less conserved compared with residues in the substrate ATP-binding sites, with the average conservation score of 0.83 ($P = 1.2 \times 10^{-3}$).[111] As shown in **Fig. 4A**, residues of substrate ATP-binding sites that anchor and orient ATP are extremely conserved, including important motifs such as GXGXXG, DXXXXN, DFG, APE, and DXXXXG, with X indicating any amino acid and the conserved K/E ion pair; this finding is in good agreement with the previously aligned sequences available in the kinase sequence database.[112] By sharp contrast, residues of allosteric ATP-binding sites are markedly variable (**Fig. 4B**). **Fig. 4C** shows the projection of residues of allosteric ATP-binding sites onto residues of substrate ATP-binding sites in order to further unravel the differences in evolutionary conservation of allosteric and substrate

Abbreviations: *SAT*, ATP sulfurylase; *UMP*, uridine monophosphate kinase; *Topo*, DNA topoisomerase II; *ATCase*, aspartate carbamoyltransferase; *cN-II*, cytosolic 5′-nucleotidase II; *PFK-1*, phosphofructokinase 1; *RNR*, ribonucleotide reductase; *GP*, glycogen phosphorylase. (C) Mapping the residues of allosteric ATP-binding sites on residues of substrate ATP-binding sites. The 25 conserved residues derived from a multiple sequence alignment of all known human protein kinases are selected as a reference. (D) The global structural similarity of allosteric ATP-binding sites measured by a PS-score. The PS-score is between 0 and 1. (E) The global structural similarity of substrate ATP-binding sites measured by a PS-score.

ATP-binding sites. Twenty-five conserved residues (P1–P25, starting at the N terminus) that comprise the substrate ATP-binding sites were selected as a reference. These residues were identified by performing a multiple sequence alignment of all known human protein kinases.[113,114] The occurrences of residues in each position of the allosteric ATP-binding sites are significantly different compared with those in the substrate ATP-binding sites. Aside from the sequence difference between allosteric and substrate ATP-binding sites, the pocket similarity measured by the pocket similarity score (PS-score) between the two binding sites is also distinct. The PS-score was calculated based on backbone geometry, side-chain orientation, and chemical similarity of the aligned pocket-lining residues.[115] As shown in Fig. 4D, the global structural similarity of the allosteric ATP-binding sites is low, with

a mean PS-score of 0.3, compared with the high structural similarity of substrate ATP-binding sites, with a mean PS-score of 0.6 (Fig. 4E). Taken together, these data indicate that allosteric ATP-binding sites have evolved along different evolutionary pathways compared with the highly conserved substrate ATP-binding sites, which confers subtype selectivity on allosteric modulators as compared to orthosteric ligands.

2.11.4 Allosteric Modulators

Identification of allosteric sites in proteins is a prerequisite for the screening and optimization of allosteric modulators. Currently, it is challenging to find and characterize new allosteric sites by experimental approaches. Indeed, the vast majority of known allosteric sites were serendipitously discovered while measuring the binding affinities or kinetics between proteins and ligands. However, computational approaches for identifying allosteric sites provide useful empirical knowledge that complements existing experimental techniques. While impressive progress has currently been achieved, the predictive methods developed thus far still fall short of fully predicting experimental observations. The shape and pharmacophoric properties of allosteric sites are not necessarily similar to those of highly conserved orthosteric sites; that is, allosteric sites have evolved along different evolutionary pathways compared with orthosteric sites. In many cases, allosteric sites cannot be easily predicted from the unbound protein structures, thus emphasizing that most of the allosteric sites are remarkably adaptable. In addition, some of allosteric sites exist exclusively in intermediate states pertaining to activation or deactivation processes of proteins.

Thus far, ~71500 allosteric modulators in the library of ASD v3.0 bound to more than 1300 allosteric proteins have been reported, including GPCRs, protein kinases, ligand-gated ion channels, peptidases, phosphatases, transcription factors, and nuclear receptors. Fig. 5 shows time-dependent discovery of allosteric modulators. Overall, a small fraction of allosteric modulators was reported before the year 2000. After that, the interest in the discovery of allosteric modulators was fueled by technical breakthroughs in studying protein allostery, which was evidenced by the increasing number of allosteric modulators during the period of 2000–15. Remarkably, in the past 5 years, the number of allosteric modulators underwent an explosive growth. In particular, the number of allosteric modulators targeting the two largest families of drug targets, GPCRs and kinases, has been pronouncedly enriched.

Allosteric modulators can be divided into three classes, positive allosteric modulators (PAMs), negative allosteric modulators (NAMs), and neutral allosteric modulators or silent allosteric modulators (SAMs), based on their pharmacological effects on the affinity and efficacy of orthosteric ligands bound to the same target.[116] PAMs enhance the affinity of the orthosteric ligand, while NAMs decrease the affinity of the orthosteric ligand. Allosteric modulators function by exerting either positive or negative modulation in cooperation with orthosteric ligands to achieve a potential "ceiling effect" (i.e., maximal receptor occupancy may not translate into a maximal amplitude of receptor activation), which avoids side effects and receptor desensitization and downregulation that are elicited by chronic treatment with an orthosteric agonist.[117–120] In addition, SAMs refer to substances that occupy allosteric binding sites without affecting receptor function. The prominent differences in the magnitude of the allosteric effects induced by different allosteric modulators or the allosteric effects of a modulator that depend on the type of orthosteric ligand used as a probe for receptor activity are referred to as probe dependence.[116]

Interestingly, in the case of GPCRs, distinct chemical structures of allosteric modulators bound to the same receptor are capable of differentially activating specific subsets of downstream signaling pathways; this phenomenon is defined as functional selectivity (also known as stimulus bias, biased signaling, ligand-dependent stimulus trafficking, or biased agonism).[121–125] The origin of functional selectivity can be explained by the dynamic fluctuations in the conformation of receptors, and a specific agonist selects the conformation that is compatible with its binding, thereby stabilizing this receptor conformation at the exclusion of others. In

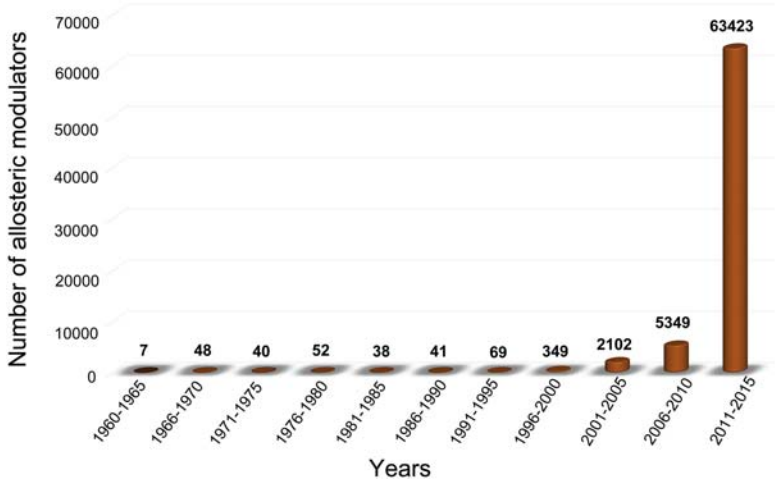

Fig. 5 Time period dependence of discovering allosteric modulators.

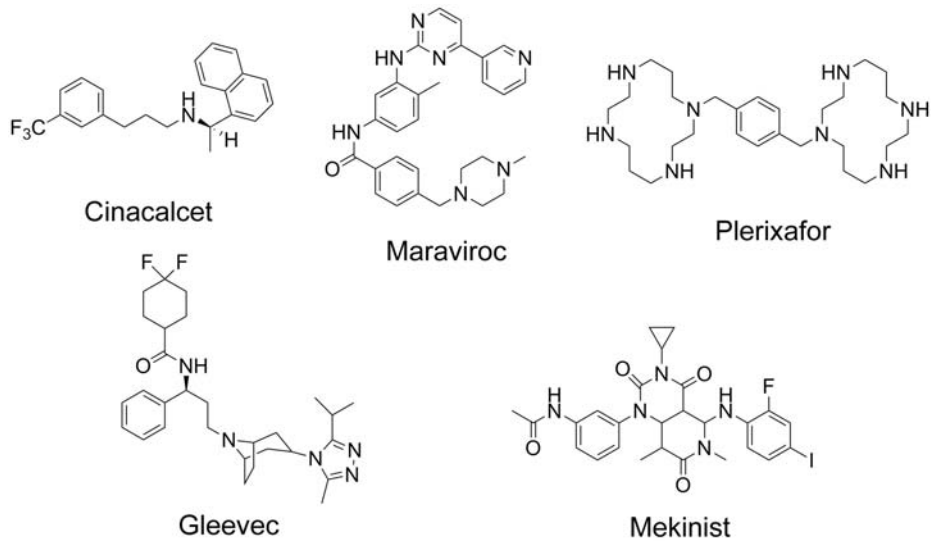

Fig. 6 Chemical structures of allosteric modulators already approved and marketed as drugs.

this scenario, a unique allosteric modulator can activate a specific pathway because each conformational state imparts a specific repertoire of signaling behaviors. As a result, allosteric modulators can induce specific changes in receptor conformation, which may exclusively activate a specific signaling pathway, thereby providing a basis for functional selectivity.[126–133]

Totally, five allosteric drugs have earned approval from the US Food and Drug Administration (FDA), including three GPCRs and two kinase allosteric drugs (Fig. 6). For example, Amgen's cinacalcet acts as a PAM of calcium-sensing receptor to treat chronic renal failure. Pfizer's maraviroc acts as a NAM to inhibit the CC chemokine receptor type 5 (CCR5) for the treatment of HIV infection. Genzyme's plerixafor, as a NAM of the chemokine receptor CXCR4, was used to mobilize hematopoietic stem cell in cancer patients. Novartis's Gleevec was used to treat chronic myelogenous leukemia and gastrointestinal stromal tumors in the Bcr–Abl tyrosine kinase. GlaxoSmithKline's Mekinist, in combination with dabrafenib, was approved for the treatment of patients with B-Raf V600E/K-mutated metastatic melanoma.

2.11.4.1 Chemical Structure and Physicochemical Properties

Currently, numerous allosteric modulators are under study in clinical trials to treat diseases ranging from chronic kidney failure to cancers, HIV, pain, diabetes, Alzheimer's disease, Parkinson's disease, and others.[86] Overall, the discovered allosteric modulators are helpful to the understanding of the structural and physicochemical properties of these substances, which may provide the principles and rationale for allosteric drug discovery.

By systematic investigation of the differences between allosteric modulators and nonallosteric compounds, van Westen et al.[134] showed that the molecular weight of allosteric modulators falls within a much narrower range compared with that of nonallosteric compounds. For example, in the class B GPCR ligands, statistical analysis shows that the molecule weight for the allosteric modulators is in a range from 305 to 569 Da for 95% of the allosteric modulators tested, whereas it is in a range from 334 to 3591 Da for 95% of the nonallosteric ligands tested. Moreover, allosteric modulators are predicted to be slightly better to Lipinski's rule of five (75% vs. 66%) than nonallosteric compounds. These observations suggest that allosteric modulators are more susceptible to development into orally available drugs than nonallosteric compounds. In addition, comparison of binding affinities between allosteric modulators and nonallosteric ligands shows that the absolute potency for allosteric modulators is lower than that of nonallosteric ligands (5.96 log units vs. 6.66 log units, $p < 0.01$).[134]

Regarding physicochemical properties, a comparative analysis between allosteric modulators in the ASD and nonallosteric ligands in other well-known databases, including MDL Drug Data Report (MDDR) (Accelrys, Inc., San Diego, the United States, 2009), Chinese Natural Product Database (CNPD) (NeoTrident Technol. Ltd., Beijing, China, 2005), Comprehensive Medicinal Chemistry (CMC) (Accelrys, Inc., San Diego, the United States, 2009), and DrugBank,[135] was performed. It should be noted that allosteric modulators tend to be more hydrophobic than nonallosteric ligands, supporting the notion that the predicted average hydrophobicity index (3.98) of allosteric modulators, quantified by a measure called SlogP, is generally greater than that of nonallosteric ligands (3.54 for MDDR, 2.77 for CNPD, 2.32 for CMC, and 0.91 for DrugBank) (Fig. 7). This result is reminiscent of the hydrophobic nature of allosteric sites, which, in turn, is suitable for recruiting hydrophobic allosteric modulators. Another remarkable difference is that the average number of rotatable bonds is calculated to be 7.47 for allosteric modulators in ASD, significantly smaller than that of nonallosteric ligands in other databases (11.0 for MDDR, 10.7 for CNPD, 9.33 for CMC, and 9.63 for DrugBank) (Fig. 7). Indeed, sp^2-hybridized carbon bonds and aromatic bonds are highly enriched in allosteric modulators,[134] indicating that allosteric modulators are more rigid than nonallosteric compounds. This finding is consistent with the mode of action of

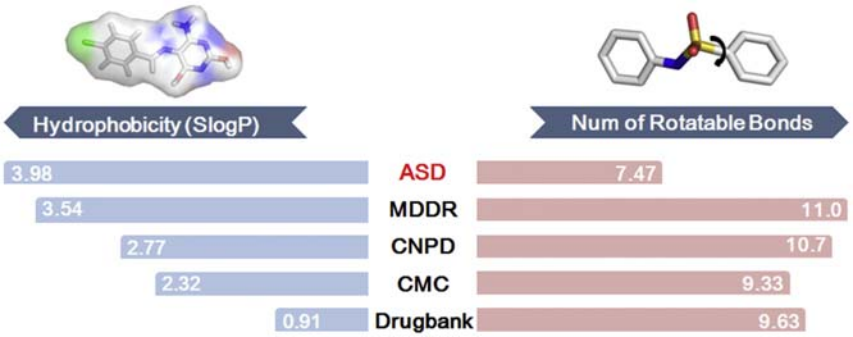

Fig. 7 The predicted average hydrophobicity and number of rotatable bonds for allosteric modulators in ASD and nonallosteric compounds in MDDR, CNPD, CMC, and DrugBank.

allosteric modulators via binding in distinct structural locations of proteins instead of orthosteric sites and the ability of the rigid structures of allosteric modulators to potentiate the specific ligand–host allosteric interactions that stabilize the active or inactive conformations of proteins.

2.11.4.2 "Allo-Modulator Like"

Based on the differences of chemical structure and physicochemical properties between allosteric modulators and nonallosteric ligands, Wang et al.[136] developed a classification model to distinguish allosteric modulators from nonallosteric ligands. They performed systematic analyses of eighteen molecular descriptors, including molecular weight (MW), average MW (MW per atom), number of atoms, number of bonds, number of rotatable bonds (RBN), rotatable bond fraction, unsaturation index, number of rings (nR), number of circuits, number of ring systems, number of rings in the largest ring system (nRIS), complexity of ring systems, number of hydrogen-bond acceptors, number of hydrogen-bond donors, hydrogen-bond acceptor fraction, hydrogen-bond donor fraction, SlogP, and topological polar surface area. They summarized several structural requirements that are shared by allosteric modulators. These features are referred to as "Allo-Modulator Like" and presented as follows: (i) $MW \leq 600$, (ii) $RBN \leq 6$, (iii) $2 \leq nR \leq 5$, (iv) $nRIS = 1$ or 2, and (v) $3 \leq SlogP \leq 7$. This empirical rule can positively filter more than 80% of the known allosteric modulators deposited in ASD and provides a guideline for the rational design and optimization of allosteric modulators. The "Allo-Modulator Like" rule was developed into a web server that can be accessed at http://mdl.shsmu.edu.cn/ASD/.[71]

2.11.4.3 Privileged Scaffolds

The concept of privileged scaffolds, first proposed by Evans and coworkers in 1988, is defined as the ability of multiple molecules of the same scaffold bearing bioactivity to cover a broad spectrum of target proteins.[137] In general, privileged scaffolds exhibit favorable drug-like properties and are amenable to the synthesis of combinatorial compound libraries with extensive pharmaceutical applications.[138] Over the past two decades, a host of privileged scaffold-based libraries have proved capable of effectively capturing potent and selective ligands for a wide variety of targets to improve R&D productivity.[139,140] Inspired by these advantages, the privileged scaffolds for allosteric modulators are explored, aiming to offer a viable starting point for the rapid discovery and optimization of novel allosteric modulators.

Table 2 lists the high frequencies of privileged scaffolds in allosteric modulators, with each privileged scaffold covering more than 15 types of allosteric targets. The 12 privileged scaffolds include indole, biphenyl, naphthalene, diphenylmethane, benzo[*d*][1,3]dioxole, *N*-phenylbenzamide, quinoline, oxydibenzene, 1*H*-benzo[*d*]imidazole, 1-benzylpiperazine, 2,3-dihydrobenzo[*b*][1,4]dioxine, and 1-phenylpiperazine, as enumerated in Table 2, among which indole appears to be the most frequently used as a privileged scaffold for allosteric modulators, with 44 protein targets associating with the indole-containing scaffold. Indole-containing derivatives have the advantage to mimic the structure of peptides, which represent a very important class of molecules to develop novel drugs with different modes of action.[141] More than 30 marketed drugs contain indole scaffold. Among them, seven drugs are in the top-200 best selling drugs by US retail sales in 2012.[142] Notwithstanding, there are no allosteric drugs containing indole scaffold in the market. Considering the availability of cocrystal structures of ligand–target complexes, nine types of targets in complex with their allosteric modulators harboring indole privileged scaffold have been determined by X-ray crystallography. In all of the aforementioned cases, indole-containing derivatives serve as allosteric inhibitors for modulating the functions of targets by either direct or indirect interactions (Fig. 8), such as tryptophan for anthranilate synthase (PDB ID: 1I1Q), chorismate mutase (PDB ID: 1CSM), and tryptamin 2,3-dioxygenase (PDB ID: 2NW8); 5-fluoro-1*H*-indole-2-carboxylic acid-(2-mercapto-ethyl)-amide for caspase 7 (PDB ID: 1SHL); 3-(2-carboxy-ethyl)-4,6-dichloro-1*H*-indole-2-carboxylic acid for fructose-1,6-bisphosphatase 1 (PDB ID: 1LEV); 3-(carboxymethyl)-5,7-dichloro-1*H*-indole-2-carboxylic acid for farnesyl pyrophosphate synthase

2.11.5 Allosteric Protein–Ligand Interactions

2.11.5.1 Noncovalent Allosteric Modulators

The vast majority of the currently reported allosteric modulators are noncovalent. For example, PDK1, a master kinase that belongs to the Ser/Thr AGC protein kinase family, plays a key role in the regulation of physiological processes, such as cell proliferation, differentiation, and survival.[143] PDK1 possesses a hydrophobic pocket positioned in the N-lobe of the kinase, referred to as the PIF pocket, which has been demonstrated to interact with the C-terminal hydrophobic motifs (HMs) of its substrates.[144,145] The catalytic activity of PDK1 can be allosterically enhanced by the binding of phosphorylated HMs to the PIF pocket;[146,147] this pocket is distant from the ATP-binding site. Based on the PIF pocket of PDK1, Rettenmaier et al.[148] recently developed a fluorescence polarization (FP) competitive binding assay to screen for small-molecule compounds that compete with PIFtides (an activating peptide motif on downstream substrate kinases) to bind to the PIF pocket. Using the FP assay, they screened ~154,000 compounds and identified 1280 hits for dose response. Among these initial hits, one of the small molecules, diaryl sulfonamide RS-HTS (**Fig. 9**), is the most potent, which had a K_d value of 15 μM measured by the FP assay and an IC_{50} value of 20 μM by the surface plasmon resonance (SPR) assay. Subsequent structural modifications of RS-HTS identified two regioisomers RS1 and RS2 (**Fig. 9**); the two small molecules bind to the PIF pocket of PDK1 with K_d values of 1.5 and 9 μM, respectively. The determination of the cocrystal complexes between PDK1 and RS1 (PDB ID: 4RQK) (**Fig. 10A**) and RS2 (PDB ID: 4RQV) (**Fig. 10B**), together with ATP, clearly exhibits that both RS compounds bind to the N-terminal PIF pocket, distal from the ATP-binding site. In the PIF pocket, the sulfonyl group of both RS compounds engages in a salt bridge with Arg131 in the helix αC, and both aromatic substituents of RS1 and RS2 form hydrophobic interactions with Leu155 in the β5 sheet.

2.11.5.2 Covalent Allosteric Modulators

A major challenge in drug discovery is how to reduce drug dosage and increase specificity of compound candidates, because high dosage is frequently associated with toxicity. Compared with noncovalent drugs, covalent drugs have potential pharmacological advantages because they may be administrated in lower doses due to the maintenance of longer lifetime of the drug–target complex.[149] Covalent drugs are compounds bearing a bond-forming functional group of low reactivity, following binding to the target protein and then reacting with a specific nucleophilic residue (usually cysteine) at the target site.[150,151] The irreversible binding of covalent drugs to proteins allows for the prolonged duration of drug action on the target, which has the potential to contribute the selectivity and reduce the toxicity that is often caused by high dosage. However, covalent allosteric drugs not only

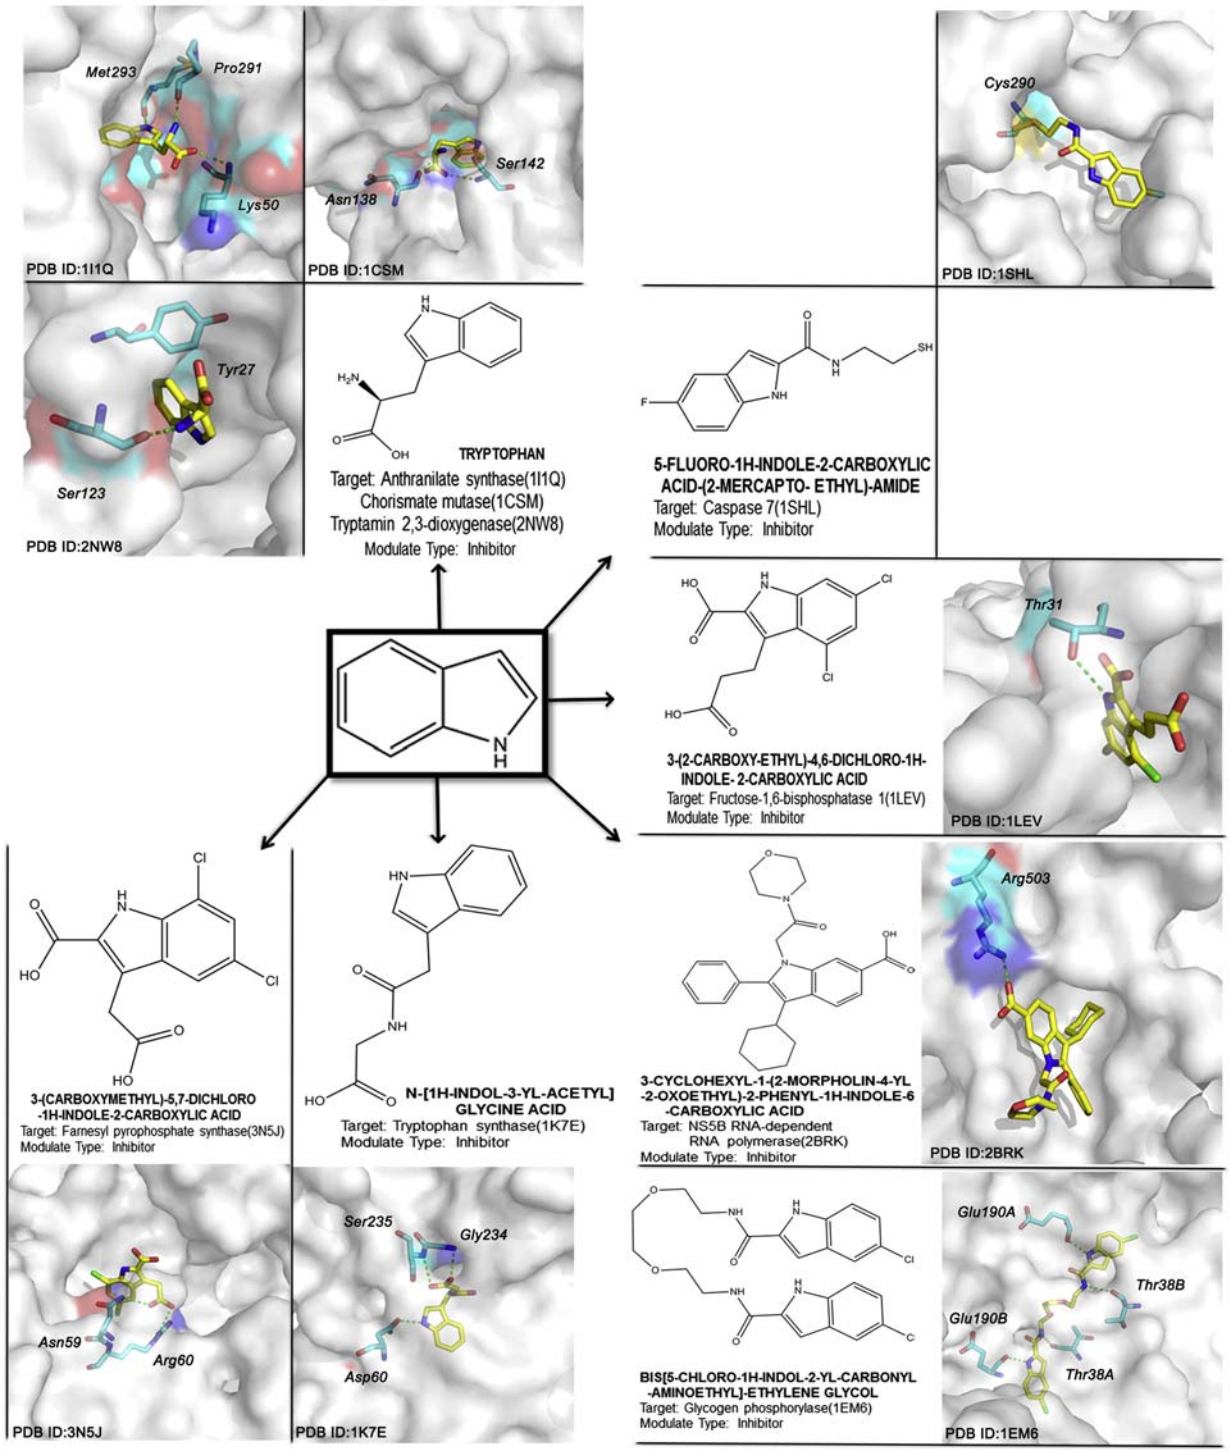

Fig. 8 Cocrystal structures of allosteric targets in complex with their allosteric modulators harboring indole scaffolds. Hydrogen-bonding interactions between allosteric targets and allosteric modulators are depicted by *green dotted lines*.

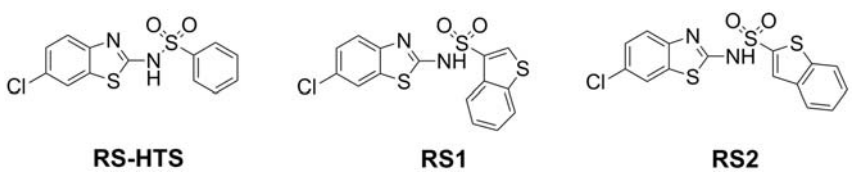

Fig. 9 Chemical structures of the diaryl sulfonamides RS-HTS, RS1, and RS2.

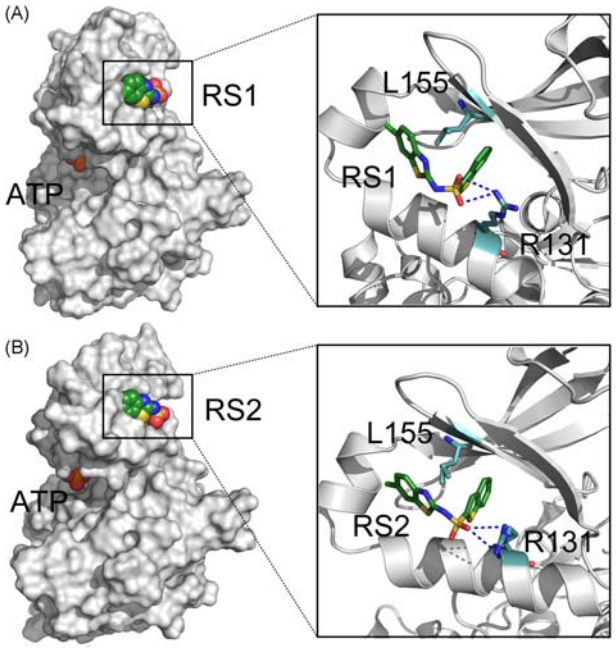

Fig. 10 The binding modes of RS1 (A) and RS2 (B) with PDK1. Salt bridges are depicted by *blue dotted lines*.

possess the pharmacological merits of covalent drugs but also have additional benefit of the higher specificity of allosteric drugs. Thus, covalent allosteric drugs present a novel direction in therapeutic drug development.[152,153]

In the oncogenic Ras protein, somatic mutations such as Gly12, Gly13, and Gln61 mutations are the most common activating lesions found in human cancers, including pancreatic, colorectal, and lung cancers.[154–156] In the case of G12C mutation, this mutation creates a nucleophilic cysteine that can be used to design covalent allosteric modulators. Ostrem et al.[157] harnessed a disulfide-fragment-based screening approach to screen a library of 480 disulfide-containing small-molecule compounds against K-Ras4B^{G12C}-GDP. Structure–activity optimizations of the initial hits identified the compound **6** (Fig. 11A), which showed a higher potency compared to initial hits. To uncover the structural details of the binding between compound **6** and G12C K-Ras4B, the X-ray

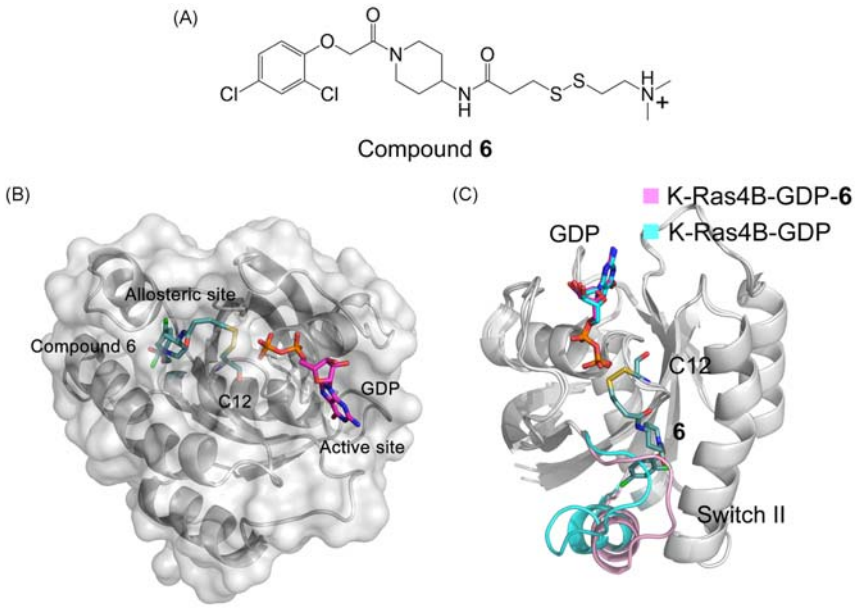

Fig. 11 (A) Chemical structure of compound **6**. (B) Surface representation of K-Ras4B^{G12C}-GDP-**6** (PDB ID: 4LUC) showing the compound **6** bound to the switch II pocket, S-IIP. (C) Backbone superimposition of the crystal structure of K-Ras4B^{G12C}-GDP-**6** onto that of K-Ras4B^{WT}-GDP (PDB ID: 4Q21). The switch II region in the structures of K-Ras4B^{G12C}-GDP-**6** and K-Ras4B^{WT}-GDP is colored in *pink* and *cyan*, respectively.

structure of G12C K-Ras4B-GDP in complex with compound **6** was determined (PDB ID: 4LUC). The structure revealed that compound **6** forms a disulfide bond with Cys12 (Fig. 11B), and because of this binding, a new allosteric pocket is generated beneath the effector binding switch II region, termed S-IIP (Fig. 11C). The covalent binding of compound **6** to K-Ras4B^{G12C} prevents the downstream effectors, such as Raf and PI3K, from binding to K-Ras4B^{G12C}, thereby inhibiting the downstream signaling mediated by Ras.

2.11.5.3 Bitopic Ligands

The bitopic ligand, also named dualsteric ligand, is a kind of allosteric modulators, which are referred to a single chemical entity consisted of an orthosteric pharmacophore covalently linked to an allosteric pharmacophore.[158] In this regard, a bitopic ligand can bind simultaneously to both the orthosteric and allosteric binding sites of proteins. In principle, the orthosteric portion is responsible for binding affinity, and the allosteric portion is accountable for the selectivity of the protein subtype of interest.[159] As a consequence, the ability of the bitopic ligands to achieve improved protein affinity and selectivity is gaining increasing recognition as a tactics in allosteric drug design.

The advantages of bitopic ligands include receptor-expression-dependent pharmacology and ligand-biased signaling.[86,160,161] As in the case of the muscarinic M_2 acetylcholine (ACh) receptor (mAChR), a prototype of class A GPCRs, the ACh orthosteric binding site of the M_2 mAChR is located in a narrow cavity formed by the seven-transmembrane (TM) domains of the receptor, and the allosteric binding site is located on the extracellular entrance of the receptor. The close proximity of these two binding sites suggests the possibilities of sculpting bitopic ligands to bridge orthosteric and allosteric binding sites. Founded on this hypothesis, Steinfeld et al.[162] designed a bitopic antagonist—THRX160209—that links the orthosteric and allosteric binding sites of the M_2 mAChR. THRX160209 contains an orthosteric pharmacophore, a benzhydryl (3-BHP) moiety, and an allosteric pharmacophore, a 4-aminopiperidine moiety (4-ABP); the two pharmacophores are connected by a C7 polymethylene chain (Fig. 12A). In the M_2 mAChR inhibition radioligand binding assay, the observed affinity for THRX160209 (apparent $pK_i = 9.51 \pm 0.22$) was several orders of magnitude greater than its two parent components (apparent pK_i values < 6.0). Moreover, THRX160209 exhibited markedly higher specificity for the M_2 receptor, in a range of one to two orders of magnitude greater compared with the other four highly conserved receptor subtypes (M_1, M_3, M_4, and M_5) of mAChR.

The dopamine receptors contain five subtypes (D_{1-5}Rs) that are expressed mainly in the vertebrate central nervous system (CNS). The physiological functions of DRs are mediated by the binding of the catecholamine neurotransmitter, dopamine, to the highly conserved orthosteric site of DRs. Aberrant DR functions in the CNS have been associated with numerous neuropsychiatric disorders, including schizophrenia, attention-deficit hyperactivity disorder, and social phobia.[163–165] Recently, Lane et al.[166] characterized the first drug-like allosteric modulator, SB269652, of the D_2R. The ligand, SB269652, harbors a structural hallmark of orthosteric D_2R antagonists, the tetrahydroisoquinoline (THIQ) moiety, and a lipophilic appendage, the indole-2-carboxamide moiety (Fig. 12B); the two pharmacophores are connected by a cyclohexane linker. Via the ERK1/2 phosphorylation assay, it was shown that the binding affinity of SB269652 is much greater than that of the THIQ moiety by 17-fold. Molecular modeling and site-directed mutagenesis experiments revealed that the THIQ moiety of SB269652 occupies the orthosteric site of D_2R, whereas the indole-2-carboxamide moiety protrudes into the allosteric site lined by the extracellular interface between TM2

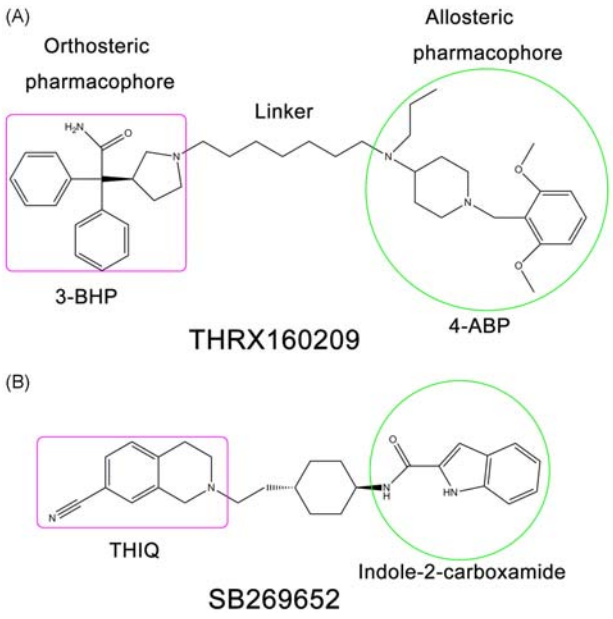

Fig. 12 Chemical structures of bitopic ligands for the THRX160209 (A) and SB269652 (B).

and TM7; the engagement of the latter is of fundamental importance to exert the allosteric pharmacology of SB269652. Furthermore, based on the functional complementation assay and [^{35}S] GTPγS binding assay, the allosteric underpinning of action of SB269652 is proposed as the binding of the bitopic ligand to one D_2R homodimer to allosterically modulate the binding of a ligand to the orthosteric site of another D_2R homodimer. This novel mechanism expands the repertoire of allosteric regulation than can be engendered by bitopic GPCR ligands.

2.11.5.4 Allo-Network Modulators

In living cells, a protein is not an isolated node. Rather, it has the potential to contact with its partners to form protein–protein interactions (PPI) in a specific circumstance.[167–169] For example, in the phosphatidylinositol 3-kinase (PI3K)/Akt signaling pathway, the master kinase PDK1 interacts with its downstream substrate, Akt, and subsequently phosphorylates the threonine in the activation loop of Akt. The active phosphorylated Akt has the ability to interact with its downstream substrate glycogen synthase kinase 3 (GSK3) and then phosphorylates the serine in the activation loop of GSK3.[170] As a result, a signal from one protein can be propagated over a long distance to the specific destination. This individual signal transduction process is called as cellular pathway. In fact, a certain protein may also be involved in more than one signaling pathway, thereby resulting in the signaling pathways in cells to be interconnected. This phenomenon is also referred to as cellular network, which, coupled with its environment, guides cell and organism behavior and is of prime importance to understanding the function and misfunction of proteins.[171,172]

The binding of a molecule may trigger conformational or dynamic changes in its target, which, in turn, propagates the perturbation signal to affect the conformations of its adjacent proteins. As such, the adjacent proteins can also transmit the conformational signal to their partners via the complex PPI interactome. Recently, Nussinov et al.[173–175] proposed a novel paradigm of drug action, "allo-network drugs," to parse out this kind of behavior. Unlike a conventional drug that directly targets an individual malfunctioning protein, an allo-network drug enables to initiate a perturbation signal in a distant protein in the cellular network to reach the target protein. Thus, the "allo-network drug" concept greatly broadens the scope of target proteins that can be exploited as drug discovery targets. Taking into account that allo-network drugs orchestrate a specific signaling pathway to shift its pathophysiological network status to normal, they are capable of achieving fewer side effects and lower toxicity.[174]

Despite the importance of allo-network drugs in the development of allosteric drugs, the exquisite characterization of PPI complex in the cellular network is a daunting task by experiments. The recent advances in the network analysis methodology, in-depth understanding of pathways and information flow in the cellular networks at atomic level, and the remarkable progress in the analysis of cellular system-level responses by means of cell-based assays will be beneficial to accelerate allo-network drugs discovery.[175,176] Thus far, several paradigms have witnessed the utilization of allo-network drugs to modulate the PPI network in the specific pathway. One quintessential example that takes advantage of allo-network drugs to interfere with a disease-specific pathway has been reported in the serine/threonine mammalian target of rapamycin (mTOR). mTOR, belonging to the PI3K-related kinase protein family, regulates cell growth, proliferation, survival, and protein synthesis. Dysregulation of the mTOR signaling pathway has implicated in human diseases, such as cancers, diabetes, and obesity.[177,178] mTOR exists in the two structurally different complexes: mTOR complex 1 (mTORC1) and mTOR complex 2 (mTORC2). The two complexes contain the same catalytic subunit, mTOR, but are engaged in significantly distinct signaling pathways. The allosteric inhibitor rapamycin/FKBP12 can selectively inhibit the mTORC1 signaling (Fig. 13), but not the mTORC2 signaling. Rapamycin/FKBP12 binds to the FKBP12-rapamycin-binding domain of mTOR, leading to allosterically disrupt the interactions between the mTOR C-terminus and the protein raptor in the mTORC1. Under this circumstance, the conformation of the protein raptor undergoes changes, preventing

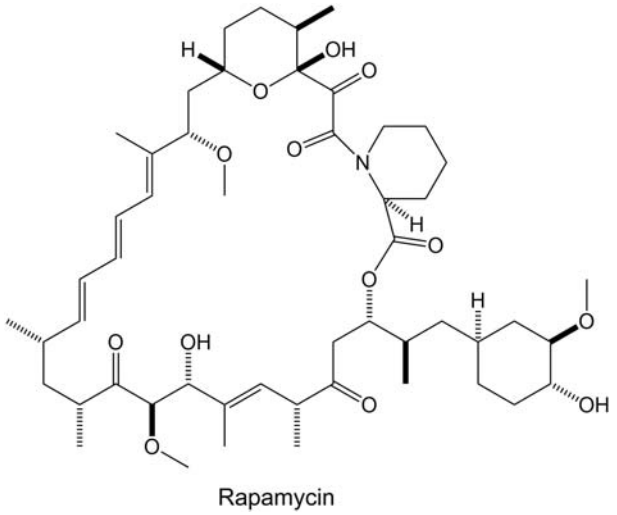

Fig. 13 Chemical structure of rapamycin.

it from the interaction with the eukaryotic translation initiation factor 4E (eIF4E) binding protein (4E-BP) substrates. This effect inhibits the downstream signaling of mTORC1.

2.11.5.5 Allosteric and Orthosteric Collaboration

In the c-Abl, modulation of c-Abl activity is achieved by an autoinhibition involving the N-terminal SH2 and SH3 domains of the protein. In the oncogenic fusion protein Bcr-Abl, the autoinhibition conformation of Abl is disrupted, resulting in CML or acute lymphoblastic leukemia.[179] The "gatekeeper" T334I mutation renders the ATP-binding site inhibitors imatinib (STI-571/Gleevec), nilotinib (AMN-107/Tasigna), and dasatinib (Sprycel) ineffective and causes clinical relapse in advanced-phase patients. Addition of GNF-5 to occupy the C-terminal Abl myristoyl allosteric pocket, coupled with the occupation of ATP-binding site by imatinib, allosterically locks c-Abl in the closed, inactivated state.[93] The cooperative actions of imatinib and GNF-5 can be used to overcome drug resistance. The determination of the cocrystal structure between c-Abl and an analog of imatinib, PD166326 (**Fig. 14A**) and myristic acid (PDB ID: 2FO0)[180] displayed that the myristic acid occupies a deep pocket in the C-lobe of the kinase domain, whereas the PD166326 is bound to the ATP-binding site (**Fig. 14B**).

The most encouraging case is the combination of the MEK inhibitor trametinib and the B-Raf inhibitor dabrafenib for the treatment of mutant B-Raf$^{V600E/K}$ metastatic melanoma.[75] This combinational strategy was approved by the FDA in the early 2014 and has been utilized to overcome the drug resistance within about 6 months in response to the treatment of B-Raf inhibitors.[181,182] The determination of the cocrystal structure between MEK1 and an analog of trametinib, TAK-733 (**Fig. 15A**), displayed that the TAK-733 is located in an allosteric pocket proximal to the ATP-binding site (PDB ID: 3PP1),[183] a typical type III binding mode (**Fig. 15B**).

2.11.6 Mechanisms of Allosteric Drug Action

The recent unified view of allostery introduced by Nussinov and Tsai suggests the existence of structural coupling between the orthosteric and allosteric sites.[184] The allosteric signals propagate from allosteric sites to orthosteric sites by virtue of multiple,

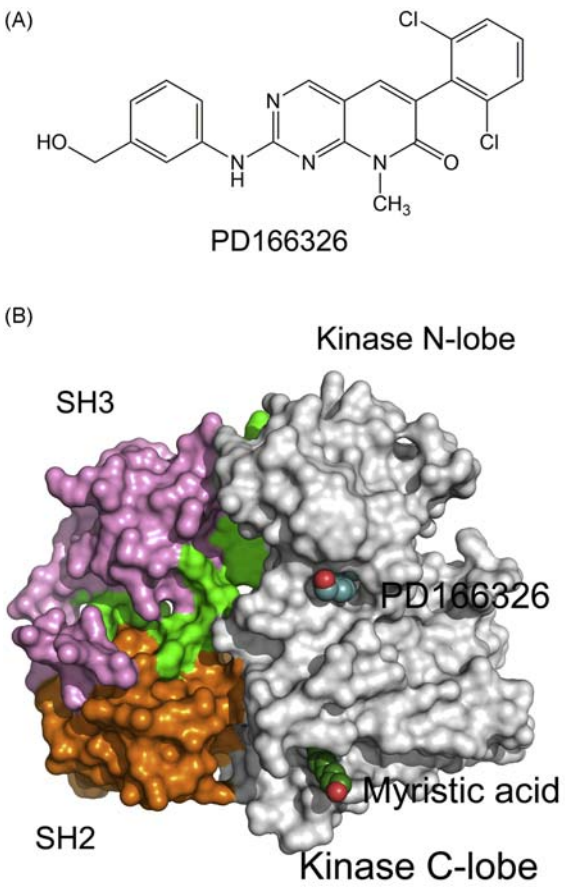

Fig. 14 (A) Chemical structure of PD166326. (B) Crystal structure of c-Abl in complex with an allosteric modulator, myristic acid located in the C-lobe of the kinase domain, and an orthosteric inhibitor, PD166326 (PDB ID: 2FO0). Fig. 15 (A) Chemical structure of TAK-733. (B) Crystal structure of MEK1 in complex with an allosteric modulator TAK-733 (PDB ID: 3PP1). ATP and TAK-733 are depicted by stick models. N-lobe, hinge domain; C-lobe are colored in *orange*, *green*, and *pink*.

preexisting pathways in all proteins, but which pathways are dominated, associated with protein topologies, specific binding events (small molecules, proteins, and DNA/RNA), covalent modifications, and cellular conditions.[185,186] Allosteric drugs bound to allosteric sites merely shift the preexisting ensemble of pathways to one specific pathway, resulting in the variation of the relative populations of the different substrates. Consequently, different chemical types of allosteric drugs can produce distinctly functional and dynamical allosteric effects of proteins. The specific allosteric ligand–protein interactions determine the extent of relative increase of the active state population of proteins in solution as a result of stabilizing the active conformation and/or destabilizing the inactive conformation.[184] This principle plays a pivotal role in specifying the allosteric drug action.

Recently, Nussinov and Tsai emphasized that allosteric drugs consist of anchor and driver atoms.[187,188] The anchor atoms, by definition, occupy the allosteric site and are engaged in favorable interactions with a highly populated conformation in the inactive and active states. These interactions between the anchor atoms of allosteric drugs and proteins do not undergo change during the protein switch from the inactive to active states and vice versa. In contrast, the driver atoms interact with proteins, and these interactions profoundly differ between the inactive and active states. The driver atoms can be further divided into attractive "pulling" or repulsive "pushing" atoms, depending on the specific interactions between the driver atoms and their corresponding residues in the allosteric sites. Guided by this concept, a formation of a stabilizing attractive interaction between drive atoms and proteins has the potential to pull the inactive conformation into the active conformation. Conversely, formation of a repulsive interaction between driver atoms and proteins can push the active conformation into the inactive conformation. Furthermore, the characteristic properties of driver atoms can be exploited to decipher allosteric ligand–protein interactions where minor or subtle modifications in allosteric drugs can lead to opposite allosteric effects, such as from agonism to antagonism. Identification of driver atoms in allosteric drugs can contribute to allosteric drug discovery.

For example, Ras proteins, small GTPases, are signal switch molecules that regulate cell fates by coupling receptor activation to downstream effector pathway that control diverse cellular responses including proliferation, differentiation and survival.[154] Ras proteins are activated by the exchange of Ras-bound guanosine diphosphate (GDP) (Ras-GDP, inactive state) with guanosine triphosphate (GTP) (Ras-GTP, active state). This exchange results in large conformational changes in the switch I and switch II regions of the Ras catalytic domains, rendering the Ras proteins in the active state that can bind to various effector proteins to stimulate signaling pathways. According to the anchor and driver identification protocol[187] that is applied on the catalytic domain of Ras in the GNP-bound (PDB ID: 3GFT) and GDP-bound (PDB ID: 4LPK) structures, two oxygen atoms from the γ-phosphate group of GNP are identified as driver atoms, which form hydrogen-bonding interactions with the residue Thr35 from the switch I region and Gly60 from the switch II region (**Fig. 16**). The two hydrogen bonds are absent in the GDP-bound structure. The driver's pulling action from the two oxygen atoms from the γ-phosphate group of GNP may pull the inactive to active Ras conformation and stabilize the Ras-GNP-bound conformation. In addition, the anchor atoms are derived from the adenine, ribose, and α-/β-phosphate groups in the both of two structures. These atoms interact with the inactive/active Ras through hydrogen-bonding interactions; these interactions do not change between the inactive and active states. For example, in the both structures, residues that interact with the anchor atoms include Gly13, Gly15, Lys16, Ser17, Ala18, Val29, Asp30, Asp119, and Ala146.

In the case of the regulatory subunit of protein kinase A (R_A), R_A functions to modulate the activity of protein kinase A in a cAMP-dependent manner and exists in two distinct and structurally dissimilar, active cAMP-bound "B" and inactive C-subunit "H" conformations.[189] The replacement of the equatorial oxygen of the cyclic phosphate of cAMP to a sulfur atom yields the R_p-cAMP. R_p-cAMP functions as an antagonist that binds to the *cyclic* nucleotide-binding (CNB) domain of R_A, thereby locking the R_A in its inactive "H" conformation. As shown in **Fig. 17**, superimposition of the crystal structures of the active cAMP bound (PDB ID: 3PNA) and inactive R_p-cAMP bound (PDB ID: 3PLQ) reveals that the dramatic conformational changes between the two structures are observed in the α subdomain distant from the CNB domain, with only small differences in the β subdomain.

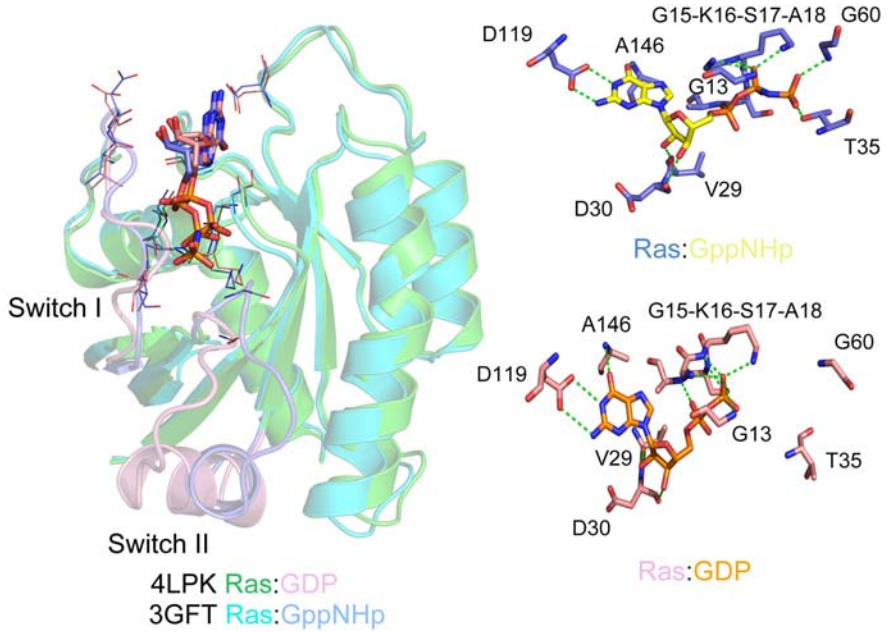

Fig. 16 Structural presentation of identified driver and anchor atoms for Ras.

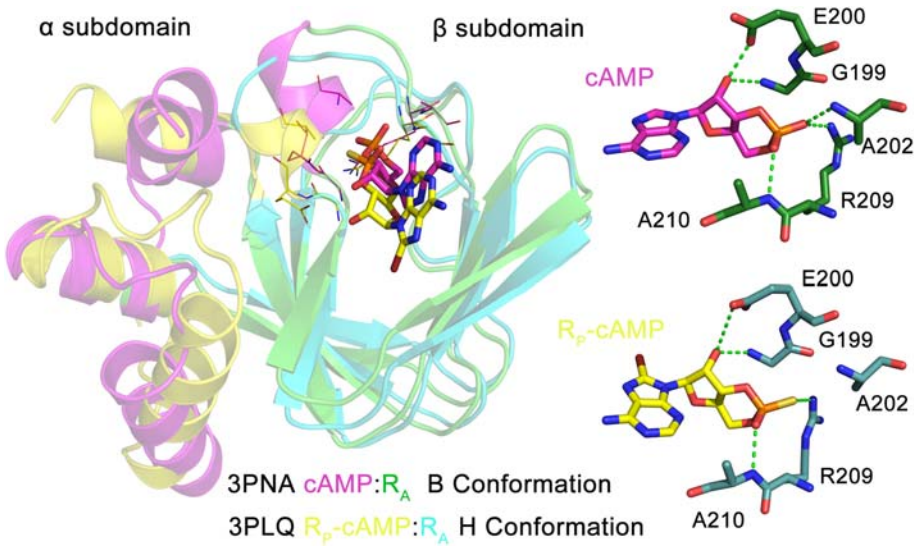

Fig. 17 Structural presentation of identified driver and anchor atoms for PKA.

The crystallographic information indicates that the activation mechanism of cAMP action is through allosteric regulation. Based on the anchor and driver identification protocol, the equatorial oxygen atom in the cAMP that is substituted with a sulfur atom R_p-cAMP is identified as a driver atom, which forms a hydrogen bond with the residue Ala202. This hydrogen bond is absent in the R_p-cAMP-bound structure. The driver's pulling action from the equatorial oxygen atom from the cyclic phosphate of cAMP may pull the inactive to active R_A conformation and stabilize the R_A-cAMP-bound conformation. In addition, the anchor atoms are derived from the hydroxyl group of ribose, one oxygen atom from the cyclic phosphate of cAMP in the both of two structures. These atoms interact with the inactive/active R_A through hydrogen-bonding interactions; these interactions do not change between the inactive and active states. For example, in the both structures, residues that interact with the anchor atoms include Gly199, Glu200, Arg209, and Ala210.

2.11.7 Conclusions

Allostery, the fundamental process by which distant sites on a given protein are coupled, has been established as an efficient and ubiquitous mechanism for regulation of functional activity. The modes of action between orthosteric and allosteric drugs are significantly distinct. The main advantage of allosteric drugs is their higher specificity and lower toxicity. Despite the increasing popularity of using allosteric modulators as therapeutic agents, a long-standing challenge in the development of allosteric modulators is the discovery of allosteric sites in proteins of interest.[190–194] The identification of allosteric sites is a first step toward screening and optimizing allosteric modulators. Remarkably, in the last decade, the development of approaches for the finding of allosteric sites has considerable progress in many proteins,[195] such as enzymes and GPCRs, which provide novel opportunities to design allosteric modulators in more drug targets. Owing to the remarkable merits of allosteric modulators and the considerable interest invested in their development, we believe that the repertoire of allosteric modulators should be burgeoning in the pharmaceutical industry and drug discovery program.

2.12.1 Introduction

Epigenetic modulation of gene expression involves changes in gene expression and/or phenotype that are mediated by processes that do not involve alterations in the primary sequence of DNA. Epigenetic control of gene expression occurs in one of the three ways: (1) methylation of DNA at specific CpG dinucleotides in gene promoter regions, (2) recruitment of transcription factors that are incorporated into epigenetic complexes, and (3) covalent modification of histone proteins. These reversible chromatin remodeling modifications at promoter-specific chromatin marks determine, in part, whether specific genes are in an open/transcriptionally active conformation or a closed/transcriptionally repressed conformation,[1,2] and also solve the fundamental problem of storing approximately 2 m of DNA in a cell nucleus with an average diameter of 6 μm. Conceptually, enzymes that participate in epigenetic modulation of gene expression can be divided into three categories: writers, erasers, and readers.[1,3] In addition to methylation of DNA at CpG islands, the status of the epigenetic code is determined by the formation and breakdown of specific posttranslational modifications (PTMs) at histone lysine (acetylation, methylation, ubiquitination, sumoylation, crotonylation, butyrylation, and propionylation) and arginine (methylation, citrullination, and ADP-ribosylation) residues, as well as phosphorylation of serine, tyrosine, and threonine.[4–6] Taken together, CpG island methylation and histone PTMs at defined lysine and arginine residues make up an epigenetic "landscape" whereby cellular gene expression can be tightly and accurately controlled. Prior to 2004, the field of epigenetics was focused on two primary processes, histone acetylation/deacetylation[1,7] and DNA methylation.[8] At present, the epigenetic landscape is highly regulated by multiple enzymes, corepressor proteins, and transcription factors that form specific epigenetic complexes at a given promoter.

DNA methylation has been the most intensely studied of the epigenetic modulation processes, primarily in the context of DNA methylation changes that occur in cancer. These changes include hypermethylation of DNA at CpG dinucleotides in promoter regions and reduction of methylation in the body of the gene.[9–11] DNA methyltransferase (DNMT) inhibitors are well-known epigenetic modulators that have been used extensively in cancer chemotherapy.[12,13] Importantly, the process of DNA methylation is not an isolated event, and there are a number of functional links between changes in DNA methylation at CpG islands and alterations in the PTM of histone proteins.[14]

The process of histone lysine acetylation/deacetylation is the most extensively studied of the histone PTMs. The acetylation status of histones is controlled by opposing enzymes that covalently modify specific histone lysines. Histone acetyltransferases (HATs) promote histone hyperacetylation, which removes the positive charge on the ε-lysine and allows DNA to assume an open conformation known as euchromatin. In contrast, the histone deacetylases (HDACs), which catalyze acetyl group cleavage,[7,15] restore the lysine positive charge, which contracts DNA into a closed conformation known as heterochromatin. Normal mammalian cells efficiently control chromatin architecture in part by maintaining a balance between HAT and HDAC activities. Both the zinc-dependent[16,17] and sirtuin[18,19] classes of HDACs have been regarded as validated drug targets for a number of years, and four HDAC inhibitors have reached the market (vorinostat, panobinostat, belinostat, and romidepsin), with several other drug candidates in Phase II or III trials (**Table 1**).[20]

Historically, lysine methylation was thought to be a stable PTM that could only be reversed by the synthesis of new protein. Histone lysine methylation/demethylation was first described in 2004 with the identification of lysine specific demethylase 1 (LSD1),[21] but the value of LSD1 as a drug target for the treatment of cancer was not demonstrated until 2007.[22] To date, there are two known flavin-dependent histone demethylases, KDM1A and KDM1B, also known as LSD1 and LSD2, respectively.[23]

Table 1 Histone deacetylases involved in human chromatin remodeling

Zinc-dependent histone deacetylases		
HDAC	*Number of amino acids*	*Subcellular location*
Class I		
HDAC1	482	Nucleus
HDAC2	488	Nucleus
HDAC3	428	Nucleus
HDAC8	377	Nucleus
Class IIa		
HDAC4	1048	Nucleus/Cytoplasm
HDAC5	1122	Nucleus/Cytoplasm
HDAC7	855	Nucleus/Cytoplasm
HDAC9	1069	Nucleus/Cytoplasm
Class IIb		
HDAC6	1215	Cytoplasm
HDAC10	669	Cytoplasm
Class IV		
HDAC11	H3K9	Nucleus/Cytoplasm
NAD-dependent histone deacetylases (sirtuins)		
Class III		
SIRT1	747	Nucleus/Cytoplasm
SIRT2	352	Cytoplasm
SIRT3	399	Nucleus/Mitochondria
SIRT4	314	Mitochondria
SIRT5	310	Mitochondria
SIRT6	355	Nucleus
SIRT7	400	Nucleolus

Subsequently, five more families of histone demethylases that require Fe(II) and α-ketoglutarate as cofactors were identified, termed KDM2–6.[24] Because KDM26 share the common feature of possessing a Jmj domain, they are collectively termed Jumonji KDMs. To date, more than 30 Jumonji demethylases have been identified. The discussion in the following section will focus on drug development involving DNMT inhibitors and efforts targeting epigenetic histone writers, erasers, and readers.

2.12.2 Epigenetic Modulation via DNA Methylation/Demethylation

Methylation of DNA for the purpose of epigenetic control of gene expression occurs at specific cytosine residues. These cytosines are usually located in CpG islands, which are sequences of $\geq$200 base pairs with a GC percentage of 50% or greater. In human DNA, CpG dinucleotides are relatively rare, with the exception of gene promoters, which generally feature CpG islands.[25] The methylation/demethylation cycle for cytosines in CpG islands is shown in **Fig. 1**. A specific DNMT transfers a methyl group from *S*-adenosylmethionine (SAM) to the 5-position of the pyrimidine ring of cytosine, forming 5-methylcytosine. A total of eight DNMTs are known (DNMT1, DNMT1b, DNMT1o, DNMO1p, DNMT2, DNMT3A, DNMT3b, and DNMT3L), but only DNMT1, DNMT3A, and DNMT3b are important in epigenetic modulation.[26] Methylation can be either de novo when CpG on both strands receive a methyl group or maintenance when one strand is already methylated, and the DNMT uses the methylated strand to methylate the complementary strand. DNMT3A and DNMT3b are responsible for de novo methylation of DNA, and they play a major role during embryogenesis and genomic imprinting. DNMT1 can also perform de novo methylation but is largely responsible for maintenance methylation during epigenetic modulation.[27] In cancer, hypermethylation is observed at CpG islands, along with hypomethylation in the corresponding gene body.[26] These changes in DNA methylation lead to gene silencing, including tumor suppressor genes that play a role in preventing the development of cancer. For this reason, DNMT1 has long been regarded as a potential target for antitumor agents.

Although DNA methylation contributes to stable and heritable gene silencing, it is known that DNA demethylation can occur by one of the two routes.[28] During early development, DNA methylation patterns are set through de novo methylation at CpG islands. During replication, methylated DNA bases are restored in the hemimethylated copy by DNMT1, which uses the original strand as a methylation template. However, when DNMT1 is not present or is inhibited, 5-methylcytosine is replaced by cytosine in the copy, and thus replication dilutes methylation of DNA. DNA demethylation can also be catalyzed by specific enzymes, as shown in **Fig. 1**, and can proceed by either an oxidation or a deamination pathway.[27,28] The oxidative route is catalyzed by the ten-eleven translocation enzymes (TETs), proceeding in stepwise fashion to form 5-hydroxymethylcytosine, 5-formylcytosine, and then 5-carboxycytosine. Both 5-formylcytosine and 5-carboxycytosine can be converted to an abasic form by thymine-DNA glycosylase (TDG). In addition, 5-methylcytosine and 5-hydroxymethylcytosine can be deaminated by activation-induced deaminase (AID)

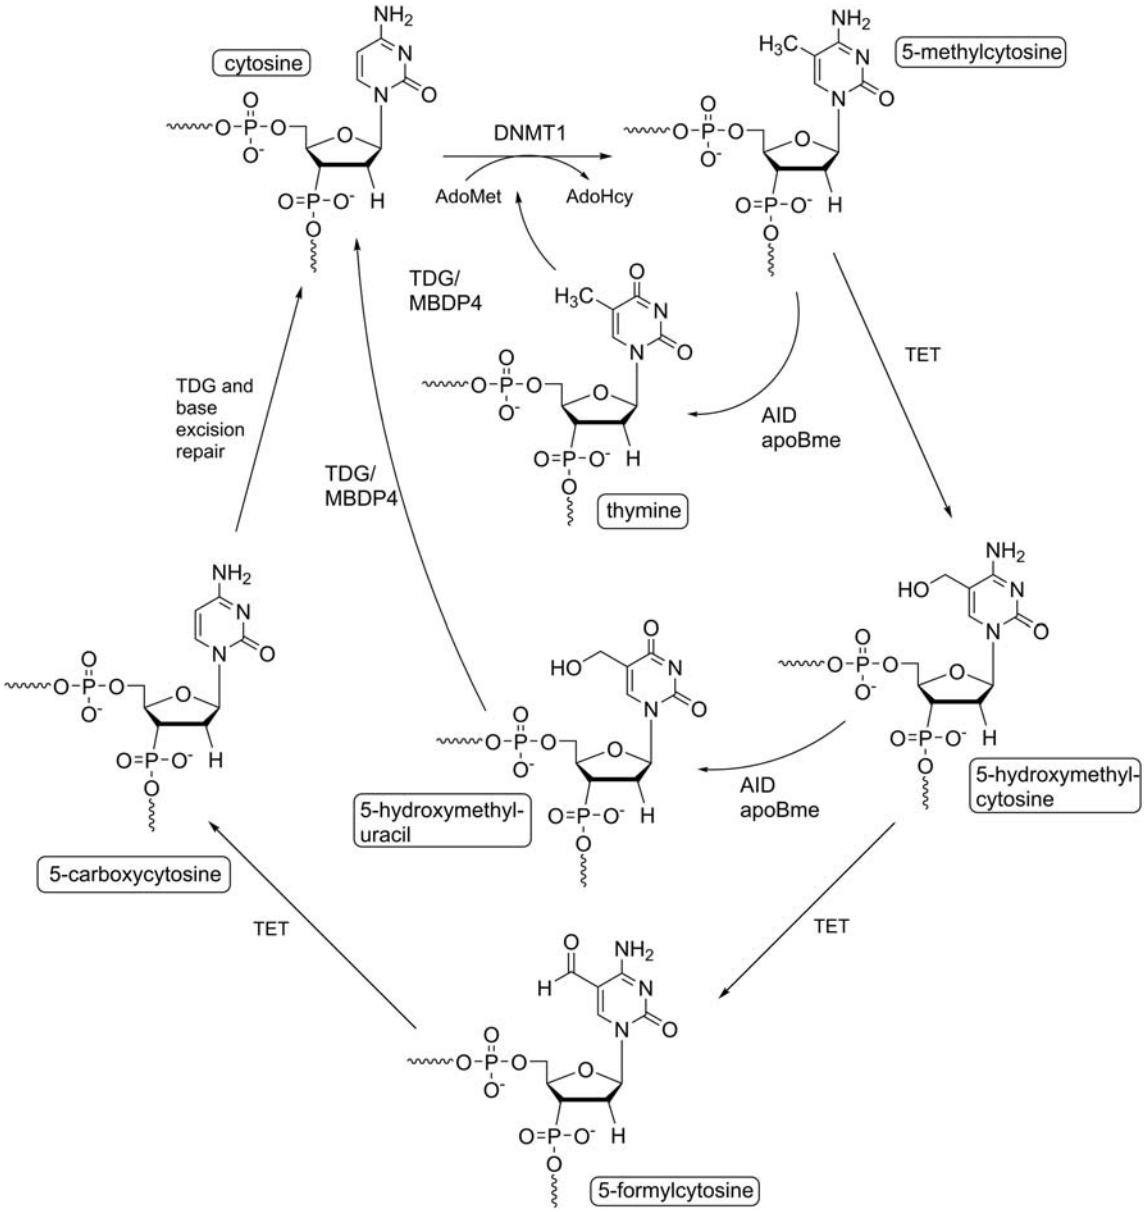

Fig. 1 The mammalian DNA methylation/demethylation cycle. *TET*, ten-eleven translocation enzymes; *AID*, activation-induced deaminase; *apoBme*, apolipoprotein B mRNA editing enzyme; *TDG*, thymine-DNA glycosylase; *MBDP4*, methyl-CpG binding domain protein 4 (MBDP4).

and apolipoprotein B mRNA editing enzyme (apoBme) to form thymine of 5-hydroxymethyluracil, respectively. These two deaminated species are recognized as a base mismatch and are converted to the abasic form by TDG and methyl-CpG binding domain protein 4 (MBD4). The abasic form is then replaced by base excision repair.

Hypermethylation of CpG islands is a hallmark of early-stage cancer and occurs in a gene- and cell-specific manner. DNMT inhibitors were first identified in the 1960s[29] and have emerged as effective cancer chemotherapeutics.[30,31] DNMT inhibitors fall into one of the two classes: nucleoside analogs and nonnucleoside compounds. Two nucleoside analogs, 5-azacytidine (5-AC) and 5-aza-2′-deoxycytidine (**Fig. 2**), have been approved for use in myelodysplastic syndrome and leukemia by the FDA.[32] These agents must be incorporated into DNA, where they serve as covalent inhibitors, such that a cysteine residue on the enzyme is appended to the 5-position of the analog.[33] However, 5-AC and 5-aza-2′-deoxycytidine exhibit poor chemical stability, a lack of specificity for DNMT1 in relation to other DNMTs, and they produce significant adverse side effects.[13,34] The deaminated analog of 5-AC, zebularine (**Fig. 2**), inhibits DNMT1 by promoting ubiquitin-targeted degradation of the enzyme.[35] It has increased stability and is relatively nontoxic; however, the high plasma concentrations required to produce adequate demethylation in vivo have hindered its clinical development.[36] The related pyrimidine-2-one nucleoside THU[37] and its analogs[38] are potent inhibitors of deoxycytidine deaminase. Two additional nucleoside-based inhibitors of DNMT, 5-fluoro-2′-deoxycytidine[39] and

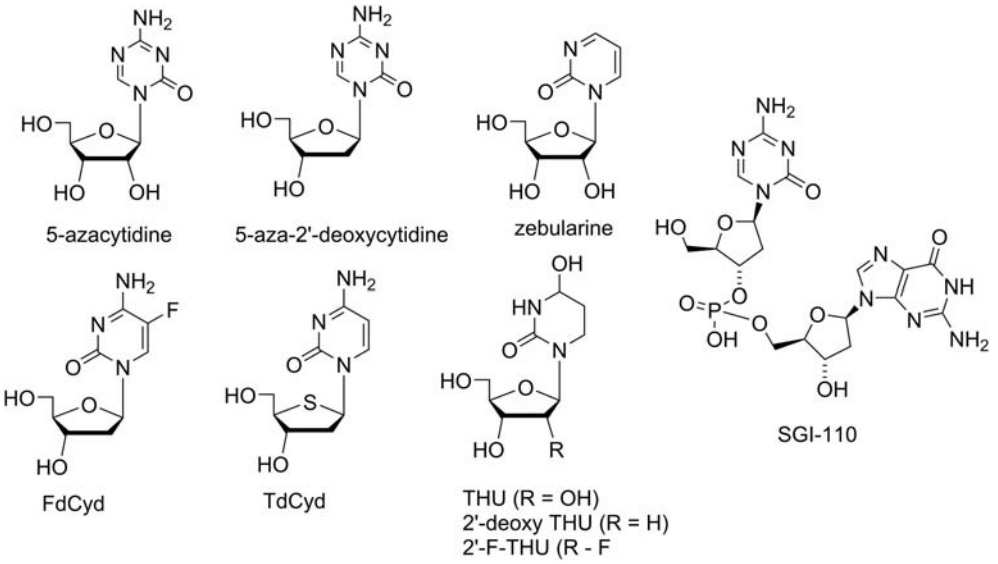

Fig. 2 Nucleoside-based DNMT1 and cytidine deaminase inhibitors.

4′-thio-2′-deoxycytidine (TdCyd)[40] (Fig. 2), have been entered into human clinical trials. TdCyd has been shown to be incorporated into DNA, where it acts as a potent inhibitor of DNMT. The CpG dinucleotide derivative SGI-110 is an efficient prodrug form of 5-aza-2′-deoxycytidine that exhibits increased resistance to cytidine deaminase, improved solubility, and enhanced cell penetration.[41]

Nonnucleoside inhibitors of DNMT (Fig. 3) constitute a structurally diverse group of compounds, and to date none of these have been particularly successful for a variety of reasons. However, nonnucleoside DNMT inhibitors do possess one advantage. Since they do not need to be incorporated into DNA, inhibitors selective toward each of the DNMT isoforms can ultimately be identified. Within this category, a number of known drugs can act as DNMT inhibitors. Examples include procainamide, which inhibits the hemimethylase activity of DNMT1,[42] and 6-mercaptopurine and 6-thioguanine, which like zebularine down regulate DNMT1 through ubiquitin-targeted degradation. The quinoline derivative SGI1027 acts as a hypomethylating agent and promotes the reexpression of tumor suppressor genes by blocking DNMT1 activity.[43] While more potent analogs related to SGI1027 have been synthesized, they still possess weak activity against DNMT1, especially in cell-based assays.[44] The polyphenol (−)-epigallocatechin-3-gallate was identified from a screen of 114 flavones and flavanones and found to be a high nanomolar inhibitor of DNMT1.[45] Also discovered in this initial screen was a series of 3-chloro-3-nitroflavones. Some of these nitroflavones were found to inhibit DNMT1. Additional screening by the same group resulted in the identification of diclone, a small halogenated naphthoquinone that is classically used as pesticide and fungicide. Diclone acted as a potent inhibitor of the DNMT3A/3L complex and was found to possess an EC_{50} of 460 nM against cultured DU145 prostate cells. Genistein has been shown to inhibit the hemimethylase activity of DNMT1, most likely by binding to the catalytic domain. Genistein also decreased CpG methylation in the promoter region of multiple tumor suppressor genes and increased the mRNA expression of these genes.[46] The rationally designed *N*-phthaloyl-L-tryptophan RG108, discovered through a virtual screen using a homology model derived from bacterial C5-DNMT, was shown to be a modest inhibitor of DNMT1, presumably by binding in the catalytic pocket.[47] Subsequently, analogs of RG108 that featured a substituted quinazoline-2,4(1H,3H)-dione in place of the phthalimido moiety showed enhanced activity against DNMT1. In particular, the 2-nitropyridylsulfenyl- and 2,4-dinitropyridylsulfenyl analogs produced the best inhibition (95%-98% inhibition at 500 μM).[48] Using a multistep docking approach of lead-like compounds with a homology model of the catalytic site of DNMT1, Kuck et al. identified seven new molecules with detectable DNMT1 inhibitory activity.[49] Six of these compounds appeared selective for DNMT1 and did not inhibit the DNMT3B methyltransferase. The most active in the series was the salicylic acid dimer NSC14778. The anthraquinone laccaic acid and several analogs were identified by high-throughput screening using a truncated form of DNMT.[50,51] Finally, using a scintillation proximity assay, a library of 180,000 compounds was screened against murine DNMT3A. The resulting 12 hits generated H_2O_2, and hence reactive oxygen species, and as such were not suitable for development. Further experiments revealed SW155246, did not generate peroxide, had an IC_{50} of 1.2 μM for DNMT1, and showed good selectivity for DNMT1 over DNMT3B/3L.

2.12.3 Epigenetic Control of Gene Expression via Histone Lysine and Histone Arginine PTM

2.12.3.1 Histones and the Epigenetic Control of Gene Expression

Histone proteins are octamers, consisting of one H_3-H_4 tetramer and two H_{2A}-H_{2B} dimers.[52] Histones are directed to DNA by their predominate positive charges[53] that interact with the negative charges on the DNA backbone. These proteins then interact with double-stranded DNA in such a way that a section of approximately 147 base pairs of DNA are wrapped around the histone

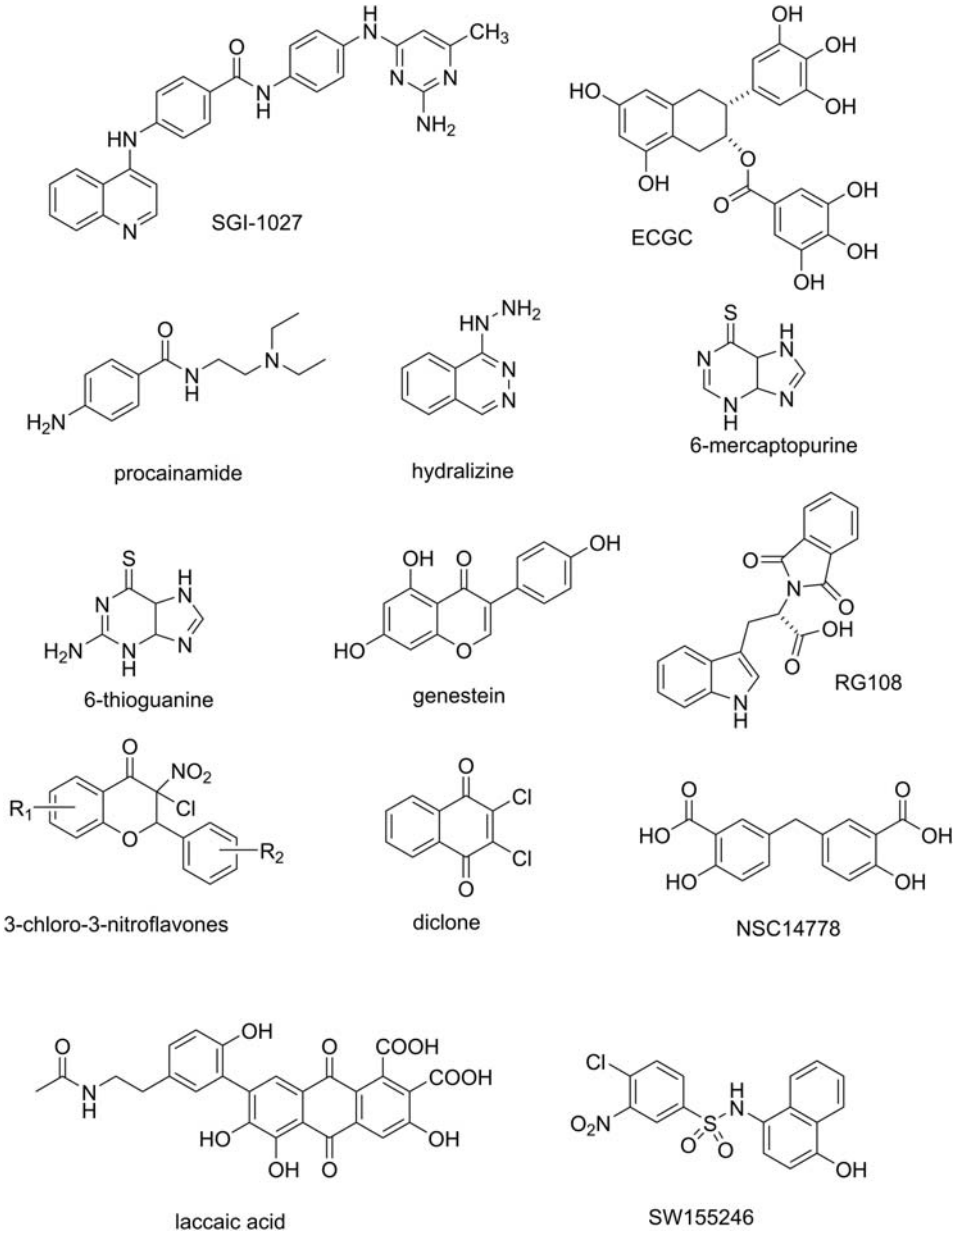

Fig. 3 Nonnucleoside inhibitors of DNMTs.

octamer, forming a structure known as a nucleosome (Fig. 4). As part of this structure, charged histone lysine tails protrude through the DNA strand and participate in the electrostatic binding of histones to DNA. Specific lysine and arginine residues on these histone tails become sites for chromatin PTMs, allowing for regional remodeling within higher order chromatin structure.[1]

As shown in Fig. 5, there are specific residues that undergo various PTMs, the most important of which are methylation at lysine and arginine, acetylation of lysine, phosphorylation of serine, and ubiquitination of histones H2A and H2B. The tail of histone H3 exhibits the highest number of PTM sites and can be methylated at R2, K4, K9, R17, R26, K27, K36, and K79 (K79 not shown); acetylated at K14, K18, and K23; and phosphorylated at S10 and S28. Histone H3 protein can also be methylated. The PTM sites on the tails of histones H4, H2A, and H2B are distinct from each other and from H4. It is notable that histones H2A and H2B can be ubiquinated.

2.12.3.2 Epigenetic Writers

2.12.3.2.1 Inhibitors of HATs

As stated earlier, histones can be posttranslationally modified by the addition of acetyl groups to lysine or by the addition of methyl groups to both lysine and arginine. These reactions are carried out by HATs or one of the several histone methyltransferases (KMTs),

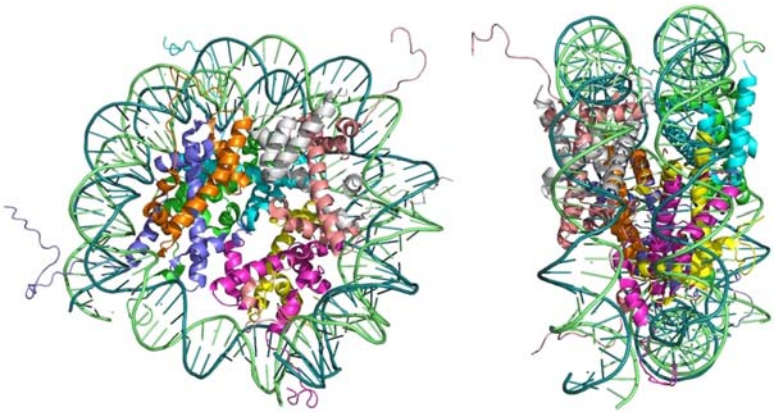

Fig. 4 The structure of the human nucleosome core particle in front and orthogonal views. Histone tails can be seen protruding from the histone proteins in the core. Adapted from Protein Data Bank structure PDB 3azh.

respectively. In the case of lysine acetylation, conversion of the terminal amino group of lysine to an amide serves two functions. Acetylation of the ε-amino groups of lysine cancels the positive charge, which allows DNA to assume a relaxed, transcriptionally accessible form (euchromatin).[1,7] This allows greater access to DNA by transcription factors and RNA polymerase and promotes regional gene expression. By contrast, deacetylation of histone lysine residues by HDACs restores the positive charge at ε-amino group, resulting in a densely packed form of chromatin (heterochromatin) that is transcriptionally inactive. Acetylated lysine residues also serve as recognition and binding sites for specific histone readers such as bromodomain-containing proteins (BCPs),[54,55] which will be discussed later in this chapter. The association of these reader proteins with an acetylated lysine on the histone tail also promotes transcription (Table 2).

Because nuclear-localized HATs acetylate a variety of nonhistone lysine residues,[56] they are more correctly referred to as lysine acetyltransferases (KATs). These enzymes are classified into five families based on structural homology and catalytic mechanism,[57,58] but only three of these constitute the major classes that are involved in chromatin remodeling: the GNAT superfamily (KAT1, KAT2A, KAT2B, and KAT9, formerly called HAT1, Gcn5, PCAF, and ELP3, respectively), the p300/CBP family (KAT3A and KAT3B, formerly called CBP and p300, respectively), and the MYST family (KAT5, KAT6A, KAT7, and KAT8, formerly called Tip60, MOZ, HBO1, and MOF, respectively).[59–62] These acetyltransferases can exhibit gene-specific or global effects on transcription, depending on their structure. They often participate in multisubunit protein complexes that determine substrate specificity. All KATs require acetyl CoA as a cosubstrate and despite having low sequence homology, they all exhibit a conserved acetyl CoA binding pocket.[57] The p300/CBP and GNAT family acetyltransferases appear to play a role in cancer, and elevated KAT activity has been observed in asthma and chronic obstructive pulmonary disease.[63] The levels of the acetyltransferase p300 have been suggested as biomarkers for prognosis in both lung and prostate cancers.[64,65] Mutations and/or deletions in the p300 or CBP genes

have been observed in several types of cancer and thus may play a role in tumorigenesis.[66–68] Acetyltransferases from the GNAT and MYST families have also been implicated in cancer through a variety of mechanisms, which have recently been reviewed.[62]

Only a handful of HAT inhibitors have been identified to date (**Fig. 6**) and were useful as chemical tools in delineating the enzyme mechanism and identifying the role of various KATs in cancer. These inhibitors are classified as bisubstrate analogs, natural products, or synthetic small molecules.[69] Lau et al. described the synthesis and application of a bisubstrate adduct between lysine and acetyl CoA, a potent ($IC_{50} = 500$ nM) and selective ($\sim$200-fold) bisubstrate inhibitor of KAT3B that displayed an unusual catalytic mechanism.[70] Interestingly, addition of a 20-mer peptide analogous to the sequence of the H3 lysine tail produces a compound that is selective for KAT2A ($IC_{50} = 300$ nM) and KAT2B over KAT3B.[71] A number of natural products such as curcumin (KAT3B inhibitor), garcinol (KAT3B inhibitor), and anacardic acid (nonselective KAT inhibitor) act as micromolar inhibitors of KATs.[63] Small molecule synthetic analogs of these natural product KAT inhibitors were also found to inhibit KATs. The most notable derivatives of anacardic acid reported by Eliseeva et al., which feature long-chain fatty acid moieties, produced HAT inhibition that correlates with its antiproliferative effects, and caused H4 hypoacetylation in MCF7 cells in vitro.[72] In addition, isothiazolone derivatives have been shown to inhibit the GNAT family acetyltransferase KAT2B,[73] while α-methylene-γ-butyrolactones described by Biel et al. have been shown to inhibit the GNAT family acetyltransferase KAT2A.[74] Gao et al. discovered the KAT3B inhibitor C646, which

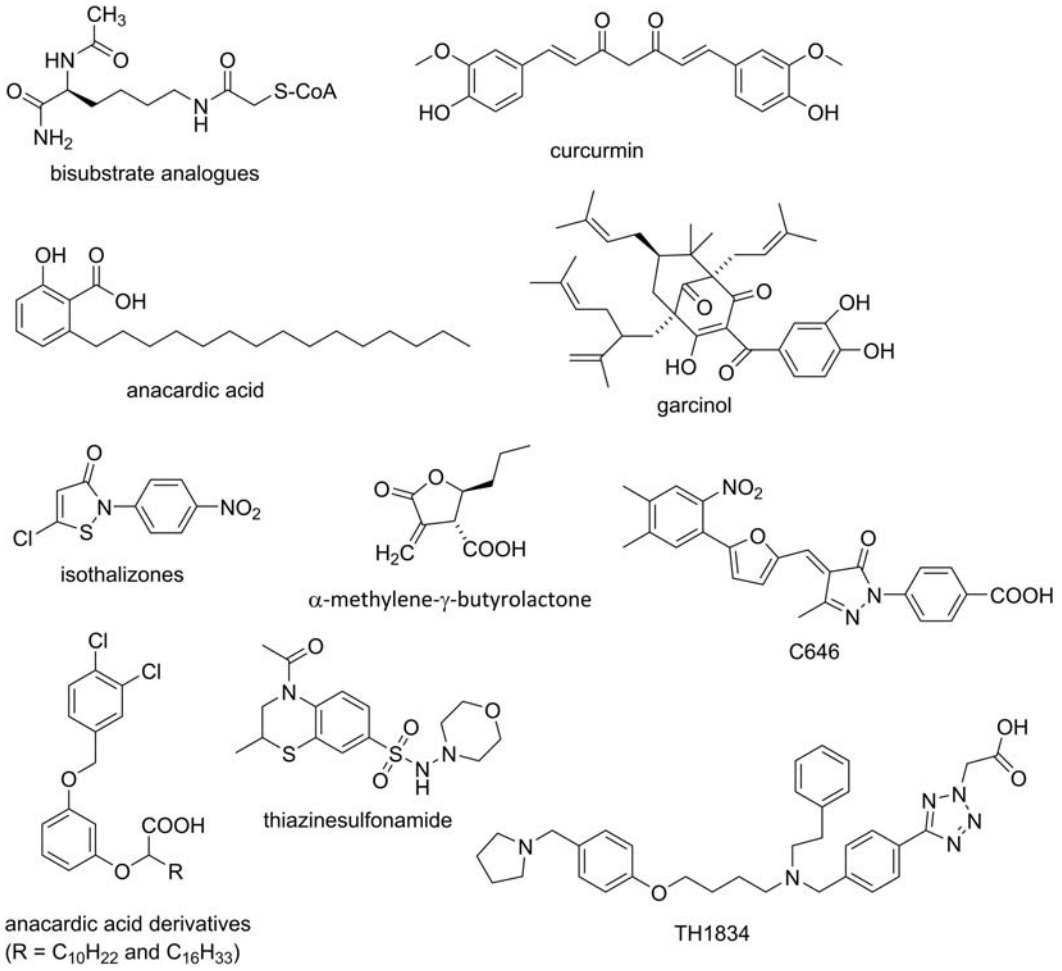

Fig. 6 Known inhibitors of histone acetyltransferases.

induces cell cycle arrest and apoptosis in AML1-ETO-positive acute myelocytic leukemia.[75] Finally, an inhibitor of KAT5 was recently reported[76] (TH1834) that reduced KAT5 activity by 60% at 500 μM.

2.12.3.2.2 Inhibitors of histone methyltransferases (KMTs and protein arginine methyltransferases, PRMTs)

Lysine residues on histone tails undergo methylation of the ε-nitrogen at specific histone lysine and arginine chromatin marks.[7,77] There are six lysine residues (histone 3 lysine 4, H3K4; H3 lysine 9, H3K9; H3K27; H3K36; H3K79; and H4K20) and five arginine residues (H3R2, H3R8, H3R17, H3R26, and H4R3) on histone protein tails that have been shown to undergo methylation[73] catalyzed by more than 50 lysine methyltransferases (KMTs)[78–80] and 11 PRMTs.[77,81,82] All KMTs and PRMTs require SAM as methyl donor and produce the by-product *S*-adenosylhomocysteine (SAH), which is recycled through salvage pathways. Histone KMTs generally target a specific lysine residue and can promote or repress transcription, depending on the lysine residue involved.[79,83,84] The eight classes of histone KMTs involved in chromatin remodeling include seven SET1 domain KMTs, five SET2 domain KMTs, six KMTs in the SUV39 group, EZH1 and 2, three KMTs in the PRDM group, four KMTs in the other-SET group, and one non-SET domain KMT.[85] Except for the nonSET KMT hDOT1L, all histone KMTs contain a conserved 130 amino acid SET (SU(VAR)3–9, enhancer-of-Zeste, Trihorax) domain that catalyzes the methyl transfer.[80,86,87] As shown in **Fig. 7A**, histone KMTs catalyze the stepwise conversion of unmethylated histone lysines to the mono-, di-, and trimethylated forms. There are also two separate groups of PRMTs, five Type I PRMTs and four Type II PRMTs. Type I PRMTs methylate arginine to produce *N*-monomethyl arginine (**Fig. 7B**). From there, a second methyl group can be added to the same carbon to form gem-*N*,*N*-dimethylarginine, or a Type II PRMT can methylate the second arginine nitrogen. Importantly, aberrant methylation of histone arginines and lysines is linked to carcinogenesis[88,89] and possibly to coronary disease.[90]

Although efforts to identify histone KMT and PRMT inhibitors are in early stages, a number of promising compounds have been discovered. Most of these histone methyltransferase inhibitors compete with either SAM or the histone substrate.

A large number of inhibitors of DOT1L has been reported by Epizyme,[91,92] of which the most noteworthy are EPZ04777 and EPZ5676 (**Fig. 8**). EPZ04777 is a potent, SAM-competitive inhibitor ($IC_{50} = 0.4$ nM) that selectively inhibits H3K79 methylation

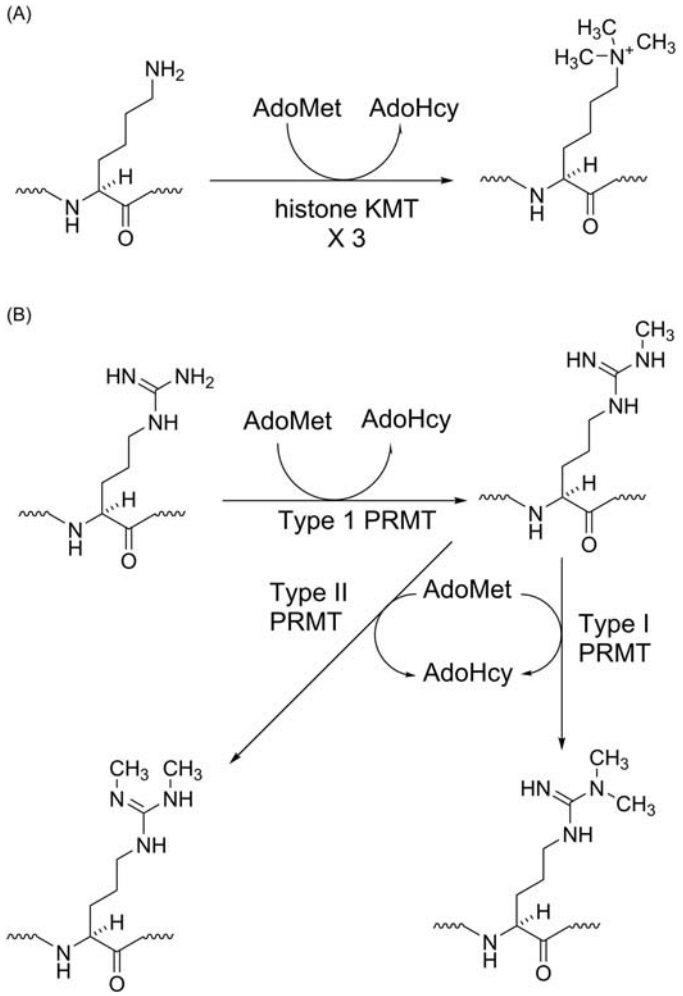

Fig. 7 The histone KMT and histone PRMT methylation reactions.

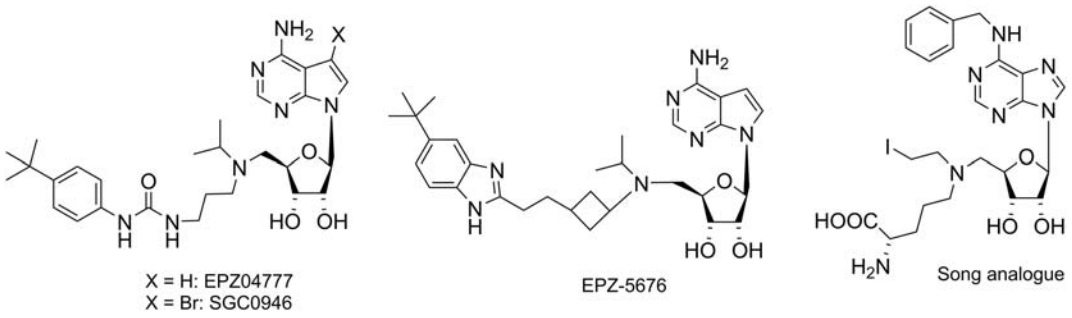

Fig. 8 Inhibitors of the KMT DOT1L.

and blocks expression of leukemogenic genes in MLL cells in vitro.[93] The efforts to improve the pharmacokinetic properties of EPZ04777 led to the synthesis of EPZ-5676 (pinometastat), a conformationally rigid analog of EPZ04777 that displayed improved potency ($K_i < 0.08$ nM) and selectivity for H3K79 (>37,000-fold).[94] A phase I clinical trial has been initiated for EPZ5676 to evaluate it as a therapy for acute leukemia bearing MLL-rearrangements. In an attempt to elucidate the mechanism, the 7-bromo analog of EP04777, SGC0946, was synthesized. SGC0946 is slightly more potent against DOT1L ($IC_{50} = 0.3$ nM, 100-fold selective), reduces H3K79 dimethylation, and selectively kills MLL cancer cells.[95] A series of inhibitors that resemble SAH were reported from Song's laboratory, and one of the most potent inhibitors, compound **10** ($IC_{50} = 38$ nM) reported by Yao et al., showed weak/no activity against other KMTs or PRMTs.[96] More recently, surface plasmon resonance was used to identify DC-L115, which exhibits an IC_{50} of 1.5 μM against DOT1L and selectively inhibits MLL-rearranged cell proliferation (IC_{50} 37.1 μM).[97]

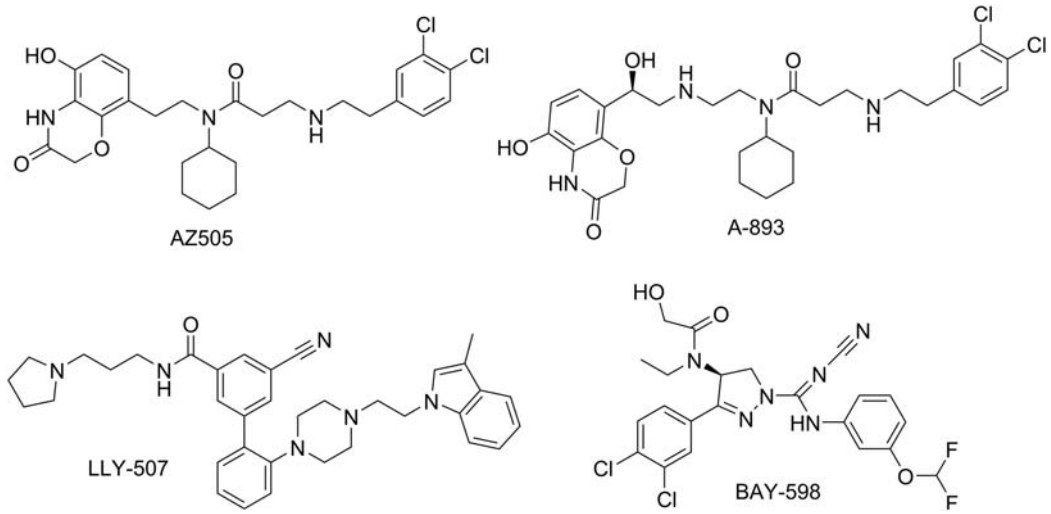

Fig. 9 Inhibitors of the KMT SMYD2.

AZ505 (Fig. 9) acts as a potent ($IC_{50} = 0.12$ μM) and selective inhibitor of SMYD2, the oncogenic protein that represses the functional activities of tumor suppressors such as p53 and Rb.[98] A cocrystal of SMYD2 with AZ505 showed that it is a substrate competitive inhibitor of the enzyme. Sweis et al. then developed AZ505 analogs with improved activity, including A-893, which exhibited an IC_{50} of 2 nM against SMYD2 and suppressed p53K570 methylation in the A549 lung carcinoma line. The compound known as LLY-507 (Fig. 9) acts as a potent and selective inhibitor of SMYD2, with an IC_{50} of 15 nM and 100-fold selectivity over the related family members, SUV420H1 and SUV420H2.[99] Most recently, the SMYD2 inhibitor BAY-598 was developed, which exhibits an IC_{50} of 27 nM against SMYD2 and can enhance the activity of doxorubicin in vivo.[100]

The mycotoxin chaetocin (Fig. 10) reported by Greiner et al. inhibits the KMT Su(var)3–9 from *Drosophila* ($IC_{50} = 0.8$ μM) and produces antitumor effects in vivo.[101] More recently, it was demonstrated that chaetocin causes a 25-fold induction of latent HIV-1 expression without activation of T-cells, suggesting that it may be useful in clearing latent HIV from infected cells.[102] The compound BIX-01294 reported by Kubicek et al. inhibits the G9a KMT and produces a reduction in histone H3K9 dimethylation (but not mono- or trimethylation) in several cell lines.[103] BIX-01294 and its homologs also exhibit potent antimalarial activity in both chloroquine-sensitive and -resistant strains, an effect that is mediated through histone KMT inhibition.[104] Liu et al. reported UNC0224 (Fig. 10), a potent G9a inhibitor with an IC_{50} of 15 nM. Structure-based lead optimization of UNC0224 led to the

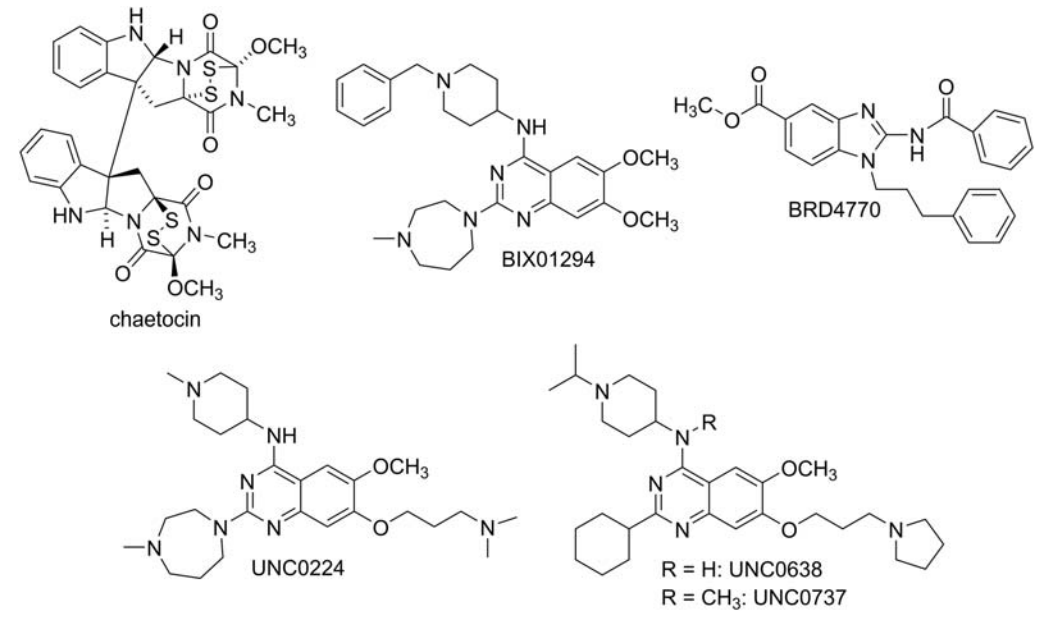

Fig. 10 Inhibitors of the KMT G9a.

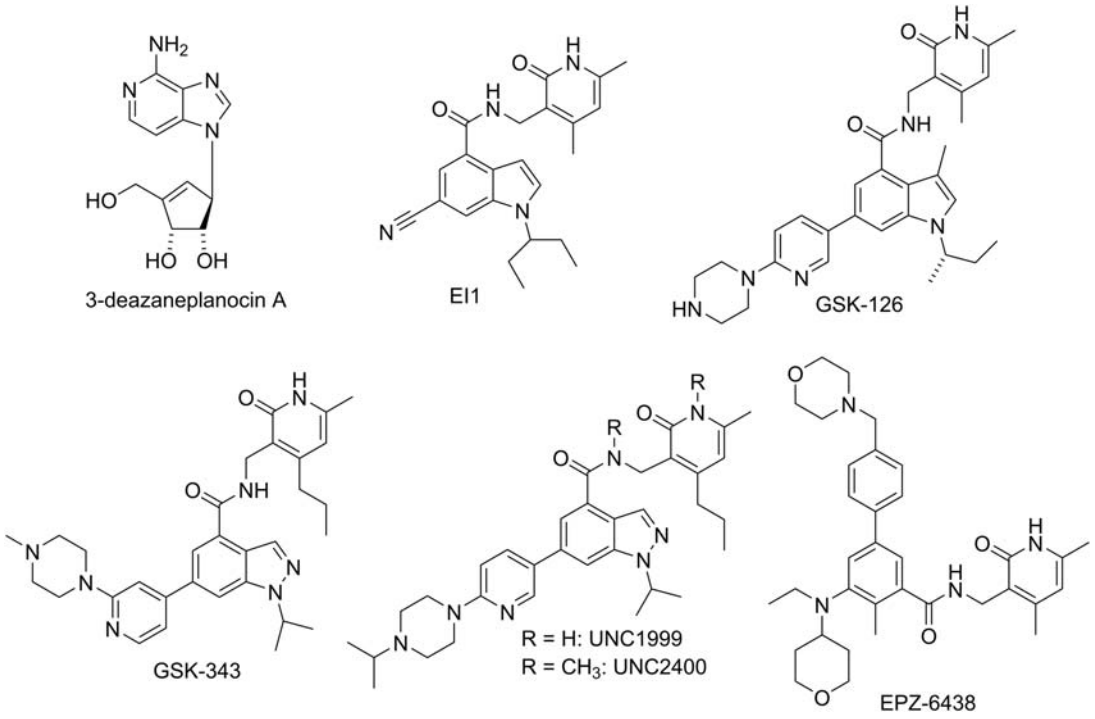

Fig. 11 Inhibitors of the KMT EZH2.

discovery of UNC0638 (R = H), a potent (IC_{50} for G9A = 15 nM and for GLP = 19 nM) inhibitor of histone KMTs G9a and GLP with excellent selectivity compared to numerous epigenetic and nonepigenetic targets.[105] Structure/activity studies revealed that conversion of the molecule to UNC0737 (R = CH_3) destroys the inhibitory activity of the analog, suggesting that H-bonding between Asp 1083 of G9a and the aminoquinazoline moiety in UNC0638 is required for binding to the active site of G9a. The purine analog BRD4770 (Fig. 10) inhibits the histone KMT G9a and induces senescence in pancreatic adenocarcinoma cells in vitro.[106]

EZH2 plays a significant role in a multitude of cancers including prostate, breast, and bladder, and thus became a target for the discovery of specific inhibitors. The EZH2 inhibitor 3-deazaneplanocin A (Fig. 11) depletes EZH2 levels while inhibiting the formation of K3K27me3 in acute myeloid leukemia (AML) cells.[107] Significant depletion of EZH2 activity was observed in cultured AML cells when 3-deazaneplanocin A was combined with panobinostat, a pan-HDAC inhibitor.[107] It was also reported that 3-deazaneplanocin A as a single agent inhibits tumor cell growth in nonsmall cell lung carcinoma in vitro through induction of a G1 cell cycle arrest.[108] Qi et al. carried out high-throughput screening against a recombinant PCR2 protein complex containing EZH2 that eventually resulted in the design of El1 (Fig. 11). This compound elicited potent inhibitory activity against both wild-type (IC_{50} = 15 nM) and Y641F mutant enzymes (IC_{50} = 13 nM).[109] In addition to being highly selective for EZH2 when compared with EZH1 (90-fold selectivity) or other HMTs (10,000-fold selectivity), EI1 inhibits H3K27 methylation, reduces cell proliferation, and initiates cell cycle arrest and apoptosis.

Based on a combination of high-throughput screening and subsequent lead optimization, McCabe et al. identified a series of novel, SAM-competitive indole-based EZH2 inhibitors.[110] The representative compound GSK-126 (Fig. 11) inhibited both wild-type and mutant EZH2 with similar potencies ($K_i^{app} = 0.5 - 3.0$ nM) and displayed 1000-fold selectivity over other methyltransferases and 150-fold selective over EZH1.[110] In addition, GSK-126 inhibited the proliferation of EZH2 mutants in both diffuse large B-cell lymphoma cell lines and xenografts. Through structural modification, Verma et al. discovered GSK-343 ($K_i^{app} = 1.2$ nM), in which an indazole moiety is substituted for the indole in GSK-126.[111] Both compounds GSK-126 and GSK-343 decreased H3K27me3 levels in a dose-dependent manner. Despite GSK-343 being more potent, it was precluded from advancement to clinical studies due to high clearance as suggested by rat pharmacokinetic studies.[111] Konze et al. later disclosed UNC1999, an orally bioavailable, SAM-competitive inhibitor that exhibited high in vitro potency (IC_{50} 45 nM) for wild-type and mutant EZH2 as well as the closely related H3K27 methyltransferase EZH1. UNC1999 potently reduced H3K27me3 with an IC_{50} of 124 nM in MCF7 cells. Interestingly, the close homolog UNC2400, in which a pair of N-methyl groups was added to UNC1999, was 1000-fold less potent than UNC1999 and did not show any activity in cell preparations. All of the compounds shown in Fig. 11 are in preclinical (3-deazaneplanocin, EI1, GSK-343, and UNC1999) or Phase I (GSK-126) clinical trials.

Through a combination of screening and iterative medicinal chemistry, Knutson et al. designed a novel class of pyridine-based EZH2 inhibitors. The SAM-competitive inhibitor EPZ6438 (tazemetostat, Fig. 11) displayed a K_i value of 2.5 nM and a selectivity index of 35-fold over EZH1 and >4500-fold over other PMTs.[112] EPZ6438 inhibited H3K27me3 levels leading to specific killing of

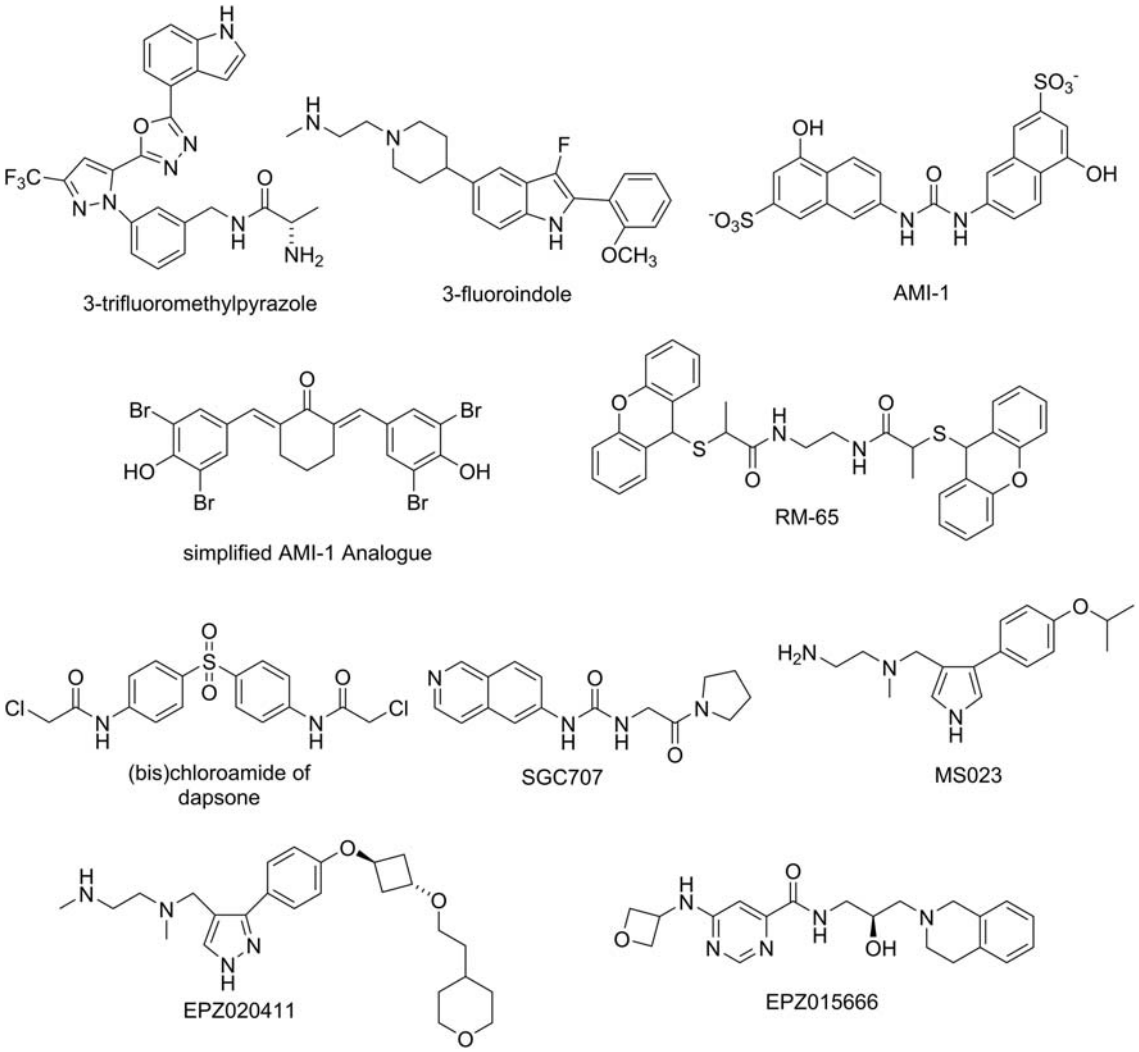

Fig. 12 Selected inhibitors of arginine methyltransferases (PRMTs).

lymphoma cell lines. Epizyme recently initiated a Phase I/II clinical trial to evaluate EPZ6438 as a treatment for nonHodgkin lymphoma in patients with EZH2 SET domain mutants.

A number of groups are involved in the design and synthesis of selective histone PRMT inhibitors (Fig. 12). A high-throughput screening using full-length coactivator-associated arginine methyltransferase 1 (CARM1, PRMT4) followed by hit-to-lead optimization results in a 3-trifluoropyrazole (Fig. 12) with an IC_{50} of 27 nM.[113] A 3-fluoroindole derivative was also identified with an IC_{50} of 30 nM against CARM1. Both compounds exhibited selectivity indices of >300-fold against PRMT1 and 3.[113] X-ray crystallography showed that the 3-fluoroindole analog occupies the substrate-binding pocket and the high selectivity arises from sequence differences between PRMT4 and PRMT1/3. A random screen of a compound library carried out by Cheng afforded nine PRMT inhibitors with structures related to AMI-1 ($IC_{50}=8.81$ μM).[114] Further studies have shown that AMI-1 is selective for PRMT over KMT and produced an in vivo effect on arginine methylation.[114] Subsequent studies revealed structure-optimized analogs with increased potency against PRMT1 and PRMT4 that modulated T-helper cell cytokine production.[115] Analogs of AMI-1 bearing 2-bromo- and 2,6-dibromophenol moieties linked through unsaturated cyclic spacers, such as the simplified AMI-1 analog shown in Fig. 12, equally inhibited PRMTs, HKMT, HAT, and SIRTs, thus behaving as multiple ligands for these epigenetic targets.[116] A related series of linear and cyclic urea analogs produced modest inhibition of PRMT1 and PRMT5.[117] Using a combination of pharmacophore-based virtual screening methods and radioactive methylation assays, Wang et al. identified compounds A9 and A36, which disrupted PRMT1 function by directly targeting the substrate H4 and that were more effective than AMI-1.[118] Dillon et al. used a high-throughput screening approach to identify two novel inhibitors selective for PRMT1 over other SAM-requiring protein methyltransferases.[119] Spannhoff et al. conducted a focused virtual screening of 9000 compounds and a subsequent optimization of a hit molecule that resulted in compound RM-65. This compound inhibited PRMTs RmtA ($IC_{50}=46$ μM) and PRMT1 ($IC_{50}=55$ μM) without affecting lysine methyltransferase SET7/9. In silico docking experiments suggested that RM-65 acts as a bisubstrate mimic occupying

both the arginine and SAM binding pockets.[120] Acylated derivatives of *p*-aminobenzenesulfonamides and the antileprosy drug dapsone also act as inhibitors of PRMT1.[121] The (bis)chloroacetyl amide of dapsone (Fig. 12) selectively inhibited human PRMT1 (IC_{50} 1.5 μM) and was selective for PRMT1 over the arginine methyltransferase CARM1 and the lysine methyltransferase Set7/9.[121] It also showed anticancer activity in MCF7a and LNCaP cells in vitro and blocked androgen-dependent transcription specifically in a reporter gene system.

The allosteric inhibitor SGC707 was shown to inhibit PRMT3 with an IC_{50} of 31 nM[122] but did not inhibit members of a panel of 27 protein methyltransferases. In an A549 cell preparation, SGC707 was able to reduce H4R3me2 with an EC_{50} of 225 nM. X-ray crystallographic studies of the complex between SGC707 and PRMT3 suggest that the inhibitor occupies a cavity >15 Å from the enzyme active site. EPZ020411 (Fig. 12) inhibits PRMT6 with an IC_{50} of 10 nM and exhibits good selectivity (>10-fold) against PRMT1 and 8.[123] In cellular assays, EPZ020411 produced a dose-dependent decrease of H3R2me2 (EC_{50} 640 nM). In contrast to the enzyme-specific inhibitors described earlier, MS023 is a pan-inhibitor of type I PRMTs.[124] It was designed based on the structures of the 3-trifluoromethylpyrazole PRMT4 and the PRMT6 inhibitor EPZ020411. MS023 exhibited an enzyme IC_{50} of 30, 119, 83, 4, and 5 nM against PRMT1, 3, 4, 6, and 8, respectively. Treatment of MCF7 cells with MS023 significantly decreased levels of H3R2me2 and H4R3me2 with EC_{50} values of 56 and 9 nM, respectively. Remarkably, if the primary nitrogen of MS023 is converted to a hydroxyl, then the resulting compound, MS094, is inactive against PRMTs. EPZ015666 acts as a potent and selective inhibitor of PRMT5 (IC_{50} = 22 nM)[125] and exhibited potent antiproliferative activity against Z-138 mantle cell lymphoma cell lines Z-138 and Maver-1 (EC_{50} = 96 and 450 nM, respectively). This potent cellular activity likely occurs because PRMT5 is dramatically overexpressed in this type of tumor. EPZ015666 also possessed in vivo antitumor activity in xenograft mouse models involving the Z-138 and Maver-1 cell lines.

2.12.3.3 Epigenetic Erasers

2.12.3.3.1 HDACs

As mentioned above, the acetylation status of histones is controlled by a balance between two enzymes, HAT, which promotes histone hyperacetylation, and the HDAC, which catalyzes acetyl group cleavage. Acetylation of the ε-amino groups of lysine residues located at N-termini removes the positive charge and loosens the tightly wound chromatin.[7,52,126] This allows greater access to DNA by transcription factors and RNA polymerase and promotes the expression of various transcriptional products. By contrast, transcriptional repression dominates at times when DNA methylation occurs at promoter CpG islands. Methylation of DNA results in the recruitment of HDACs and subsequent deacetylation of lysine tails restores the positive charge and thus promotes formation of closed chromatin (Fig. 13). The recruitment of HDAC activity by DNA methylation is an important event in epigenetic silencing.[127] Normal mammalian cells exhibit an exquisite level of control of chromatin architecture in part by maintaining a balance between HAT and HDAC activities. There are currently 11 known mammalian HDAC isoforms that can be divided into three structural classes: Class I HDACs[128] include HDAC isoforms 1, 2, 3, and 8. Class I HDAC proteins are characterized by a highly conserved catalytic site sequence homology and have molecular weights between 42 and 55 kDa. They contain a nucleus localization sequence (NLS) in addition to their catalytic domain. These enzymes catalyze histone deacetylation by a zinc-dependent mechanism.[129] Class II HDACs include HDACs 4, 5, 6, 7, 9, 10, and 11[130] and are characterized by their sequence homology in both the C-terminal catalytic domain and the N-terminal regulatory domain. Class II HDACs have molecular weights between 120 and 130 kDa and are also zinc-dependent deacetylases. Class II HDACs are further divided into Class IIa (HDAC 4, 5, 7, and 9), which feature an NLS, and Class IIb (HDAC 6 and 10), which lack an NLS, but feature a second catalytic domain that is active in HDAC6, but does not function in HDAC10. HDAC6 can also acetylate tubulin and contains a C-terminal zinc finger that has a very high affinity for free ubiquitin and ubiquitinated proteins. Structural comparisons among different Class I and II HDACs, as well as HDAC homologs from different species that share significant homology with human classical HDACs, reveal a conserved group of active site residues, suggesting a common mechanism for the metal-dependent hydrolysis of acetylated substrates. Class IV contains a single HDAC, 11, which is similar in size to Class I HDACs, but has low sequence homology. The Class III HDACs were identified based on their similarity to the NAD-dependent yeast transcriptional repressor protein Sir2.[131–133] Unlike Class I and II HDACs, Class III HDACs, which have not been well characterized in mammalian systems, do not require zinc and as such are unresponsive to known HDAC inhibitors (see below). Class III HDACs use NAD^+ as a reactant to deacetylate acetyl lysine residues of protein substrates forming nicotinamide, the deacetylated product, and the metabolite 2′-*O*-acetyl-ADP-ribose.

Overexpression of HDACs correlates positively with tumor growth by promoting silencing or abnormal transcription of crucial genes that control cell cycle regulation, apoptosis, DNA repair, and chromatin structure.[134] The irregularity in HDAC function thus contributes to the initiation and progress of several tumors. In some tumor cell types, excessive hypoacetylation of histones results in the under-expression of growth regulatory factors such as the cyclin-dependent kinase inhibitor $p21^{Waf1}$ and thus contributes to the development of cancer. Specific mutations can result in hypermethylation of DNA and formation of aberrant transcriptional proteins that recruit HDAC's, resulting in excessive deacetylation of lysine residues on histone tails. As a result, chromatin is condensed and transcription is repressed, causing inactivation of the tumor suppressors including $p21^{Waf1}$.[135] These results are typically seen in addition to a variety of cell signaling aberrations that occur in response to excessive histone deacetylation. These changes have the potential to produce a malignant phenotype resulting from a combination of genetic abnormalities and epigenetic modifications leading to dysregulation of critical genes controlling cell proliferation, differentiation, and death. These changes include modification of the histone code, including changes in histone acetylation, and alteration in DNA methylation patterns. Considerable data highlight the important role that methylation of cytosine residues in promoter regions plays in the

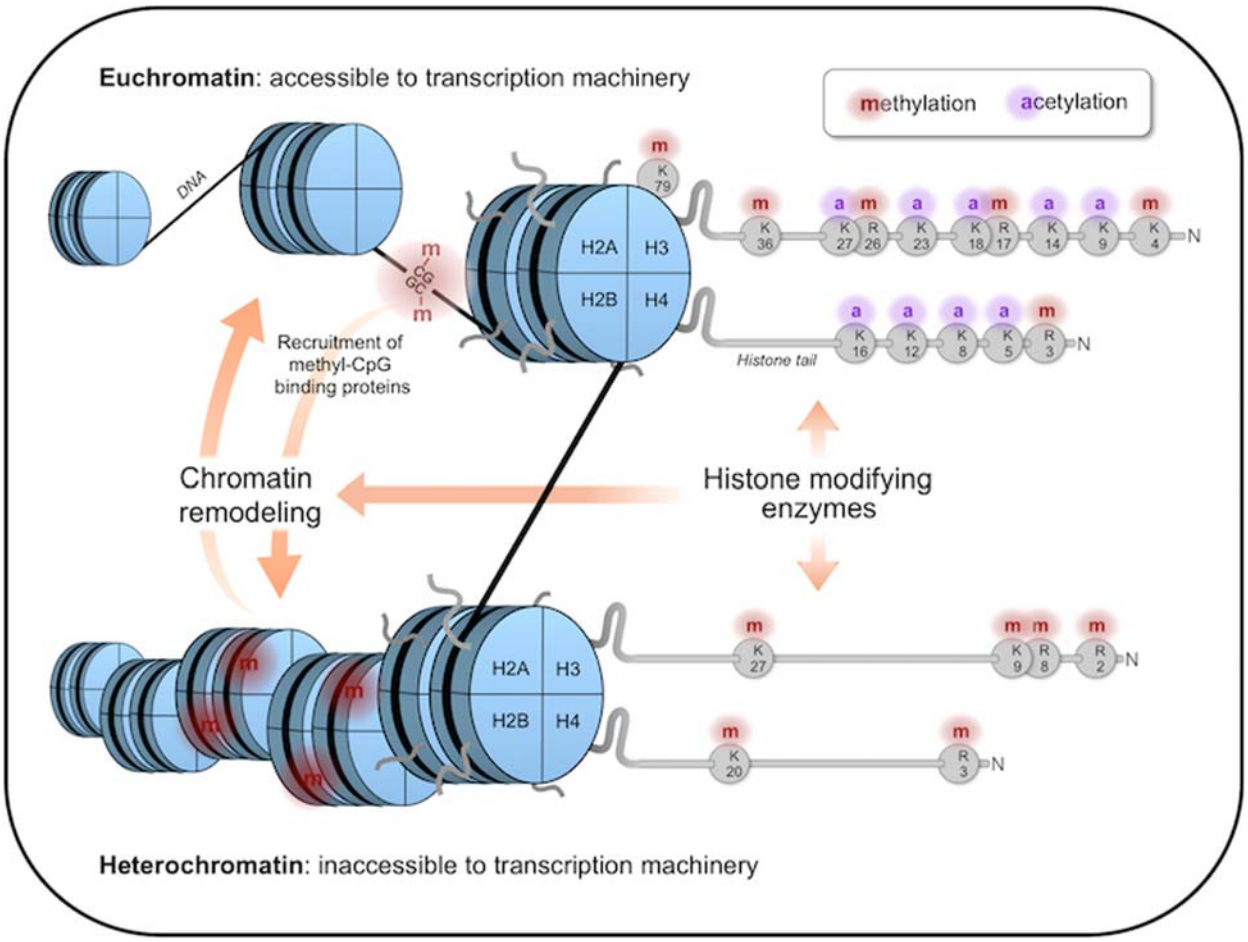

Fig. 13 Epigenetic regulation of gene expression wherein DNA alternates between euchromatin and heterochromatin via histone modifying enzymes. https://fortyfourandtwo.net/2016/08/08/the-chromatin-code.

transcriptional silencing of genes.[136] HDAC inhibitors suppress histone deacetylation and enhance gene expression by promoting the formation of euchromatin and reversing gene silencing.

Histone hyperacetylation caused by HDAC inhibitors such as trichostatin, MS-275, and SAHA (Fig. 14) can cause growth arrest in a wide range of transformed cells and can inhibit the growth of human tumor xenografts.[135,137–139] HDAC inhibitors restore normal cell cycle and apoptotic functions in human tumor cells. Known HDAC inhibitors fall into distinct structural classes (Fig. 14) including hydroxamic acids, benzamides, short-chain carboxylic acids, and cyclic peptides. A current effort in the design of additional HDAC inhibitors is the discovery of isoform-specific HDAC inhibitors. Such molecules would be of great value as chemical tools for elucidating the roles of HDAC isoforms in both normal and cancer cell lines.

Recent clinical studies have demonstrated that synergistic reexpression of genes that are silenced through promoter methylation can be achieved by the sequential application of DNMT inhibitors and HDAC inhibitors, resulting in an enhanced response to antitumor therapy.[140,141] However, clinical experience with MS-275 and other HDAC inhibitors demonstrate that step-down dosing of the HDAC inhibitors is often required to minimize toxicity. Consequently, effective HDAC inhibitors having minimal toxicity on their own may provide excellent candidates for combination with demethylating agent like 5-AC and 5-aza-2′-deoxycytidine.

There are thousands of papers that describe the efforts to develop HDAC inhibitors with enhanced efficacy, improved pharmacokinetic profiles, and significant isoform specificity. As such, a comprehensive review of HDAC drug discovery research is beyond the scope of this article, and therefore this article will focus on novel HDAC inhibitors published since 2010. Cho et al. synthesized a series of pyridone-based hydroxamic acids and evaluated the HDAC inhibition profile of the resulting compounds.[142] The most promising of these analogs (Fig. 15) produced potent HDAC inhibition (IC_{50} 0.07μM) and was highly selective for HDAC1 (Class I) and HDAC6 (Class II) enzymes. Using the conventional HDAC pharmacophore model, Marek et al. designed LMK235, which inhibited HDAC with an IC_{50} of 0.65 μM), a value comparable to vorinostat ($IC_{50}=0.53$ μM) against global cellular HDACs. LMK235 was also more cytotoxic to the human cancer cell lines A2780, Cal27, Kyse510, and MDA-MB231 than vorinostat[143] and produced a synergistic antitumor effect when combined with cisplatin. LMK235 exhibited a novel HDAC isoform selectivity profile and produced nanomolar inhibition of HDAC4 ($IC_{50}=12$ nM) and HDAC5 ($IC_{50}=4$ nM). It was also metabolically stable

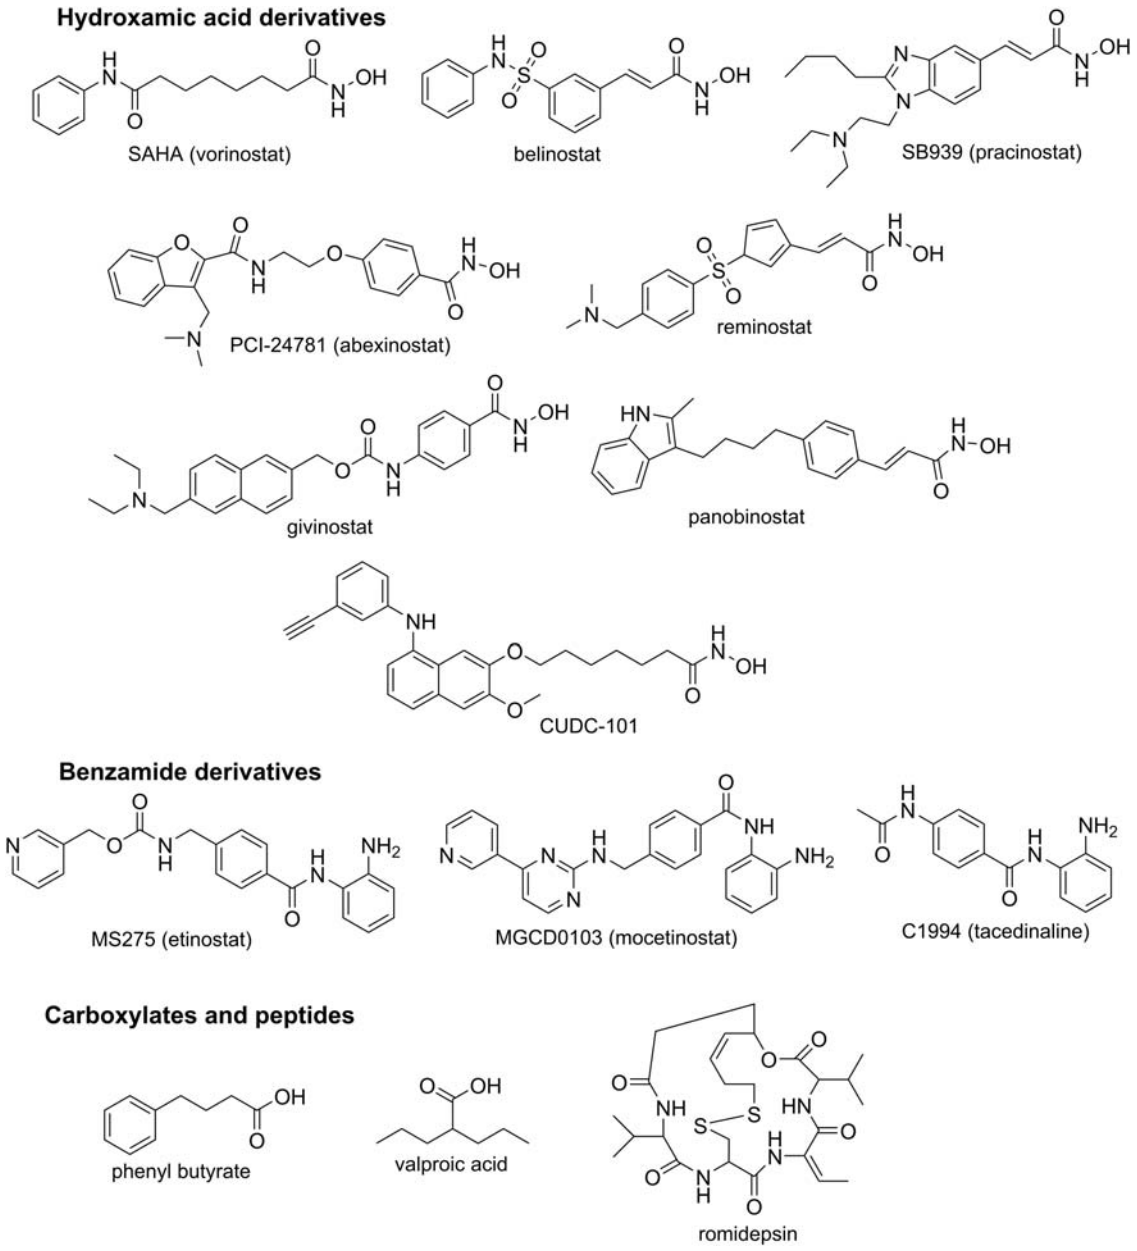

Fig. 14 HDAC inhibitors that are currently marketed or in human clinical trials.

in mouse liver microsomes and produced growth inhibition of various cancer cell lines. Giannini et al. described ST7612AA1, a thioacetate-ω(γ-lactam carboxamide) derivative that had an IC_{50} value of 70 nM against NCI-H460 lung cancer cells in vitro, was orally active and metabolically stable, and was more effective than carboplatin in limiting tumor volume in a xenograft model.[144] The benzamide MC2392 was found to induce caspase-8-dependent cell death accompanied by RIP1 induction and production of reactive oxygen species. Solid tumors and leukemia did not respond to MC2392, but in the presence of the PML-RARα repressive complex, it initiates cell death. The authors suggest a model in which MC2392 binds to the RARα moiety and inhibits the HDACs that are components of the repressive complex responsible for the transcriptional impairment in acute promyelocytic leukemia, suggesting a context-dependent targeted therapy.[145] There are numerous additional examples of novel HDAC inhibitors; the reader is directed to an excellent review on the subject.[139]

Although initially designed as antitumor agents, HDAC inhibitors are finding utility in a variety of noncancer disease states. By way of example, the HDAC3-selective inhibitor RGFP966 ($IC_{50} = 80$ nM) was found to persistently reduce cocaine-seeking behavior.[146] HDAC inhibitors can also cause increases in glucocerebrosidase activity in Gaucher's disease by modulating the levels of molecular chaperones. Other treatment applications for HDAC inhibitors include liver and kidney fibrosis,[147] encephalomyelitis,[148] stroke and neuroprotection,[149] Huntington's disease,[150] and a host of other applications. The NAD^+-dependent

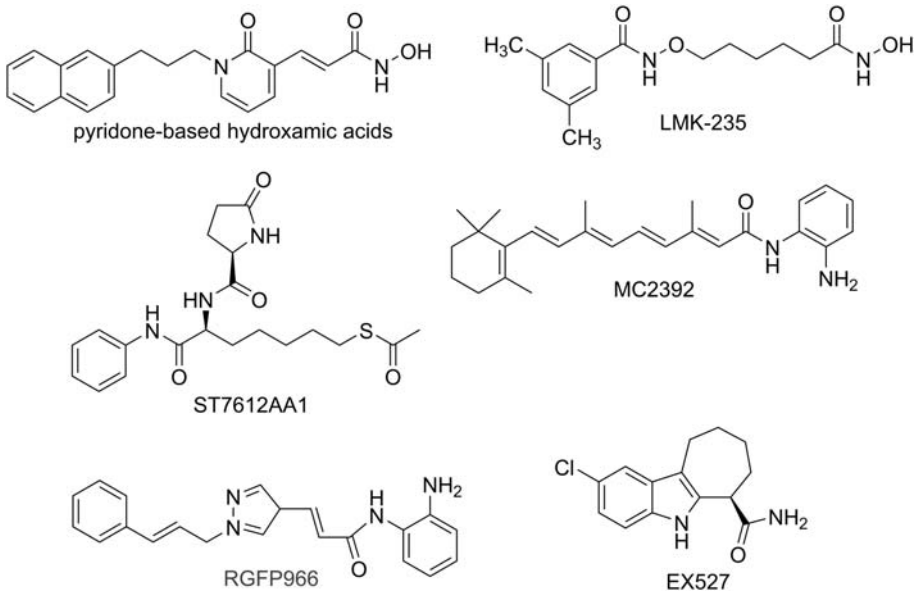

Fig. 15 Recent examples of novel HDAC inhibitors.

deacetylase SIRT1 regulates transcription via deacetylation of transcription factors such as PPARγ, NFκB, and the tumor suppressor protein p53. In the 2.5 Å crystal structure of the SIRT1 catalytic domain (residues 241–516) bound to NAD^+, EX527 ($IC_{50}=98$ nM) binds deep in the catalytic cleft, where it displaces NAD^+ and forces it into an extended conformation that sterically prevents substrate binding,[151] thus defining a novel mechanism of HDAC inhibition. Yu has identified a hydroxamate-based inhibitor of HDAC6 that is not toxic to cancer cells, but may serve as a lead for the treatment of sepsis or inflammation, since it produced a 40% improvement in survival in a lipopolysaccharide-induced mouse model of endotoxemia.[152] Recent research suggests that HDAC6 may play a significant role in a number of cellular processes. Ellis has demonstrated that HDAC6 may represent an optimal target for future immunosuppressant therapeutics with a particular role in organ transplantation.[153]

2.12.3.3.2 Histone demethylases (KDMs)

2.12.3.3.2.1 Histone lysine demethylases

Histone lysine and arginine methylation, formerly thought to be permanent PTMs, are not static modifications. This was validated when it was discovered that removal of methyl groups from H3K4 mono- and dimethyllysines was catalyzed by LSD1, (aka BHC110 or KDM1A) in a complex where it is associated with the CoREST protein.[21] Since histone 3 dimethyllysine 4 (H3K4me2) is a key chromatin mark found associated with promoters of active genes,[154,155] oxidative demethylation of histone 3 methyllysine 4 (H3K4me1) and H3K4me2 by LSD1 is associated with transcriptional repression. Overexpression of LSD1 results in aberrant demethylation of this mark and therefore silences tumor suppressor genes important in human cancer.[22] In light of this observation, LSD1 has become a validated target for the development of a new class of antitumor drugs that mediate their effects through inhibition of LSD1.[156] Interestingly, when LSD1 associates with the androgen receptor rather than CoREST, it becomes a specific demethylase for H3K9me and H3K9me2.[157] In addition, inhibitors of LSD1 unlock the all-trans-retinoic acid (ATRA)-driven therapeutic response in nonAPL AML through epigenetic reprogramming, suggesting that LSD1 may contribute to AML pathogenesis by inhibiting the normal prodifferentiative function of ATRA and paving the way for new combinatorial therapies for AML. A distinct form of LSD1, which was termed LSD2 or KDM1B,[158,159] has the same substrate specificity, but does not bind to CoREST, because it lacks the requisite tower domain necessary for CoREST binding. LSD2 appears to play a distinct epigenetic role from LSD1.

It is important to understand that chromatin-modifying enzymes do not function independently but rather exist as components of histone-modifying epigenetic protein complexes. For example, the LSD1/CoREST epigenetic complex is comprised of HDAC1, HDAC2, BRAF30, CoREST, and BCH80, while the LSD1 NURD complex contains HDAC1, HDAC2, Mi2, MBD, RbAp, and MTA proteins.[160] A number of other LSD1-containing complexes exist, including LSD1-AR/ER, MLL-UTX, and PRC2-RBBP2, to name but a few. It has recently been shown that silencing of the human gene that codes for γ-globin, a component of fetal hemoglobin, is mediated by the DRED complex, which forms early in life and silences the γ-globin gene.[161] In light of the importance of these epigenetic complexes, it is likely that inhibition of a given enzyme within an epigenetic complex may lead to alterations in gene expression due to disassembly of the complex.

Since the discovery of LSD1 in 2004, a number of additional histone lysine demethylases (KDMs) have been identified. Histone demethylases are classified in one of the six families termed KDM1–KDM6, as shown in **Table 3**. A discussion of the histone lysine substrate specificity, the effects they have on gene expression, and the roles they play in cancer and other diseases has recently been reviewed.[162–164] Briefly, the KDM1 family, consisting of LSD1 and 2, are flavin-dependent amine oxidases that show specificity for

either H3K4 or H3K9. The catalytic mechanism for demethylation by LSD1 and 2 requires a protonated nitrogen moiety, and thus flavin-dependent histone demethylases can only demethylate monomethyl- and dimethyllysines. The histone demethylases in classes KDM2–KDM6 all utilize Fe(II) and 2-oxoglutarate cofactors and thus do not have the same substrate restriction.[165] They are able to demethylate the mono-, di-, and trimethylated forms of lysines H3K4, H3K9, H3K27, H3K36, and H1K26 on the histone tail. The 2-oxoglutarate-dependent histone demethylases are members of the Jumonji family; so named because they contain the JmjC (Jumonji) protein domain within their structure.[166] KDMs in classes 2–6 belong to six subfamilies termed JMJD1, JMJD2, JARID1, UTX/Y-JMJD3, PHF, and FXBL. However, to avoid confusion brought about by different names for each, the nomenclature is changed to KDM2–KDM6 enzymes (**Table 3**).

The KDM2 subfamily is comprised of two histone demethylases, KDM2A (JHDM1A, FBXL11)[167] and KDM2B (JHDM1B, FBXL10),[168] both of which are specific for H3K36me and H3K36me2, recognize unmethylated GpG island DNA, and target the polycomb repression system. The KDM3 subfamily contains three KDMs: KDM3A (JMJD1A, JH-DM2A, and TSGA),[169] KDM3B (JMJD1B, JHDM2B, and 5qNCA),[170] and KDM3C (JMJD1C, JHDM2C, and TRIP8).[171] The KDM3 subfamilies are specific for H3K9me and H3K9me2 and act as transcriptional activators. The KDM4 subfamily is comprised of KDM4A (JMJD2A and JHDM3A),[172] KDM4B (JMJD2B, JHDM3B),[173] and KDM4C (JMJD2C, JHDM3C, and GASC1).[174] KDM4s can demethylate H3K9me2 and H3K9me3, leading to the activation of transcription; or H3K36me2 and H3K36me3, leading to transcriptional repression. The KDM5s KDM5A, B, C, and D demethylate H3K4me2 and H3K4me3, leading to transcriptional repression, while KDM6A and B demethylate H3K27me2 and H3K27me3, promoting transcriptional activation.

It is now well established that H3K4 methylation mediated by LSD1 is one of the drivers in cancer initiation and progression. This observation has generated considerable interest in the design and development of novel LSD1 inhibitors for use as antitumor agents. These inhibitors can be broadly classified into at least four classes: (1) peptide-based inhibitors, (2) tranylcypromine (TCP) analogs, (3) oligoamines, and (4) other small molecule inhibitors.

Peptidic analogs of the 21 amino acid H3K4 substrate region of LSD1, aziridinyl-K4H3$_{1-21}$, propargyl-K4H3$_{1-21}$, and *N*-methylpropargyl-K4H3$_{1-21}$ (**Fig. 16**) were synthesized in an effort to identify novel active site-directed inhibitors of LSD1. The

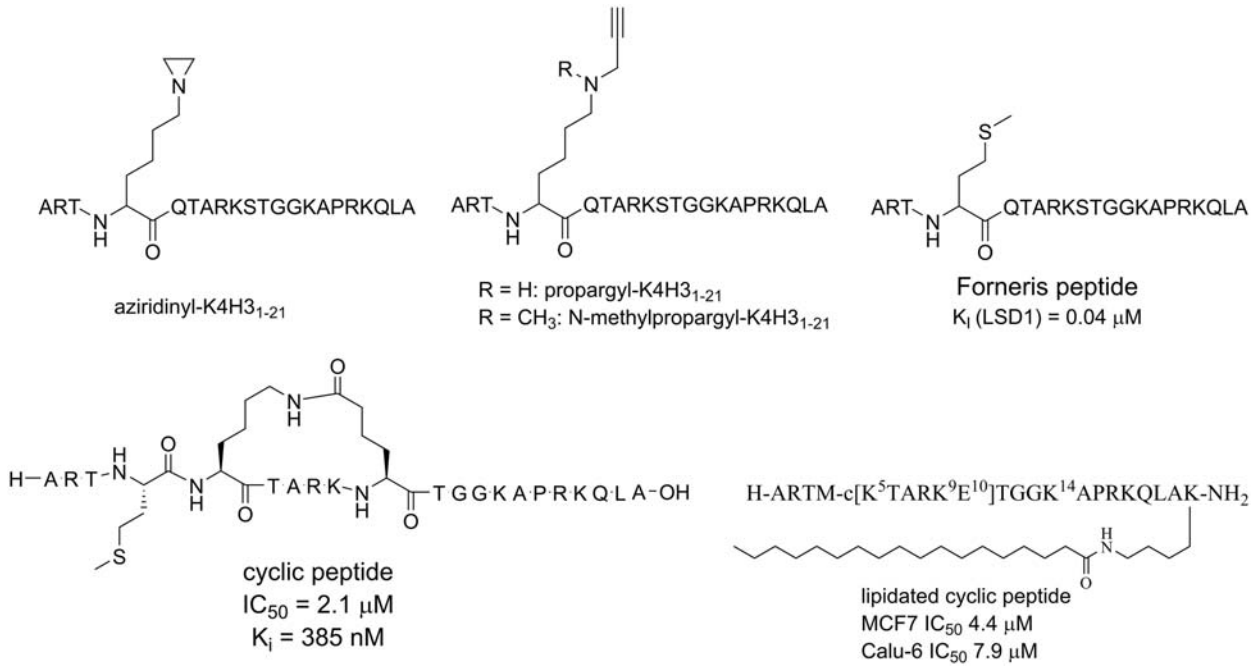

Fig. 16 Examples of peptide-based inhibitors of LSD1 (KDM1A).

aziridinyl derivative reversibly inhibited LSD1 with an IC_{50} of 15.6 μM, while propargyl-K4H3$_{1-21}$ produced time-dependent inactivation with a K_i of 16.6 μM.[175] The analogs propargyl-K4H3$_{1-21}$ and *N*-methylpropargyl-K4H3$_{1-21}$ were later shown to produce time-dependent inactivation of LSD1 through formation of a covalent adduct with the enzyme-bound flavin cofactor; thus these peptides were valuable as tools to elucidate the mechanism of LSD1.[176,177] Dancy et al. reported a number of peptide-based inhibitors that exhibited good LSD1 inhibition.[178] While these analogs acted as efficient probes to unravel the mechanism of LSD1, their poor bioavailability precluded their potential for further advancement.[178] Forneris et al. described a 21-mer peptide analogous to the H3K4 substrate region of LSD1, wherein Lys4 was replaced by a methionine. This linear peptide was a potent inhibitor of recombinant LSD1 with an K_i value of 0.04 μM and of LSD1 bound to CoREST with an K_i value of 0.05 μM.[179] The X-ray structure of this peptide bound to LSD1/CoRESt revealed that it assumed a cyclic orientation in the binding site. This crystal structure was used as a template to design cyclic peptide inhibitors of LSD1. Cyclic peptides are generally considered to be more stable against proteolytic enzymes than their linear counterparts[180] and can facilitate elucidation of bioactive conformations that are important for biological activity. Subsequently, a 21 amino acid cyclic peptide (Fig. 16) was synthesized and found to inhibit LSD1 with an IC_{50} of 2.1 μM and a K_i value of 385 nM.[181] This cyclic peptide was seven-fold more stable than the Forneris peptide in rat plasma. These cyclic peptides, although potent inhibitors of the purified enzyme, exhibited poor cell penetration. A lipidated version of the most active cyclic peptide (Fig. 16) retained the potency of the parent against the enzyme and had good antitumor activity in MCF7 and Calu-6 cell culture preparations. The lipidated compound also promoted a cellular increase in H3K4me2, as measured by PCR.

Because of the homology between LSD1 and monoamine oxidases (MAOs), classical MAO inhibitors such as pargyline and TCP were among the first small molecule LSD1 inhibitors that were tested and reported in the literature. The classical MAO inhibitors phenelzine and TCP are effective LSD1 inhibitors but act as pan-oxidase inhibitors that show no selectivity between LSD1 and MAO. A large number of inhibitors based on the TCP scaffold have been synthesized, and compounds in this class have been extensively reviewed elsewhere.[182] Johnson et al. disclosed novel LSD1 inhibitors containing piperidinyl analogs of phenyl cyclopropylamine.[183] A representative compound from this series was shown to be highly potent against LSD1 (mean $pIC_{50} = 8.3$) and very selective when compared to MAO-B ($pIC_{50} = 4.1$). Three TCP analogs from this series (Fig. 17) developed by GlaxoSmithKline (GSK2879552, GSK-LSD1, and GSK2699537) act as mechanism-based inhibitors of LSD1 and form adducts with the flavin ring of FAD. These compounds are highly specific for LSD1 and do not inhibit MAO-A or MAO-B. The clinical compound, GSK2879552, has a K_i^{app} of 1.7 μM and a k_{inact} value of 0.11 min^{-1}.[184] GSK2879552 entered phase I dose escalation study in subjects with AML. A similar TCP analog, ORY-1001,[185–187] is also in phase I/II clinical trials for AML through a collaboration between Oryzon and Roche. Neelamegam reported a series of brain-penetrating TCP analogs, the most promising of which is RN-1.[188] RN-1 inhibited LSD1 with an IC_{50} of 10–70 nM (depending on the assay used) and was highly selective for LSD1 over MAO-A and B. They used this compound to show that LSD1 inhibition can abolish long-term memory formation without affecting short-term memory, providing further evidence for the importance of reversible histone methylation in the function of the nervous system. A series of pyrrole and indole-containing TCP analogs have recently been described,[189,190] the most potent of which is shown in Fig. 17. This compound not only inhibited LSD1 with an IC_{50} of 40 nM, but also inhibited MAO-A (IC_{50} 160 nM).

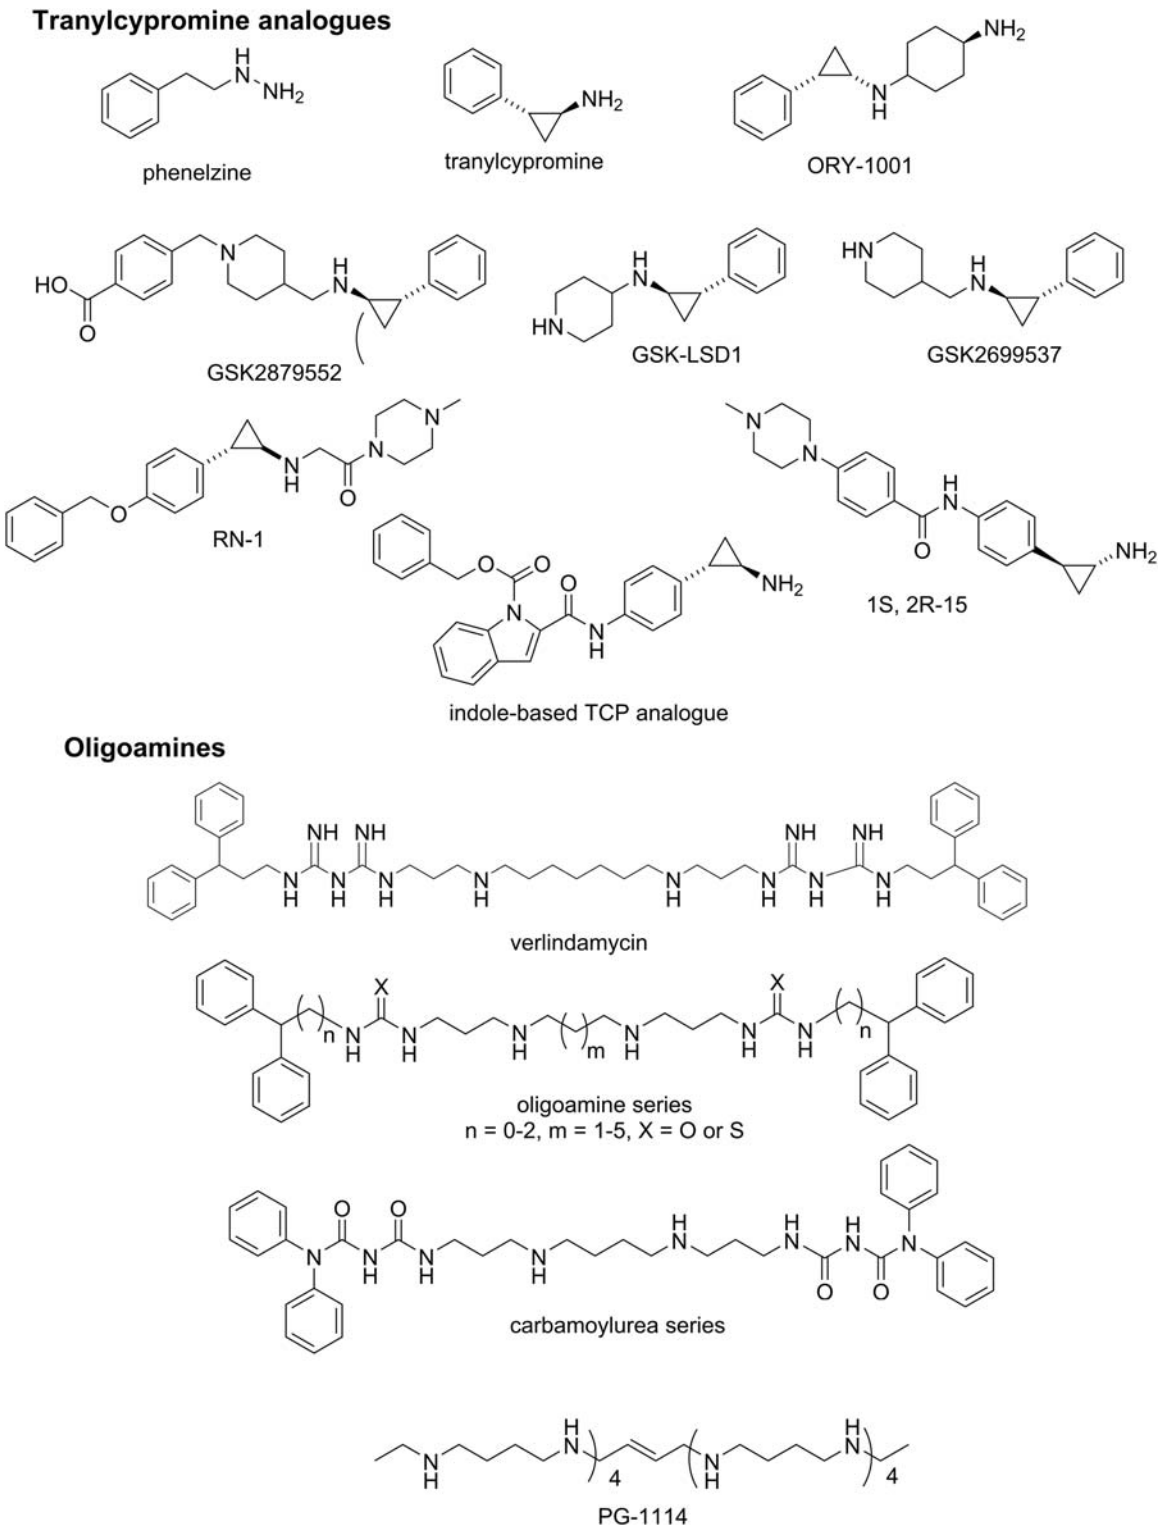

Fig. 17 Tranylcypromine- and oligoamine-based inhibitors of LSD1.

Vianello reported a TCP analog, compound 1S,2R-15 (Fig. 17), that inhibited LSD1 with an IC_{50} of 84 nM. The analog produced 85% growth inhibition in APL blast cells at 250 nM and 60% growth inhibition in THP1 cells at 500 nM. It also prolonged survival by 62% in a murine leukemia model, although at a relatively high oral dose (22.5 mg kg^{-1}).[191] For a comprehensive description of TCP-based LSD1 inhibitors, the reader is referred to the excellent review by McAllister et al.[192]

Due to the structural similarity between LSD1 and the polyamine-metabolic enzyme spermine oxidase, a series of (bis)guanidine and (bis)biguanude polyamine oxidase inhibitors were evaluated for activity against LSD1. This resulted in the identification of the first small molecule inhibitor of LSD1, the (bis)biguanide verlindamycin, which was reported in 2007. Verlindamycin was found to act as a noncompetitive inhibitor of LSD1 with a K_i value of 0.6 μM and caused a promoter-specific increase in H3K4me2 and the corresponding reexpression of silenced tumor suppressor genes (*SFRP*1, *SFRP*4, *SFRP*5, and *GATA*5) in HCT116 colon tumor cells.[22] Verlindamycin and the related oligoamine PG-11144 also had in vivo efficacy when combined with the deoxynucleotide methyltransferase (DNMT) inhibitor 5-AC in a mouse xenograft model.[193] Isosteric replacement of the biguanide moiety in verlindamycin with a urea, thiourea, or carbamoylurea resulted in the discovery of (bis)ureido- and (bis)-thioureido-oligamines and bis-substituted carbamoylureas (**Fig. 17**) that were more potent than verlindamycin with regard to LSD1 inhibition and reexpression of silenced tumor suppressor genes.[194] Subsequent SAR studies demonstrated that the most active epigenetic modulators were (bis) ureas or (bis)thioureas that had an $n=1$ and an $m=3$ or 4.[195] Three out of nine compounds with the 3-5-3 backbone produced >95% inhibition of the enzyme at 10 μM in a fluorimetric assay. The compound where $m=3$, X=S, and $n=2$ displayed potent LSD1 activity ($IC_{50}=5.5$ μM) and produced significant cytotoxicity in an MTS reduction assay ($IC_{50}=4$ μM). It also induced significant reexpression of aberrantly silenced tumor suppressors such as SFRP2, HCAD, GATA4, and p16 in Calu6 lung adenocarcinoma cells. Importantly, this analog was also found to be an effective growth inhibitor of the MCF7 estrogen receptor-positive breast tumor cell line ($IC_{50}=5.6$ μM) and the estrogen receptor negative MDA-MB-231 breast tumor line ($IC_{50}=9.2$ μM) in vitro, but was less effective against the MCF10A breast epithelial cell line ($IC_{50}=19$ μM). When evaluated in an Hs683 glioma xenograft, it was well tolerated and effective in limiting tumor growth without weight loss in combination with 5-AC but was less effective than 5-AC plus verlindamycin or PG-11144.

In addition to TCP analogs, which are all mechanism-based, irreversible inhibitors of LSD1, a number of reversible inhibitors have appeared (**Fig. 18**). As part of an effort to identify novel LSD1 inhibitor scaffolds, Hazeldine et al. carried out virtual screening of the Maybridge Hitfinder 5 compound library and identified a series of amidoxime as potential LSD1 inhibitors.[196] In this model, amidoxime A contained a hydrophilic moiety that appeared to be situated near the FAD cofactor and a hydrophobic substituent that was bound in the hydrophobic pocket. It was a weak inhibitor of LSD1 (11.4% at 10 μM) and promoted a 1.6-fold increase in global H3K4me2 levels in the Calu-6 lung tumor cell line. Optimization studies led to the identification of the ortho fluoro derivative amidoxime B, which was a modest inhibitor of LSD1, but produced a 12.4-fold increase in global H3K4 methylation at 10 μM and then to amidoxime C and related analogs. Compounds in this series served as epigenetic modulators that produced increases in H3K4 methylation as high as 3700-fold, including amidoxime C (39% inhibition of LSD1 at 10 μM with an accompanying 837-fold increase in global H3K4me2 levels). Under the same conditions, TCP and pargyline at 10 μM produced an 18.4% and 69.8% inhibition of LSD1. Recently, Abdulla et al. reported that, in a fluorimetric assay, various natural polyphenols such as resveratrol, curcumin, and quercetin were identified as LSD1 inhibitors.[197] Inhibition of LSD1 by resveratrol and curcumin appears to inhibit myogenesis in cell culture by inhibition of myogenic gene expression. These natural polyphenols have a novel mechanism that should be elucidated, since their inhibitory activity appears to be independent of their antioxidant properties.

By combining the key ligand attributes of oligoamines, MAO inhibitors, and a methionine-based LSD1 peptide inhibitor,[179] Dulla et al. reported a small series of phenyl oxazoles containing either amine or guanidine moiety.[198] The representative compound shown in **Fig. 18** displayed a good LSD1 inhibition profile (in vitro IC_{50} of 9.5 μM; cellular $IC_{50}=1.3$ μM in cultured MDA-MB-231 cells) and induced apoptosis in zebrafish embryos, suggesting the therapeutic potential of these compounds. Namoline, a γ-pyrone derivative, was shown by Willmann et al. to inhibit LSD1 ($IC_{50}=51$ μM) but not MAO-A and B.[199] Namoline caused increases in H3K4me2 and H3K4me, and it silenced androgen receptor-mediated gene expression, leading to reduced proliferation of LnCAP prostate tumor cells in vitro and in vivo. Schmitt and coworkers recently described a series of nonpeptidic propargylamine LSD1 inhibitors.[200] These compounds, which contained the propargyl and other warhead moieties, were only modestly potent ($IC_{50}=22.2$ μM for the compound shown in **Fig. 18**) and produced increases in H3K4me2 in MCF7 cells (1.6–1.7-fold) only at concentrations of ≥100 μM. Although these compounds contain a propargyl moiety that is present in previously described inactivators of LSD1, no enzyme kinetic data were presented.

Fiskus and coworkers reported a series of reversible benzohydrazide inhibitors such as SP-2509 (**Fig. 18**)[187,201] that attenuated the binding of LSD1 with CoREST, increased the transcription activating mark H3K4Me3 at target gene promoters, and increased the levels of p21, p27, and CCAAT/enhancer binding protein A in cultured AML cells. Coadministration of SP2509 and the HDAC inhibitor panobinostat in an immune-depleted mouse model of human AML afforded significantly better survival than either agent alone with minimal toxicity and represents a potential for cure of the immune-depleted mice engrafted with AML cells expressing NPM1 mutation. Kutz and coworkers recently described a series of potent LSD1 inhibitors based on a novel 3,5-diamino-1,2,4-triazole scaffold.[202] The two best inhibitors in the series, C1 and C15 (**Fig. 18**), act as potent LSD1 inhibitors, with IC_{50} values of 1.19 and 2.22 μM, respectively. Compound C1 is a competitive inhibitor of the enzyme, with a K_i of 2.2 μM. Both C1 and C15 show a high degree of specificity for LSD1 in vitro and do not inhibit MAO-A or MAO-B at concentrations up to 100 μM. Both cause significant increases in cellular levels of the transcription-activating mark H3K4me2. Importantly, these inhibitors exhibit low toxicity to mammalian cells in vitro, and thus they may show utility in the treatment of epigenetically based diseases where cell death is not a desired endpoint. The 1,2,3-triazole-dithiocarbamate hybrid shown in **Fig. 18** produced specific and robust inhibition of LSD1 (IC_{50} 2.1 μM) as well as inhibition of migration and invasion in the gastric cancer cell line MGC-823.[203] *N*′-(1-Phenylethylidene)-benzohydrazide is a potent and specific LSD1 inhibitor, but its activity in a xenograft of castration resistant prostate tumor appears to be due to cytotoxicity unrelated to LSD1 inhibition.[204,205] GSK354, a novel tricyclic pyridine analog, was

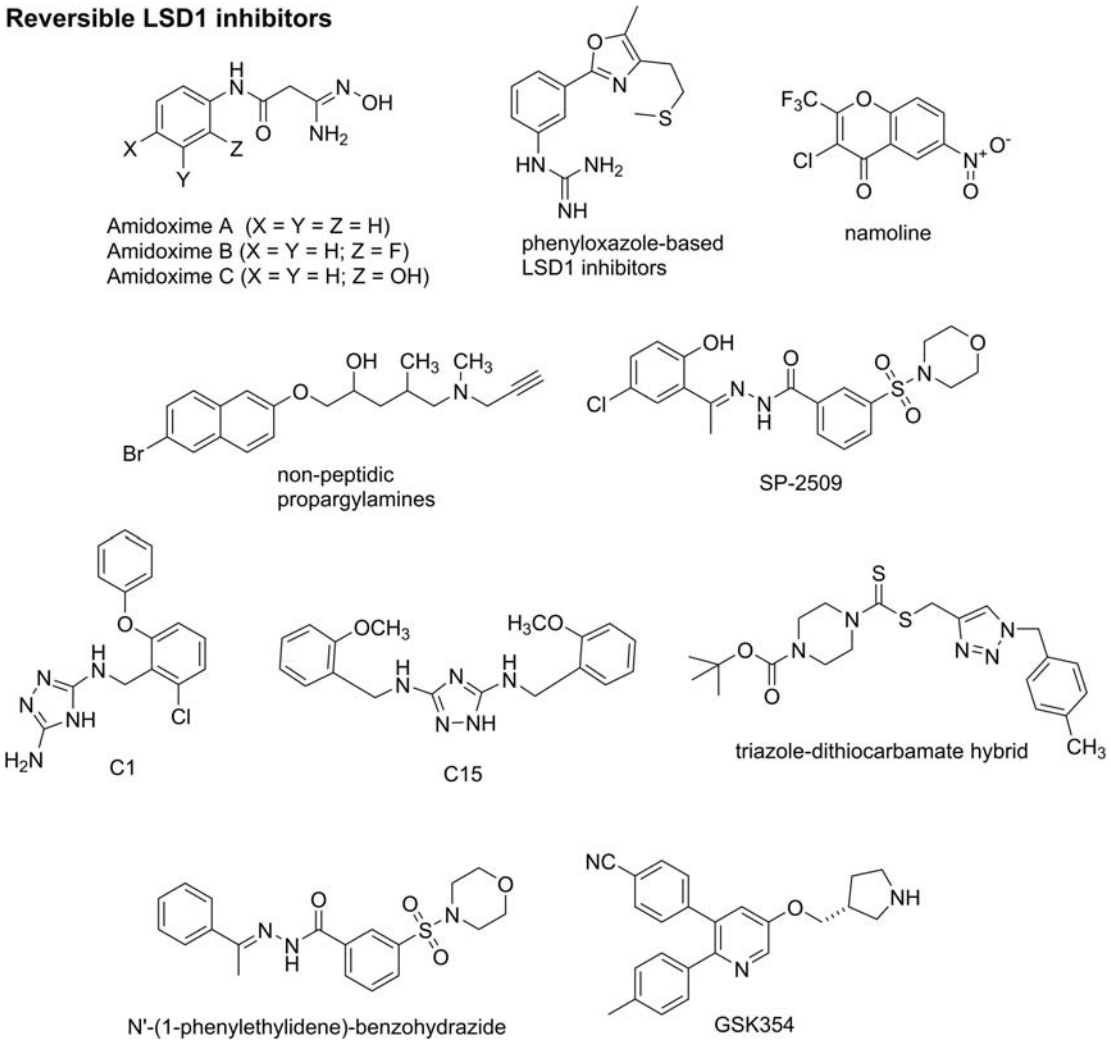

Fig. 18 Reversible inhibitors of LSD1.

found to be a potent LSD1 inhibitor ($IC_{50} \leq 100$ nM) and highly selective (MAO $IC_{50} \geq 200$ μM). This compound is not being developed but is considered a chemical probe suitable for use in biological function studies.[206]

Considering the importance of JmjC domain-containing demethylases in various cancers, intense inhibitor-design efforts were pursued to identify optimal compounds that elicit good activity and selectivity. These inhibitors (**Fig. 19**) are classified into at least five categories: (1) hydroxamic acids, (2) oxalyl derivatives, (3) pyridyl analogs, (4) flavanoids/catechols, and (5) hydroxyquinolines. A comprehensive review of inhibitors of JMJD demethylases has recently been published.[192]

It has been hypothesized that compounds that coordinate with Zn^{2+} (such as HDAC inhibitors) may also coordinate with the Fe^{2+} present in JmjC demethylases. However, when the known HDAC inhibitor SAHA was tested against JMJD2E, a weak inhibition was observed ($IC_{50} = 540$ μM) suggesting that it was not the case.[207] Subsequently, it was reported that hydroxamic acids linked to tertiary amines or cyclopropane groups through alkyl chains can efficiently inhibit KDM4 and KDM2A activities, respectively.[208] However, through screening and hit-to-lead optimization, the long-chain hydroxamic acid shown in **Fig. 19** was discovered. This compound exhibited an IC_{50} against KDM5A of 3.3 μM, and was reasonably selective over KDM4C and KDM3A. A number of other hydroxamates have been synthesized as jumonji demethylase inhibitors, and some success has been achieved with inhibitors selective for KDM2A. One of the potent hydroxamic acid inhibitors reported so far is 3-hydroxyphenyl hydroxamic acid ($IC_{50} = 28$ μM; 4.8 μM with preincubation against JMJD2E).

Rose et al. identified a series of metal-chelating inhibitor scaffolds that mimic the 2-oxoglutarate cofactor in Fe(II)-2-oxoglutarate-dependent histone demethylases.[207] *N*-Oxalyl glycine, R = H, displayed an IC_{50} of 78 μM when tested against JMJD2E. Interestingly, the IC_{50} dropped to 24 μM with 30 min preincubation. Several other derivatives of N-oxalylated D-amino acids were synthesized, the most active being an *N*-oxalylphenylalanine ($IC_{50} = 5.4$ μM) containing a *p*-bromobenzene sulfonyl substituent.

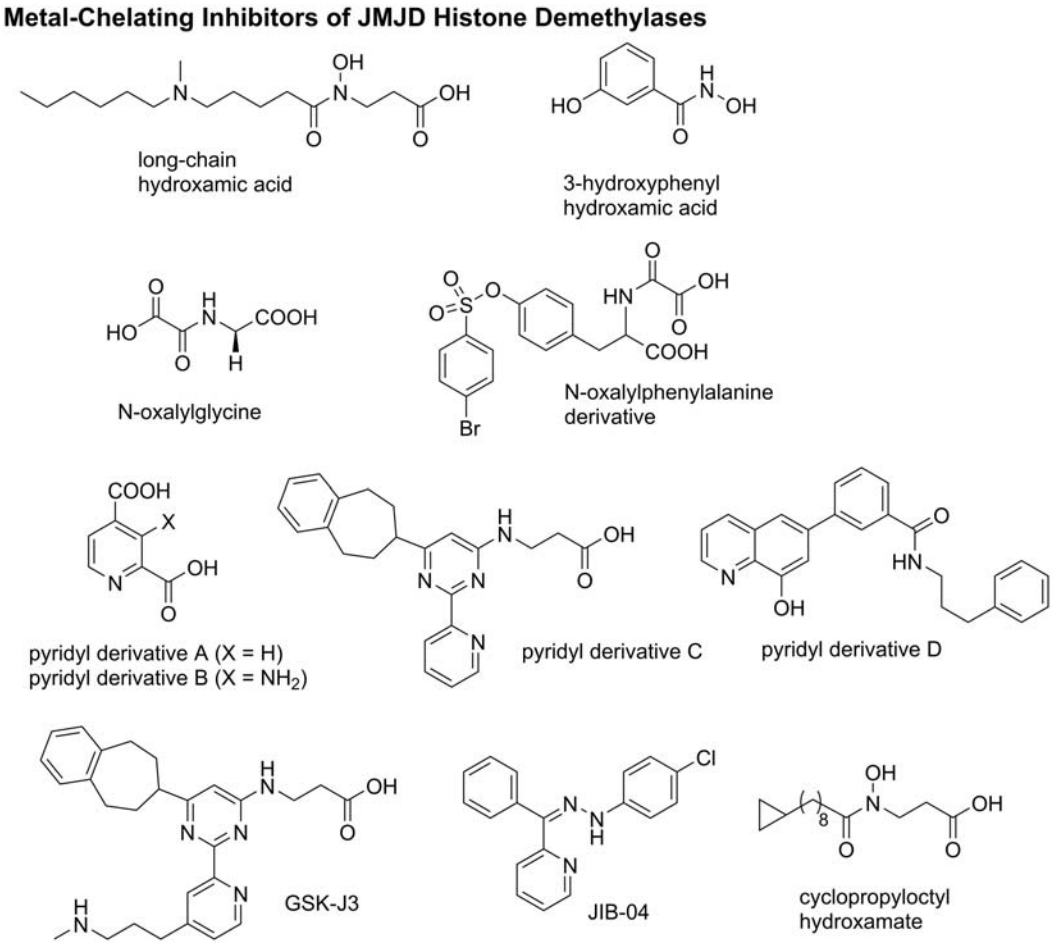

Fig. 19 Metal-chelating inhibitors of JMJD histone demethylases.

Thalhammer et al. tested the JMJD2E inhibition of pyridyl carboxylates (Fig. 19) that are known to interact with Fe^{2+} in collagen/hypoxia-inducible factor. Pyridyl derivative emerged as a good inhibitor with IC_{50} value of 1.4 μM. Continuing studies produced additional analogs such as pyridyl derivative B and C, with IC_{50} values of 0.11 and 2.5 μM, respectively, against JMJD2E.[209] More recently, hydroxyquinolines related to pyridyl derivative D have been discovered. This compound is a potent inhibitor of KDM4B (IC_{50} 10 nM), has low micromolar activity against KDM4A, 4C, and 5A, and does not inhibit LSD1. Pyridyl derivative D is cytotoxic against LNCaP cells in vitro with an IC_{50} of < 1 μM.[210]

Kruidenier et al. reported one of the most potent JMJD3 (KDM6) inhibitors thus far.[211,212] Based on a structure-based and chemoproteomics approach, they synthesized a series of beta-alanine derivatives containing 2-(pyridinyl)-4-pyrimidine moiety. One of the potent inhibitors in the series, GSK-J3, is highly active against JMJD3 ($IC_{50} = 60$ nM), shows no activity against a panel of other family members, and reduces lipopolysaccharide-induced proinflammatory cytokine (TNF-α) production by human macrophages, a process regulated by JMJD3 and UTX. The compound known as JIB-04 specifically inhibits the activity of the Jumonji family of histone demethylases in vitro, in cancer cells, and in tumors in vivo. Interestingly, it is not a competitive inhibitor of α-ketoglutarate. Studies show that JIB-04 alters transcriptional pathways, thus blocking cell viability, reducing tumor burden, and prolonging survival. The cyclopropyloctyl hydroxamate shown in Fig. 19 was found to be a potent inhibitor of KDM2A ($IC_{50} = 6.8$ μM), KDM7A ($IC_{50} = 0.2$ μM), and KDM7B ($IC_{50} = 1.2$ μM) but only produced modest increases in H3K27me2.[213] However, this analog showed antiproliferative activity against the KYSE150 esophageal squamous cell carcinoma line.

Sakurai et al. designed and implemented a robust and miniaturized high-throughput kinetic assay to identify JMJD2E inhibitors.[214] Naturally occurring flavonoids (such as myricetin, baicalein, and β-lapachone) and catechols (such as dopamine, (*S*)-carbidopa, and fenoldopam) were identified as hits with IC_{50} values ranging from 2 to 10 μM.

2.12.3.4 Agents Targeting Epigenetic Reader Proteins

Histone PTMs signal for changes in gene expression using specific reader proteins that either recruit or stabilize various components of the transcriptional machinery.[4] There are at least 26 families of reader proteins that function to interpret signals from methylated

lysines and arginines, acetylated lysines, phosphorylated serines and threonines, and even unmodified histones (Table 4, Fig. 20). A complete discussion of these reader proteins, their specificities for histone PTMs, and their effects on transcription is not included in this article, since it is the subject of an excellent review.[4] The methyllysine reader group has been the most completely characterized, but bromodomains have received the most attention as drug targets.[215] The term bromodomain refers to the Bromodomain and Extra-Terminal (BET) family of human proteins (BRD2, BRD3, and BRD4), which feature two highly conserved N-terminal bromodomains as well as a C-terminal domain with potential for more divergence in sequence.[216,217] There are eight families of BCPs, and to date, 61 bromodomains have been identified as components of 46 large, multidomain protein BCPs. Within BCP reader proteins, bromodomains fold to form a highly conserved four-helix bundle structure, creating a deep hydrophobic cavity that recognizes and binds acetyllysine. Acetylated lysine makes several contacts with these hydrophobic residues, and the complex is stabilized by a hydrogen bond with a highly conserved asparagine. Lysine acetylation recruits transcriptional coactivators such as p300 and the bromodomain-containing cyclic AMP-responsive element binding protein (PCAF).[54,55] The bromodomain found in PCAF is one of the three known protein domains that act as acetylated lysine-binding elements [the other two are DPF and double pleckstrin

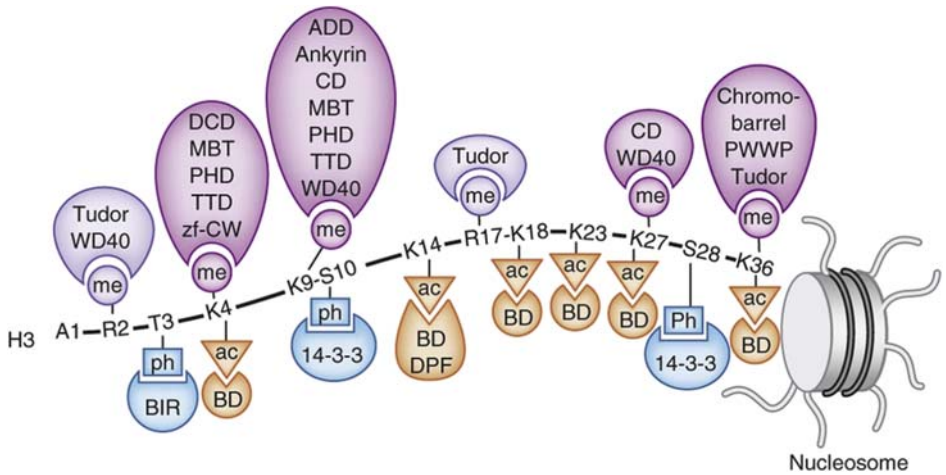

Fig. 20 Epigenetic reader proteins and their PTM ligands. From Musselman, C.A.; Lalonde, M.E.; Cote, J.; Kutateladze, T.G. Perceiving the Epigenetic Landscape Through Histone Readers. Adapted from Musselman et al. *Nat. Struct. Biol.* **2012**, *19* (12), 1218–1227.

homology (PH) domains].[215] These coactivators have inherent autocatalytic acetyltransferase activity, and also recruit transcription factors into a complex that promotes active gene transcription, and therefore play a key role in the activation of transcription.[7,218] Aberrant HDAC overexpression results in the reduction of acetylated lysine and the loss of BCPs, leading to transcriptional repression. HDAC inhibitors have been shown to synergize with p300 autoacetylation to restore acetyl lysine levels and the binding of bromodomain-containing transcription factors, activating transcription.[19] This series of events promotes the expression of various transcriptional products. Based on these facts, it is clear that small molecule inhibitors of the interaction of bromodomains with acetyllysines could serve as epigenetic modulators with therapeutic value. Because BET proteins can play a role in the development of cancer, they are a rational target for the discovery of antitumor agents. Specifically, BRD4 influences mitotic progression by binding to transcriptional start sites of genes and directing postmitotic transcription, mediates transcriptional elongation and has been linked to c-MYC dependent transcription as well as positive transcription elongation factor complex-induced increased growth promotion.[219,220]

Mujtaba et al. utilized an NMR-based screening approach to identify small molecules that could bind to the PCAF bromodomain and disrupt its function.[221] Although *N*-aminopropyl-2-nitro-4-methylaniline (**Fig. 21**, $IC_{50} = 1.6$ μM) disrupted the PCAF BRD/Tat-AcK50 protein/protein interaction,[222] it was found to bind to PCAF in the peptide-binding groove and not at the acetyllysine site. Subsequent efforts to design small molecule bromodomain inhibitors have focused largely on the BET family of bromodomains. Filippakopoulos et al. used structure-based design techniques to discover (+)JQ1, an optically active molecule that contains the thienodiazepine moiety that binds to BET bromodomain and disrupts the binding of acetyllysine to the BRD4 bromodomain. This interaction promotes cellular differentiation and growth inhibition in a NUT midline carcinoma cell line.[216] Nicoteme et al. performed a physical screen to identify molecules that can upregulate the ApoA1 reporter gene. They ultimately discovered GSK525762, a potent inhibitor containing the benzodiazepine moiety, that binds to the tandem bromodomains of BET with high affinity ($K_d = 50.5–61.3$ nM).[223] GSK525762 offers protection against LPS-induced endotoxic shock and bacteria-induced sepsis and is currently in clinical trials to evaluate efficacy in patients with NUT midline carcinoma and other cancers. The observation that the triazolodiazepine nucleus was a common structural feature in bromodomain inhibitors led to the discovery that clinically approved benzodiazepines, most notably alprazolam, had low micromolar affinity for the BRD4 bromodomain. The compound known as RVX-208 is an orally acting bromodomain inhibitor produced by Resverlogix Corporation. The quinazolinone analog RVX-208 is 15- to 30-fold more active against the BET family reader BRD2 compared to BRD1.[224] By contrast, diazobenzenes MS436[225] and olinone[226] preferentially bind to the BRD1 BET family proteins. RVX-208 removes atherosclerotic plaque via reverse cholesterol transport and is currently in Phase IIb trials.[227] Lastly, OTX-015, a novel orally acting BET bromodomain inhibitor produced by OncoEthix, induces potent antiproliferative effects that are associated with cell cycle arrest, cellular senescence, or apoptosis. The compound was in Phase I clinical trials where it is evaluated against acute leukemia and other hematological malignancies, but that trial was stopped after 1 year.[228] Incyte is also conducting a phase I/II clinical trial for patients with advanced malignancies, but the structure of the compound being evaluated, INCB054329, has not been disclosed.

A number of other bromodomain inhibitors with a variety of therapeutic properties have been reported. Hewings et al. used X-ray crystallographic structures to design a substituted 3,5-dimethylisoxazole A,[229] which had an IC_{50} of 4.8 μM against BRD4 and 1.6 μM against BRD2. A similar analog, 3,5-dimethylisoxazole B, was identified through focused fragment screening by Bamborough et al.[230] 3,5-dimethylisoxazole B exhibited enhanced water solubility and IC_{50} values of 0.5 μM against BRD2, BRD3, and BRD4. This molecule has been shown to possess antiinflammatory activity in a cellular assay system. Dawson et al. reported IBET-151, which inhibits transcription in MLL-fusion leukemia cells by inhibition of BRD3 ($K_d = 20$ nM) and BRD4 ($K_d = 100$ nM) binding to acetyllysine.[231] The benzimidazole analog BIC-1 (**Fig. 21**) was found to block the association of BRD2 with acetylated H3K12 with a dissociation constant of 28 μM.[232] Using structure-based fragment assessment and optimization, Fish et al. discovered PFI-1 (**Fig. 21**), a novel small-molecule that can be used as a chemical probe to study the BET family.[233] Wagner et al. pursued structure-based drug design strategy and reported the discovery of UNC669 ($IC_{50} = 6$ μM), a potent L3MBTL1 inhibitor that displayed fivefold increase in binding affinity compared to the native peptide H4K20me1. The same group also discovered UNC1215, the first potent L3BMTL3 antagonist ($K_d = 120$ nM) that is selective against other members of the MBT family as well as against other reader domains.[234,235] Two selective inhibitors recently developed by the SGC, SGC-CBP-30 and I-CBP112, have low nanomolar potencies for the CBP/EP300 bromodomains.[236] The literature has linked CBP/EP300 to a number of disorders, including (but not limited to) AML and a number of neurodegenerative diseases. The BAZ2B bromodomain inhibitor GSK2801 exhibits high affinity and selectivity for BAZ2B and the closely related protein BAZ2A (K_d of 136 and 257 nM, respectively).[238] Collectively, these studies indicate that specific inhibitors of bromodomain binding have promise for use as biological probes of bromodomain function and for development as novel therapeutic agents. In addition, at least five pharmaceutical companies have bromodomain inhibitors in phase I or II clinical trials.[236] There has been considerable progress in the identification of compounds that disrupt epigenetic reader protein binding to their corresponding epigenetic marks, but a full discussion of all such inhibitors is beyond the scope of this article. However, recent progress in this area has been reviewed.[239,240]

2.12.4 Conclusion

It is evident that the field of epigenetics is a rapidly evolving area of research and the amount of information regarding the topic is formidable and expanding. This article is meant to give the reader a broad view of the processes involved in the epigenetic control of

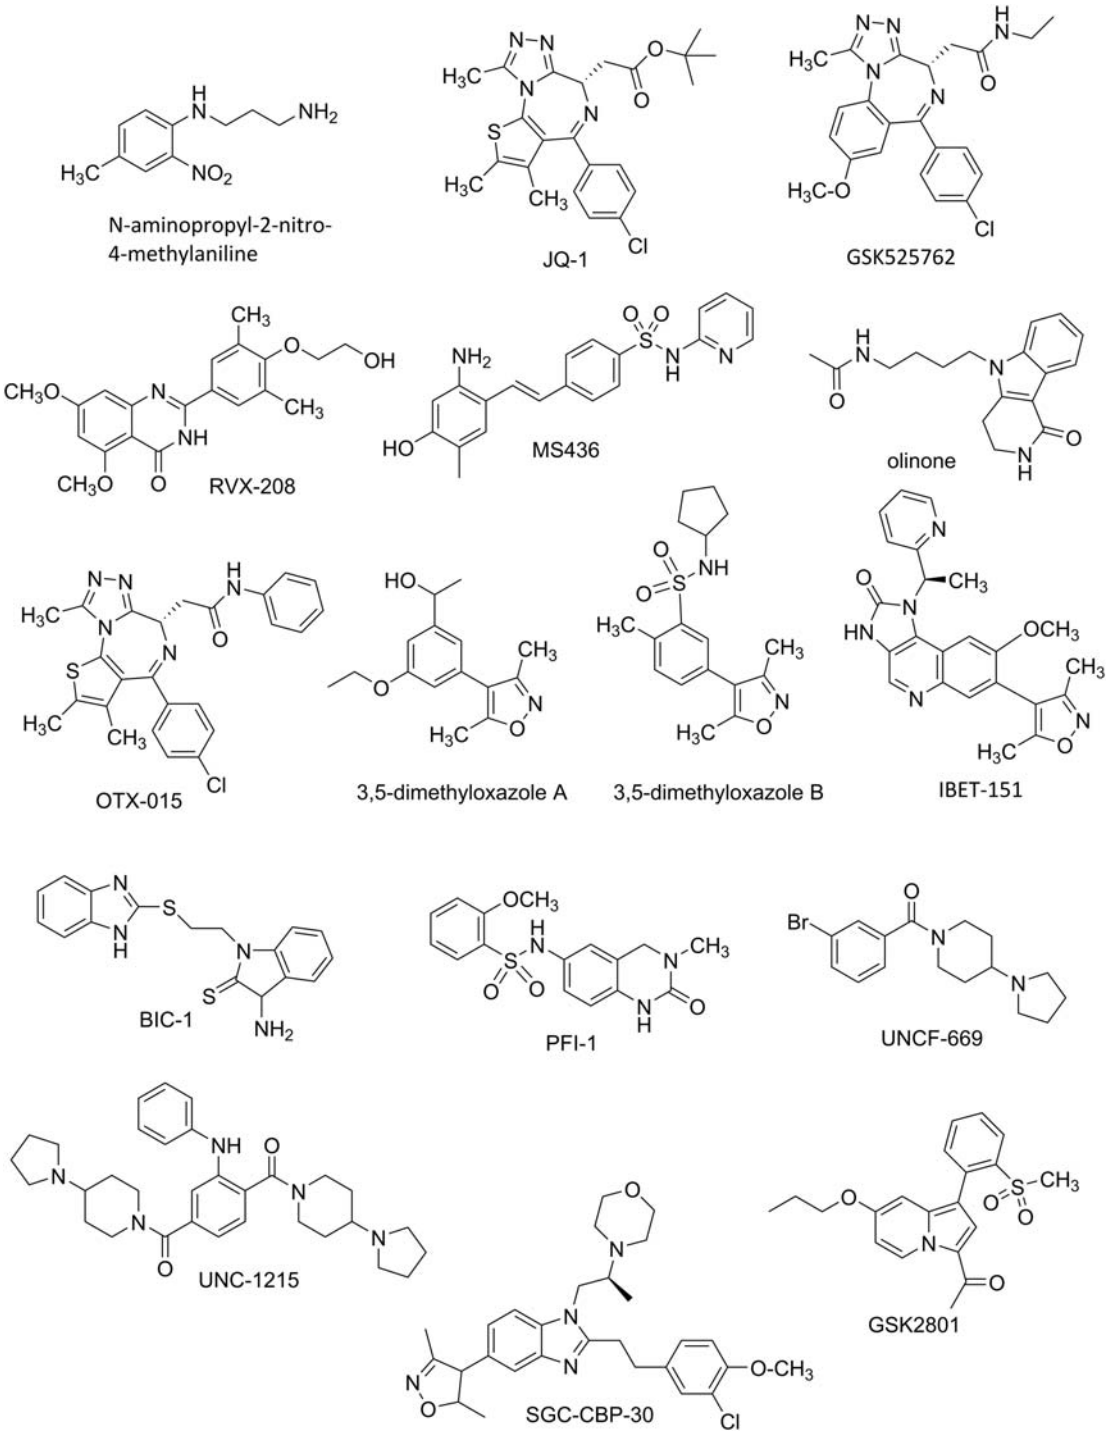

Fig. 21 Inhibitors of the interactions of bromodomain proteins with acetylated lysines.

gene expression, to define epigenetic enzymes and proteins that have become targets for drug discovery, and to provide examples of compounds developed to interact with various aspects of epigenetic modulation. As epigenetic research continues to expand, it will provide a more complete view of the epigenetic landscape and the interaction between various players involved. New targets for drug discovery will be identified and will ultimately result in an arsenal of therapeutic agents to treat diseases with an epigenetic basis. These agents will hopefully be useful for controlling the epigenetic processes that underlay a variety of important maladies and provide a new treatment paradigm for cancer and for a variety of other diseases.

2.13.1 Introduction

Protein–protein interactions (PPIs), which refer to physical contacts between two or more proteins as a result of biochemical events and/or electrostatic forces, play an important role in human physiology and pathophysiology. The interactions of two or more proteins participate in virtually all cellular processes, including gene regulation, DNA replication, cell growth, cell differentiation, cell apoptosis, signal transduction, transcriptional activation, and many others. Abnormal PPIs either through the loss of an essential interaction or via the formation of a protein complex at an inappropriate time or location are associated with various human diseases, such as cancer and central nervous system (CNS) disorders.[1] While it is estimated that there are approximately 130,000 to 650,000 PPIs in the human interactome,[2,3] only a very limited number of them have been investigated for drug discovery. Construction of the interactome is considered as a critical step after the human genome project.[4] Systematically mapping gene and protein interactions will assist in understanding how genes are involved in various signaling pathways and how these pathways function in disease states. Therefore, PPIs represent a rich source of novel drug targets, which are substantially different from the traditional G-protein-coupled receptors (GPCRs), ion-channel, and enzyme target classes. Over the past two decades, PPIs have attracted increasing attention in the research field along with rapidly expanding studies of relevant strategies and technologies (Fig. 1).

Based on different standards of classifications, PPIs can be divided into homo-oligomers versus hetero-oligomers, stable interactions versus transient interactions, or covalent versus noncovalent interactions. Various PPIs can be identified by in vitro (eg, protein arrays, tandem affinity purification, affinity chromatography, coimmunoprecipitation, X-ray crystallography, and nuclear magnetic resonance (NMR) spectroscopy), in vivo (eg, yeast two-hybrid and synthetic lethality), and in silico methods (eg, computational PPI prediction methods).[5–10] Selectively abrogating these PPIs may provide a promising strategy for drug discovery. PPI inhibitors can be classified into two categories: antibodies (eg, Avastin[11] and Herceptin[12]) and small molecules, such as peptides, peptidomimetics, and nonpeptide small molecules, which are the major focus of this article. Small molecules modulate PPIs through at least three different mechanisms: orthosteric inhibition, allosteric modulation, and interfacial binding/stabilization.[13] Despite a number of challenges, research effort on finding small-molecule, protein–protein modulators has made significant progress over the past decade.[14] Some of these molecules have been advanced into different phases of human clinical trials and several of them have even reached the market (Table 1).

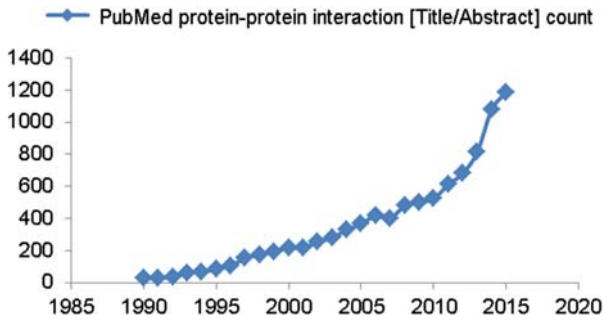

Fig. 1 Search results using the keyword "protein–protein interactions" in the title and abstract from PubMed on Nov. 19, 2015. *Horizontal axis*: publication year; *vertical axis*: numbers of publications having "protein–protein interactions" in the title and abstract.

Table 1 Selected small molecular PPI inhibitors in human clinical trials

Name	*Company*	*Clinical Phase*[a]	*Interactome*	*Indications*
Maraviroc	Pfizer	Launched	CCR5–gp120	HIV infection
Tirofiban	Merck	Launched	Fibrinogen–GPIIb/IIIa	Non-ST elevation acute coronary syndrome (ACS)
SAR1118	Sunesis	Phase III	LFA-1–ICAM-1	Dry eye; Keratoconjunctivitis sicca
Venetoclax	Abbvie	Phase III	Bcl-2/Bcl-x_L–Bak/Bad	Chronic lymphocytic leukemia
Tramiprosate	Neurochem	Phase III[b]	Amyloid-β aggregation	Alzheimer's disease
Tanespimycin	Bristol-Myers Squibb	Phase III	Hsp90–Src	Multiple myeloma; gastrointestinal stromal tumors; primary peritoneal cavity cancer; stage III/IV ovarian epithelial cancer
RVX-208	Resverlogix	Phase III	Bromodomain–acetylated histone	Type II diabetes; coronary artery disease; cardiovascular diseases
Navitoclax	Abbvie	Phase II	Bcl-2/Bcl-x_L–Bak/Bad	Chronic lymphocytic leukemia; prostate cancer
LCL161	Novartis	Phase II	XIAP–Caspase-9	Breast cancer; leukemia; recurrent plasma cell myeloma; refractory plasma cell myeloma
GSK525762	GSK	Phase I/II	Bromodomain– acetylated histone	Nut midline carcinoma; other cancer
RO5045337	Roche	Phase I	p53–MDM2	Neoplasms; sarcoma; myelogenous leukemia
AMG232	Amgen	Phase I	p53–MDM2	Advanced malignancy; advanced solid tumors; cancer

[b]Failed likely due to pharmacokinetics and tolerability issues.

In this article, we discuss the critical role of PPIs associated with various human diseases and different approaches to the identification of small molecular inhibitors targeting PPIs. The highlights on recent advances in developing such modulators as novel therapeutics are also presented.

2.13.2 Critical Role of Protein–Protein Interactions in Various Diseases

Aberrant PPIs may result in various human diseases. Numerous studies have identified and characterized specific interactions associated with a variety of disease systems, including cancer, CNS disorders, inflammation, and other human conditions.[15]

2.13.2.1 Cancer

PPIs form important signaling nodes and hubs in numerous signaling pathways that promote tumorigenesis, tumor progression, invasion, and metastasis. Thus, disruption of specific PPIs critical in cancer processes may provide an effective and novel therapy.[16]

B-cell lymphoma 2 (Bcl-2) family proteins regulate the mitochondrial signaling which is one of the two principal processes (intrinsic and extrinsic apoptotic signaling pathways) leading to apoptosis.[17–19] Interactions between the Bcl-2 family members decide the fate of cells—to die or to live. The antiapoptotic proteins like Bcl-2 and Bcl-x_L heterodimerize with the proapoptotic members, such as Bak, Bax, Bim, and Bad, through the conserved BH3 domain.[20] Overexpression of antiapoptotic Bcl-2 family proteins is implicated in both the pathology and drug resistance of various hematopoietic malignancies and solid tumors.[21,22] Targeting the BH3 domain or BH4 domain, where Bcl-2 interacts with Bcl-2 members or non-Bcl-2 family proteins, is a promising strategy for cancer therapy.[23–26]

The tumor suppressor p53 plays an important role in the regulation of cellular process and its inactivation is a frequent causal event in the development and progression of cancer.[27–29] One critical inhibitory mechanism is mediated by overexpression of mouse double minute 2 homolog (MDM2). MDM2 amplification has been found in about 11% of all tumors and is reported at higher levels in certain tumor types, including hepatocellular carcinoma (44%), osteosarcomas (20%), and soft tissue sarcomas (31%).[30,31] MDM2 binds to the p53 transactivation domain, blocking p53-dependent transcriptional activity. Disturbing the MDM2–p53 interaction can result in the release of p53 from MDM2, thereby restoring the tumor suppressor function of wild-type p53.

Mixed lineage leukemia 1 (MLL1), a histone H3 lysine 4 (H3K4) methyltransferase, is crucial for definitive hematopoiesis and embryonic development and has been implicated in a number of cancers.[32–34] Deregulation of MLL1 is associated with acute lymphoid leukemia (ALL) and acute myeloid leukemia (AML). MLL1 works optimally when in complex with other components: WD40 repeat protein 5 (WDR5), retinoblastoma-binding protein 5 (RbBP5), absent small homeotic disks-2-like (ASH2L), and DPY-30 (WRAD).[35] The MLL1/WDR5 PPI is essential for MLL1 enzymatic activity. Targeting the WDR5–MLL1 PPI is proven to be a practical approach to inhibiting the activity of MLL1 complex, providing a novel therapeutic strategy for acute leukemia harboring MLL1 fusion proteins.[36,37]

Yes associate protein (YAP) and transcriptional coactivator with PDZ-binding motif (TAZ) are targets and terminal effectors of Hippo pathway whose dysfunctions are involved in cancer development.[38] The Hippo pathway is a newly discovered functionally conserved signaling network that is critical for controlling organ size by modulating both cell proliferation and apoptosis.[39–41] Inhibition of this signaling induces YAP/TAZ translocation to the nucleus, where they would interact with other proteins, such as transcriptional enhancer associate domain (TEAD) transcription factors (TFs), triggering the expression of cell proliferation-promoting genes.[42]

A growing list of validated PPIs as targets for cancer therapeutic development has been reported, including S100B–p53,[43] XIAP–caspase,[44] Ras–SOS,[45] EGFR–HER2,[46] HER2–HER3,[47] Max–Myc,[48] Akt–Bad–14-3-3,[49] MLL–menin,[50] VEGF–VEGFR,[51] and bromodomain–acetylated histone.[52] A new concept of cancer genomics has led to the discovery of a number of genomic alternations that drive tumorigenesis and/or progression,[53,54] and contributed to the rapid development of protein interaction networks. The identification of cancer-specific onco-fusion proteins has increased knowledge of PPI-mediated epigenetic mechanisms and also revealed numerous PPIs that are directly associated with cancer pathology.[16]

2.13.2.2 Central Nervous System Disorders

PPIs are strikingly important for cellular processes in CNS including neurite outgrowth, synaptic formation and modulation, neurotransmission, signal transduction, and the induction of apoptosis.[55,56] Aggregation and/or misfolding of proteins, such as transthyretin (TTR), immunoglobulin light chain (LC), serum amyloid A (SAA), and amyloid-β (Aβ), may cause a number of neurodegenerative disorders.[57,58] It is reported that Aβ aggregates promote Alzheimer's disease (AD).[59–62]

The GPCR heteroreceptor complexes in the CNS are attracting more and more attention and have emerged as novel targets for the treatment of Parkinson's disease (PD), schizophrenia, drug addiction, anxiety, and depression, opening new avenues in neuropsychopharmacology.[63,64] The striatal adenosine A2A and dopamine D2 heteromeric receptor complexes exist in equilibrium with A2A and D2 homoreceptor complexes on the plasma membrane in the striato-pallidal GABAergic neurons where they strongly modulate excitability. This occurs via their ability to counteract the inhibitory D2R signaling to multiple effectors upon agonist

activation of the A2AR protomer.[65–67] These proteins may act as important antiparkinsonian targets based on the existence of antagonistic A2A–D2 receptor–receptor interactions within them.[68]

Glycogen Synthase Kinase 3 (GSK3) has important roles in neuronal polarity and synaptic plasticity, and it has been found dysfunctional in a plethora of brain disorders.[69–71] The fibroblast growth factor 14 (FGF14)-voltage-gated sodium (Nav) channel complex is identified as a new target of GSK3.[72] Inhibition of GSK3 reduces the assembly of the FGF14-Nav channel complex, modifies FGF14-dependent regulation of Na^+ currents, and induces dissociation and subcellular redistribution of the native FGF14–Nav channel complex in hippocampal neurons.

2.13.2.3 Inflammation and Autoimmune Diseases

The Kelch-like ECH-associated protein 1 (Keap1) and Nuclear factor erythroid 2-related factor 2 (Nrf2) pathway is one of the most important cytoprotective mechanisms acquired in vertebrates over the course of evolution. The Keap1–Nrf2 interaction plays a critical role in the protection of human body against drug toxicity and stress-induced diseases.[73] Direct and competitive Keap1–Nrf2 PPI inhibitors have been shown to be effective for enhancing Nrf2 activity, which has an important role in the protection against various diseases, including acute lung injury, chronic obstructive pulmonary diseases, autoimmune disease, inflammation, cancer, neurodegenerative disease, and cardiovascular disease.[74–78]

Nuclear factor kappa B (NF-kB) essential modulator (NEMO), also known as IkB kinase γ (IKKγ), is the regulatory subunit of the inhibitor of IKK complex, an essential component of the canonical NF-kB signaling pathway.[79–81] IKK complex, composed of NEMO and the catalytic alpha and beta subunits (IKKα and IKKβ), can activate NF-kB signaling, resulting in activation of genes involved in inflammation, immunity, cell survival, and other pathways. Thus, disruption of the NEMO–IKKα/β interaction that holds the complex together has emerged as a promising therapeutic target.[82]

Human coxsackievirus B3 (CVB3) causes a number of clinical manifestations including myocarditis, pancreatitis, and meningitis.[83–86] A recent study identified the host factor Golgi matrix protein 130 (GM130) as a novel target of CVB3, which may implicate in the pathogenesis of CVB3-induced acute pancreatitis.[87] The interaction of viral protein VP1 with GM130 disrupts GM130–GRASP65 complexes and may cause GM130 degradation, leading to disruption of the Golgi ribbon and development of acute pancreatitis in mice.

Tankyrase (TNKS), a member of the poly(ADP-ribose)polymerase (PARP) family, interacts with a variety of proteins involved in a wide range of biological functions.[88] In the case of adaptor protein 3BP2, mutations of the TNKS-binding motif underlie the human disease cherubism, a condition characterized by inflammatory lesions of the facial bone.[89]

Tumor necrosis factor (TNF) receptor-associated factor 6 (TRAF6) is a cytoplasmic protein that mediates signaling from the TNF superfamily receptors (TNFRSFs). The interactions between TRAF6 and TNFRSFs activate NF-kB family and activator protein 1 (AP1) family TFs, triggering immune and inflammatory responses and modulating bone homeostasis,[90] representing a promising target for the treatment of rheumatoid arthritis (RA).[91]

Blocking the IL-2/Interleukin-2-receptor (IL-2/IL-2R) interaction is important in suppression of immune responses.[92,93] The PPI between CD2 on T cells and CD58 on antigen-presenting cells(APCs) plays a significant role in the early stage of immune responses,[94] which are critically associated with inflammatory and autoimmune diseases.[95] CD40–TRAF6 interactions are also known to play an essential role in several inflammatory diseases.[96] More interactions remain to be elucidated.

2.13.2.4 Cardiovascular Disease

It is reported that a Golgi-localized membrane protein progestin and adipoQ receptors 3 (PAQR3) interacts with Scap and SREBP and tethers them to the Golgi to modulate cholesterol homeostasis.[97] Dysregulation of cholesterol homeostasis is closely associated with the pathogenesis of many human diseases, including atherosclerosis, myocardial infarction, and stroke.

Targeting PPIs, such as PDE4D5–β arrestin, PDE4–HSP20, and AKAP complexes within the cyclic adenosine 3′,5′-monophosphate (cAMP) signaling system, is a promising therapeutic strategy for cardiovascular disease.[98] cAMP participates in the fine control of excitation–contraction coupling in the heart, and thus dysfunction of this signaling cascade induces cardiac disease. The multifunctional scaffold protein β-arrestin orchestrates the dynamic redistribution of PDE4D5 in heart and airway cells, following the activation of the β2-adrenergic receptors.[99–101] An active pool of PDE4 is then recruited to the site of cAMP synthesis to initiate the desensitization process. AKAPs are important in the maintenance of distinct cAMP signaling compartments in cells.[102] Some AKAPs organize downstream cardiac signals that are driven by PKA via binding and anchoring PKA to sequester and localize the enzyme in the vicinity of its substrates and other signaling proteins. AKAPs are considered as a new and emerging target of drug development for chronic heart failure.[103] Small-molecule FMP-API-1 (**1**, **Fig. 2**), an inhibitor of AKAP–PKA interactions, was discovered to increase contractility of cultured rat cardiac myocytes and intact hearts.[104]

Besides the interactions mentioned earlier, a number of other PPIs related to cardiovascular disease are under investigation and will contribute to the discovery of new drugs in clinic. For example, inhibition of the complex formed by von Willebrand factor (vwf) and platelet glycoprotein (GP) Ib-V-IX is important for the development of antithrombotic agents.[105]

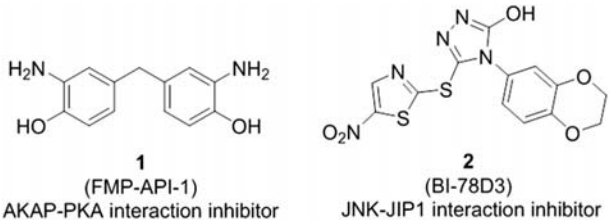

Fig. 2 Chemical structures of PPI inhibitors FMP-API-1 and BI-78D3.

2.13.2.5 Infectious Diseases

Many infectious diseases are results of abnormal PPIs involving endogenous proteins and proteins from pathogens. Atg8, the ubiquitin-like (Ubl) protein essential for formation and maturation of autophagosomes in autophagy in Eukarya, is partially conjugated to the membrane of the apicoplast under nonstarvation conditions in *Plasmodium*.[106–108] A second thioester intermediate formed by Atg8 transferred to its E2-like conjugating enzyme Atg3 and their noncovalent interaction are required for the lipidation of Atg8 to phosphatidylethanolamine (PE) in membranes in most eukaryotes. Inhibition of this PPI to prevent *Plasmodium falciparum* Atg8 (*Pf*Atg8) lipidation represents a promising strategy for antimalarial therapy.[109]

Viral E2 protein is critical for both replication and segregation of papilloma viruses which can cause warts and other diseases. It was reported that E2 protein interacts with C-terminus of bromodomain-containing protein 4 (BRD4) to form a physical tether between the viral plasmid and the host cell mitotic chromosomes.[110,111] Given that overexpression of C-terminus of BRD4 is enough to interrupt the interaction and stop the transmission of viral DNA into daughter cells, targeting E2-BRD4 interaction may be a promising therapeutic strategy for papilloma virus infection.

In addition, some other important PPIs, such as LEDGF–integrase interaction in HIV disease,[112] AMA1–RON2 interaction in malaria,[113] and ZipA–FtsZ interactions in bacterial infection,[114] have also demonstrated potential for developing new therapeutic interventions for infectious diseases.

2.13.2.6 Other Diseases

Jun N-terminal kinases (JNKs), serine threonine protein kinases, and members of the mitogen-activated protein kinases (MAPK) family, phosphorylate and activate a variety of cellular factors involved in various diseases including diabetes, atherosclerosis, and neurodegenerative diseases.[115] JNK-interacting protein-1 (JIP1) is a scaffolding protein that binds JNK via a specific, high-affinity D-domain. JIP1 can enhance JNK signaling by creating a proximity effect between JNK and upstream kinases.[116] JNK binding-domain of JIP1 acts as a competitive inhibitor of JNK signaling and restores normoglycemia in a mouse model of type 2 diabetes.[117–119] A screened compound BI-78D3 (**2**, **Fig. 2**) was shown to displace biotinylated JIP1 from GST-JNK1 and selectively inhibit JNK activity at nanomolar concentrations.[120] Moreover, BI-78D3 is effective for concanavalin A-induced liver damage in mice and restores insulin sensitivity in mouse model of type 2 diabetes in a few hours. Thus, JIP1 mimetic targeting JIP1–JNK interaction is feasible and effective, holding promise for new classes of JNK inhibitors.

Orally administered agonists of hormone erythropoietin (EPO) receptor are highly desired to replace the recombinant EPO to cure anemias caused by kidney failure through promoting the production of red blood cells.[121] Inhibitors of the SH2 domain as antiresorption agents may be used against osteoporosis.[122,123] More applications of PPI modulators remain to be explored in other human diseases in the future.

2.13.3 Protein–Protein Interactions as Drug Targets

Targeting PPIs by small molecules was once considered "undruggable" due to their large, flat interactive surfaces that lack apparently tractable cavities.[124,125] The average volume of pockets seen at protein–protein interfaces is only 54 Å, whereas traditional drug target proteins have one or two disproportionately large pockets with an average volume of 260 Å.[126] The interface contains six such small pockets on the average.[127] A small-molecule PPI inhibitor will likely target three to five small pockets in the protein–protein surface and take advantage of protein adaptability. In addition, unlike the traditional drug targets, PPIs do not have endogenous ligands that serve as potential starting points for medicinal chemists. As PPIs are largely dependent on hydrophobic contacts, such an inhibitor may suffer pharmacokinetic issues including poor solubility. Facilitated by the achievements in developing hotspots, screening techniques, and computational analyses, PPIs as drug targets now become possible and as a result, significant progress has been made in this field.

2.13.3.1 Hotspots and Allosteric Sites

Accumulating studies have shown that PPIs are critically dependent on some key residues ("hotspots") at the interface. Hotspots refer to a small subset of residues on the protein–protein interface contributing to the majority of the binding free energy.[128]

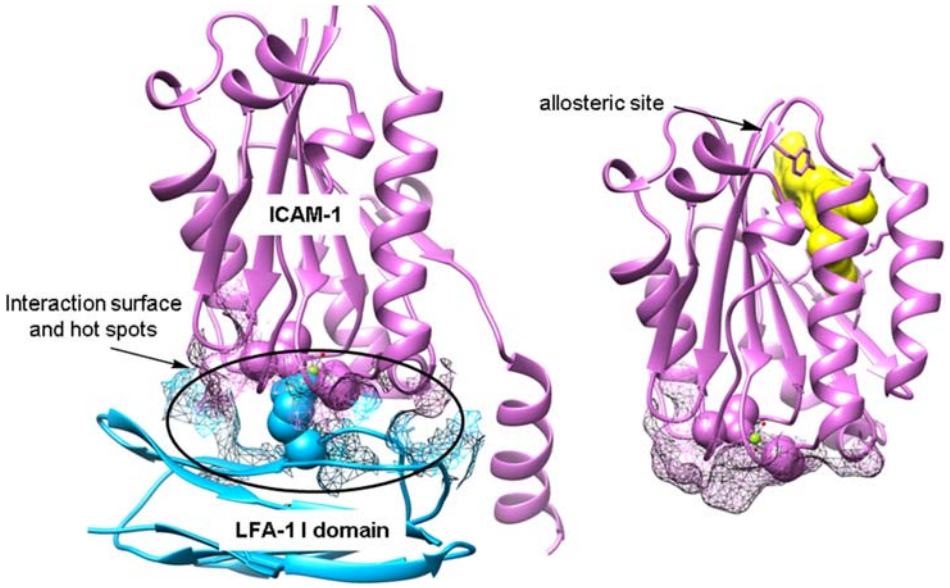

Fig. 3 Exemplary representation of interactive surface, hotspots, and allosteric site. *Left panel*: Complex of LFA I domain and ICAM-1 (PDB Code: 3BN3); Interaction surface and hotspots are depicted. *Right panel*: Complex of ICAM-1 with BMS-587101 (PDB Code: 2ICA); BMS-587101 is shown in *yellow*.

They are often surrounded by a ring of more polar residues that act as an "O-ring" to exclude bulk water from the immediate environment of the hotspots. Hotspots can also be considered as a site on a therapeutic target that has high propensity for ligand binding in the drug design. As an exemplary representation of the concept, the interaction surface and hotspots of LFA-1 complexed with ICAM-1 is depicted in **Fig. 3** (left panel). Hotspots are often identified by experimental methods (eg, alanine scanning, NMR, and crystallographic methods) or computational methods.[129,130] Substitution of a hotspot by an alanine leads to a significant decrease in the free energy of binding ($\Delta\Delta G_{binding} > 1.5$ kcal mol^{-1}).[128] Systematic analysis of alanine mutants on amino acid residues in protein–protein binding sites indicates that the amino acid composition of hotspots may be enriched in tryptophan (W), arginine (R), and tyrosine (Y).[131,132] NMR and crystallographic methods with mutational data provide useful information to define hotspots in 3D structures of protein complex. Also, computational methods have been developed to predict hotspots as a complementary method to the alanine scanning experiments, which may be faulted due to false positives and the possible omission of binding hotspots.[133] To date, a number of software programs, such as PredHS, iPred, and HotPoint,[134–136] are available for the identification of hotspots. Taking hotspots as the starting points for ligand identification is considered as an essential strategy for the development of PPIs.[137] No matter if it is the α-helix or nonlinear epitopes mediating the PPI, a mimetic that reproduces the key recognition features of the hotspots can act as a competitive inhibitor.[137–139]

Allosteric sites are where ligands bind to the target protein distinct from the protein–protein interface. Taking LFA-1 complexed with ICAM-1 as an example (**Fig. 3**, right panel), it is clear that the allosteric inhibitor BMS-587101 binds to a pocket that is distinct from their interactive surface. This kind of binding hinders the macromolecular interaction in an allosteric manner through inducing changes in either the static conformation or the dynamic properties of the target protein(s).[140–142] Disruption of a PPI occurs upon the binding of a ligand to a PPI allosteric site without competing with the binding protein partner. The primary advantages of developing allosteric modulators include the high level of control over the PPI modulation and often improved identification of the suitable allosteric sites.

2.13.3.2 Identification of Druggable Protein–Protein Interactions

The characteristics of a druggable PPI have been identified and explored.[143–145] The Vajda group found that the druggable PPI sites include a cluster of binding hotspots, which are distinguishable from other regions of the protein because of their concave topology combined with a pattern of hydrophobic and polar functionality.[146] Meanwhile, the hotspot pocket tends to undergo different induced-fit rearrangements when the target protein interacts with different protein partners and small-molecule ligands. The critical components of this adaptivity are largely local, involving primarily low energy side chain motions within 6 Å of a hotspot.[146] The druggability of a binding site increases logarithmically with total surface area and apolar contact area, while it decreases logarithmically with polar contact area, which plays a decisive role in recognizing drug-like small molecules.[147] Surface roughness and pocket shape are also crucial for the druggability of a protein pocket.[148] The amino acid residues around druggable PPI pockets (higher frequency of aromatic residues and methionine observed) are obviously different from that in the other areas on the protein surface.[149,150] An increasing number of charged residues can play a negative role on the druggability of a pocket.[143]

2.13.3.3 Small Molecular Protein–Protein Interaction Inhibitors

Small molecular PPI inhibitors can be classified as peptides, secondary structure mimetics, and nonpeptide small molecules. They have unique advantages and disadvantages different from those small molecules targeting traditional enzymes. It is a double-edged sword that typical PPI interfaces are usually very large. On the one hand, this large surface area is difficult to target, but on the other hand, it offers more room to encode selectivity compared with the conserved traditional substrate binding site.[151] Increased selectivity benefits the reduction of the likelihood of off-target toxicities. Meanwhile, in order to maximize the surface contact area, PPI inhibitors need to be large and lipophilic with more rings and fewer rotatable bonds. This brings about big challenges on optimizing ADME property and improving druggability. In addition, PPI inhibitors may reduce the susceptibility to resistance mutations because of the distinct structural features that underlie PPIs.[152] Meanwhile, it is more feasible to control the pharmacokinetic property of PPI inhibitors compared with the traditional active-site inhibitors as PPI inhibitors are prone to be more solvent exposed. It is also observed that the appearance of a nitro moiety is quite common in PPI modulators.[153] Proper replacements of such a group are needed, because aromatic nitro may be potentially toxic when it is metabolized in the body.[154]

2.13.4 Strategies to Generate Protein–Protein Interaction Inhibitors

Characterization of protein interaction interfaces is the first step to develop small-molecule inhibitors of PPIs. The understanding of the PPI interface provides strong support for the efforts to discover novel small-molecule PPI inhibitors.[155]

2.13.4.1 Peptides and Peptidomimetics

The easiest way to generate a PPI inhibitor is to cut out the amino acid sequence of an interacting epitope in a similar fashion to that we mentioned in the section of hotspots. A peptidomimetic is a small protein-like chain designed to mimic that peptide. In a broad sense, peptidomimetics include peptide backbone mimetics, functional mimetics, and topographical mimetics.[156] Native peptides are easily accessible in light of standard synthetic protocols and have a lot of advantages, such as high selectivity and specificity. But their developments are limited due to the intrinsic weaknesses including chemical/physical instability, tendency for aggregation, short half-life, fast elimination, and low membrane permeability.[157] To address these issues, various approaches are taken to design peptidomimetics. For example, peptide bonds can be replaced with other chemical scaffolds. Also, amino acid residues, which are prone to hydrolysis, can be changed into other kinds of amino acids or nonpeptide fragments to increase their stability. Cell-penetrating peptides, such as the transcription trans-activating (TAT) sequences, are developed to solve the problem of membrane permeability. TAT-$IDP_{DD/AA}$ is an analog of TAT-Pep2, which is a competitive inhibitor of the Bcl-2–IP3R interaction. Asp–Asp (DD), the aspartyl protease site in TAT-Pep2, was replaced with Ala–Ala in TAT-$IDP_{DD/AA}$. This strategy reduced proteolytic cleavage, increased cellular uptake, improved the stability, and ultimately reinforced the efficacy of TAT-$IDP_{DD/AA}$.[158] The critical sequence often exists in the form of an α-helix, or β-sheet when it is a part of a protein. Thus chemical modifications (eg, cyclic[159] and stapled[160] forms) are required to maintain its secondary structure as the peptide itself is usually a random coil in solution. Stabilizing of the secondary structure offers an opportunity for oral peptides and helps to improve patient convenience and compliance. Cyclization is the simplest way to introduce a conformational constraint often via connecting two suitable sites (head to tail, backbone to side chain, or side chain to side chain). The all-hydrocarbon staple is another kind of chemical interventions, conferring α-helical structure, protease resistance, cellular penetrance, and biological activity.[161] N-methylation, establishment of intramolecular hydrogen bonds, and building hydrophobic faces are all effective approaches to stabilizing secondary structure.[157] ATSP-7041 (**3**, **Fig. 4A**), a potent and selective stapled peptide reactivator of the wild-type p53 tumor suppressor protein, has shown great promise to enter clinical trials based on its preclinical results. ATSP-7041 targets the interactions of p53 with its major negative regulators MDM2 and MDMX, which are overexpressed in some cancers with equipotent nanomolar inhibitory activity. In addition, it suppresses tumor growth in animal models of multiple human xenograft models (eg, breast cancer and bone cancer).[162,163] Furthermore, it displays favorable drug-like and pharmacokinetic properties such as efficient cell membrane penetration and potential for once-weekly dosing. From the cocrystal structure of ATSP-7041 with MDMX (**Fig. 4B**, right panel), it is revealed that the peptidomimetic is bound in the p53 binding site of MDMX (**Fig. 4B**, left panel).

2.13.4.2 High-Throughput Screening

High-throughput screening (HTS) is a widely used method for discovering hits in traditional targets. When it is applied to PPIs, the first problem lies in low hit rates due to the different chemical space of PPIs from traditional compound libraries. The HTS hit rate is as low as 0.0001% in the identification of JIP-JNK inhibitors performed by Chen et al.[164] Tremendous efforts have been made to build new libraries suitable for PPIs such as peptide libraries,[165–167] α-helix mimetic library,[168] iPPI-DB,[169] and natural product libraries. The most widely used HTS techniques for PPIs include the two-hybrid assay, affinity purification, fluorescence polarization (FP), and fluorescence resonance energy transfer (FRET).[170–172] One of the advantages with HTS is that it works even when the structure information of a target protein is not available. In addition, HTS can also be applied to reveal inducible pockets in protein–protein interfaces, as well as allosteric modulators.[16] However, the limitations include the low hit rate due to incompatible libraries and the potential false positives, which need to be eliminated. The discovery of nutlins and benzodiazepinediones as p53–MDM2

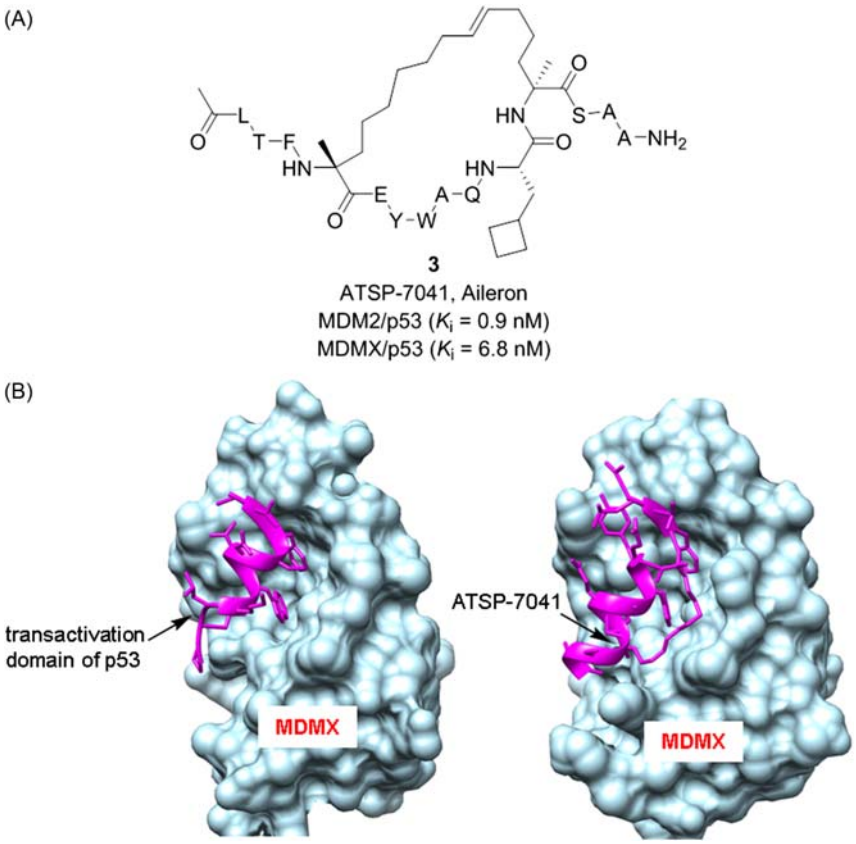

Fig. 4 (A) Chemical structure of PPI inhibitor ATSP-0741. *L*, Leu; *T*, Thr; *F*, Phe; *E*, Glu; *Y*, Tyr; *W*, Trp; *A*, Ala; *Q*, Gln; *S*, Ser. inhibitors is one of the most successful examples in identifying PPI inhibitors through HTS.[173,174] RG7112, a nutlin derivative, is currently in Phase I clinical trials for the treatment of leukemia and solid tumors.[175,176]

2.13.4.3 Fragment-Based Drug Design

Fragment screening and fragment-based drug design (FBDD) are effective to discover protein–protein inhibitors. It is based on identifying small chemical fragment hits, which may bind only weakly to the biological target, and can be optimized via fragment linking, fragment evolution, fragment modification, and fragment self-assembly to produce a lead with a higher affinity.[153,177] A fragment is usually defined as a small organic molecule that follows the "rule of three" (RO3; the molecular weight of the compound $\leqslant$ 300, ClogP $\leqslant$ 3, the number of H-bond donors $\leqslant$ 3, the number of H-bond acceptors $\leqslant$ 3, the number of rotatable bonds $\leqslant$ 3, and polar surface area (tPSA) $\leqslant$ 60 Å^2).[178] It is suggested that some of these strict criteria should be compromised for fragments of PPIs.[179] There are a variety of methods to screen and validate the fragment hits including NMR, MS, X-ray crystallography, surface plasmon resonance (SPR) spectroscopy, tethering, differential scanning fluorimetry (DSF), and isothermal calorimetry (ITC).[177] Weak fragments bound to different hotspots can be connected by a linker and further optimized to generate a high-affinity lead with increased drug-likeness. Fragment screening has higher hit rates, higher ligand efficiency (LE; LE = 1.37 pIC_{50}/number of heavy atoms), and a larger chemical space compared to HTS. In the fragment screening of HIF–TACC3 inhibitors, the hit rate reached 2.3%.[180] Nevertheless, it also has high demands for detection equipment and specific expertise.[181] Meanwhile, it is not applicable for proteins whose structures are unclear. The development of ABT737 and its derivatives ABT263/ABT199 as Bcl-2 inhibitors are outstanding cases of application through FBDD. ABT199, currently in Phase III clinical trials, represents the most promising Bcl-2 inhibitor to be approved by US Food and Drug Administration (FDA) in the future.

2.13.4.4 Virtual Screening

Virtual screening (VS),[182] a computer-aided drug discovery approach comprising the in silico screening of a compound library, is a complementary method to HTS given the work burden of screening compound libraries. The ligand-based

(or pharmacophore-based) approach and structure-based VS are two general screening techniques used in VS.[183] The former model emphasizes the chemical features of compounds important for efficient protein binding.[184] The latter one depends on the structural information of the binding pocket on the target protein.[185] One of the most commonly applied VS methods is molecular docking, by which drug-like compounds are placed into the binding site on their receptor structure virtually, and the binding affinity is evaluated in terms of energy scoring function. Docking methods are used in different stages of identifying a lead compound, such as modeling the protein complex and screening for hotspots on the interactive surface and small molecular PPI modulators.[186] Because of protein flexibility, computational methods appear critically important to search the conformational space of the protein surface and druggable pockets. Though significant progress (eg, predefined structural ensembles[187]) on modeling induced fit effects has been made, two main barriers still remain: comprehensive sampling techniques and scoring.[151,188] As to the screening of small molecular inhibitors, the rule-of-five guideline may be inappropriate. A number of new rules have been developed to predict the physicochemical properties as well as toxicities of PPI inhibitors.[189–191] The hit rate of VS may also be higher than HTS. In the VS of IFN-α–IFNAR inhibitors, it is as high as 16.7%.[192] NSC 66811, a novel p53–MDM2 interaction inhibitor, was discovered via virtual database screening strategy with a hit rate of 14.9%. It mimics three p53 residues (Leu26, Trp23, and Phe19) critical for the interaction and binds to MDM2 with a K_i value of 120 nM.[193]

2.13.5 Highlights on Recent Advances in Drug Discovery Targeting Protein–Protein Interactions

2.13.5.1 Cancer

2.13.5.1.1 Bcl-2/Bcl-x_L–Bak

Developing BH3 mimetics, such as Bcl-2 inhibitors disturbing the interactions between Bcl-2 and proapoptotic proteins, has attracted tremendous attention over the past decade. The AbbVie researchers conducted an NMR-based screening and discovered two fragments (Compounds **4** and **5**, Fig. 5) bound with different sites of Bcl-x_L, with IC_{50} values of 300 and 4300 μM, respectively.[194] Through linking strategy, NMR-based structure information guided parallel synthesis, and reasonable optimization, a potent Bcl-2 inhibitor ABT-737 (Compound **6**, Fig. 5) was obtained. It effectively binds to Bcl-x_L, Bcl-2, and Bcl-w with K_i values less than 1 nM, rather than Bcl-B, Mcl-1, and A1 ($K_i = 0.46 \pm 0.11$ μM, >1 μM, and >1 μM, respectively).[195,196] ABT-737 was shown to disrupt an intracellular Bcl-2 family PPI via a mammalian two-hybrid system. It causes tumor regression in established human tumor xenograft models and displays synergistic cytotoxicity with chemotherapeutics and radiation. However, a major drawback of ABT-737 is its poor oral bioavailability. Thus, a second generation of Bcl-2 inhibitor **7** (ABT-263, Fig. 5A) was developed, with an oral bioavailability of 20% to 50% in preclinical animal models.[197] ABT-263 also displays high affinity for Bcl-x_L, Bcl-2, and Bcl-w and selectivity over Mcl-1 and A1. From the cocrystal structures, it clearly occupies the same pocket where BH3 domains of proapoptotic proteins bind to Bcl-x_L (Fig. 5B). With better PK profiles and effective preclinical in vivo tumor regression studies, ABT-263 was enrolled into clinical trials. However, concomitant on-target thrombocytopenia caused by Bcl-x_L inhibition limits its efficacy.[198] Therefore, a third generation of Bcl-2 inhibitor **8** (ABT-199, Fig. 5A), a selective Bcl-2 inhibitor, was created.[199] ABT-199 has a subnanomolar affinity for Bcl-2 with K_i value less than 0.01 nM, more than 1000-fold selectivity over Bcl-x_L ($K_i = 48$ nM) and Bcl-w ($K_i = 245$ nM) in a time-resolved FRET competition binding assay. It exhibits single-agent cell-killing activity against a number of non-Hodgkin's lymphoma (NHL) cell lines including diffuse large B-cell lymphoma (DLBCL). ABT-199 suppresses tumor growth in a variety of human hematological tumor xenografts as a single agent or in combination with other anticancer agents. More importantly, ABT-199 has obviously reduced effects on platelets compared with ABT-263 due to selective inhibition of Bcl-2. Currently, it is under Phase III clinical trials and has recently been granted breakthrough therapy designation for the treatment of 17p deletion relapsed-refractory chronic lymphocytic leukemia (CLL) (http://abbvie.mediaroom.com/).

2.13.5.1.2 MDM2–p53

RO5045337 (compound **9**, Fig. 6A) is the first clinical MDM2 inhibitor designed to occupy the p53-binding pocket of MDM2. It was derived from a series of *cis*-diphenyl substituted imidazoline-containing compounds known as "nutlins" screened by SPR.[173] RO5045337 shows high MDM2 affinity ($IC_{50} = 18$ nM) in a homogeneous time-resolved fluorescence (HTRF) assay that utilizes the N-terminal domain of recombinant human MDM2 protein and a peptide derived from the binding site of p53.[176] From the cocrystal structure (Fig. 6B), RO5045337 efficiently occupies the major three pockets P1, P2, and P3, which are originally filled with residues Leu26, Trp23, and Phe19 of p53. It effectively inhibits 15 different cancer cell lines expressing wild-type p53 with IC_{50} values in the range of 0.18–2.2 μM, while 5.7–20.3 μM inhibitory activity against cancer cell lines with p53 mutation. RO5045337 also displays favorable pharmacokinetic properties with an AUC value of 251.2 $\mu g \cdot h\ mL^{-1}$, C_{max} value of 15.5 $\mu g\ mL^{-1}$, and longer half-life ($t_{1/2} = 8.8$ h).[200] It effectively suppresses the growth of established tumor xenografts of SJSA1 and MHM osteosarcoma cell lines with MDM2 gene amplification and overexpression of MDM2 protein in nude mice. In clinical trials, it has been investigated against a wide range of cancers, such as sarcoma, myelogenous leukemia, and hematologic neoplasms. RO5045337 displays good human PK profile and signs of antitumor efficacy in patients; however, it has adverse events including neutropenia and thrombocytopenia.[175]

SAR405838 (**10**, Fig. 6A) was discovered by Wang group at the University of Michigan and advanced into phase I clinical trials in 2012.[201] It was optimized from a series of spirooxindoles designed using a structure-based approach to mimic the three key p53-binding residues: Phe19, Trp23, and Leu26.[202] SAR405838 has high affinity to MDM2 with an IC_{50} value of 0.88 nM. It is

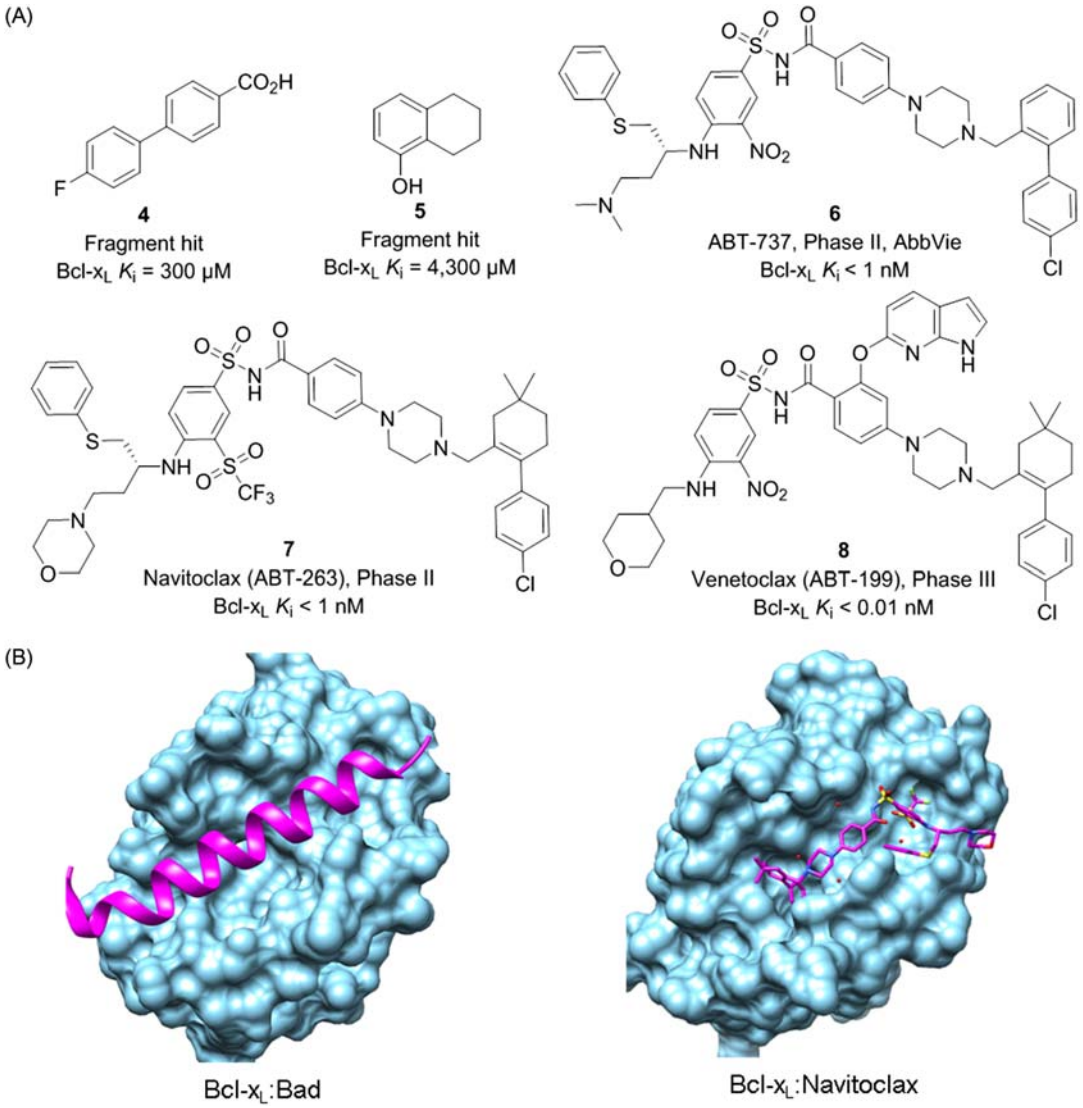

Fig. 5 (A) Chemical structures of selected Bcl-2 inhibitors. (B) *Left panel*: Cocrystal structure of Bcl-x_L and full length Bad (PDB code: 2BZW). *Right panel*: Complex of Bcl-x_L and ABT-263 (PDB code: 4LVT).

revealed by the cocrystal structure of MDM2/SAR405838 complex that SAR405838 not only occupies the pockets original filled by Phe19, Trp23, and Leu26, but also gains additional interactions including hydrophobic contacts of Cl with MDM2 and π–π stacking of 2-fluoro-3-chlorophenyl with the His96 of MDM2. Moreover, the N-terminus of MDM2 (residues 10–18) refolds and has extensive interactions with SAR405838 via Val14 and Thr16. SAR405838 potently inhibits cell growth in diverse cancer cell lines (eg, SJSA-1, RS4;11, LNCaP, and HCT-116) with wild-type p53 and displays high selectivity (>100-folds) over cancer cell lines with mutated or deleted p53. SAR405838 achieves either durable tumor regression or complete tumor growth inhibition in mouse xenograft models of SJSA-1 osteosarcoma, RS4;11 acute leukemia, LNCaP prostate cancer, and HCT-116 colon cancer.[201] Currently, it is under Phase I clinical trials to assess its safety, tolerability, and pharmacokinetics in patients with advanced stage cancer.

Several other MDM2 inhibitors targeting MDM2–p53 interactions are in Phase I human clinical trials such as AMG232 (compound **11**, Fig. 6) developed by Amgen.[203] They display promising implications for the treatment of human solid cancers and leukemia as a single agent or in combination with traditional chemotherapy agents and molecularly targeted agents.

2.13.5.1.3 WDR5–MLL

MM-102 (Compound **12**, Fig. 7) is a peptidomimetic to inhibit the MLL1–WDR5 interaction based on the binding motif derived from MLL1.[36] It binds to WDR5 with $K_i < 1$ nM and inhibits MLL1 activity potently in a fully reconstituted in vitro H3K4 methyltransferase assay. Cocrystal structure of MM-102 and WDR5 indicates that the Arg side chain of MM-102 inserts deeply into the central channel of WDR5 and all the nitrogen atoms in the molecule engage in either intra- or intermolecular hydrogen bonds.

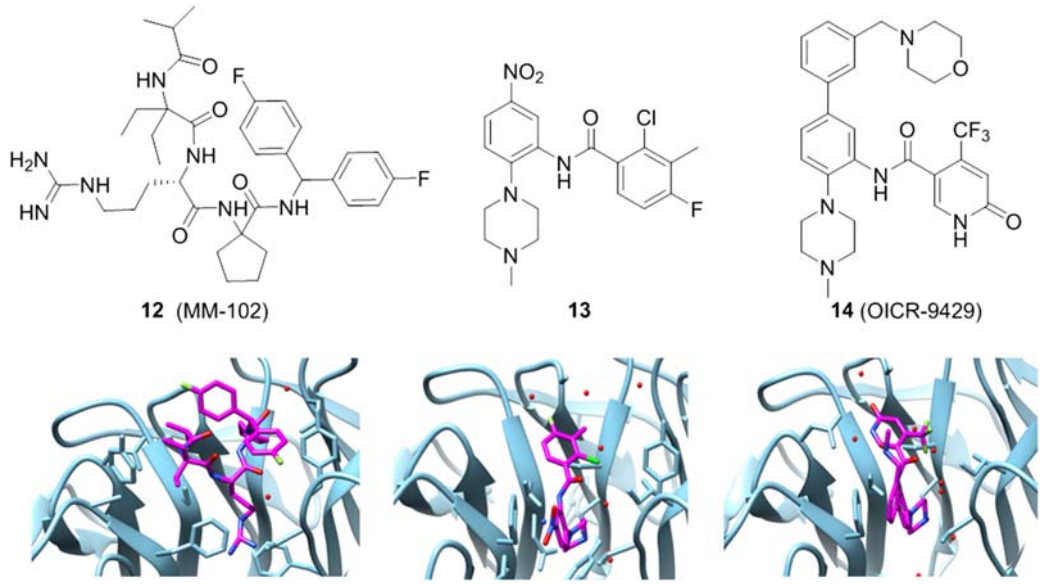

Fig. 7 Chemical structures of PPI inhibitors MM-102 (**12**), **13**, OICR-9429 (**14**) and their cocrystal structures with WDR5 (PDB codes: 4GM8, 4IA9, and 4QL1).

MM-102 effectively decreases the expression of two critical MLL1 target genes (HoxA9 and Meis-1) in bone marrow cells transduced with MLL1-AF9 fusion construct. It also specifically inhibits cell growth and induces apoptosis in leukemia cells harboring MLL1 fusion proteins.[36] Based on the screening result of an established assay that can detect displacement of a fluorescein-labeled WIN peptide (GSARAEVHLRKS) from its binding pocket in WDR5 using FP,[204,205] further optimization led to the discovery of compound **13** (**Fig. 7**).[37] It has a greater than 25-fold gain in potency compared to its parent compound. Further modification has resulted in a potent MLL–WDR5 interaction inhibitor OICR-9429 (Compound **14**, **Fig. 7**), which binds WDR5 with an IC_{50} of 93 nM. OICR-9429 selectively inhibits proliferation and induces differentiation in p30-expressing human AML cells, indicating that WDR5 is a promising therapeutic target in CEBPA-mutant AML.

2.13.5.1.4 Bromodomain–acetylated histone

BET (bromodomain and extraterminal domain) family is a class of well-known bromodomain proteins. Member proteins (eg, BRD2, BRD3, BRD4, and BRDT) binding to acetylated lysine residues in histone tails represents an activation marker of gene expression. Among them, BRD4 is reported to involve in the pathogenesis of various cancers including NUT midline carcinoma (NMC) and AML.[206–208] Since the discovery of (+)-JQ1, which binds tightly to the first and second bromodomains (BD1 and BD2) of BRD4 competing against acetylated histone, a number of novel inhibitors have been reported and several of them are enrolled into clinical trials. RVX-208 (**15**, **Fig. 8A**) is now in Phase II clinical trials with stable coronary artery disease. It is not a BRD4-specific inhibitor, but a pan-BET inhibitor and prefers BD2 of BET proteins. Cocrystal structures of RVX-208 with BRD4 BD1 and BRD2 BD2 are shown in the form of surface presentation (**Fig. 8B, i** and ii). I-BET762 (**16**) and OTX-015 (**17**),[209,210] analogs of benzodiazepine (BZD), are now in Phase I clinical trials for NMC and acute leukemia, respectively. BZD, a well-known privileged structure, is widely used in clinical drugs for anticonvulsant, sedative, and anxiolytic purposes working via the gamma-aminobutyric acid (GABA)-A receptor.[211] Repurposing of privileged structures is very popular in recent years,[212] and BZDs have been applied to

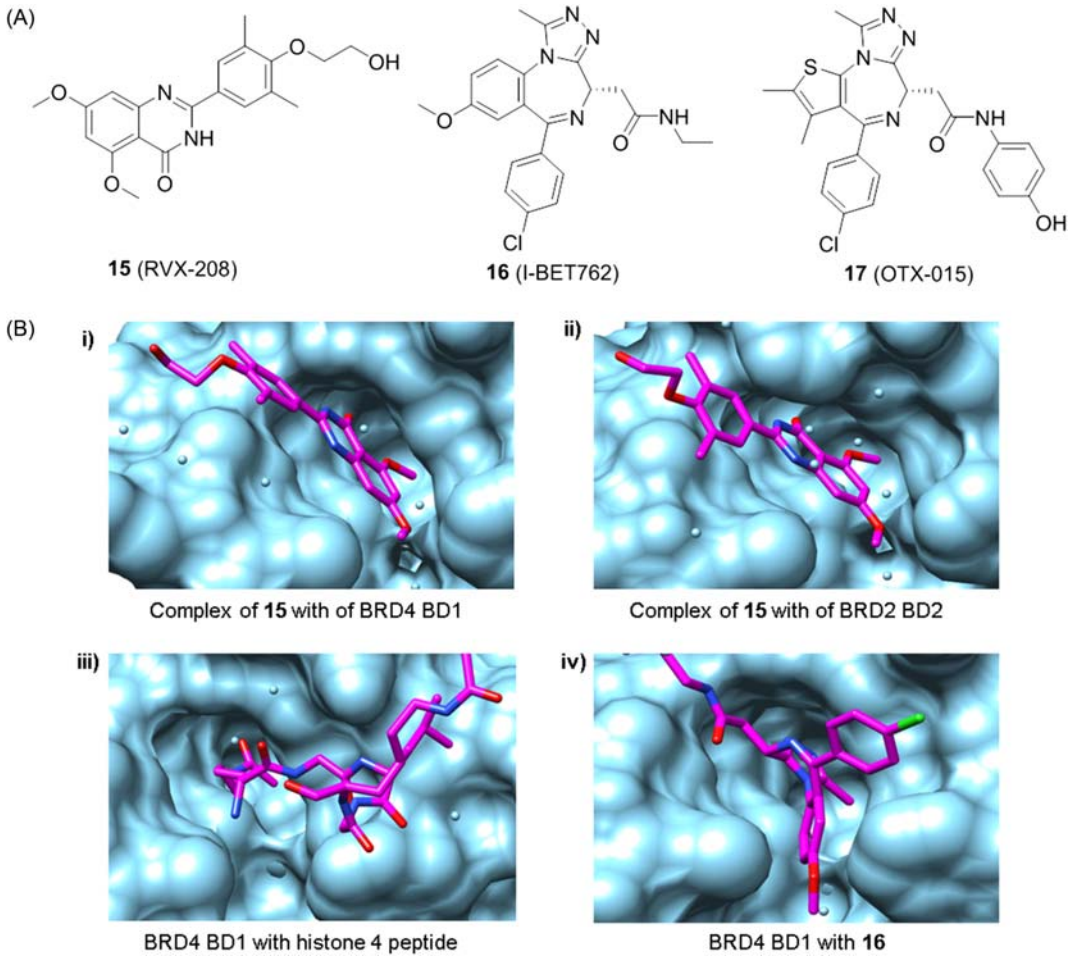

Fig. 8 (A) Chemical structures of bromodomain–acetylated histone inhibitors **15**–**17**. (B) Cocrystal structures of bromodomain–acetylated histone inhibitors. (i) Complex of **15** with BRD4 BD1 (PDB code: 4MR4). (ii) Complex of **15** with BRD2 BD2 (PDB code: 4J1P). (iii) Complex of BRD4 BD1 with histone 4 peptide (PDB code: 3UW9). (iv) Complex of BRD4 BD1 with **16** (PDB code: 4C66).

interactions with BET proteins by fusing to an isostere of benzene or thiophene starting from (+)-JQ1. Neither (+)-JQ1 nor I-BET762 shows interaction with the BZD binding site on the GABA receptor.[213,214] The tortuous BZD scaffold of I-BET762 helps it extend beyond the binding region that a lysine-acetylated histone would occupy (Fig. 8B, iii and iv).

2.13.5.2 Central Nervous System Disorders

2.13.5.2.1 PDZ Domain Interactions

The PSD95/DlgA/ZO-1 homology (PDZ) domain is involved in interactions between many different proteins in a variety of cellular contexts. Interaction of neuronal nitric oxide synthase (nNOS) with the protein postsynaptic density-95 (PSD-95) was reported to induce nitric oxide (NO) overproduction, neuronal injury,[215] and impaired regenerative repair after stroke in rats.[216] Given that the salt bridge (between Asp62 and Arg121, Fig. 9A, left panel) is structurally required and hydrophobic residues (Leu107 and Phe111, Fig. 9A, left panel) are crucial for the nNOS β-finger interacting with PSD-95, ZL006 (**18**, Fig. 9A, right panel) was designed by connecting a hydrophobic ring and a hydrophilic ring through a flexible linker. ZL006 not only selectively blocks the ischemia-induced nNOS–PSD-95 association, displaying potent neuroprotective activity in vitro, but also ameliorates focal cerebral ischemic damage in mice and rats subjected to middle cerebral artery occlusion (MCAO) and reperfusion, without inhibiting NMDAR function, catalytic activity of nNOS or spatial memory, indicating ZL006 may treat stroke without major side effects.[215] Another nNOS–PSD95 inhibitor IC87201 (**19**, Fig. 9A, right panel) was yielded by a high-throughput screen using in vitro binding assay. It reverses NMDA-induced thermal hyperalgesia in mice potently and reverses mechanical allodynia induced by chronic constriction of the sciatic nerve via intrathecal administration.[217]

PSD-95 and the related MAGUK proteins contain three consecutive PDZ domains, and thus trimeric ligand **20** (Fig. 9B) was designed to target all three PDZ domains by introducing a PDZ3-binding peptide moiety via a cysteine-derivatized NPEG linker.[218] It has optimal length for targeting the PDZ1–2–3 proteins of PSD-95 and high affinity with K_i value of 3.3 nM. Based on a series of indole analogues derived from peptide-mimetics of C-terminus of PDZ ligands,[219] compound **21** (Fig. 9B) was developed to disrupt the interaction between the PDZ protein PSD-95 and the C-terminal domain of the 5-HT_{2A} serotonin receptor.[220] Its inhibitory activity against interactions between PSD-95 and the 5-HT_{2A} receptor in vitro was confirmed by $^{1}H-^{15}N$ heteronuclear single-quantum coherence (HSQC) experiments. Compound **21** significantly suppresses mechanical hyperalgesia in an experimental model of traumatic neuropathic pain in the rat, which can be abolished by the coadministration of the 5-HT_{2A} receptor antagonist M100907.[220]

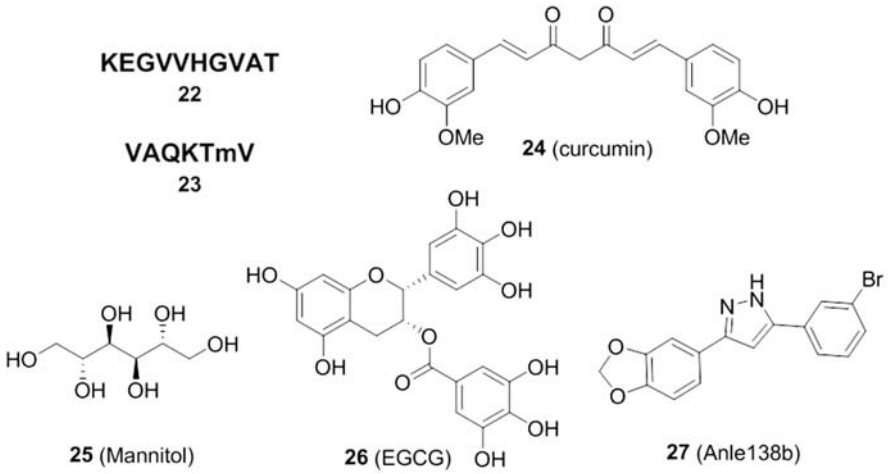

Fig. 10 Chemical structures of α-synuclein aggregation inhibitors **22**–**27**.

2.13.5.2.2 α-Synuclein aggregation

Targeting α-synuclein holds great promise for the treatment of PD.[221–223] Both peptides **22** and **23** (Fig. 10) are able to disrupt the aggregation of α-synuclein. Peptide **22** was generated from residues 45–54 (KEGVVHGVAT) where most early-onset mutations are located,[224] while peptide **23** was derived from residues 77–82 (VAQKTV), which is identified as key residues within amyloidogenic protein sequences by solid-state nuclear magnetic resonance (ssNMR).[225] Polyphenols including compounds **24**–**26** inhibit initiation and/or growth of α-synuclein fibrils. Compound **24** was shown to bind specifically to oligomeric intermediates instead of monomeric α-synuclein indicated by fluorescence and two-dimensional nuclear magnetic resonance (2D-NMR) data.[226] Mannitol (**25**), a blood–brain barrier (BBB) disrupter, interferes with α-synuclein aggregation in vitro and in vivo without adverse toxicity.[227] It reduces the amount of α-synuclein aggregates in a Parkinson drosophila model and the mThy1-human α-synuclein transgenic mouse model. EGCG (**26**) directly binds to unfolded polypeptide chains and inhibits β-sheet formation (an early event in the amyloid formation cascade) by redirecting aggregation prone polypeptides into off-pathway protein assemblies.[228,229] Anle138b (**27**), developed based on a logical HTS combined with medicinal chemistry modification, blocks the formation of α-synuclein aggregates in vitro and inhibits oligomer accumulation, neuronal degeneration, and disease progression in three different PD mouse models in vivo.[230]

2.13.5.3 Inflammation and Autoimmune Diseases

2.13.5.3.1 LFA-1–ICAM-1

Compound **28** (Fig. 11A) is an LFA-1 antagonist through blocking its binding of ICAM-1. It was generated by mimicking nonlinear protein epitopes of ICAM-1 (eg, E34, K39, M64, Y66, N68, and Q73), responsible for its association with LFA-1 (Fig. 11B, left panel).[138] Compound **28** exhibits potent inhibition of ICAM-1/LFA-1 binding, with an IC_{50} value of 1.4 nM in LFA-1 ELISA assay, inhibits mixed lymphocyte reaction (MLR) with an IC_{50} value of 3 nM, and also exhibits significant antiinflammatory effects in vivo. BMS-587101 (Compound **29**, Fig. 11A) was optimized from spirocyclic hydantoin based LFA-1 antagonists and is a potent inhibitor of LFA-1-mediated adhesion in the T-cell/HUVEC adhesion assay with an IC_{50} value of 20 nM. Also, it shows moderate potency in vitro mouse adhesion assay and good PK property in several preclinical species. Moreover, BMS-587101 displays efficacy in two different in vivo models of inflammation.[231] However, it was terminated in Phase II clinical trials likely owing to insufficient efficacy. A second generation ICAM-1/LFA-1 interaction inhibitor BMS-688521 (**30**) with an enhanced potency was obtained through exploring carboxylic acid substituted heterocycles appended to the pyrrolidine ring of the spirocyclic hydantoin core.[232] NMR and X-ray crystal structure (Fig. 11B, right panel) shows that this series of compounds bind to the I-Domain allosteric site (IDAS) of the I-Domain, which is distinct from the site LFA-1 I domain interacting with ICAM-1 (Fig. 11B, middle panel). Based on the pharmacophore analysis of screening hits with micromolar potency against the binding of LFA-1 to ICAM-1, A-286982 (**31**) was developed via searching different linkers to connect a piperazine to occupy a newly identified binding pocket.[233] It has IC_{50} values of 44 and 35 nM in an LFA-1/ICAM-1 binding assay and LFA-1-mediated cellular adhesion assay, respectively. Further optimization of A-286982 through fragment-based NMR screening led to compound **32**, with improved solubility and oral bioavailability. Tetrahydroisoquinoline (THIQ)-derived LFA-1/ICAM-1 antagonists were evolved from an analog of compound **28** by cyclization.[234,235] A systematic structure–activity relationship (SAR) study yielded SAR1118 (**33**), which is currently in Phase III clinical studies as an ophthalmic solution for treating dry eye.[236]

2.13.5.3.2 Keap1–Nrf2

Direct and competitive Keap1–Nrf2 PPI inhibitors have been shown to be effective for enhancing Nrf2 activity, which is important in the protection against various diseases, including acute lung injury, chronic obstructive pulmonary diseases, autoimmune

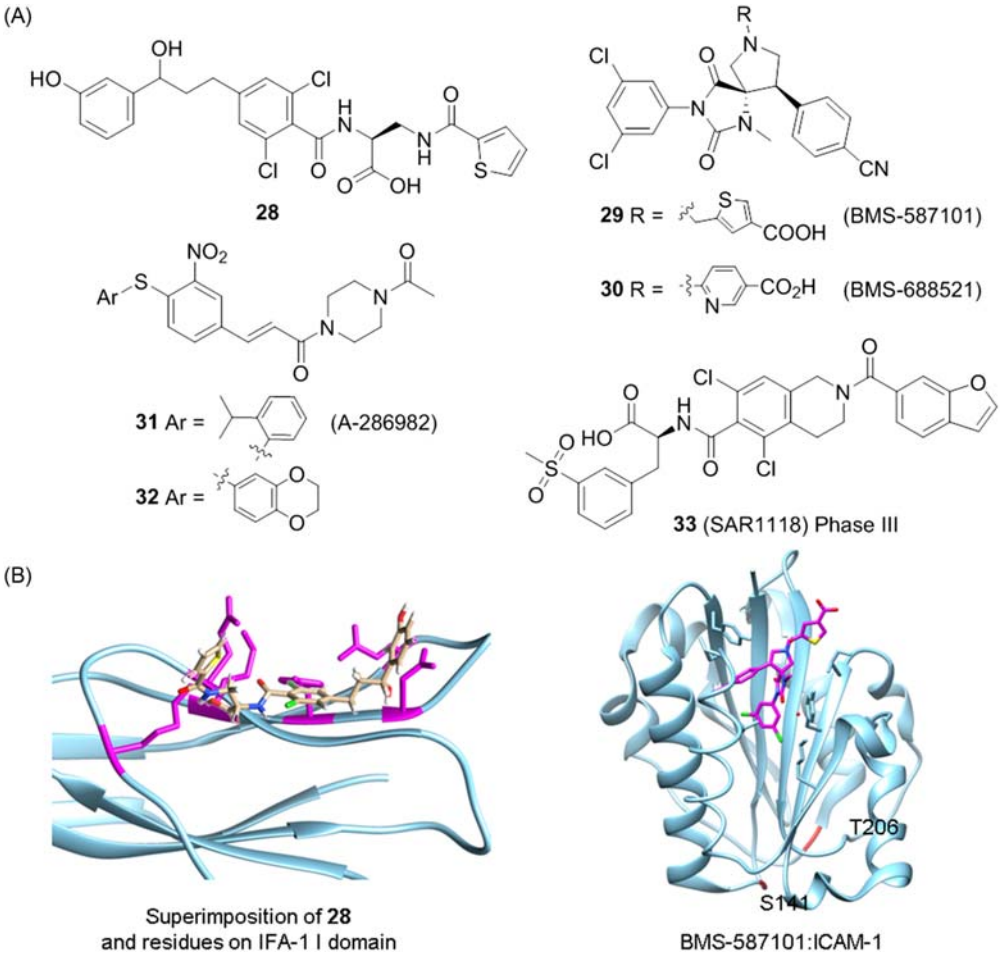

Fig. 11 (A) Chemical structures of PPI inhibitors **28**, BMS-587101, A-286982, and SAR1118. (B) *Left panel*: Superimposition of **28** and ICAM-1 epitope. *Right panel*: BMS-587101:ICAM-1 complex (PDB code: 2ICA).

disease, inflammation, cancer, neurodegenerative disease, and cardiovascular disease.[237] Both peptides (compounds **34** and **35**, Fig. 12A) that mimic Nrf2 and small-molecule Nrf2 activators (compounds **37**–**40**, Fig. 12A) have been reported to disrupt the Keap1–Nrf2 PPI. Compound **36** was identified by VS,[238] while compound **37** was discovered by HTS.[239] Structure-based design of the PPI Inhibitor of Nrf2–Keap1 led to compound **38**. It is the first compound that binds to Keap1 with K_D value of 3.59 nM at the single-digit nanomolar level.[240] Compound **38** cannot only disrupt the Nrf2–Keap1 interaction effectively ($EC_{50} = 28.6$ nM) in the FP assay but also activate the Nrf2 transcription activity in the cell-based ARE-luciferase reporter assay in a dose-dependent manner. Further chemical modification of this compound for improving the physicochemical properties (especially solubility) and in vivo inflammatory effects yielded compound **39** with *p*-acetamido substituents on the side chain of phenyl rings.[241] An exploratory in vivo experiment in a lipopolysaccharide (LPS)-challenged mouse model displayed that compound **39** could reduce the level of circulating proinflammatory cytokines induced by LPS and relieve the inflammatory response. Compound **40** was developed by taking advantage of the available crystal structures of the human Keap1 Kelch domain through an in silico fragment-based approach. It drives the formation of the "open" conformation of the Keap1–Nrf2 complex in a live cell-based imaging experiment.[75] RA839 (**41**), obtained by a screening effect, prevents the interaction of an Nrf2-derived peptide that includes the sequence of Keap1 binding ETGE motif with the Keap1 Kelch domain potently ($IC_{50} = 0.14 \pm 0.04$ μM, FP assay).[242] In mice, RA839 can acutely induce Nrf2-target gene expression in liver. Cocrystal structures of peptides derived from Nrf2, **37**, and RA839 with Keap1 (Fig. 12B) show overlapping binding sites of the ligands.

2.13.5.4 Cardiovascular Disease

Tirofiban (**42**, Fig. 13), an Arg-Gly-Asp (RGD) peptide mimetic, was designed via pharmacophore-based VS to disrupt the fibrinogen–glycoprotein (GP) IIb/IIIa (also known as integrin α_{IIb}/β_3) interaction, which bridges platelets together inducing platelet aggregation.[243] It is a reversible and selective antagonist of fibrinogen binding to the GP IIb/IIIa receptor, with a K_d value of 15 nM. It occupies the same pocket as fibrinogen peptide bound to GP IIb/IIIa (Fig. 13). Given the positive results of Platelet

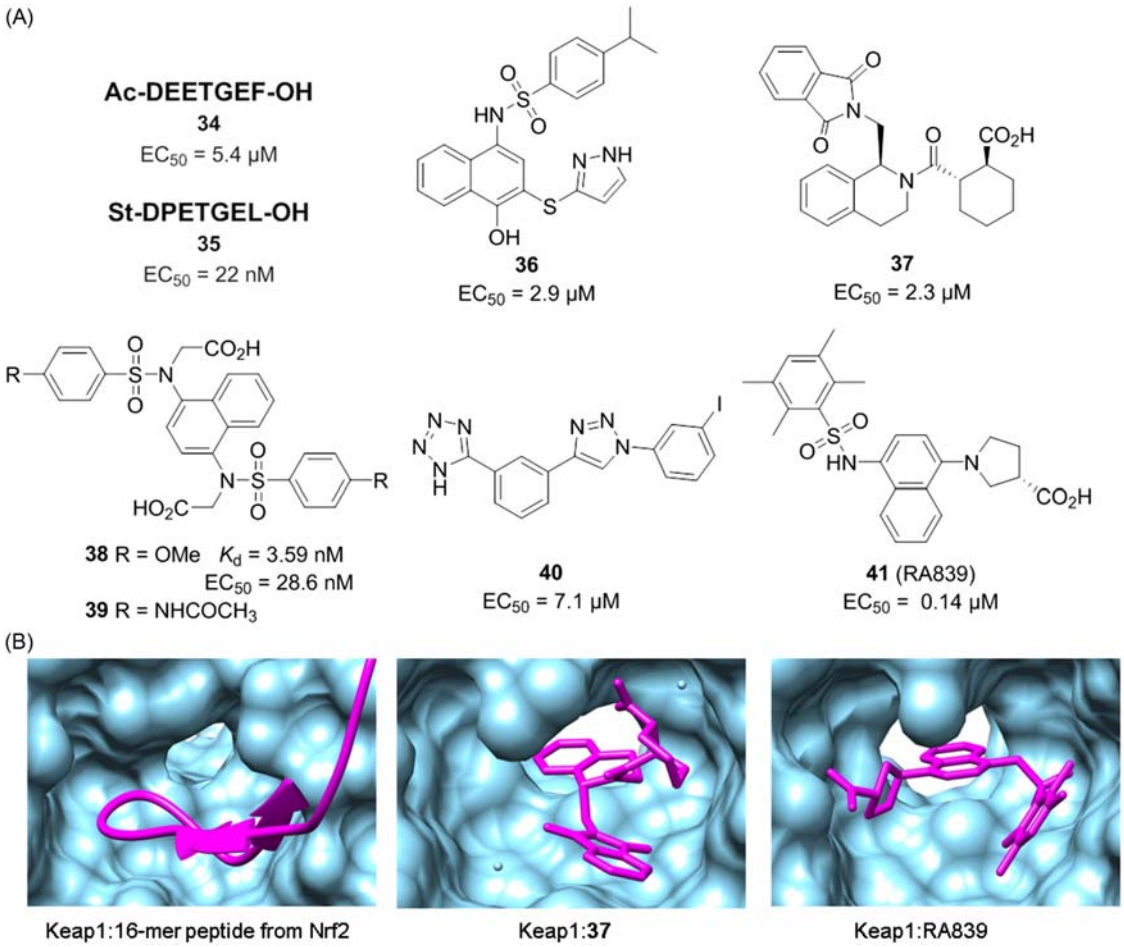

Fig. 12 (A) Chemical structures of PPI inhibitors **34**–**41**. (B) Cocrystal structure of Keap1 and Nrf2 (*left*, PDB code: 2FLU), **37** (*middle*, PDB code: 4L7B), and RA839 (*right*, PDB code: 5CGJ).

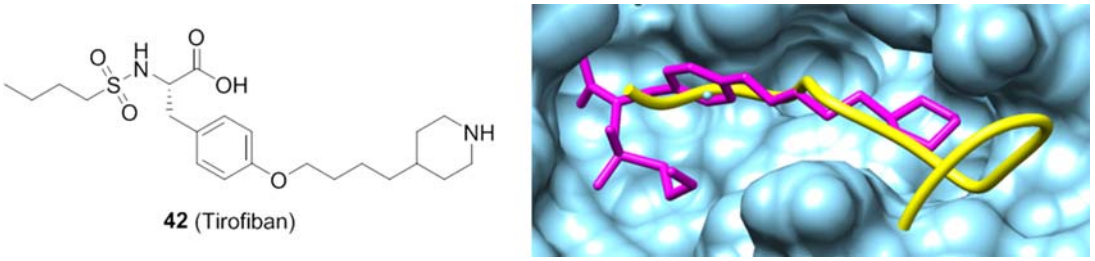

Fig. 13 *Left panel*: Chemical structure of tirofiban. *Right panel*: Overlay structure of fibrinogen peptide (*yellow*) and tirofiban (*magenta*) bound to GPIIb/IIIa (PDB codes: 2VDO and 2VDM).

Receptor Inhibition in Ischemic Syndrome Management (PRISM) clinical trials,[244,245] tirofiban was approved by FDA in 1998 for the treatment of acute coronary syndrome (ACS). From 1998 to 2000, it was the most widely used small-molecule GP IIb/IIIa inhibitor; however, it soon fell out of favor due to the inferiority of the original dosing regimen.[246] The high-dose bolus (HDB) regimen of tirofiban bounced back by achieving therapeutic platelet inhibition faster than that with the original dosing regimen and was subsequently approved by FDA in 2013.

2.13.5.5 Infectious Diseases

Modulating PPIs offers great potential to develop new drugs to treat various infectious diseases, such as HIV, bacterial infection. For instance, Maraviroc (**43**, Fig. 14), an allosteric modulator of the interaction between the chemokine receptor CCR5 and HIV-1

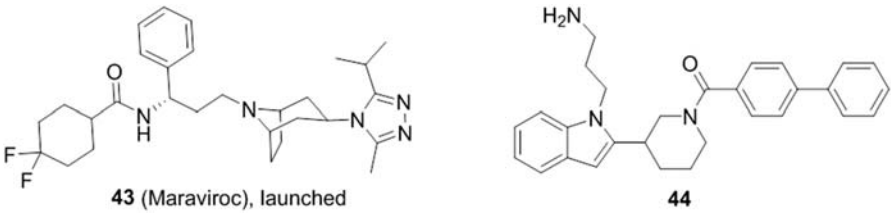

Fig. 14 Chemical structures of PPI inhibitors **43–44**.

gp120, was approved by FDA in 2007 to treat HIV infection.[247] Compound **44**, an inhibitor of cell division in *Escherichia coli* and *Bacillus subtilis*, binds to ZipA at FtsZ-binding site.[248]

2.13.6 Concluding Remarks and Future Prospects

Despite various challenges, developing small molecular PPI inhibitors has made great progress, with some of them available in the market and a number of them progressed into different phases of clinical trials. PPIs participate in virtually all cellular processes and are involved in a wide range of disease process, but only a limited of them are explored. Thus, developing modulators of PPIs including PPI inhibitors and stabilizers[249,250] holds promising therapeutic potential.

The understanding of protein–protein interactive interface provides strong support for the efforts to discover small-molecule PPI inhibitors. It is not necessary for the inhibitors to interact with all the residues on the large and flat interactive surface but simply the efficacious hotspots. The hotspot pocket then tends to undergo different induced-fit rearrangements when the target protein interacts with different protein partners and small-molecule ligands. Therefore, X-ray crystallography of the apoprotein structure may not provide druggable pockets directly. Computational methods may be enlisted in this effort to search the conformational space of the protein surface.

Currently, there are two general strategies to identify small molecules to inhibit PPI: screening and rational design. Because inhibitors targeting PPIs are usually large and more hydrophobic, and different from traditional inhibitors, the screening hit rates of PPI inhibitors are relatively low. New PPI focused libraries have been developed including natural products library, peptidomimetic library, multicomponent reactions (MCRs) developed library, etc. It is imperative to create new rules for PPI inhibitors. More libraries are in urgent need, possibly containing compounds outside the "Rule of Five" to increase the screening hit rates of PPIs. Peptides, peptidomimetics, and nonpeptides small molecules can be designed based on the analysis of interactive surface to mimic its partner. Peptides are believed to have higher selectivity which potentially leads to low toxicity, while the stability and permeability limit their development. Stapled peptides, cyclic peptides, and small molecules, which mimic protein secondary structures and have improved properties, may provide a wealth options. Nonpeptide small molecular disrupters of PPIs are usually large but more specific to their target. Different targets often require different chemotypes. To this end, fragment-based screening may be favorable, and more efficient than HTS.

The era of PPI-based drug discovery is coming with more and more knowledge and experience gained. It is reasonable to believe that targeting various PPIs through small-molecule drug discovery will bring more therapeutic benefits to patients in the future.

2.14.1 Introduction

The ability to obtain the sequence of the genome, the "blueprint" of life, is of very high importance to understand the underlying biology. Consequently, this is of great interest and need in every field encompassing biology like medicine, pharmaceuticals, microbiology, agriculture, and farming. In medicine, the push towards identifying the causal genetic aberrations which drive the disease and tailoring the therapy to target it (targeted therapy) has gained high prominence. This places more emphasis on achieving genome sequencing with high accuracy and efficiency with regards to time and cost requirements.

Early technologies or the first generation genome sequencing technologies were revolutionary in formulating a practical way of gleaning the genome sequence. The pioneering technology was the chemical degradation or the chemical cleavage method from Maxam and Gilbert.[1] This method is based on selective cleavage of single-strands of DNA by a combination of chemicals like dimethylsulfoxide, hydrazine, and piperidine. This coupled with radiolabeling of DNA strands at the 5′-end, resulted in a DNA strand substrate which could be separated on acrylamide gels and identified by autoradiography. This method was effective and was used in pioneering genome sequencing studies.[2,3] However, it was cumbersome due to the compulsion to use harmful toxic chemicals, radioactivity, and acrylamide gels. These drawbacks were partially overcome by another method referred to sequencing by chain termination method or more famously known as Sanger Sequencing which completely revolutionized genome sequencing at large scale.[4] This method uses the sequencing by synthesis approach where a DNA strand to be sequenced is used as template over which a complementary strand is synthesized by Taq-DNA polymerase using a mixture of normal and dideoxy nucleotides. The incorporation of dideoxy nucleotides results in termination of the strand growth (hence the name "chain termination method"). Radiolabeling was used to tag the strands which when resolved on an acrylamide gels could provide the genomic sequence. Although radioactivity was used, the procedure eliminated the use of hazardous chemicals and being enzymatic was considerably more efficient than the chemical cleavage method and thus represented a major improvement. This technology was further improved and made safe with the use of distinct fluorescent-labeled dideoxy nucleotides which when incorporated in a growing strand resulted in distinct fluorescence. This, when coupled with separation of the DNA fragments using capillary electrophoresis and computerized base calling programs (referred as automated Sanger sequencing) drastically improved the efficiency and sequencing capacity of Sanger sequencing. Automated Sanger sequencing methodology has been a dominant force and resulted in an explosion of genomes being characterized and made it feasible for widespread use for routine genome sequencing for research and clinical use. It was also instrumental in achieving the first-ever completed sequence of the human genome.[5] However, Sanger sequencing still had drawbacks, such as low to medium throughput and relatively small size of the genomic areas which could be sequenced in a reasonable amount of time. A revolution in genome sequencing approach and analysis capabilities to deal with large amount of information was needed to take genome sequencing to the next level. This was possible by the onset of massively parallel sequencing technologies which are referred to as the second generation of "next generation sequencing" (NGS) technologies which have permanently changed the face of genome sequencing capability, cost, accessibility, and efficiency. The nature of these technologies, their advantages, and challenges for implementing them for routine clinical applications have been discussed in this chapter in detail.

2.14.2 Second Generation or NGS Technologies

The hallmark of the NGS technologies is the ability to perform massively parallel sequencing of millions of DNA strands simultaneously, which is coupled with the ability to collect, process, and analyze this information facilitated by the revolution in data

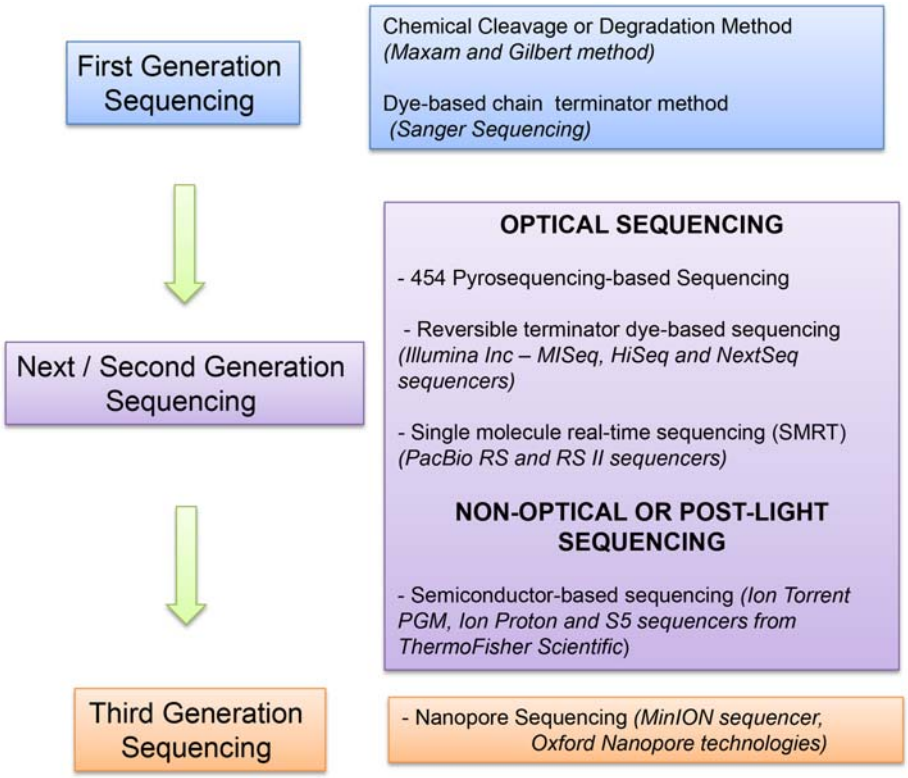

Fig. 1 Summary and evolution of sequencing technologies. A schematic diagram representing the onset of pioneering technologies of chemical cleavage and chain termination methods of genome sequencing followed by the massively parallel next generation sequencing platforms and the revolutionary third generation sequencing platforms which could be expected to appear as mainstream technologies.

processing and computing. The coming-of-age of these two capabilities (sequencing and data processing) created a perfect storm that helped in an explosion of the NGS technology innovation and implementation for diverse applications. Numerous excellent reviews and papers regarding the technologies, the fundamental basis of their technologies and their advantages have been published.[6–10] The following is a summary of the most commonly used NGS technologies along with their strengths and weaknesses and the challenges of validating them for routine clinical use.

The NGS technologies which proliferated immediately as successors of automated Sanger sequencing, utilized similar principles of using a DNA strand as a template to build a complementary DNA strand during sequencing (sequencing-by-synthesis or SBS) and optical detection. These are referred to as optical imaging or light-based NGS technologies. A detailed description of the light-based NGS technologies is provided below and summarized in Fig. 1.

2.14.2.1 Pyrosequencing-Based Optical NGS Technology

This technology uses the approach of pyrosequencing, where the DNA strand to be sequenced is used as template and the synthesis of the complementary strand is accomplished by flowing each deoxy nucleotide tri phosphate (dNTPs) one a time. If the dNTP introduced is complementary to the nucleotide in the template DNA strand, it is incorporated in the growing strand by the formation of a phospho-diester bond and the release of a pyrophosphate. The released pyrophosphate is coupled to a luciferase mediated enzymatic reaction which generates an optical signal each time a nucleotide is incorporated and hence the name pyrosequencing.[11] This technique was employed on a large scale in the Roche/454 sequencer to facilitate massive parallel sequencing. Here, the DNA strands to be sequenced were amplified on to microscopic beads by emulsion PCR and deposited into microscopic wells on PicoTitrePlates (PTPs). SBS is performed by flowing each nucleotide at a time along with other reagents necessary for DNA synthesis. The PTPs are coupled to a high-resolution camera to detect the light generated by the pyrophosphate-coupled luciferase activity on the incorporation of a nucleotide in the millions of strands tested simultaneously. This platform can generate sequencing reads of up to 700 bp but suffers from high sequencing error rates in the regions of homo-polymer stretches where the same nucleotides are repeated in the sequences (polyA, polyC, etc.). In these areas, when a nucleotide complementary to the homo-polymer stretch is released into the reaction mixture, it results in simultaneous incorporation of several nucleotides and generation of a light signal that may not be proportional to the number of nucleotides incorporated. This results in the calling of false mutations like deletions

(disproportionately lower optical signal to the total nucleotides incorporated) or false substitutions due to misalignment of sequence.

2.14.2.1.1 Optical sequencing using distinctly labeled fluorescent nucleotide

This is the most widely used model of optical sequencing currently and is characteristic of the sequencing platforms of various capacities from Illumina Inc. This technology also uses the SBS mode of using the DNA strand of interest as a template over which the complementary strand is synthesized using 3′-OH group blocked fluorescently labeled dNTPs. The sequencing is performed in a flow-cell which has a minute glass tubes or lanes on the internal surface of which individual DNA strands are clonally amplified to generate distinct clusters, which are used as templates for SBS. The sequencing reaction is started by introducing the polymerase and a mixture of four labeled dNTPs into the flow-cell. Once a complementary nucleotide is incorporated, further growth of the strand is arrested due to the unavailability of the free 3′-OH group. After each incorporation, the fluorescently labeled growing strands are imaged with high sensitivity cameras to get the information regarding the incorporated nucleotide in the millions of DNA strand clusters simultaneously thus achieving massive parallel sequencing. After imaging, the modification protecting the 3′-OH group is enzymatically cleaved making way for the incorporation of the next nucleotide and thus starting the next cycle of nucleotide incorporation, followed again by imaging. These successive repetitive steps are referred to as sequencing "cycles" and as the 3′-OH group blocking is reversible it is referred to as the "reversible terminator-based" sequencing methodology. As imaging is performed after each cycle of nucleotide incorporation and distinct fluorescent labeling of the nucleotides, the sequencing time is relatively long but is compensated or justified by the high quality of sequence obtained and low error rates. Also, the DNA strands in the clusters can be sequenced in one direction or in both directions, which is referred to as "single reads" or "paired-reads," respectively. Bi-directional sequencing is the preferred approach due to its high accuracy especially in applications that are used to screen for mutational changes in the DNA.

This methodology of sequencing forms the basis of all Illumina sequencers of different capacities like the table top medium-capacity MiSeq sequencer and a variety of high capacity HiSeq sequencers (HiSeq 2500, 3000, 4000, HiSeq Xten, etc.) which currently represent the most commonly used NGS-based sequencers for targeted small scale and comprehensive large scale genomic sequencing applications. Furthermore, a recently released Illumina sequencer called NextSeq uses a slightly different approach of using only two different fluorescent labels for sequencing. Here, two nucleotides (dATP and dCTP) have distinctly labeled fluorescent tags; dTTP has both of these tags and has an overlapping fluorescent signature whereas dGTP is unlabeled. This two-channel approach helps in decreasing the time required for sequencing in comparison to the four dye labeled workflow and thus increasing the efficiency. The NextSeq also has a sequencing capacity between MiSeq and a HiSeq and serves as the right platform for the medium–high throughput sequencing requirements.

2.14.2.1.1.1 Single molecule real-time sequencing technologies

This is a unique method of optical or light-based sequencing where SBS is used as the basis, but unlike the Illumina platforms, the sequencing of the DNA strand is gleaned continuously without interruption as the complementary strand is being synthesized and hence is also referred to as "real-time DNA sequencing." This technology is characteristic of the sequencer from Pacific Biosystems (PacBio RS and RS II sequencers).[6,12] Here, sequencing is performed in numerous units called as zero-mode waveguides at the bottom of which a single molecule of DNA polymerase is immobilized which binds to a DNA template strand to be sequenced and performs SBS using four distinct fluorescent-labeled dNTPs. As a single DNA strand is replicated the fluorescence from the labeled dNTPs being incorporated is imaged and recorded in real-time similar to a video recording, it is referred to as "single molecule real-time sequencing technology (SMRT). Consequently, this provides a high speed of DNA sequencing and as a single strand is used, it does not require PCR amplification of the DNA strands to be sequenced (thus eliminating PCR-based bias of target DNA to be sequenced) and sequencing of very long reads become possible. Generally, the strands used for sequencing are circular DNA strands obtained by incorporating hair-pins on either side and can be sequenced multiple times by the polymerase thus generating repeated sequencing of the same DNA strand. The most obvious advantage of the SMRT sequencing systems of PacBio is the long read lengths which can achieved. These range from 1500 bp to 60 kb and this ability represents a drastic advantage over other NGS technologies whose read lengths vary from 100 to 600 bp. Consequently, the SMRT sequencing sequencers are platforms of choice for genome assembly which is more accurate and efficient by using the long contiguous reads generated.[12–15] Due to its capability to sequence a single strand of DNA which is different from the typical NGS platforms where clonal clusters of PCR-amplified DNA strands of are sequenced SMRT sequencing is also considered as the third generation sequencing technology (akin to the nanopore-based sequencing platforms discussed later in this chapter).

2.14.2.2 Nonoptical NGS

The majority of the NGS platforms currently in widespread use are light or optical signal recording platforms. However, there are some sequencing platforms which are not light based and use drastically different and revolutionary technologies as described below.

2.14.2.2.1 Semiconductor based nonoptical sequencing system

This is a revolutionary NGS platform (referred to as postlight sequencing), which monitors and measures the protons from the 3′-OH group during the formation of phospho-diester bonds during SBS to sequence the DNA.[16] The approach used is similar

to pyrosequencing used in Roche/454 sequencer, where SBS is performed on microscopic beads with clonally amplified DNA strands using unlabeled dNTPs which are introduced one at a time in a predetermined order. These beads are deposited in microscopic wells, each large enough to accommodate one bead and SBS is performed and interfaced with a semiconductor chip. Incorporation of a nucleotide results in the release of a proton, which when occurring simultaneously on all clonal DNA strands on the bead results in millions of protons being released to proportionately decrease the pH of the well microenvironment, which is recorded by the semiconductor chip as a change of voltage. Each chip has millions of wells and with each flow of nucleotide across them results in simultaneous sequencing of strands clonally amplified on millions of beads thus facilitating massive parallel sequencing. This sequencing technology is used in the IonTorrent sequencing platforms from ThermoFisher Scientific (Ion Personal Genome Machine or Ion PGM, Ion Proton, and Ion S5 sequencers) that are finding wide use in low and medium throughput genome sequencing applications.[17–22]

Several studies pertaining to the performances of the optical and nonoptical sequencing technologies, and their comparison with respect to their sequencing capacity, accuracy, and the associated costs have been published and serve as valuable resources for laboratories to decide upon a choice of NGS technology and sequencer for implementation.[7,23–25]

2.14.3 Third Generation Genome Sequencing Technologies

These technologies represent recent advances of genome sequencing methodologies which are drastically different for the first and second generation sequencing platforms and represent radical changes and improvements. An example is the Nanopore sequencing technology, which is based upon sequencing single molecule of DNA by passing it through a nanoscale pore across which a small voltage is imposed. As the DNA molecule passes through the pore, it temporarily blocks the pore creating a nucleotide-specific change in the voltage which can be detected and correlated to glean the sequence.[26–28] As a variation, an exonuclease linked to the nanopore can cleave each nucleotide which passes to the pore. The identity of the nucleotide can be obtained by the signature alteration of the voltage across the pore resulting in the sequencing of DNA. This mode of sequencing can be used to generate sequence both small and very large DNA strands (as long as 50 kb) and could prove very valuable for both targeted or whole exome and genome sequencing applications. On the whole, the nanopore technology has a potential to decrease the costs drastically and time of large scale genome sequencing.[29] Currently, this mode of sequencing is being used in the MinION nanopore sequencer (Oxford Nanopore Technologies) and is being evaluated for various applications.[30]

2.14.4 Implementation of NGS Technologies for Clinical Applications

The capacity of NGS sequencing platforms to perform massively parallel sequencing of DNA and RNA is very desirable and valuable in routine clinical use for clinical purposes. They provide the capability of simultaneously sequencing a large volume of samples for multiple markers for a variety of genomic aberrations in a relatively short time at lower costs as compared to the traditional sequencing platforms. However, majority of the NGS platforms and the associated technologies are meant for research-use-only purposes and their implementation requires their vetting or thorough validation for routine clinical use. This is a very important prerequisite and NGS tests being more complex in comparison to the traditional tests, makes their thorough validation challenging. In recent years, in order to provide guidance, several regulatory agencies like the College of American Pathologists (CAP), Association for Molecular Pathology (AMP), American College of Medical Genetics, US Centers for Disease Control and Prevention (CDC) provide important reference and resource for a laboratory which intends to implement NGS technologies.[31–34]

The general approach for validation includes thorough testing and establishing the basic performance characteristics of the platform as defined by guidelines which have been in use for any high-complexity molecular test.[35] A list of these parameters and their significance has been provided in **Table 1** and summarized in **Fig. 2**. However, in comparison to the earlier sequencing and genotyping methodologies, the NGS technologies are associated with higher complexity at every level, be it wet bench preparation, sequencing, data interpretation, storage, and clinical reporting. This required reinterpretation and modification of the previous guidelines, and defining novel approaches to ensure adequate validation of the NGS platforms. This reinterpretation has been provided in guidelines proposed by several agencies as mentioned earlier. In addition to the published guidelines from agencies, several laboratories have published details of validating numerous NGS platforms which serve as a very important resource for the performance characteristics of the technologies and the associated challenges and advantages.[36–40] Reports of cross laboratory cost analysis for routine implementation of NGS tests are also available which are very helpful for the labs to consider the financial implications of NGS testing and choose the most well-suited platform and workflows.[41]

2.14.5 Clinical Utility of NGS Technology

The massively parallel sequencing capability of NGS technologies provides powerful solution for clinical screening of genomic in a clinical setup be it to screen for germ line aberrations of significance in hereditary medical syndromes, physical and mental health, somatic aberrations in cancers and characterization of microbial populations in infectious diseases. The ability of NGS to sequence multiple genomic areas in multiple samples simultaneously with a single input of DNA or RNA provides a crucial advantage in

Table 1 Performance parameters of NGS platforms for validation before clinical implementation[a]

Performance parameters	*Details*	*Significance/comments*
Analytical sensitivity	Number of samples positive for mutation and are classified as positives	Capacity to detect true sequence variants as detected by orthogonal gold standard technologies like Sanger Sequencing (false negative rate)
Analytical specificity	Number of samples conformed as negative for mutations and are classified as negative	Rate of mutations detected which are false positive
Accuracy	Concordance of sequence obtained by the NGS platform and the reference sequence	Error rates of the NGS technology
Precision or reproducibility	The capacity to achieve accurate results across many repeats performed by multiple users	Measure of reproducibility (interuser, instrument, and sequencing run reproducibility)
Limit-of-detection	The lower limit of mutation detection	Limit-of-detection for different variants (single and multinucleotide mutations, insertions, deletions, gene amplifications, and fusions)
Sequencing depth and allelic frequency cutoffs for detection	Minimum sequencing depth necessary for confident detection of mutations	To be individually established for each variant type

[a]As recommended by published studies.[31,35]

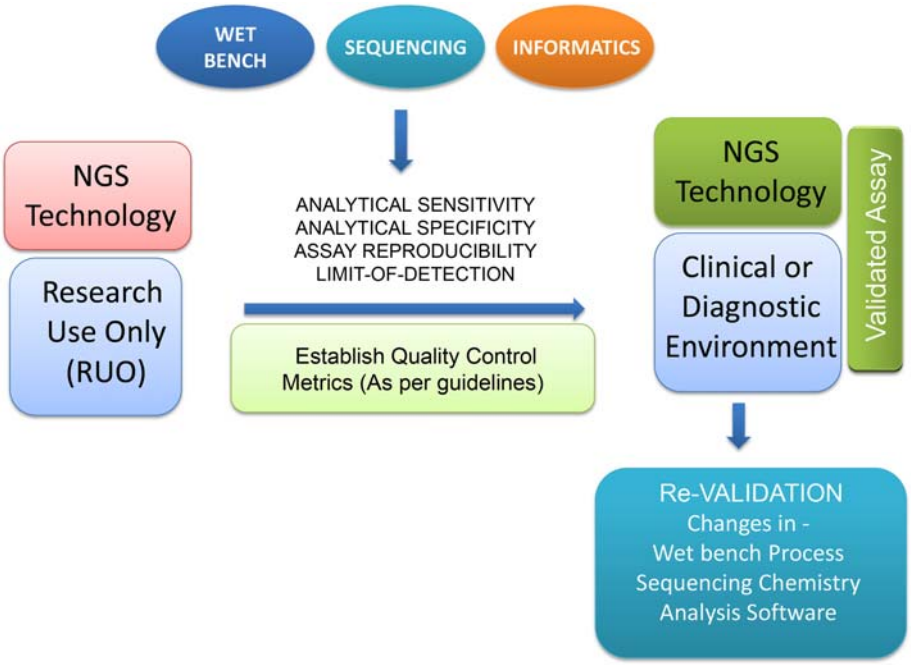

Fig. 2 NGS assay validation for clinical implementation. Assay performance parameters which need to be validated and established prior to implementation of NGS assay in a clinical laboratory as per guidelines are shown.

a clinical setup in order to screen for established markers in an accurate and timely manner. The impact of NGS for clinical genomic testing can be understood by better considering the example of routine screening of tumor samples for markers of prognostic and predictive significance. In a clinical setup, screening of solid tumors and hematological cancers needs screening of multiple markers for a variety of genomic aberrations like SNVs, insertions, deletions, gene copy number variations, and fusions from often very limited tumor material. This was a major challenge for the low and medium throughput classical sequencing technologies like Sanger and pyrosequencing. The advent of NGS technologies provided a feasible solution to meet these demands. Consequently, in a relatively short time, NGS has found active application in clinical diagnostic laboratories. For cancers, the early NGS tests implemented screened relatively limited regions of a limited number of markers of clinical significance.[37–39] During this crucial initial phase, the diagnostic community, which was used to simpler single-gene screening tests realized the challenges of analyzing, interpreting, reporting, and storing complex and sizeable NGS information and evolved to overcome them. The regulatory agencies also realized these challenges and provided timely guidelines for conducting, interpreting, and reporting NGS-based clinical tests which helped the diagnostic community with the technical and ethical challenges of extensive genomic testing.[31–33] Subsequently,

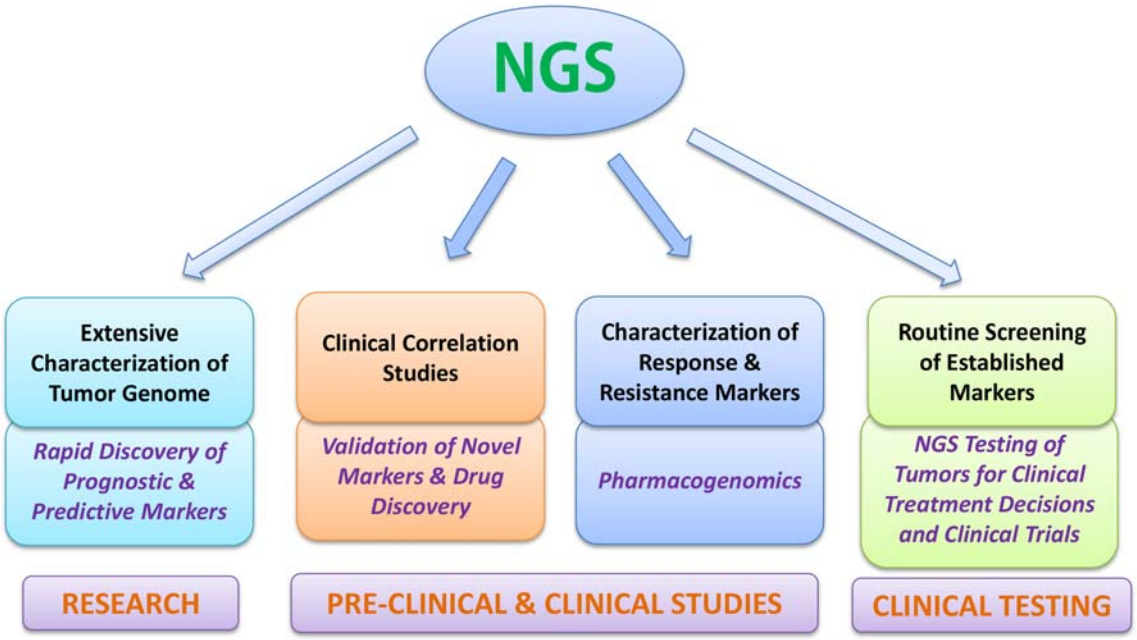

Fig. 3 The clinical utility of NGS. The implementation and utility of the massively parallel NGS technologies in every aspect of clinical workflow starting from discovery, characterization, and establishment of markers to drug discovery and routine screening of clinical samples has been depicted.

building on this initial experience and taking advantage of improving NGS and its technologies associated with the workflow starting from target capture, library preparation and informatics solutions for analysis and interpretation there has been a considerable surge in the implementation of more extensive NGS testing for clinical purposes. Consequently in a recent and relatively short time, there has been a surge in implementing clinical NGS tests ranging from targeted screening of hundreds of markers of clinical significance and extending into sequencing whole exome or genome.[40,42–44] More recently, the NGS technologies have started to make inroads into screening of nucleic acids in liquid biopsies, which is set to revolutionize precision medicine by providing minimally invasive option for early detection and monitoring of disease progression and response to therapies.[45] A schematic representation of the intimate involvement of NGS technology in every stage related to oncology is presented in **Fig. 3**.

In addition to routine screening of tumors, genome screening by NGS technology is also rapidly establishing as important component of clinical trials thus playing critical role as a link between initial discovery of a marker of clinical significance and establishing its targetability, clinical utility, and inducting as a marker to be screened for standard of care and precision medicine.[46,47] In comparison to earlier trials which utilized a single or a limited set of markers, NGS screening of patient samples facilitates screening a higher number of samples and variant types with very high sensitivity, which is very advantageous in order to simultaneously associate multiple treatment arms to a trial thus revolutionizing the approach.[47]

2.14.6 NGS in Drug Discovery and Development

Screening of cellular nucleic acids to understand their role and interactions with the cellular machinery forms a key aspect of understanding signaling and regulatory networks and key to identifying and establishing new targetable markers. NGS, with its capability to screen nucleic acids with high sensitivity is increasingly being used in several aspects associated with characterizing nucleic acids like identification of genomic mutations, gene copy number aberrations and fusions, characterizing modulation of gene expression by alteration of chromatin dynamics and RNA-seq to measure relative levels of gene expressions, and noncoding RNAs.[48] Subsequent to identification of targetable markers, NGS also plays a key role in discovery and development of relevant drugs and vaccines. The key areas include evaluation of genomic causes characterizing the absorption, metabolism, and excretion of the drug (pharmacokinetics), and the tolerance, toxicity, and resistance of drugs in an individual and tailoring the drugs and doses accordingly (pharmacogenomics).[48,49] This information is crucial in establishing population and individual-based drug tolerance, effectiveness, and resistance. In addition to this, NGS analysis is also extensively used for detection and characterization of diseases, host-pathogen interactions, evaluation of microbial population diversity, and evolving of strains and drug-resistance of pathogens with relation to infectious diseases caused by microorganisms.[50,51] Additionally, NGS is also extensively used for design of vaccines and facilitating screening of large number of longitudinal samples, characterization of interaction of the pathogen with the host, and characterization of the host immune response.[52–54]

To summarize, NGS technologies represent a major revolution in genome sequencing technologies which have provided unprecedented capacity for obtaining genome sequencing information for application in every branch of biological sciences. They are also characterized by unprecedented level of complexity of technology, volume of data output, difficulty of interpretation, and their ethical and economic consequences. They are also associated with a very rapid rate of progress and innovation resulting in an ever-changing landscape of sequencing technologies and their applications. With the expected onset and proliferation of the third and fourth generation sequencing technologies, this revolution is bound to gain momentum and has the potential to have major impact on precision medicine by revolutionizing disease characterization, drug design and discovery, and facilitation of personalized therapy.

2.15.1 Introduction

High-content screening (HCS) or high-content analysis (HCA) encompasses highly multiplexed, microtiter plate amenable, and automated fluorescent microscopy-based measurement of biological activity at the organelle, cell, or organoid levels in response to treatment with chemical compounds or other substances. In contrast to conventional bioassay technologies, which have one or two readouts of activity per treatment, HCS allows scientists to measure the responses of an individual organelle, cell, or organoid to compound treatments using many features. The ability to simultaneously study many features and combinations of these features makes the HCS technology powerful yet challenging.[1–8] Enabled by more sophisticated image acquisition, analysis, and informatics technologies and driven by needs for complex cell biology studies, over the past two decades HCS has overcome many technical obstacles and gained broader acceptance across the entire drug discovery pipeline, including target validation, lead discovery, lead optimization, toxicity studies, drug delivery, and translational biomarkers.[9–21] This chapter will focus on lead discovery, lead optimization, and toxicity studies.

2.15.2 HCS and Complex Cell Biology

2.15.2.1 Applications of HCS for Different Cellular Processes

The ability of HCS to provide both spatial and temporal resolutions makes it an ideal assay technology for studying complex cell biology. Like standard high-resolution microscopes, HCS can be applied to study many cellular processes for both target-based and phenotype-based screening at higher throughput. Some of the events, such as protein expression, epigenetic modifications, and/or posttranslational modifications (acetylation, phosphorylation, citrullination, etc.), can be analyzed by conventional assay technologies, such as Western Blots or total immuno-fluorescent intensity readouts. However, HCS methods often use fewer cells with higher sensitivity and deliver more comprehensive information on a compound's effects on cells or organoids, not only for the intended targets or processes, but also for the entire cellular/tissue network, thus providing more insightful knowledge about the compound's efficacy and potential adverse effects.

The forte of HCS is its use of microscopy that can be applied to create enlarged views of single cells and associated subcellular structures with high resolution, such that one can analyze and visualize cellular processes otherwise intractable using conventional assay technologies. These cellular processes often play pivotal roles in diseases and understanding these processes is critical for the development of therapies. A particular HCS-based assay could be developed based on one of four basic types: intracellular protein translocations, cellular/organoid morphology alterations, organelle structure changes, and cell subpopulation redistributions; or based on combinations of these four basic types, making HCS versatile yet heavily reliant on sophisticated image analysis and informatics tools to interpret results.

The intracellular protein translocation assay is a hallmark of HCS. Examples are internalization of G-protein coupled receptors to start signal cascades, translocation of glucose transporter from cytoplasm to the cell surface to facilitate glucose uptake, tubulin polymerization and redistribution in response to cytotoxic compounds, and translocation of a transcription factor from the cytoplasm to the nucleus to initiate or modulate gene expression.[22–24] Cellular/organoid morphology alteration is another common assay for HCS. Examples are oligodendrocyte differentiation for myelin sheath production and neuron protection, neurite or axon outgrowth for central nervous system (CNS) regeneration, epithelial-mesenchymal transition (EMT) to initial cancer metastasis, and angiogenesis to support tumor growth. The size changes in tumor spheroids are often used to measure the potency of anticancer drugs.[25–29] The ability of HCS to create enlarged views of subcellular structures provides unmatched methods to study organelle structure changes. Micronucleus tests are often conducted in toxicological screening for potential genotoxic compounds. Mitochondrial structure assays have been used to identify genes that are associated with neurodegenerative diseases. Quantification of lipid droplets has been utilized to study mechanisms of metabolic diseases.[30–33] The ability to measure responses from different subpopulations of cells in a single well of a microtiter plate makes HCS an incomparable tool for studying rare cellular events, cellular heterogeneity, cocultures, and other complex biology. Examples are analysis of cell cycle, investigation of cell differentiation, characterization of immune cells in tumor microenvironments, and depiction of cell migration, and wound healing and fibrosis in fibroblast and epithelial cocultures.[34–42]

2.15.2.2 Complex Cellular Models for HCS

Many factors beyond pathophysiological relevance could contribute to decision-making on selection of cellular models. These factors include, but are not limited to, availability of cells, donor-to-donor variation, stability of cell lines, ease-of-handling for screening, cost, safety, and signal strength and variability. Balancing robustness of screening vs. mimicking of disease environment is important for conducting a successful HCS.

Early HCS campaigns reported in literature were often based on overexpressing target proteins in cancer cell lines, such as HeLa and U2OS. Except for cancer indications, most of these immortalized cancer cell lines lacked connectivity to the pathophysiology of diseases for which therapies were sought. To reduce bench-top-to-bedside translation risks, more pathophysiologically relevant and predictive cellular models have been characterized and applied in both target-based and phenotype-based HCS campaigns in recent years.[43–46]

2.15.2.2.1 Primary cells from human or rodents

Although primary cells from diseased human organs collected during surgical or postmortem procedures are considered as bona fide disease models for drug discovery, conducting high-throughput or medium-throughput HCS using human primary cells, from diseased or normal organs, face tremendous challenges. First, apart from serious ethical challenges, supplies of primary cells, such as primary and metastatic tumors, beta cells or islets, hepatocytes, adipose cells, kidney epithelial cells, and different types of brain cells, are scarce; these cells also have limited-to-zero capacity for proliferation. Second, donor-to-donor variation, including differences in genetics, medical history, and sample preparations, will make screening results very difficult to interpret. Third, diseased cells are surrounded by different cell types in the organ, and responses to external stimuli from these diseased cells in different locations of the organ could be variable due to tissue heterogeneity. Finally, access to human primary cells frequently requires strict Institutional Review Board (IRB) approvals, research collaborations, and complex material transfer agreements with hospitals or other institutions. These logistical challenges can be time-consuming and tedious. Therefore, in the foreseeable future, with the exception of blood cells, human primary cells are likely to be used primarily for lead discovery using a limited-size chemical library, and for lead optimization, toxicity, and translational biomarker studies. For these applications, imposing

limitations on donor demographics and/or prescreening of donor cells are valuable approaches for minimizing donor-to-donor variation.

The use of primary cells from animals—especially rodents—for HCS could be more feasible. Rodent-to-rodent variation could be minimized when rodents with identical genetic backgrounds are used for sample collection, and many on-site animal facilities can make sample preparation procedures more transparent. However, increasing evidence suggest that the biomedical translation between rodent and human is very limited. For example, the correlation between rodent in vivo models and clinical trials for immune-related diseases has been shown to be extremely poor.[47] It is also well-known that the homology between human and rodent proteins could be very limited, with additional significant interspecies differences in signaling pathways. Therefore, prior to using primary cells from rodents or other animal models for HCS-based drug discovery, one must rigorously validate if animal models mimic the biology and pathophysiology of human diseases. Furthermore, in the follow up studies, an assay using human cells must be conducted in parallel to confirm the translation between species.

2.15.2.2.2 Pathophysiologically-relevant cell lines: immortalized human cells, stem cells or iPSC-derived cells

Many well-studied immortalized human cell lines, derived from normal or diseased human tissues that retain characteristics of the original cell types, make excellent cellular models for drug screening. However, these immortalized cells may contain genetic and metabolic abnormalities due to their derivation. Therefore, during reagent validation and assay development, one should ensure that key pathways involved in targeted diseases are still active in the selected cell lines.

Recent developments in research involving adult stem cells and induced pluripotent stem cells (iPSCs) could provide predictive, stable, and scalable cellular models for drug screening. A range of adult stem cell types that can be differentiated into a variety of cellular lineages are available. For example, multipotent mesenchymal stem cells could be used to generate osteoblasts, chondrocytes, hepatocytes, adipocytes, and other cell types.[48] Because iPSCs are derived directly from the somatic tissues of normal persons or patients, this technology overcomes major ethical concerns that have afflicted the use of embryonic stem cells. Furthermore, iPSCs provide an unlimited source of proliferating cells, and when combined with new generation gene editing technologies such as Clustered regularly interspaced short palindromic repeats (CRISPR), iPSC has tremendous potential to become a versatile tool for generating disease relevant and scalable cells for HCS.[49] Many iPSC differentiation protocols for cardiomyocytes have been reported and validated. Protocols for other cell types in different organs have also been described. However, current differentiation protocols are not optimal. Even minor variations in protocols could result in altered degrees of differentiation, with assorted genetic and morphologic changes. Often, purification of partially differentiated cells is necessary in order to obtain meaningful screening outcomes. Significant investment in technology is needed in order to substantially improve differentiation protocols, thus providing disease-relevant cellular models truly amenable for HCS-based lead discovery.[50–54]

2.15.2.2.3 Organoid and three-dimensional (3-D) cellular models

A single cell type, grown in a two-dimensional (2-D) monolayer culture, frequently does not mimic the in vivo microenvironment, morphology, and physiology of diseased tissues. New molecular entities identified through 2-D cell culture models based on transformed cell lines have often failed in animal models or in expensive clinical trials. Recently, the number of publications on 3-D organoids, including microtissues, tissue explants, and tumor spheroids using various cell types has increased significantly, mainly with three types of approaches: (1) using physiologically-relevant primary cells and human tissue-derived cells to build the 3-D models; (2) using multiple types of cell lines that are derived from corresponding tissues and tumors; (3) fabricating an appropriate extracellular matrix (ECM) or micropattern to mimic the microenvironment; or combinations of these three approaches. HCS has played a pivotal role in applying 3-D cellular models for drug screening or toxicity studies, by providing readouts at whole organoid level using low magnification, or at single cell and subcellular resolution using more sophisticated *z*-stacking imaging acquisition method. When *z*-stack is performed, a set of confocal images are taken from the specimen so that the image area along the *x*- and *y*-axes remains the same but the distance from the objective (*z*-axis) is different for each image. As the distance between adjacent images is precisely controlled in the z-stack, it can be used to construct a 3-D image.[55–64]

The development of screening models using coculture of multiple cell types, or construction of 3-D organoids with multiple cell types, is driven by the hypothesis that when different cell types are placed together, they tend to self-assemble in an orderly manner. This order is based on specific interactions between surface proteins expressed on different types of cells, as well as the presence of secreted autocrine and paracrine factors, to support each other for growth and renewal. Thus, the in vitro multiple cell type 3-D organoids could reasonably—though not entirely—mimic the morphology, physiology, and in vivo environment. Such models could be significantly more predictive than those based on 2-D confluent monocultures. The major weakness of the in vitro 3-D cellular models is that the organoids grown using the three approaches described above lack vascular and lymphatic vessels. This inhibits circulation of nutrients, metabolites, and small molecules, and does not mimic host immune responses. Recent development of human organs-on-chips could circumvent this lack of circulation issue.[65]

2.15.2.2.4 Methods for cellular models validation and quality controls

It is imperative that all cellular models be validated prior to conducting drug screening. Genotyping is inexpensive, making it worth considering for any cell line that is acquired through a commercial source or a collaborator. mRNA profiling could be a first-line tool to ensure that key pathways involved in the targeted diseases are present in the cellular models. Biomarker or protein marker verification and/or metabolic profiling of relevant signaling pathways could be second-line tools to verify the activation of these key pathways. Functional responses, such as responses to insulin stimulation by pancreatic islets in a glucose-dependent manner, or

responses to chemokines by immune cells, are the ultimate tests needed to warrant the authenticity of the models. Furthermore, the maximum passage number of cells with acceptable functional responses must be determined prior to the start of screening, to ensure the quality of large-scale or long-term screening. Alternatively, protocols using cryopreserved cells could be considered to ensure run-to-run consistency. Finally, it is important to make sure that the use of cellular models complies with safety regulations, and that the cell lines to be used are mycoplasma free.

2.15.2.3 Complexity and Multiplicity of HCS Assay Readouts

2.15.2.3.1 Uniqueness of HCS assays and associated detection reagents

It is not a trivial task to develop HCS-based assays in the laboratory. A detailed description of the assay development steps can be found in the NIH Assay Guidance Manual.[3] Each complex cellular model would have its own unique proliferation, differentiation, and other stimulation conditions that could have been defined in literature. The uniqueness of HCS assays starts from cell plating. The ability to spread cells evenly in a well of microtiter plates for 2-D assays, or to form uniform 3-D structures in terms of both organoid size and intercellular microenvironment, is often determined by the plate types and cell culture media used. For example, 2-D epithelial cells could prefer collagen I-coated flat-bottom plates and 3-D tumor spheroids could have a preference for poly-hema coated U-bottom plates.[63] A comprehensive plate coating selection guide for different cell types can be found in https://www.corning.com/media/worldwide/cls/documents/CLS-C-DL-006.pdf

Live-cell kinetic imaging is commonly used for microscopy-based assays. However, for lead discovery, lead optimization, and toxicity study purposes, the most common HCS practices use end-point reading methods with fixed cells. Cell fixation and permeabilization usually are realized by using combinations of paraformaldehyde and/or methanol at different concentrations, incubation times, and temperatures, depending on the purpose of the study. For example, to determine protein trafficking to the cell surface, a gentle fixing condition typically would be used to minimize permeabilization of cell membrane, thus increasing the chances of antibodies to recognize cell surface proteins and limiting access of the antibodies to intracellular proteins.

Unlike bright-field imaging in which cell number, morphology, and migration are monitored using transmitted lights, fluorescent imaging relies on tagging different proteins or organelles with various fluorophores at distinguishable colors (wavelengths) to detect changes in cellular processes of interest. Several protein/mRNA/organelle labeling technologies based on different principles are commercially available. Intellectual property positions and costs of reagents could determine the selection of labeling methods. It is imperative to ensure that the labeling methods do not interfere with normal cell cycles, protein function, or with the cellular processes important for the studies.

Typically, protein and organelle labeling methods are based on (1) Immunofluorescence assays in which fluorescent-labeled specific antibodies are used to detect the expression levels, locations, and interactions of proteins of interest, (2) fluorescent proteins (Green fluorescent protein (GFP), Red fluorescent protein (RFP) and their variants), and alternatives such as SNAP-tag, Halo-tag, and fluorogen activating protein, as biosensors for protein expression and trafficking, and as fluorescent donor and acceptor pairs in fluorescence resonance energy transfer (FRET)-based protein–protein interaction assays, (3) organelle specific fluorescent dyes, such as dyes with high affinity for the nucleus, cell membrane, mitochondrion or lysosome, and (4) chemical probes. Examples are fluorescent dye or quantum dot labeled receptor ligands, enzyme substrates, and complementary nucleotides for DNA or RNA. Fluorophores which emit at the yellow wavelength region normally are brighter (have higher fluorescence quantum yields), but often are susceptible to interference from auto-fluorescence of cell or organoid, or from highly cell permeable and nonspecific compounds with strong fluorescent emission in the yellow region. To minimize interference from auto-fluorescence, red-shifted dyes are often used. However, most commercially available red-shifted dyes are not as bright as yellow ones. Therefore, many efforts have been dedicated to discover new generations of red-shifted dyes with higher quantum yield and better stability.[66] Even with very bright dyes, sometimes the expression levels of proteins of interest are too low to detect. To this end, several tactics to increase the payload of florescent dyes, such as the use of secondary and tertiary antibodies, branched DNA, and proximity-ligation assay methods could be used to amplify assay signals to improve the robustness of HCS assays.

A novel cellular and tissue imaging technology that could be applied for lead optimization and toxicity studies has recently emerged. This imaging mass cytometry technology uses rare-earth metals, instead of fluorescent dyes, to label antibodies that recognize proteins of interest, thus increasing multiplicity to greater than 40. Coupled with immunohistochemical and immunocytochemical-like data analysis methods, and enabled by high-resolution laser ablation for spatial recognition, rare-earth metal abundance measurement by time-of-flight mass spectroscopy method allows for the determination of expression of different proteins in tissues at individual cells.[67]

2.15.2.3.2 Multiplicity of HCS

The multiplicity of HCS is demonstrated in two categories. The first one is the ability to extract multiple features based on one simple fluorescent or bright-field readout. For example, a nuclear stain image would enable scientists to obtain information on cell numbers which are connected with apoptosis, necrosis, or cell proliferation, and on nuclear structures that are associated with toxicity, cell differentiation, or other cellular events. One bright-field image could be used for cell number, morphology, colony formation, and/or chemotaxis studies, though the bright-field image technology is not optimal for lead discovery because compounds with poor solubility often interfere with the readout method. The second one is the ability to read at multiple wavelengths, and to generate higher levels of information by combining multiple features extracted from images taken at different wavelengths. To balance multiplicity and throughput and to minimize cross-talk from different fluorophores for a given bioassay, most

HCS instruments acquire up to four images simultaneously at different fluorescent wavelengths, plus one bright-field image. Highly multiplexed assays are often used in lead optimization and in toxicity studies. In reality, the degree of multiplicity is also limited by availability of specific antibodies and their selectivity, the relative abundance of proteins of interest in the cells, kinetics of signaling cascades, and the compatibility among different detection reagents.

For cell-based HCS, because most cellular events are observed at the single cell level, to develop robust assays one must ensure that statistically significant number of cells is captured. Using microscopy objectives with magnifications of 4× to 10× normally allow for the capture of sufficient numbers of cells per well within a high-density microtiter plate (384- or 1536-well formats), but often at the cost of image resolution. For assays that require higher subcellular resolutions, such as assays for intracellular protein translocation and for subcellular structure changes, microscopy objectives with higher magnification (20×, 40× or higher) and higher numerical aperture (N.A.) should be used (see section "Image Technologies and Instruments"). In combination with acquiring images from multiple fields in a well, the requirements for significant cell numbers and for higher resolution could be met, yet screening throughput may be sacrificed. Overall, information content, cost, and throughput must be carefully balanced during HCS assay design and development.

The flexibility of HCS readout is built on the technology's ability to visualize subcellular structures and to distinguish subpopulations of cells. The images acquired thus contain an immense amount of information. However, in most HCS-related publications, only two to three features were used for assay quality control and positive hit identification, and most information about the cells/tissues and the compounds were not utilized. To maximize the benefits of HCS on complex cell biology, more sophisticated and user friendly statistical and informatics tools must be developed and applied to extract all relevant and nonparallel features. These features could be clustered into different measurements and used for assay QC and hit identification, and could be further grouped to define phenotypes of cells or mechanisms of action of compounds.[68,69]

2.15.2.3.3 Complexity of readout vs. stages of drug discovery

Not surprisingly, different stages of drug discovery have different emphasis on HCS assay readouts. Regardless of target-based or phenotype-based high-throughput screening approaches, to accommodate throughput requirements on image acquisition and process with constrained budget, HCS assays for lead discovery[70] purposes normally would be developed to answer limited questions such as if compounds modulate a specific function with selectivity, and if the compounds cause any significant cytotoxic effects. Consequently, most HCS assays for lead discovery use a few features during image acquisition and analysis for hit selection and compound ranking. Also, to accommodate throughput and cost requirements, scalability of cell production and pathophysiological relevancy of the cellular models are equally important for selecting cellular models. To this end, immortalized human cell lines and iPSC-derived physiologically-relevant cells are reasonable cellular models for lead discovery.

To maximize benefits from HCS technology, for lead optimization[71] and toxicity studies, more features are acquired and analyzed from HCS-based assays using more complex cellular systems that are physiologically and/or disease relevant. In addition to the structure–activity-relationship for primary targets or phenotypes, other features often acquired from HCS readouts are signaling pathways, selectivity against other targets, potential adverse effects on "untouchable" pathways, or simply cell health. For translational biomarker studies, human or animal tissues are often the subjects for study of interactions between malfunctioned cells and other cell types in a disease tissue microenvironment. Examples are interactions between cancer cells and immune cells, and epithelial cell-fibroblast interactions in lung fibrosis.

2.15.3 Image Technologies and Instruments

HCS is the application of automated microscopy and image analysis for cell-based or organoid-based assays. The fundamentals of image acquisition and image analysis of HCS are very similar to that of fluorescent microscopy. Several commercial and noncommercial websites offer extremely detailed information about microscopy, and readers are encouraged to visit these sites listed at the end of this chapter.

To meet throughput, resolution, flexibility, and information-rich requirements, an ideal HCS system should have the features summarized in **Table 1**.

The capabilities of commercially available instruments vary with particular emphasis.

2.15.3.1 Wide Field Imagers

HCS platforms with wide field imagers are the workhorses for studying various cellular processes to support lead discovery, lead optimization, and toxicity studies. These instruments are often built around inverted research microscopes from major vendors such as Nikon, Zeiss, Olympus, etc., and include both fluorescent and bright-field imaging capabilities. Commercially available wide field imagers frequently cited in literature are summarized in **Table 2**.

2.15.3.2 Confocal Imager

By adding a spatial pinhole at the confocal plane of the lens to eliminate out-of-focus light, confocal microscopy gains the optical resolution and contrast of a micrograph, which leads to sharper images that ease image analysis processes, and enable better z-

Table 1 An ideal HCS system for drug discovery

Optical requirements	Options to select fluorescence vs. transmitted light, and wide field vs. confocal.
	High-quality objectives for different resolution and sample type needs.
	Powerful and stable light sources to excite different fluorophores commonly used for bioimaging.
	Multiple fluorescent excitation and emission filter combinations to detect multiple fluorescent probes in one experiment without cross-talk.
	Large chip-size cameras with high sensitivity, high frame rates, large dynamic range, broad spectral sensitivity, and high resolution.
	Autofocus for fast image acquisition.
Automation requirement	Workflow-oriented and simple to navigate software for setting up interface between reader, robotic arm, and peripheral instruments (incubator, plate stacks, …)
	Compatibility with image acquisitions from microtiter plates with various densities (6, 24, 96, 384, and 1536-well format), tissue slides, and tissue microarrays
	Built-in liquid handling for investigating fast cellular events.
	Environmental controls for live-cell time course studies.
Image analysis	Intuitive graphical user interface to enable biologist users to rapidly set up image acquisition protocol and image analysis algorithm.
	Balances flexibility with ease-of-use
Data management	HCS data workflow management software to facilitate large-scale image storage, query, retrieval, analysis, and visualization.

Table 2 Commercially available HCS instrument

Yokogawa		Cell Voyager™ CV7000

stacking for 3-D imaging.[64] But this comes at a cost of reduced light signal and limitation of sampling only from a single point in the specimen at any given moment. To overcome this problem, most HCS instruments with confocality use Nipkow spinning disk or laser scanning confocal microscope methodologies to increase illumination and the number of points in the specimen that can be imaged simultaneously. Because of these additional functions, confocal imaging is often more expensive, and takes longer to complete a screening compared to wide field imaging. Confocal HCS instruments are best used for determining small and complicated changes at subcellular levels, complex 3-D structures, or samples with high background fluorescence. Commercially available confocal imagers reported in literature are listed in Table 2.

2.15.3.3 Laser Scanning Cytometers

These cytometers use multiple laser beams at different colors to scan across the entire bottom of assay plates and detect fluorescent emissions using photomultiplier tubes. These imagers generate images equivalent to, at maximum, a low NA 20× objective of microscopy, often best used to detect protein expression levels, cell numbers, and cell morphology changes. However, the laser scanning cytometers can acquire images at very high speeds with large depth of fields (in the range of about 200 μm in *z*-axis), which enables whole-well image acquisitions at high speed, independent of plate well density, thus empowering imaging of simple spheroid and organoid size changes, or counting cell number changes in multiple cell layers, without the requirement of assembling images from different z-stacks.

Acumen™ e^{X3} by TTP Labtech, Velos™ laser Scanning cytometer by Molecular Devices, and Compucyte™ iCyte by Beckman Coulter, are examples of instrument in this category.

2.15.3.4 HCS Instrument With Niches

There are niche HCS instruments on the market. Although only possessing a few features as shown in the "ideal HCS" instrument list (Table 1), these instruments were built for specific purposes, and they perform their intended functions very well. For example, the

IncuCyte™ ZOOM system by Essen Bioscience consists of a microscope framework that can reside in a cell incubator, allowing live cell analysis in both bright-field and fluorescence modes. The Celigo™ S system by Nexcelom is often used for both bright-field and fluorescence-based analysis of tumor spheroids and stem cell colonies. The Amnis™ ImageStream X by Amnis provides combined Fluorescence-activated cell sorting (FACS) and HCS functions for single cell analysis by acquiring both stain intensity and images of cells passing through a flow cuvette. The ToxInsight™ IVT platform by Cellomics/Thermo Fisher is designed to specialize in identifying potential toxic liabilities in newly identified compound. Lastly, the Kinetic Image Cytometry™ by Vala Sciences has a built-in electric stimulation mechanism, allowing one to perform patch-clamp-like studies of ion channels, and can often be applied for cardiotoxicity studies.

2.15.4 Image Acquisition and Analysis

2.15.4.1 Image Acquisition

Capturing high-quality images of representative cellular processes of interest is essential for subsequent image analysis. For HCS-based lead discovery, lead optimization, and toxicity studies, it is important to balance screening speed with information content based on individual program needs. Assay plates containing baseline vs. induced or positive vs. negative control samples should be ready before setting image acquisition protocols. Image acquisition optimization often includes selection pixel resolution and magnification, weighting number of objects captured for analysis vs. details of cellular structures, balancing signal intensity vs. background and noise, choosing location of images and number of image fields per assay well, and determining frequency of autofocusing, time of exposure, and number of z-stacks needed for 3-D image, etc.[3]

2.15.4.2 Screening Compatible Image Analysis Software

Embedded computer software for automated image acquisition, analysis, and management is an instrumental component of HCS and is often the key factor that differentiates different HCS platforms. Most of the HCS platforms described in section "Image Technologies and Instruments" of this chapter come with image analysis software that runs in real time or immediately after the image acquisition. Greater than 80% of image analysis needs for complex cell biology processes described in this chapter could be accomplished by this platform-associated image analysis software, and vendors also provide thorough training for new users.

Platform-independent image analysis software is available in both free open source and commercially available formats. ImageJ and CellProfiler[71] are two popular open source softwares. The image analysis speed of these open source softwares is relatively slow, and often could be sped up using a computational system with multiple CPUs (central processing units). Commercially available and highly flexible software such as Definiens, Media Cybernetics, and MATLAB may be needed for very complicated cellular process analysis. Image analysis using these platform-independent software packages often requires very skilled programmers with essential biology knowledge.

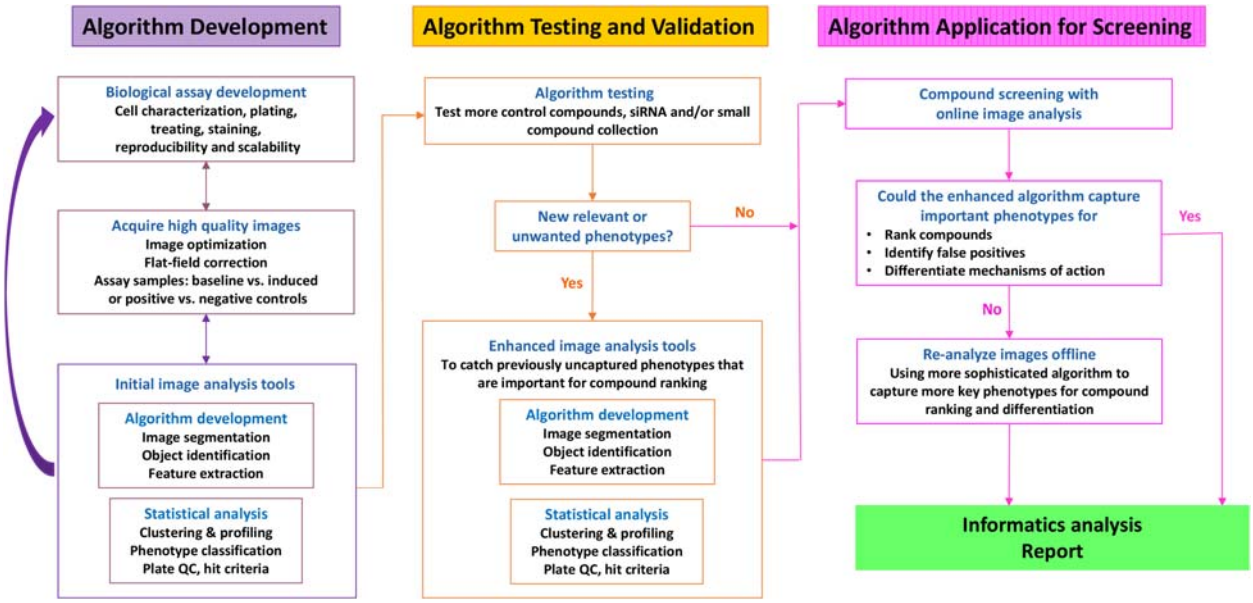
2.15.4.3 Image Analysis Algorithm Development

The image analysis algorithm development is an iterative process (**Scheme 1**), and the quality of the algorithm is heavily dependent on the quality of the cellular assays, the sharpness of images acquired, and the depth of knowledge on disease biology and associated phenotypes. The NIH Assay Guidance Manual e-book on HCS[3] devotes one section to this topic and readers are encouraged to read the e-book.

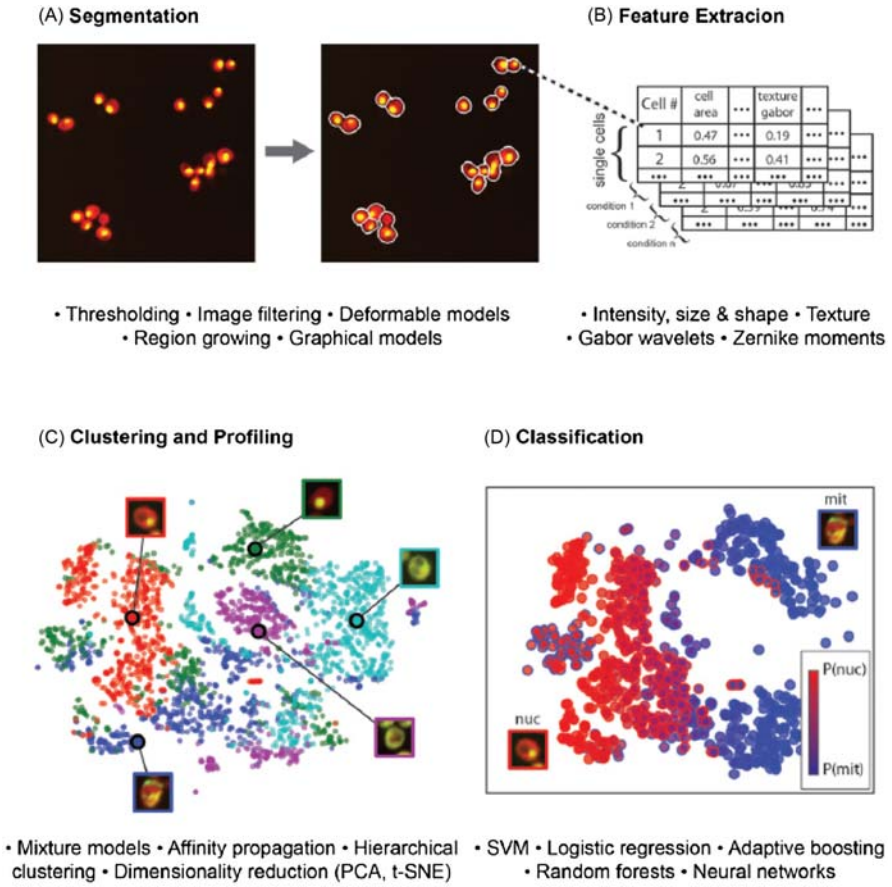
After flat-field correction to remove artifacts from images that are caused by variations in the pixel-to-pixel sensitivity of the detector and/or by distortions in the optical path, image analysis normally starts with segmentation of images for object identification[68,69,72–80] (often cells, but could be organelles or tissues) based on a combination of fluorescent intensity thresholding and image area selection algorithm, followed by accurate extraction of features within, about, and among the identified objects. Hundreds of features can be extracted for each segmented object (e.g., intensity, size, shape, and texture), and many of the features are highly correlated. To reduce the dimensionality of the features, both supervised and unsupervised machine learning classification algorithms[81,82] can be applied to cluster features, and to group the clusters into different phenotypes. **Scheme 2** demonstrates one example of using a trained logistic regression model to discriminate cell populations based on the distribution of a GFP-tagged protein colocalized with nuclear (nuc) and/or mitochondrial (mit) in cells.[82] For complex cellular assays, the combinations of multiple features or clusters are often critical for establishing assay QC standards and for hit identification criteria.

Although high dimension features, clusters, or phenotypes could be generated from HCS campaigns, to balance information content and computation time needed, typically only features that are important for ranking compound potency, identifying false positives, and differentiating mechanisms of action would be extracted. Bioassay designer, algorithm developer, and disease biology expert must work together to determine key features to be captured and clustered during bioassay and algorithm development.

Before finalizing the newly developed image analysis algorithm, it is imperative to test the algorithm in a small trial, against relevant siRNA or small molecular collections, to verify the algorithm is capable of apprehending and discriminating important and relevant phenotypes, filtering out false positives and identifying compounds with undesirable adverse effects. Often, fine-tuning of algorithm is necessary prior to applying the algorithm for screening. After completing the entire HCS-based screening, adjustment of image analysis algorithm and reanalysis of images offline are often necessary under certain circumstances. For



Scheme 1 A typical image acquisition and analysis workflow during assay development and screening.



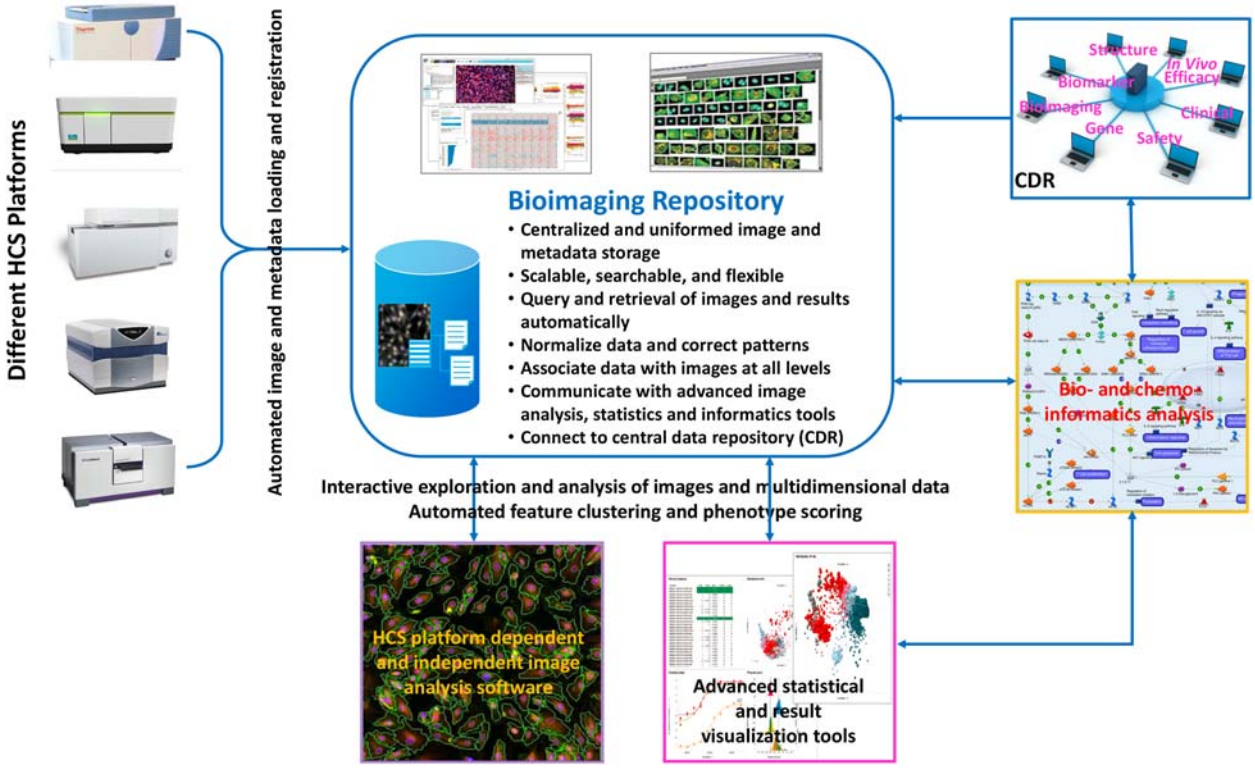
Scheme 2 Typical steps involved in analyzing microscopy images. From Kraus, O. Z.; Frey, B. J. Computer Vision for High Content Screening. *Crit. Rev. Biochem. Mol. Biol.* **2016**, *51*, 102–109, http://dx.doi.org/10.3109/10409238.2015.1135868, figure 1.

example, (1) a simplified algorithm was used during screening to reduce instrument time, but unwanted plate patterns were observed during screening QC inspection. Therefore, application of a normalization factor for result analysis is needed; (2) new phenotypes associated with important biological processes were observed upon manual inspection of hits, modification of algorithm could be necessary in order to capture or to differentiate these phenotypes. A highly effective and flexible HCS data management system would be needed in order to conduct large-scale image reanalysis (see section "HCS Data Workflow Management, Statistical Analysis and Informatics").

2.15.5 HCS Data Workflow Management, Statistical Analysis and Informatics

Although HCS provides richly-descriptive information, how to extract the most critical information for the disease-relevant cellular processes in a timely manner is still a challenge to the drug discovery institutions. A streamlined HCS image acquisition, storage, query, analysis, and retrieval workflow, coupled with sophisticated statistical and informatics tools is crucial to extract meaningful information from several to hundreds of gigabytes (GB) of data generated per HCS campaign. For small laboratories with a single HCS platform, the associated vendor's data management solution is a reasonable approach. For large institutions with multiple HCS platforms, it is worthwhile to build a centralized and unified HCS data management system to enable cross-platform and cross-program data mining, comparison, and information extraction.

HCS data management starts with image capture. The captured images, along with metadata, must be stored and registered in an overarching bioimaging repository with appropriate architectures, suitable for long-term storage and iterative retrieval and reanalysis. Image analysis numerical descriptors at the individual cell level, such as cell morphology, and protein abundance and location, must be linked to images and associated metadata. The metadata includes, but is not limited, to program information, compound structures, reagent information, image acquisition settings, plate barcodes, and well locations. Metadata is critical for meaningful statistical and informatics analysis. The repository must be accessible for platform-dependent and- independent image analysis software for interactive image/data exploration, as well as advanced statistical analysis and informatics tools for automated scoring of complex phenotypes. The automated scoring should be able to combine multiple extracted features per cell/well, and be performed in plate-batch manner for timely image analysis. Furthermore, the repository must be coupled to institutional central data repository to enable establishment of relationships with other information, such as gene expression, biomarkers, structures, in vivo results, safety, and clinical outcomes (**Scheme 3**). Finally, it is important to develop data retention policies for effective data management.



Scheme 3 A streamlined HCS data management workflow.

A picture is worth a thousand words. Often, numeric results calculated based on an initial image analysis algorithm do not capture all key aspects of the images. A bioimaging repository's capability to retrieve images associated with a set of compounds, and to present the images to downstream visualization tools such as SpotFire™, is a must for refining image analysis algorithms. Furthermore, the ability to generate on-the-fly summaries of millions of data points and to communicate these data points to downstream advanced statistical analysis (e.g., machine learning capability) and informatics tools is also required. Although software platforms, such as Phaedra by Johnson & Johnson, CellProfiler Analyst by Broad Institute, and OMERO by University of Dundee; and commercial software such as GeneData Screener for HCS by GeneData and Columbus by Perkin Elmer, have been reported to have both abilities mentioned here, most software for bioimaging repository applications still need major enhancements to meet speed, flexibility, and complexity requirements for HCS applications in lead discovery, lead optimization, and toxicity studies.[83–87]

Finally, to leverage rich information obtained via HCS campaigns and extract broadly impactful underlining disease knowledge across related therapeutic areas, more sophisticated bioinformatics tools are required for pathway mapping and mechanisms of action studies, and for establishment of holistic relationships with other information, such as proteomics, next gen sequence, in vivo results, and safety and clinical outcomes.

2.15.6 Application of HCS in Various Therapeutic Areas and in Toxicity Studies

HCS has been applied to almost all therapeutic areas and functional departments in both academic and industrial settings for drug discovery and development. This chapter will focus on recent applications related to complex cell biology in oncology, CNS, metabolic diseases, rare diseases, infectious diseases, and toxicity studies.

2.15.6.1 Epithelial-Mesenchymal Transition (EMT)

Despite advancements in therapies developed for the treatment of cancer, patient prognosis and mortality rates have improved insignificantly for patients with metastatic cancer. An underlying mechanism promoting metastasis in many types of cancer is EMT. EMT is now considered a valid target for drug development in cancer, as well as in fibrosis. EMT starts when epithelial cells are stressed by injury or inflammation and the cells lose their epithelial characteristics such as tight junction protein expression (e.g., ZO-1) and apical-basolateral polarity (Cobblestone shape for both cell and nucleus morphologies), and acquire a mesenchymal phenotype characterized by cadherin gene-expression shift and a clear front-rear polarity (elongated shape for both cell and nucleus morphologies) (Fig. 1A). The mesenchymal cells are then ready for migration and invasion.[88,89]

It is reasonable to assume that small molecules or other substances capable of inhibiting the loss of epithelial markers and/or the gain of mesenchymal markers could be used to antagonize EMT, and subsequently prevent cancer metastasis. HCS-based compound screening for EMT blockers has been reported. The HCS-based screening exemplified here was conducted in 2-D monolayer cell culture format using pooled human primary renal proximal tubule epithelial cells (RPTECs) seeded in collagen I-coated 96-well plates. The RPTEC of eight donors were evaluated separately for their suitability in a TGF-β1 induced EMT assay, quantified by a combination of three features derived from HCS results: cell morphology, nuclear morphology, and epithelial marker ZO-1. Cells from six donors were selected for High throughput screening (HTS). Each donor's cells could be proliferated up to four passages without sacrificing assay robustness. Compounds were incubated with the RPTEC in the presence of TGF-β1 for 72 h in serum free medium, followed by cell fixation and staining for nucleus, cytoplasm, and epithelial marker ZO-1. Positive hits were identified based on their ability to inhibit the TGF-β1 induced EMT by reversal of morphology from elongated to cobblestone for both cytoplasm and nucleus shapes, plus restoration of ZO-1 marker (Fig. 1B).[90] Compounds optimized based on hits identified via the screening have demonstrated efficacy in in vivo cancer models.

2.15.6.2 Three-Dimensional Organotypic Culture Mimics Ovarian Cancer Microenvironment

Ovarian cancer is highly aggressive. Metastatic ovarian cancer patients have less than 10% survival rate. Based on clinical observations, it is believed that ovarian cancer cells initially travel through the peritoneal fluid to the surface of other abdominal organs to start metastasis. Human omentum consists of well-organized mesothelial cells at the top, fibroblast cells as the basis, supported by ECM. When ovarian cancer cells reach the omentum surface, they will adhibit, invade and grow, thus initiating metastasis (Fig. 2A).

It was believed that creating a tumor microenvironment that accurately reflects the complex biology of ovarian cancer should help the medical community to understand the underlying mechanisms of metastasis, as well as to identify new therapeutics. To assemble a 3-D model, clinicians collected noncancerous omental tissue from consented patients undergoing abdominal surgery. In the laboratory, mesothelial cells and fibroblasts, two of the predominant cell types found in omental tissue, were isolated and cultured. In the presence of ECM proteins, these cells were then mixed and allowed to self-assemble for over 48 h into a multilayered cell culture model mimicking ovarian cancer microenvironment (Fig. 2B and C). The model was used in HTS to identify compounds that could inhibit ovarian cancer cell line SKOV3ip1–GFP adhesion, invasion, and growth in the 3-D organotypic culture, therefore having the potential to prevent human ovarian cancer metastasis. Specifically, compounds dissolved in Dimethyl sulfoxide (DMSO) were added to the organotypic culture immediately after SKOV3ip1–GFP cancer cells were added.

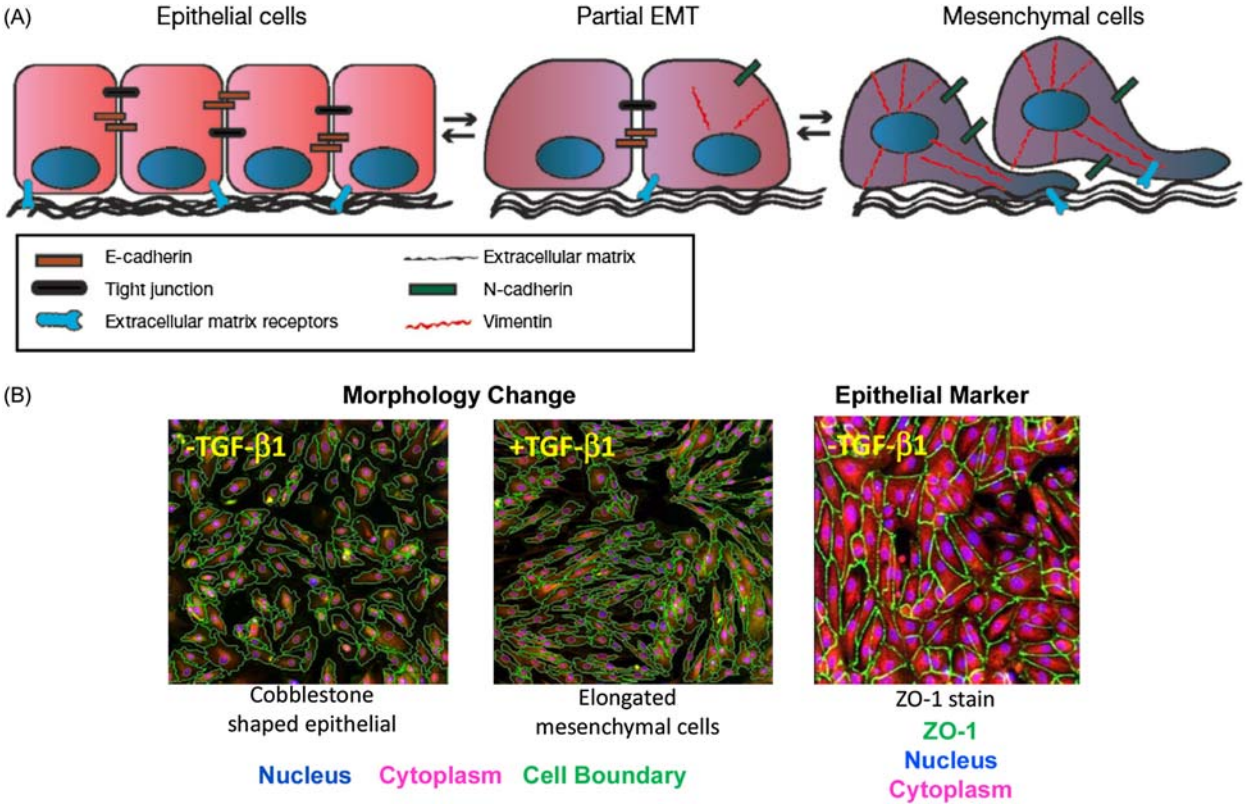


Fig. 1 Epithelial to mesenchymal transition (EMT). (A) EMT involves a cellular phenotypic shift. Epithelial cells are characterized by Cobblestone-like morphology, intact cell–cell contacts, expression of tight junction protein (e.g., ZO-1), barrier function, and lack of movement. During the EMT process, cells with partial EMT appear characterized by the incipient presence of a front-rear polarity and have leaky cell–cell contacts. At the same time upregulation of the mesenchymal markers vimentin, N-cadherin, ZEB1 and 2, SNAIL, SLUG, and matrix metalloproteinases begin. In addition, these partial EMT cells express lower amounts of E-cadherin and ZO-1 than epithelial cells. After finalization of EMT, the established mesenchymal cells have a clear front-rear polarity with no or few cell contacts. The expression of mesenchymal proteins is increased, and a cadherin gene-expression shift, most often from E-cadherin into N-cadherin expression. (B) High throughput high-content screening for specific small-molecule inhibitors of TGF-β1 induced EMT by following the reversal of morphology from elongated to cobblestone for both cytoplasm and nucleus shape, plus restoration of epithelial marker ZO-1 expression, using primary human epithelial cells. Fig 1A From Jakobsen, K. R.; Demuth, C.; Sorensen, B. S.; Nielsen, A. L. The Role of Epithelial to Mesenchymal Transition in Resistance to Epidermal Growth Factor Receptor Tyrosine Kinase Inhibitors in Non-Small Cell Lung Cancer. *Transl. Lung Cancer Res.* **2016**, *5*, 172–182, figure 1

After 18 h of incubation, cancer cells remaining in the cell culture medium were aspirated, and the organotypic culture was washed. Then Acumen, the HCS instrument with a large depth of field enabling image acquisition of multiple cell layers was used to count the SKOV3ip1–GFP cells that adhibited and/or invaded in the 3-D organotypic culture. Hits identified from the HTS screen were triaged, and selected compounds were tested in in vivo adhesion and invasion, prevention, and intra-ovarian intervention studies. Beta-escin and tomatine were selected as the lead compounds due to demonstrated efficacy in the three in vivo models described.[91]

2.15.6.3 Invadopodia and Cancer Invasion

The transition of cancer from benign to metastatic form requires the acquisition of various cellular properties, including migratory ability and invasiveness. Invasive characteristics facilitate tumor escape through the basement membrane barrier, as well as local invasion and remodeling of the tumor microenvironment in the primary and metastatic sites. Various studies have correlated the ability of cancer cells to form invadopodia with invasiveness. Invadopodia is an actin-rich cell membrane microstructure that can protrude into the ECM to start invasion (**Fig. 3A**).[92]

The mechanism of invadopodia formation is not well characterized. Therefore, a HCS-based assay was established and used to screen against the Library of Pharmacologically Active Compounds (LOPAC) for invadopodia modulators. For primary screening, NIH 3T3 cells transformed with activated Src (Src-3T3) were used. This cell line uniformly expresses many invadopodia per cell, which eases image acquisition and analysis. Src-3T3 cells were plated and grown in 384-well optical plates for 3 days, incubated with compounds for 16 h, then fixed and stained with 4′,6-Diamidino-2-Phenylindole, Dihydrochloride (DAPI) to visualize nuclei

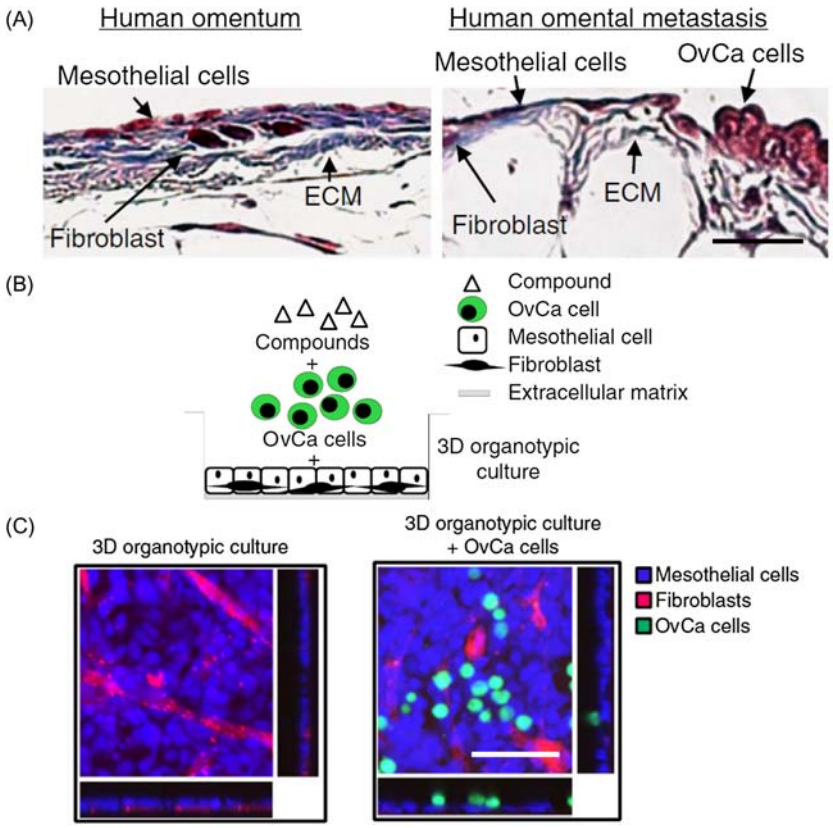

Fig. 2 3-D organotypic culture mimics ovarian cancer microenvironment. (A) Tissue images of human omentum, normal vs. with metastatic ovarian cancer cells. Fibroblast, *red*; mesothelial cells, *blue*; ovarian cancer cells (SKOV3ip1–GFP), *green*. The *square images* were the views from the top of a well in 1536-well plates. The images on the sides were Z-plane reconstruction of optical sections with orthogonal view of maximum intensity. Scale bar indicates 100 μm. Modified from Kenny, H. A.; Lal-Nag, M.; White, E. A.; Shen, M.; Chiang, C.-Y.; Mitra, A. K.; Zhang, Y.; Curtis, M.; Schryver, E. M.; Bettis, S.; Jadhav, A.; Boxer, M. B.; Li, Z.; Ferrer, M.; Lengyel, E. Quantitative High Throughput Screening Using a Primary Human Three-Dimensional Organotypic Culture Predicts in vivo Efficacy. *Nat. Commun.* **2015**, *6*, 6220, figure 1.

and phalloidin for F-actin (Fig. 3B). The primary screening identified five invadopodia inhibitors and two activators. The ability of these seven compounds to decrease or increase gelatin degradation by Src-3T3 were confirmed using FITC-gelatin-coated glass coverslips observed under microscopy. In follow up studies, hits Purvalanol A and GCP74514A were shown to significantly reduce both the fraction of cells positive for invadopodia and the number of invadopodia per cell in human squamous cell carcinoma of the head and neck cells (SCC61). Hits Paclitaxel and Cantharidin, on the other hand, increased the number of invadopodia per cell. Furthermore, degradation of FITC-gelatin by invasive cancer cell lines SCC61, C8161.9 (melanoma), OVCAR8 (ovarian cancer), and NCIH460 (nonsmall cell lung cancer) can be prevented by Purvalanol A or GCP74514A, but enhanced by Cantharidin or Paclitaxel (Fig. 3C). Finally, in a subsequent mechanism study, Cdk5 was identified as the targeted protein for Purvalanol A and GCP74514A, and was confirmed to play a key role in invadopodia formation, therefore becoming a potential target for cancer therapy.[93]

2.15.6.4 Oligodendrocyte Progenitor Cell (OPC) Differentiation and Remyelination

Oligodendrocytes provide insulation for neurons by producing a myelin sheath around axons. It is believed that in multiple sclerosis (MS) patients, the myelin sheath is damaged by inflammation, which could cascade to axonal damage, disruption of neuronal signaling, and eventually oligodendrocyte and neuronal cell death (Fig. 4A). Standard MS therapies are aimed at preventing further immune-mediated damage of myelin. While these drugs have some disease modifying activity for patients, they fail to slow disease progression or prevent disability. Alternatively, experts in the field are considering drugs that would promote the enhanced differentiation and myelination capacity of resident OPCs, and consequently restoration of axonal conduction, based on the following observations: (1) OPCs constitute up to 5% of adult human brain cells and are the predominant source of myelinating oligodendrocytes in the CNS, (2) these resident OPCs have the capacity to differentiate into oligodendrocytes and remyelinate axons in response to damage caused by disease, aging, or injury. However, in many conditions, including MS, the

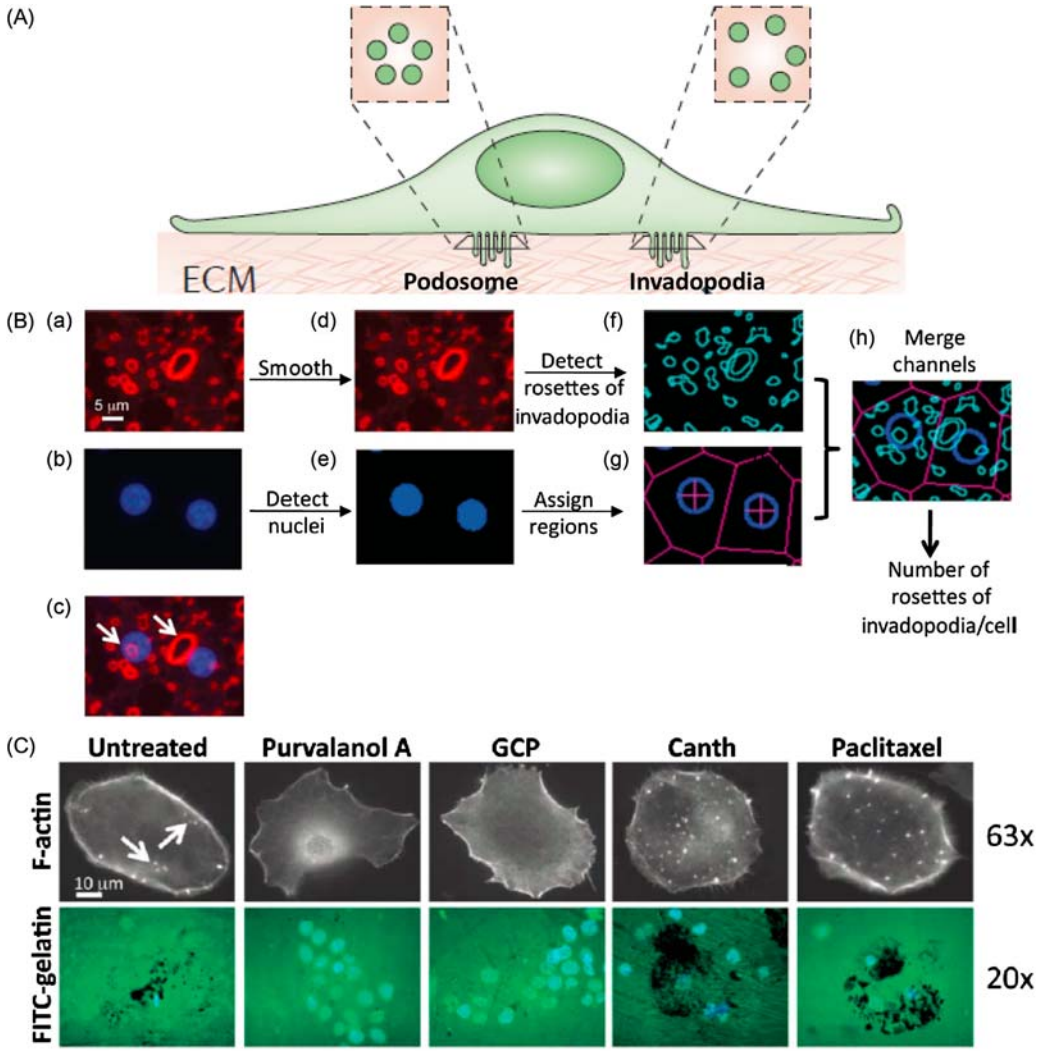

Fig. 3 Invadopodia and cancer invasion. (A) Depending on the cell type and stimuli provided, invadopodia and podosomes can form as individual puncta or as rosettes on cell surface membranes, both are actin-rich microstructures that protrude into the extracellular matrix (ECM), and could be used by cancer cells for invasion. (B) HCS Image analysis for invadopodia formation in Src-3T3 cells in 384-well plate. Cells stained with phalloidin for F-actin (*red*) (a) and with DAPI for nuclei (*blue*) (b). The overlay of both channels is displayed in (c). The image background for the red channel was subtracted and a 3-by-3 median filter was applied to smooth the image and remove fine actin fibers (c). Nuclei detection was applied (e) and nuclear parameters were extracted from the segmented DAPI image. From the nuclei masks (e), cellular regions were assigned to each nucleus (g). The red channel was segmented using fluorescence aggregate detection to find rosettes (f). Finally, the detected nuclei, assigned cellular regions, and detected rosettes were merged (h) and the number of detected rosettes was calculated on a cell-by-cell basis. (C) Effects of active compounds on invadopodia formation and cancer cell invasiveness. SCC61 cells were grown on FITC-gelatin coated coverslips; treated with DMSO control, 2 μM Purvalanol A, GCP74514A (GCP), Cantharidin (Canth), or Paclitaxel. It was then assayed for invadopodia formation (F-actin) and gelatin degradation (FITC-gelatin). Representative invadopodia are highlighted with *white arrows* in the upper left panel. (A) From Murphy, D. A.; Courtneidge, S. A. The "Ins" and "Outs" of Podosomes and Invadopodia: Characteristics, Formation and Function. *Nat. Rev. Mol. Cell Biol.* **2011**, *12*, 413–426, figure 2. (B) Modified from Quintavalle, M.; Elia, L.; Price, J. H.; Heynen-Genel, S.; Courtneidge, S. A. A Cell-Based High-Content Screening Assay Reveals Activators and Inhibitors of Cancer Cell Invasion. *Sci. Signal.* **2011**, *4*, ra49, figure 1. (C) From Quintavalle, M.; Elia, L.; Price, J. H.; Heynen-Genel, S.; Courtneidge, S. A. A Cell-Based High-Content Screening Assay Reveals Activators and Inhibitors of Cancer Cell Invasion. *Sci. Signal.* **2011**, *4*, ra49, figure 2.

resident OPCs ultimately fail to repair the myelin damage, leading to permanent functional deficits. Therefore, screening for compounds that can differentiate OPCs into oligodendrocytes is a reasonable approach to identify potential lead compounds for MS therapy.

A new method was developed to generate screening-scale OPCs from mouse stem cells. The mouse OPCs were thoroughly validated using gene array for genomic integrity, immuno-staining for key biomarkers, RNA-seq for gene expression and purity, and in vivo transplantation for myelinogenic functions. A HCS assay based on nuclear and antimyelin basic protein (MBP) stains

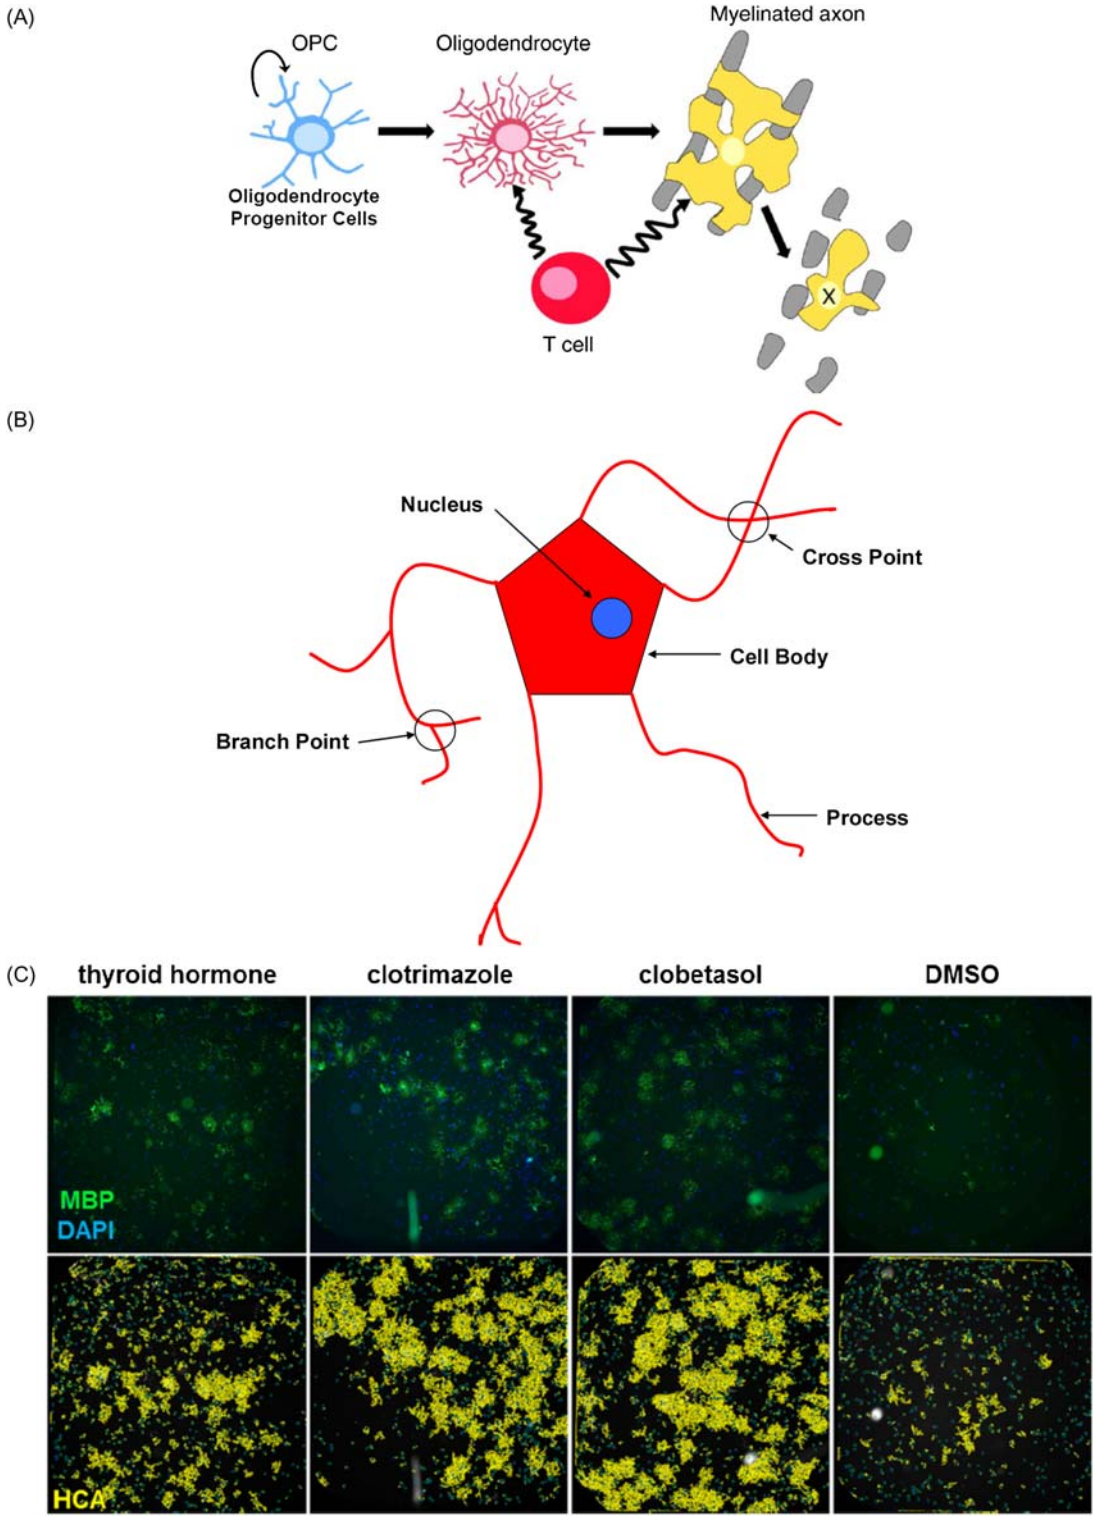

Fig. 4 Oligodendrocyte progenitor cell (OPC) differentiation and remyelination. (A) Cellular dynamics of multiple sclerosis (MS) pathology. OPCs could be differentiated into oligodendrocytes which produce myelin sheaths to protect axon. Overactive T cells of MS patients could damage the myelin sheaths and further destroy axons. (B) Typical cell morphology of OPC. (C) Images taken by InCell 2000 from a 1536-well plate, for OPCs treated with positive control compound thyroid hormone, negative control DMSO, and clotrimazole and clobetasol, two hits identified via screening. T.; Factor, D. C.; Miller, T. E.; Nevin, Z. S.; Kantor, C.; Sargent, A.; Quick, K. L.; Schlatzer, D. M.; Tang, H.; Papoian, R.; Brimacombe, K. R.; Shen, M.; Boxer, M. B.; Jadhav, A.; Robinson, A. P.; Podojil, J. R.; Miller, S. D.; Miller, R. H.; and Tesar, P. J. Drug-Based Modulation of Endogenous Stem Cells Promotes Functional Remyelination In Vivo. *Nature* **2015**, *522*, 216–220, extended data figure 2.

was established to search for compounds that can differentiate mouse OPC into oligodendrocytes characterized by increased MBP protein expression and number of processes (Fig. 4B). Results from screening against FDA-approved drug collection were published, and 22 hits were identified based on EC50 and TC50 combination scores. Fig. 4C shows images taken by InCell 2000 from 1536-well plates. The 22 compounds were tested in human OPCs to ensure cross-species activities. Of these compounds, clobetasol and miconazole were prioritized for further characterization and both demonstrated efficacy in mouse ex vivo cerebellar slice cultures and in Lysophosphatidylcholine (LPC) lesion mouse model.[94]

2.15.6.5 Lipid Accumulation in Adipocytes

Phenotypic screening provides a nonbiased approach to chemically interrogate the proteome in its pathophysiologically-relevant environment, and accordingly increase the chances of revealing authentic disease mechanisms and identifying potential therapies. However, the biggest challenge of phenotypic screening is the identification of the molecular targets of bioactive hit compounds. Without a target (or targets), chemical optimization and preclinical toxicity studies on phenotypic screening hits are daunting tasks, and translation of potential drugs discovered by phenotypic screening into clinical applications would face significant obstacles.

In the study demonstrated here, a HCS-based phenotypic screening was conducted in preadipocytes against a focused small-molecule library of carbamates designed to inhibit the serine hydrolase enzyme super family. The extent of lipid accumulation and adipocyte differentiation were visualized by fluorescent lipid Nile Red (shown in green in Fig. 5A). Several carbamates including WWL 113 specifically promoted adipocyte differentiation and lipid storage in the fat cells. These molecules could be beneficial for obesity-linked insulin resistance patients, working to reduce levels of circulating free

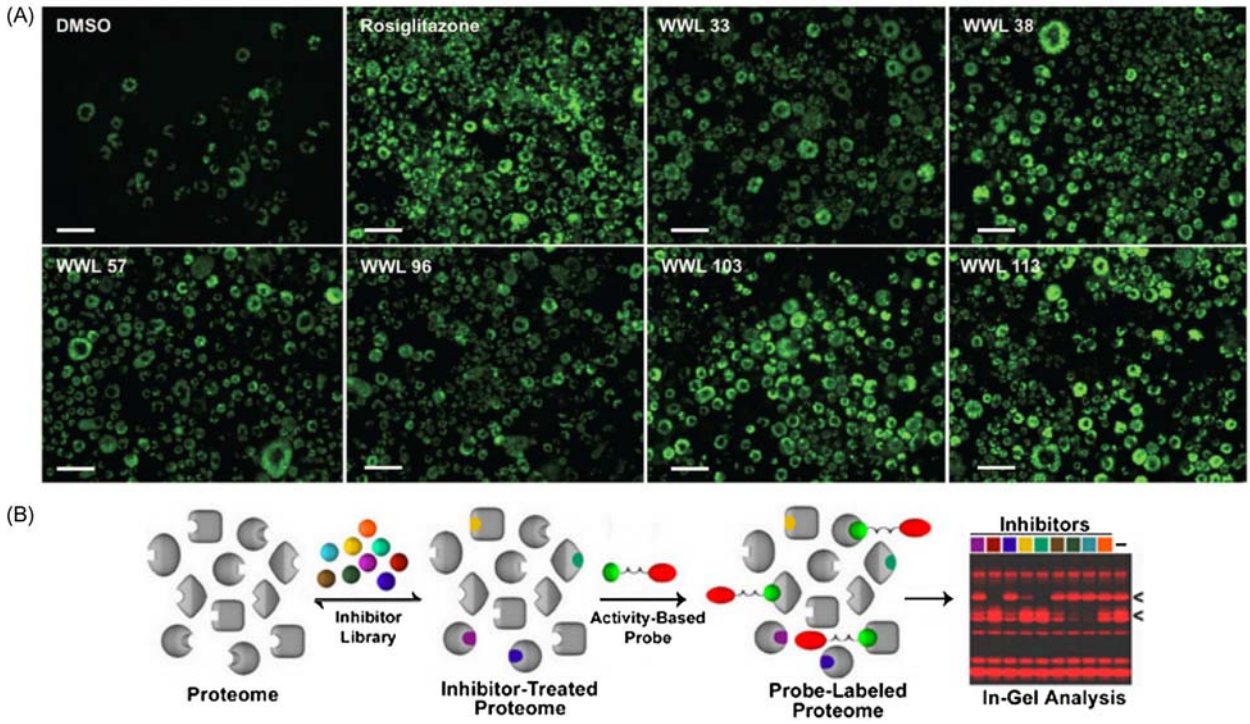

Fig. 5 Lipid accumulation in adipocytes. (A) A phenotypic screening against a focused set of bioactive compounds targeting serine hydrolase superfamily in 3T3-L1 cells was conducted. 3T3-L1 preadipocytes were induced to differentiate into adipocytes 2 days postconfluence in the presence of 10 μM individual compounds. Two days later, induction media was replaced with maintenance media and compounds refreshed. On day 7, the extent of lipid accumulation (marked by fluorescent lipid Nile Red, shown in *green*) and adipocyte differentiation was evaluated by HCS-based assay. WWL 113, along with other compounds, were identified as lipolysis inhibitors. Scale bar indicates 100 μm. (B) Competitive ABPP strategy was used to identify the molecular target(s) of WWL 113 in the cells. ABPP technology monitors changes in the functional state of serine hydrolases directly in the cells. ABPP probe includes three elements: an enzyme active-site directed reactive group, a linker and a fluorophore tag. For serine hydrolase superfamily, the reactive group is fluorophosphonates (FP), a near-universal activity probe for the enzyme family. The fluorophore tag allows visualization of probe-labeled proteins in the gel. In the competitive mode of ABPP technology, inhibitors will displace the probe associated with the enzymes, lead to the disappearance of protein band(s) in the gel. (A) From Dominguez, E.; Galmozzi, A.; Chang, J. W.; Hsu, K.-L.; Pawlak, J.; Li, W.; Godio, C.; Thomas, J.; Partida, D.; Niessen, S.; O'Brien, P. E.; Russell, A. P.; Watt, M. J.; Nomura, D. K.; Cravatt, B. F.; Saez, E. Integrated Phenotypic and Activity-Based Profiling Links Ces3 to Obesity and Diabetes. *Nat. Chem. Biol.* **2014**, *10*, 113–121, supplementary figure 1. (B) From http://www.scripps.edu/cravatt/research.html, figure 3.

fatty acids, restoring normal lipid partitions among tissues, potentiating adipocyte function, and subsequently enhancing systemic insulin action.[95]

In order to identify the molecular target(s) of WWL 113 and other hits obtained via the HCS-based phenotypic screening, a competitive activity-based protein profiling (ABPP) strategy was used. ABPP technology monitors changes in the functional state of enzyme families directly in the cells. An ABPP probe includes three elements: an enzyme active-site directed reactive group, a linker and a fluorophore tag. For the serine hydrolase superfamily, the reactive group is fluorophosphonates (FP), a near-universal activity probe for the enzyme family. The fluorophore tag allows visualization of probe-bound proteins in the gels. In the competitive mode of ABPP technology, inhibitors such as WWL 113 displace the probes associated with the proteins, leading to protein band(s) disappearing in the gel (**Fig. 5B**).[96] Next, the fluorophore tag of the ABPP probe was replaced by biotin, and used as a capture probe to separate probe-labeled proteins from unlabeled ones. WWL 113, as an inhibitor of the hydrolase enzyme, competed with the biotinylated probe, and consequently reduced the amount of proteins pulled down. The pulled down proteins were then subjected to tryptic digestion and mass spectroscopy analysis. Using this approach, two carboxylesterase enzymes, Ces3 and Ces1f, were identified as the molecular targets for WWL 113. Ces3 and Ces1f are endoplasmic reticulum glycoproteins that have been previously associated with adipocyte lipolysis. Treatment of two mouse models of obesity-diabetes with WWL 113 ameliorated multiple features of metabolic syndrome, validating the ABPP strategy described above for accelerating the identification of true therapeutic targets and the development of new therapies.[95]

2.15.6.6 Lysosomal Storage Disease

Niemann–Pick disease type C (NPC) is a rare autosomal recessive genetic disease caused by mutations in the NPC1 or NPC2 gene. The NPC genes encode proteins to regulate cholesterol transport from late endosomes-lysosomes to other intracellular compartments, such as the trans-Golgi network and plasma membrane caveolae. Deficiency in NPC1 or NPC2 proteins results in malfunction of intracellular cholesterol trafficking and lysosomal accumulation of unesterified cholesterols (**Fig. 6A**). This lysosomal lipid storage defect causes progressive neurodegeneration and eventually leads to disability and death of patients.

A number of agents have been reported to have therapeutic potential for treatment of NPC. Hydroxypropyl-β-cyclodextrin (HPBCD), methyl-β-cyclodextrin (MBCD), and δ-tocopherol are known to reduce brain cholesterol accumulation and increase life span in NPC1 mouse models. The effect of the three compounds on the reduction of lysosomal cholesterol accumulation has been confirmed in the NPC patient-derived fibroblasts and primary mouse neurons. However, these agents have not been directly evaluated in human NPC neuronal cells, the type of cells that are more relevant to the disease pathogenesis. Therefore, NPC patient iPSC-derived neuronal cells were generated and used for drug efficacy evaluation.

Fibroblasts from an NPC1 patient were reprogrammed to iPSCs using a commercially available virus reprogramming system that expresses Oct3/4, Sox2, Klf4, and cMyc factors. The pluripotency of patient iPSC thus generated was confirmed using immunofluorescence staining on Oct4, Sox2, SSEA4, and TRA-1-81, and similar patterns were observed and compared to iPSC generated from normal human fibroblasts. Further characterization of the patient iPSCs showed a normal karyotype, typical teratoma formation, and original NPC1 gene mutations.

Using commercial reagents, the NPC1 iPSC were first differentiated into neural stem cells (NSCs), expanded, and confirmed for expression of NSC markers nestin and Sox2 by fluorescent staining. The NPC1 NSC were then differentiated into neuronal cells, and neuronal phenotype was confirmed using Tuj1, Map2, and neurofilament markers. The time required for NPC1 neuron maturation, cell morphology changes, and expression of neural markers was similar to that of control wild type (WT) iPSC.

An enlarged lysosome with accumulated unesterified cholesterol is a major phenotype of the disease. Three dyes were used to characterize WT and NPC1 NSC and neuronal cells, and the phenotype was confirmed in NPC1 NSC and neuronal cells. The dyes used were: Filipin, a dye that stains unesterified cholesterols in cells; LysoTracker dye that locates cellular acidic compartment and could be used to observe lysosome size changes; and nuclear dye. **Fig. 6B** showed that upon increasing cellular cholesterol levels by exposing cells to a higher percentage of serum in culture media, the accumulation of unesterified cholesterols in NPC1 iPSC-derived neuronal cells was much faster and more significant compared to WT iPSC-derived neuronal cells, as evidenced by higher intensity of Filipin stain and larger lysosome body size. Finally, HPBCD, MBCD, and δ-tocopherol were used to treat both NPC1 iPSC-derived NSC and neuronal cells, and their ability to ameliorate cholesterol accumulation in lysosomes in these cells was confirmed (**Fig. 6C**). Therefore, the NPC1 patient iPSC-derived NSC and neuronal cells are appropriate models for efficacy evaluation on NPC disease modifying drugs.[97]

2.15.6.7 Progeroid and Abnormal Nuclear Structures

Hutchinson-Gilford progeria syndrome (HGPS) is caused by mutations in the LMNA gene encoding prelamin A and lamin C proteins. These mutations result in an internally truncated form of prelamin A (called progerin). Because of the truncation, its farnesylated carboxyl-terminal cannot be processed correctly, making the farnesylation permanent. Farnesylated progerin then accumulates at the nuclear rim, leading to abnormal nuclear shapes, compromised chromatin maintenance and DNA repair functions, and other unknown damages (**Fig. 7A**). These cause patient to age prematurely. Target-based drug discovery approaches failed, given that the abnormal cellular phenotypes make it difficult to determine whether progerin drives the HGPS phenotype or are only

bystanders. To circumvent this issue, a phenotypic screening assay was established and applied to identify leads for progerin therapies with potential novel mechanisms.

In phenotypic screening, the first and most important action is to select and validate appropriate cellular models. It was found that primary cells from HGPS patients were not suitable for HTS, because these cells were restricted in their in vitro growth, and showed considerable donor variability in phenotypes and responses. An inducible GFP-progerin cell line, along with two control cell lines, were engineered using human dermal fibroblasts and validated against patient cells prior to being used for HTS. Protein markers used to validate screening cell lines are: progerin—the disease causing protein; lamin B1 and LAP2—nuclear structure proteins; HP1g and H2K27-3M—chromatin structure proteins; gH2AX and 53BP1 foci—DNA damage activation markers (Fig. 7B).

Three different phenotypes were expected from three cell lines expressing different LMNA gene variants in human dermal fibroblasts; this hypothesis was confirmed experimentally. Normal Lamin A gene led to normal nuclear structure and low level of DNA damage. Progerin gene led to abnormal nuclear structure and high level of DNA damages. A mutation in progerin gene, C661S, protected progerin from being processed by farnesyltransferase, keeping progerin in the nucleus without destroying the nuclear structure (Fig. 7C).

The inducible GFP-progerin cell line was used for HCS-based screening in 384-well format. Four parameters were collected: cell number for toxicity, GFP-progerin for disease protein levels, Lamin B1 nuclear structure for early HGPS indication, and gH2AX DNA damage signal for late HGPS indication. L-744, 832 a farnesyltransferase inhibitor, was used as a positive control. Assay window was very small and multiparameter analysis was needed for assay quality controls and hit identification. NIH FDA-

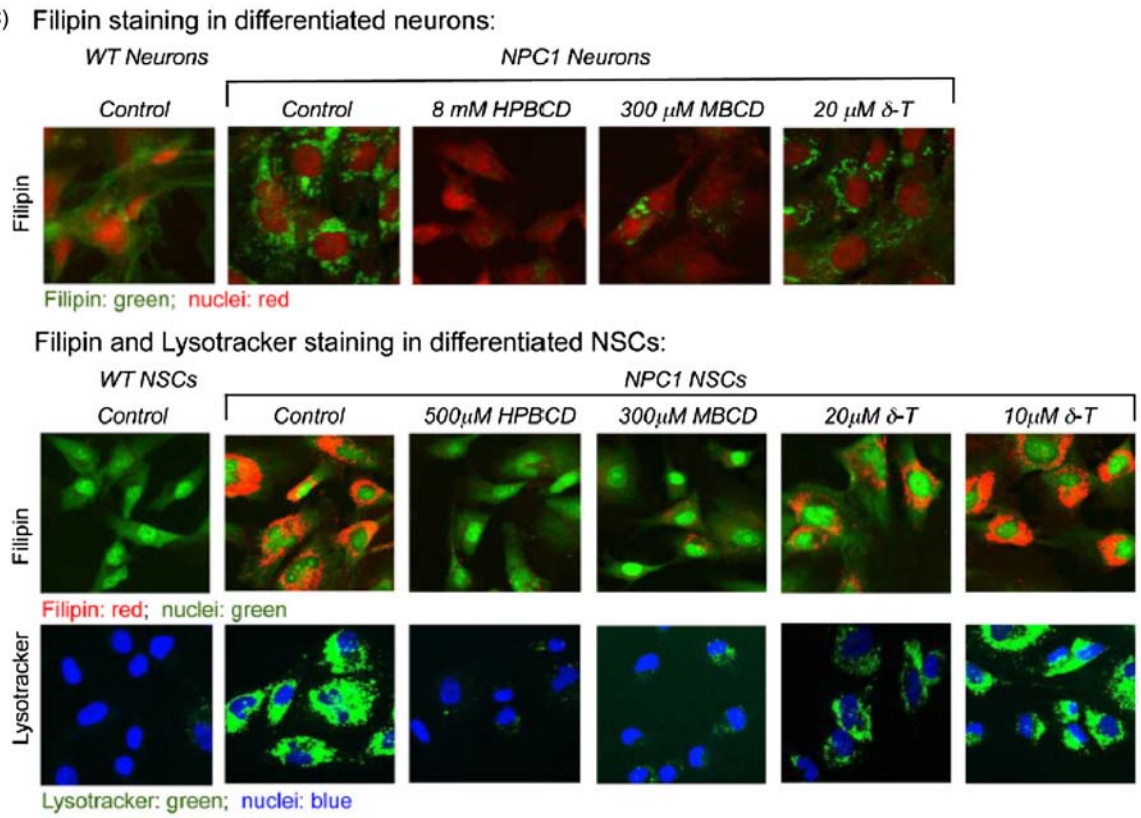

Fig. 6 (*continued*).

approved drug collection was screened at four concentrations. Hits were defined as compounds with at least two out of four concentrations having impacts on at least one protein readout. Twenty-seven compounds were confirmed as leads in HGPS patient primary cells, 11 of them corticoids, three phosphodiesterase inhibitors (PDEi), three adrenergic agonists, two retinoids, and eight others. Retinoids and corticoids were selected as candidates based on their capability to reduce DNA damage signs and GFP-progerin levels, and to restore nuclear and chromatin structures. Other analogs of retinoids demonstrated similar efficacy, in line with literature reports that retinoid bound nuclear receptor Retinoic acid receptors (RARs) can repress lamin A, progerin, and lamin C expression at the mRNA levels. PDEi and adrenergic agonists predominantly affected lamin B1 and/or gH2AX without affecting progerin levels.[98]

2.15.6.8 Leishmanial Proliferation in Macrophage

Leishmaniases are neglected parasitic diseases causing severe morbidity and mortality. They are caused by protozoan parasites that belong to the genus Leishmania. No vaccine exists against any form of leishmaniasis and most of the existing antileishmanial drugs have serious side effects.

Metacyclic promastigotes, the extracellular form in the life cycle of leishmania, are inoculated by the bite of an infected sandfly resulting in recruitment of neutrophils and uptake of parasites by neutrophils, dermal dendritic cells, and resident tissue macrophages. Promastigotes differentiate to amastigotes within macrophages and live within acidic phagolysosomes where they replicate, form parasitophorous vacuoles (PVs), and cause lesions either in the tissue site or in the systemic organs (Fig. 8A and B(a)). Since the innate immune cells are weakened by the parasites, the resolution of infection with all leishmania species will depend on effective responses from T cells and other adaptive immune cells, but the mechanisms are not well characterized.[99,100]

The assay illustrated here highly mimics the pathological conditions of leishmanial amazonensis infectious conditions. The highly virulent lesions-derived amastigotes of leishmanial amazonensis were genetically modified to stably express a DsRed2 fluorescent protein reporter, and propagated in Swiss nu/nu mice by subcutaneous injection. After 6–8 weeks, amastigote inoculation lesions were excised and amastigotes were purified from the lesions. Homogeneous populations of 6 day-old mouse macrophages differentiated from bone marrow progenitors were placed in 384-well plates and allowed to form monolayers. DsRed2-amastigotes freshly purified were then added to the macrophage monolayer at three amastigote per macrophage ratio. The amastigote-macrophage coculture was allowed to incubate for 48 h prior to the addition of 10 μM test compounds. Images of live infected

macrophage cultures preincubated 60 min with Hoechst nuclear dye and LysoTracker dye for PV were acquired on an HCS reader after 3 days of incubation with compounds. All incubation temperatures were at 34°C.

By allowing real-time monitoring of the live-interaction between virulent amastigote and primary macrophages, this approach offered many advantages over conventional assay methods. It allowed the identification of both fast-acting and slow-acting compounds, functioning via killing the amastigote inside the PV directly or by activation of microbicidal mechanisms of the host macrophage (Fig. 8B(b–c)). The assay also permitted monitoring the health status of host macrophages by visualizing their nuclear morphology with the permeant DNA probe Hoechst 33342. In the presence of a toxic compound like cycloheximide, dead macrophages were easily differentiated from healthy cells and identified by the loss of nuclear integrity (Fig. 8B(d)).

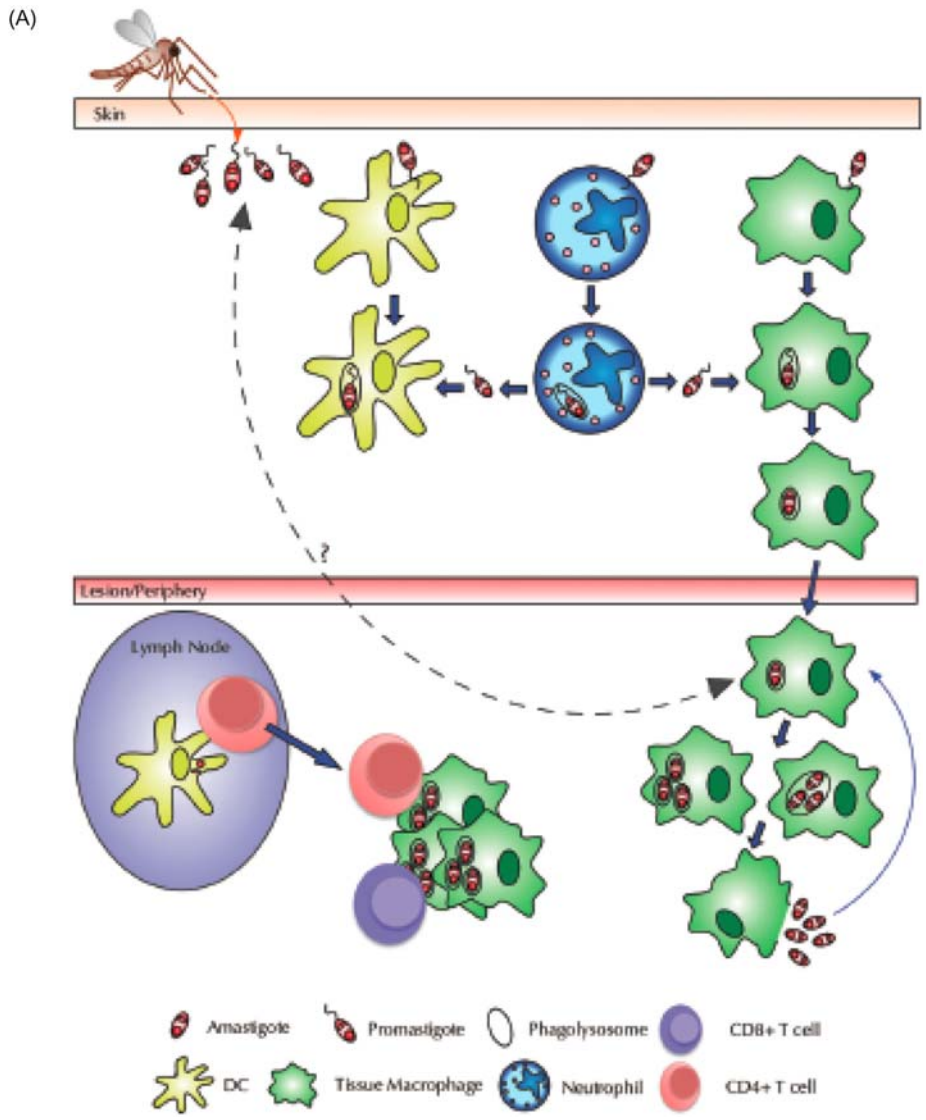

Fig. 8 Leishmanial proliferation in macrophage. (A) The life cycle of Leishmania parasites. Promastigotes are inoculated by the bite of an infected sandfly resulting in recruitment of neutrophils and uptake of parasites by neutrophils, dermal dendritic cells, and resident tissue macrophages. Promastigotes differentiate to amastigotes within macrophages and live within acidic phagolysosomes where they can replicate and cause lesions either in the tissue site or in the systemic organs. B. Leishmania amazonensis strain lodges and multiplies within acidic phagolysosomes of macrophages to form parasitophorous vacuole (PV). Six day-old macrophages were seeded into 384-well microplates and incubated with Leishmania amazonensis DsRed2 expressing amastigotes (red) for 48 h. (a) Phase contrast image demonstrates the lodging of the amastigotes within PV. (b to d) Images of living infected macrophage cultures pre-incubated 60 min with Hoechst nuclear dye (blue) and LysoTracker dye for PV (green) were acquired on a HCS Opera reader after 3 days of incubation with compounds. Fig. 8 (*continued*).

As a pathologically relevant model system, the amastigote-macrophage coculture also provides a powerful tool to further elucidate the cellular processes associated with intracellular infection and the host immune response to pathogen mechanisms, thus identifying new targets for more effective leishmanial therapies.[101]

2.15.6.9 Tubulin Polymerization and Redistribution

Microtubules are a component of the cytoskeleton. α,β-Tubulin heterodimers organize into structures called protofilaments. Ten to fifteen protofilaments associate to form the hollow cylindrical polymers of microtubules. The dynamics of microtubule assembly and disassembly play crucial roles in the development and maintenance of cell shape, in transportation of vesicles, mitochondria and other components throughout cells, in cell signaling, and in cell division and mitosis (**Fig. 9A**).[102]

A number of well characterized anticancer drugs have demonstrated cytotoxic effects by altering microtubule dynamics in cancer cells, consequently disrupting the formation of mitotic spindles and the progression of mitotic process. For example, paclitaxel binds to a pocket within β-tubulin that putatively counteracts the effect of Guanosine triphosphate (GTP) hydrolysis, resulting in stabilization of microtubule structure. Also vinblastine interferes with microtubule dynamics by causing tubulin depolymerization. The stabilization of microtubules or disruption of tubulin polymerization by these compounds leads to cell cycle arrest and cancer cell death. As a result, monitoring effects on microtubule polymerization is indispensable to understanding the mechanisms of action for cancer chemotherapy medications.[103,104] On the other hand, many other therapeutic approaches aim to avoid interference of tubulin dynamics, given that this may cause cytotoxicity. Therefore, an assay that can accurately monitor microtubule dynamics is broadly applicable to drug discovery programs seeking to optimize and progress lead compounds.

A HCS-based assay was established to systematically monitor tubulin polymerization in A549 cells in order to understand the mechanisms of action for anticancer drugs and to evaluate potential cytotoxicity on lead compounds or drug candidates for other disease indications. In examples illustrated in **Fig. 9B**, A549 cells were treated with DMSO control, 2 μM vinblastine or paclitaxel for 3, 6, or 18 h. Microtubule structure (green) was visualized by fluorescent labeling using anti-α-tubulin rat primary antibody followed by Alexa-488-labeled antirat antibody. Nuclei were counterstained using Hoechst 33342 (blue). Normal microtubule network structure was visible in the DMSO treated control cells. Stabilization of the microtubules by paclitaxel was evidenced by a thickening of the microtubule fiber that was most prominent at 18 h. Vinblastine caused disruption of the microtubule network, leading to a diffused staining of α-tubulin that was also visible after 3 h and lasted up to 18 h.

This HCS-based assay platform enables the monitoring of tubulin polymerization status by directly measuring the acute effects of drug candidates on the cellular tubulin network with the capability to dissect the mechanisms of action. It distinguishes in a quantitative manner between compounds that act as tubulin stabilizers vs. those that are tubulin destabilizers. In addition, using a multiplexed approach, this analysis also allows one to simultaneously monitor physiological cellular responses and associated cellular phenotypes. Understanding the mechanisms of action might lead to improved dosing regimens and allow for the design of combination therapies with other "molecularly targeted" drugs.[105]

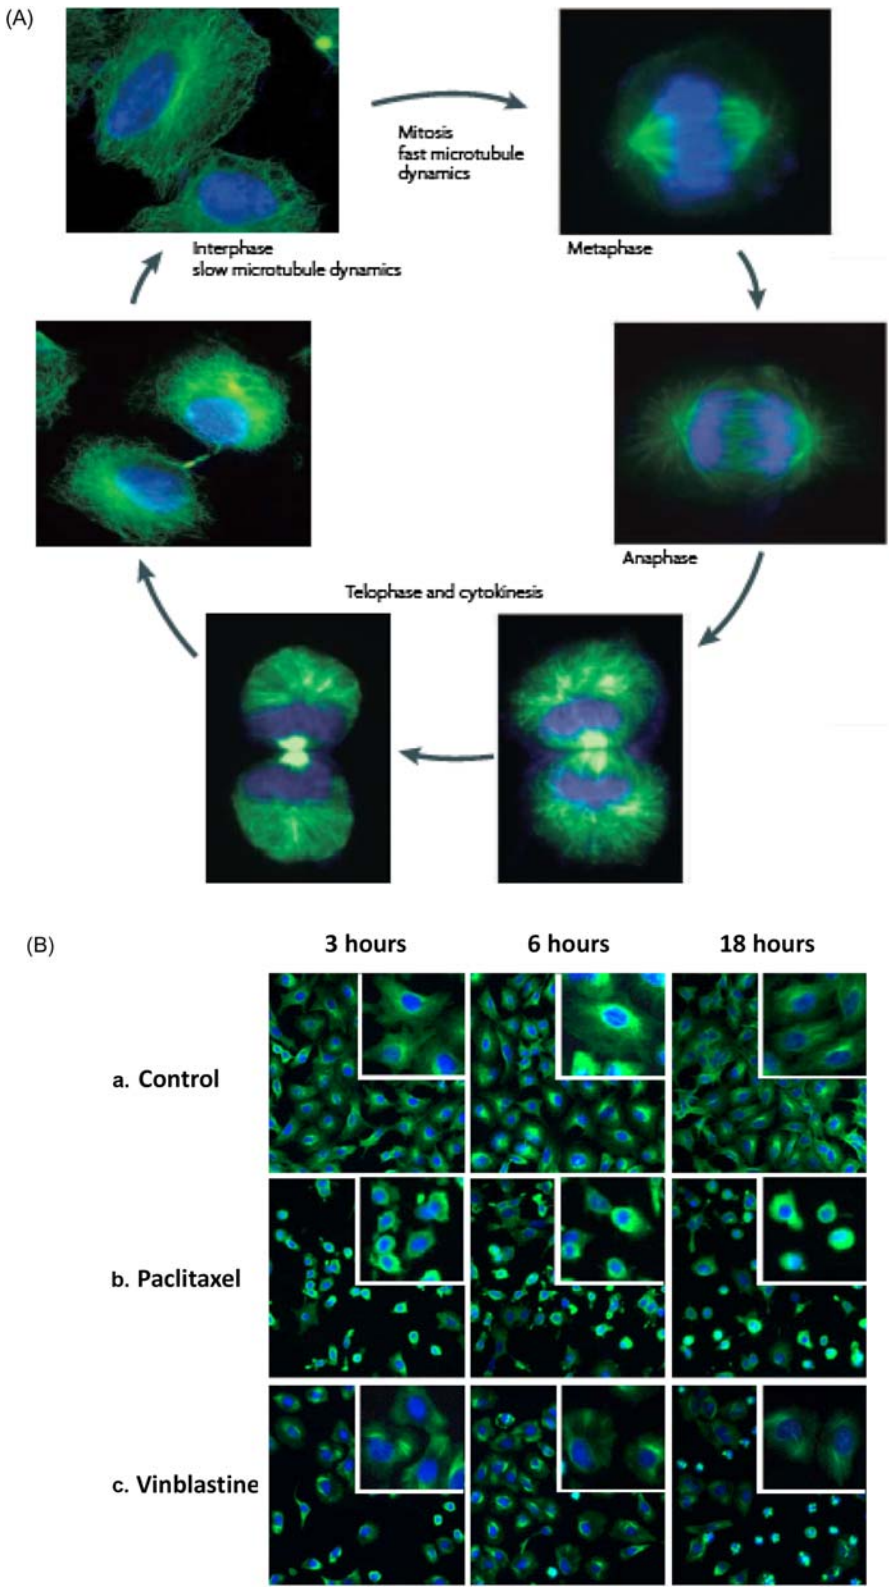

Fig. 9 Tubulin polymerization and redistribution. (A) Microtubule changes during the cell cycle. Microtubules are tubular polymers of tubulin proteins. Microtubule structures (shown in *green*) undergo marked morphological changes to mediate specific functions throughout the cell cycle. Microtubule dynamics vary during the cell cycle, being least dynamic in interphase cells and most dynamic during mitosis, making this an important target for anticancer drug design. DNA is shown in *blue*. (B) High-content images of fluorescently-labeled α-tubulin in A549 cells treated with tubulin-active compounds. A549 cells were treated with DMSO control, 2 μM vinblastine or paclitaxel for 3, 6, or 18 h. Microtubules were visualized by Alexa-488 labeled anti-α-tubulin antibody (*green*), nuclei were counterstained by Hoechst dye (*blue*). Enlarged images are shown in the inserts to further visualize the changes in microtubule network upon the different treatments. (A) Modified from Kavallaris, M. Microtubules and Resistance to Tubulin-Binding Agents. *Nat. Rev. Cancer* **2010**, *10*, 194–204, figure 1. (B) Modified from Sum, C. Med.* **2014**, *8*, 16–26, figure 1.

2.15.7 Conclusions

To increase the success rate of drug discovery, more predictive in vitro bioassays and in vivo disease and/or safety models are in demand. Due to its flexibility and information-rich nature, the bioimaging-based HCS assay technology, in combination with pathophysiologically-relevant complex cellular models, has demonstrated significant predictivity enhancement over conventional in vitro assay technologies, and has generated tremendous impact on drug discovery, ranging from target identification and validation, lead discovery and optimization, to translational medicine. In summary, there are three critical factors that determine the success of a HCS campaign. First, it is important to maintain balance between physiological relevancy and scalability of the complex cellular models, and balance between information content and screening throughput. In the early phase of drug discovery, utilizing immortalized human cell lines or iPSC-derived tissue relevant cells, and general and inclusive image acquisition protocols and analysis algorithms are reasonable approaches. In the late phase of drug discovery, more primary cells from normal or diseased tissues, or patient iPSC-derived cells are likely required, and more sophisticated image acquisition protocols and analysis algorithms allowing differentiation between different mechanisms of action would be necessary. Second, it is critical to establish an overarching bioimaging repository platform with appropriate architectures. This repository should facilitate interactive exploration and analysis of images and multidimensional data from different HCS reader platforms, automated feature clustering and phenotype scoring using more sophisticated statistical analysis tools, and pathway mapping and mechanisms of action studies using advance bioinformatics software. Third, the establishment of an interdisciplinary HCS core team is essential which could include highly skilled associates in cell biology, HCS assay technology, image analysis algorithm development, IT for HCS data management workflow, advanced statistical analysis, and informatics analysis. HCS technology has a steep learning curve. Integrating knowledge from the skilled associates from different disciplines would not only accelerate the assay development and screening process, but would also ensure that "fit-for-purpose" complex cellular models and image analysis algorithms are used to investigate the diseases of interest.

2.16.1 Introduction

More than 90% of drugs that pass through preclinical studies fail to meet the desired efficacy or safety margins required in subsequent clinical trials. As a result, successful drug development requires decades of research that costs hundreds of millions to billions of dollars.[1–3] While there are many factors that contribute to the high attrition rate of drug candidates, it is reasonable to argue that our drug discovery models are a significant contributing factor due to their inability to identify drug leads that are safe and effective

in humans. In the modern era of drug discovery, two-dimensional (2D) cell-based assay models have been the dominant approach used to study cellular processes in human disease and for high-throughput drug discovery.[2] 2D-cell models are relatively cost-effective and highly amenable to high-throughput and high-content screening (HTS/HCS) drug discovery, but their cellular responses and phenotypes do not effectively recapitulate the pathology of human disease.[4] Once lead drug candidates are identified, they are assessed for toxicity and efficacy using animal models that provide a controllable experimental environment with complexities similar to those observed within human cells and organs. However, the use of animals in drug research is far from ideal as these models are expensive, time-consuming, low-throughput, vary widely in results among species, and limited by controversial ethical issues.[2] Although animal models remain an important component in the drug development pipeline, there is an unmet need for more predictive efficacy and toxicology models that are amenable to HTS/HCS drug discovery. Over the past decade there has been a boom in concerted multidisciplinary efforts by scientists and biomedical engineers with a vision of developing three-dimensional (3D) ex vivo tissue models of human organ function and other models of human anatomy and disease.[5,6] These 3D models are referred to as organoid, organotypic, or spheroid and are often used interchangeably within the collective literature.[5,7] In this book chapter we will utilize the term organoid for a simple yet elegant description of 3D tissue culture.

Organoids have the distinct feature of self-assembly when relevant microenvironment components are present such as extracellular matrix (ECM) proteins or fibroblast cells (mesenchyme components). Importantly, organoids can be generated from human primary tissues, induced pluripotent stem cells (iPSC), and from existing human cell lines (e.g., the multicellular tumor spheroid model, MCTS).[2,5–9] Various types of organoid models have been reported, including mammary gland, salivary gland, kidney, lung, small intestine, colon, liver, stomach, pancreas, prostate, optic cup, brain, blood vessels, and human tumors.[2,5–9] Importantly, organoids are superior to 2D cell culture models of human disease and function, and in some cases rival animal models, for example cerebral organoids.[10] Organoid models are built using formats that are highly amenable to HTS/HCS such as the liquid overlay, ECM embedded, mechanically supported culture systems, microfluidics, and microchip technologies. The adaptability to HTS/HCS drug and other therapeutic discovery methodologies will be critical to improving our developmental therapeutics pipeline and success rate. Organoids are poised to fill the unmet need to identify more effective therapies with improved clinical translation success rates; therefore, they can be considered as the future of biomedical research. The marriage of high-throughput technologies such as HCS applied to organoid research and therapeutic screening will be important to achieve the promise of precision medicine (Fig. 1).[11] Hence, this book chapter will focus on 3D organoids and technologies applied to high-content screening drug discovery.

2.16.2 High-Content Screening and Analysis

High-throughput screening (HTS) is a technology platform that enables researchers with the capacity for large-scale screening of compound libraries in a rapid and cost-effective manner. In the late 1990s, a more sophisticated HTS drug discovery platform,

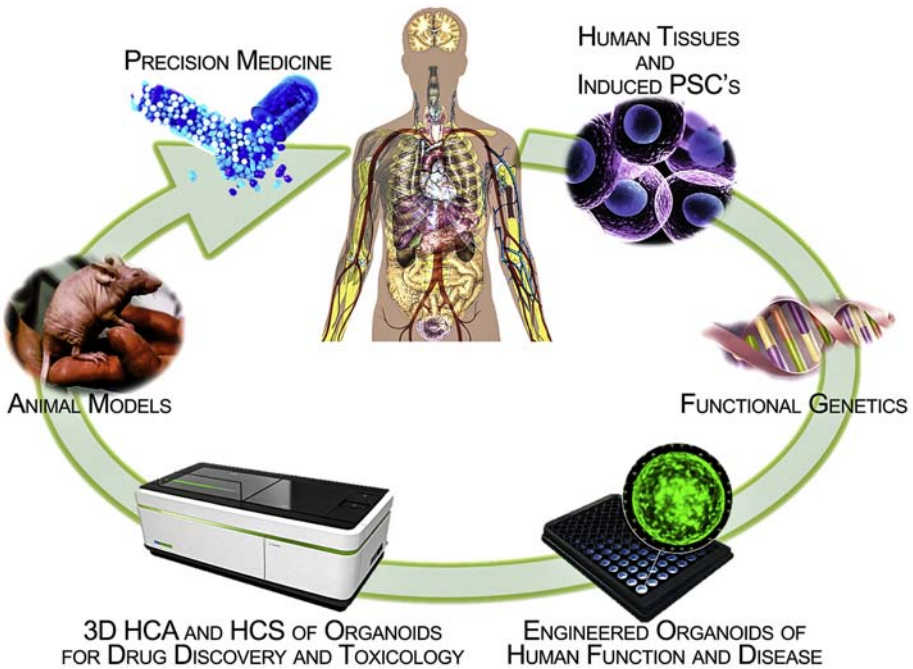

Fig. 1 The marriage of HCS with organoid models will be a key technology component to achieve more effective therapies and the promise of precision and personalized medicine for human disease.

known as high-content screening (HCS), emerged that combines HTS robotic handling technologies together with high-resolution microscopy and multiparametric acquisition and data analysis, also known as high-content analysis (HCA).[12,13] HCS and HCA technology has been quickly adopted by the pharmaceutical industry and government research institutions to characterize preclinical drug candidates and is now integrated into all aspects of contemporary drug discovery. Moreover, the growing availability of HCS instrumentation coupled with funding support from government agencies has spurred an emergence of academic HTS/HCS screening centers and core facilities, promoting worldwide applications of HCS in academia.

HCS image processing can be combined with machine learning to extract objects of interest from biological images and to subsequently analyze data derived from these collections of objects on a population level, constructing biologically meaningful conclusions. The ability to conduct multiple independent measurements simultaneously is one of the most powerful features of HCS. In contrast to traditional HTS, which has a single read out of activity, HCS is able to deliver many properties or features of individual cells or organisms in parallel. In addition to the target-specific fluorescence readouts, multiple parameters such as cytoplasm shape, size, area as well as information about nuclear intensity allow scientists to simultaneously monitor the temporal and spatial relationships between multiple cellular targets in an intact biological system. In addition to the increased content, sophisticated HCA in HCS provides information such as intracellular protein relocation or organelle quantification that is difficult to obtain by conventional methods. Owing to the multiplexing and multiparametric characteristics of HCA, HCS assays are considered to produce higher hit rates compared to conventional bioassays.[14] A typical flow chart for high-content screening experiment consists of four major stages: assay development, image acquisition, image analysis, and data analysis.

2.16.2.1 HCS Assay Development

Developing a high-content assay involves setting up a measurable and reliable reporter of a biological activity and converting it to a quantitative readout. A typical HCS assay consists of a biological sample (individual cells in culture, 3D organoids and tissue samples, or whole organisms) processed to extract a visible readout after appropriate reporter transduction or sample staining that is acquired through automated microscopy and quantified by image analysis. Factors such as the cell seeding density, plate type, plate layout, fluorescent probes, substrate concentrations, and assay kinetics require careful optimization for HCS.

2.16.2.1.1 Assay plates

The choice of assay plate is critical to a successful screening campaign, with advances in miniaturization and detection technologies; current HTS/HCS experiments are usually performed in a highly automated, standardized, and controlled fashion using 96- to 384- or 1536-well microtiter plates provided by suppliers such as Corning, ThermoFisher, and Greiner Bio-One. HCS plates must have excellent optical quality and provide a suitable environment for cellular growth to attain the maximal scan performance capability from high-content imaging systems. Clear flat bottom black plates are recommended for fluorescence-based reading technologies to achieve high quality images with lower background signal and minimal cross talk. The bottom material of an opaque plate is generally made of polystyrene or glass. Tissue culture-treated polystyrene plates with the ability to bind proteins and to support cell attachment are the most commonly used plate type in HTS and are suitable for many HCS applications. Glass is one of the flattest materials and exhibits excellent optical properties, but is less suitable for cell culture. Both glass and plastic bottoms can be coated with various biomolecules to improve the adherences of cells and/or mimic appropriate biological conditions of the assay. Synthetic polypeptide like Poly-D-Lysine (PDL) and a variety of ECM proteins including collagen, laminin, and fibronectin are available for this purpose. The thickness of the plate bottom is another important parameter of the imaging plates as it has implications for the choice of microscope objectives; thin-bottomed ($<200\ \mu m$) plates are recommended for high numerical aperture (NA) objectives as they typically have a short working distance. Thick bottom ($>250\ \mu m$) plates require the use of long working distance (WD) objectives, which typically have a lower numerical aperture.

2.16.2.1.2 Automation

Automation is essential for HTS/HCS; the core of the automated system resides in one or more automatic multichannel liquid handling instruments, which are crucial to the production of high quality data. High-content assays require a great deal of liquid handling since they typically have a relatively large number of steps, including aspirating, transferring, dispensing, and mixing liquids. Commercially available robotic liquid handlers and reagent dispensers can transfer or dispense volumes from the picoliter to milliliter range and greater. These fully automated liquid handling workstations can manage compound addition and dilutions, reformatting of reagent stocks, and complicated immunofluorescence staining protocols. Recent advances in acoustic dispensing have unlocked the potential of high-throughput dose matrix analysis, allowing the creation of efficient and flexible compound synergy assays.[15] Microplate washers tremendously improve the speed and accuracy of many different washing procedures and are particularly useful for high-content assay automation. In addition, most HCS assays use microtiter plates that have been standardized by the American National Standards Institute (ANSI) and Society for Laboratory Automation and Screening (SLAS),[16] which facilitates the use of microplates across plate-handling robots and liquid handling instruments. Robotic plate handling is the key to connecting individual workstations and creating an integrated screening laboratory. Robots and plate stacking arrays are highly amenable to high-content imaging systems, allowing automated integration and increased throughput.

2.16.2.1.3 Fluorescent probes

Labeling technologies have drastically expanded recently; an increasing variety of commercially available fluorescent antibodies and dyes has provided unprecedented insight into intricate cellular events. The most commonly used fluorescent labels are fluorescent proteins, fluorescent dyes, and antibodies.[17] For HCS assays, probes should accurately reflect the underlying biology and minimize the artifacts while avoiding cross talk. Multiplexed fluorescence labeling is one of the most important features in HCS, which involves the use of different sets of fluorescent probes, whose spectral properties are sufficiently distinct, to allow the discrimination of fluorescent signals related to different biosensors. There can be significant bleed through from one fluorescent probe to another due to their broad excitation and emission spectra. The excitation wavelengths chosen should take into account the peak properties of the fluorescent targets to minimize cross excitation. The filters in the emission path must be optimized to minimize cross talk between the different fluorescence emitters and that is directly dependent on the dichroic filter in the optical path. Cell staining simulation tool from Invitrogen,[18] and fluorescence spectrum viewer from Thermo Fisher Scientific,[19] Semlock,[20] and BD Biosciences[21] are useful online applications for choosing fluorescent dyes and assessing their compatibility.

2.16.2.2 Image Acquisition

With a robust assay in hand, the next step is for sophisticated image acquisition hardware. Imagers for HCS are microscopes that automatically capture and store fluorescent images from wells of microtiter plates. Much more than a standard microscope, a high-content imager could also incorporate an automated platform for plate handling and image processing software to quantify the data collected under specified parameters. Since the introduction of automated cell imager in 1997,[12] numerous technological advances and hardware improvements such as auto-focusing and sample positioning have spurred development of automated brightfield and confocal images and laser scanning cytometers. Lamp, light-emitting diodes (LEDs), and lasers are the three typical excitation light sources of HCS imagers. Xenon arc, metal-halide, and mercury lamps provide a broad spectrum to excite many fluorescent dyes and proteins. Lasers and LEDs are currently the optimal choices due to their stable, narrow light output and long lifespan.

Image acquisition is a crucial step for high-content screening as the image quality determines the overall screen quality. Proper selection of the exposure parameters (e.g., exposure time, imaging height), excitation filters, emission filters, and objectives of the microscope is essential to capture the subcellular details for the phenotype while providing sufficient cell counts for robust statistics. As out of focus or over exposure leads to loss of information in the fine structure of images and degradation in the performance of segmentation algorithms in the image processing step, care must be taken to minimize imaging artifacts during an HCS experiment.

2.16.2.3 Image Analysis

The automated image analysis process, or HCA, aims to extract numerical information from large sets of bioimages. Image analysis can be divided into four major steps, including image correction, image segmentation, object tracking, and feature extraction.

2.16.2.3.1 Image correction

Image correction serves to enhance image quality and create a more pronounced distinction between background signal and objects. Imperfections of the optical system (e.g., variation in the output from the light source, slight component misalignment, or even dust on lenses) and unequal excitation of the fluorophore could create nonuniform illumination of the sample and thus differences in signal. Compensation of uneven illumination of the sample during image acquisition is a common step to improve image quality. In addition, microscope systems often produce peripheral illumination as the light is channeled through the various lenses and apertures. Flat-field correction is a standard calibration procedure used to correct peripheral illumination artifacts and normalize signal intensity level, which consists of correcting raw images with a reference image containing no sample. Gray-level transformation and image filtering are other typical image processing techniques for converting an input image into a new image with better visibility.[22]

2.16.2.3.2 Image segmentation

Segmentation is the process of partitioning an image into multiple regions by assigning the same label to the pixels with common features; segmented objects or shapes are often called regions of interest (ROI). The function of image segmentation in an image analysis system for cellular and tissue engineering is to identify biologically meaningful objects such as a nucleus or another functional tissue region for further quantitative characterization.[23] Objects in biological images are often far more difficult to be recognized than typical daily-life images due to their ambiguous boundaries. This is the most challenging step of image analysis and often requires careful optimization of key parameters in order to identify the boundary of each cell and the subcellular compartments correctly so that subsequently extracted cellular features can correctly represent the cellular phenomenon of interest.

Segmentation algorithms consist of multiple image processing steps that either remove pixels or separate large objects from the underlying, closely spaced objects that represent the biological specimen. Image processing filters can be used to enhance general contrast of the images or shapes that have to be segmented. There are various predefined algorithms for segmentation, which are commonly used to identify targeted objects in HCS analysis. Due to its simplicity, thresholding is one of the most commonly used segmentation methods that compares the values of each image pixel to preset threshold values and to label pixels.[22] Values above the threshold are identified as objects and those values below the threshold are considered background. Edge detector or sharpen filters could be useful to detect objects and increase intensity separation with adjacent elements, making thresholding easier. More sophisticated methods including watershed transform, Markov random field (MRF), and model-evolution approaches help split overlapping objects and have been successfully applied to cell segmentation in microscopy.[22]

2.16.2.3.3 Object tracking

Object tracking is used to identify the motion traces of the objects of interest using time-lapse images. For cell-based assays, this refers to the process of identifying and linking segmented cells from frame to frame in the image sequence to obtain cell trajectories. Automated tracking of cells in time-lapse microscopy images enables high-throughput measurements of a range of dynamic cell behaviors, including cell cycle progression, migration and invasion, and apoptosis as well as the reconstruction of cell lineages (parent-daughter relationship). Traditional tracking approaches establish spatiotemporal correspondence between two neighboring time points based on their morphology, position, and motion.[24] More sophisticated algorithms solve this correspondence over multiple image frames simultaneously, achieving significantly better accuracy.[25,26]

2.16.2.3.4 Feature extraction

Once the segmentation process has been successful, the identified objects are used to extract quantifiable features from images. Unlike human eyes that are only sensitive to relative intensity values, computers can easily determine absolute intensity of regions within an image. This ability is used to categorize segmented objects into different features such as morphology, texture, and spatial distribution. These features are extracted from single or multiple fluorescence channels from the same field of view and are used to characterize the phenotypes encountered in each image.[27]

Intensity is the most basic measurement that comes from the image sensor and is related to the number of photons captured on the sensor during the exposure time. The total intensity, or integrated intensity, represents an aggregation of all the pixel intensities combined to make up the unit area. The intensity of a pixel is related to the amount of marker at that location; thus, the measured total intensity is proportional to the amount of substance labeled. The mean intensity feature is the average accumulation of pixel intensities per unit area.

Morphology features characterize the size and shape of an object of interest in the image.[28] For globular objects, the size measurements include area, radius, and perimeter while the shape is described by features such as length of the major and minor axes, orientation, compactness, symmetry, and roundness. Features like curvature, number of branch points, cross-link spaces, and cross-link densities are frequently used to describe tubular objects. Furthermore, the ratio of the same morphological feature from different biological structures can be used as a phenotype to reflect the relative morphological change between different objects. For instance, the ratio of the length and width of an object can serve as a measure of elongation, which may be of biological interest.

Texture is a property that represents the surface and structure of an image.[28] Texture descriptors characterize spatial smoothness and regularity for each marker, and are often used for characterizing the fine patterns of protein localization. Typical descriptions associated with image texture properties are smooth, rough, granular, spotty, fibrous, line patterns, etc. Texture analysis is a special technique that can be used to quantify biological effects, which makes use of the patterns or structures of the fluorescent region rather than using the average intensity or shape of the region.

2.16.2.3.5 Machine learning

Machine learning is a rich and rapidly advancing field of computer science and is widely used in HCS to classify biologically meaningful pattern features that are traced by fluorescent markers.[29] Machine learning is particularly superior to conventional image processing programs when it comes to solving complex multidimensional data analysis tasks that are not easily described by a few parameters. In general, machine-learning approaches can be broadly classified into two categories: supervised and unsupervised learning. Supervised machine learning methods aim to make accurate predictions of large sets of data samples based on a few training examples. These methods can be applied to cell phenotypic recognition and clustering on the basis of hundreds of quantitative nuclear features. In this approach, the user generates a training data set by annotating some representative examples according to predefined classes. The machine learning algorithm (e.g., support vector machines, adaptive boosting, and random forest) automatically infers the rules to discriminate the classes, which can then be applied to independent large data sets. Supervised machine learning has been an important backbone for analysis pipelines in many HCS projects.[30] Unsupervised learning, by contrast, extracts information from the data completely independent of prior user definition and enables the exploration of novel phenotypes. The goal of unsupervised machine learning is to group data points into clusters on the basis of a similarity measure or to facilitate data mining by reducing the complexity of the data. Unsupervised learning algorithm (e.g., k-means clustering, Gaussian mixture model, and hierarchical clustering) makes no initial assumptions about how the data are related and instead seeks to discover and characterize the hidden distribution of data. These methods are extremely useful to distinguish between image perturbations resulting from small molecules or RNA interferences in cases where the phenotype is unknown.

There has been tremendous growth in the computational methods for automated learning and discovery over the past three decades. Machine-learning tools such as CellProfiler Analyst,[31] CellOrganizer[32] and PerkinElmer's PhenoLOGIC plug-in can be trained to identify and count cells belonging to different subpopulations and have been optimized for the needs of large-scale microscopic image data. For example, the PhenoLOGIC plug-in provides advanced supervised machine learning technology for scientists to develop the image analysis algorithms for highly robust and statistically relevant classification of cells using a simple learn-by-example approach. After categorizing examples of objects or regions with a few clicks of the mouse, the software combines the most meaningful parameters to identify all similar objects or regions in all other images of the same experiment. Machine learning holds the potential to replace most manually programmed analysis pipelines eventually to facilitate assay development and increase processing throughput.[33]

2.16.2.4 Data Analysis

A central goal of image analysis is the conversion of microscopic images into biologically meaningful quantitative data. Recent development of quantitative HTS (qHTS) that performs multiple concentration experiments in a low-volume cellular system[34] and the increasing size of chemical and biological libraries used in HCS campaigns generate overwhelming amounts of complex multidimensional data sets in a short period of time. Mining these large HCS datasets relies heavily on computational approaches for efficient and unbiased quality assessment and interpretation. HCS, unlike HTS cell-based assays, often has large variability because of heterogeneous cellular populations in a given well. In practice, all HTS assays contain both random and systematic variability that contribute to the "noise" associated with the experimental data. HCS multiparametric assays also introduce several new sources of variability such as image acquisition parameters, size of the imaged area, and the data extraction algorithm.

2.16.2.4.1 Statistical evaluation

There are various biological, instrumental, and environmental factors that contribute to assay performance in HCS; thus, detecting systematic error is essential during assay validation and optimization of assays. Statistical evaluation of the assay performance is a very critical step to determine if the data collected from each plate meet the minimum quality requirements. A number of statistical parameters have been developed to evaluate the quality of HTS assays.[35] Statistical analysis is also pivotal in the hit selection process from primary screens and in the evaluation during confirmatory screens.

2.16.2.4.1.1 Signal to background ratio and signal to noise ratio

Signal-to-background ratio (S/B) is the simplest method for calculating assay performance, taking the ratio of the mean value of the positive control responses to the background or negative control responses (**Table 1**, entry 1), but it does not contain any information regarding data variability. Signal-to-noise ratio (S/N) is used in imaging as a physical measure of the sensitivity of an imaging system. S/N is defined as the ratio of the difference between the positive and negative controls to the variance of the negative controls (**Table 1**, entry 2); however, S/N only captures the variability of the negative controls group. Consequently, both S/B and S/N are considered weak parameters to represent the dynamic signal range for an HTS.

2.16.2.4.1.2 Z′-factor

The Z'-factor indicates how well separated the positive and negative controls are, given the variation present in both control populations. This dimensionless statistical parameter represents the ratio of the difference between the means and the standard deviations (SD) of the positive and negative populations (**Table 1**, entry 3) and proves to be very useful to capture and compare variability caused by assay biology and instrumentation.[36] The Z'-factor quantitatively estimates the robustness of a single data point assay by characterizing the screening window that could be used to identify hits. The highest possible value of Z'-factor and related robust Z-factor is 1; negative values indicate that distinguishing between positive and negative controls is not possible. In general, a Z'-factor of 0.5 or greater is considered an excellent assay for a high-throughput screen. For many large-scale multiple-parameter HCS campaigns it may be difficult to validate an assay using Z'-factor based on only one parameter,[37] but it is possible to improve Z'-factor analysis by combining data from multiple output parameters. The simple, easy-to-calculate Z' statistic is the most widely accepted measure of HTS/HCS assay performance.

2.16.2.4.1.3 V-factor

The V-factor complements the Z'-factor statistic in that it gives a more realistic measure of the overall assay performance by accounting for intermediate points in the dose–response curve that have higher variability due to effects of computation and

Table 1 Formulas of HTS quality control parameters

Entry	*Method*	*Formula*
1	Signal to background ratio	$S/B = \frac{Mean_{pos}}{Mean_{neg}}$
2	Signal-to-noise ratio	$S/N = \frac{\lvert Mean_{pos} - Mean_{neg} \rvert}{SD_{neg}}$
3	Z'-factor	$Z' = 1 - \frac{3\times(SD_{pos}+SD_{neg})}{\lvert Mean_{pos} - Mean_{neg} \rvert}$
4	V-factor	$V = 1 - 6 \times \frac{\sqrt{\frac{1}{n}\sum_1^n (f_{exp} - f_{pos})^2}}{\lvert Mean_{pos} - Mean_{neg} \rvert}$
5	SSMD	$\beta = \frac{Mean_{pos} - Mean_{neg}}{\sqrt{SD_{pos}{}^2 + SD_{neg}{}^2}}$

$Mean_{pos}$ and $Mean_{neg}$: mean of positive control and negative control; SD_{pos} and SD_{neg}: standard deviation of positive control and negative control; f_{exp} and f_{mod}: experimental and model values of the assay measure at a given concentration; n: the number of experimental points in the dose–response curve.

dispensing errors, rather than just the positive and negative controls alone. *V*-factor, proposed by Ilya Ravkin,[38] can be interpreted as the generalization of Z'-factor to the dose–response curve as it reverts to Z'-factor if there are only two dose points (**Table 1**, entry 4). *V*-factor can also be used to compare different image analysis algorithms.

2.16.2.4.1.4 Strictly standardized mean difference

Recently, strictly standardized mean difference (SSMD) has been proposed as a statistical parameter for the contrast analysis of two groups.[39] SSMD, denoted as β, is defined as the ratio between the difference of the means and the standard deviation of the difference between controls (**Table 1**, entry 5). SSMD differs from Z'- and *Z*-factor by its ability to handle controls with different effects, which enables the selection of multiple quality control criteria for assays. SSMD estimates tend to be closer to population values than the equivalent *t*-statistics. Due to its basis in probabilistic and statistical theories, SSMD is a better quality control parameter than the empirically derived Z'-factor. SSMD is developed primarily for accessing data quality in RNAi screenings as it anticipates unequal phenotypic variance in either the positive or negative controls, preventing either one from dominating the calculation.[40,41]

2.16.2.4.2 Data normalization

Normalization of raw screening data corrects systematic errors occurring in a plate-specific manner without disrupting the results in other plates, making measurements comparable across plates. There are two main approaches for normalizing HTS/HTS data: control-based and non-control-based.[35]

2.16.2.4.2.1 Control-based normalization methods

Positive controls and negative controls are commonly used in HTS to represent maximum and minimum assay readout signals. Control-based percent inhibition or activation is the most common and simple data normalization technique; it is defined as the ratio of the sample measurement to the mean value of negative controls within each plate (**Table 2**, entry 1).[42] Similarly, normalized percent inhibition process removes the plate-to-plate variability by subtracting the mean value of negative controls from raw sample data and dividing the absolute difference between the means of the positive and negative controls (**Table 2**, entry 2). The percent of control and normalized percent inhibition found in table 2, are data normalization methods that bring the assay readout values into a standardized numerical range (0–100% scale) for intuitive interpretation. Hit-identification can then be easily accomplished by assigning a percent cut-off value relative to the assay signal window. However, these two procedures do not incorporate any information regarding the distribution or variability of the controls.

2.16.2.4.2.2 Z-score and robust Z-score

The *Z*-score or standard score, which permits the comparison of scores among different plates, is a statistical score calculated from only the sample values (no controls) on plate-by-plate basis.[43] *Z*-score has the advantage of incorporating information regarding the variability of the control distribution and simply measures the effect of one perturbation normalized to the mean and standard deviation of the whole plate (**Table 2**, entry 3). *Z*-score is frequently used in HTS to indicate the extremity of the observation in relation to the control distribution, but while this method is accessible, it has a few limitations. First, both the mean and the standard deviation are sensitive to the number of outlying values of highly active compounds on the plate. Second, *Z*-score statistical method implicitly assumes that the vast majority of compounds on a plate is inactive and is only valid for normal of the phenotypic quantification, both of which are not always satisfied in practice, especially in cellular imaging assays. An alternative to the *Z*-score, robust *Z*-score, accounts for different variability effects across HTS plates to provide unbiased data normalization. It substitutes the

Table 2 Formulas of data normalization methods

Entry	Method	Formula	Notes
1	Percent of control	$\frac{X_i}{\text{Mean}_{\text{pos}}} \times 100$	X_i, raw measurement of the ith sample; Mean_{pos}, mean of positive control; Mean_{neg}, mean of negative control
2	Normalized percent inhibition	$\frac{X_i - \text{Mean}_{\text{neg}}}{\text{Mean}_{\text{pos}} - \text{Mean}_{\text{neg}}} \times 100$	X_i, raw measurement of the ith sample; Mean_{pos}, mean of positive control; Mean_{neg}, mean of negative control
3	*Z*-Score	$\frac{X_i - \text{Mean}_{\text{sample}}}{\text{SD}_{\text{sample}}}$	$\text{Mean}_{\text{sample}}$ and $\text{SD}_{\text{sample}}$ are the mean and standard deviation of all the sample measurements on a plate
4	Robust *Z*-Score	$\frac{X_i - \text{Median}_{\text{sample}}}{\text{MAD}}$ $\text{MAD} = 1.4826 \times \text{median}\left(\lvert X_i - \text{Median}_{\text{sample}}\rvert\right)$	$\text{Median}_{\text{sample}}$ is the median of all the sample measurements on a plate; MAD is the median absolute deviation
5	*B*-Score	$\frac{Y_{ijp}}{\text{MAD}_p}$ where, $Y_{ijp} = X_{ijp} - \text{Mean}_p - \text{Row}_{ip} - \text{Column}_{jp}$ and, $\text{MAD}_p = 1.4826 \times \text{median}\left(\lvert Y_{ijp} - \text{Median}_{\text{sample}}\rvert\right)$	Y_{ijp} (median polish) and X_{ijp} are the random error estimate and the sample value on the ith row and jth column of the pth plate. Mean_p is the plate average, Row_{ip} and Column_{jp} are the estimate systematic artifacts for the ith row and jth column of the pth plate. MAD_p is the median absolute deviation of the random error estimate on the pth plate

control mean and standard deviation with the control median and median absolute deviation (MAD) for outlier resistant dispersion estimates (Table 2, entry 4).[44]

2.16.2.4.2.3 B-score

The *B*-score or better-score is another non-control-based statistical normalization parameter designed to correct systematic biases. Better than *Z*-score, *B*-score uses iterative mathematical modeling to reduce the impact of systematic row, column, and plate artifacts in HTS data. The mathematical model of the *B*-score involves the residual values calculated from two-way median polish algorithm and the sample MAD to account for data variability (Table 2, entry 5).[45] The *B*-score adjusts for intra-plate variability, effectively normalizing observations for data that exhibit row and/or column effects. However, implementation of the *B*-score is not trivial, as the data must be processed using a programming language or sophisticated statistical software such as R or MATLAB. Therefore, while the *B*-score method offers a powerful tool for data processing, it also presents a formidable barrier to accessibility and understanding.

2.16.2.4.3 Hit selection

The major goal for HTS and HCS data analysis is to maximize the identification of biologically relevant hits from a large library (e.g., small molecules), while minimizing false positives that require expensive time-consuming follow-up assays to confirm the hits. In most cases, the most active samples will be selected as hits; however, the challenge lies in selecting the marginally active hits. Thus, it is crucial to select a reasonable cut-off value that will result in a manageable quantity of hits for secondary confirmatory assays while reducing the false positive hit rates. Combining a robust statistical method such as the *B*-score or *Z*-score with the control-based percent activity will facilitate the selection of the most appropriate threshold. A wide range of more sophisticated hit identification techniques is available to improve the quality of the results generated from HCS;[46] most of these hit identification methods can be defined as distance from the mean or the median that takes into account the variance. In addition, hit selection is frequently coupled with orthogonal methods to classify hits. In small molecule screens, the hits will be pooled by structural properties to identify common scaffolds. In RNA interference (RNAi) screens, enrichment analysis is needed to link identified gene sets of interest to significant biological pathways and process networks.

2.16.2.4.3.1 Mean ± standard deviations

Depending on the normalization method and the performance of the controls, a simple method of selecting a set of reasonably robust hits is to calculate the mean and standard deviation of the dataset; sample values that are two or three SD above the mean for activation assays or below the mean for inhibition assays can be identified as hit limits.[43]

2.16.2.4.3.2 Strictly standardized mean difference

SSMD is a robust parameter to capture the magnitude of the RNAi effects with various sample sizes. In addition to its role in defining the robustness of a screen (introduced in Section "**Strictly standardized mean difference**"), SSMD values calculated on individual wells can be used as a hit selection parameter in HTS/HCS data analysis due to its ability to account for the phenotypic variability that can occur for either the hits or controls in RNAi screens. The SSMD parameter used for primary screens without replicates holds a linear relationship with the *Z*-score method.

2.16.2.4.4 Data visualization

Data visualization is essential for understanding and interpreting complex data extracted from cellular images and is very effective for uncovering abnormalities and outliers. There are numerous multivariate graphical methods and tools commonly used for the visualization of the screening data in various formats such as bar charts, whisker plots or box plots, scatter and trellis plots, heat maps, and frequency plots. Box plots display multiple descriptive statistics and can help identify outliers within a distribution. Scatter plots are especially useful for visualizing correlations between replicates to assess reproducibility. Heat maps use a color scale to display the intensity of the readout from multivariate experiments. Hive network plots[47] and glyph-based PhenoPlots[48] are useful tools to represent multidimensional cellular measurements in an intuitive manner. TIBCO Spotfire® is a common visualization software platform that allows for integration of images with various plots, vital to the analysis and exploration of high-content data. High Content Profiler™ from PerkinElmer, an integrated solution within Spotfire environment, simultaneously supports multiple HCS data management systems and provides a one-stop solution for quality control analyses, data normalization, and data exploration with real-time multivariate visualization techniques. Genedata Screener offers a user-friendly solution to take full advantage of the rich volume of multiparametric data from HCS. The software allows review of images directly next to the calculated results, providing instant confirmation of phenotypic changes and biological events. Specific visualizers such as cell density plots, overlay plots, and compare plots also enable for quick overview to identify interesting results.

2.16.2.4.5 Data reduction methods

HCS is a technique that is designed to capture a vast number of features of individual cells in large data-rich files. However, the complexity and volume of the data are often the limiting factor in HCS data analysis. One solution for data reduction is to eliminate redundant feature collection while avoiding the loss of important details during HCA. Dimensionality reduction is a widely used machine learning method; it aims to transform very high dimensional data into a more compact, low-dimensional representation, while limiting the loss of information contained within the data. Dimensionality reduction can be classified into two branches: linear

and nonlinear. Nonlinear techniques include Laplacian Eigenmaps, local tangent space analysis (LTSA), local linear embedding (LLE), and diffusion maps.[49] Linear transformation techniques for dimension reduction include factor analysis,[50] linear discriminant analysis (LDA),[51] and the widely used principal component analysis (PCA).[52] Many dimensionality reduction methods have been successfully applied to HCS data analysis for image feature reduction.[53,54] By focusing on the relevant uncorrelated readouts, dimension reduction and feature selection will help efficiency and accuracy of the data analysis without losing essential biological information.

2.16.3 High-Throughput 3D Culture Technologies

Established 3D cell and tissue culture techniques (Table 3) can be divided into two main categories. The first category is macroscale 3D culture systems that are specifically designed to overcome the limitations of traditional 2D in vitro systems. The second category

Table 3 Summary of 3D culture methods

Methods	*Advantage*	*Disadvantage*	*Adaptable for HCS*
Spinner Flask	Simple Mass production of spheroids Long-term culture Perfusion of nutrients	Require special equipment No spheroid uniformity control Slow spheroid formation High shear force for cells	No
Rotating Wall Vessel Bioreactor	Low shear stress for cells Several options available Mass production of spheroids Long-term culture Perfusion of nutrients	Require expensive equipment No spheroid uniformity control Slow spheroid formation	No
Solid Scaffold	Simple Variety of available materials Customizable	Hard to recover products Possible scaffold-to-scaffold variation Biocompatibility and biodegradability issues of scaffold material	Limited
Naturally Derived Hydrogel	Biocompatible Mimicking native ECM Compatible with other 3D culture methods Can be mass produced	Batch-to-batch variation Constituent may interfere with downstream assay analysis Gelling mechanism Limited options for modification Hard to recover desired product	Limited
Synthetic Hydrogel	Functionalized easily Biocompatible Reproducible No animal trans-contamination Compatible with other 3D culture methods	Lack of cell type-specific niches and organ-specific structures May not be transparent Gelling mechanism Hard to recover product	Limited
Hanging Drop Plate	Uniform spheroid size Rapid and consistent spheroid formation No specialized equipment required Control over coculture patterns	Labor intensive and time consuming Low stability, droplet can detach from plate Long-term culture difficult Difficult to change growth media Not suitable for scale-up Need to transfer spheroids for analysis	Yes
Micropatterned Plate	Uniform spheroid size Customizable patterns for different cell types Consistent spheroid formation No specialized equipment required	Hard to retrieve spheroids Limited spheroid size Biocompatibility and biodegradability issues of scaffold material Cost	Yes
Non-adherent Surface Plate	Simple, easy to scale up Rapid and consistent spheroid formation No specialized equipment required	Nonuniform spheroid size Hard to defined coculture cellular composition	Yes
Magnetic Levitation	Uniform spheroid size Scaffold-free Rapid and consistent spheroid formation	Uncertain effect of magnetic nanoparticles Require magnetic holding drive Physiological changes to the cells caused by external forces are not well characterized	Yes
Microfluidic Device	In vitro organ-specific systems Perfusion of nutrients Uniform spheroid size Consistent spheroid formation Analysis may be integrated into the device	Material compatibility issue with hydrophobic compoundsHard to retrieve spheroids Long-term culture difficult Require expertise to operate	Yes

is 3D cell culture screening systems developed to increase the throughput capacity of traditional 3D cell culture systems. In recent years, advances in the establishment of organoid models have stimulated commercial activity around 3D-based technologies, resulting in a number of highly specialized solid scaffolds, hydrogels, bioreactors, and multiwell microplates, and other technologies have been commercialized (Table 4). These 3D models and products range in complexity and offer researchers an array of 3D cell and tissue culture tools and methods to fit their specific needs.

2.16.3.1 Traditional 3D Culture Techniques

Culture systems were initially developed for macroscale production of 3D models with in vivo like cell–cell and cell–matrix interactions independent of tissue culture plastic attachment. Macroscale 3D culture typically utilizes milliliters to liters of reagents using enclosed bioreactors or hundreds of microliters of reagents using multi-well plate formats. Some of the most commonly used 3D macroscale culture systems include rotating cell bioreactors, solid scaffolds, and natural and synthetic matrices. While most traditional mass production 3D culture methods are not directly applicable to HTS/HCS, there is great potential for these techniques to become applicable by developing automated technologies to harvest and transfer organoid structures to HTS/HCS platforms. In addition, technologies that would allow for cryogenic preservation of 3D structures such as those available for single-cell suspensions would also improve the supply and throughput necessary for HTS/HCS in 3D.

2.16.3.1.1 Spinner flask and rotating wall vessel bioreactors

Spinner flasks were first developed in the 1970s for culturing large amounts of 3D multicellular spheroids.[55] By continuously stirring cells in suspension with an impeller or magnetic stir bar, spinner flasks allow cells to naturally aggregate and then differentiate into robust 3D structures, typically forming multicellular spheroids. The rotation speed is properly controlled such that it is fast enough to prevent cell suspension from settling but slow enough to avoid cell damages due to shear forces from the moving fluid. The movement of fluid provides a controlled environment to transport nutrients and waste from the spheroid surface, mimicking the transport mechanism in tumors in vivo. However, although limited, a drawback of the spinner flask culture method is a relatively high shear stress resulting from the spinning impeller or stirring mechanism that may affect the cellular physiology. The rotating wall vessel (RWV) bioreactor, known commercially as the Rotary Cell Culture System (RCCS), was developed to address this limitation. The RCCS was originally invented at NASA Johnson Space Center in 1990s to simulate the microgravity conditions in space based on the principle of clinorotation[56]; it is a dynamic system that suspends cells in a low-shear stress, microgravity-mimicking environment. Instead of stirring the whole culture suspension with internal mechanical agitator as in the spinner flask bioreactor, the RCCS suspends cells without generating cell damaging mechanical forces. As the RWV rotates, culture fluid can reach a near-laminar flow condition, and cellular aggregates cultured in the fluid are in a state of free fall, but never reach the bottom of the vessel because of the constant rotation of the device. This mild fluid turbulence growth environment allows anchorage-dependent cells to readily aggregate and form into 3D organoids while simultaneously producing high mass transfer of nutrients and oxygen. Additionally, RCCS technology allows several cell types to be cocultured to generate relevant 3D tissues. The spinner flasks and rotating cell bioreactors prevent cells from adhering to the container walls by keeping cell suspensions in constant motion and are suitable for long-term culture and large-scale production. A major limitation of both systems is the variability of the size and shape of the 3D culture.

2.16.3.1.2 Solid scaffolds

Solid scaffolds of diverse size, structure, stiffness, porosity, permeability, and mechanical characteristics have been developed and fabricated for 3D cell culture.[57] These scaffolds are made of a broad range of materials, including metals, ceramics, glass, polymers, and composites. These inert matrices can be engineered into thin membranes that fit into conventional cell culture plasticware, ranging from Petri dishes to 384-well plates (Table 4). In particular, 3D insert scaffolds can be fabricated from both biodegradable (e.g., polycaprolactone, PCL) and nonbiodegradable polymers (e.g., polystyrene, PS). PCL is a biodegradable polymer used in many FDA-approved surgical implants and drug delivery devices for tissue engineering and regenerative medicine applications. Polystyrene is a non-cytotoxic polymer that is frequently used in the fabrication of various cell culture vessels; the transparency of the polystyrene 3D insert scaffold makes it easy for researchers to observe the cell growth directly using an inverted microscope. The scaffolds provide initial support to the seeded cells, localize the cells in the appropriate spaces, and provide physical and biological cues for adhesion, migration, proliferation, differentiation, and eventually formation of tissues and organoids. Currently, scaffolds have been used for model tissue architecture of bone, cartilage, ligament, cardiovascular system, nerve, skin, vascular, neural, and liver.[58]

The 3D precision microfabrication technology provides microfabricated scaffolds with well-defined pore sizes, ranging from 200 to 500 microns. Once scaffolds are inserted, cell treatment and assay component dispensing procedures are performed in a manner akin to that used with 2D cell culture, which means routine 2D cell culture protocols can easily be adapted to 3D cell culture without adding expensive instruments. Nutrients easily flow through the evenly spaced pores and channels, allowing cells to migrate and fill the spaces within the scaffold and form 3D structures. The arrangement of fibers and pores allows cells to remain close to nutrient sources, enabling exchange of nutrients, waste material, and gases mimicking in vivo function. One drawback of using solid scaffolds is the extensive separation steps associated with recovering desired products from the matrix. In addition, matrix stiffness, permeability, and the material used for constructing the scaffold can impact cell adhesion, growth, and behavior. Imaging may also become difficult depending on the scaffold size, transparency of material, and depth capacity of the microscope.

Table 4 Commercially available 3D culture products

Method	*Product*	*Company*
Solid Scaffold	3D Inserts, Hydroxyapatite disc, and β-TCP disc	3D Biotek
	AlgiMatrix 3D Cell Culture System	ThermoFisher
	3D Petri Dish	Microtissues
	Dot-Cult, Confo-Cult, and ECM Graft	ExCel Matrix Biologic Devices
	3D CelluSponge	InvitroCue
	Cellusponge, Cellusponge-Galactose, and Cellusponge-Collagen	Bio-Byblos Biomedical
	Alvetex Synthetic Scaffold and Well Insert	Reinnervate
	RAFT 3D Cell Culture System	Lonza
	SeedEZ and GradientEZ	Lena Biosciences
	Biomerix 3D Scaffold	Biomerix
	OptiMaix-3D	Matricel
	Nanobiomatrix Sheets, Discs, and Plates	Synthecon
	CellCream, CellCrown, and CellVessel	Scaffdex
	3D Aligned Nanofiber Inserts, and 3D Cell/Tissue-Based Models and Kits	Neuromics
	BIOFELT Bioabsorbable Scaffold	ETE Medical
	AK-Polyfibers	Akron Biotech
	Mimetix 3D Cell Culture Scaffolds, and Tissue Culture Plates	Electrospinning.
	Vers3D	Screvo
	MIGHTY Atelocollagen Sponge, and Atelocollagen Honeycomb Sponge	ReproCELL
	NanoAligned, and NanoECM 3D Cell Culture Scaffolds	Nanofiber Solutions
	IVS Inserts, and 3D Tissue Fabrication Kit	InvivoSciences
Bioreactor	ProCulture Spinner Flasks	Corning
	Magna-Flex and Celstir Spinner Flasks	Wheaton
	Bell-Flo Spinner Flasks	Bellco Glass
	Nalgene Polycarbonate Magnetic Culture Vessel	ThermoFisher
	Rotary Cell Culture System, and RCCMax Perfusion Systems	Synthecon
	Universal Turning Device miniPERM Bioreactor	Sarstedt
	U-CUP Perfusion Bioreactor with Ceramic and Collagen Scaffolds	Cellec Biotek
	3D Perfusion Bioreactor	3D Biotek
	Z®RP Bioreactor with Z®RP Sponceram	Glen Mills
	TissueFlex Microreactor	CN Bio Innovations
	DASGIP Benchtop Bioreactors for Cell Culture	Eppendorf
	ambr 250 bioreactor vessels	sartorius
	Alvetex Perfusion Plate	Reinnervate
	Nucleo Bioreactor Platform	ATMI LifeSciences
	VECELL Gas Permeable Plate and Petri Dish	Nacalai
	MicroBrx, Primer, Multi-6, AutovaxID, Maximizer, and Xcellerator Bioreactor	Biovest International
	Quasi-Vivo Products (QV500, QV600 and QV900)	Kirkstall
	BioSep Acoustic Perfusion System	Applikon Biotechnology
	3D Manufacturing Platform (Proprietary Bioreactor System)	Pluristem Therapeutics
	Quantum Cell Expansion System (3D Hollow Fiber Bioreactor)	Terumo BCT
	μ-Slide III 3D Perfusion	Ibidi
	Hollow Fiber Cell Perfused Bioreactor System	FiberCell Systems
	3D Perfusion Co-culture Models	KiYATEC
	BISS Bioreactor Systems	BISS TGT
Non-adherent Surface	Ultra-Low Attachment Surface Spheroid Microplates	Corning
	Cultrex Spheroid Formation and Invasion Plate	Trevigen
	Nunclon Sphera Surface	ThermoFisher
	CELLSTAR Cell Culture Vessel with Cell-Repellent Surface	Greiner Bio-One
	CellCarrier Spheroid Ultra Low Attachment Microplates	PerkimElmer
	Lipidure-COAT Plates	NOF
	Low Attachment Plates, and Happy Cell Advanced Suspension Medium	Happy Cell
	Non-Adherent Culture Dish	ExCel Matrix Biologic Devices
	PrimeSurface Low Cell Adhesion Products	Sumitomo Bakelite
	GravityTRAP Ultra-Low Attachment Plate	InSphero

Table 4 Commercially available 3D culture products—cont'd

Method	*Product*	*Company*
Hydrogel	Matrigel Matrix, PuraMatrix Peptide Hydrogel, and Cell Recovery Solution	Corning
	MaxGel Human ECM, HydroMatrix, and Upstate ECL Cell Attachment Matrix	MilliporeSigma
	PathClear 3D Culture Matrix, Organoid Qualified Basement Membrane Extracts	Trevige
	MAPTrix HyGel	Kollodis Biosciences
	HepatoCue	InvitroCue
	Gletrex, Laminin, Collagen, Fibronectin and Gelatin	ThermoFisher
	QGel Assay Kit	QGel
	Extracel, Mebiol Thermoreversible Hydrogel, and various 3D Matrix Products	CellSystems
	3D HuBiogel Culture System	Vivo Bioscience
	PGmatrix	PepGel
	Alginates, Chitosans and Sodium Hyaluronates	NovaMatrix
	Collagen I-3D Gelling Kit	ScienCell
	GrowDex Wood-based Cellulose Nanofibril Hydrogel	UPM Biochemicals
	Hystem Hydrogel Products, Glycosil and Heprasil Hyaluronan Acid	ESI BIO
	MyEZGel	Applied StemCell
	AlphaMax3D Human ECM, Collagel, and AlphaGEL3D Hydrogels	Neuromics
	ArtiGel Matrix	CELLON
	PureCol EZ Gel, VitroCol, Nutragen, and other ECM	Advance BioMatix
	CosiGel Hydrogel	Interchim
	FlowMatrics Liquid 3D Cell Culture Matrix	FlowMatrics
	PanaceaGel for 3D Cell Culture	Menicon Life Science
	Biogelx Powder	Biogelx
	AlphaBioGel, Collagel Hydrogel, and Bovine Base Hydrogel Coated Plate	Alphabioregen
	BIOMIMESYS, BIOMIMESYS Adipocyte and Hepatocyte	Celenys
	minisys G Hydrogel	irisbiosciences
	3-D Life Hydrogel and Hydrogel Component	Cellendes
Hanging Drop Plate	Perfecta3D Hanging Drop Plates, and Spheroid Transfer Tool	3D Biomatrix
	GravityPLUS 3D Hanging Drop Cell Culture Platform	InSphero
	96-Well Clear Polystyrene Hanging Drop Plates	TTP Labtech
	IMAPlate 5RC96	NCL New Concept Lab
Micropattened Plate	NanoCulture Plate, and NanoCulture Dish	SCIVAX
	Micropattened CYTOOplates and CYTOOchips, and OncoSphere System	CYTOO
	Elplasia Three-Dimensional Culture Plate	Kuraray
	Nanosurface ANFS Cell/Tissue Culture Dish and Plates	NanoSurface Biomedical
	AggreWell 400, 400Ex, and 800 Plate	StemCell
	HepatoPac Micropatterned Tissue Culture Plate	Hepregen
	Cell-able Plate	Toyo Gosei
Magnetic Levitation	Spheroid Bioprinting Kit, and NanoShuttle-PL	n3D Bioscience
	GEM Magnetic Alginate Microcarrier, BioLevitator	Global Cell Solutions
Microfluidic Device	iuvo Microchannel 5250 Microconduit Array Plate	BellBrook Labs
	CellDirector 3D	Gradientech
	OrganoPlates 9601	MIMETAS
	Droplet System with Mitos Duo XS-Pump	Dolomite
	CellASIC ONIX2 Microfluidic Platform, and M04S Microfluidic Plate	SigmaMillipore
Other 3D Cell and Tissue Culture Product	BioWiggler Magnetic Stirrer	Global Cell Solutions
	Seahorse XF^{e}96 Spheroid Microplates and FluxPaks for Metabolic Analysis	Agilent Technologies
	Cytodex Surface Microcarriers	GE Healthcare
	SoloHill Microcarriers	PALL
	HyQsphere Microcarriers	ThermoFisher
	Cell-in-a-Box Cell Encapsulation Kit	MillporeSigma (Austrianova)
	CnT-Prime Epithelial Culture Medium	CELLnTEC
	UpCell using Temperature Cell Harvest Technology	CellSeed
	ECM Coated 3D Cell Culture Systems using Stem Cells	Celprogen
	Oris 3D Embedded Invasion Assay	Platypus Technologies
	3D Collagen Cell Contraction Assay	Cambridge Bioscience
	CellTiter-Glo 3D Cell Viability Assay	Promega
	Various 3D Tissue Model Products	Alphabioregen
	3D Insight Human/Rat Liver, Human/Rat Islet, and HepG2 Tumor Microtissues	InSphero

2.16.3.1.3 Hydrogel

Unlike rigid scaffolds, hydrogels are comprised of networks of cross-linked polymer chains or complex proteinmolecules of natural or synthetic origin.[59] Hydrogels are highly absorbent and can contain as much as 99.9% water, providing them with a high degree of flexibility that displays solid-like material properties. These gels are sufficiently porous, to enable nutrient and waste exchange, and possess sufficient mechanical properties for self-supporting. Due to their significant water content, hydrogels possess biophysical characteristics very similar to natural tissues and serve as highly effective matrices for 3D cell culture. Hydrogels need to be dispensed at specific temperatures and concentration to prevent premature gelation, which may disqualify them from using with many liquid handling systems associated with HTS. The enormous versatility of hydrogel materials makes it possible to design scaffolds with predefined mechanical properties, as well as with desired biofunctionality. Hydrogels can be used as stand-alone 3D matrices or combined with other technologies, such as solid scaffolds, permeable supports, cellular microarrays, and microfluidics devices. Scaffolds derived from biological, synthetic, or natural sources have been widely used for the engineering of functional tissues and organs such as cartilage, skin, bone, bladder, blood vessels, heart, liver, and lung. Hydrogels can be employed in 3D culture systems in a variety of ways. They can be used as a coating reagent to embed cells within scaffold proteins in a liquid state. Alternatively, cells can be seeded either overlaying on top of polymerized ECM gels or sandwiched between layers of ECM hydrogels. Like all 3D culture models, the morphology, growth, and functionality within the hydrogel matrix depend on the physical properties such as permeability and stiffness as well as biophysical and biochemical component extracellular interactions and signals.

ECM from natural sources has served as an important tool for biologists and is most commonly used for applications of 3D cell culture due to its structural and mechanical similarity to native tissues. The inherently biocompatible and bioactive matrices not only provide a scaffold to which the cells can attach and reorganize into 3D structures but also deliver the correct microenvironment of soluble growth factors, hormones, and other molecules and components that cells interact with in an in vivo environment. Naturally derived hydrogels for cell culture are typically composed of common ECM proteins such as collagen, fibrin gel derived from thrombin cleavage of fibrinogen, stromal ECM synthesized by fibroblasts, and reconstituted basement membrane (e.g., Matrigel).[60] Collagen I, a fibrous protein found in connective tissues, is the most abundant protein in humans.[61] It is widely used as a thin layer on tissue-culture surfaces to enhance cell attachment and proliferation. In addition, type I collagen can self-assemble into a 3D supramolecular gel in vitro, making it a logical choice as a cell culture scaffold to promote more in vivo-like cellular morphology and function. Matrigel matrix is another ECM-based natural hydrogel that has been used extensively for 3D cell cultures in vitro and in vivo. Extracted from the Engelbreth-Holm-Swarm (EHS) mouse sarcoma, a tumor rich in ECM proteins, this reconstituted basement membrane contains laminin, collagen IV, entactin/nidogen, proteoglycans, and a number of growth factors. In addition, naturally derived polysaccharide alginate (extracted from brown seaweed algae) and chitosan (extracted from crab/shrimp shells) have been extensively used as hydrogel ECM for cell encapsulation, cell and drug delivery, and tissue engineering. Although natural matrices help recreate the in vivo environment by providing cells with the geometry, biochemistry, and signaling cues found in vivo, inherent batch-to-batch variability in composition and limited modification of biochemical and mechanical properties are considered limitations for obtaining consistent and reproducible outcomes.

Synthetic matrices closely mimic natural extracellular matrices while offering the flexibility for customization with growth factors, attachment factors, and proteins creating an ECM that can be optimized for specific 3D culture models. These materials typically possess a structural backbone, cell-binding ligands, and a cell-friendly crosslinking mechanism. The most common of these include polyethylene glycol (PEG)-based hydrogels and self-assembling peptides. Various bioactive components facilitating the release of biomolecules and morphogens from the extracellular microenvironment can be deposited in the hydrogel. Without the uncontrolled effects of unknown growth factors, such chemically defined synthetic scaffold materials have the advantage of improved reproducibility and reduced risk of animal transcontamination. Furthermore, synthetic matrices offer more defined properties than natural matrices by controlling adhesive moieties, proteolytic sites, and the mechanics of the material more precisely by modifying the polymer architecture. To more closely mimic the natural functions of an ECM, such hydrogels are covalently modified with cell adhesion peptides containing cell recognition motifs of ECM proteins and cell-degradable cross-linker molecules containing matrix metalloproteinase-cleavable peptides.[62]

2.16.3.2 HCS Compatible 3D Cell Culture Platforms

Traditional 3D culture systems require large volumes of reagents and cells, and are not compatible with HTS systems; in addition, the high costs associated with the reagents needed for these 3D culture methods have hindered the widespread adoption of these technologies. An ongoing challenge is to develop in vitro 3D organoid models that are compatible with industrial-scale applications and readily automated for HCS.[63] To increase the throughput of compound screening in 3D cell culture, assays are required to be compatible with robotic systems including liquid handling technologies, which are generally in a 96- to 1536-well microtiter plate format, which allows accurate aspiration and dispensing of assay reagents and screening compounds in a timely manner. Accordingly, there has been an increase in the design, development, and utilization of more in vivo like 3D culture systems with better functions, lower cost and labor, and enhanced throughput. Reproducible mass production of spheroids and organoids is a promising path in which 3D culture systems can be incorporated into mainstream drug development processes. Available high-throughput compatible 3D organoid screening platforms can be classified into five main categories: hanging drop plates, liquid overlay using non-adherent binding plates, micropatterned plates, magnetic levitation, and microfluidic devices.

2.16.3.2.1 The hanging drop method

The hanging drop method relies on gravity to promote self-assembly for spheroid formation; it was originally used by adding cell droplets to the inside of standard tissue culture lids.[29] This antiquated method has been adapted for HTS via the development of 96-well and 384-well arrayed microfluidic hanging drop plates.[64] Hanging drops of mono- or cocultures are created by dispensing small volumes of cell suspension into access holes on the top of the plate without the need for any support matrices. Spheroid size is controlled by the number of cells from as few as 50 cells to as many as 15,000 cells. The resulting suspended media droplets utilize gravitational force to aggregate cells over the course of hours to days allowing for spheroid formation. Different from traditional microtiter plates, the hanging drop plates are carefully designed to form a discrete droplet of media sufficient for cellular aggregation, while at the same time they are small enough to prevent the droplets from being dislodged during manipulation.[65] Reagents, drugs, and cells can be added to or removed from each hanging drop through the access hole in the plate by hand-held pipette or by robotic liquid handling equipment to ensure reliable media exchange and consistent and stable formation of the spheroids. Evaporation of medium from the hanging drop during spheroid maturation or long-term incubation in the drop can alter the ionic strength of the medium and impact the consistency of spheroid; commercialized handing drops plate system contains either a humidifier pad saturated with buffer (GravityPLUS™ from InSphero) or a complementary lid and tray as well as a water reservoir constructed around the periphery of the culture plate (Perfecta3D® from 3D Biomatrix) to minimize evaporation (**Table 4**). Spheroids generated with hanging drop method can also be embedded into biological scaffolds to mimic the ECM surrounding cancer tumors. The downside of this method is the relatively high cost of the plate, low stability of the droplets toward mechanical shocks, and plate movement. Hence, spheroid integrity may be compromised during media change or drug screening. In addition, handing drop plates require a transfer step of spheroids into a receiver plate for imaging and analysis.[66]

2.16.3.2.2 The liquid overlay methods with non-adherent surface plates

The formation of spheroids can also be achieved by modifying vessel surfaces with non-adherent natural polymers such as agarose and poly-2-hydroxyethyl methacrylate (polyHEMA) to prevent cells from adhering to any ECM while promoting cell-to-cell attachment.[67] Thus, non-adherent surfaces promote cells of mono- or cocultures into a suspended state that enables aggregation and 3D spheroid formation. Using this method, tumor spheroids of uniform sizes and morphologies can be obtained within 24 h, providing a relatively faster alternative to bioreactors. The ultra-low attachment surface is available in plates, dishes, and flasks, as well as 96-well and 384-well plates that are suitable for high-throughput spheroid production and screening applications (**Table 4**). Well bottoms of these HTS/HCS compatible plates usually possess either a round, tapered, or V-shaped geometries that facilitate single spheroid formation in the middle of the well, making it easier to find, image, measure, and analyze. In addition, this method represents a flexible and automation-friendly platform for the generation and long-term cultivation of organoids.[68]

2.16.3.2.3 Micropatterned plates

Micropatterned plates are a novel technology for 3D cell culture that combines the advantages of scaffold-based technologies with the ease of use found in other platforms to facilitate spheroid formation in a consistent and reproducible manner.[69,70] Each plate contains micrometer-sized patterns regularly arrayed on the bottom of each well that can be fabricated using several methods, including lithography, chemical and physical roughening, electrospinning, or electrospray (**Table 4**).[71] Patterns can be of various shapes, including square, round, or square with slits between the barriers of adjacent wells. The geometry of these patterns has been used to dictate the size and distribution of integrin-mediated adhesions, cell shape, and cytoskeletal architecture as well as multicellular organization. Wells can also be coated to create a low adhesion surface within each micro-space pattern to minimize cell adherence without altering the physical or chemical attributes of the microenvironment. In addition, the bottom of the plate is made of a thin, transparent film that is suitable for microscopic imaging of the cellular structures. Once seeded on the microtiter plate with micropatterns imprinted on its bottom, cells attach and stretch out over the non-adhesive surface and the geometric distribution of adhesive contacts between cells and substrate induces reproducible polarization of the cell machinery. Cell position, cell shape, cell polarity, and internal cell organization become normalized, which can facilitate reliable and sensitive quantitative analysis.

2.16.3.2.4 Magnetic levitation

Magnetic levitation can be used to spatially organize cells into useful 3D shapes and models by manipulating the magnetic fields.[72] The magnetic levitation method relies on biocompatible magnetic nanoparticles to be taken up by cells prior to 3D culture. Treated cells then become magnetic and can be manipulated with an external magnetic field that is strong enough to force cell aggregation that can promote organoid formation. In particular, when a magnetic field is applied above the culture plate, cells are levitated from the bottom surface, where they interact and aggregate with each other to form larger 3D cultures. Once magnetized cultures are generated, they become the building block material for the magnetic 3D bioprinting process. With magnetized spheroids, medium exchange is made easy by using magnetic force to hold them in a stationary position during aspiration, thereby minimizing spheroid loss. If necessary, spheroids can also be picked up and transferred between vessels with proper magnetic tools. The magnetic nanoparticles act at the cellular level, allowing for culture medium to be scaled down in size suitable for HTS.[73,74] This method has been shown to induce the formation of ECM within hours after levitation by the magnetic field and maintain cellular phenotype for days. The most basic application of the magnetic levitation method is to culture 3D cell cultures under different biochemical or environmental conditions and then analyze them using common biological research techniques. Even though magnetic nanoparticles have been shown to not affect macro cell functions such as proliferation, viability, metabolism,

and oxidative stress in short term,[75] their uncertain long term and other unknown effects are a significant shortcoming of this method. In addition, physiological changes to the cells caused by external forces are not well characterized. Overall, the magnetic external force works as an invisible scaffold that rapidly aggregates cells to induce cell–cell interactions and ECM synthesis, making magnetic levitation an effective tool to generate structurally and biologically representative 3D structures.

2.16.3.2.5 Microfluidic devices

Microfluidic devices, particularly organ-on-a-chip, are an emerging powerful technique that has been used for 3D cell culture on miniaturized chips, facilitating experiments on a small scale.[76] Various microfluidic devices fabricated with polydimethylsiloxane (PDMS) have been developed to culture spheroids in micro-wells, micro-chambers, or on micro-textured surfaces to overcome many challenges associated with 3D culture models. Microfluidic devices allow for high-throughput production and analysis of size-controlled spheroids. Many of these platforms are equipped with biosensors for real-time imaging and monitoring of the system (Table 4).[64] These devices allow for controllable culture by manipulating the flow of liquids and the precise placement of cells within geometrically confined micro-channels.[77] In addition, supporting ECM can also be added into these chambers to encourage ECM–cell interactions and promote their assembly into 3D structures. Microfluidic generation of cell-laden hydrogel beads has been demonstrated as a rapid fabrication method for multicellular three-dimensional tissue constructs.[78] Microfluidic-based technologies can be automated and are suitable for efficient screening of 3D spheroids and organoids under various conditions. Although microchips may be the next wave of 3D tools, many of the current versions require considerable expertise to operate and troubleshoot, limiting their widespread adoption.

2.16.4 Hardware and Software for 3D HCS

Incorporating 3D organoid culture models with HTS/HCS screening is essential, providing more relevant human disease platforms to survey compound libraries for drug discovery. However, moving from 2D to 3D adds not only one more dimension in terms of shape and volume, but also a higher level of complexity with respect to assay preparation, image acquisition, visualization, and data analysis, creating several technological challenges. The first and most obvious challenge of 3D optical imaging is that the resolution along the *Z*-axis of the microscope is poor compared to the resolution in the lateral dimensions due to the inherent limit imposed by the point spread function (PSF) in conventional microscopes. Other hurdles related to 3D imaging include light scattering, light absorption, and optical aberrations associated with tissue samples that are hundreds of micrometers thick, requiring more sophisticated fluorescence microscopy techniques normally applied to 2D cell imaging.[79] Meanwhile, the photobleaching and photodamage must also be low enough to allow live imaging at needed speed for an extended period of time. Furthermore, the complex structure of 3D tissues poses additional challenges not only for image acquisition but also for image analysis and quantification. Researchers and microscope makers alike are constantly striving to push the boundaries of resolution, speed, and sensitivity, the so-called eternal triangle of microscopy systems. Advances in imaging technology such as scientific complementary metal-oxide semiconductor (sCMOS) cameras and high numerical water immersion apertures, more powerful light sources, and higher throughput capability of the imaging systems over past decades have aided the rapid measurement and quality of in-depth imaging beyond a few millimeter thickness in tissues.[8,80] Powerful and user-friendly imaging analysis and mining software for high-content images are also rapidly evolving toward robust quantitative HCA of 3D organoids.

2.16.4.1 HCS Hardware

Live cell imaging with high- and super-resolution technologies now allows for the acquisition of data in a more biologically relevant context, providing greater insight into cellular function than what was previously been possible. Most commercially available high-content imaging systems (Table 5) are tailored for 2D monolayer cell models but are capable of acquiring image stacks with defined optical Z-plane sections that can be used to explore the complexities of 3D culture models, including organoids and primary human tissue slices. As with most technologies, there is no one-size-fits-all solution to support imaging of organoids in 3D. Therefore, each imaging modality has relative strengths and weaknesses that must be considered during HCS in 3D. Deploying an automated HCS system with a suitable microscopy technique will be a costly and time-consuming process with the abundant available options; it is therefore important to carefully compare key specifications like light source, illumination methods (optics), filter and objective options, field of view, spatial resolution, image stack recording rate, and built-in image acquisition and storage software along with factors such as technical support and customer service before making a final decision.[81]

2.16.4.1.1 Brightfield and widefield microscopy, and live-cell 3D imaging

The detection of white light transmitted through thin and transparent specimens, known as brightfield microscopy, is the most basic optical microscopy illumination technique.[82] Brightfield microscopy is widely used to characterize morphological or behavioral changes using whole organisms. However, exploiting brightfield microscopy for colorimetric analysis of 3D cellular or tissue sections is not ideal and will result in a low contrast image due to light absorption and light scattering. Widefield microscopy is a type of fluorescence imaging that relies on illumination of the entire field of view (width and depth) by exciting the florescent molecules of interest and simultaneous detecting the emitted fluorescence using the digital camera sensors such as charge-coupled device (CCD) or sCMOS.[83] Widefield imagers are faster and provide higher signal intensities when working with dimmer

Table 5 Available 3D high-content screening systems

3D HCS system	*Optics*	*Light source*	*Software*	*Company*
Opera Phenix	Confocal/Widefield	Laser	Harmony/Columbus	PerkinElmer

[b]SIM, Structured Illumination Imaging.

samples. The depth of the field (DOF) or effective focus range of objective lens determines how much of the specimen appears in focus. In non-confocal (widefield) mode, emission light from the focal plane competes with fluorescence originating from outside the plane. Significant flaring and light scatter can occur, creating a blurry, low-contrast image. This will obscure the resolution of features and fine details that lie in the objective focal plate, especially in large specimens such as tissue or small organisms, and samples with a substantial fluorescence signal both within the cells and in the extracellular matrix. For instance, the depth of field for a 20× long WD objective with 0.45 NA is approximately 4.6 μm deep, if the sample thickness is around 138 μm, 30 sections of the images are needed to accurately capture the sample in its entirety. Widefield microscopy-based imaging can provide in-depth information about individual cell structure, function, and relative location as well as overall changes in the morphology and growth of the 3D structure. Therefore, widefield imaging is becoming a standard readout method by providing images of sufficient quality despite the lack of resolution on depth.

Live-cell 3D imaging is perhaps one of the most rewarding and challenging of microscopy applications.[84] In one way, 3D imaging of living cells gives researchers a more detailed and accurate spatial visualization of the interplay of cells and their components than was possible. On the other hand, overexposure may cause cellular damage that leads to altered biological behavior, negatively impacting experimental analysis, and interpretation. Effects of phototoxicity are cumulative and directly proportional to excitation light intensity and total photon load.[85] Therefore, balanced strategies to maximize light collection efficiency while minimizing excitation of the total sample volume are crucial in advancing non-invasive time-lapse 3D imaging. Intracellular staining options are limited in live cell work, as few dyes can cross cellular membranes. Other than utilizing genetically encoded fluorescent

proteins (i.e., green fluorescent protein, GFP and red fluorescent protein, RFP), transmitted light imaging techniques such as differential interference contrast (DIC) and phase contrast are widely used to visualize live cells independent of chemical staining. Automatic phase contrast and fluorescence imaging and analysis platforms such as the IncuCyte (Essen Bioscience) and BioStation CT (Nikon Instrument) offer a non-perturbing imaging approach to obtain detailed images of live cells with various filters and condensers. These imaging systems have been used to track the formation of 3D structures and quantify morphological drug responses with 3D organoids using time-lapse imaging.[86–88] The combination of resolution, depth, excellent contrast level, and fast imaging speed gives researchers the flexibility to view subtle and dynamic processes taking place deep within cells. These systems reside in a standard cell culture incubator with stable environment control of humidity, temperature, and CO_2 concentration. They are compatible with a variety of cell culture vessels including 96–384 well plates. All of the images are automatically collected according to a user-defined schedule and the imaging process is completely noninvasive and non-perturbing to cell health. In addition, conventional brightfield and widefield microscopies have also been used to image spheroids and time lapse has been used to view and quantify the self-assembled kinetics of spheroids and microtissues.[89,90] 3D images are analyzed with maximal projections in real time, providing deeper insight into active biological processes that is not possible using single-point and end-point measurements.

2.16.4.1.2 Confocal microscopy

Confocal microscopes provide better depth resolution and increased image contrast by using a light barrier via a fixed size slit, pinhole, or electronic shutter to reduce the amount of out-of-focus light reaching the detector.[91] Rather than uniformly illuminating the sample at the same time, a pinhole-sized point of excitation energy is projected into the sample in a point-scanning confocal microscope, and fluorescence from only this single point reaches back to the photomultiplier tube (PMT) detector. Light from above and below the plane of focus will not go through the pinhole; so most of the light reaching the detector is from the focused spot. The confocal image and related intensity data are captured point-by-point and computationally reconstructed after the completion of image acquisition. Point-scanning confocal systems also have variable pinhole and optical zoom, providing more flexibility. In particular, confocal high-content imaging systems are able to record the localization and intensity of multiple fluorescent reporters, providing a simple yet powerful technique for effective imaging of relatively thick specimens. In addition to help determine the optimal focus height for each spectral channel, Z-stacks or optical sections are predominantly used in conjunction with the confocal acquisition mode to obtain "depth-encoded" image sequences at different focal planes without actually cutting the 3D sample into thin slices (Fig. 2). These serial image sections can be stacked together to generate a 2D planar projection using Maximum Intensity Projection (MIP), which contains the features from all the image planes and displays the maximum values from the viewpoint to the plane of projection, or aligned and reconstructed to create a high-resolution 3D rendering of the sample and its interior to obtain detailed information regarding cellular phenotypes.

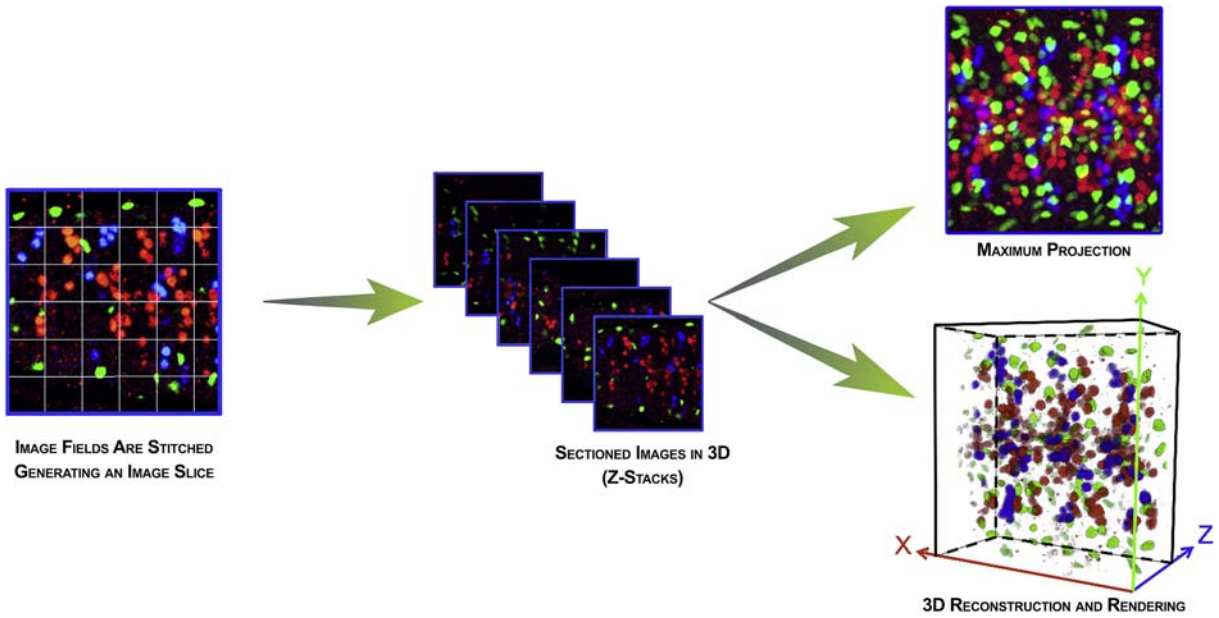

Fig. 2 A typical workflow of 3D image acquisition and visualization. In any given image slice, fields of view are stitched together. The resulting images are optically sectioned into Z-stacks that can be combined to generate a maximum intensity projection image. The Z-stacks can also be reconstructed to create a high-resolution 3D rendering of the image slices. The data above represent the late-embryonic-stage nervous system of *Drosophila* and were generated from a test dataset provided by Vaa3D open-source software developer (**Table 7**) using Fiji image processing software.[95] The 3D reconstructed image was generated from Vaa3D software with the same dataset.

However, by trading efficiency for clarity, most of the total excitation signal is intentionally blocked by the light barrier and excluded from measurement, resulting in dimmer emission signal and longer imaging times. One approach is to combine confocal imaging with high-power light pulses such as lasers or solid-state illuminators and water immersion lenses without paying the penalty of reduced sensitivity due to spectral cross talk;[123] laser scanning confocal microscopy (LSCM, also referred to as confocal laser scanning microscopy, CLSM) generates sharp images of 3D culture models necessary for further imaging analysis. An alternative solution to increase the speed of capture is to utilize multipoint Nipkow disk as in spinning disk confocal microscopy (SDCM) (e.g., Opera Phenix and Operetta from PerkinElmer, ImageXpress Micro Confocal and ImageXpress Micro 4 from Molecular Devices, and Cell Voyager 7000S from Yokogawa Electric, **Table 5**),[124] which has multiple small pinholes to increase the number of points in the specimen that can be imaged simultaneously. For example, the Operetta high-content imaging system, equipped with spinning disk confocal technology, has been used to image colorectal and breast cancer organoids.[125,126] Reid et al. used T47D luminal breast cancer organoids to specifically track and target a subpopulation of cancer stem cells that were marked by cytokeratin 5 (CK5) promoter-GFP (CK5Pro-GFP) reporter.[125] Using built-in Harmony software the authors developed an image analysis sequence to quantitate CK5Pro-GFP expression within Z-stack optical slices and the entire organoid using maximal projections. In yet another application, Zhou et al. utilized the Operetta to track the reversion of epithelial-mesenchymal transition (EMT) within colorectal cancer organoids using a fix and stain method to measure EMT biomarker expression.[126] By employing a software-controllable rolling shutter on an sCMOS camera, line-scanning confocal high-content imager (e.g., IN Cell Analyzer 6000 from GE Healthcare) is also able to acquire images through an adjustable aperture to fit different lighting conditions with tremendous sensitivity that is comparable to SDCM.[127] Issues such as phototoxicity toward live cells and photobleaching toward fluorescent molecules are drastically reduced in these systems, particularly when imaging multiple Z-sections, making them perfect fits for time-lapse live cell observation. In general, widely used confocal high-content imagers offer great image resolution with high sensitivity and flexibility for deep biological insights from cellular and tissue samples, becoming an integral tool for drug screening and life sciences research.

2.16.4.1.3 Two-photon microscopy

Multiphoton fluorescence microscopy is a powerful research tool that combines the advanced optical techniques of laser scanning microscopy with long wavelength multiphoton fluorescence excitation to capture high-resolution 3D images of samples tagged with highly specific fluorophores.[128] Although two-photon excitation (TPE) microscopy does not produce images with higher resolution than confocal microscopy, it does allow for increased depth of penetration into thick specimens. The penetration depth in confocal microscopy is limited by absorption of excitation energy throughout the beam path and by specimen scattering that affects the delivery of both the excitation and emission photons to the focus. Rather than exciting the fluorophore with one photon and generating fluorescence throughout the entire beam path, a fluorophore is excited by ultrafast laser via near-simultaneous absorption of two longer wavelengths and lower energy photons in two-photon microscopy,[129] which provides distinct advantages. The deep red and near-infrared radiation has orders of magnitude less absorption in biological specimens compared to UV or blue-green light used in one-photon microcopy. Furthermore, the long wavelength significantly reduced light scattering, and offers much better excitation beam penetration depth and enhanced *Z*-axial resolution compared to confocal microscopy.[130] More specifically, two-photon excitation occurs only at or near the focal plane where the laser light is most concentrated, restricting the emission to the narrow focal region and providing sectioning ability without the use of a pinhole. Furthermore, the limited excitation region greatly reduces phototoxicity because photobleaching is largely confined to the vicinity of the focal volume, resulting in increased viability of live cell culture during long-term imaging.[131] The multiphoton approach is a good alternative to confocal microscopy and is routinely applied to imaging experiments that require deep penetration into 3D samples such as intact tissues and animals.[132,133]

2.16.4.1.4 Light sheet fluorescence microscopy

Light sheet-based fluorescence microscopy (LSFM), also known as selective or single plane illumination microscopy (SPIM), has emerged as a versatile and indispensable microscopy technique for fast, high-resolution volumetric imaging of complex thick biological samples.[134,135] The excitation laser beam of LSFM is passed through a cylindrical lens becoming a thin sheet of light that illuminates the focal plane followed by detection in the direction perpendicular to excitation, requiring much less energy to illuminate samples compared to widefield and confocal fluorescence microscopy.[136] The thickness of the light sheet can range between 2 and 6 μm, but may also be thinner than the depth of field of the detection system. Thus, only fluorophores close to the focal plane of the detection system are excited, generating an inherently thin optical section. Another advantage of this method is that images are recorded from one plane at a time, boosting detection efficiency while reducing phototoxicity and photobleaching. LSFM can be used to image virtually any plane with multiple views obtained from different angles. In summary, with low and efficient energy light input, fast recording speed, high sectioning capability, reduced phototoxicity, and multichannel fluorescence imaging,[137] LSFM produces high quality, well-registered optical sections of complex and highly scattering specimens, representing a promising approach for 3D fluorescence microscopy.[138] LSFM has been used for high-resolution 3D imaging of multicellular specimens,[139–142] which has provided the opportunity to study subcellular or even cellular structural details of 3D tissues. For example, Wenzel et al. have reported an HCS assay model of breast cancer using T47D MCTS uniformly arrayed in 384-well plates to detect small molecules that specifically target quiescent cells.[142] 3D HCA was achieved using custom-built LSFM[143,144] and Imaris image analysis software. Light sheet microscope is commercially available from major optical manufacturers such as ZEISS,

LaVisionBioTec, and Leica (Table 5). In addition, a high-throughput imaging microscope for high-speed imaging of entire live embryos based on light-sheet microscopy has recently been developed,[145] demonstrating the future utility of light-sheet-based HCS instruments.

2.16.4.1.5 Laser scanning cytometers

In addition to microscopy, flow cytometry can be used to simultaneously measure multiple events within single cells and populations of cells.[146] It also has the ability to both analyze and sort large sized particles similar to 3D spheroid structures. For example, the BioSorter and COPAS platforms developed by Union Biometrica are fully automated systems for sorting and dispensing large particles ranging from 20 to 1500 microns in diameter. However, limitations of flow cytometry such as the lack of time-resolved measurements, the inability to analyze subcellular localization of fluorochromes, and the inability to analyze the same cell with multiple probes have spurred the development of the image cytometer by performing high-content assays providing both rich morphological and biochemical information.[147] Automated 2D image flow cytometers such as Amnis ImageStream^{x} Mark II from MilliporeSigma and iCyte from Throlabs (Table 5) combine the detailed imagery and functional insights of microscopy with speed, sensitivity, phenotyping abilities, and real-time population data analysis of flow cytometry in a single instrument, to produce high levels of information with minimal investigation time. This unique combination enables a broad range of applications that would be impossible using either technique alone.[148] The built-in software removes the adoption barriers associated with image analysis through a cytometric approach that is user friendly and provides full statistical analysis and composite imaging. Numerical data are displayed as bivariate scattergram plots or traditional cytometric histograms from the derived image data. An important extension of the image cytometry system is the addition of 3D resolution with the help of laser scanning imaging cytometry (LSC) that employs laser-spot scanning illumination.[149] The detection system, which combines PMTs for fluorescence detection and photodiodes for absorbance and scatter detection, offers excellent quantitative cytometric performance and imaging capabilities (field of view $\sim$400 mm^2, focal depth $\sim$200 μm). Furthermore, LSC can image the entire depth of a well without Z-stack assembly or changing focus height in a single scan, allowing differentiation between low and high concentration of signals in a short time frame.[150] This technology is effective for rapid high-throughput identification (quantity, area, and volume) of cells, colonies/spheroids, and model organisms, and particularly suited to the analysis of 3D cultures, as even large objects ($>$1 mm diameter) can be imaged without stitching multiple images. Commercial (i.e., Acumen Cellista from TTP Labtech) and custom-built high-throughput 3D image cytometer enables rapid detection of colony positive objects with predefined thresholds for 3D high-content analysis of spheroids without generating huge data output.[151–153] For example, Kenny et al. measured migratory fluorescent ovarian cancer within an organoid model of the ovary omentum and peritoneum.[153] The HCS assay was analyzed using a TTP Labtech Acumen eX3 fluorescent cytometer. Interestingly, this model was used in both 384-well and 1536-well plates, which gave comparable results despite the scale platform.

2.16.4.2 HCS Software

As the complexity of the biological systems continues to increase, from simple 2D cell cultures to more physiological 3D organoids, the size and complexity of acquired imaging data will continue to grow. With the technology to perform high-content image-based screenings now accessible to many labs, there are growing demands for powerful software tools that enable the acquisition, analysis and visualization, and management of large multidimensional image data sets.

2.16.4.2.1 HCS image acquisition software

In broad terms, there are two types of commercial software programs available for HCS image acquisition. The first one comes bundled with the imaging system and is tailor-made by the manufacturer to drive their own instruments (Table 5). However, built-in applications do not interact with devices from other companies. This type of software can range from the basic picture-taking packages designed for general digital microscopes to highly sophisticated applications that are capable of visualization and quantitative measurements of multidimensional images. The second type of customary proprietary image acquisition software packages are designed to work with most imaging platforms by third-party developers. These software applications such as ScanImage (Vidrio Technologies), SlideBook (Intelligent Imaging Innovations), and Image-Pro Insight (Media Cybernetics) provide their own image acquisition, processing, and analysis functions (Table 6). They are also compatible with a wide variety of motorized microscopes, scientific cameras, illuminators, and other microscope accessories from different manufacturers. Commercially available software packages usually have intuitive and easy-to-use graphical user interface (GUI) and do not require extensive computer skill to master. However, they lack flexibility and have limited opportunities for users to customize or extend their function. Commercial software is often expensive, and depending on the software maintenance agreement, typically there is an extra cost for the updates of the software offered by the respective vender. Open-source software, such as μManager and YouScope, is a cost-effective bioimage software option that not only is able to control many high-content imaging devices on the market but also numerous custom-built imaging systems.[154–156] These packages are free to download and are compatible with various computer operating systems. To take the advantage of the open-source model, the source code of the software is readily available for modification and can be further customized for those with computer programming expertise. For instance, μManager's intuitive graphical user interface and programming interface let anyone write code to control microscope related equipment, resulting in a large and growing list of supported equipment. In addition, μManager's plug-in capabilities allow new application-level functionality to be added for specialized techniques.

Table 6 HCS software for image acquisition, analysis, and data management

Types	*Name*	*Main features and related references*	*URL*	*Cost*
Image Acquisition	μManager	Complete image acquisition and microscope control package with HCS Site Generator plugin[154,155]	https://micro-manager.org https://open-imaging.com	Free/Commercial
	YouScope	Control automated microscopes. Generating protocols graphical interface[156]	http://langmo.github.io/youscope	Free
	ScanImage	Control of various microscopes for neuroscience imaging[157]	http://vidriotechnologies.com	Commercial
	SlideBook	Managing everything from instrument control to image processing and data analysis[158]	https://www.intelligent-imaging.com/slidebook.php	Commercial
	i-Solution	Streamline image capture, measurement, and enhancement process[159]	http://www.imt-digital.com	Commercial
	Image-Pro Insight	Advanced image acquisition software for scientific cameras[160]	http://www.mediacy.com/imageproinsight	Commercial
Image Analysis	Fiji/ImageJ	Bioimage analysis bundle with a broad collections of plugins[92–94]	http://fiji.sc http://imagej.net	Free
	CellProfiler	Interactive exploration and analysis of high-throughput image-based data[161,162]	http://cellprofiler.org	Free
	CellProfiler Analyst	Exploring and analyzing image-derived data. Machine learning tools for identifying complex and subtle phenotypes[31,163]	http://cellprofiler.org	Free
	ITK	Includes leading-edge algorithms for registering and segmenting multidimensional data[164]	https://itk.org	Free
	PhenoRipper	Image block-based tools for rapid exploration and interpretation of high-content microscopy data[165]	http://awlab.ucsf.edu/Web_Site/PhenoRipper/default.htm	Free
	ilastik	Interactive image classification, segmentation, and analysis[166]	http://ilastik.org	Free
	Cell Cognition	Cross platform high-content image analysis on the single cell level[167]	http://cellcognition.org	Free
	TLM-Tracker	Cell segmentation, tracking, and lineage analysis in time-lapse microscopy movies[168]	http://www.tlmtracker.tu-bs.de/index.php/Main_Page	Free
	CellOrganizer	Building accurate models of cell organization directly from microscope images[32]	http://cellorganizer.org	Free
	scikit-image	Image processing library that implements algorithms and utilities for research[169]	http://scikit-image.org	Free
	CellClassifier	Automated classification of single-cell phenotypes with supervised machine learning methods[170]	http://www.pelkmanslab.org/?page_id=63	Free
	Image-Pro Premier	Segment, count, classify, and analysis 2D image. Process and enhance image, data management[171]	http://www.mediacy.com/imageprepremier	Commercial
	DCILabs	Personalized packages such as Neurite Outgrowth and Cell Invasion Assay for HCA[172]	http://www.dcilabs.com/Software.php	Commercial
	Aphelion Dev	Object recognition and measurements, option for 3D image processing.[173,174]	http://www.adcis.net	Commercial
	GSA Image Analyser Batch	Object surface calculation, object length calculation and object counting of images in batch mode[175]	http://image.analyzer.batch.gsa-online.de	Commercial
Data and Workflow Management	KNIME	Integration scientific workflow systems for data analytics and reporting[176,177]	https://www.knime.org/knime	Free/Commercial
	openBIS for HCS and microscopy	Open platform for managing scientific information. Review, brows, annotate, visualize, and analysis images produced in HCS experiments[178]	https://sis.id.ethz.ch/software/openbis-screening.html	Free
	BisQue	Store, visualize, organize, and analyze images in the cloud[179]	http://bioimage.ucsb.edu/bisque	Free
	OMERO	Client–server software for management, visualization, and analysis of biological images[180,181]	https://www.openmicroscopy.org	Free
	Orange	Visual programming software for data mining, machine learning, and workflow management[182]	http://orange.biolab.si	Free
	Pipeline Pilot	Automation and standardization of data preparation and collation. Integrates image data to a unified Image Collection computing framework[176,183]	http://accelrys.com/products/collaborative-science/biovia-pipeline-pilot	Commercial

2.16.4.2.2 Deconvolution

Deconvolution is a computationally intensive image processing technique to reassign light back to its correct plane of focus, producing images with higher contrast and resolution.[184] By taking advantage of PSF that provides information about the microscope's optical characteristics such as the instrument modality and objective lens parameters, a mathematical model is generated to predict the distribution of out-of-focus light caused by the inherent optical limitations of the instrument. Out-of-focus light can then be compensated with iterative deblurring and restoration algorithms from the deconvolution software (Volocity from PerkinElmer, Huygens from Scientific Volume Imaging, etc.), which mathematically erase preexisting noise by redistributing every point of light back into its correct focal plane, resulting in a cleaner image. At the same time, the relative intensities in the image remain largely untouched after restoration, preserving the quantitative relationship in the image analysis.[185] Deconvolution can be used to increase the resolution of widefield and confocal images and is frequently used with 3D Z-stack images.[186] It can also increase the signal-to-noise ratio within the image, resulting in potentially better image segmentation results. However, due to the heavy computational requirements, deconvolved images cannot provide immediate feedback during an experiment.

2.16.4.2.3 HCS image visualizations and analysis software

As microscopy technology develops, images are carrying more and more information in the form of additional dimensions. The number of dimensions in an image is equal to the number of pieces of information needed to identify individual pixels. In a 2D image, a pixel is identified by its x and y coordinates. A voxel or volume element for 3D images is at location (x, y, z). In fluorescence microscopy, a four-dimensional (4D; x, y, z, λ) image is generated by inserting spectral channel λ that represents different imaging channels to an existing 3D image. In time-lapse fluorescence imaging, a voxel's location is specified as a spatiotemporal five-dimensional (5D) point, (x, y, z, λ, t). As dimensionality and size of image data sets continue to grow, visualization together with summarization of the results becomes more challenging, creating the need for software tools that can be used to explore multidimensional image data directly and efficiently.

One of the major advances in recent years is the development of proprietary and open-source bioimage informatics software packages (**Table 6**). These applications enable batch analysis of large data sets to better exploit the multiparametric nature of HCS.[187] Most HCS assays are currently analyzed using commercial instrumentation with bundled software to extract useful information from the phenotypes of interest. These dedicated software platforms have a sizable number of tools that a user can script together to form an image analysis workflow for high-throughput quantitative analysis of image datasets (**Table 5**). For example, an image analysis sequence of Harmony software (PerkinElmer) usually contains sections such as find objects (Find Nuclei, Find Cytoplasm, Find Spots, etc.), define regions of interest (Select Cell Region and Select Region), quantify properties in regions (Calculate Intensity, Morphology and Texture Properties), identify subpopulations (Filter by Property), and calculate readout values (Define Results) (**Fig. 3**). Third-party stand-alone software packages (e.g., Image-Pro Premier and Aphelion Dev) are not integrated with HCS instrumentation forcing image HCA to be done separate from image acquisition. Nonetheless, both integrated and third-party application platforms are flexible and can support sophisticated analyses. While commercial software applications offer more tools and features as well as support for biological visualization and image analysis, open-source software such as ImageJ/Fiji[92–94] and CellProfiler[161,162] prove to be a reliable and cost-effective alternative for postprocessing and management of HCS image sets. For example, Fiji software is a Java-based application for microscopy that provides the ability to write customized plug-ins.[92] Fiji supports a large collection of image formats used by the microscopy community and is compatible with Mac, Linux, and Windows computer operating systems. Most of the aforementioned software packages only provide functions to visualize and analyze 2D images.

While 2D HCS analysis software are well developed and user friendly, they are currently not translatable to more sophisticated 3D organoid models. Therefore, HCS industry developers and researchers are investing in software solutions that are compatible with 3D HCA.[8] Several commercial software applications such as Imaris (Bitplane), Amira (FEI), and ImagePro Premier 3D (Media Cybernetics) (**Table 7**) are becoming widely used for performing 3D image visualization and analysis tasks. Besides commercially available comprehensive tools, there are also numerous freely available open-access 3D imaging software packages (**Table 7**) that are shared and supported by a broad base of scientific community, designed for scientist with little or no programming knowledge. Most of these programs allow user to explore, rotate, and render 3D images in incredible detail and clarity. They also contain flexible

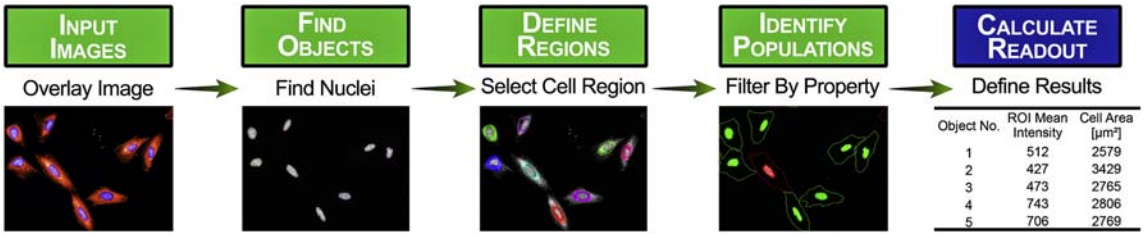

Fig. 3 A flowchart of an image analysis sequence using Harmony high-content imaging and analysis software (version 4.1, PerkinElmer). Fetal human lens epithelial FHL 124 cells were stained with Hoechst 33342 (*blue*) to detect nuclei and RFP (*red*) to detect α-smooth muscle actin (α-SMA) within cell images. Images were captured using a 20× long WD objective with a PerkinElmer Operetta High-Content Imaging System.

and sophisticated toolboxes to measure shapes, volumes, and distances of the 3D objects with precision. Open-sourced Visualization Toolkit (VTK) is a favorite choice for developing customized 3D visualization tools due to its extensive information visualization framework and 3D interaction widgets.[105,106] Similarly, Vaa3D is a cross platform software application geared toward biological visualization of multidimensional images.[95,96] In addition, Vaa3D can find, measure, track, and chart objects for accurate 3D quantitative measurements from single images or large data sets. Icy, funded by Institut Pasteur and France Bio Imaging, is another software application for bioimage informatics that provides a powerful platform for third-party developers to design specialized 3D plug-ins such as 3D-OrthoViewer, Active Cells 3D, Crop 5D, FastFilter3D, and Animation 3D.[99] Web-based BioSig3D is a computational platform that provides end-to-end solutions for HCS of 3D cell culture models.[111] It integrates advanced bioinformatic analysis and links visualized raw or processed 3D volumetric data with experimental variables for quality control. By employing one or more of these versatile image analysis packages (Table 7), visualization and on-the-fly analysis of MCTS and other 3D cell culture model can be accomplished faster and more efficiently, transitioning 3D HTS/HCS into a more quantitative and reproducible technique for drug discovery.

2.16.4.2.4 HCS workflow platform

HCS data contain a diversity of information from multiple sources, including details pertaining to screening libraries, acquired image stacks, HCA data, and quality control statistics and hit selection results. Many free and commercial software tools are now available to tackle the problems that occur in each step of bioimage analysis; however, large amounts of data are transferred manually between these applications, which is time-consuming and error-prone. To improve productivity and increase efficiency, it is crucial to utilize a workflow management software application that covers all aspects of these HCA functionalities to automate the image analysis and hit assessment during HCS. Flexible workflow systems such as KNIME and Pipeline Pilot (**Table 6**) are able to integrate diverse types of resources and facilitate data exchange during HCA. By seamlessly integrating existing software tools with ever-growing number of data sources, KNIME enables users to conveniently build and share specific data analysis pipelines (nodes).[176,177] The business model of KNIME involves licensing enterprise components that allow users to exchange workflows and build Web portals. The base product, KNIME Analytics Platform, is a free open-source package for integrated data access, data mining, statistics, visualization, and reporting. The KNIME Image Processing Extension provides connections to state-of-the-art bioimage analysis software packages, such as ImgLib2 (default programming framework for multidimensional image processing),[188] ImageJ, OMERO, and CellProfiler. KNIME Image Processing nodes can be combined with other available KNIME extensions (e.g., cheminformatics extensions) to generate a comprehensible HCA workflow.[189] Pipeline Pilot is BIOVIA's graphic workflow application that automates the scientific data flow. Pipeline Pilot has the ability to process and integrate all types of data including numerical, text, chemical structure, biological structure, and image data. Its Imaging Collection component enables researchers to process, segment, measure, export, apply advanced learning algorithms, and create custom interactive reports with image-data links. Complete image processing and analysis protocols can be created without ever performing complex scripting or programming, making the Pipeline Pilot a useful HCS informatics platform.[183,190]

2.16.5 Perspective of the Key Limitations of 3D HCA and HCS Technologies

As discussed throughout this chapter, 3D organoid models have superior advantages over traditional 2D cell culture methods. However, it must be recognized that major challenges remain, which limit the widespread use of organoids for HCA/HCS drug discovery. The major challenges identified from this chapter include: (1) the high cost of 3D cell-based imaging and screening compared to 2D. Specifically, everything from plates (e.g., hanging drop plate) to biological reagents (e.g., Matrigel) to high-content imaging acquisition (instrumentation time and custom features); (2) 3D organoid structures exhibit a higher degree of variability and heterogeneity compared to 2D systems. Therefore, every technical aspect in the assay protocols must be carefully optimized to minimize well-to-well and plate-to-plate variation; (3) Analyzing the vast amounts of data generated from 3D HCS poses other significant challenges due to the fact that most imaging analysis programs are tailored to meet the needs of 2D HCS. Currently, there is no single software package that covers all aspects of 3D HCA required for segmenting, tracking, visualizing, quantifying, and batch analyzing organoids. Finally, most 3D models remain relatively simplistic; however, this area of biomedical and tissue engineering research is progressing rapidly, which will likely yield more complex and sophisticated organoid models in the near future. Therefore, in addition to addressing the current challenges, imaging and software companies must anticipate, prepare for, and develop solutions to 3D imaging challenges that will arise from more complex organoid models.

2.16.6 Outlook and Conclusion

The development of safe and effective drug therapies to prevent or treat human disease is arguably one of the most challenging human pursuits. Tremendous resources and time are devoted to accomplish this pursuit by industry, government, and academia alike. Despite our success in the endeavor to provide safe and effective drug therapies, the drug discovery and development process has a remarkably low success rate and high financial cost. However, the future of the drug discovery and development pipeline is brighter than ever before due to our technological advances and ever improving understanding of human anatomy and disease on the cellular and biological level. We are now poised with the ability to reproduce complex human anatomy and disease, ex vivo, in the form of 3D organoid models that are uniformly scaled and adaptable for high-throughput drug discovery. The marriage of automated HCS with 3D models of human disease holds the potential to discover more effective drug therapies with improved translational clinical success rates. Moreover, organoids can be produced from primary human tissues and genetically functionalized to study individual human disease or even populations, providing a platform to develop precision medicines.

2.17.1 Introduction

The past decade has seen resurgence of label-free screening techniques for drug discovery driven by several important developments. First, the dominance of target-based approaches in drug discovery has been coincident with the steady decline in pharmaceutical research and development in the past decades.[1–3] Label-dependent target-based screens are found to be more productive for discovering follow-on drugs, but less so for first-in-class drugs than phenotypic screens.[4] Second, as growing efforts have been directed towards unmet therapeutic needs and unexploited biological mechanisms, pharmaceutical innovation has become increasingly challenging and a predetermined mechanism of action (MOA) for screening may be deemed to fail to deliver positive results.[5] MOA refers to the specific biochemical interaction through which a drug substance produces its biological or pharmacological effect. Third, drug pharmacology is much more complicated than initially thought. Numerous studies have shown that, although drugs are traditionally optimized against a single protein, many drugs display clinically relevant polypharmacology,[6,7] pathway-selective on-target pharmacology,[8,9] divergent phenotypic pharmacology,[10,11] and network pharmacology,[12,13] besides metabolism, which is a well-known complicating factor. Polypharmacology refers to the specific binding of a drug to more than one target, while on-target pharmacology is the biological activity of a drug after binding to a specific target; phenotypic pharmacology is the cell-/tissue-specific action of a drug, and network pharmacology is the action of a drug in which the drug modulates more than one target in a signaling network.[14] Fourth, binding affinity has been traditionally used as a primary surrogate for predicting the in vivo efficacy of drug molecules; however, recent studies suggest that the nonequilibrium biochemical MOA of drug molecules is advantageous for developing efficacious drugs.[15–18] Biochemical MOA describes the kinetics, in particular receptor residence time (the reciprocal of K_{off}), as related to the mechanism of drug action.[15] Fifth, as the centerpiece of target-based drug discovery, labeling techniques have advantages associated with high sensitivity, molecular specificity, and compatibility to high-throughput screening (HTS) or high content screening, but disadvantages related to label interferences,[19,20] cell alterations,[21] and constraints in target/MOA screened.[22] Label-free screening techniques overcome these limitations by offering unbiased approaches to investigate the binding and functions of drug–target interactions in native and physiologically relevant environments.[22] Advances in instrumentation and methodologies in the past decade have made various label-free techniques useful for drug discovery (**Table 1**).

In this article, the principles of these label-free screening techniques and how to best implement them in the workflow of drug discovery process are discussed (**Fig. 1**). Specifically, mass spectrometry (MS)-based proteomics is useful for target identification.[23,24] Proteomics is the systemic determination of gene and cellular function directly at the protein level. Resonant waveguide grating (RWG) biosensor is capable of HTS or even ultra-HTS using engineered or native cells,[25,26] while virtual screening based on protein structure has become a reality for screening tens of millions of compounds computationally.[27–29] Nuclear magnetic resonance (NMR) has found its role in fragment screening.[30,31] Surface plasmon resonance (SPR) has become the leading technique for kinetic profiling.[32] Both RWG and electric biosensors have been used for real-time cell phenotypic profiling of drug molecules, enabling high

Table 1 Label-free screening techniques used in drug discovery

Technique	*Key features*	*Key applications in drug discovery*
MS[a]	Molecular ions	On- and off-target identification Polypharmacology determination Drug metabolism determination
RWG	Direct binding DMR in living cells	Biochemical-based HTS Cell-based HTS Quantitative SAR Polypharmacology Lead prioritization Biochemical MOA assessment
SPR	Drug association and dissociation	Drug kinetics profiling
Electric biosensor	Cell-substrate impedance	Quantitative SAR Polypharmacology Toxicity assessment
LBVS	Ligand similarity	On- and off-target identification Chemical library expansion Ultra-HTS
SBVS	Molecular docking, X-ray structure, homology structure	Target druggability Ultra-HTS Bind mode determination
NMR	Chemical shifts, relaxation time, etc.	Fragment screening Bind mode determination
ITC	Heat	Thermodynamics profiling
BLI	Drug association and dissociation	Biologics kinetics profiling

[a]Abbreviations. *MS*, mass spectrometry; *RWG*, resonant waveguide grating; *SPR*, surface plasmon resonance; *DMR*, dynamic mass redistribution; *HTS*, high-throughput screening; *SAR*, structure–activity relationship; *LBVS*, ligand-based virtual screening; SBVS, structure-based virtual screening; *NMR*, nuclear magnetic resonance; *ITC*, isothermal titration calorimetry; *BLI*, biolayer interferometry; *MOA*, mechanism of action.

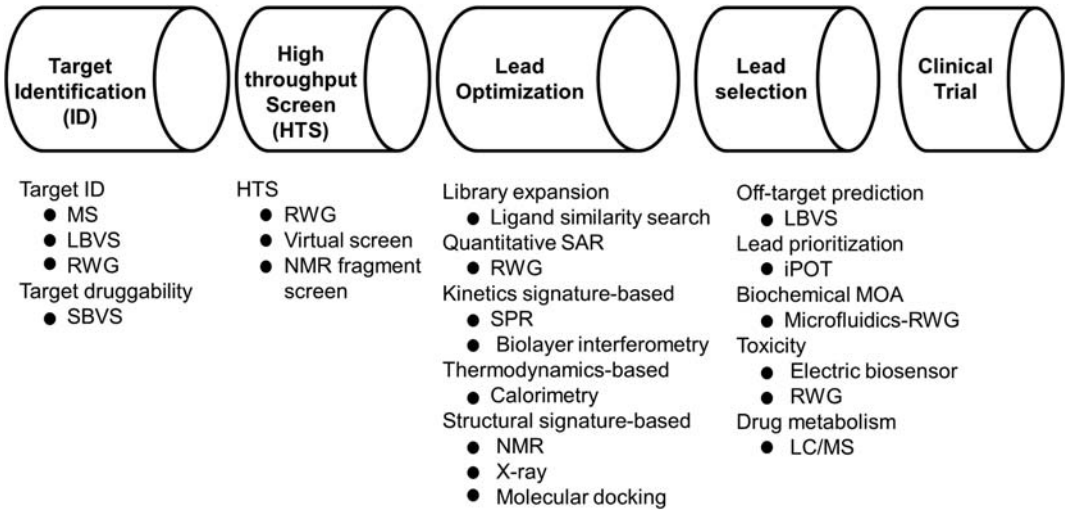

Fig. 1 Label-free screening techniques and how to best implement in drug discovery process. Mass spectrometry-based proteomics (*MS*), ligand-based virtual screening (*LBVS*), and resonant waveguide grating (*RWG*) biosensor are useful for target identification, while structure-based virtual screening (*SBVS*) is applicable to determine the druggability of targets. For high-throughput screening (*HTS*), three label-free techniques are RWG-based biochemical and cell assays, virtual screening, and NMR-based fragment screening. For lead optimization, ligand similarity searching can quickly expand the compound library, while RWG enables quantitative structure–activity relationship (*SAR*) analysis, surface plasmon resonance (*SPR*) and biolayer interferometry for kinetics profiling, calorimetry for thermodynamics profiling, and NMR, X-ray and molecular docking for the structural determination of drug–target interactions. For lead selection, LBVS is applicable to off-target prediction, while label-free integrative pharmacology on-target (*iPOT*) is suitable for lead prioritization, microfluidics RWG for biochemical mechanism of action (*MOA*) determination, RWG and electric biosensors for toxicity assessment, and liquid chromatography/MS (*LC/MS*) for drug metabolism profiling.

resolution mapping of divergent pharmacological activities of distinct drug molecules for a specific target, which is crucial to lead optimization and selection.[33,34] Label-free techniques are also useful for assessing drug safety. MS-based proteomics approaches[24] and chemical similarity analysis[29] are useful for identifying possible off-target effects, while RWG or electric biosensors are useful for assessing potential cardiotoxicity, neurotoxicity, or hepatotoxicity of lead candidate molecules using advanced cell models.[35]

2.17.2 Label-Free Screening Techniques

2.17.2.1 Mass Spectrometry

MS is well-known to accurately measure the weight of a molecule in terms of its mass-to-charge ratio (m/z) using a mass analyzer after the molecule in the gas phase is electrically charged using an ion source. The two common techniques to volatize and ionize proteins or peptides are electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI). ESI ionizes the samples out of a solution, while MALDI ionizes the samples out of a dry, crystalline matrix via laser pulses.

There are four major types of MS analyzers; namely, ion trap, quadrupole, time-of-flight (TOF), and Fourier transform (FT) ion cyclotron analyzers, each with its own physical principle and analytical performance.[36] The ion trap analyzer uses a resonant electric field in a quadruple section to capture and excite ions. The quadrupole analyzer uses a time-varying electric field between four rods to create a stable trajectory to trap and excite ions. The TOF instrument uses a flight tube to accelerate ions to high kinetic energy and separate them based on arrival times at a detector as a result of different velocities. The FT-MS analyzer such as Orbitrap uses a strong magnetic field to trap ions. All these analyzers can scan different fragments in a sample to create a mass spectrum. Nowadays, hybrid instruments have been designed and widely used to combine the capabilities of different mass analyzers. Owing to its high accuracy in mass determination, Orbitrap is the most popular technique for proteomics applications.

With advances in instrumentation and methodologies, MS has been used to generate human proteome maps[37,38] and to characterize the expression, quantity, modification state, and interactions of the proteins that constitute a proteome using different strategies.[39,40] The most frequently used shotgun or discovery approach uses a liquid chromatography and MS (LC–MS) to detect precursor ions in a survey scan, so large sets of MS and tandem mass spectrometry (MS/MS) data are generated and used to identify vast numbers of proteins contained in biological samples based on characteristic peptide fragmentation patterns. For directed or targeted proteomics approaches, affinity purification of interaction partners or enrichment of specific organelles or protein modifications is performed upfront, so specific, predetermined segments of a proteome are identified and quantified. The most recent data-independent analysis approach can be used to identify all proteins in each sample. These approaches profile different subsets of the proteome with distinct comprehensiveness, reproducibility, selectivity, sensitivity, accuracy, and dynamic range.[41]

MS-based proteomics consists of several critical steps. Regardless of whether the protein complement of a sample is analyzed directly, fractionated, or affinity purified, proteins extracted from cells or tissues are first digested to peptides. Peptides in the mixture

are then separated, typically with a gradient of aqueous/organic solvent in high-performance LC. The peptides are then converted to gas phase ions mostly by ESI via direct on-line coupling of the effluent of the column, and transferred into the mass spectrometer, where peptide fragment ion spectra are recorded. The resulting fragment ion spectra are used to assign peptide sequences from which the corresponding proteins are inferred. The fragment ion spectra are also indicative of specific amino acid modifications, and quantity of a sample peptide or protein.[40]

For expression proteomics, both label-free and isotope-labeled approaches are used to determine quantitatively the changes in protein expression. Label-free quantification directly compares the signals of the same peptides in different experiments. Stable isotope-labeled approaches compare the signal of a peptide with that having a heavy version of specific amino acid residue, the incorporation of which is achieved either by chemical derivatization or by metabolic labeling. In metabolic labeling, stable isotope labeling with amino acids in cell culture (SILAC) is achieved by culturing one cell population in media containing only normal essential amino acids (eg, arginine or lysine), and another cell population in media containing only heavy forms of the amino acids.[42] SILAC labeling leads to a defined and easily recognizable mass difference.

For interaction proteomics analysis, affinity purification followed by MS (AP-MS) is the method of choice for studying protein–protein interactions, elucidating the composition and dynamics of biological networks, and correlating dynamic network rewiring with the cellular phenotype.[40] AP-MS uses the bait protein of interest to pull down its interacting proteins.

2.17.2.2 Resonant Waveguide Grating Biosensor

RWG belongs to a family of label-free optical biosensors, including grating coupler, photonic crystal biosensor, and optical waveguide lightmode spectroscopy, that use a diffractive nanograting waveguide structure to create a surface-bound electromagnetic wave, also known as evanescent wave, under light illumination for biosensing. The evanescent wave is sensitive to changes in local refractive index, a function of local mass density at the sensor surface.

RWG is the only label-free technique that is capable of screening drugs based on both the binding of drug molecules to receptors immobilized on the sensor surface[18] and the drug-induced dynamic mass redistribution (DMR) in living cells[34,43–47] (Fig. 2). RWG is made readily in microtiter plate formats (eg, 96-, 384-, and 1536-wells), the standard footprint for drug screening. Integrating a RWG system with automation enables HTS and even ultra-HTS.[25,26] Notably, the DMR signal of a drug molecule, recorded as the shift in resonant wavelength or angle using RWG systems, is a real-time cell phenotypic response that reflects the systems biology of the receptor(s) activated by the drug molecule,[48–51] as well as the systems pharmacology of the drug molecule in the cell tested.[52–54] Furthermore, owing to its noninvasiveness and high sensitivity in measurement, RWG enables screening of drugs using native and physiologically relevant cells including primary[55,56] and stem cells,[57] in addition to recombinant cell lines commonly used in conventional label-dependent screens.

2.17.2.3 Surface Plasmon Resonance

SPR employs light excited surface plasmon polaritons (SPP) to detect the binding of ligands to the receptors immobilized on a gold surface. Similar to RWG, SPP is also a surface-bound electromagnetic wave but arising from the interaction of light with mobile surface chargers in gold layer. Coupled with robust microfluidics to reliably control drug–target interactions, SPR has become the gold standard to characterize the kinetics of ligands binding to the receptors of interest.[58] The on and off rate constants are estimated by regression of the association and dissociation curves. Similar to RWG, SPR also detects changes in local refractive index. In the recent years, SPR has also been used for profiling the functional responses of drug–target interactions in living cells but with low throughput.[59] Interestingly, most SPR instruments operate in visible wavelength range. Switching to near- and mid-infrared wavelength range permits SPR to probe cellular responses with much longer sensing depth than conventional SPR or RWG (typically <200 nm).[60]

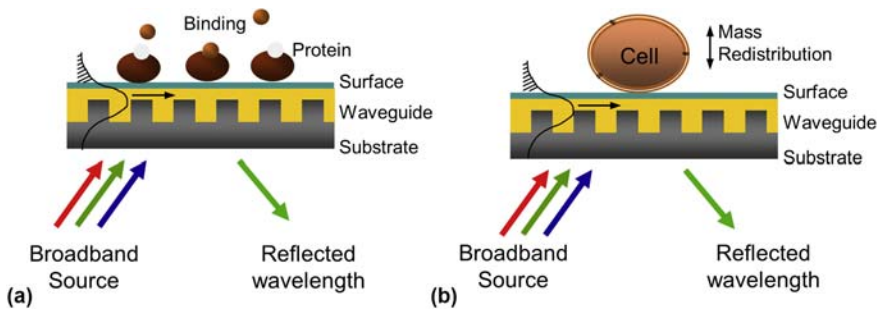

Fig. 2 Resonant waveguide grating (*RWG*) biosensor for both affinity biochemical assay (A) and functional cell-based assay (B). For biochemical assay, RWG measures the wavelength shift in the reflected light arising from the binding of small molecules to the proteins immobilized on the surface of the biosensor. For cell-based assay, RWG measures the wavelength shift in the reflected light arising from the drug-induced dynamic mass redistribution within the cells.

2.17.2.4 Electric Biosensor

Electric biosensor uses a low electrolyte interface to detect the impedance of the cell-electrode system under electric fields generated with sinusoidal voltages.[61] When the electric fields are applied, the cellular plasma membrane acts as an insulating barrier directing the current to flow between or beneath the cells, leading to extracellular and transcellular currents, respectively. The extracellular current (a function of the intercellular conduction) can be separated from the transcellular current (a function of cell-membrane capacitance) and is commonly used for cell-based assays. Here, cells are cultured onto a microelectrode array substrate and then exposed to sinusoidal voltages that are swept through a range of frequencies in a continuous wave mode. For cell assays, a reference impedance value is first obtained in the absence of cells. After cells are added, the changes of impedance relative to the reference impedance value are then calculated and recorded in real time as a unit-less cell index signal. The cell index signal is a function of changes in electrical conductivity or permeability of the cell layer arising from the morphological remodeling upon stimulation.[62]

2.17.2.5 Virtual Screening Techniques

Structure- and ligand-based virtual screening (SBVS and LBVS, respectively) are two primary computational approaches for screening. These approaches are considered to be label-free in broad terms, and can be integrated with other label-free screens. Unlike empirical and trial-and-error approaches, these computational techniques can be applied to maximally exploit the available chemical space at minimum cost to identify virtual hits that need to be experimentally confirmed.[63]

SBVS computationally screens compound library, often up to tens of millions of compounds, using known structures of protein targets.[27–29] Here, compounds from the database are docked into a known binding site of the targeted proteins to predict their binding potentials to form a stable complex. Hits are selected based on ranking using one or several scoring functions, and tested experimentally. For SBVS, it is necessary to have protein tertiary structure, ligand active conformation, and binding mode available before docking. Protein structures may be determined experimentally by X-ray crystallography or solution phase NMR, or predicted by homology modeling.

LBVS identifies key 2D or 3D chemical structures or molecular descriptors (a pharmacophore) of known active molecules (and sometimes inactive derivatives) for a target protein and uses them to query compounds in databases.[64–66] LBVS assumes similarity principle—similar compounds will be likely to have similar properties and will bind to the same group of proteins. Specifically, compounds are first annotated with a unique data (bit) string such as SMILES string. Compounds in the database are systematically compared with the query ligands at the pharmacophore level using a distance measure such as Tanimoto coefficient. The highest ranked molecules by similarity are predicted as the most likely candidate to bind, and are selected and tested experimentally. A pharmacophore is an abstract description of molecular features, which are necessary for molecular recognition of a ligand by the target protein.[67] The Tanimoto coefficient is the ratio of the number of features common to both molecules (the intersection of the data strings) to the total number of features (the union of the data strings), and gives values in the range of zero (no bits in common) to unity (all bits the same).[68] It is prerequisite for LBVS to have a relatively large set of known ligands for the target proteins.

2.17.2.6 Nuclear Magnetic Resonance

NMR spectroscopy is one of the most pivotal methods to study drug–target interactions in solution, because it is a robust technique to provide information on protein structure, dynamics, and interaction at an atomic level in solution, although it has the low absolute sensitivity. NMR spectroscopy parameters such as changes in chemical shift, nuclear Overhauser effects (NOEs), relaxation times, or diffusion constants can serve to interrogate molecular interactions and binding.

Two types of NMR experiments have been used in fragment-based drug discovery. Ligand-based NMR measures small molecule ligand resonance, while protein-based NMR measures the resonances of the isotopically labeled protein(s). When the size of the target protein allows, both NMR approaches can be used synergistically to provide a complete picture for an interaction.[69] Recently, there has been a strong emphasis on a broad range of ligand-based methods, such as diffusion experiments, saturation transfer difference, NOE pumping, water LOGSY, SALMON, and transferred NOE.[70,71] NMR-based experiments have key advantages associated with their ability to detect weak binders.

2.17.3 Target Identification

Crucial to drug discovery is to determine target engagement by a drug in cells or tissues. Most clinically available drugs achieve their therapeutic effect(s) necessarily through direct binding to one or a few target proteins.[72] However, target identification for small molecules is often the rate limiting step in drug discovery.[73] Several label-free screening techniques have been applied to identify primary and off-targets of drug molecules at an unprecedented scale, given that they offer unbiased means to survey drug–target interactions in cells.

2.17.3.1 MS-Based Proteomics for Target Identification

MS-based proteomics has been developed as an unbiased approach to elucidate the MOA of drug molecules in the context of the proteome as expressed in the targeted cell or tissue. There are three major chemical proteomics techniques, global proteomics, AP-MS, and activity- or affinity-based protein profiling (ABPP) approaches.[24]

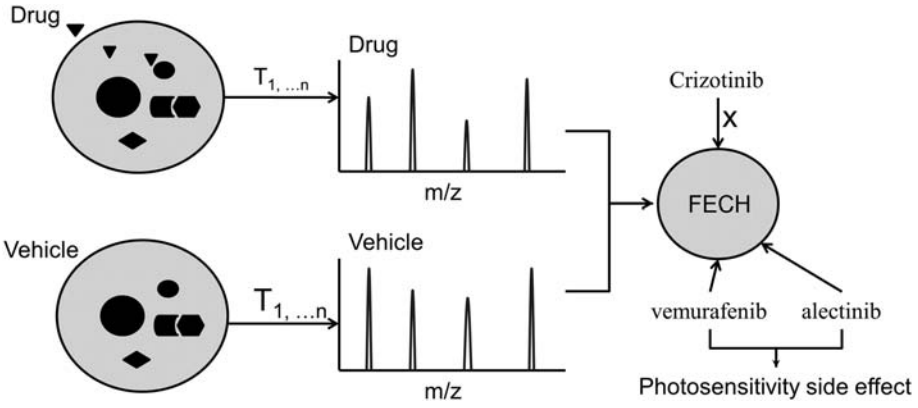

Fig. 3 A thermal proteome profiling (*TPP*) approach to identify off-target of drugs. Cells are cultured in the presence and absence of a drug (drug vs. vehicle). Samples of intact cells are then subjected to extraction with buffer. For each condition, the cell extract is divided into 10 aliquots, each followed by heating at a specific temperature. After digestion with trypsin, each sample is labeled with a different isotope tag, and analyzed by LC–MS/MS. The TPP of drugs in K562 cells led to identification of the enzyme FECH as an off-target of the two kinase drugs vemurafenib and alectinib, but not crizotinib. Schematic drawing based on the data reported in Ref.[75]

The global proteomics approaches compare the protein expression or posttranslational modifications of a drug treated cell, tissue, or animal sample with those of a control counterpart. Quantification of protein abundance and activation is achieved by either stable isotope labeling or spectral counting. These approaches have advantages in that they are unbiased and measure endogenous targets without drug modification. However, they also have disadvantages in that the observable changes are limited by the analysis depth and are often restricted to the most abundant proteins, since no target enrichment is used.[24] Recently, a MS-centric proteomics method based on ligand-induced stabilization of the target protein(s), termed cellular thermal shift assay[74] or thermal proteome profiling (TPP),[75] has been developed to directly monitor target engagement inside cells (**Fig. 3**). Savitski et al. performed thermal profiling using quantitative MS to study cancer drug pharmacology at the entire proteome.[75] They acquired quantitative thermal stability data for 5299 proteins (about 30% of the entire human proteome!) from human chronic myeloid leukemia K562 cell, and delineated 51 kinase targets and 2 heme biosynthesis enzymes including coproporphyrinogen-III oxidase and ferrochelatase (FECH) for the pan-specific kinase inhibitor staurosporine. They also found FECH as an off-target of several kinase inhibitors including vemurafenib and alectinib, but not crizotinib. FECH deficiency is genetically linked to protoporphyria, suggesting that the photosensitivity induced by vemurafenib and other drugs is mediated by FECH. Of note, they did not detect the majority of high-affinity targets for dasatinib. These results suggest that although it will miss proteins due to insufficient abundance and/or solubility or the absence of a significant ligand thermal effect, the TPH approach is useful in analyzing the on- and off-targets of drug molecules.

The AP-MS approaches employ a ligand conjugated solid substrate (eg, resin or bead) to capture and purify the interacting proteins in a sample, which are then subjected to the LC–MS/MS analysis. This type of approaches has been widely used to identify on- and off-targets of many kinase inhibitors, a family of ligands that are known to display polypharmacology.[76] For instance, using an affinity resin having seven kinase inhibitors immobilized ("kinobeads"), Bantscheff et al. found that the kinobeads can capture 307 nonredundant kinases in total as well as other ATP- and purine-binding proteins from 14 different human and mouse cell lines.[77] They further applied the kinobeads to the quantitative profiling of three tyrosine kinase ABL inhibitors, bosutinib, imatinib, and dasatinib, and found that in K562 cells imatinib binds to 13 proteins including ABL/BCR-ABL, ARG, and two novel targets (DDR1 and quinone oxidoreductase NQO2), while dasatinib and bosutinib have broad target profiles (39 and 53 kinases, respectively) including the three imatinib targets BCR-ABL, ARG, and DDR1. Interestingly, they also identified five downstream signaling pathway targets that underwent substantial downregulation of their phosphorylation status in response to imatinib.

The ABPP approaches employ activity-based chemical probes to covalently capture and subsequently purify one class of biological targets. Recently, Frei et al.[78] designed and synthesized a biocompatible chemoproteomic probe incorporating three independent functionalities: an *N*-hydroxysuccinimide ester for conjugating the reagent to a ligand containing a free amino group, a protected hydrazine that reacts with aldehydes in carbohydrates on glycoprotein receptors after exposure the cells to gentle oxidizations with sodium metaperiodate, and a biotin group for the affinity purification of the captured glycopeptides for mass spectrometric analysis. They used this probe to label intact mature vaccinia viruses, and found the cell surface proteins AXL, M6PR, DAG1, CSPG4, and CDH13 as binding factors on human cells.

Although certain protein classes (kinases and proteases in particular) can be profiled using a plethora of probes, there are few ways to assess drug binding of other families such as G protein-coupled receptors (GPCRs), ion channels, or solute carriers. Recently, Niphakis et al.[79] described a set of lipid-based chemical proteomic probes and their global interaction map in mammalian cells. They found in HEK293T cells that these probes gave rise to distinct protein labeling profiles; for instance, the fatty-acid-amide-based probe (AEA-DA) showed substantial labeling of both soluble and membrane proteins. From HEK293T and Neuro2a cells these lipid probes were found to be able to enrich more than 1000 proteins in total, of which primarily involve in protein transport,

lipid metabolism, and host–virus interactions. Furthermore, they confirmed the MOA of the dual PTGS1/2 inhibitor (±)-flurbiprofen and the selective PTGS2 inhibitor rofecoxib. Beside the known interactions with PTGS, rofecoxib-, but not (±)-flurbiprofen, was found to interact with aldose reductase-related protein 2 (AKR1B8).

2.17.3.2 Label-Free Cell Phenotypic Profiling for Target Identification

RWG measures DMR, while electric biosensor measures impedance signals arising from cell morphological change-related ionic redistribution in living cells.[33] Both DMR and impedance signals can be viewed as kinetics cell phenotypic responses of compounds, which contain target- and pathway-specific information.[34] Therefore, label-free cell phenotypic profiling approaches have advantages for target identification over traditional phenotypic approaches, which mostly rely on discrete, descriptive, empirical, and endpoint results using isolated tissues or animals, which, by themselves and individually, may offer little insights about the MOA of drugs.[80]

For label-free inhibitor screens, target hypothesis is predefined by the reference agonist cognate to the receptor of interest, so target interactions can be confirmed using direct binding assays or conventional pharmacological tools. For label-free cell phenotypic profiling that directly monitors the cellular responses of compounds, target hypothesis can be generated through similarity analysis, which compares the phenotypic profiles of compounds to those of known reference (probe) molecules.[14,25,26] For instance, Abassi et al. used the kinetic impedance profiling technique to monitor the impact of compounds in a library on the entire life cycle of cancer cell lines.[81,82] Through comparison with the kinetic profiles of marketed drugs and other probe molecules with known MOAs, they identified and deconvoluted targets for multiple classes of cell growth-inhibitory natural products and discovered novel mechanisms for existing drugs (eg, monastrol as a calcium channel inhibitor).[82]

Label-free cell phenotypic profiling can be combined with chemical biology and/or genetic manipulation techniques (eg, RNA interference (RNAi), clustered regularly interspaced short palindromic repeats-mediated gene deletion or editing) to deconvolute targets/pathways. Recently, our DMR agonist profiling of a library of 72 ion channel ligands had shown that pinacidil, a known K_{ATP} channel opener, triggered a robust negative DMR in A431, A549, HT29, and HepG2C3A, but not HepG2 cells[83] (Fig. 4). Given that the expression and function of K_{ATP} channel in the liver cell line HepG2C3A is unknown, we applied RNAi knockdown of known K_{ATP} channel component and pathway proteins to decode the pinacidil activated channel to be a SUR2-containing K_{ATP} channel, whose activation triggers signaling through Rho kinase (ROCK) and Janus kinase-2 (JAK2) and JAK3. Follow-up pharmacological assays using known probes further confirmed these results.

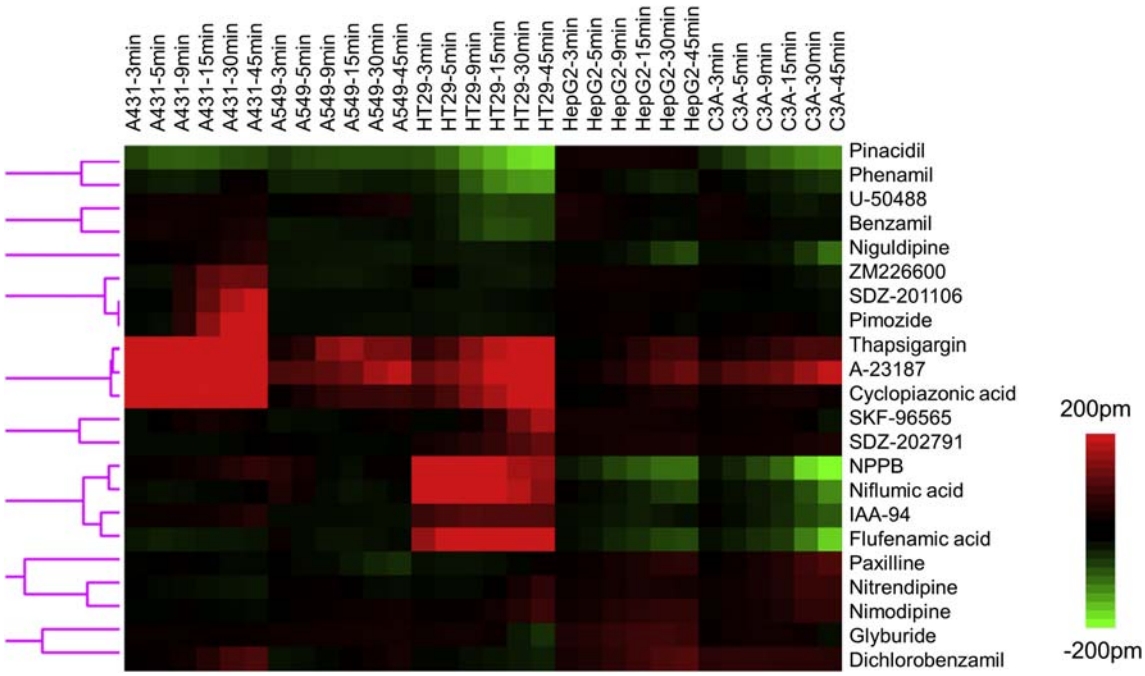

Fig. 4 Label-free cell phenotypic profiling for identifying mechanism of action of drugs in cells. DMR heat map of ion channel ligands that are active in five cell lines, A431, A549, HT29, HepG2, and C3A. This heat map was obtained using clustering analysis of the DMR profiles of the ion channel ligands in the five cell lines. For each ligand, the real responses at six discrete time points post stimulation (3, 5, 9, 15, 30, 45 min) in each cell line were used for the cluster analysis. Only ligands that led to a DMR greater than 50 pm or less than −50 pm in at least one cell line were included in this analysis. 2.17.3.3 Ligand-Based Virtual Screening for Target Prediction

LBVS uses the known pharmacophores of targets that are well annotated with ligands to compute and predict the on- and off-targets of compounds from databases. One of the productive techniques is similarity ensemble approach (SEA), which combines statistical models derived from the BLAST algorithms with chemical similarity.[64–66] SEA predicts a likely target for a compound when the known ligands for a target resemble the "bait" compound much more closely than would be expected at random. Using this method, Shoichet et al. had discovered novel targets for over 30 drugs.[64,65,84] The most notable is their discovery of primary targets of seven orphan drugs including σ-receptor for three antitussives clemastine, cloperastine, and nepinalone; dopamine D_2 receptor for the antiemetic benzquinamide; muscarinic M_1, M_2, and M_3 receptors for the muscle relaxant cyclobenzaprine; three aminergic transporters (SERT, NET, and DAT) and $5HT_2$ receptors for the analgesic nefopam; and cyclooxygenase-2 for the immunomodulator lobenzarit.[84]

2.17.4 High-Throughput Screening

The identification of hits in the early stage of drug discovery has relied heavily on HTS. In the past decade, four major types of label-free techniques have been attempted for HTS and even ultra-HTS. RWG has been used in (ultra)HTS for hit identification using both biochemical and cell-based assays, while NMR has been used for fragment screening, and computational approaches for predicting the binding potential of millions of compounds to target proteins that are well annotated with structures or ligands. Generally, unlike labeled techniques that are often limited to detect compounds competing with the same binding site of the labeled probe used, label-free can detect hits for all possible binding sites of the target protein.

2.17.4.1 RWG Biosensor for (Ultra)HTS

RWG enables affinity-based HTS using purified proteins, where the proteins are immobilized onto the biosensor surface via either covalent bonding or high-affinity biotin–avidin interaction, and compound binding is detected directly. For instance, Wells et al. used the RWG to screen inhibitors that perturb the interaction between $G_{\beta\gamma}$ protein and SNARE (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors).[85] They identified both inhibitors and enhancers for the $G_{\beta\gamma}$–SNARE interaction, a downstream event of voltage-dependent calcium channels and signaling mediated through $G_{i/o}$-coupled presynaptic GPCRs such as dopamine D_2 receptor, $5HT_1$ serotonin receptors, M_4 muscarinic receptor, and $GABA_b$ receptors. Geschwindner et al. compared several different assay formats afforded by the RWG including direct binding, surface competitive binding, inhibition in solution and protease degradation assays for their performance in screening fragments for the protease trypsin I.[86] They found that the inhibition in solution assay delivered hits similar to NMR-based counter screen. Here, the binding of a compound to the target protein occurs free in solution, and a reference compound is tethered onto the biosensor surface and serves as the probe to determine the change of free target protein concentration in the presence of the compound.

RWG also enables HTS and even ultra-HTS using native cells including both adherent and suspension cells, primary and stem cells.[25,26] RWG-enabled HTS using living cells has several advantages. First, it is unbiased and thus permits the identification of distinct classes of ligands for the receptor of interest, such as antagonists, agonists, and allosteric modulators. For instance, Gitschier et al.[87] developed a triple-addition RWG cellular assay for simultaneously screening agonists, allosteric potentiators, and antagonists for muscarinic M_1 receptor. Here, the screen is performed in three sequential steps, and measures the DMR at 14 min of compounds, the DMR at 30 min of acetylcholine at its EC_{20} dose, and finally the DMR at 30 min of acetylcholine at its EC_{80} dose. Acetylcholine is the nonselective, orthosteric muscarinic receptor agonist. They used this assay to screen a library of approximately 180,000 compounds and found that out of all compounds screened, 0.6% were identified as hits in agonist mode, 0.05% as hits in potentiator mode, and 3% as hits in antagonist mode. Follow-up study confirmed 675 to be agonists, and 45 to be positive allosteric modulators.

Second, RWG enables multitarget screen. The agonist screen that identifies compounds to trigger detectable DMR is multitarget by nature. For instance, Zhang et al.[88] screened 320 fractions from two Traditional Chinese Medicinal (TCM) plants using three cell lines A431, A549, and HT29 and identified multiple fractions to be active at GPR35, a poorly characterized GPCR, as well as niacin that activates an endogenous GPR109A in A431 cells. Similarly, the antagonist screen also enables multitarget screens. For instance, we had developed a duplexed assay to screen both agonists and antagonists for histamine H_1 and β_2-adrenergic receptors (β_2-AR), both endogenously expressed in A431.[89] Out of 1280 compounds screened, we found that the agonism screen correctly identified all known agonists for several endogenous GPCRs including H_1, P2Y, adenosine, and β_2 receptors (**Fig. 5**), while the antagonism screen identified 77 apparent ligands for the β_2-AR, and 51 apparent antagonists for the H_1 receptor. Correlating the agonism profile with the antagonism profile of each compound further segregated the hit compounds into both receptor-specific agonists and antagonists, and pathway modulators.

Third, RWG enables HTS with relatively low false positives and negatives, compared to conventional secondary messenger assays (eg, Ca^{2+} mobilization).[90] Conventional label-dependent screens are known to generally result in high negative rates (mostly due to the bias defined by the molecular hypothesis for the screen) and high false positive rates (mostly related to the chemo-physical properties such as aggregation, colors, or fluorescence of compounds, and the presence of compensatory targets/pathways).[91]

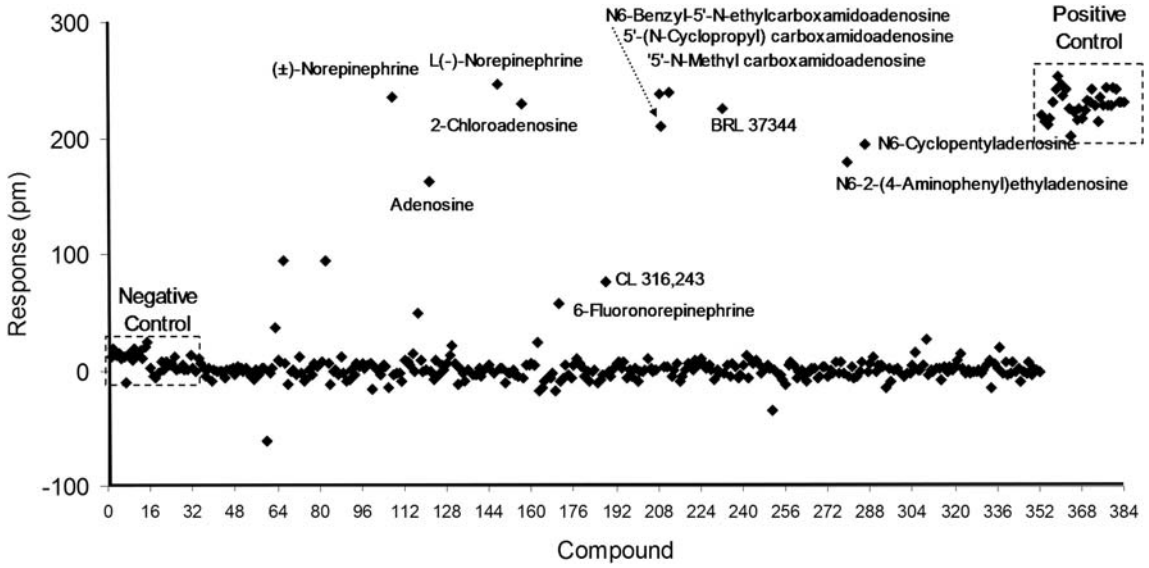

Fig. 5 RWG enables multitarget agonist screening. A hit map example from a single 384-well RWG plate shows the DMR amplitude at 50 min as a function of compounds. The positive hits for both the β_2-adrenergic and adenosine receptors were indicated. Reproduced with permission from Tran, E.; Fang, Y. Duplexed Label-Free G Protein-Coupled Receptor Assays for High Throughput Screening. *J. Biomol. Screen.* **2008**, *13*(10), 975–985.

2.17.4.2 Molecular Docking for Ultra-HTS

Molecular docking or SBVS has become an indispensable ultra-HTS technique and has started making an impact on drug discovery and development, in part due to increasing numbers of X-ray structures of proteins, in particular ligand-bound proteins, and in part due to well-annotated databases such as PubChem, ChEMBL, ZINC, and DrugBank, which provide public access to the structures and biological activities of millions of chemicals.[29]

SBVS assumes that the structures of a target will provide a template to predict the binding of compounds. The accuracy of SBVS-based prediction can be improved by using ligand-bound receptor structures, thus reducing false positives and negatives. SBVS has two clear advantages. First, it has theoretically ultra-high throughput with low cost, enabling sampling of a much larger number of compounds. Second, SBVS often results in true hit rates significantly greater than empirical HTS.[92–95] Although SBVS is mostly limited to targets with known structure and hits identified in a virtual screen still need experimental confirmation, SBVS can be used as a complementary technique to empirical screen.

One of the most exciting developments in SBVS is the recently available over 200 X-ray structures of GPCRs, many of which are in complex with ligands of varied pharmacology, peptides, antibodies, or G protein.[96,97] GPCRs are one of the most important classes of drug targets. These structures offer an unprecedented opportunity to discover new drug candidate molecules. Kolb et al. used molecular docking to virtually screen a library of close to one million commercially available, "lead-like" molecules against the inverse agonist carazolol-bound β_2-AR structure, and predicted and confirmed using a radiobinding assay 5 novel inverse agonists and 1 antagonist, the best of which has a K_i of 9 nM.[98] This study suggests that SBVS can be effective for discovering high quality hits, but the docking hits apparently bias toward the conformation stabilized by the bound ligand. SBVS has been used to identify novel ligands against X-ray or homology models of many other GPCRs, such as adenosine A_{2A} receptor, D_3 dopamine receptor, and CXCR4 receptor. It is worthy to note that SBVS is mostly limited to protein targets with known structure, while LBVS is limited to a small set of drug targets that are well annotated with known ligands.[29] Combining SBVS with LBVS, together with improved chemical similarity analysis tools, could further boost the productivity of virtual screening for drug discovery.[99,100]

2.17.4.3 NMR Spectroscopy for Fragment Screening

NMR spectroscopy, as a highly versatile structure analysis tool, is useful for fragment screening, as well as validating hits and assessing target druggability.[30,31] Many different NMR techniques including reporters, spin labels, monitoring methyl group resonances, and affinity tags have been developed to improve sensitivity and/or throughput. NMR is unique in many aspects. First, unlike many ligand-binding techniques, NMR is applicable to any class of compounds with a broad range of affinity from covalent to millimolar. NMR can reliably detect binding up to single digit millimolar K_d values, often the only hits found for challenging targets.[101] Second, NMR is applicable to almost all soluble proteins, natively unstructured proteins, and membrane proteins. Third, unlike other techniques except for X-ray crystallography, NMR can be used to determine the binding sites of fragments and modes of binding. Fourth, unlike labeled techniques, NMR detects binding directly so it does not usually suffer from false positives. Fifth, NMR detects all possible binding sites including novel binding "hot spots" such as allosteric sites and sites that result from protein conformational changes.

NMR-based fragment screening does not require a priori knowledge of protein function or endogenous binding partners as needed in many other types of assay. There are numerous successful examples illustrating the power of NMR-based fragment discovery in the literature (reviewed in Ref.[69]). For instance, Wu et al. described a HTS by combining NMR with the basic principle of combinatorial chemistry to screen a large library of fragments ($>10^5$ compounds) on a common backbone, and identified novel ligands for the ligand-binding domain of the EphA4 receptor with good binding affinity and selectivity.[102] This approach seems particularly suited to target large protein–protein interaction surfaces. EphA4 receptor is a protein-tyrosine kinase belonging to the ephrin receptor subfamily, and is implicated in mediating developmental events and linked to the neurodegenerative disease Amyotrophic lateral sclerosis.

2.17.5 Lead Optimization

Hits identified in a screen are first confirmed using a series of testing including dose response curves using the same assay for screening; orthogonal testing with different assay(s); secondary screening using functional assay(s); medicinal chemistry evaluation of synthetic tractability; hit ranking and clustering; freedom to operate evaluation; preliminary assessment of drug-likeness; and early assessment of toxicity, metabolism, and stability-related risks. Once hits are confirmed, next critical step is to expand hits by synthesis of analogs and to generate and optimize lead candidate compounds with a goal to improve potency, reduce off-target activities, and achieve desired physicochemical/metabolic properties. Label-free screening techniques have played an essential role in lead optimization, since they have been used to determine almost every important aspect of drug–target interactions starting from affinity to kinetics, structure, and thermodynamics.

2.17.5.1 LBVS to Expand Compound Library

To initiate lead optimization, several compound clusters are usually chosen from the hits identified based on a number of parameters including ligand efficiency and lipophilic efficiency, and used to expand the compound library for lead generation. Instead of custom chemical synthesis using classical organic, combinatorial, or high-throughput chemistry approach, searching for molecules based on similarity or substructure from public and private compound databases is an effective means to rapidly expand chemical library so analogs can be quickly obtained and novel and highly potent lead-like compounds can be identified. In the recent years, there are increasing number of public chemical databases including PubChem,[103] ChemBank,[104] DrugBank,[72] ChemBL,[105] and ZINC[106]; these databases contain millions of compounds annotated with biological and pharmacological activities.

2.17.5.2 RWG to Perform Quantitative Structure–Activity Analysis (SAR)

RWG can be used to perform quantitative structure–activity relationship (SAR) analysis for lead candidate compounds. This can be done using both bio-affinity binding and cell-based assays. RWG-enabled cell assay has advantages in rich information content, real-time kinetics, highly flexible assay formats, and high throughput, wide pathway coverage, and ability in multitarget profiling and screening.[25,26] Therefore, SAR analysis using RWG can provide information regarding the efficacy, potency, mode of action, and off-target effects of lead-like compounds.

Recently, we had combined the RWG-enabled cell phenotypic profiling technique with a chemical similarity search approach to discover different classes of ligands for GPR35 (Fig. 6). DMR screening of an internal chemical library of 660 compounds, originally synthesized for applications in nonlinear optics and organic field-effect transistors, led us to identify several 2-(4-methylfuran-2(5*H*)-ylidene)malononitrile compounds to be GPR35 agonists.[107] Considering the similarity of these compounds with tyrphostins, which are tyrosine analogs designed as the first generation of tyrosine kinase inhibitors, we hypothesized and confirmed that a group of tyrphostins such as tyrphostin-25[108] and multiple tyrosine metabolites including 5,6-dihydroxyindole-2-carboxylic acid (DHICA) and 3-Nitro-L-tyrosine are GPR35 agonists.[109,110] Our DMR screening of a library of 880 natural products also identified 13 natural phenols as GPR35 agonists.[111] Searching substructures of active compounds from the DrugBank led us to identify the fragment compound catechol and pyrogallol,[112] and a group of nitrophenol containing drugs such as entacapone, tolcapone, and nitecapone as GPR35 agonists, among which 4,4′-(2,2-dichloroethene-1,1-diyl)bis(2,6-dinitrophenol) displays high potency with an EC_{50} of 6 nM.[113]

2.17.5.3 SPR to Characterize the Binding Kinetics of Lead-Like Compounds

Binding kinetics is concerned with the rate constants of ligand association (k_{on}) and dissociation (k_{off}); and the ratio of the two defines the equilibrium dissociation constant ($K_d = k_{off}/k_{on}$). Compared to binding affinity, the kinetics, in particular receptor residence time, of a drug has found to be better correlated with its clinical efficacy, safety, duration of action, tolerability, indication, and therapeutic differentiation.[15,16] For instance, drugs with slower off-rates give longer duration of action, more likely leading to a once-a-day dosing. For instance, the long lasting anti-bronchiodilatation drug tiotropium dissociates 10 times slower from its primary target, muscarinic M_3 receptor, than from M_1 and M_2 receptors, resulting in an improved selectivity for this drug over other mixed $M_1/M_2/M_3$ antagonists.[114] Tiotropium exhibits similar binding affinity at both M_2 and M_3 receptors; the M_3 receptor in airway tissues is the primary target for its efficacy, while the M_2 receptor in body is responsible for its cardiovascular side effects.

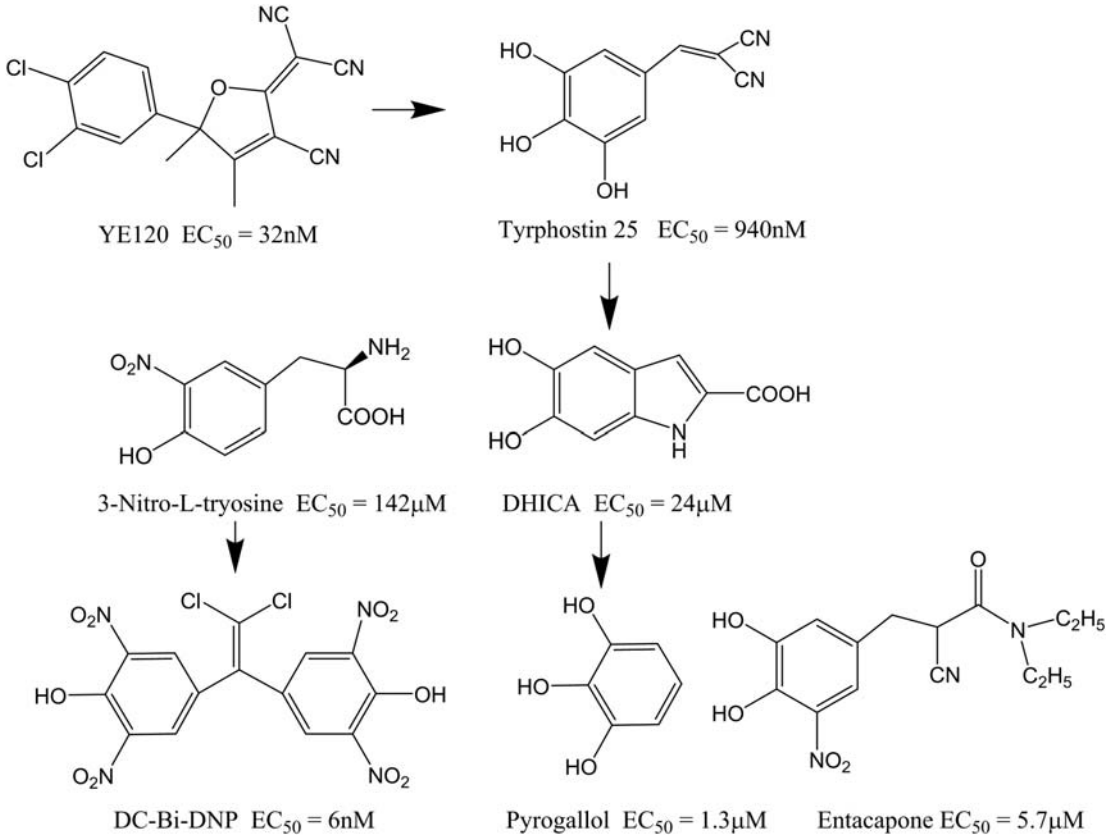

Fig. 6 Combining label-free cell-based screen with chemical similarity search quickly identifies native and novel ligands. YE120 was first identified as a full agonist for GPR35 in HT29 from our label-free screen. SAR results led us to search for and profile known malononitrile-containing compounds from public database, yielding a family of tyrphostins (eg, tyrphostin-25) and multiple tyrosine metabolites (eg, DHICA and 3-nitro-L-tyrosine) as GPR35 agonists. Substructure search of active hits identified from public database yielding DC-Bi-DNP as one of the most potent agonist known for GPR35, and nitrophenol containing drugs such as entacapone as GPR35 agonists. EC50 values reported were obtained using dynamic mass redistribution assays in HT29 cells.

The drugs such as tiotropium that work well because of kinetic differences were not designed that way. Thus, understanding kinetics earlier prospectively would be of great value, since it gives access to more diverse chemical space, more scope for intellectual property, and better defined biology. SPR is the standard technique now routinely used in laboratories for characterizing the affinity and kinetics of drugs binding to target proteins in vitro. SPR is applicable for a wide range of protein classes, particularly soluble proteins including enzymes, kinases, and proteases. However, applying SPR to GPCRs has been slow.[115] Recently, the use of thermostablized or tagged wild-type GPCRs has made it possible to use SPR to characterize ligand–GPCR interactions including adenosine A_{2A} receptor[116] and β_1-AR,[117] both of which contain a number of point mutations to improve thermostability and are further stabilized in a specific conformation in complex with a specific ligand.

Biolayer interferometry (BLI) is an alternative for profiling binding kinetics, mostly for antibodies. Instead of microfluidics used in SPR, BLI dips optical microfibres directly into the wells of standard plates for kinetic measurements with relatively higher throughput.[118] Given that there is plentiful evidence showing that compounds with the same affinity but different on- and off-rates can have a very different biological activity profile, there is a strong demand for high-throughput kinetic profiling techniques.

2.17.5.4 Isothermal Titration Calorimetry to Characterize the Thermodynamics of Lead-Like Compounds

Thermodynamic binding is influenced by multiple factors, including hydrogen bonding, hydrophobic interactions, desolvation, residual mobility, dynamics, and the local water structure, all of which contribute to the binding.[119] Ligand binding occurs only when it is associated with a negative Gibbs free binding energy ΔG, which is the sum of two energetic terms, an enthalpic term (ΔH) and an entropic term ($-T\Delta S$); $\Delta G = \Delta H - T\Delta S$. The equilibrium dissociation constant K_d is related to ΔG; $K_d = e^{\Delta G/RT}$, where R is the universal gas constant and T the absolute temperature.

There are three ways to medicinal chemistry optimization based on binding thermodynamics. The most common strategy is to optimize ΔG,[120] but it can be difficult primarily due to the frequently observed enthalpy–entropy compensation for drug–target binding.[121] Alternatively, leads can be optimized by decreasing ΔH to dominate over disfavored ΔS changes, or by increasing

ΔS to compensate for ΔH penalties.[122] Therefore, discriminating enthalpic from entropic term is useful for medicinal chemistry optimization purpose.

Isothermal titration calorimetry (ITC), as a label-free homogenous solution-based assay, is the most common approach to determine the binding thermodynamics. Current ITC can use a small cell volume ($\sim$200 μL) to detect binding-induced heat by stepwise adding a ligand solution (each about 1.4 μL). The binding isotherm obtained is then used to calculate binding constant K_d, ΔH, and ΔS. The differences in entropic and enthalpic contributions reflect different binding modes, making it possible to distinguish ligands with similar binding affinity. However, ITC has low throughput and sensitivity, requires large sample volumes, and generally is rather limited to highly potent and entropy-driven ligands. Compared to conventional ITC, the recently developed enthalpic array technique has higher throughput using as little as $\sim$500 nL of sample.[123]

Thermodynamic profiling has been used to guide lead optimization. Geschwindner et al.[124] recently reviewed their thermodynamics profiling guided efforts in optimizing inhibitors for β-site APP cleaving enzyme 1 (BACE1), a key player in the production of toxic amyloid beta clusters in brain. These inhibitors span a K_D range from about 10 μM to 10 nM, with ΔH_{obs} values from -11 to $+1$ kcal mol^{-1} and ΔS_{obs} values from -8 to $+3$ kcal mol^{-1}, typical for a hit identification–early lead optimization campaign. These studies confirmed the quite common occurrence of enthalpy entropy compensation for binding, and thermodynamics properties are well correlated with lipophilic ligand efficiency—a common metric often used to estimate the specificity of binding and can generally be written as $-$Log(potency) $-$ Log(partition coefficient).

2.17.6 Lead Selection

Following lead optimization, drug discovery projects then prioritize and select appropriate lead candidate molecules for animal and preclinical testing. Label-free screening techniques have a role to play in lead selection ranging from on- and off-target identification to biochemical MOA determination to drug safety assessment. Effective lead prioritization and selection is essential for controlling the costs of drug discovery.

2.17.6.1 Virtual Screening Techniques to Identify Potential off-Target Effects of Lead Molecules

The efficacy of a drug is critically dependent on the extent of its engagement at primary target; however, adverse drug reactions (ADRs) are often due to excessive binding of the drug in toxicity prone cells or its off-target interactions. Animal and clinical studies over the past century have established the association of over 70 protein targets with ADRs.[125] Both SBVS and LBVS are capable of identifying potential off-target effects of lead-like molecules, which is important to derisking toxicological liabilities in drug discovery. Lounkine et al. applied LBVS to predict the activity of 656 marketed drugs on 73 unintended "side-effect" targets.[66] They established several new ADR associations; for instance, the abdominal pain side effect of the synthetic estrogen chlorotrianisene was mediated through its inhibition of the enzyme cyclooxygenase-1.

2.17.6.2 RWG-Enabled Cell Phenotypic Profiling to Prioritize Lead Molecules

Typical screening campaigns screen millions of compounds, leading to identification of tens of thousands of hits. After optimization, about 100 lead-like molecules are selected for animal testing. Current approaches to prioritize and select lead molecules for in vivo testing are mostly idiosyncratic and unpredictable. Recently, we developed a RWG-based label-free integrative pharmacology on-target (iPOT) approach to analyze a family of ligands with diverse modes of action for β_2-AR,[11,126] and another for μ-, δ2-, and k-opioid receptors.[127,128] This approach leverages the power of RWG to detect functional receptome in living cells, as well as the sensitivity of drug-induced DMR to pathway intervention by small molecules or genetic manipulation. The iPOT can be performed using a panel of probe molecule-modulated cells, or a panel of different recombinant or disease relevant cell lines. We found that the iPOT is capable of generating self-referenced pharmacological activity map, enabling the classification of lead-like molecules into distinct clusters, each of which may share a common molecular MOA, so representative lead-like molecules from each cluster shall be selected for in vivo testing.

2.17.6.3 Microfluidics RWG to Elucidate the Biochemical MOA of Lead Molecules

Elucidating the biochemical MOA of drug candidate molecules is a critical step in drug discovery. The label-free cell phenotypic signals, measured by either DMR or impedance, were found to be influenced by the molecular or biochemical MOA of drugs, such as biased agonism,[54] binding kinetics,[129,130] binding orientation,[131] and transport mechanisms.[132] The biased agonism describes ligand-dependent selectivity for a specific signal transduction pathway over others downstream the same receptor, and is common to GPCRs and potentially other classes of receptors.[14] Although there was a positive correlation between the efficacy and receptor residence time of ligands for adenosine A_{2A} receptor[129] or M_3 muscarinic receptor,[130] the label-free profiling in living cells under static conditions often does not directly manifest the biochemical MOA of drugs.

Microfluidics RWG is the best suited to elucidate the biochemical MOA of a family of ligands having different binding kinetics for a specific receptor. Microfluidics is the most effective means to control the duration of a ligand exposed to the cells, so it is possible to determine whether the effect of the ligand is short or long acting. Using microfluidics RWG, we found that the activation

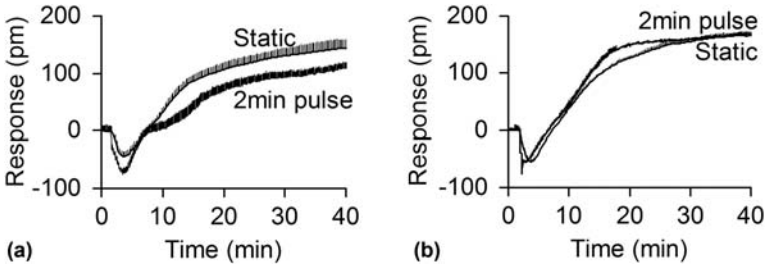

Fig. 7 Microfluidics RWG to elucidate the biochemical mechanism of action of drugs. The DMR signals induced by distinct β_2-AR agonists, (A) 2 nM salbutamol and (B) 5 nM pindolol, under the 2 min pulse stimulation in comparison with the sustained stimulation (static) conditions. Salbutamol is a short acting agonist, while pindolol is a moderately long acting partial agonist. Data represents mean + s.d. ($n = 3$). Reproduced from Goral, V.; Jin, Y.; Sun, H.; Ferrie, A. M.; Wu, Q.; Fang, Y. Agonist-Directed Desensitization of the b2-Adrenergic Receptor. *PLoS One* **2011**, *6*, e19282. with through the Creative Commons Attribution License.

of the β_2-AR in A431 with a pulse of its agonists as short as 1 min is sufficient to trigger a sustained response, whose sustainability is dependent on the receptor residence time of the agonist (Fig. 7),[133] as well as the concentration and stimulation duration of the agonist.[134] For antagonists, DMR profiling using microfluidics RWG also allowed estimation of the residence times of different antagonists acting at M_3 receptor in native cells.[135]

The cell-membrane permeability and transport mechanism are important for the efficacy of drugs acting at intracellular targets. Recently, using microfluidics RWG we found that the efficacy of inhibitors to block epidermal growth factor receptor signaling is mostly related to cellular uptake and efflux via efflux transporter such as breast cancer resistance protein (BCRP/ABCG2), instead of receptor residence time.[132] Furthermore, microfluidics RWG can also be used to detect ligand-directed desensitization and resensitization.[133,136,137]

2.17.6.4 Electric Biosensor to Assess Compound-Induced Toxicity

Drug toxicity/safety assessment is essential to drug discovery and development. Drug-induced toxicities in liver, heart, kidney, and brain currently account for more than 70% of drug attrition and drug withdrawal.[138] Label-free techniques including RWG and electric biosensors can be used to assess compound-induced cardiotoxicity,[139,140] skeletal muscle hypertrophy,[141] hepatotoxicity, and neurotoxicity.[35]

Drug-induced cardiovascular toxicity remains one of the most common causes for attrition of drugs, creating a need for using better, more predictive in vitro models and high-throughput techniques to assess cardiotoxicity early in drug discovery process. Stem cell-derived cardiomyocytes represent highly physiologically relevant and robust systems to assess accurately compound-induced cardiotoxicity. The recently developed high frequency electric impedance biosensor system has been used to detect compound-induced cardiotoxicity by monitoring the effect of drugs on the beating patterns of primary or stem cell-derived cardiomyocytes. This system was found to be able to recapitulate known effects of various known modulators of cardiac function.[139] We recently also developed a high frequency RWG imager to measure the compound-induced cardiotoxicity (Fig. 8).[140] Results showed that, after culture for 11 days, induced pluripotent stem cell-derived cardiomyocytes form a monolayer on the biosensor surface and

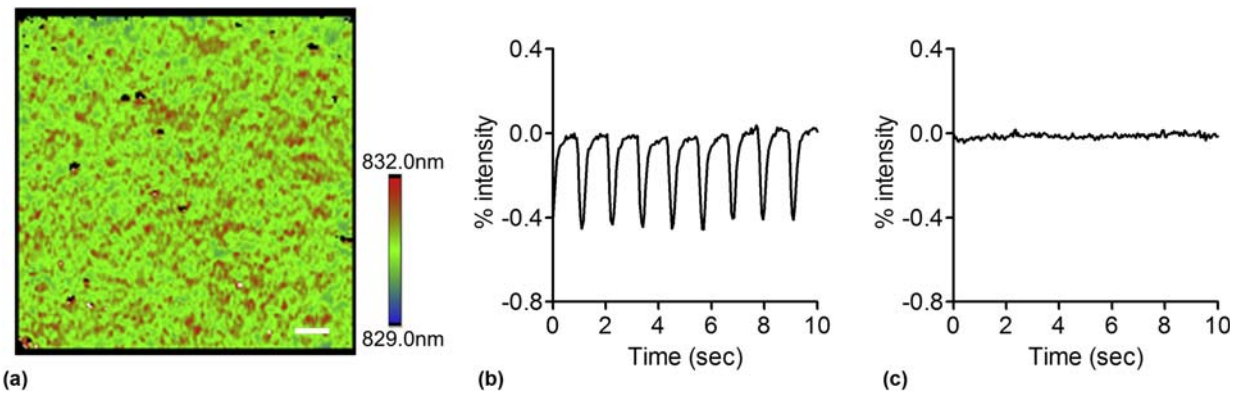

Fig. 8 High frequency resonant waveguide grating system for detecting compound-induced cardiotoxicity. (A) A resonant wavelength image of a biosensor covered with human-induced pluripotent stem cell-derived cardiomyocytes after cultured for 11 days at 37 °C. (B and C) The intensity modulation pattern before (B) and 1 min (C) after treatment with 10 μM isradipine.

beat in a synchronized fashion, resulting in a regular beating pattern consisting of a series of minimal valleys. The treatment of cardiomyocytes with isradipine, a known toxic compound, for 1 min completely stopped their beating.

Recently, Rakhilin et al.[141] applied an electric biosensor to demonstrate that the changes in electrical impedance as a function of cellular adhesion in real time correlate well with variation in myotube thickness caused by atrophy or hypertrophy agents, suggesting that impedance can be used as a reliable and sensitive biomarker for myotube atrophy or hypertrophy.

2.17.6.5 LC/MS to Detect the Metabolites of Lead Molecules

Detecting metabolites of lead molecules is critical to appreciate their bioavailability, pharmacokinetics, and pharmacodynamics. Certain drug metabolites may display biological activities different from the drug itself. For instance, aspirin exerts its clinical efficacy primarily through cyclooxygenases 1/2, but we found that several of its metabolites display agonistic activity at GPR35.[142,143] LC/MS emerged as a powerful means to study drug metabolism.[144] Lead molecules having at least one easily ionizable functional group can be routinely analyzed with LC/MS using ESI, while less polar compounds such as steroids can be analyzed using atmospheric pressure chemical ionization or atmospheric pressure photoionization. Combining LC/MS with in vitro drug metabolism systems such as hepatocytes or liver microsomal fractions can be fruitful for detecting drug metabolites.

2.17.7 Summary

Recent advances in instrumentation and methodology have made several label-free screening techniques applicable to different stages of drug discovery. Depending on the objectives of specific screening campaigns, different label-free strategies can be used to facilitate drug discovery. For follow-on drug discovery, the molecular mechanism of action (MMOA) sought is known, label-free can be implemented in a way similar to conventional label-dependent screens, and lead-like molecules can be optimized and advanced based on binding affinity and efficacy. On the other hand, for first-in-class drug discovery, the desired MMOA is unknown, label-free should be combined with labeling techniques to provide systematic comprehension of the druggability of the target and lead-like molecules. Label-free screening techniques have a bright future in drug discovery and development.

2.17.8 Outlook

The past decade has seen dramatic expansion of label-free techniques, ranging from electronic biosensors (eg, semiconducting silicon nanowires, carbon nanotubes, and electrochemical impedance spectroscopy) to mechanical biosensors (eg, quartz crystal microbalance, integrated surface acoustic wave biosensors, and microcantilevers) to photonic biosensors (eg, optical microcavity sensors, whispering gallery mode biosensors, and liquid-core optical rings resonators). Many of these biosensors have not been used in drug discovery, while some (eg, SPR, RWG, and impedance biosensor) have found limited applications. Any label-free techniques have to address four critical questions in order to be adopted in drug discovery; namely, throughput, information content, practicability in daily operation, and compatibility to current workflow. Drug discovery demands label-free with high throughput, high information content (eg, kinetics in binding or cells or tissues), and high temporal and spatial resolution.[145] On the other hand, label-free cell-based assays generally have caveats associated with low molecular specificity and unclear cellular mechanisms for the signals obtained. Elucidating the contextual relevance of label-free cell profiles of drug molecules to cell biology and signal transduction is essential to advance and drive the wide adoption of label-free technologies.[14]

2.18.1 Introduction

Life science research is focused on linking molecules and signaling pathways to biological phenomena such as the emergence of adverse events and disease. Undoubtedly, traditional approaches have provided many valuable insights and will continue to do so. However, the reductionist understanding of the behavior of individual elements or specific interactions in isolation is not always sufficient, because biological systems are dynamic, and are composed of many parts that interact with each other in a regulated manner. The complex networks of interactions between the many diverse molecular and cellular entities of an organism are ultimately responsible for maintaining tissue homeostasis and driving adaptive responses to the environment. It is the perturbation of these networks of interactions that lead to adverse outcomes and disease.[1]

Systems biology is a highly interdisciplinary approach that integrates many levels of knowledge. It combines experimental approaches with computational methods to study the dynamic interactions between the diverse molecular and cellular entities within a biological system. Systems biology aims to consider the biological system as a whole. As described in this article (section "Experimental Technologies"), systems biology depends on data produced by rapidly developing -omics technologies, such as transcriptomics, metabolomics, and proteomics. In the early days, when high-throughput omics technologies emerged, it was customary to analyze lists of differentially expressed molecular entities using dedicated web applications to identify affected pathways.[2,3] Today's analytical methods are far more sophisticated as computational scientists have developed ways to reduce the complexity and distil information from huge amounts of data produced by high-throughput measurement technologies. These include algorithms to probe for causal inferences from molecular patterns, and the use of a priori knowledge represented as biological network models that can be used to filter the data based on biological context.

In this article, we also summarize applications that showcase how systems-based approaches impact drug discovery,[4] pharmacology and toxicology,[5,6] and medicine.[7] Finally, we touch upon the many challenges faced by systems biology when dealing with large amounts of heterologous data.

2.18.2 Experimental Technologies

2.18.2.1 Transcriptomics

Genome-wide omics methods play critical roles in basic and translational research and are now making their way into the clinic. The methods reviewed here embrace "global" approaches to biological studies. Microarrays pioneered studies on the expression of thousands of genes in parallel, instead of just a handful of genes at a time. This concept has been extended further with the introduction of newer technologies, most notably next-generation sequencing (NGS), to dramatically increase our understanding of biological pathways and networks. Emerging single-cell technologies have greatly improved our ability to understand diverse cellular interactions by separating out the functional characteristics of individual cell types. Importantly, all of the methods reviewed here have radically increased the amounts and types of data that must be comprehensively analyzed and evaluated. Bioinformatics is now accepted as a critical component of modern science because adequate computational infrastructure and expertise are required to fully interpret the mass of information. The modern scientific community recognizes the value of interpreting data holistically, because this is how biology works. Indeed, the genome, transcriptome, and all the other "-omes" work together, and we are beginning to see technologies that can integrate multiple datasets, together with the development of statistical and algorithmic approaches to make sense of the data. This overview provides a top-level summary of several excellent reviews of this field. Throughout the article, the reader is directed to the relevant reviews for in-depth descriptions of methodological details and applications.

2.18.2.1.1 Microarray technology

Examining gene expression is central to understanding gene function. Many of the initial molecular biology methods to study gene expression, such as the Northern blot, were applicable to known genes and were limited to examining a handful of genes or samples in a single run. The desire to examine thousands of genes in parallel led to the development of microarrays in the 1990s. The earliest microarrays were produced by robotically depositing probes on glass microscope slides.[8,9] The probes were typically complementary DNAs (cDNAs) hundreds of bases long, and were limited to genes that had been cloned. In the 1980s and 1990s, when little genome sequence information was available, microarray density was limited because relatively few probes could be generated.

High-density arrays became available when Affymetrix pioneered photolithography synthesis methods, as used in the semiconductor industry, for fine-detailed printing of 25-mer oligonucleotides.[8,9] In contrast to the two-color dye approach of spotted microarrays, these microarrays used one fluorescent dye.[9] The high-tech production method meant these arrays were relatively expensive, prohibiting large-scale studies. Specialized setups were required and image acquisition demanded a proprietary Affymetrix scanner. However, as costs and printing quality improved, Affymetrix became the clear leader in microarray technology. Despite the success of this technology platform, Affymetrix microarrays were only available for a limited number of species.

Microarray experiments generated a substantial amount of data, which required the development of new bioinformatics algorithms and statistical methods to assign hybridization signals to the correct genes, based largely on annotations supplied by the commercial vendor or through academic efforts. Scientists using early microarray technologies also needed to consider the

evolving annotation efforts at the time. For example, probes had multiple names or were sometimes mislabeled, complicating data analysis. Significant annotation efforts by the academic and commercial sectors have dramatically improved annotations. However, the substantial increase in genomic and transcriptomic sequencing efforts in recent years means that potential issues in gene/protein annotations should still be considered.

Data analyses and statistical methods for large-scale datasets have advanced substantially in recent years. Many early microarray studies suffered from inadequate statistical rigor, and the importance of applying rigorous statistical analysis to microarray data is now widely recognized. Because of the variety of microarray platforms and technologies originally available, a coalition of scientists was formed to provide standardized protocols and quality control metrics. Data reporting standards should now adhere to the Minimal Information about a Microarray Experiment (MIAME), which has led to consistent documentation of experimental parameters and data analysis. Another consortium effort, the Microarray Quality Control (MAQC), examined microarray reproducibility across labs and provided a valuable reference dataset to understand sources of error. Despite the advent of NGS technology, which generates comparable biological information[10,11] and reveals substantial additional biological insights, Affymetrix microarray technology remains a mature platform of choice with high reproducibility. This platform is ideally suited to experiments where comparability with studies carried out in the past decade is crucial.

2.18.2.1.2 RNA-sequencing

Traditional microarray technologies, like single and dual channel microarrays, are quickly being surpassed by RNA-sequencing (RNA-seq)[11] as the preferred approach for large-scale transcriptomic analysis, particularly as sequencing costs rapidly decrease. The advantages of RNA-seq over microarrays include de novo transcript and gene discovery, and deep (high coverage) sequencing that allows researchers to detect rare variants. The sample preparation and processing steps for RNA-seq are similar to those used for traditional microarray technologies: that is, RNA extraction, RNA fragmentation, and cDNA synthesis, followed by library construction, with the added component of high-throughput sequencing.[12] Millions or billions of reads can be generated, assigned quality scores, aligned to reference genomes, and indexed to coding regions/exons/junctions to identify transcripts of interest. Once the transcript's identity is known or reasonably assigned, the data can be examined for differential gene expression, pathway analysis, or integration with epigenomic, proteomic, or other types of data. These bioinformatics steps require sophisticated open source or commercial bioinformatics applications, and significant in-house investment in personnel with the necessary data analysis expertise.

The major NGS platforms differ in their costs, run times, read sizes, error rates, and computational resource requirements. Illumina uses sequence-by-synthesis technology, whereas Ion Torrent relies on proton detection to decipher sequences. Although the sequencing cost per gigabase varies among sequencing instruments, Illumina sequencing is typically cheaper than other platforms, and thus is widely viewed as the industry leader. Read length is another important difference between platforms, because shorter reads are more challenging to assemble and consume more computational resources.

Sequence data analysis is an essential part of RNA-seq experiments because billions of short reads are generated, and the downstream data analysis is complex. Most NGS platforms have similar postprocessing steps once the raw sequence data are available: read mapping, read counting, normalization to account for process bias, and statistical tests to distinguish true signals from noise (e.g., to detect differential gene expression).[13] Read-quality and read-mapping algorithms are fairly well established. Briefly, assessing read quality begins by removing adaptor sequences, known contaminants, low-quality bases, and over-represented sequences. The remaining reads are considered to be high quality and are appropriate for mapping to a reference genome(s). In contrast, computational approaches to detect differential gene expression, splice variants, and allele-specific expression continue to evolve. The sheer number of bioinformatics options can be overwhelming for those not well-versed in scientific programming and scripting. Organizations often underestimate the level of resources (i.e., bioinformatics personnel) required to set up, develop, maintain, and manage bioinformatics resources. Indeed, Han et al.[12] described 54 distinct programs developed solely for RNA-seq processing and analysis, each with their own specific advantages and disadvantages (some significant and some subtle).

2.18.2.1.3 MicroRNA expression

MicroRNAs (miRNAs) are short noncoding RNAs that regulate gene expression and target essentially all coding transcripts. Because they can silence gene expression, there has been tremendous interest in their use as molecular tools to explore biological processes and pathways. Despite their promise, miRNAs present unique challenges for research, including their short-length, sequence homology within families, inaccurate prediction algorithms, multiple target sequences, and the difficulty in identifying mature miRNAs from pre-miRNAs.[14]

Several technologies have been developed that take advantage of the unique characteristics of miRNAs, particularly their utility in modulating or inhibiting gene expression.[15] These methods, which can be broadly divided into miRNA/non-miRNA-specific, and gene/non-gene-specific, have enabled a wide variety of experimental manipulations in basic research and drug discovery applications, and miRNAs themselves are potential biomarkers. For example, the miRNA expression profile associated with melanoma was reported,[16] and several studies have shown the potential of miRNAs as biomarkers of multiple sclerosis.[17]

Profiling-based methods for identifying miRNA targets span a variety of approaches.[18] Briefly, they can be categorized as protein arrays, microarrays/RNA-seq, proteome profiling, and ribosome mapping. These methods can generally be applied to any type of sample, although the proteome profiling methods require expensive mass spectrometry (MS) and bioinformatics infrastructure and expertise.

Like RNA-seq, the analysis of miRNAs poses several analytical challenges because of the peculiar structure of miRNAs. Thus, identifying miRNA–target interactions remains a key focus of many of the available bioinformatics prediction algorithms, most of which are web-based.[18] Typically, miRNAs have multiple targets and the known and/or putative interactions are recorded in databases such as miRTarbase (experimentally identified interactions) and miRecords (experimentally identified and predicted interactions).[19,20]

2.18.2.1.4 Single-cell transcriptomics

A major challenge in many biological studies is to identify the functional contributions of specific cell types in heterogeneous tissues. The development of methods to isolate single cells and construct libraries from them has led to discoveries that would not have been possible using traditional transcriptomic approaches. The advantage of single-cell transcriptomic sequencing (scRNA-seq, see Fig. 1A) is that it allows researchers to determine the functional contribution of individual cell types to the biological system. This method can also determine how specific cell types contribute to processes such as splicing, allele-specific expression, and cellular signaling.

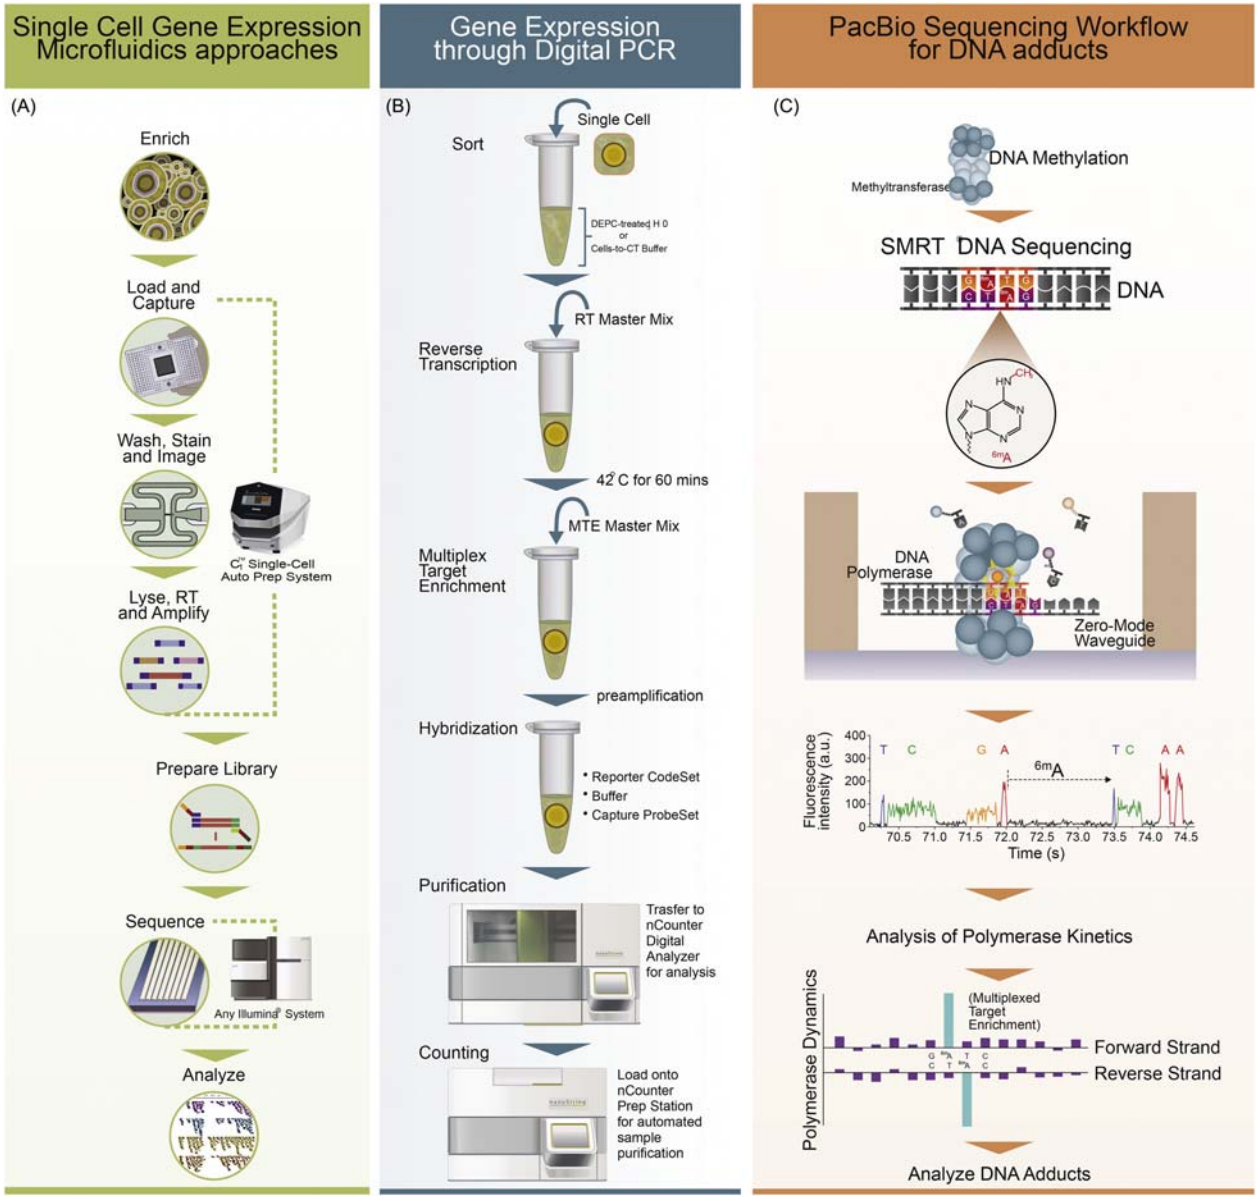

Fig. 1 Some -omics technologies. *Panel* (A) shows the workflow for the next-generation sequencing technology applied to the gene expression measurements in a single cell using microfluidic approaches. *Panel* (B) describes one of the "digital PCR" approaches that counts the gene transcripts directly without using PCR amplification. *Panel* (C) outlines measurements of DNA adducts including DNA methylation using third-generation sequencer RSII from Pacific Biosciences Inc.

Individual cells must be isolated based on their cellular phenotype and/or cell surface markers using methods that maintain the cell in its native state. Commonly used methods include mechanical dispersion followed by enzymatic treatment and subsequent isolation by fluorescence-activated cell sorting, micromanipulation, and laser-capture microdissection.[21] Notably, spatial information about isolated cells as they existed in three-dimensional space is lost, and this may affect the outcomes being explored. Because a single human cell contains 10–30 pg total RNA, amplification by several hundred-thousand-fold, usually by multiple displacement analysis, polymerase chain reaction (PCR), or multiple annealing and looping-based amplification cycles, is required to generate sufficient material for analysis.

Several methods of single-cell analysis have been reviewed by Zhang et al.[21] Single-cell whole genome sequencing is an effective method to screen for copy number variants and single nucleotide variants. However, since the exome encompasses ~1% of the whole genome, yet contains ~85% of variants implicated in disease, single-cell whole exome sequencing often provides sufficiently rich information to examine coding sequences. Other studies have used state-of-the art methods to examine the single-cell genome and transcriptome simultaneously. The scRNA-seq approach has all the advantages of RNA-seq (i.e., it provides a snapshot of the global transcriptome) and offers additional capabilities. For example, emerging protocols have allowed researchers to better understand heterogeneous cell populations by examining cell-to-cell variation and expression level heterogeneity.[22]

Single-cell analytical methods are rapidly evolving. Most single-cell isolation protocols published to date have focused on messenger RNAs, leaving substantial opportunities to develop new methods,[23] such as those to analyze noncoding RNA species. Although isolation protocols and technologies continue to improve, they are labor intensive and require specialized and expensive equipment. In addition, the current protocols result in poor yields, with an estimated recovery of ~10% of the transcriptome, generally resulting in poor sensitivity. Thus, detecting low-abundance transcripts has proven difficult because such transcripts often are at or below the noise level. Several technological improvements are expected in the near future that will further facilitate the effective use of single-cell sequencing approaches, including improved microfluidic cell-isolation systems, amplification methods, and normalization methods.[24,25]

2.18.2.1.5 Quantitative and digital PCR

The PCR method is essential for amplifying nucleic acid sequences, and novel chemistries, instrumentation, and detection methods are still being introduced. Real-time quantitative PCR (qPCR) has been used in numerous research and clinical settings. The qPCR detection methods may be categorized according to the method used to detect the amplified DNA.[26] Intercalating dyes have been available for many years and are inexpensive, but they do not typically distinguish between specific and nonspecific amplified products. Probes that combine donor and acceptor moieties (with different excitation and emission spectra) in the same molecule are also available, but each has unique advantages and disadvantages.

Digital PCR (dPCR, **Fig. 1B**) enables the parallel processing of millions or billions of individual PCR reactions in tiny droplets, facilitating transcriptomic and genomic analyses. For example, combining the advantages of dPCR with NGS provided enhanced and sensitive detection of very-low-level residual chronic myeloid leukemia.[27] That study used the Fludigm (R) platform, one of the first dPCR systems to be developed. A more recently developed direct digital transcript counting system known as the nCounter Gene Expression Assay (NanoString Technologies, Inc.) does not use PCR because of its well-known amplification bias. Instead, nCounter digitally monitors up to 800 different nucleotide probes simultaneously. Because of the complex nature of dPCR experiments, these systems require sophisticated statistical methods for data analysis.[28]

2.18.2.2 Identification of Adduct Formation by Sequencing

Methylation of DNA occurs in all organisms[29,30] and plays an important role in many biological processes. Methylated DNA can be detected using a variety of methods, including immunoprecipitation, bisulfite conversion-based methods, and microarrays. Some methods are better designed to examine genome-wide methylation and are useful to discover methylation events, whereas other methods are better suited to examine methylation events in specific regulatory regions or at loci of interest. Kurdyukov et al. provide a comprehensive overview of methods for analyzing differentially methylated DNA regions.[31] The amount of sample required and CpG (cytosine nucleotide followed by a guanine nucleotide) coverage vary significantly among methods, and both parameters are important considerations when developing experimental strategies. Currently, the leading method to detect the DNA methylation is whole genome bisulfite sequencing, which provides 100% CpG coverage and requires 50–100 ng DNA.

A detailed illustration of the technical and mechanistic differences among genome-wide DNA methylation mapping methods and descriptions of their advantages and disadvantages are provided by Marzese et al.[30] and Olkhov-Mitsel et al.[32] Several methods have been validated in hundreds of publications, and some methods are still evolving as protocols are improved. Nevertheless, there are several robust methods available for use in genome-wide and targeted methylation studies, such as those used by Illumina or Pacific Biosciences RSII sequencing protocols (**Fig. 1**).

Examination of additional types of DNA modifications, beyond just CpG methylation, is collectively referred to as DNA adductomics, or the study of the "exposome." These modifications/adducts arise from chemical and environmental insults and are studied using a variety of methods, especially MS-based methods.[33]

2.18.2.3 Proteomics

Proteins are the workhorses in biological networks. They define biological structures, mediate biological activities, and compute and transmit information among different biological entities. The proteome is the complement of all proteins in a biological system, including their posttranslational modifications, localizations, and specific functional states. Proteomics subsumes a broad range of protein analytical methods that are designed to identify and quantify a large number of proteins simultaneously. Most importantly, these methods have been designed to address central scientific questions in the field, for example, how the proteome of a cell or tissue enables specific biological processes and how these are affected by different disease states. In the systems biology context, the questions are similar, but their emphasis is often shifted toward a more quantitative—and possibly more predictive—understanding of how proteins interact to facilitate the emergent properties of complex adaptive biological systems.

To unravel this complexity, a broad range of complementary proteomics methods are needed to fully capture the functional proteome of a biological system. In the following sections, we discuss the main proteomics methods that are used in systems biology studies to measure (1) protein expression, (2) protein localization, (3) protein translation and degradation, (4) protein modification, (5) protein activity, and (6) protein interactions.

2.18.2.3.1 Protein expression profiling

How the expression level (i.e., abundance) of proteins changes under different conditions or compares across different biological systems is among the most basic information on the functional involvement of proteins in a biological process. There are several alternative methods to profile protein expression, which can be broadly classified as affinity-reagent and MS-based methods.

Antibodies are the classical affinity reagents used to profile protein expression. Currently, and despite its limitations, the western blot is still the most commonly used assay to measure changes in protein expression. High-throughput versions have been developed[34,35]; for example, Ciaccio et al. developed microwestern arrays that were used to reconstruct the epidermal growth factor (EGFR) signaling network.[34] However, due to their dimension, even these miniaturized western blot methods are limited to a few target proteins. Protein arrays, which are extensions of classical enzyme-linked immunosorbent assays, allow for higher throughput and more sensitive protein quantification.[36] For these assays, antibodies are spotted at defined positions onto a solid support, the generated array is incubated with the protein sample to be tested, and binding to the spotted antibodies is measured—usually with another pool of detection antibodies. For example, Straussman et al. used antibody arrays to discover the role of hepatocyte growth factor signaling in the innate resistance of melanomas to targeted inhibitor treatment.[37] Alternatively, for reverse-phase protein arrays, the protein samples to be profiled are spotted onto a solid support (e.g., a slide) and are then directly probed with labeled antibodies against the targets of interest.[36]

In addition to antibodies, alternative affinity probes offer specific analytical benefits. For example, aptamers are DNA or RNA molecules that can form secondary or tertiary structures capable of specifically binding to proteins and other cellular targets.[38] Considered as the chemical equivalent to antibodies, aptamers can be used in a microarray format to profile protein expression.[39] Another advantage is that they can support hybridization to DNA microarrays.[40] For example, this method was used recently to identify protein markers of aging.[41]

Affinity-reagent-based methods are also used to profile protein expression, but these methods critically depend on the availability of high-quality affinity reagents.[42–44] For example, one study tested 49 commercially available antibodies against 19 signaling receptors, and found that most of them bound to more than one target.[45] Another study showed that approximately one-quarter of 246 antibodies used in epigenetic studies lacked specificity.[46]

Methods based on MS are gaining popularity for protein expression profiling.[47] This is mainly due to their high specificity and the ability to conduct experiments without predefined target lists (untargeted approaches). The data from such analyses can then be complemented with highly specific and quantitative MS-based targeted assays in the follow-up studies. Such MS-based methods are further facilitated by recent developments in instrumentation and methodology that increase the depth and sensitivity of proteome analyses.[48–50]

MS-based protein profiling can be performed as either a top-down approach, where intact proteins are analyzed directly, or more commonly as a "bottom-up" or "shotgun" approach. In the latter case, the isolated proteins are first cleaved into peptides with a specific protease (most commonly, trypsin and Lys-C) and subsequent (chromatographic) separations, identifications, and quantifications are conducted at the peptide level.[51]

While this "divide and conquer" approach eases the analytical steps, it requires specific tools to reassemble peptide information into protein information, and to prevent the loss of correlations between different regions of the same protein. Peptide identification is at the core of "bottom-up" approaches. Commonly, the peptides injected into the mass spectrometer are identified based on two levels of information: the molecular weight of the peptide, and its fragmentation pattern. For identification, the experimental peptide fragmentation pattern is matched to all theoretical fragmentation patterns of the peptides encoded in the genome of the studied organism. Statistical methods are used to calculate the probability of wrong assignments, which yields highly reliable peptide identification (e.g., Refs. 52,53).

Peptide/protein quantification is the next critical component of protein profiling approaches. The available methods differ in their quantitative accuracy and ease of implementation. Generally, MS-based quantification methods are divided into those that work on native peptides (label-free methods) and those that require peptide modification (label-based methods). The simplest label-free quantification method is spectral counting.[54] It relies on the fact that peptide identification in the "bottom-up" workflow represents a statistical sampling procedure in which the probability of identifying a peptide is proportional to its abundance. In this

rather coarse quantification method, the number of identifications assigned to a given protein is used as a measure of its abundance. More recent label-free quantification approaches rely on integrating the signals of the peptide elution peaks as the measure of abundance—essentially, as a measure of the total number of ions detected for a given peptide.[55] Recently, label-free quantification approaches have improved significantly and are gaining popularity, especially because of their ease of implementation.

Label-based methods require modification of the sample before analysis. The main objective is to make peptides derived from different samples distinguishable, which then allows for multiplexed analysis of different samples. The advantage is that the concurrent processing and analysis of these multiplexed samples ensures that the quantities of derived peptide are directly comparable by removing the variability that is introduced by separate analytical steps. Commonly, these label-based methods rely on the use of heavy isotopes to introduce a mass shift between the different multiplexed samples. One commonly used method is stable isotope labeling in cell culture.[56] In the original implementation of this method, specific isotope-labeled amino acids are incorporated into the whole proteome of a cell culture. Cell cultures that are experimentally compared (e.g., control vs. treatment) are labeled with isotope-labeled amino acids with a different mass for each condition. After the experiment, the samples to be compared are mixed and analyzed using the conventional label-free workflow. Because the peptides derived from the different conditions are shifted in mass, the elution peaks can be integrated separately and directly compared among multiplexed samples.

In other label-based quantification methods, the peptide modifications are introduced at a later step and do not require metabolic labeling. This is crucial when metabolic labeling is not possible, for example, in the case of most clinical samples. Isobaric-tag-based quantification (e.g., iTRAQ® and tandem mass tag (TMT) labeling) relies on chemical modification of the isolated peptides after the protease digestion step (**Fig. 2**).[57–59] Again, different samples are labeled with different tags, pooled, and analyzed together by MS. Currently, this method allows for multiplexing of up to 10 samples; that is, the use of up to 10 distinguishable tags. In these methods, "isobaric" indicates that each tag of a series has the same total mass; that is, a given tagged peptide derived from different multiplexed samples is indistinguishable at the level of the whole peptide. Only during the peptide fragmentation step are reporter ions with specific masses released from each sample. The intensity ratios between these reporter ions are used for relative quantification. Of note for systems biology applications, these isobaric-tag methods are especially good for detecting statistical differences in protein expression, but tend to underestimate the ratios between reporter ions.[60,61]

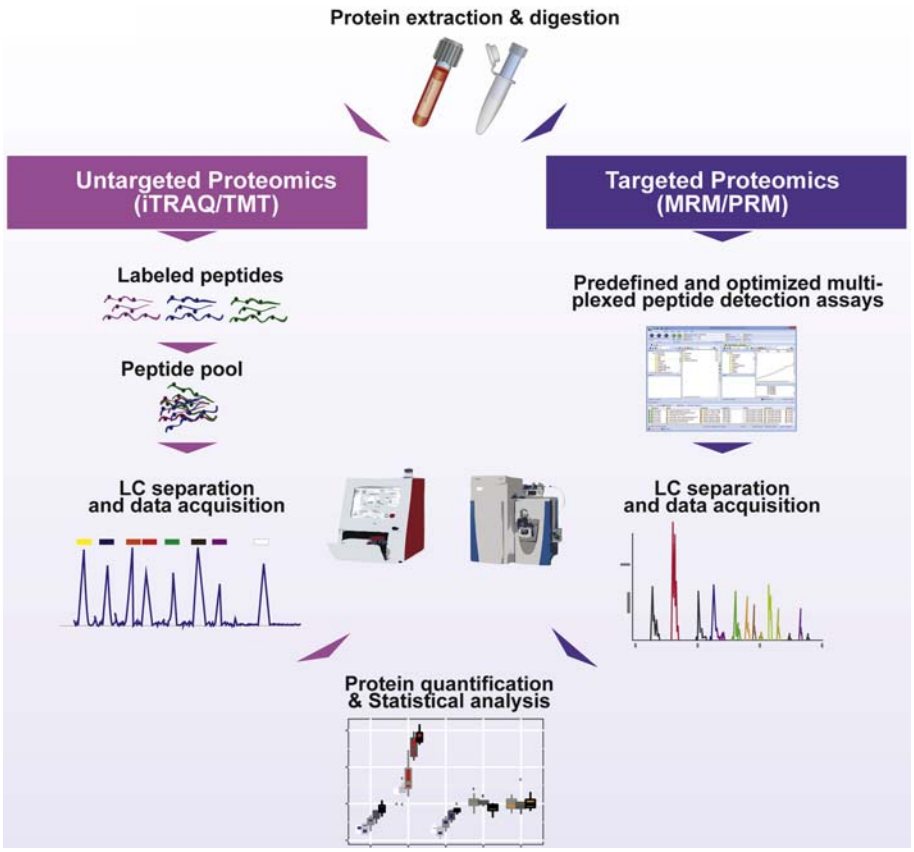

Fig. 2 Mass spectrometry-based proteomics workflows. (*Left*) Untargeted proteomics workflow with isobaric-tag based quantification (iTRAQ or TMT). (*Right*) Targeted proteomics workflow with multiple reaction monitoring (MRM) or parallel reaction monitoring (PRM). The untargeted (isobaric-tag) workflow allows for multiplexed analyses of peptide sample pools with different chemical tags/labels for each sample. The targeted workflow allows for more accurate quantification of a (smaller) predefined set of peptides/proteins.

All of these methods were established for untargeted analyses of proteomes. They work without predefining or optimizing assays for a specific set of peptides/proteins. However, as these methods rely on statistical sampling of the proteome, consistency of the measurements across MS runs is not always guaranteed, and it is difficult to validate assays for specific peptide sets. This is why "shotgun" proteomics methods are usually complemented by targeted proteomics methods, especially for clinical applications or to establish systems biology models.[62,63] While the general detection and quantification principles are similar, targeted proteomics—for example, the multiple reaction monitoring (MRM) and parallel reaction monitoring (PRM) methods—relies on predefined (and optimized) specific multiplexed peptide detection assays (see **Fig. 2** for details). To further increase the accuracy of quantification, a heavy-isotope-labeled internal standard peptide is commonly included for each quantified peptide. This strategy supports robust quantification, even among different laboratories.[64]

Finally, data-independent (DIA) acquisition methods are becoming increasingly popular. These methods are conceptually located between untargeted and targeted proteomics approaches and combine untargeted acquisition with targeted computational analyses of the proteome.[52] In these methods, the mass spectrometer is programmed to acquire the fragmentation patterns (and possibly peptide masses) of a large fraction of the proteome. Then, specific spectral libraries are used to deconvolute these complex fragmentation datasets and compute the quantities of peptides and proteins. The advantages of these methods include their high quantification accuracy with broad proteome coverage, the ease of comparisons across MS runs with limited missing values, and the ability for targeted reanalysis of the same data sets for different target sets.[49,52]

2.18.2.3.2 Spatial proteomics

The functions of proteins strongly depend on their localization in the cell and tissues. For example, translocation of transcription factors to the nucleus is a common regulatory mechanism that is also a central element of several systems biology models of signal transduction.[65]

Antibody-based assays to determine the localization of proteins, using either colorimetric or immunofluorescence visualization, are a mainstay of cellular biology.[66] More recently, these techniques have been adapted to characterize the localization of larger sets of proteins. For example, Uhlen et al. generated a map of the human tissue proteome that provided spatial localization of proteins from the tissue level to the single-cell level.[67] For this purpose, the authors combined RNA-seq and an extensive immunohistochemistry data set (more than 13 million images annotated by pathologists). The results of this *tour de force* are available at www.proteinatlas.org. In a related project, Stadler et al. conducted a large-scale subcellular localization study for more than 500 human proteins, which were detected by visualizing antibody-based immunofluorescence and expressed fluorescent fusion proteins.[68] These two studies represent large-scale projects that rely on extensive infrastructure, and will likely be out of reach for individual labs. Recently, however, a relatively simple protocol for multiplexed immunofluorescence analysis was described.[69] Named cyclic immunofluorescence (CycIF), this method makes use of alternating antibody staining and bleaching cycles. In the initial report, CycIF allowed for simultaneous expression profiling of up to 15 targets in a cellular population. A similar approach was taken by Gerdes et al. for the multiplexed single-cell analysis of formalin-fixed, paraffin-embedded cancer tissue.[70]

Alternatively, MS-based methods are also available to characterize the localization of proteins. Commonly, these rely on a combination of fractionation methods (e.g., of subcellular compartments or cell types), with MS-based identification and quantification of the differentially enriched proteome fractions as described in the "**Protein expression profiling**" section. Boisvert et al. used this approach to analyze the proteome response to DNA damage in three different cellular compartments: the cytoplasm, the nucleus, and the nucleolus.[71] An interesting result was that DNA damage triggered the relocation of proteasomal components into the nucleus, which was likely related to changes in their intricate intracellular dynamics under different cellular states and responses.[72] Recently, Christoforou et al. further refined this approach to analyze the spatial proteome of mouse pluripotent stem cells.[73] For this, digested proteins from 10 differentially enriched subcellular fractions (cytosol, chromatin-enriched, and eight density-gradient fractions) were labeled with 10-plex isobaric TMT and then identified and quantified by liquid chromatography coupled with MS (LC–MS/MS). These analyses provided detailed localization information for more than 5000 proteins and yielded insights into organelle structures, protein complex localizations, and the localization of protein isoforms.

Other methods combine MS with imaging approaches to reveal the localization of proteins. In matrix-assisted laser desorption/ionization imaging MS, ion spectra of a tissue slice are spatially resolved.[74] Tissue sections are placed on a solid support and coated with a chemical matrix that supports desorption and ionization of molecules when irradiated by a laser. During the experiment, the tissue is scanned by a laser and the ion spectra that are measured for each x,y-coordinate are compiled into a two-dimensional map of ion intensities. However, identification of proteins from the obtained complex ion spectra remains a challenge.[75] An alternative with a much lower spatial resolution is the combination of laser-capture microdissection with LC–MS/MS-based expression proteomics.[76] Recently, this technique was used to analyze protein expression in neurons from the temporal cortex of patients with Alzheimer's disease.[77] Finally, the spatially targeted optical microproteomics (STOMP) method has been developed to provide a higher resolution analysis.[78] In this method, two-photon laser scanning microscopy is used for specific affinity photo-labeling of proteins in a selected tissue region. This allows for specific enrichment and MS-based identification of the photo-labeled proteins in the selected tissue region. In the test case, STOMP was able to identify known and novel amyloid plaque components from Alzheimer's disease samples.

2.18.2.3.3 Proteome synthesis and degradation

Protein levels are regulated both at the level of protein synthesis and degradation. The hypoxia-inducible transcription factors (HIF) are key regulators of the hypoxic stress response, and are examples of proteins with tightly regulated degradation.[79] Under normoxic

conditions, HIFs are rapidly degraded by a mechanism that involves hydroxylation of key proline residues by members of the oxygen-sensitive prolyl hydroxylase enzyme family.[80] By contrast, low-oxygen conditions prevent hydroxylation and protein degradation, resulting in rapidly increasing levels of the HIFs that trigger the activation of hypoxic stress-response programs. As this hypoxic stress response is central to several biological processes including cancer development, systems biology models have been devised to better understand this response. For example, Nguyen et al. derived a mathematical model of HIF-1a regulation by hypoxia, which was able to confirm the overall network topology and provided insights into the complexity of the regulation of HIf-1a degradation during the hypoxic stress response.[81]

More tools to measure degradation and synthesis rates at the proteome-scale are needed to expand our knowledge of the role of regulated protein degradation and synthesis.[82] Several MS-based methods have been devised, which combine isotope labeling and/or pharmacological inhibition of translation with quantitative LC–MS/MS-based proteomics measurements. For example, Schwannhauser et al. developed a method for the global analysis of protein translation using pulsed addition of heavy-isotope-labeled amino acids to a cell culture.[83] The labeled amino acids are taken up by the cells and incorporated into newly synthesized proteins. Subsequently, MS-based proteomics analyses allow for proteome-wide measurement of the incorporation of these isotope-labeled amino acids into newly synthesized proteins, yielding estimates of relative protein translation rates. Using this approach, Selbach et al. demonstrated the global but relatively mild effects of miRNAs on protein synthesis.[84] To measure protein degradation rates, Larance et al. globally blocked translation with the inhibitor cycloheximide and measured the amounts of remaining proteins by LC–MS/MS-based proteomics.[85] This analysis reemphasized the importance of regulated protein degradation in regulating the cell cycle.

To complement these analyses, proteomics methods that support the global analysis of protein ubiquitination have been devised. Polyubiquitination of proteins serves as a specific tag to target proteins for proteasomal degradation, and a whole machinery of specific and well-regulated ubiquitin ligases controls this process.[86] Upon oxidative stress, the ubiquitin ligase adaptor protein Keap1 is inactivated, which stabilizes its substrate Nrf2—a key transcriptional regulator of the oxidative stress response.[87] Proteomics studies to measure global protein ubiquitination commonly rely on an affinity-enrichment strategy for ubiquitinated peptides.[88] To enrich ubiquitinated peptides, Kim et al. used a monoclonal antibody that recognizes diglycine-containing isopeptides. These isopeptides are generated when ubiquitinated proteins are digested during sample processing for LC–MS/MS-based quantitative proteomics analysis.[89] This strategy quantified 19,000 ubiquitinated peptides in approximately 5000 proteins.

2.18.2.3.4 Protein phosphorylation profiling

As already discussed for protein ubiquitination, specific protein modifications are central to the regulation of protein levels and activities.[90] Phosphorylation—likely the best understood protein modification—regulates enzymatic activity, stability, complex formation, and localization. All of these cellular processes are tightly regulated by the opposing activities of kinases and phosphatases, which are organized into intricate phosphorylation networks that function as sophisticated signal processing units to elicit specific cellular responses.[91]

Quantitative phosphorylation profiling by MS is a well-established technique.[92] Analogous to the protein ubiquitination analysis, after digestion of proteins into peptides, phosphorylated peptides are enriched before being identified and quantified by MS. Several different phospho-peptide enrichment methods are available. Because of the availability of high-affinity antibodies for tyrosine (Tyr)-phosphorylated proteins, antibody affinity enrichment has been the centerpiece for phospho-profiling studies focused on the effects on phospho-Tyr-signaling. For example, Rubbi et al. conducted a phospho-Tyr profiling study to dissect the regulatory interactions between the BCR-ABL1 oncogene and Src-family kinases in leukemia.[93] Drake et al. also used this approach to identify druggable kinases in prostate cancer tissue samples.[94] Antibody-based enrichment to profile serine and threonine phosphorylation is hampered by the lack of highly specific anti-phospho-serine/threonine antibodies, although phosphorylation-motif-specific antibodies have recently become available (e.g., for the AKT kinase phosphorylation motif).[95,96] Thus, metal-based affinity enrichment is most commonly used for global phospho-profiling of phospho-serine/-threonine/-Tyr peptides. Titanium dioxide and immobilized iron ions are commonly used as affinity reagents because of their strong affinity for phosphorylated peptides (e.g., Refs. 97–100). Of note, because of the lower abundance of phospho-Tyr residues, their coverage can be limited and the combination of antibody- and metal-based affinity-enrichment approaches can be beneficial.[101]

A common challenge encountered with these phospho-profiling methods is that they require a relatively large sample input (sometimes in the milligram range) and have a low throughput. To allow for high-throughput analyses of phospho-proteomes, Humphrey et al. recently described a scalable phosphoproteomics platform that can quantify hundreds of phospho-proteomes at a depth of $>10{,}000$ phosphorylation sites.[102] This was achieved through streamlined protocols and parallel processing in 96-well plates. In the initial study, this method was used to characterize the phospho-proteome response of mouse liver to insulin stimulation at a high temporal resolution (starting <15 s after insulin stimulation) and depth ($>25{,}000$ phosphorylation sites). Another recent study demonstrated that phospho-peptide enrichment coupled with targeted MS can accurately quantify signaling networks, such as the DNA damage signaling network.[103] Clearly, while providing lower coverage (107 phospho-sites in that case), such targeted and well-validated quantification methods are well suited to generate data for cellular dynamics models and for use in a clinical setting.

Beyond phospho-profiling, related affinity-enrichment and MS assays have been developed for various other protein modifications, including acetylation,[104] methylation,[105] O-linked β-*N*-acetylglucosamine modification,[106] and lipid modification.[107]

2.18.2.3.5 Proteome activity profiling

Several proteomics methods can either measure protein activity directly or provide readouts that depend on the activity state of the proteins. Kinase inhibitor profiling with "kinobeads" is an example of the latter.[108] In this chemical proteomics approach, a collection of nonselective kinase inhibitors is immobilized onto beads ("kinobeads"). Because these kinase inhibitors target the active sites of a broad collection of kinases, the beads can be used as affinity reagents before the LC–MS/MS analysis of the kinome; that is, the set of all (bound) kinases. Importantly, because the active sites are targeted, binding of other active site inhibitors will interfere with binding and deplete the targeted kinases in this experiment. In their original report on this method, Bantscheff et al. used it to characterize kinase inhibitor profiles for leukemia and identified the kinases DDR1 and the oxidoreductase NQO2 as novel targets of the BCRABL1 inhibitor imatinib.[108]

Active site probes can assess the activities of enzymes in the proteome more directly.[109] At the core of this technology lie chemical probes that are designed to covalently bind to the active site of the enzyme class of interest. These probes carry tags that, for example, allow for affinity purification of the modified proteins/peptides and their subsequent identification and quantification by LC–MS/MS (or western blot). Probes are available for a broad range of enzyme classes including serine hydrolases, cysteine proteases, metallohydrolases, kinases, and other nucleotide-binding proteins. A protocol has been established to quantify proteasome activity in living cells.[110] This protocol was used to demonstrate that interferon gamma rapidly induced immunoproteasome activities in respiratory cells of the lung. This result demonstrated that nonimmune cells can contribute to the adaptive immune response to intracellular infections.[111]

Even more direct proteomics assays to profile enzyme activities have been devised, including peptide microarrays to profile kinase activities.[112,113] For this, a large collection of peptides with kinase recognition sites are synthesized and arrayed on a microarray slide. To measure kinase activities, these chips are incubated with purified kinases or cellular lysates and fluorescently tagged with anti-phospho-peptide antibodies. Alternatively, phospho-specific affinity reagents are used to produce a readout of the kinase activities (i.e., phosphorylation levels). Similar peptide microarrays have been developed to quantify the activities of other enzymes. For example, Rauh et al. developed a peptide microarray to characterize the activity of protein deacetylases.[114] Kubota et al. also devised a MS-based strategy to measure kinase activities.[115] In this assay, synthesized peptide libraries with a preselected distribution of kinase recognition sites are incubated with cellular lysates. Phosphorylation of these peptides is then quantitatively assessed using LC–MS/MS and kinase activity patterns are compared among samples.

2.18.2.3.6 Protein interaction profiling

Proteins function in the context of complex biological networks. Unraveling these interactions is at the core of systems biology research, and several approaches have been devised to analyze interactions among proteins on a large scale.[116,117]

Functional genomics approaches to detect protein interactions rely on the engineered expression of potentially interacting molecules in a cell. Such systems are designed in a way that interacting molecules result either in cell survival or the expression of a detectable marker. The yeast two-hybrid (Y2H) system is the best-known assay to detect protein interactions. In the classical Y2H assay, the two proteins to be tested are coexpressed in yeast cells, one fused to the DNA-binding domain and the other to the transactivation domain of a transcription factor. If the two proteins interact, a functionally active transcription factor is reconstituted, which then mediates the expression of a reporter gene that either allows the yeast colonies to grow in the presence of a toxicant, or that can be detected with a colorimetric assay. Large-scale versions of this assay have been devised, in which many interactions between many protein pairs are tested in an array format. The growth or specific color-staining of yeast colonies in the array indicate specific protein–protein interactions (PPIs). Genome-scale Y2H approaches have been used to define PPI networks in viruses, bacteria, and human cells (e.g., Refs. 118–121).

Protein and peptide arrays have also been used to characterize protein interaction networks. In an early study, Jones et al. constructed protein microarrays comprising nearly all Src homology 2 (SH2) and phosphotyrosine-binding domains of the human genome, and probed them to detect binding to 61 Tyr-phosphorylated peptides from the EGFR receptor family.[122] Measuring the equilibrium dissociation constants of all these interactions allowed for quantitative comparisons of the binding specificities among the various family members—with potential implications for their roles as oncogenic drivers. More recently, Yu et al. established "self-assembly" protein arrays with 10,000 human proteins, and identified their interactions with two effector proteins (SidM and LidA) from the bacterium *Legionella pneumophila*.[123] To assemble the human protein array, the authors used the "nucleic acid-programmable protein array" approach, in which DNA encoding human genes is spotted onto a microarray slide, and then proteins are synthesized in situ through in vitro transcription/translation. Because the translated proteins carry a tag, they are directly captured on the array by cospotted anti-tag antibodies, and can then be probed by bacterial effector proteins. This assay was able to reproduce 18 of the 20 known targets for these effectors and revealed three novel host interaction proteins.

Protein microarrays are complemented by peptide microarrays. Peptide microarrays are limited to the detection of interactions with linear epitopes, but are easier to produce and allow for more control over the spotted peptide sequences, including their post-translational modifications. Recently, Tinti et al. used this technology to profile the binding landscape of SH2 domains to the human phospho-Tyr peptidome. In total, 6202 phosphopeptides with phospho-Tyr in the center position were synthesized and spotted in triplicate onto a microarray slide. Afterward, these chips were probed with a collection of 99 human SH2 domains. The data obtained supported the creation of a probabilistic interaction network for SH2 domains and suggested intriguing biological links; for example, between the Tyr-phosphatase SHP2 and the phosphorylated Tyr in the extracellular signal-regulated kinase activation loop in growth factor signaling.

Affinity purification of protein complexes coupled with identification of complex components by LC–MS/MS is an effective and proven method to characterize protein interaction networks.[124] These approaches are based on classical protein pulldown and coimmunoprecipitation protocols, but LC–MS/MS is used instead of western blots to identify and quantify the components of the protein complex. The main challenge of these approaches is that they require high-affinity binding reagents for the proteins of interest. Commonly, this challenge is circumvented by engineered expression of proteins with a tag for which high-affinity purification reagents are readily available. For example, an early affinity purification study on yeast used a library of yeast strains that were engineered to express each yeast gene as an affinity-tagged fusion protein.[125] For mammalian systems, viral delivery systems, bacterial artificial chromosome transgenics,[126] and most recently, genome engineering[127] have been used to express tagged proteins for affinity purification. Another common challenge is how to distinguish true from false-positive interactions. For this, quantitative MS can distinguish between specific and unspecific binders.[128,129] Recently, Hein et al. used a protein complex and an LC–MS/MS enrichment approach to define an extensive human interaction network of 5400 proteins and 28,500 interactions.[130] The authors expressed 1330 GFP-tagged proteins under the control of their native promoter in a human cell line, affinity-enriched the protein complexes with anti-GFP antibodies, and then conducted label-free quantification of these protein complexes. Importantly, this quantitative approach provided measures of the specificity, stoichiometry, and abundance of human protein complexes, and demonstrated that protein networks are dominated by weak interactions, with only a few stable complexes with balanced protein stoichiometry.

Beyond PPIs, proteomics methods have been developed to characterize protein binding to other classes of molecules. This includes methods to identify targets for pharmacological inhibitors,[131] natural products,[132] and toxicants.[133]

2.18.2.3.7 Special considerations and outlook

Systems biology is about understanding how biological functions and responses emerge from the complex, dynamic interactions in biological networks. Proteomics methods cover a broad range of the proteomic space, from expression levels, to modifications, to activities, to interactions. Beyond providing insights into the roles of individual proteins, proteomics approaches have demonstrated their value to further our understanding of systems-level properties—for example, how robustness is built into biological networks,[134] how modularity is used as a basic building principle to structure biological functions,[125,128] how complex interactions within signaling networks govern cellular responses,[135] and how complex signatures can identify diseases.[136]

Clearly, different systems-level questions will benefit from different proteomics methods. When the protein properties of interest (e.g., localization, posttranslational modification) have been selected, the main consideration is the potential tradeoff between quantitative accuracy and sample throughput. As discussed earlier, protein quantification is constantly improving, allowing for larger numbers of proteins to be quantified with high accuracy. Protein and peptide array methods are high-throughput, but rely on the availability of highly specific affinity reagents. Targeted proteomics methods are best suited for MS-based assays if precise quantification of a few proteins is required (e.g., for pharmacodynamics, PD modeling approaches).[103] If global network dynamics is the topic of interest, then nontargeted methods are better suited. DIA MS forms a middle ground between the two classical extremes and has the potential to combine the advantages of both worlds toward broad and accurate quantification of proteome responses.[137]

Proteomics instrumentation and methods are still rapidly evolving. It is expected that these improved and more accessible "third-generation" proteomics tools will be indispensable in cell biology and molecular medicine in the future.[138] Such methods will allow us to reach a true systems-level understanding of dynamic physiological and disease processes. Clearly, to this end, integration of proteomics data with other data modalities presented in this article is the key to gaining a comprehensive understanding of biological systems.[139,140]

2.18.2.4 Metabolomics

Metabolomics aims to provide a comprehensive description of the metabolome representing all cellular metabolites in one living system at a specific time. With respect to systems biology approaches, metabolomics adds to the classical -omics technologies (i.e., transcriptomics and proteomics) for a complementary and holistic understanding of the behavior of a living system within its environment. The characterization of the cellular metabolome represents the intermediates and end-products of all enzymatic reactions in a biological cell. This information allows for the evaluation of the cell's biochemical activity and, furthermore, its biochemical networks, which predict the organism's molecular physiology and changes in phenotype.[141,142] In addition to metabolomics terminology focusing on endogenous metabolites alone, metabonomics includes the characterization of metabolites related to external stimuli, like xenobiotic metabolites, dietary metabolites, responses to disease, or extragenomic factors such as gut microflora. Besides unbiased hypothesis-free nontargeted approaches, several hypothesis-directed approaches have been also established. These include metabolic profiling[143–145] focused on predefined metabolites related to specific pathways of interest, and metabolic fingerprinting[143] to provide rapid, high-throughput sample classification information and metabolite target analysis for quantitative analysis of a limited number of metabolites for specific pathways. As a result of rapidly growing interest from academia, industry, and government, metabolomics has been a part of the National Institute for Health road map initiative since 2003.[146] Along with the immense growth in metabolomics technologies, this broad interest has led to strong positioning of this field in the life sciences.

Metabolomics covers a wide range of research areas, including plant biology,[142,147] biotechnology industrial processes,[148] toxicology,[149] drug development,[150] clinical diagnostics,[143,151] biomedical research[152] including diagnostic and prognostic

biomarkers, responses to medical treatment,[146] and environmental factors impacting human health. Specific examples of how this and other -omics technologies can advance different fields are discussed elsewhere in the article.

2.18.2.4.1 Methods and recent developments

Despite the tremendous progress in instrumentation technologies, no single analytical technology can cover the metabolome comprehensively. Usually, multiple methods with complementary characteristics are used. Nuclear magnetic resonance (NMR) and MS techniques are most commonly used in metabolomics research,[153,154] while different separation techniques coupled to MS platforms are chosen if greater sensitivity is required.[155] Shotgun approaches that avoid separating the sample matrix before MS were established some time ago for high-throughput lipidomics.[156] Researchers from Eidgenössische Technische Hochschule (ETH) Zurich recently developed a shotgun approach for real-time metabolome profiling of about 300 metabolites to monitor metabolite dynamics.[157] Separation techniques are required for comprehensive metabolome characterization because of the complex nature of the cellular matrix. Gas chromatography (GC) and LC coupled to MS (GC/MS and LC/MS, respectively) are widely used in combination because of their complementary coverage of the range of metabolites. Each of them provides a multiplicity of methods to analyze different metabolite classes. A typical workflow is shown in Fig. 3.

Complex sample preparation procedures represent a high risk of changing the sample composition. Therefore, sample preparation is generally kept as simple as possible, and is preferably limited to quenching of metabolism and metabolite extraction using the crude extract for analyses.[158] Nevertheless, more complex sample preparation procedures are sometimes unavoidable. Such procedures include protein precipitation, solvent changes for GC/MS analysis due to incompatibility of aqueous media, and/or derivatization procedures. Recently, scientists developed a technique for direct injection of aqueous media samples from incubated microsomal or S9 fractions, cell culture media, or smoke-bubbled phosphate buffered saline in two-dimensional GC coupled with time-of-flight MS (GC × GC-TOF MS).[159,160]

2.18.2.4.2 Mass spectrometric platforms for metabolomics

Many separation and MS methodologies have been established for each instrument platform. Most often, multiple complementary methods are used within a platform to achieve the most comprehensive metabolome coverage. In addition to the key LC/MS and GC/MS platforms, capillary electrophoresis coupled to MS (CE-MS) has recently been established in the metabolomics research. This technique is relevant for the metabolomics research because of its complementary character, in that it allows for analyses of ionic and highly polar metabolites.[161,162]

2.18.2.4.2.1 LC/MS

LC-based separations for nontargeted analyses are usually based on reversed-phase chromatography, hydrophilic interaction chromatography, or ion exchange chromatography.[163–165] Developments in column stationary phases have provided a tremendous diversity of separation properties. New polymer-coated core shell stationary phases provide stability and robustness for large sample series, and well-defined small particles enlarge the surface area for analyte-to-stationary phase interactions, which are beneficial for effective separation. The high pressure stability of modern stationary phases increases the sensitivity and decreases the separation times of modern Ultra Performance Liquid Chromatography applications, allowing for high-throughput capabilities. The combination of MS and LC has evolved dramatically, especially in life science research. The traditional LC–MS/MS triple-quadrupole instrumentation has largely been replaced by accurate mass analyzers. The TOF mass analyzers that provide sufficient mass resolution and mass accuracy are frequently combined with a quadrupole mass filter and a collision cell in the front end, allowing for collision-induced dissociation (CID) fragmentation experiments (MS^2). The obtained fragmentation mass spectra are a valuable tool for metabolite confirmation and, to some extent, metabolite identification. Recent revolutionary MS concepts based on Thermo Electron Corporation's Orbitrap technology provide unprecedented mass accuracy, resolution, and fragmentation capabilities for MS^n experiments, combined with high sensitivity and robustness.[165,166] Different ionization techniques are often used to broaden the metabolite coverage. Commonly used ionization techniques include atmospheric pressure ionization using electrospray ionization (ESI) in positive and negative modes, as well as atmospheric pressure chemical ionization (CI) to complement the ESI data.

In addition to the classical approach of acquiring data in full-scan mode followed by, or combined with, data-dependent MS^2, several MS-based generic substance class screening approaches have been established. These focus on specific metabolite classes using either diagnostic fragment ions; for example, glycerophospholipid classes of phosphatidylcholine (m/z 184), phosphatidylethanolamine (m/z 141), and phosphatidylinositol (m/z 241), or characteristic neutral losses of the head group of phosphatidylserine (loss of m/z 185).[167] Traditional approaches to screen glutathione adducts use the characteristic neutral loss of pyroglutamate (m/z 129) and the diagnostic precursor ion in negative ionization mode (m/z 272).[168] Recent improvements to stable isotope-dilution techniques for generic screening of glutathione adducts have increased the comprehensiveness, selectivity, and sensitivity of these methods.[169,170] A mixture of stable isotope-labeled and nonlabeled glutathione is applied as a nucleophile to conjugate electrophilic compounds or metabolites, for example, in microsomal bioactivation experiments. High-resolution accurate MS is then carried out to screen the resulting specific isotopic fingerprint of the conjugates. Scientists at Philip Morris International have established a generic stable isotope-dilution-based glutathione adducts screening method to identify electrophilic smoke constituents and metabolites, including downstream reduction metabolites, derived from bioactivation of smoke compounds using microsomal and S9 fractions.[171] This method was compared with those using different nucleophiles to screen generic electrophilic compounds.[172]

2.18.2.4.2.2 GC/MS

For decades, GC/MS has been a well-known technology in metabolomics research. Various stationary phase materials covering a wide range of polarities are available for separation. These materials are based on chemically immobilized modified silicon oil, poly ethylene glycol, and recently developed ionic liquids.[173] Mass spectrometers have evolved from traditional unit mass resolution single-quadrupole or triple-quadrupole technologies toward TOF analyzers with fast data acquisition rates, accurate mass and high resolution, often combined with MS^2 capabilities, and finally toward the recently introduced GC-coupled Orbitrap technology.[174,175] Newly developed GC × GC-TOF MS methods provide comprehensive chemical characterization in metabolomics. These techniques are capable of chromatographically resolving highly complex matrices and thus, represent a standard technique in GC/MS-based metabolomics approaches.[176,177] Such methods will further benefit from recently introduced GC × GC high-resolution accurate mass TOF technology.[178] The most common ionization technique in GC/MS-based metabolomics is electron ionization (EI), which provides standardized high-energy fragmentation mass spectra that allow for simple and fast structure identification based on comparisons of the mass spectra with those in commercial databases. The structural identification of compounds that are not present in commercial databases requires additional information (besides manual interpretation of EI mass spectra) derived from low-energy ionization techniques like CI in positive and negative ionization modes. In CI, different gases (e.g., methane, isobutene, or ammonia) are used to adduct charged CI molecules to the analyte. Information on the molecular mass of the adduct provides the elemental composition. Further information on compound substructures can be obtained by CID fragmentation with different collision energies.

2.18.2.4.2.3 Spectral processing

Metabolomics studies yield highly complex data with respect to chemical composition. Typically, several thousand compounds can be separated and detected with a specific method. However, the huge number of samples that are needed to address biological

variance require advanced spectral processing strategies. Spectral processing aims to reproducibly and sensitively quantify of all the detectable features (information subsets; e.g., a specific ion intrinsically related to a metabolite) in the complete sample set while reducing the number of false positives, including system-immanent features, often referred to as noise reduction. Huge metabolomics datasets require data reduction strategies that do not significantly reduce the information content (e.g., conversion of accurate MS profile data into centroidic data).

Spectral processing strategies for MS generally consist of multiple processing steps that can differ slightly according to the data-processing software. Spectral preprocessing typically includes spectral deconvolution, peak detection and integration, and peak alignment and normalization.[153,179,180]

The aim of spectral preprocessing is to separate sample-related spectral information from systemic noise, thereby increasing spectral quality. Strategies for noise reduction include simple baseline subtraction or more sophisticated spectral deconvolution algorithms. The LC/MS mass spectra acquired in the ESI mode often produce multiple additional adducts like sodium, potassium, and ammonia adducts next to the protonated molecular ion, thereby complicating the data analysis. Modern LC/MS metabolomics software therefore includes automated adduct- and isotope-clustering algorithms to reduce data complexity.

Peak or feature detection, often referred to as peak-picking procedures, screens the whole dataset to detect analytical signals that reflect the applied peak-picking parameters. Typically, a huge dynamic range in peak abundance (sometimes up to 50 or 60) needs to be considered, which represents a significant challenge for robust peak detection and integration, especially for poorly separated peaks or small peaks close to major ones. The GC × GC-TOF MS data are often processed using the vendor software package ChromaTOF,[176] which includes an algorithm for peak picking based on unique masses. This algorithm is suitable for discriminating analytical signals related to a true peak from the background noise. Strategies based on binning of spectral data to process huge datasets with limited computational performance have been complemented by peak-based approaches that use several different strategies like wavelet-transformation, and recursive threshold or local maxima peak detectors.[181–183] The disadvantages of binning approaches (e.g., the occurrence of peaks masses at bin borders and subsequent rejection or splitting between bins) have been overcome by overlapping bins followed by a postprocessing step to remove double findings from overlapping bins.[184]

Peak alignment of metabolomics datasets is an essential processing step to generate a high-quality results matrix. Huge analytical datasets inherently produce variations upon data acquisition. The analyzed sample matrix can affect the column material in both LC/MS and GC/MS platforms, resulting in continuous peak shifts or modified separation characteristics such as broadened peak width. Such peak shifts and modifications in separation characteristics have different effects depending on the metabolite class.[185,186] Although analytical-quality samples can, to a certain extent, ensure controlled data acquisition, it is not practically possible to maintain the relevant criteria for all observed peaks. Chromatographic shifts and peak broadening can occur in a linear, that is, small changes in carrier-gas flow in GC, or nonlinear manner, that is, matrix–stationary phase interaction in LC can change analyte–stationary phase interactions for specific compounds, like phenolic, acidic, or basic compounds depending on the nature of interaction and compounds physicochemical properties, that is, pK_a/pK_b. Shifting of the mass accuracy over time appears in systemic drifts in most cases.[187] A common obstacle for GC/MS is the accumulation of matrix-related components, like nonvolatized or thermally degraded components (often referred to as "dirt" in the injection system). These substances can result in the disappearance of small peaks over time because of their increasing adsorptive effects within the injection system, that is, accumulation of wax compounds like long-chained fatty alcohols, lipids in plant extracts, or carbohydrates introduced into a hot injection system resulting in a multiplicity of reaction products critical for maintaining inertness of the injection system.

Various peak alignment strategies have been established. These strategies can be classified into linear methods or nonlinear warping methods.[183,188] Both strategies try to maximize the correlation between the whole spectra set and the complete dataset. A common strategy in GC/MS-based methods is the concept of linear retention indices introduced by Kovats, known as the Kovats Index (KI).[189] Typically, a set of *n*-alkanes are used as retention index markers for nonpolar analytical columns to transform absolute retention times into an index system that adapts to chromatographic shifts. Different retention index systems have been established depending on column characteristics. For example, a retention index based on free fatty acid methyl esters is often used for polar columns. Linear retention index systems represent a powerful approach to correct for chromatographic shifts, and often are used to construct retention index prediction models for structure identification.[172,190,191] Nevertheless, such approaches have limited applicability for aligning shifts related to individual substance classes. To align individual shifts related to individual compounds, nonlinear warping techniques based on physicochemical properties have been developed. They are most commonly used in LC/MS-based approaches because of the higher complexity of compound interactions, and because this separation system favors individual compound shifts over systematic linear shifts.[188] The nonlinear warping techniques include segmental correlation optimized warping or dynamic time warping.[153]

Normalization of the analytical dataset is a crucial step for metabolite quantification and the accurate evaluation of relative differences (x-fold changes). Normalization can be performed according to endogenous stable metabolites (e.g., creatinine in urine), total peak areas, or by the addition of stable isotope-labeled internal standards to the sample. Selecting an internal standard that is structurally closely related to the metabolite of interest generally results in the most accurate concentration estimates. Advanced approaches that use metabolite clustering to determine the structural similarity to a set of internal standards can provide good concentration estimates for a wider range of metabolite classes. In LC/MS, ion suppression or enhancement effects in soft ionization techniques can significantly affect semiquantification, particularly if the chromatographic environment (matrix composition, and/or embedding of a metabolite) changes between samples.

2.18.2.4.3 Structure identification

Compound identification is widely recognized as a major bottleneck in metabolomic approaches and high-throughput nontargeted characterization of complex matrices. The most straightforward strategy to identify metabolites is to compare experimental mass spectra with those in commercially or publicly available mass spectra databases. The highly standardized mass spectra generated by electron impact ionization used in GC/MS has led to the establishment of huge commercial databases like the NIST14[192] and Wiley mass spectra libraries,[193] which together contain >950,000 mass spectra of 760,000 unique compounds. Mass spectra information is also housed in specialized libraries like the Maurer/Pfleger/Weber[194] or Golm Metabolome Databases (GMDs),[195] which cover several hundred thousand MS spectra of chemicals. These databases and libraries have enabled GC/MS to become a powerful structure identification tool. Nevertheless, the metabolite coverage is small compared with the total number of estimated metabolites within biological systems. For example, less than 10% of the known metabolites present in compound databases like the Human Metabolome Database (HMDB)[196] and Metabolomics Database, METLIN[197] are linked to mass spectral data. Because the majority of MS databases for GC/MS include only unit mass-resolved mass spectra, additional accurate mass measurements obtained using modern high-resolution instruments are not sufficiently utilized.

There is a low level of confidence in the proposed structures of resolved components if the structures are purely based on simple mass spectral library queries. To increase the level of confidence, manual verification and interpretation of the mass spectral library search must be carried out. While commonly used search algorithms for EI mass spectra like implemented in the NIST spectral database collection represents powerful tools to preselect possible structural candidates, the MS scientist can interpret based on expert knowledge the relevance of sometimes small fragments compared with the overall spectrum, providing essential information for the absence or presence of molecular substructures to help for the decision process on the proposed structural candidates. Finally, for unequivocal compound identification, confirmation with reference standards is required. Additional parameters (orthogonal information) derived from chromatographic analyses, such as the retention time or KI, can improve the level of confidence in structures proposed from mass spectral library searches. Also, addition of prediction model parameters such as KI can dramatically improve the confidence of compound identification. Several models that predict KI values based on molecular structures and properties, known as quantitative structure–property relationship (QSPR) models, have been developed.[191] Similarly, second-dimension retention times from GC × GC-TOF MS can provide additional information.

Computer-assisted structure identification approaches combine chromatographic and mass spectral data to accelerate and standardize the identification of compound structures. An automated platform for high-throughput identification of small molecules by GC × GC-TOF MS was recently developed and validated. This method is based on matching experimental MS data, first-dimension separation KI, second-dimension separation relative retention time, and the KI-correlated boiling point with MS databases, and includes QSPR-based models of the other parameters. The match factor of each parameter is combined to give an overall score, which corresponds to the confidence for the proposed structure.[198]

The use of high-resolution instrumentation for GC/MS means that elemental composition can be derived from accurate mass and isotope profile analyses. Combined with soft ionization techniques like CI, these methods allow for the establishment of compound database-type approaches to identify the structures of metabolites that are not present in MS databases.

Many commercially or publicly available in silico mass spectral prediction software tools have been introduced to simulate mass spectral fragmentation of EI spectra. Such software packages include MOLGEN-MSF (University Bayreuth), ACD/MS Fragmenter (Advanced Chemistry Development Inc.), and Mass Frontier (HighChem Ltd.). However, because of the complexity of fragmentation pathways in high-energy EI, in silico prediction software still provide inconsistent prediction quality, limiting their use for structural identification.[199]

Historically, structure identification by LC/MS was driven by analyzing classical target reference compounds and generating individual user mass spectral fragmentation databases. Fragmentation mass spectra in LC/MS were far from being standardized, because they were strongly affected by the diversity of instrument types, fragmentation energies, and collision cell design. More recently, generic structural identification approaches in LC/MS have become more focused on accurate mass instrumentation combined with compound-centric databases, like METLIN,[197,200] ChemSpider,[200,201] GMD,[195] HMDB,[196] and PubChem,[202] or pathway-centric databases, like the Kyoto Encyclopedia of Genes and Genomes (KEGG),[203] WikiPathways,[204] and BioCyc.[205] Recent attempts to standardize experimentally derived fragmentation mass spectra have been very successful; for example, ramped or stepped collision energies for classical CID or kinetic excitation combined with collision (linear ion trap hybrid instruments).[206] Other recent developments include higher-energy collisional dissociation (HCD, specific to Orbitrap-type instruments), where fragmentation is performed after ion transfer from the C-trap to an external HCD cell, and the option of stepped normalized collision energies.[207] A comparison between ramped or stepped CID fragmentation and stepped HCD could demonstrate sufficient similarity, which would be the first step toward building a standardized fragmentation mass spectral library for LC/MS. Consequently, an increasing number of fragmentation mass spectra have been included in compound-centric databases.[208] Methods for using in silico mass spectral fragmentation data in generic structure identification workflows are much more evolved in LC/MS than in GC/MS. Scheubert et al.[209] classified in silico fragmentation approaches into two types of methods: rule-based approaches using fragmentation rules that were extracted from the MS literature; and combinatorial approaches that generically dissect a compound into hypothetical fragments. The best-known examples of rule-based approaches are Mass Frontier and ACD MS Fragmenter. Among the combinatorial approaches, MetFrag results in high-quality predictions. MetFrag has recently been included in METLIN.[210,211]

2.18.2.4.4 Metabolomics data evaluation

Data evaluation procedures are as diverse as other focus areas, and a multitude of scientific groups are working on this topic. Different approaches are discussed in detail in a recent review by Alonso et al.[153] In general, data evaluation approaches can be classified into univariate analysis methods, like Student's *t*-test and analysis of variance, or multivariate analysis methods, like principle component analysis (PCA), partial least-squares discriminant analysis (PLS-DA), orthogonal PLS-DA (O-PLS-DA), support vector machines (SVMs), and hierarchical clustering analysis (HCA). Univariate analyses are often used to compare a limited number of sample groups with or without the use of correction methods for type I (false positive) or type II (false negative) errors. Multivariate approaches can be divided into unsupervised methods, like PCA or HCA, and supervised methods, like PLS-DA, O-PLS-DA, and SVMs. While unsupervised methods are frequently used to gain a rapid overview of group classification, supervised methods are used to identify the metabolites that make the greatest contribution to variance among sample groups (e.g., loadings). The O-PLS-DA method further emphasizes the contribution of the variable of interest while separating it from uncorrelated variables (orthogonal components). Performance of the models is usually assessed by receiver operating characteristics curves, where an area under the curve value greater than 0.7 indicates a good predictive model.

Pathway analysis and network integration are other essential steps in interpreting metabolomics data. Their integration in systems biology or systems toxicology is discussed in section "**Network-based modeling approaches for systems biology**."

2.18.2.4.5 Special considerations and outlook

Analytical approaches covering a huge number of metabolites have been available for biological research since the early 1970s. However, metabolomics is still seen as an emerging technique with much room for further development. Unlike other -omes, the metabolome is not composed of multiple combinations of a limited number of building blocks (like amino acids), which simplifies analytical approaches, but in fact the huge chemical diversity of the metabolome complicates analytical strategies. The components of the metabolome have an extensive range of physicochemical properties, huge ranges in concentrations, and limited stability. The metabolic profile of a biological system requires the investigation of kinetics because of its highly dynamic nature. Metabolites are often involved in multiple pathways (influenced by feedback regulation) and can serve as substrates, intermediates, and products, which complicates the interpretation of observed results. Additional analyses (e.g., mass flux balance analysis supported by advanced mathematical models and high-performance computing) may be required to interpret metabolomic data. Biological variances cause similar difficulties to those inherent to other -omics technologies. Depending on the types of biological samples and focus of the research, huge sample numbers must be analyzed to obtain significant results.

Although there are many obstacles, there is a rapidly growing metabolomics community that is facing the huge challenges in metabolomics studies. There is also continuously growing interest from academia, industry, and government to drive technological development. Developments in instrumentation such as high-performance accurate mass spectrometers, rapidly growing coverage of the metabolome and its mass spectra in databases, and improvements to in silico fragmentation algorithms are key factors for improving the quality of metabolomics research. The availability of reference compounds for confirmation or quantitative purposes has been improved by complementing classical organic synthesis with genetic engineering. The integration of metabolomics with the other -omics techniques is leading to a holistic and rapidly evolving systems biology approach.

2.18.3 Network-Based Modeling Approaches for Systems Biology

In previous sections, we discussed the numerous high-throughput technologies to measure the contents of various molecular species (transcripts, proteins, or metabolites) in biological samples. These technologies have provided large amounts of data, which have fueled the iterative discovery cycle underlying systems biology (**Fig. 4A**). That is, experimental data are fed into computational models that are then explored to extract hypotheses to be tested in new experiments. These experiments then provide new data to restart the discovery cycle.[212] These iterative processes naturally bring us to this section's topic, which deals with quantitative modeling approaches and how to integrate systems-wide data into an interpretable biological context. As a note to the reader, we will not cover the "standard" computational biology approaches involving statistical models that are used to detect significant abundance changes at molecular levels,[213] nor will we discuss the interpretation of their results in terms of predefined lists of protein-coding genes.[214] Instead, we focus on approaches that use network models to capture the complexity of biological systems and their behaviors under different conditions.[215] Networks explicitly encode the interactions among relevant molecular entities. Such interactions have turned out to be the key for understanding the variety of observed phenotypes. Indeed, the sequencing of the human genome has revealed a lower number of protein-coding genes than initially expected (approximately 20,000), and has highlighted the importance of other mechanisms for generating biological diversity.[216] Together with alternative splicing and posttranslational modifications, the ability to precisely regulate the expression of the protein-coding genes is the most relevant of these mechanisms. This regulation of expression levels mainly results from the interactions among genes themselves. This fact provides the ideal starting point for the network-based modeling approaches used in systems biology.

In this section, we first describe how typical network models are constructed either by mining the scientific literature or by using molecular expression data. Then, we describe two examples of network-based methodologies that address concrete biomedical problems using a systems biology approach.

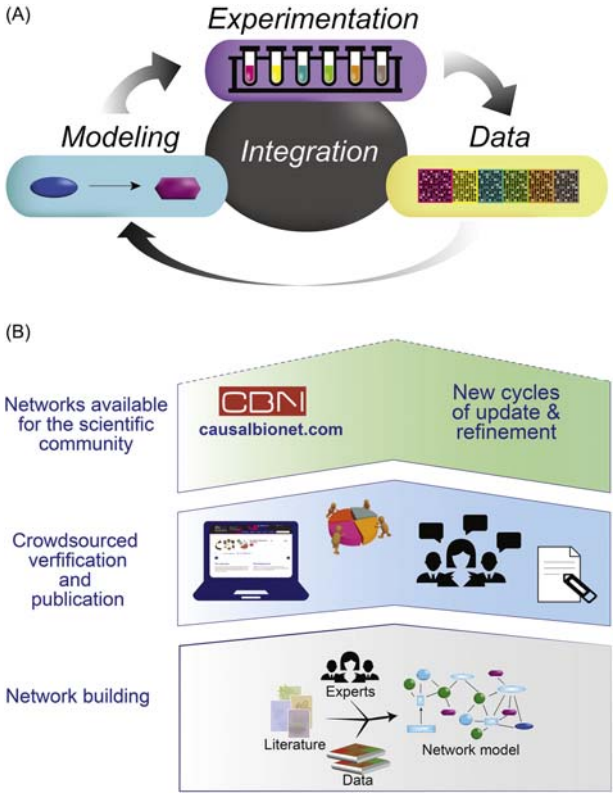

Fig. 4 Network models for systems biology. (A) Discovery cycle in Systems Biology: high-throughput -omics data provide untargeted comprehensive information about the system, enabling exploration of many different aspects using quantitative modeling. This can lead to novel hypotheses to be experimentally tested. (B) Flowchart for assembling and maintaining causal network models: to ensure their scientific acceptability, multiple steps are necessary to preserve their quality and objectivity, especially when some of the mechanisms are still incompletely understood.

2.18.3.1 Literature-Driven Network Model Building

The scientific literature contains much information about gene interactions, and modern search tools allow researchers to efficiently retrieve specific pieces of information. However, to achieve a satisfactory systems biology-based description of a given biological process, large-scale mining of hundreds of scientific articles is required. The results usually consist of a collection of pathways or networks that bring together genes involved in similar biological functions. Typical examples of such collections are the KEGG database or the WikiPathways resource.[204,217] The main advantage of literature-based network models is the quality of their content, as their assembly involves human curation and uses reliable "raw" material. Their main disadvantage is that they do not include all ~20,000 protein-coding genes, since the coverage of the genes is far from uniform and literature-mining efforts must be selective to be efficient. In the context of the aforementioned iterative discovery cycle underlying systems biology, the main application of these network models is to enable the interpretation and the integration of systems-wide -omics data.

In the following section, we focus on a specific type of literature-based network model that will appear several times later in this article: the causal network model. Essentially, causal network models represent more refined and more comprehensive versions of the familiar biological pathway models (e.g., describing the regulation of proliferation by kinase signaling) that makes them more suitable for computational analyses.

For clarity, we restrict the discussion to a "steady state" modeling approach, where time dependence is deliberately ignored. Although this might appear to be an oversimplification, this approach works well when using these networks with experimental -omics data. This is because -omics data are generated by merging the molecular content of millions of cells, and thus, represent a temporal average over the fastest time scales of the system. In other words, the experimental -omics data effectively measure a "quasi-steady state." A dedicated discussion of time-dependent modeling is given in section "Mathematical Models for Network Biology."

The specificity of causal network models is then given by both:

1. the nodes, which are quantifiable biological entities such as protein abundances, transcript levels, protein phosphorylation sites, and protein activities.
2. the edges, which describe direct and signed cause-and-effect relationships supported by evidence in the literature, for example, activity of a transcription factor increases abundance of its regulated transcripts and activity of a kinase increases the phosphorylation of its targets.

It is also important to note that "causal" does not necessarily mean "direct" in a physicochemical sense. A causal relationship can also be indirect and, if supported by the literature, it can be included in causal network models. The main feature of the causal network models discussed here is that they are genuinely mechanistic. That is, their nodes correspond to biological functions or activities at molecular or cellular levels, and they are not limited to transcript levels or protein abundance, like other network types used in systems biology.

Another important feature is the semantics of their node and edge labels, which is based, in our case, on the Biological Expression Language (BEL), a programming language that allows for a flexible representation of biological processes in a computable format (http://www.openbel.org/). The BEL statements are extracted from the Selventa Knowledgebase (http://selventa.com), which stores the results of mining of selected scientific literature and the contents of public and proprietary databases. This knowledgebase contains 1.5 million nodes (biological concepts and entities) and more than 7.5 million edges (connections between nodes). The knowledgebase must be licensed, like similar sources of curated biological knowledge that require extensive mining of the scientific literature (e.g., Biobase and Ingenuity Pathway Analysis[218]). However, the openBEL portal contains an increasing amount of publically available material extracted from the Selventa Knowledgebase, such as the "BEL Large Corpus" (http://www.openbel.org/).

The design and assembly of causal network models have been an iterative multistep process complemented by a crowdsourcing initiative (**Fig. 4B**). The biological boundaries of each network were first defined by a team of discipline-specific experts, who were guided by a literature survey of the relevant signaling pathways related to the process of interest. The BEL-encoded causal relationships that described the pathways covered by the biological boundaries of the network were extracted from the Selventa Knowledgebase. These relationships were assembled to populate the "literature network model" with causal relationships within the boundaries of tissue context and biological mechanisms. The content of the literature network model was augmented by a data-driven step based on relevant context-specific transcriptomics datasets available from public data repositories.[219] For this purpose, discipline-specific scientific experts conducted a terminal manual review, thus refining the content and connectivity of the integrated network model. The resulting causal network model was then submitted to a peer-reviewed open-access publication, where reviewers helped to improve the quality of its content.[220] A further curation step took place in the framework of the Network Verification Challenge of the Systems Biology Verification project (SBVImprover).[221] This challenge was based on an innovative crowdsourcing approach where a large community (>50) of contributors were allowed to vote on various edges and nodes of the networks via a dedicated web interface. A "moderator" supervised the votes for each model and, together with a panel of experts, made decisions to include or exclude node and edges based on the community's choices.

The design and assembly process described earlier has been repeated for approximately 50 networks, each of them first defined by its biological boundaries. The purpose of these definitions was not only to match the high-level biological functions described by the single network, but also to cover globally the essential biological processes and responses of healthy lung tissues.[220] As a result, a hierarchical organization was chosen with five main network families on the top—each with a subset of the approximately 50 causal network models: cell proliferation,[222] cellular stress,[223] cell fate,[224] pulmonary inflammation,[225] and tissue repair and angiogenesis.[226]

Systems biology, and network approaches in particular, exploits large amounts of biological knowledge to accurately interpret the results of -omics analyses. Biological curation, "biocuration," aims to harness and preserve biological insights in databases in a format that can be used in computational approaches. It organizes biological information into well-annotated, computable statements that can be visualized as a model describing certain area of biology.[227] Since manual curation can be extremely labor- and time-intensive, computational approaches are being developed to extract causal relationships from the scientific literature. One such workflow combines text mining with expert reviews by scientists for accurate and easy conversion of scientific text into a computable form.[228]

2.18.3.2 Data-Driven Interaction Network Inference

While "literature-driven network model building" can yield high-quality representations of the known biology, it is labor intensive and limited by the availability of relevant publications. Fortunately, with the advance of omics technologies, increasing amounts of data are available in clearly defined and specific experimental contexts. This has attracted the interest of the systems biology community, and many approaches have been developed to reconstruct networks from the available data, a process known as "reverse engineering of networks."

2.18.3.2.1 The goal of network inference

These network inference approaches start with a given set of molecular entities (nodes, say $X_1,\ldots,X_n$), which, for example, can be genes, proteins, or metabolites. Data involving these molecular entities are available and the goal is now to effectively leverage these data to infer the connections between those entities (**Fig. 5A** and **C**).

Several types of interaction networks are commonly studied: gene networks (or gene regulatory networks) are representations of gene–gene regulation; protein functional networks describe the interplay of proteins or protein activities[229]; while PPI networks describe physical interactions between proteins that form complexes.[230] Experimental techniques can provide information on network structures (chip-on-chip data for transcription factors, Y2H,[231] or affinity purification/MS for PPI networks)[232] (see Methods section). However, these methods are labor intensive and costly, can produce false positives and false negatives, and do not necessarily reveal the functional relevance of the detected interactions. Thus, even with these experimental data available

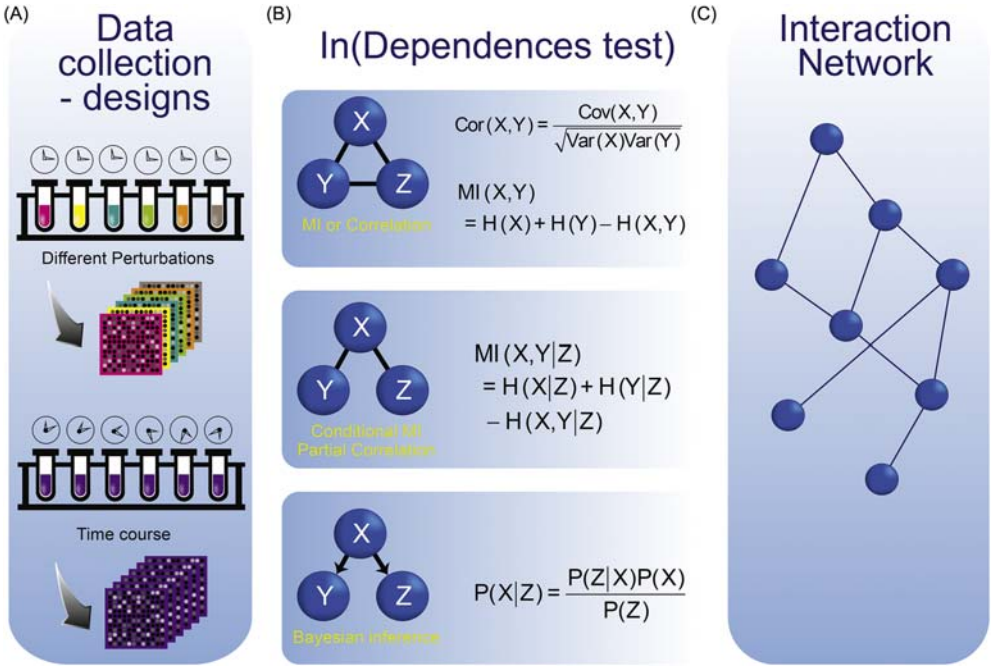

Fig. 5 High-level description of the interaction network inference problem. (A) Experimental data are gathered following a specific experimental design. (B) Method and statistical measure of interaction between the measured molecules are selected depending on the scope and goal of (C) the network model.

(as structural network templates), data-driven network reconstruction is still necessary to complement the results and to extract functionally relevant models that predict relevant biological phenotypes.

The use of these in silico methods for inferring interaction networks based on omics data, such as transcriptomics or proteomics, has grown rapidly. The development of algorithms to address this challenging task has been at the heart of the Dialogue for Reverse Engineering Assessment and Method (DREAM) challenges (http://dreamchallenges.org).[233] In these challenges, the participants were asked to reconstruct a genome-scale regulatory network from a large collection of microarray data sets to predict a PPI network of 47 proteins and predict the genes for transcription factor binding (DREAM2); infer a signaling network from flow cytometry data (DREAM 3); infer simulated gene regulation networks and predict gene expression measurements (DREAM 4); and infer simulated and in vivo gene regulation networks (DREAM5). More recently, the participants were asked to predict outcomes of perturbations in systems biology models after being given the complete and incomplete structures of the model for a gene regulatory network (DREAM7).[233–237]

2.18.3.2.2 Experimental data

The choice of a computational method depends not only on the scope of the biology to capture (e.g., genome-wide vs. biological process specific), but also on the experimental design underlying the collected omics data (**Fig. 5A**). Longitudinal (time-series) data require the algorithm to be tailored toward dynamic responses and can leverage differential equations describing the (bio-) chemical reactions occurring over time. Perturbation or gene silencing data are also appropriate for inferring networks (http://dreamchallenges.org/).[233] Factorial designs can be leveraged to infer networks.[238] Finally, large compendiums of data have been used[239] to infer genome-wide networks related to a specific tissue or disease.

2.18.3.2.3 Inferring edges using pairwise measures

Independent of the type of data at hand, different computational approaches may lead to very different interpretations of the resulting network (**Fig. 5B**)—for example, as discussed here for "relevance networks," "Markov networks," and "Bayesian networks."

Relevance networks, for example, rely only on the correlation structure (or the mutual information, MI) between the molecular entities: an edge between a pair of entities $\{X_i, X_j\}$ (e.g., two genes) is defined, if these show statistically significant correlation in the data. For longitudinal data additional computing steps (e.g., dynamic correlation[240]) are used to account for the time-dependent nature of the data, or time-delayed gene regulation can be inferred based on cross-correlation and network deconvolution.[241] While these approaches are straightforward and applicable at a large scale, the resulting networks cannot describe causalities.[242] Indeed, if (gene) A regulates both (genes) B and C, but B and C do not interact with each other (**Fig. 5B**, bottom), then it is likely that all the edges among A, B, and C will appear in the (correlation-based) relevance network (**Fig. 5B**, top). Consequently, relevance networks capture community structures between genes but cannot unravel the true nature of the underlying causal mechanisms. The solution

to this problem relies on the concept of conditional independence between molecular entities leading, for example, to Markov[243] or Bayesian networks.[244]

For Markov networks, which are undirected networks (Fig. 5B, middle), the key quantity considered for each interaction is the conditional MI: $MI(X_i, X_j|X_1,\ldots X_{i-1},X_{i+1},\ldots,X_{j-1},X_{j+1},\ldots X_n)$.[245] The MI is an information theory measure for the dependence of two random variables and the conditional MI is 0 if and only if X_i and X_j are independent conditional on all the other variables. Therefore, we could theoretically infer a network structure where an edge is present whenever the above quantity is significantly nonzero. Unfortunately, testing conditional independence usually requires too much data and is computationally intractable. However, when the variables X_i are assumed to be multivariate Gaussian, the conditional MI is equivalent to the partial correlation, which is easier to estimate. This approach, called Gaussian graphical modeling, has been successfully applied to small problems (a few dozen nodes). For larger problems, approximation to the full conditional independence can be achieved by considering all the kth order conditional MI: $MI(X_i, X_j|X_s)$, where s is any subset of indices of size k not containing i and j. This strategy is at the heart of the path-consistency algorithm PC,[246] which has been adapted to MI, and was validated in the benchmark gene regulatory networks in the DREAM challenge.[247]

Additional approaches to distinguish direct from indirect interactions have been developed. In the method called Algorithm for the Reconstruction of Accurate Cellular Networks (ARACNE), triangles in the relevance network inferred from MI are further tested using data-processing inequality (DPI).[245] The DPI states that if $X \rightarrow Y \rightarrow Z$ is a Markov chain then $MI(X,Y) \geq MI(X,Z)$. Consequently, the algorithm removes edges with lower MI value. Alternatively, in the so-called Minimum Redundancy Network approach, the principle of maximum relevance/minimum redundancy[248] is used to distinguish direct from indirect interactions.[249] In a nutshell, for each entity of the network X_i, its potential regulators are sequentially ranked according to the score defined as the MI with X_i (maximum relevance) minus the average MI with the other potential regulators (minimum redundancy). An edge is deleted if the minimum of the score obtained when ranking according to X_i, and X_j is below a given threshold.

Bayesian networks have also been used to derive causal interaction networks because they rely on the conditional independence concept (Fig. 5B, bottom). The structure of the network can be inferred by maximizing the full posterior distribution, but this problem is usually intractable even for moderately sized problems. Therefore, sampling methods such as Markov chain Monte Carlo have been proposed, and structure-learning algorithms relying on scores such as Bayesian information criteria have been developed. Bayesian networks can also be used to model time-series data; these are known as dynamic Bayesian networks.[250]

2.18.3.2.4 Algorithms tailored to time-series data

The inference of interaction networks from time-series data (longitudinal design) can benefit from specific model representations and methods. A common approach is to assume that the data are observed from a generative model which is a set ordinary differential equation (ODE) (see e.g., Ref.251). The ODE describes how the system, in its current state and under predefined parameters, changes over time. The simplest way to describe the temporal behavior of a system is to perform a first-order approximation of the dynamic of that system. This involves linear equations of the form:

$$\frac{dX_i}{dt}(t) = a_i + \sum_{j \neq i} b_j^i X_j(t)$$

where the coefficients b_k are nonzero only for the regulators of X_i. Using the fact that data are collected in a time-series $x_i(t_1),\ldots,x_i(t_n)$, the derivatives at t_k are approximated by $X_i(t_{k+1}) - X_i(t_k)/t_{k+1} - t_k$. Finally, $X_i(t_{k+1}) - X_i(t_k)/\ t_{k+1} - t_k$ is regressed against the potential regulators: $a_i + \sum_{j \neq i} b_j^i X_j(t)$. Fitting procedures such as LASSO,[252] elastic net,[253] or any other approach leading to a sparse solution can then be used to discover the regulator set of X_i. The nonzero coefficients serve to build the interaction network by defining an edge (and its sign) between X_i and X_j if the coefficient b_j^i is nonzero (or above a given threshold). For example, the best performer in the DREAM3 challenge used the elastic net as a fitting procedure.[254]

Finally, a network inference method can be a hybrid method, in the sense that it can leverage both data and knowledge from the literature in a supervised manner. For example, SIRENE[255] leverages both transcription factor target knowledge and gene expression data by learning a supervised model—it trains a binary classifier to discriminate between genes known to be regulated and genes known not to be regulated by the transcription factor, based on the expression data. The classifiers associated with the set of transcription factors are then applied to each gene not used during training. The obtained scores are then combined across all different models to rank the candidate transcription factor–gene interactions. In Ref.256, this supervised approach was shown to outperform unsupervised ones such as ARACNE, providing promising results.

In conclusion, reverse engineering of the interactions among molecular species based on experimental data remains a difficult problem. Many challenges remain and as pointed out in the DREAM challenges, the network reconstruction task remains unsolved.[257] Despite this, it is a key approach to understand molecular species as a whole.

2.18.3.3 Scoring of Causal Biological Network Models

Given the systems-wide -omics data and the causal network models discussed earlier in this article, our goal is to integrate these two elements to gain mechanistic insights that enable a systems biology-based interpretation of the underlying experiment. As briefly mentioned at the beginning of this section, computational biology methods allow researchers to quantify changes in abundance at

the molecular level and to test their statistical significance. Analogously, the "network-scoring" approach presented later allows researchers to:

1. quantify changes in activity or "perturbation amplitudes" for network nodes describing molecular mechanisms (not only molecular abundance).
2. quantify network perturbation amplitudes (NPAs) obtained by aggregating the corresponding node-level values to assess changes in the activity of high-level biological function described by the network.

The scoring of causal network models ultimately reduces system complexity by replacing approximately 20,000 protein-coding genes with approximately 2000 nodes distributed in about 50 causal network models (Fig. 6). Such a feature offers a valuable advantage from the point of view of biological understanding, given that the interpretation of molecular-level -omics data requires significant efforts in terms of data processing and integration of existing biological knowledge.[258–260] As discussed in the next section, the scoring of causal network models has opened the door to a variety of applications and opportunities in contexts ranging from individual-based diagnostics to mechanism-based evaluation of toxicants.

In essence, the network-scoring approach is based on the earlier-mentioned NPA concept, which was introduced to assess the biological impact of an exposure to a biologically active substance, and which was expected to be useful in pharmacology or toxicology contexts.[261] At the time of its development, most existing approaches for network-based analyses of -omics data focused on evaluating statistical significance based on *P*-values, which were obtained by testing the distribution of changes in the gene

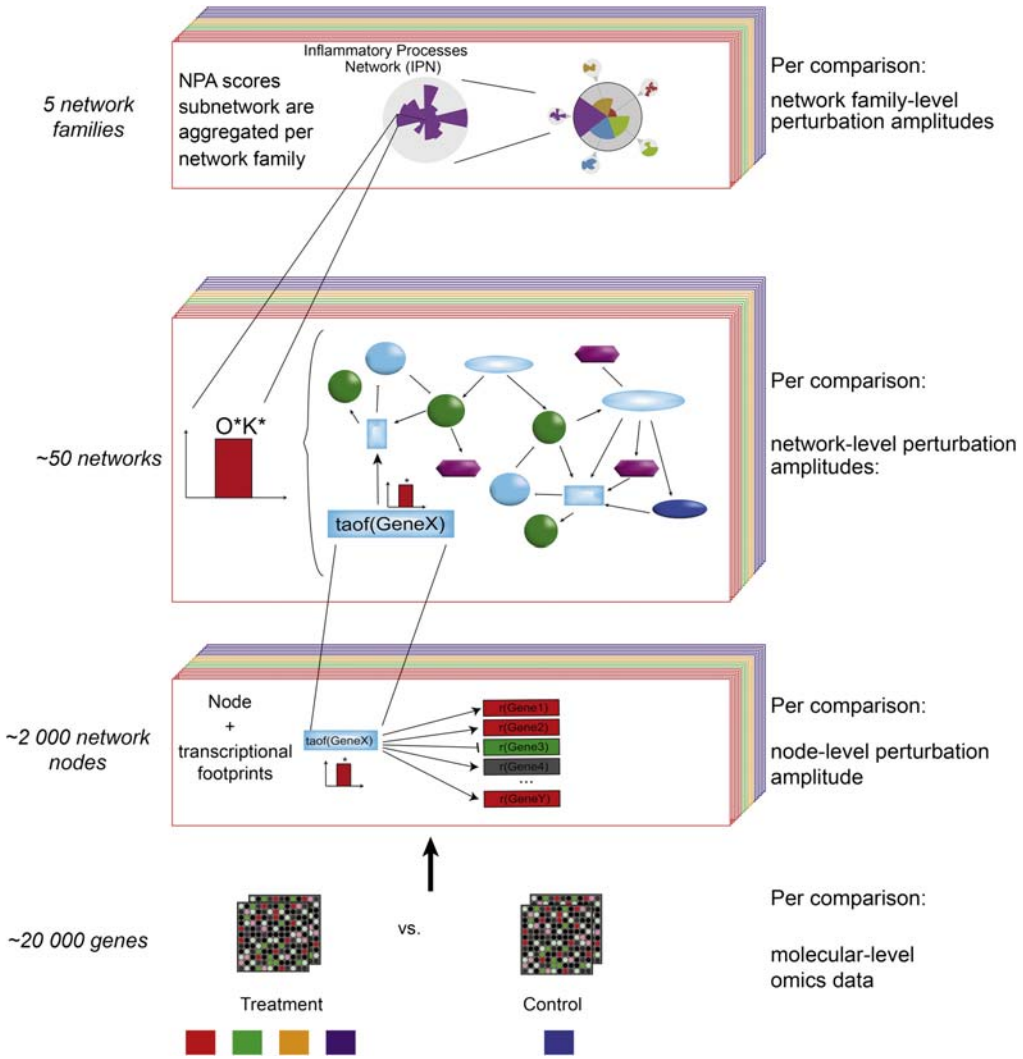

Fig. 6 Schematic representation of the network perturbation amplitude (NPA) methodology. The hierarchical structure of the causal network models (nodes → networks → network families) is completed by the corresponding transcriptional footprints matching the experimental data measuring treatment-induced changes in transcript abundance. Changes in the activities of higher-level network model entities are calculated by the NPA method and allow seamless bottom-up examinations of treatment effects at various levels of mechanistic precision and data complexity.

abundance in the considered network.[262] The main purpose of NPA quantification was to derive an authentic amplitude of the effect, as opposed to a significance *P*-value or an abstract score. This amplitude would be used not only for comparison with other treatments (other doses, exposure durations, etc.), but also for comparison with phenotypic endpoints associated with a network that can be experimentally measured independently of -omics data. This feature would provide the connection between molecular-level -omics data and phenotypic measurements, which fits well with the guidelines of 21st century toxicology, see what follows.[263,264]

From the details described earlier, it became clear that molecular-level -omics data and causal network models are the two main inputs for a network-scoring NPA calculation. The description in the previous subsection "Literature-Based Network Model Building" mentioned the hierarchical organization of the approximately 50 networks. When taken together, these networks cover the essential biological processes and responses of healthy lung tissues (see, e.g., Hoeng et al.[265] and Phillips et al.[266]). To safely apply the NPA method and obtain biologically sound results, careful a priori network selection needs to be done to match the cellular content of the experimental samples that yielded from -omics data. This is particularly true for the pulmonary inflammation network family, which contains many cell-specific networks such as "macrophage signaling" or "mast cell activation."

A further essential aspect of the causal network models is the way they integrate molecular-level -omics data. In the case of transcriptomics, most network nodes can be attached to a set of causal edges ending exclusively in transcript nodes. These end nodes constitute the "transcriptional footprint" of the biological entity described by the common start node of the edges. The biological meaning of a transcriptional footprint is straightforward when the start node describes the activity of a transcription factor protein—detecting changes in the abundance of its regulated transcripts provides indirect information about changes in the activity of the transcription factor itself. This idea can be generalized to any biological activity as long as their transcriptional footprints are available, as it is the case in the Selventa Knowledgebase. Typically, the size of these transcriptional footprints ranges from a lower limit of five to an upper limit of several hundred, depending on the types of methods that were used to experimentally validate the tested causal relationships, and the "depth" of the scientific literature mining used to build the Selventa Knowledgebase. The integration of other types of -omics data is possible in principle, especially proteomics data, as long as causal relationships between the changes in the corresponding molecular entities can be retrieved from the scientific literature. However, it is practically more difficult, because the Selventa Knowledgebase used to build the networks does not yet contain enough causal edges ending with measurable molecular entities that are not transcriptomic.

The actual NPA calculation consists of a series of steps that follow the arrows of the augmented network structure sketched above: from transcriptional footprints (genes) to network nodes to networks to network families (Fig. 6).

- The first step is to calculate the node-level perturbation amplitudes. This is achieved by aggregating the changes in abundance of all the genes contained in the transcriptional footprint of the considered node, multiplied by the sign of the corresponding edge.[267] The result is accompanied by two statistics quantifying (1) its 95% confidence interval, which should not contain 0 to have an effect, and (2) its specificity *P*-value, which is deduced from its comparison with the null distribution of perturbation amplitudes of the same node when assigned randomized transcriptional footprints.
- The second step is to calculate the network-level perturbation amplitudes. This calculation requires more advanced graph-theoretical concepts (e.g., the signed Laplacian matrix of the network). It provides a global score aggregating over the network an edge-based measure of sign coherence between the perturbation amplitudes of the edge start and end nodes.[268] A network-based interpolation procedure is first used to ensure that perturbation amplitudes are defined for all nodes, even those without transcriptional footprints. The result is accompanied by three statistics quantifying (1) its 95% confidence interval, which should not contain 0 to have an effect, (2) its *O*-specificity, which is deduced from its comparison with the null distribution of the perturbation amplitudes obtained for adequately randomized versions of the network transcriptional footprints, and (3) its *K*-specificity, which is deduced from its comparison with the null distribution of the perturbation amplitudes obtained for adequately randomized versions of the network itself.
- The third step is to derive perturbation amplitudes for a network family, which requires that at least two abundance change calculations, or "contrasts," are contained in the transcriptomics dataset. One of them is considered as the "reference" according to the experimental design. The calculation aggregates only the significant perturbation amplitudes of the networks contained in the network family; that is, only those that satisfy the three statistics described earlier (confidence interval, *O*- and *K*-specificities). To make the results comparable across multiple contrasts and possibly network families, normalization to the value of the reference contrast is performed.[265] When there is a large difference in network sizes within one family, additional normalization schemes might be used.[269]

Performed in the order nodes → networks → network families, the three steps provide perturbation amplitude values at three levels of reducing mechanistic complexity (Fig. 6). As the changes in transcript abundance constitute the initial and most complex data, they are suitably positioned at the bottom of the NPA values. When available, the accompanying statistics allow the researcher to prioritize investigations on the entities yielding the strongest signals. Practically, the top-down approach is very appealing for data interpretation and provides a rapid overview of the structure of systems behavior under various treatments by collecting the associated "mechanistic fingerprints."[270] In the "Application" section, several examples of the use of NPA methodology are discussed.

2.18.3.4 Mathematical Models for Network Biology

In sections "Literature-Driven Network Model Building" and "Data-Driven Interaction Network Inference," we discussed the inference of network structures from literature and data, and in section "Scoring of Causal Biological Network Models" we

described how this information can be combined with experimental -omics data to gain mechanistic insights from a systems biology perspective. Although we used causal network models that contain the idea of temporal order, the actual time evolution of the system has never been considered explicitly. This is because -omics data captures the systems in a "quasi-steady state" that is sufficient to reflect the causal relationships contained in the network models. However, in further modeling steps, it makes sense to address the time evolution aspect and to develop a modeling framework in which networks can be used to predict the dynamic behavior of the system based on the interactions between its nodes. The ultimate goal of network reverse engineering is not only to infer the network's structure, but also to model its dynamic behavior by modeling the evolution of every species over time. The laws of enzyme and chemical kinetics must be described in ODE systems with sufficient detail to reproduce time-course experimental data and to predict the network outcome.

2.18.3.4.1 From interaction network to mathematical dynamic model

The models of cellular behavior and phenomena are conveniently represented as schematic diagrams of the interactions among the involved species to describe the reactions of the network. Generally, these interactions correspond to those discussed in section "Scoring of Causal Biological Network Models." However, some fine-tuning is often required during the development of these mathematical models, for example, taking into account the following nonexhaustive list of considerations.

For open systems, arrows without parents and arrows without children are drawn to represent the exchange of material with the outside environment (dashed arrows in Fig. 7A). This is not incompatible with the interaction network described previously—the decision to treat the system as open or closed affects mainly the equation rates, and this decision is made before writing the set of equations.

Inhibition can be represented as arrows from the inhibitor molecule to a reaction between two other molecules (edge starting at "E" in Fig. 7A). This specific aspect is usually not captured when inferring the interaction network as the majority of the algorithms will output a negative edge between "E" and "B," but will usually be unable to distinguish the inhibition of the reactions "A → B" and "F → B" (Fig. 7A).

Not every species in a model can be or has been measured. For example, phosphorylation events might be included in the model but not appear in data-driven interaction networks, or may require the addition of intermediate molecules.

Some reactions are considered instantaneous and related equations can be simplified (also known as the rapid equilibrium assumption) to describe the dynamic on a given time scale.

If all dynamic reactions linked to species A occurs on a fast timescale (compared with those of other species), an algebraic (as opposed to differential) equation may be used to model the system. This situation is called the quasi-steady-state assumption.

The goal of such models is to predict the temporal evolution of the species concentration starting from initial concentrations in a fixed volume via various reaction rates. The reaction rates may depend on the concentration of the reactant and also on the physicochemical conditions (pH, temperature).

Some additional assumptions can be made to make the problem tractable. A typical assumption is that the reactant is homogeneously distributed throughout the volume, in which case the reaction volume is said to be well stirred. This implies that the rates are constant in space.

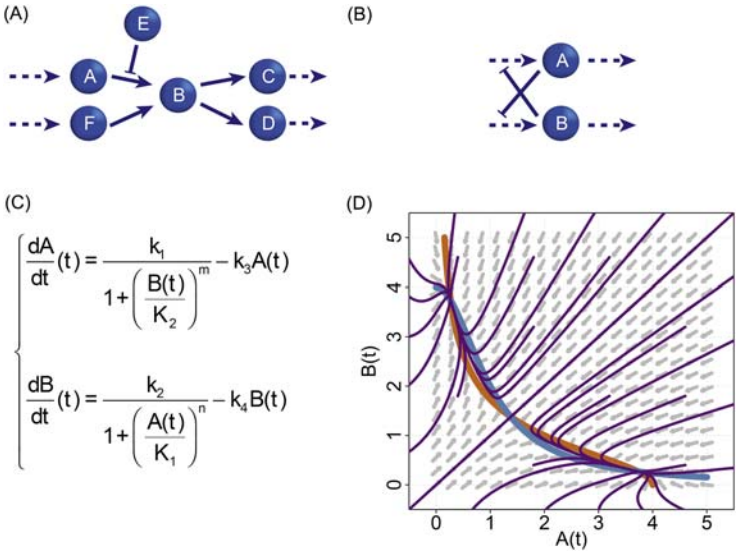

Fig. 7 (A) Typical diagram describing a dynamic network, whereby the production rate of B from A is inhibited by E; (B) a simple system of dual inhibition; (C) ordinary differential equations (ODE) associated with the system in B); (D) flow field (*gray arrows*), trajectories (*purple curves*), and nullclines (*orange curve* for A and *blue curve* for B). Nullcline intersections indicate steady states of the system. For lower k_1 there would be only one steady state (the "low A and high B"); for higher k_1 only the steady state for "high A and low B" would remain.

2.18.3.4.2 Stochastic versus deterministic models

A model is said to be deterministic if its trajectories are reproducible. That is, once the conditions and parameters are set, the behavior is determined unambiguously. In contrast, a stochastic model is a model in which randomness plays a role in determining the output of the system. A well-known example is the Lotka–Volterra prey–predator model where stochastic and deterministic models differ significantly. This typically happens in systems biology either when there are few available molecules (typically in a gene transcription and translation model) or when thermal agitation of individual molecules induces randomness. When many molecules are assumed to be present all the time, the concentrations are considered to vary continuously, as opposed to an integer value of molecule abundance. Deterministic models lead to differential equations while stochastic models rely on the description of continuous time stochastic processes, such as Markov processes described by the master equation.[271] The latter relies on stochastic mass action kinetics, whereby the probability of a reaction occurring is proportional to the probability that the reactants meet. In contrast, (continuous) mass action kinetics assume that the rate of a chemical reaction is proportional to the product of the concentrations of the reactants. Each reactant appears with the power equal to its molecularity in the reaction.

The application of mass action will lead to an ODE system describing the time evolution of the concentration of each species as follows: $\mathrm{d}x/\mathrm{d}t = S\nu(x)$, where S is the stoichiometric matrix of the system. This applies to chemical reactions but also to enzyme kinetics.

2.18.3.4.3 Enzyme kinetics

Enzymatic reactions follow the classical "lock-and-key" model, where the free enzyme E binds to its substrate S to form the enzyme–substrate complex (C1), which is then catalyzed into the enzyme–product complex (C2) from which the free enzyme and product are released: $\mathrm{S}+\mathrm{E} \leftrightarrow \mathrm{C}_1 \leftrightarrow \mathrm{C}_2 \rightarrow \mathrm{P}+\mathrm{E}$. This model represents the vast majority of the reactions that occur in a cell. Enzyme-catalyzed reaction rates can be modeled by Michaelis–Menten kinetics, assuming that:

- the timescale for conversion of the enzyme–substrate complex to the enzyme–product complex is faster than those of other reactions, hence the reaction becomes $\mathrm{S}+\mathrm{E} \leftrightarrow \mathrm{C} \rightarrow \mathrm{P}+\mathrm{E}$.
- the product never binds to the free enzyme.
- the substrate is far more abundant than the enzyme, $\mathrm{S} \gg \mathrm{E}$ (implying that the complex C is in a quasi-steady state). This assumption typically does not hold when modeling PPIs in signaling cascades.
- the total enzyme concentration is constant (conserved moiety) because it is not consumed by the reaction.

Putting all those arguments together and applying the law of mass action, the rate of $\mathrm{S} \rightarrow \mathrm{P}$ is represented as follows: $V_{\max}\mathrm{s}/K_{\mathrm{M}} + \mathrm{s}$.

Enzymatic activity is tightly regulated in the cell by different mechanisms[272] such as competitive inhibition, noncompetitive inhibition, mixed inhibition, allosteric inhibition, and cooperativity. Each of those mechanisms has specific kinetic rates and equations. Table 1 shows some common examples.

2.18.3.4.4 Model parameter fitting

Obviously, understanding each type of reaction in the model is not sufficient to predict its output. One quickly realizes that, even for systems involving only a few reactions, the number of parameters can increase rapidly, leading to serious difficulties. Some of the kinetic constants might be known, some others could be measured in vitro, but generally these constants are unknown to the modeler. A classical approach is to generate time-series data for some of the species involved in the model, for the time scale under study. Then, the parameters are fitted to the experimental output, typically using a maximum likelihood or least-squares formulation. As opposed to a problem that can be solved with simple optimization techniques (e.g., convex problems), this approach leads to nonconvex optimization problems that require advanced optimization solvers. For global optimization methods, the computational cost usually increases exponentially with the number of free parameters. Therefore, advanced global

Table 1 Common types of enzymatic reactions and their associated rates

Name	*Reaction scheme*	*Rate*
No inhibition (Michaelis–Menten)	$\mathrm{S}+\mathrm{E} \leftrightarrow \mathrm{C} \rightarrow \mathrm{P}+\mathrm{E}$	$\nu = V_{\max}\mathrm{S}/\mathrm{S} + K_{\mathrm{m}}$
Competitive inhibition	$\mathrm{S}+\mathrm{E} \leftrightarrow \mathrm{C} \rightarrow \mathrm{P}+\mathrm{E}$ $\mathrm{I}+\mathrm{E} \leftrightarrow \mathrm{C}_{\mathrm{I}}$	$\nu = \frac{V_{\max}\mathrm{S}}{\mathrm{S}+K_{\mathrm{m}}\left(1+\frac{I}{K_{\mathrm{I}}}\right)}$
Allosteric (noncompetitive) inhibition	$\mathrm{S}+\mathrm{E} \leftrightarrow \mathrm{ES} \rightarrow \mathrm{P}+\mathrm{E}$ $\mathrm{I}+\mathrm{E} \leftrightarrow \mathrm{EI}$ $\mathrm{I}+\mathrm{ES} \leftrightarrow \mathrm{ESI}$ $\mathrm{S}+\mathrm{EI} \leftrightarrow \mathrm{ESI}$	$\nu = \frac{V_{\mathrm{m}}\mathrm{S}}{(\mathrm{S}+K_{\mathrm{m}})\left(1+\frac{I}{K_{\mathrm{I}}}\right)}$
Hill cooperativity (X molecule binding to protein P)	$\mathrm{P}+\mathrm{X} \leftrightarrow \mathrm{P}X_1$ $\mathrm{P}X_1+\mathrm{X} \leftrightarrow \mathrm{P}X_2$ $\mathrm{P}X_{n-1}+\mathrm{X} \leftrightarrow \mathrm{P}X_n$	$\nu = X^n/K^n + X^n$

Rates are valid under the same assumptions as those for Michaelis–Menten kinetics.

optimization methods (such as generalized simulated annealing, particle swarm optimization, or genetic algorithms) have to be used. The computational optimization of the parameters in a systems biology model can easily be underdetermined. If some initial guesses are available, then restricting the search space around those values may help avoid over-fitting. In the Biomodel database,[273] the median size of the network model is about a dozen reactions, which highlights the difficulty in estimating all kinetic constants.

2.18.3.4.5 Model simplification: S-systems

A simplified parameters search was proposed by Michael Savageau:[274] all production (respectively, consumption) terms are lumped together into a single power-law as follows:

$$\frac{dx_i}{dt} = \theta_i \prod_j x_j^{\alpha_{ij}} - \mu_i \prod_j x_j^{\beta_{ij}}$$

where the signs of the exponents are positive except for inhibition and the θ and μ values are positive. This dramatically reduces the number of parameters[275] and has led to the development of several parameter-optimization methodologies.[276] Another approach to reduce the number of parameters is to consult the literature to identify key parameters that have been confirmed experimentally.

2.18.3.4.6 Model analysis and validation

Nonlinear dynamic systems show a wide range of behaviors. A global behavior analysis can, however, be overwhelming. Hence, focusing the analysis near a particular operating point is a common approach. An advantage of the local analysis of a system is that it allows for a linear approximation over a small domain. The stability around steady states is analyzed by evaluating the eigenvalues of the Jacobian matrix (containing all the partial derivatives) of that system. Visualization of the phase plane (e.g., with direction fields) and nullclines (i.e., coordinates where time derivatives are 0) can also provide information on the type of dynamic behavior and help detect, for example, limit cycles.

Another important aspect is a sensitivity analysis; that is, how sensitive the solutions or steady state are to changes in different parameters. A sensitivity analysis is usually applied to study local sensitivity, to determine the effect of *small* changes in parameters on the global solution. For example, a change in parameter values can lead to a qualitative change in long-term dynamic behavior (i.e., changes in the number of steady states or their stability). The parameter values at which this happens are known as bifurcation points. Some simple systems exhibit bi-stable behavior, and a bifurcation analysis can show how the system can abruptly change from one basin of attraction to another (i.e., switch its steady state). Despite this apparently complex behavior, even very simple systems can show bi-stabilities.[277] The system described in Ref. 278 (**Fig. 7B** and **C**) is one such example. While the constant k_1 increases (**Fig. 7C**), the system becomes bi-stable as shown by the three intersections of the nullclines (the nullcline for $X_i(t)$ is the solution to $dX_i/dt(t) = 0$ solved for X_j) (**Fig. 7D**). Bi-stability is an essential property of the apoptotic machinery, as the status "alive" must be stable and resistant toward minor accidental trigger signals. Bi-stable behaviors have been proven both experimentally and theoretically to be governed by several signal transduction pathways leading to cell fate decision. A typical example is the bi-stability of receptor-induced apoptosis through the caspase cascade.[279] In Ref. 280, the pathway of caspase activation was shown to be essential for apoptosis induction by various stimuli, including cytotoxic stress. Depending on the context, a caspase is activated either gradually or in a switch-like fashion, and this determines whether caspase activation irreversibly leads to cell apoptosis. By analyzing a quantitative kinetic model, the authors showed that inhibition of Casp3 and Casp9 by apoptosis inhibitors resulted in implicit positive feedback that induced bi-stability.

Last but not least, model validation is of prime importance. A common way to validate a model is to apply it to "hold-out" data, which is a subset of data not used for fitting purposes. The modeler checks the accuracy of the predictions to assess the quality of the model. This procedure can be repeated many times by randomly selecting the "hold-out" data. However, this can lead to over-optimism if not performed properly (see e.g., Ref.281). Another proposed approach is to compare the hold-out data predictions to a completely unsupervised solution.[282]

In conclusion, mathematical models describing the dynamic of biological processes can serve as predictive tools to provide information on various aspects, such as biological robustness, drug efficacy, and response to toxicants.

2.18.3.4.7 Model usage in systems research

PD is the study of the effects of a drug once it reaches the site of action, and toxicodynamics (TD) is the study of the effects of exposure to a toxicant. In PD/TD studies, common concepts are maximum effect (E_{max}), and the dose at which 50% of the maximum effect is reached (EC_{50}). For a drug, the therapeutic index is defined as the relationship between concentrations causing adverse effects and concentrations causing desired effects: EC_{50} (adverse effect)/EC_{50} (desired effect). Consequently, drugs with a high therapeutic index are desirable in practice. For a toxicant, its potency (the dose at which EC_{50} is reached) is the quantity of interest. While this curve can be determined by measuring a biomarker of effect, PD also focuses on ligand–receptor affinities and inhibitions. When there is competitive inhibition, where another ligand "competes" with the primary drug, a higher dose of the drug is needed to obtain the desired effect, while E_{max} can still be achieved. When there is noncompetitive inhibition, E_{max} is lowered by reducing the number of functional receptors and is not reversed by increasing the drug concentration. Enhanced PD (ePD)[283,284] refers to the concept where systems biology mathematical models and PD meet. In this context, the drug target network is modeled taking into account not only enzymatic and metabolic reactions but also epigenetic and genetic factors and

posttranslational characteristics. ePD allows researchers to predict drug responses for individual subjects with different genetic and epigenetic backgrounds.

Similarly, enhanced TD can be defined in the context of toxicology. The ePD model discussed in Iyengar et al. addresses the effect of an EGFR inhibitor (e.g., *gefitinib*®) on tumor growth. The model is a simple linear pathway: the tumor growth response is mediated through SHC1/SOS1/GBR2, KRAS, RAF1, MEK1/2, MAPK1/2 RPS6KA1, JUN, CCND1, CDK4/6, and proliferation. An additional single coherent feed-forward motif from EGFR to Raf kinase inhibitor protein (RKIP) and RAF1 is added. Finally, factors such as an activation mutation in the *EGFR* gene, hyper/hypo-methylation of the *RASAL1* promoter, and/or changes in the microRNA miR-221 (which inhibits CDKN1B, in turn inhibiting CDK4/6) are added. Then, different patient characteristics are used to predict drug efficacy: a patient with a hyper-methylated *RASAL1* gene and no other RKIP changes or miR-221 will be resistant to the therapy. In contrast, a patient with a normal *RASALP1* gene, a single nucleotide polymorphism in the *RKIP/PEPB* gene that produces a hyperactive RKIP (which inhibits RAF1), and a decreased amount of miR-221 is predicted to be highly responsive to the therapy.

When modeling all the relevant regulatory pathways, the initial conditions of the model of drug availability are crucial to make realistic predictions. In this context, ePD intimately relies on the pharmacokinetics (PK) of the drug. PK and physiologically based pharmacokinetics (PBPK)[285] aim to model drug absorption, distribution, metabolism, and excretion principle. PK models help to elucidate a drug's half-life and its distribution in the body. In particular, these models can quantify the drug concentration at its site of action, which is the initial concentration needed in an ePD model. Additional examples on how systems toxicology can be used in these areas are discussed later.

2.18.4 Systems Biology Applications

Systems biology is a powerful tool to generate hypotheses, and provides an unbiased approach to identify the components responsible for biological phenomena. High-throughput technologies are used to identify groups of molecules that are regulated similarly and that may not have been linked to the biological phenomenon previously (Fig. 8A). The network approach described earlier allows researchers to trace the network perturbation back to the individual components responsible for the observed impact and, similar to gene sets and pathways, identify known and novel mechanisms of perturbation. Importantly, this approach can draw special attention to single molecules that do not belong to any specific or known biological pathway. This allows researchers to design targeted experiments to further verify and extend the insights obtained using high-throughput approaches. Such findings can be further corroborated by research groups with long-standing expertise in investigating specific molecules and pathways identified (or not) by systems biology approaches. Likewise, network approaches can be used to unravel novel interactions among known molecular pathways, thus expanding the knowledge on how a cell or tissue functions as a whole. By profiling the molecular response when a key element is disrupted in a relevant experimental system, the network around the molecule of interest can be expanded (Fig. 8B). Undoubtedly, basic research as we know it has been, and will continue to be, revolutionized by systems biology.

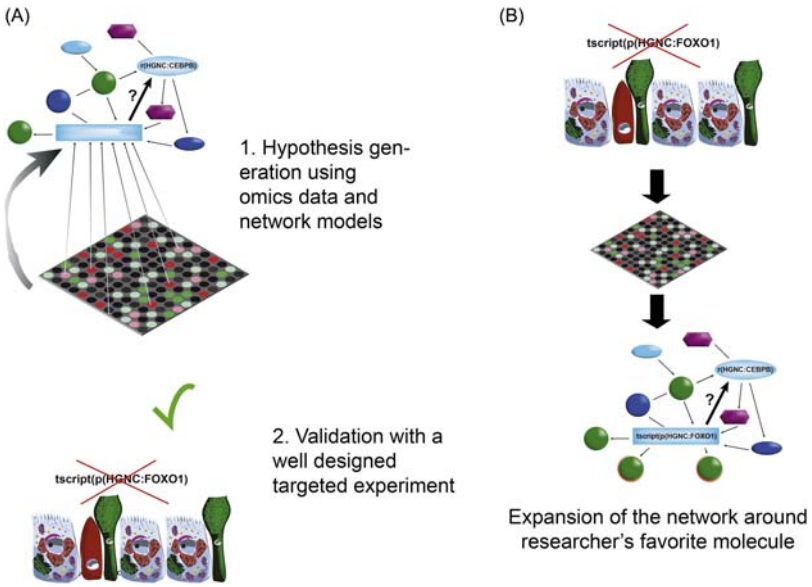

Fig. 8 Systems biology in basic research. (A) Systems biology is a powerful tool for hypothesis generation and (B) the identification of novel molecular networks.

2.18.4.1 Systems Pharmacology

2.18.4.1.1 Target identification

Systems biology approaches can be leveraged for drug development, and are then referred to as systems pharmacology. During the early stages of drug development, chemo-informatics has been commonly used for target prediction by grouping drugs based on their chemical structure,[286] and to predict off-target effects (and to identify additional targets). According to the classical view, drugs usually interact not only with their intended target but also with other molecules, "off-targets," causing potential side effects.[287,288] Moreover, while intended drug-induced effects are by definition localized, adverse, and/or off-target effects can be either local or systemic.

Consequently, systems pharmacology considers the system as a whole to predict not only how a drug may interact with its targets, but also how the drug target interacts with its network as well as how gene variants may alter the system's response to the drug.[289] Frequently used methods include chemical compound, protein structure, PPI, signaling, gene interaction, and metabolic network approaches.[290] Although networks built using a priori knowledge cover genome-scale biological detail, they usually do not cover dose- and time-dependent responses. Kinetic models, on the other hand, can rank drug targets based on their quantitative effects and simulate a drug's mode of action, even though they encompass more limited biology.[291] Moreover, even if a network can accurately predict the response to a given drug, the network is assumed to adapt when drug targets change as the network adapts.[291] A typical example is the multidrug resistance that results when a drug is transported out of the target cell.[292]

2.18.4.1.2 Adverse drug reactions

Even with well-defined targets and off-targets, some drugs can have unwanted effects or cause adverse drug reactions (ADRs). Many models have been developed to elucidate and predict adverse drug effects. For example, drugs can be grouped based on their clinical side effects,[293] and the use of different data sets and analyses of multiple side effects has been shown to improve this approach.[294] Modeling of the physiochemical characteristics of the drug with the target protein network can help connect targets and side effects by the drugs they share.[295] The topological properties of PPI networks for ADR-related proteins can predict the involvement of proteins in modulating ADRs.[296] Finally, multilevel process drug side-effect networks combine drug side effects with drug-biological process networks[297] or drug targets with drug side-effect relations.[298]

Demonstrating the power of the network approach, Zhao and colleagues derived a global concordance score and predicted biological fingerprints for 726 drugs approved by the Food and Drug Administration (FDA) based on correlations observed in pharmacological and genomic spaces.[299] Possibly the most powerful predictions are the approaches that integrate multiple similarity measures from various data types, including chemical, biological, phenotypic, and therapeutic.[300–302]

ADRs can also occur when individual characteristics disrupt the mechanism of action of a drug. Many different data types (microbiome, metabolome, lifestyle, nutrition, and genome, including transcriptome and proteome) need to be considered to fully appreciate the likelihood of an adverse effect. Integrated analyses of these data allow researchers to predict an individual's risk of an adverse response to a given drug, allowing certain at-risk individuals to be excluded from clinical trials and/or drug treatments.[286] This provides the foundation for systems pharmacology-based predictions of drug safety.

2.18.4.2 Systems Toxicology

Similar to pharmacology, the field of toxicology is progressively being "systemized." The 21st century toxicity paradigm initiated this change by recommending the inclusion of PK/PD modeling, omics data, and high-throughput technologies to assess the toxicity of potentially harmful compounds.[264] In its simplest form, the combination of high-throughput molecular profiling and computational approaches can derive signatures that describe similar behaviors of molecular species, and pathways that were not previously linked to these species. Now, -omics signatures can be viewed on their own as biomarkers of an exposure response (e.g., to cigarette smoke), as well as markers of effects of interactions between an individual's genetic background and exposure levels.[303,304] Molecular profiling can also help identify the mode of action of compounds whose health impacts are poorly understood.

Equally relevant in the context of toxicological assessment is the concept of the exposome. It refers to all of the exposures a human faces during his or her lifetime, and encompasses both external exposures to chemicals in the environment as well as internal conditions that are defined by the unique characteristics of the individual. While it will be difficult to cover all exposures simultaneously, even limited insights into the exposome will benefit the management of human well-being.[305] In particular, the serum exposome studied in the exposome-wide-association study provided the means to identify and validate markers of exposure and to distinguish between disease markers and simple exposure markers.[306] High-resolution metabolomics has been used for high-throughput relative quantification of thousands of chemicals and metabolites that activate biological pathways.[307] A more detailed review is provided in Ref.308.

The "Human Toxome" project (http://humantoxome.com/) aspires to identify pathways of toxicity by using untargeted methods instead of existing pathway knowledge. The approach is based on two types of -omics technologies: (i) transcriptomics, which is considered as a mature technology; and (ii) metabolomics, which probably best reflects actual phenotypic changes. The project seeks to establish the reproducibility of results obtained at different sites and using different technologies.[309] In the endocrine disruptor project, two independent laboratories produced high-throughput data from a breast cancer cell line treated with known endocrine disruptors. These data will be used to infer pathways of toxicity.[310] For this purpose, the consortium running the project

developed a range of bioinformatics methods to analyze the transcriptional events induced by estradiol treatment. These include the clustering of genes based on the topology of a weighted correlation network[311] as well as a new sensitive gene-enrichment method that creates a gene list ordered by expression values (as opposed to differential gene expression).[312]

Beyond toxicity pathways and molecular signatures or pathway analyses, systems toxicology combines large-scale molecular measurements with classical toxicology endpoints across multiple levels of biological organization.[6] High-throughput technologies have been used in toxicity assessments to compare the impact of tobacco products administered in vivo via the inhalation route[266,313] and in vitro.[314,315] These studies combined the traditional toxicity/disease endpoints with extensive molecular measurements. The causal biological network models described earlier were scored with transcriptomics data for quantitative impact assessment, combined with either proteomics and lipidomics analyses[266,313] or high-content-screening-based assays.[314,315] The following subsection includes another example of how systems biology can be applied to toxicological assessment.

2.18.4.2.1 Systems toxicology use case: assessment of nutraceuticals

The old saying "we are what we eat" emphasizes that dietary habits affect human health. Excessive consumption of salt, refined sugars, or saturated fats is known to increase the risk of cardiovascular and neurodegenerative diseases, as well as different types of cancer. Conversely, a higher dietary intake of fish, fruits, and vegetables seems to protect against these diseases.[316–318] Over the last two decades, several food components have been proposed to be responsible for the health benefits associated with certain dietary habits. Collectively known as nutraceuticals, these food constituents comprise multiple types of chemicals, such as polyunsaturated fatty acids (i.e., omega-3), polyphenols, isoflavones, carotenoids, and many more. Nutraceuticals have a wide range of biological effects including antioxidant, antiinflammatory, and antiproliferative properties.[319–324] Although most of these effects have been observed only in vitro, these studies suggested that nutraceuticals could protect against cancer and other diseases. However, current clinical and epidemiological data does not support these health claims.[319,321]

The apparent discrepancies between in vitro and epidemiological studies can be explained, at least partly, by some of the intrinsic characteristics of nutraceuticals. First, they have generally low-to-moderate biological activity at typical dietary doses. As a result, any potential effect could only be observed after long-term consumption. Also, they often result in a subtle (although highly desirable) beneficial effect not easily detectable in short-term clinical studies. Second, the systemic bioavailability of nutraceuticals is generally low. Thus, it is unlikely that they will reach target organs and tissues at pharmacologically relevant concentrations unless the level of exposure is very high. This is in contrast to pharmaceutical drugs, which are designed to reach target organs and exert an effect in much smaller timescales and at lower concentrations. Third, it is likely that any beneficial effect associated with a particular dietary habit results from the combined action of multiple bioactive constituents. Furthermore, other parameters (i.e., smoking status, body mass index, and age) can modulate the effects of nutraceuticals. Therefore, it is very challenging to detect the biological effects of a single constituent, even if the experimental design is adequate.[321,325,326]

Despite the lack of robust scientific evidence, nutraceuticals are generally perceived as beneficial and are widely consumed as dietary supplements at much higher doses than those naturally present in food. This, however, raises toxicological concerns. Nutraceuticals are considered as safe at dietary doses and no adverse effects are observed in standard toxicity assays. However, the consumption of supplements can result in much higher levels of exposure. Moreover, studies have shown that some of their effects are due to transcriptional and epigenetic regulation of gene expression.[327–329] These genomic effects can occur at relatively low concentrations,[329] and their potential consequences may not be detected easily in traditional toxicity assays.

Recently, we used a combination of gene expression data and high-content imaging-based endpoints to investigate the biological effects of a selected group of nutraceuticals in two in vitro cellular models: human primary endothelial cells and cryopreserved hepatocytes.[314] All of the tested compounds showed cytotoxicity in the different cell types, although the effects were observed only at doses well above dietary levels. However, we also observed significant gene expression changes in pathways regulating cell and oxidative stress responses at considerably lower doses. These effects were consistent with previous reports that nutraceuticals at high doses have a pro-oxidant effect.[330,331] Moreover, this study clearly showed how systems toxicology approaches can be useful for the toxicological assessment of nutraceuticals.

2.18.4.3 Systems Medicine: Diagnostics

By definition, a diagnostic biomarker objectively classifies subjects into groups based on phenotype, such as healthy versus sick, or early versus late stage of disease. Since the genetic makeup of an individual cannot fully explain and predict phenotypes, and since single-gene disorders are rare, measurement of individual markers has limited value in modern diagnostics. Systems biology acknowledges that disease represents the disturbance of many biological networks, and is not due to the erratic behavior of a single molecule.

As in toxicology, molecular signatures derived from high-throughput technologies can be used to classify subject groups. Such examples include genetic and epigenetic alterations,[332,333] gene expression changes (including miRNA profiles),[334] as well as proteomic and metabolic changes[335] that can be linked to phenotypes. Although molecular signatures are useful for diagnostic purposes, they are usually only correlative, and cannot provide deep insights into the complex biology underlying a disease.

Instead of considering single molecules as biomarkers, network models that consist of causal molecular interactions representing cellular processes based on prior knowledge provide static and mechanistic views of the disease state. A comprehensive network-based human disease model views the phenotype as the consequence of genetic and environmental perturbations causing specific PPIs that are linked to genome, epigenome, transcriptome, proteome, and metabolome.[336] Dynamic network biomarkers can be used to follow the disease over time and to separate the disease into different stages.[336]

Metabolomics is one of the promising technologies in cancer research[337,338] for early detection and diagnosis,[339] to search for biomarkers and altered metabolic pathways—for example, the tendency of cancer cells to rely on glycolysis and lactic acid generation rather than on full oxidation through oxidative phosphorylation (Warburg effect)—and to evaluate the efficacy of cancer treatments. Another important application is screening of newborns for inborn metabolic disorders[340–342] (e.g., fatty acid oxidation defects, organic acidemia, amino acid metabolism, and urea cycle defects), which can lead to the development of new diagnostic tests. Lipidomics techniques have been established to detect and monitor the development of cardiovascular disease,[343–345] diabetes,[346,347] inflammatory diseases,[348,349] Alzheimer's disease,[350,351] and many cancers.[352,353]

2.18.4.3.1 Personalized medicine

The contribution of systems biology to personalized medicine is undeniable. Network approaches, in particular, may provide a more elegant way to stratify subjects and explain different responses to individual drugs, and to identify the best combination of drugs to treat each patient[280] by comparisons with molecular signatures. When the key players are more or less known for a disease or treatment effect, it may make more sense to build more focused, signaling-pathway-specific network models, rather than models that encompass large biological processes (as described in section "**Systems Biology Applications**") to elucidate treatment failures in response to specific drugs. Such an approach was tested using a public dataset from patients suffering from ulcerative colitis who did not respond to anti-tumor necrosis factor (anti-TNF) treatment. Transcriptomics data from the affected tissue analyzed in the context of a network model containing three signaling pathways leading to NFκB activation, TNF-IL1α-TLR-NFκB model, allowed the identification of crucial biology to distinguish responders from nonresponders, but did not explain the treatment outcome, and others that could predict as well as explain the treatment outcome. The analysis suggested that MYD88 and TLR family members might be more important than TNF signaling to distinguish the nonresponders from the responders.[268] Without any knowledge on the genomic makeup, the approach could help in stratifying subjects and predict treatment outcomes.

It makes sense to build biomarkers and diagnostic predictors using multiple levels of data.[354] Subject stratification using multi-omics data may be the only way to manage complex diseases,[355] as proposed in the molecular-data-first approach for autism.[356] The establishment of integrative personal -omics profiles is important to ensure timely patient diagnosis, to provide personalized therapy to those who need it and will respond to it, and to follow therapeutic responses.[357–359] This new era in medicine centers around the term "Predictive, Personalized, Preventive, and Participatory (P4) medicine,"[232] which is the true medical application of systems biology[360] (**Fig. 9**). Under the P4 approach, concepts such as "biomedicalization," "quaternary prevention," "holistic medicalization," and "technoscientific transformations of health" are becoming increasingly popular. They all refer to the integration of biology, medicine, technology, and computation.[360] In his review on P4 medicine, Leroy Hood predicted that, "In 10 years each individual will be surrounded by a virtual cloud of billions of data points…"[361] Powerful, systems-based candidate biomarkers

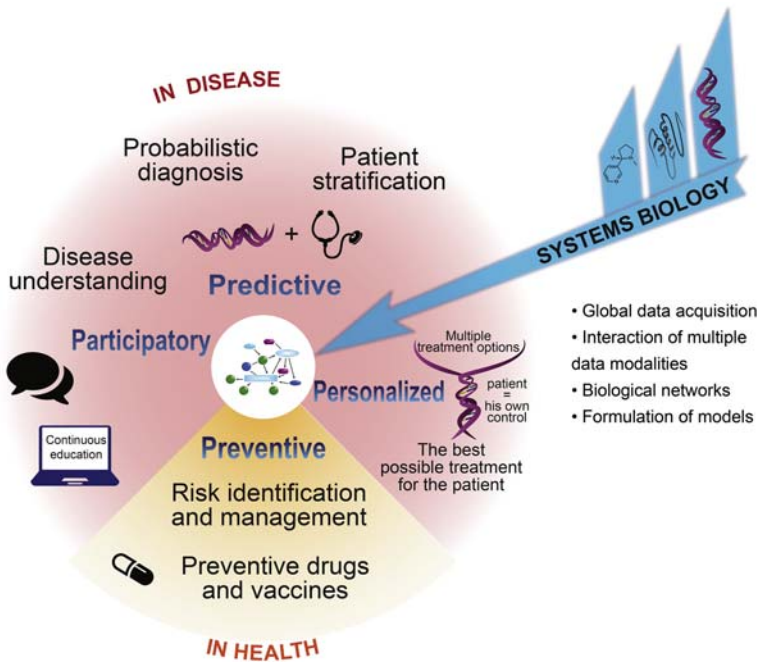

Fig. 9 Systems biology can serve many areas of P4 medicine that uses integrated personal -omics profiling to prevent disease as well as predict disease outcomes and treatment response.

for diagnostics and patient care should be verified and validated using hundreds of samples to ensure reproducibility, specificity, and sensitivity until they are sufficient to replace existing clinical tests.[332]

2.18.4.3.2 Translational systems biology

Translational medicine aims to convert information gained from basic research into human applications.[362] With a systems approach, this can be accelerated by combining insights gained from clinical trials and laboratory experiments using simplified systems.[363] Introducing higher-level biology using network biology may be a more reliable way to translate findings in preclinical systems to humans, compared with single-molecule measurements. Computational network models can be used to align preclinical in vitro and clinical findings. This approach has been demonstrated for the xenobiotic response to cigarette smoke exposure in organotypic tissue culture systems and human subjects.[364] A quantitative systems-level approach showed that the correlations of the transcriptomic response using the xenobiotic metabolism network model allowed for a robust comparison of datasets generated from in vivo samples and in vitro organotypic models. Quantification of the response in different model systems is accompanied by mechanistic insights when a network is analyzed at the level of key contributors.[364] This is relevant for translational research and could possibly be used to estimate effective doses in in vivo and in vitro systems.

Molecular profiling and detailed clinical measurements of subjects undergoing drug treatments can identify elements that are part of the same functional network. These elements can then be further investigated in simple well-controlled experimental systems to extract mechanistic features that explain the clinical symptoms. This involves systematic interference with the biological system and comparison of the unperturbed and perturbed states. The differences are considered as the in vivo functional network, the components of which can be investigated in controlled settings using in vivo, ex vivo, and in vitro approaches.[365]

The ultimate goal of translational medicine is to revisit clinical practice for more efficient patient diagnosis and better care.

2.18.4.4 Cross-Species Translation

In vivo rodent models are valuable tools to mimic human diseases and responses to treatments.[366] However, there can be substantial difficulties in translating research findings across species, and sometimes correlations are less than adequate.[367] Excluding poorly conducted large animal studies,[368] poor translatability can be due to discrepancies between human and mouse orthologous genes,[369] the failure to translate gene orthologues to biological function,[369] divergence in tissue-specific gene regulation among species,[370] and/or large differences in overall physiology.[371]

Using cultured human and rat airway cells, the species translation challenge conducted by the sbvIMPROVER Project[372] sets out to understand the limits of species-to-species translatability. The results showed that, at the cellular level, computational methods can be used to translate some specific stimuli and biological processes between rat and human based on phosphoproteomics, transcriptomics, and cytokine data.[373,374]

Future effective and robust species translation approaches will likely depend on a detailed mechanistic understanding of biological processes and how their components and parameters differ among species. The PBPK models (section "**Mathematical Models for Network Biology**") are designed to capture the adsorption, distribution, metabolism, and excretion of drugs in deep mechanistic detail—including, for example, drug-specific permeability coefficients and metabolic kinetic rates.[375] Several authors have argued that these mechanistic models are especially well suited for cross-species translation.[376–379] Some species-specific parameters can be replaced directly (e.g., blood flows and organ volumes), well-established scaling relations or predictions can be used for other parameters (e.g., permeability coefficients), and the remaining parameters can be obtained by direct measurements or fitting procedures (e.g., enzymatic rates and plasma protein binding). For example, recently, Thiel et al. systematically evaluated the translatability of PBPK models for 10 drugs between mouse and human.[380] The PBPK models were translatable between species, but the translation accuracy strongly depended on the availability of translatable model parameters—including kinetic rates and the abundance of metabolic enzymes.

Therefore, in addition to the development of well-characterized in vitro systems in relevant species, increasing modeling know-how will be a crucial part in translating preclinical findings into clinical research.

2.18.5 Special Considerations

2.18.5.1 Experimental Design and Data Production

Systems biology has initiated a new era in drug discovery, diagnostics, and toxicology, but it will take time until it will be fully accepted and leveraged. Rightfully so, because the workflows that provide information based on the analyses of thousands of data points must be well controlled, since there are many instances where bias and errors can inadvertently be introduced during data interpretation as listed in **Fig. 10** and described later.

There can be large variability among measurements, which calls for careful calculations beforehand to ensure that there is a sufficient number of biological replicates to obtain robust and useful data.[381–383] Some data modalities are also very sensitive to sample type, quality, and processing, and subject-related factors such as genetics, gender, environment, and nutrition. Such factors can drastically sway the molecular profiles. In the context of metabolomics, Courant et al. have listed several aspects that need to be taken into account to design studies involving the analysis of thousands of data points.[384] Another example describes how a routine proteomics analysis can vary among laboratories.[385]

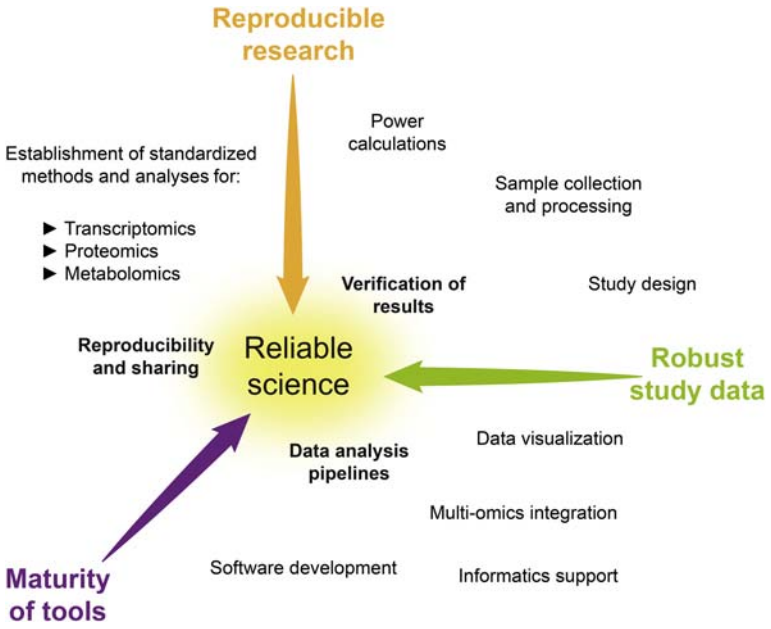

Fig. 10 Special considerations in systems biology. The figure summarizes aspects that should be taken into account to establish reproducible and reliable science. It starts with appropriate study designs and sample analysis, continues with the development of standard data analysis workflows and methods to integrate -omics data types. Finally, global data standards guarantee open data sharing and assessment of reproducibility.

Even at the same institute, with the same personnel handling the samples, there can be batch effects and/or variations related to changes in laboratory conditions, reagent lots, and individuals handling samples.[386] For gene expression profiling, the MAQC project sets out to assess the intra- and interplatform variability in microarray experiments.[387] Similar initiatives have been started around high-throughput sequencing of RNA (RNA-seq). The Sequencing Quality Control is the third phase of MAQC, and the project goal was to assess the reproducibility and comparability of RNA-seq methods by evaluating different sequencing platforms in real-world use cases.[388]

2.18.5.2 Data Evaluation

Even when there is an adequate experimental design, there are many sources of bias when handling big data. For all -omics analyses, the workflows need to be well defined and validated. Working instructions and standard operating procedures must be established, and reproducibility should be assessed using internal controls. Even so, results are not always reproducible when data are reanalyzed at different sites, partly because of differences in personal workflows and challenges in data sharing, as demonstrated in The Human Toxome Project.[310] Moreover, rapidly moving algorithm and software development requires constant bioinformatics support and specialized infrastructure to process, secure, and store the massive amounts of data that are produced.[389]

Omics technologies provide an extensive collection of distinct data at different levels (genome, transcriptome, proteome, and metabolome) that support and complement each other. The challenge lies in integrating these data types into a comprehensive analysis, and understanding the many relationships among the -omics datatypes for easier interpretation. In essence, the data from different technologies can be integrated in several ways. The data can be analyzed independently and then an explanation is formulated based on the results. Alternatively, the data can be integrated statistically by searching for associations or by using preexisting biological models to gain mechanistic insights.[390,391] Statistical and computational integration methods are still under development, and related challenges in data integration have been described.[392,393]

2.18.5.3 Data Standards and Sharing

To ensure reproducible science, which is a substantial difficulty in research today, total transparency with data-sharing and collaborative tools is needed. Experiments are often described in diverse ways with different levels of detail, sometimes purposely vague and even with incorrect descriptions. Every experiment has critical parts that need to be identified and properly annotated for full sample traceability and data reuse. Standards for experimental description and execution, terminology, data analysis, and data exchange are crucial if the data is to be shared in public repositories.[394] Without proper standards the valuable -omics data produced will remain largely unused.[395]

2.18.5.3.1 Standardization in transcriptomics

For transcriptomics, MIAME specifies the minimum requirements for experimental design, description protocols, and sample annotation, as well as raw and processed data.[396,397] However, it lacks guidelines for the terminology that should be used when describing experiments. Gene Expression-Tabular, MAGE-TAB, and MicroArray are simple, spreadsheet-based data description formats that are easily read by researchers.[398] The hierarchical Investigation-Study-Assay-Tab is a generic format for experimental representations. This initiative also develops and provides open-access tools, including conversion tools to other data formats, to aid data reporting for -omics technologies.[385,399] There are many other proposed formats, some no longer in use and some supported only by certain data repositories. However, with all the different initiatives, global standards are missing; for transcriptomics alone, there are at least 10 proposed standards and no real agreement among researchers on what constitutes a standard.[400] To address this problem, BioSharing offers a web interphase for sharing policy documents and information about the available standards as well as the possibility to register new standard initiatives.[401] The state of standards is discussed in detail in Ref. 400.

2.18.5.3.2 Standardization in proteomics

Proteomics is a rapidly maturing field, whose diversity reflects the complexity inherent in protein regulation and function. As we have seen, proteomics methods cover a wide range of protein properties including expression levels, modifications, and interactions. Each subfield has numerous sample preparation and analytical methods and instrumentation (e.g., mass spectrometers based on different principles and from different vendors). At the same time, the recent improvements in coverage and the accuracy of quantification strongly encourage the reuse of published proteomics data sets to gain deeper biological insights and to refine clinical applications. Common standards that capture the diversity of proteomics experiments are the key to facilitate effective reuse and to ensure the highest impact of proteomics in (systems) biology and medicine.

The Proteomics Standards Initiative (PSI)—an initiative formed by the Human Proteome Organization in 2002—has been the main driving force for the development and implementation of standards in the proteomics field.[402] The PSI is tasked to advance standardization in five areas: minimum information guidelines, data formats, controlled vocabularies, resources and software tools, and dissemination.

Minimum information guidelines define the minimum information that is required to understand how the study was conducted and how it can be reproduced. The first guideline, developed in 2006, is the minimum information about a proteomics experiment (MIAPE) guideline,[403] which was devised with a modular structure to allow for the diverse requirements of different proteomics experiments: MIAPE-CC describes column chromatography;[404] MIAPE-GE describes gel electrophoresis;[405] MIAPE-MS describes the generation of raw MS data;[406] MIAPE-Metabolomics Standards Initiative (MSI) describes informatics analysis workflows;[407] and MIAPE-Quan—the most recent addition—describes quantitative proteomics methods.[408]

The interoperability of data-sharing and analysis software depends on the availability of common data standards. The PSI defines two types of standard formats: Extensible Markup Language (XML) formats for computational processing; and tabular text formats for more lightweight reporting. Again, to address the diversity of proteomics methods, these formats must cover a broad range of analytical and processing results. The PSI has created XML-based file formats to store raw MS data (mzML),[409] input lists for targeted MS experiments (TraML),[410] peptide identification from MS experiments (mzIdentML),[411] and results from quantitative MS experiments (mzQuantML).[412] To promote the use of these formats, the latter two are complemented by the tabular mzTab format, which captures high-level information from both mzIdentML and mzQuantML, but is easier to work with.[413] As an important element of these formats, the PSI has also developed several controlled vocabularies to consistently and systematically capture the required information (e.g., sample types, instruments, and processing).[414]

These standardized formats and descriptions facilitate data sharing, which the PSI supports most directly through proteomics databases. The ProteomeXchange consortium provides an integrated framework for the submission and dissemination of MS proteomics data[415] and includes the PRIDE (untargeted proteomics data),[416] PeptideAtlas (targeted proteomics data),[417] and MassIVE (untargeted proteomics data, http://massive.ucsd.edu) databases.

These efforts to facilitate data sharing are very important, but are insufficient to bring proteomics into a clinical setting. To achieve this goal, standardization and understanding of the intra- and interlaboratory variability of proteomics assays is essential.[418] For example, Percy et al. developed reference kits and standardized protocols for targeted measurement of plasma proteins. This has allowed reproducible measurement of 22 plasma proteins across instruments and laboratories.[419]

Despite these advances, the translation of proteomics results into clinical practice is very limited. To date, only one proteomic biomarker assay—the OVA1 ovarian cancer test[420]—has been cleared by the FDA. With more robust and reproducible proteomics methods now available, we realize that more general factors of proteomics studies are hampering progress. Such factors include underpowered study designs, inadequate sample quality, and lack of validation.[421] We hope that the standardization initiatives will have broad impacts on the field of systems biology, leading to better overall study designs, and consequently, more robust translatability into a clinical setting.

2.18.5.3.3 Standardization in metabolomics

There are many metabolomics applications that offer a huge diversity of approaches designed to address individual scientific questions, and standardization based on common techniques is continuously progressing. Under the auspices of the Metabolomics

Society, the leading organization for promoting the growth, use, and understanding of metabolomics in the life sciences, the MSI has been formed with the goal to find a consensus for a minimum core set of necessary data (e.g., with respect to best practices in selecting and analyzing biological samples, chemical analysis, data analysis, ontology, data exchange standards, and reporting standards).[422] The MSI is organized by an oversight committee chaired by Oliver Fiehn and several subchairs according to the areas identified as being most important for describing metabolomics experiments.[423] A recent outcome is the global effort COSMOS (COordination of Standards In MetabOlomicS) for free and open sharing of metabolomics data. The metabolomics data can be in different data exchange formats, and include raw MS and NMR data, metabolite quantification and identification, and experimental metadata. Coordinated by the European Bioinformatics Institute—COSMOS has brought together European metabolomics data providers including universities and industry partners to establish and promote community standards. Open-access and exchange repositories for metabolomics experiments like MetaboLights (www.ebi.ac.uk/metabolights), Metabolomic Repository Bordeaux (http://metabolomexchange.org/rss/search/mwbs), and Metabolomics Workbench (http://www.metabolomicsworkbench.org/) have become the standards for e-infrastructures. For example, MetaboLights is a cross-species, cross-technique database that includes metabolite structures and their reference spectra as well as their biological roles, locations, and concentrations, and experimental data from metabolic experiments.[424]

Cross-platform comparisons for metabolomics methods provide valuable insights for the expected quality of analytical results, and have been established to compare quantitative metabolomics data related to primary metabolism obtained using GC/MS, LC/MS, and CE-MS platforms.[425] The outcome of such studies can be leveraged for recommendations on preferred analytical platforms for a specific research area and are very valuable to the metabolomics community.

While waiting for the establishment of standards covering all of the -omics platforms, transparent data sharing is still essential in research. Even though it is common sense to share data, it does not happen routinely, even in high impact journals, only a fraction of which enforce free data sharing.[426] Journals such as Scientific Data and its primary article type, the Data Descriptor, are dedicated to publishing scientifically valuable datasets (http://www.nature.com/sdata/). The production of data needs to be well described and annotated to allow others to reuse the data and verify conclusions.[427] A recent example is an inhalation study that was described in great detail to allow data sharing and reuse.[428]

2.18.5.4 Systems Biology Verification

Reproducible science is the key for all research areas. It can, however, not be taken for granted. While crucially important, there are many issues with the current peer review system.[429] Several aspects regarding its fairness and transparency are currently being discussed and include the anonymity of both authors and reviewers, and the compromised confidentiality of data and findings.[430] There are also criticism regarding the speed and cost of the current system.[431] One solution could be the F1000Research open science platform that proposes an open peer review to enforce open collaboration within the research community.[216] Systems biology faces special challenges in this regard, as research conclusions are always accompanied by high volumes of data that need to be analyzed with suitable expertise. The first level of systems biology verification relies on data publication that should follow the same transparency that allows independent verification, as alluded to in the previous sections.[432]

Even in the presence of the best of standards and open sharing of the omics data, significant effort should be assigned for comprehensive verification of results and methods used in systems biology. To complement the peer review system, several initiatives, such as CASP, BioCreAtIvE,[433] DREAM (discussed in more detail elsewhere in the article),[233] PROTEINCHALLENGE,[434] and sbvIMPROVER,[372] have been launched to verify methods of protein structure prediction, information extraction, gene network inference, proteomics analysis, and software development, as well as entire systems biology research workflows, respectively. Rather than relying on peer review by journals that publish results and methods, these initiatives engage crowds to evaluate existing and to contribute in developing new methods. Such innovation and verification of computational approaches could be considered as the second level of verification in systems biology.

As the third layer of verification, panels of scientific experts could be engaged to review comprehensive datasets for study design, technical aspects, as well as data analysis and interpretation. While the open peer review platform offered by F1000Research has its advantages, it may hinder honest review due to pressure by strong opinions in the field. Independent parties, such as the SciPinion (https://scipinion.com/) as the mediators of expert review, may provide the final layer of multilevel verification of systems biology research.

2.18.5.5 Education on Systems Biology

The overwhelming number of data points handled with the most sophisticated algorithms does not mean much until fully understood, accepted, and interpreted by specialized investigators. Such researchers have the knowledge and experience to crack the details of the all-encompassing information provided by systems biology. To inspire confidence in systems research, there are several initiatives that aim to educate researchers in various disciplines of systems biology (**Table 2**).

2.18.5.6 Current Status of Systems Biology in Industry

To make systems biology approaches relevant for industry in the long run, it is crucial that the data production and interpretation processes are at a level that is expected and accepted by regulatory agencies. Only then systems biology data can directly enable new

targeted treatments and support the biological safety of new drugs or other consumer products. Several points discussed in this article, especially those relating to standardization and validation of methods and analysis approaches, are key toward this important goal. Importantly, regulatory agencies—with the FDA at the forefront—have already taken action and support the development of highly reliable and robust systems biology technologies that can enable regulatory decision-making.[435] For example, the FDA has already implemented a Voluntary eXploratory Data Submission program, which enables the sponsor of an application to include omics data in a regulatory submission.[436] The idea of this program is for the FDA to learn how omics data can effectively be used in regulatory submissions. Also, to actively contribute to the development of robust omics technologies, the FDA is leading the MAQC, which aims to address technological challenges such as reproducibility, precision, specificity/sensitivity,

and data interpretation. For example, recently, in a project focused on NGS, the consortium demonstrated that RNA-seq can reliably and accurately measure relative gene expression across laboratories.[435] Importantly, initiatives focused on data generation need to be flanked by initiatives that are focused on robust and reproducible computational approaches. For example, recently, several of these computational challenges have been discussed during the Global Summit on Regulatory Science 2015, including the need for validated computational tools, validated analysis processes, and storage solutions that ensure data integrity.[437]

Despite advances, not many diagnostic or therapeutic options that are based on systems medicine have made it to the clinic. Mechanisms of the Development of ALLergy (MeDALL) was one of the first EU projects to implement a systems medicine approach for the understanding of complex chronic disease. By harvesting epidemiological, clinical and basic research data into a knowledge management platform, and by developing the allergen microarray chip combined with machine-learning methods to identify novel phenotypes, MeDALL's goal is to empower the patients themselves to know their disease.[438] Other success stories in systems medicine and network pharmacology are the multiple drugs targeting the cyclic GMP[439] as well as the inclusion of exome and genome sequencing for the diagnosis of neurodevelopmental disorders in children.[440]

All in all, the use of systems medicine in real life is not yet fully established. In their review, Mc Shane et al. list the criteria that should be used for omics-based predictors in National Cancer Institute-supported clinical trials. These criteria focus on the availability and quality of clinical specimens, issues with assays, model evaluation, clinical trial design, as well as ethical, legal, and regulatory issues.[441] In addition to these issues, depending on the diagnostic purpose, there may be differences which combinations of omics data are the most appropriate. Moreover, large-scale training of medical staff and the evaluation of the cost-effectiveness of each method are needed.[442] Nine tests that use gene expression profiling and expanded immunohistochemistry to guide the use of adjuvant chemotherapy in breast cancer management have been tested for cost-effectiveness by systematic review of evidence. While OncotypeDX was considered to be the most robust, the study stated the gaps in the evidence base and heterogeneity of patient cohorts as a weakness for such analysis.[443]

2.18.6 Conclusions

Biological systems are inherently complex. They typically contain a large number of components that interact with each other in a regulated manner. It is the sum of all the interactions between multiple components that are responsible for phenotypic plasticity. In this context, systems biology offers an unparalleled opportunity to investigate the global effects of a specific chemical (i.e., a drug or a toxicant) in a particular biological system (i.e., a cell, a tissue, or an organ). Systems biology comprises both experimental approaches that generate large amounts of data and the computational tools that enable the extraction of relevant mechanistic information from that data. Omics technologies offer nearly limitless possibilities to identify the molecular interactions in a complex system. In particular, the combination of multiple omics-based approaches results in complementary layers of information that can be integrated to provide a more accurate description of a biological system.

During the past two decades, systems-wide approaches have progressively become more common in biomedical research. Systems biology is currently used in many areas, including modern toxicology, pharmacology, and medicine, because it allows to investigate multiple biological processes that can occur simultaneously. At the same time, as with any powerful approach, there are still many challenges that need to be addressed to enable science and to fully benefit from this approach.

Acknowledgments

The authors would like to thank Dr. Stéphanie Boué and Ms. Samantha Elmhurst for the illustrations in this article.

2.19.1 Introduction

Although there is no consistent definition, chemical biology is a discipline spanning several fields, including chemistry, biology, and physics.[1] It aims to study and manipulate biological systems through chemical techniques, tools, and analyses. Medicinal chemistry is a research domain within chemical biology that links various scientific disciplines for discovery and development of new drugs.[2–4] One of the main goals of chemical biology and medicinal chemistry is to study how various small molecules affect biological systems. Recently, chemical biology has begun to use an emerging systematic screening strategy to obtain large collections of small molecules and explore their interactions with genes and proteins, a field now denoted chemogenomics, or chemical genomics.[5,6] Chemogenomics combines the latest tools of genomics and chemistry to conduct systematic screening of large-scale chemical libraries of small molecules against selected target families with the ultimate goal of identifying a small molecule that binds to and modulates the target proteins. With a one-ligand–one-target mind-set, chemogenomics is expected to validate therapeutic targets and identify drug candidates quickly and efficiently.[7]

During the past several decades, drug discovery and development have produced many effective therapeutic agents with a specific protein as a target. However, adverse side effects of drugs remain a major problem, and many drugs fail in clinical trials as a consequence of their previously unrecognized side effects.[8] One of the main reasons for this problem is that the traditional one-ligand–one-target drug design model does not consider the complex context of the *in vivo* environment, whereas multiple-target drugs may have a better opportunity to affect the key pathways and minimize toxicity issues.[9,10] Drug development should be based on the operational principles of biological systems. Biological processes are highly complex, with many components interacting with each other. Drugs exert their effects by modulating signaling networks in biological systems rather than affecting a single specific target in isolation. It is, therefore, of great importance to design network-based drugs. Indeed, for this reason, drug discovery is now moving from the conventional drug design model to a systems biology paradigm.[11–13]

Different from chemical biology and conventional reductionism, systems biology aims to describe and understand complex biological processes from a systems perspective and develop predictive models of biological systems by integrating high-throughput omics data and computational methods. Taking advantage of multidisciplinary collaboration, systems biology has developed many tools and approaches that have the potential to make a significant impact in biomedical science, including the field of drug discovery and development.[14,15] Massive amounts of omics data generated using systems biology techniques allow a comparison of gene or protein activities under different conditions and uncover global network structures. However, there is little awareness of chemistry in current systems biology studies. Integration of biological networks with large collections of small chemical entities is not only promising for target identification but also useful for understanding the mechanisms of action of drugs and identifying adverse effects.[16]

Both chemical biology and systems biology have had an increasing impact on drug discovery and drug design. Although these two disciplines have largely evolved in parallel in the recent past, there is an increasing need to integrate them to obtain a more complete picture of the way small molecules affect biological systems, which led to the emergence of a new field—systems chemical biology (SCB).[17] Systems chemical biology integrates large-scale heterogeneous data from chemical space and biological space and

provides a platform for understanding how small molecules affect biological systems with the aid of computational methods and quantitative modeling. This new discipline will not only offer new insights into biological systems but also have important applications in biomedicine. In addition, systems chemical biology provides new opportunities for drug discovery and development through systems-level research. In this article, we review the methodologies of systems chemical biology and discuss their impact on drug discovery and development.

2.19.2 Data Integration in Systems Chemical Biology

A biological system consists of a few essential elements, such as components (e.g., genes, proteins, and metabolites), their activities, and the connectivity relationships between them. Thanks to high-throughput technologies in chemical biology and systems biology, an increasing accumulation of various chemical and omics data is available on these elements of the system. Systems biology utilizes the massive omics data to reveal the entire network structure of biological systems, whereas chemical biology is focused on pairing individual compounds and targets through large-scale screening that may be real or virtual. How to store, integrate, and transform the data into translational knowledge is critical for the success of systems chemical biology.

High-throughput data from chemical space include the structure of small molecules, their activity assays, and ligand–target interactions. Advances in biotechnologies have resulted in numerous cell-based assays that are used to discover biologically active small chemical entities. The high-throughput screening commonly used in chemical biology can typically screen around 2–3 log orders of small molecules for an effect on a biological process of interest.[18] Many such data are now freely available in a variety of public databases. For example, ChEMBL is a database containing binding and functional information for a large number of drug-like bioactive compounds.[19] PubChem is a database of chemical molecules and their activities in biological assays which are maintained by the National Center for Biotechnology Information (NCBI).[20,21] ChemBank, developed through a collaboration at the Broad Institute of MIT and Harvard, is a web-based informatics environment storing data on small molecules and small-molecule screens.[22] ChemProt is a disease chemical biology database compiling annotated and predicted chemical–protein interactions, as well as disease-associated protein–protein interactions.[23] In addition, the data on ligand–target interactions have been steadily accumulated in publicly available databases. For example, STITCH is a database integrating various databases of biological pathways, drug–target relationships, and binding affinities, including BindingDB and PharmGKB.[24–26] **Table 1** lists some select chemical database resources that are publicly available and can be used for data integration in systems chemical biology.

Biological components include genes, proteins, small molecules, and metabolites. Thus far, many databases have been developed in which to deposit information on individual biological components. For example, Entrez Gene is NCBI's database for gene-specific information, which focuses on genomes that have been completely sequenced.[27] UniProtKB is the central hub for the collection of functional information on proteins.[28] There are also some databases with specific types of proteins, for example, BRENDA is a main source of functional enzyme data.[29] The Human Metabolome Database (HMDB) is an electronic database containing detailed information about small-molecule metabolites found in humans.[30] These databases provide acquisition sources for the components of biological systems relevant to systems chemical biology. Perturbations of biological systems by small molecules (drugs) lead to changes in the activities of biological components. The bioactivity of small molecules and macromolecules is commonly assessed by measuring gene expression, metabolite abundance, and protein concentration. Gene Expression Omnibus (GEO) stores massive microarray- and sequence-based gene expression datasets representing gene activities under different conditions.[31] The Human Protein Atlas (HPA) is a database containing protein expression and localization profiles for a large majority of

GEO	A functional genomic data repository supporting MIAME-compliant array- and sequence-based data submissions	http://www.ncbi.nlm.nih.gov/geo/
HPA	A database with millions of high-resolution images showing the spatial distribution of proteins in many tissues and cell types	http://www.proteinatlas.org/
KEGG Pathway	A collection of manually drawn pathway maps representing the molecular interaction and reaction networks for metabolism, cellular processes, and human diseases	http://www.genome.jp/kegg/pathway.html
MetaCyc	A comprehensive curated database describing experimentally determined small-molecule metabolic pathways and enzymes from over 2500 organisms	http://metacyc.org/
Reactome	A curated and peer-reviewed pathway database	http://www.reactome.org/
Pathway Commons	A network biology resource providing access to biological pathway information collected from different pathway databases	http://www.pathwaycommons.org/about/
MSigDB	A comprehensive collection of annotated gene sets for doing gene set enrichment analysis	http://software.broadinstitute.org/gsea/msigdb/

all human protein-coding genes based on both RNA and protein data.[32] In addition to metabolite information, HMDB also stores in situ metabolite concentration data submitted by different research laboratories.[30] **Table 2** lists select database resources of bioactivity information relevant to systems chemical biology.

Small molecules (drugs) may also affect the connectivity relationships among biological components of a biological system as they modulate signaling pathways rather than a single specific target. Data on molecular interactions, signaling pathways, and biochemical pathways under healthy and diseased conditions have also been complied. Molecular interactions that can be generated in a high-throughput manner include protein–DNA interactions,[33] protein–protein interactions,[34,35] and kinase–substrate interactions.[36] Signaling pathways transmit information through dynamic protein interaction networks. An automated high-throughput technology, luminescence-based mammalian interactome mapping, was developed for mapping dynamic signaling networks in mammalian cells.[37] KEGG Pathway is a collection of manually drawn pathway maps describing the molecular interaction and reaction networks for metabolism, cellular processes, and human diseases.[38] In addition to KEGG Pathway, there are other databases for biochemical pathways, such as MetaCyc[39] and Reactome.[40] Pathway Commons provides a network biology resource for accessing biological pathway information collected from public pathway databases.[41] The Molecular Signatures Database (MSigDB) is a collection of annotated gene sets for use in gene set enrichment analysis.[42,43] These gene sets can be divided into eight categories, including coherently expressed gene signatures representing well-defined biological states or processes, curated gene sets from online pathway databases and literature, genes annotated by the same GO terms, and genes with conserved cis-regulatory motifs. The public availability of various pathway databases facilitates mapping large-scale omics datasets and chemical datasets to signaling and biochemical pathways for biological interpretation of systems-level mechanisms. These databases and their web links are summarized in **Table 2**.

Systems biology and chemical biology have largely evolved in parallel in the past two decades. These two disciplines share many commonalities and also have unique complementary domains. As shown in **Fig. 1**, both of these disciplines have begun using high-throughput technologies to generate large-scale datasets, although for different purposes. Systems biology uses high-throughput techniques to generate massive amounts of genomic, transcriptomic, proteomic, and metabolomic data and aims to reveal the systems-level mechanisms of biology processes by data integration. Chemical biology utilizes high-throughput screens to generate large-scale chemical structures and bioactivity information of small molecules and aims to pair ligands and targets. The increasing accumulation of omics data and their modulation by small molecules make it critical to integrate chemical biology and systems biology and develop the new field of systems chemical biology.[17,44] Systems chemical biology relies on high-level integration of chemical, biological, and interactome databases using sophisticated computational methods and mathematical modeling, with an ultimate goal of understanding how small molecules manipulate a biological system as a whole, not simply individual drug targets. Systems chemical biology, therefore, will not only offer new unique insights into biological systems but also have significant impact on various aspects of drug discovery and development.

2.19.3 Computational Methodologies in Systems Chemical Biology

Computational methodologies are not only the important elements of systems biology but also an essential part of chemical biology. Systems chemical biology benefits from collaborations and interactions from multidisciplinary fields. In the development process of systems chemical biology, computational methodologies, such as data mining, machine learning, and dynamic

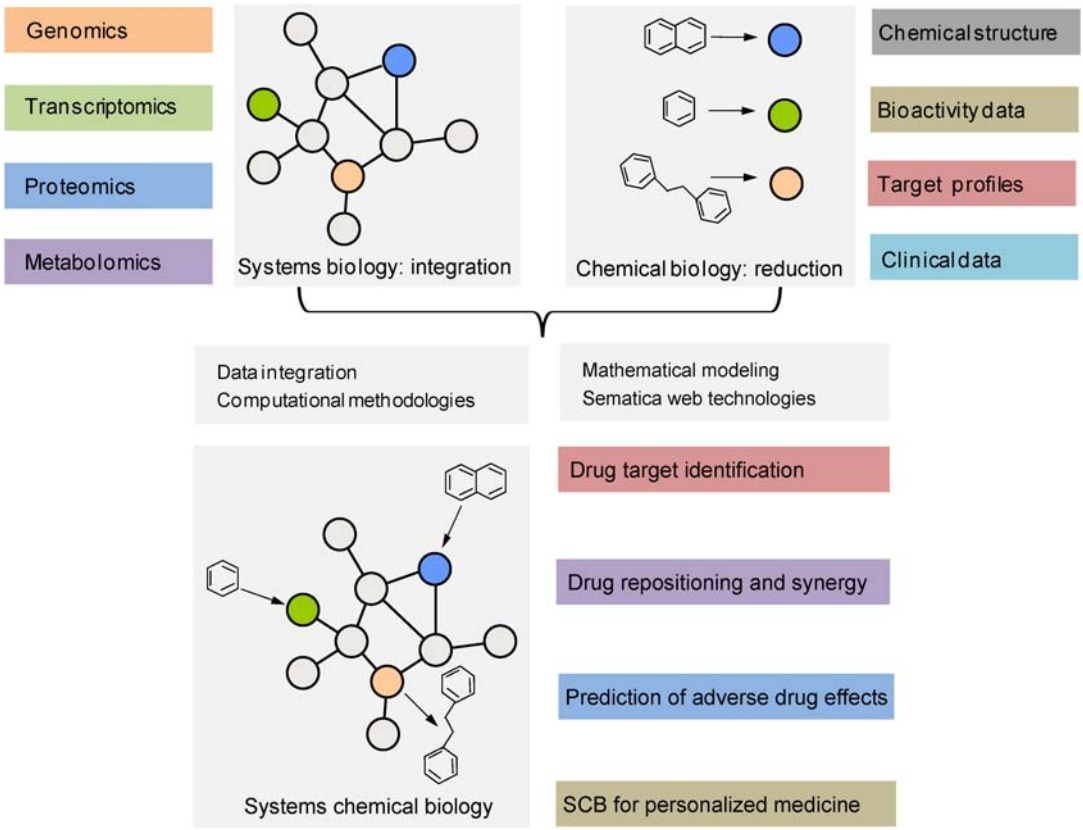

Fig. 1 Integration of systems biology and chemical biology for drug discovery.

modeling, cannot be ignored. In addition, network science and graph theory are indispensable as the topology of biological systems can be represented by an interaction network that is itself quantitatively tractable. Various data integration approaches and semantic web technologies are also very useful in this field. With the aid of these methodologies, systems chemical biology can facilitate efficient and highly predictable drug discovery.

2.19.3.1 Data Mining and Machine Learning

The explosive growth of chemical and biological data drives drug discovery from individual similarity searching using reference compounds toward automatic large-scale predictions using data mining and machine-learning approaches.[45] Such methods usually require a representative training set on which to base the models, learn model parameters, and derive a robust predictive model with good generalizability. The application of machine learning in drug discovery is extensive, including drug–target prediction, drug repositioning, and adverse drug event (ADE) prediction. For example, drug–drug chemical similarity and target–target sequence similarity represent core concepts in the chemical space and genomic space, respectively, and can be used as features of machine-learning models for predicting new drug–target interactions.[46] A unique advantage of machine-learning methods is their ability to integrate and fuse information from multiple resources and transform the data into meaningful knowledge. For example, Napolitano et al.[47] integrated data sources from drug–drug chemical similarity, target–target closeness in the protein interaction network, and correlations between drug-induced gene expression profiles into a support vector machine (SVM) classifier whose outcome is a therapeutic class for a given drug. The classifier achieves promising high-level accuracy and has the potential to affect drug discovery. Data mining and machine-learning methodologies have also been similarly applied to prediction of ADEs.[48]

2.19.3.2 Dynamic Modeling

Biological systems are not static, but are highly dynamic. Dynamic modeling is, therefore, an essential computational approach in systems chemical biology. It can simulate how a variety of perturbations of a biological system induced by a small molecule affect the behavior of the system. Such simulations are very helpful for deriving mechanistic insights about the system. Discrete logical modeling simplifies biological reality, ignores quantitative kinetic parameters, and, thus, can make qualitative (or semiquantitative) dynamic predictions of system behaviors. Flobak et al.[49] developed a dynamical logical model representing a cell fate decision network in the AGS gastric cancer cell line based on knowledge extracted from the literature and databases for discovering drug

synergy. With the aid of the software GINsim, the model can cope with the vast state space, simulate the perturbations of the network caused by anticancer drug combinations, and predict the synergistic growth-inhibitory action of some combinations of drugs. In addition, molecular dynamics simulations play an increasingly important role in drug discovery. For example, atomistic dynamic simulations of protein receptors and their small-molecule ligands are very useful in computer-aided drug discovery,[50] including virtual compound screening, identification of binding sites (both orthosteric and allosteric), and prediction of binding energies. Okimoto et al.[51] conducted a computational screen of compounds by combining molecular docking with massive-scale molecular dynamics simulations. This screening method has a much higher enrichment performance than molecular docking alone. Lastly, when specific kinetic and binding constants are known and extracellular species concentration can be calculated, forward dynamic modeling by ordinary differential equations, stochastic differential equations, or mixed models can be used to determine the combinations of drugs that maximize pathway effects and minimize ADEs.[52]

2.19.3.3 Network Analysis and Graph Theory

Biological molecules and their dynamic interactions determine the function of a complex biological system. These interactions form different types of molecular networks with characteristic topology[53] that are indispensable for understanding the systems-level mechanisms of drug action. Systems pharmacology aims to combine network analyses with pharmacokinetic and pharmacodynamic models in order to understand drug action at the systems level.[54] In addition, network modeling provides a powerful method to investigate drug discovery-related problems. One pioneering work in this regard is the contribution of a drug–target network in which FDA-approved drugs and proteins are linked by drug–target binary associations to form a bipartite graph.[55] Topological analyses of this network indicate that drugs of similar types cluster together and that newer drugs tend to target already targeted proteins. Cami et al.[56] constructed a bipartite network representation of existing drug–ADE associations and incorporated the topological features of nodes into a logistic regression model to predict new drug–ADE relationships. A chemical similarity network capturing drug–drug similarity has aided in new target prediction, as well.[57] In addition, network pharmacology approaches have also been used to map the unexplored target space and therapeutic potential of natural products, providing a systematic means by which to extend the druggable space of proteins implicated in complex diseases.[58]

2.19.3.4 Data Integration

As mentioned earlier, one unique feature of systems chemical biology is the massive accumulation of data from multiple experimental spaces. Therefore, effective integration of heterogeneous data and knowledge from different sources will be crucial for future drug discovery.[59] Data integration techniques include ensemble methods, multiple kernel learning, and information fusion. A few integrative methods have been applied in drug discovery to date. For example, a kernel regression model-based method that integrates heterogeneous data sources from the chemical space and the biological space was developed to predict potential side-effect profiles of drugs.[60] Cao et al.[61] developed a multiple evidence fusion method integrating multiple similarity measures from various data types for large-scale prediction of adverse drug reactions (ADRs). In a recent study, Zheng et al.[62] developed a weighted ensemble similarity algorithm based on ligand structural features for predicting drug targets and potential drug repositioning. In addition, semantic web technologies are highly useful for data integration in systems chemical biology as searching multiple datasets through a single framework is much more convenient than searching those datasets individually. A variety of semantic languages and tools have been designed for searching and mining large heterogeneous datasets from chemistry and biology, which have become technical enablers of systems chemical biology.[63]

Traditional drug discovery involves cell-based or target-focused screening of chemical compounds in a very expensive and lengthy process. By contrast, many drugs exert effects by modulating biological pathways rather than individual targets. With the aid of the computational methodologies described earlier, systems chemical biology approaches that integrate increasingly available data on drugs, proteins, and diseases will be beneficial to drug discovery, drug repurposing, drug side-effect prediction, and personalized medicine.[12,64]

2.19.4 Drug–Target Identification and Prioritization

High-throughput screening of biological systems has identified many biologically active small molecules. Follow-up studies typically focus on determining their precise protein targets. There are two fundamental methods in chemical genetics by which to understand the action of small molecules on biological systems: forward chemical genetics and reverse chemical genetics.[16] The former directly tests the impact of small molecules on a biological process and then follows with target identification to determine the protein responsible for the phenotype. Starting with a protein target, the latter conducts a high-throughput screen to identify candidate small molecules and then exposes biological systems to those candidates to determine compound-induced phenotypes. Some biochemical methods, such as biochemical affinity purification, can directly find target proteins that bind small molecules of interest.[65] Genetic-based target identification methods determine protein targets by performing large-scale modifications and measurements of DNA or RNA. For example, Eggert et al.[66] conducted parallel testing of both small-molecule screens and genome-wide-scale RNAi perturbation to enable identification of cytokinesis inhibitors and their targets.[66] Castoreno et al.[67] developed a RNAi-sensitized small-molecule screen to target small molecules toward a specific pathway. With these types of advances in

high-throughput technologies for systems chemical biology, large-scale genomic and chemical data have increasingly accumulated and provide unprecedented platforms for drug–target identification by computational inference and prediction. Thus far, many analytic methods have been proposed to predict new drug targets or drug–target interactions. We are particularly interested in those that utilize chemical information of drugs or small molecules, as these methods serve as the basis for systems-centric structure-based drug design as reviewed recently by Pei et al.[68]

Computational methods can be used to predict protein targets of drugs and small molecules based on data from chemogenomics and systems biology studies. One class of methods is to identify new targets of existing drugs based on the similarity of bioactivity profiles of drugs. The principle underlying these methods is that compounds with the same mechanisms of action tend to have similar chemical structure or activities across different biological assays. For example, Keiser et al.[69] developed a statistics-based chemoinformatics approach that explores the chemical similarities between drug and ligand sets to predict thousands of unanticipated drug–target interactions. From a more granular perspective, bioorthogonal or orthogonal bioorthogonal chemistries can be used to determine the targets of specific drug molecules and their interaction partners in complex networks in situ, respectively.[70] Target prioritization and drug–target identification methodologies have rarely taken the cellular interaction environment into account in conventional pharmacology. It is necessary and beneficial to consider cellular context as many phenotypes are caused by the effects of ligand on multiple-target proteins. Yamanish et al.[71] performed a novel analysis that revealed significant correlations between drug structure similarity, target sequence similarity, and the drug–target interaction network topology and subsequently integrated chemical and genomic spaces into a pharmacological space to predict drug–target interactions using supervised learning for a bipartite graph. They further incorporated pharmacological effects into the prediction algorithm as they found drug–target interactions better correlate with pharmacological effect similarity than with chemical structure similarity.[72] A recent study presented a new computational target identification method called Chemical Similarity Network Analysis Pulldown (CSNAP) that utilizes chemical similarity networks for large-scale drug–target profiling.[57] CSNAP clusters diverse chemical structures into distinct subnetworks representing consensus chemical patterns, which likely target common proteins.

Some methods complement existing chemical structure-based and ligand-based target prediction methods. Drug targets may display unique topological features in the human interactome. Mitsopoulos et al.[73] presented a systematic computational analysis of topological parameters of the human interactome and identified several distinctive topological patterns that distinguish druggable proteins in cellular networks.[73] Advances in biotechnologies make it possible to collect genome-wide responses to genetic and chemical perturbations. A massive number of somatic mutations have been accumulated as a result of these technologies. Some proteins may contain 'driver' mutations that are critical for the pathogenesis of a complex disease and, thus, could be potential drug targets. Zhao et al.[74] hypothesized that mutations at protein–ligand binding-site residues are likely to be druggable targets and developed a structural genomics-based Bayesian inference method incorporating the somatic missense mutations into protein–ligand binding-site residues to prioritize druggable mutations. Currently, information about drugs and drug targets in publicly available online databases is biased toward established drugs and drug–target interactions. Rask-Andersen et al.[75] collected a data set of clinical trial drug–target interactions based on CenterWatch's Drugs in Clinical Trials Database and identified 475 potentially novel clinical trial drug targets.

Systems chemical biology integrates data from chemical, genomic, and phenotypic spaces and uses network-based approaches and systematic strategies to prioritize and predict drug targets (**Fig. 2**). Incorporation of chemical structure and activity information into drug–target identification can make the prediction more accurate. Such computational prediction can provide useful target candidates that are subject to validation using biochemical methods or chemical genetics methods. In addition, systems chemical biology approaches not only provide drug–target candidates but also offer novel insights into the systems-level mechanisms of drug action derived from omics data. Systems chemical biology is expected to have a significant impact on virtual screening of chemical libraries and increase research productivity in drug discovery in the future.

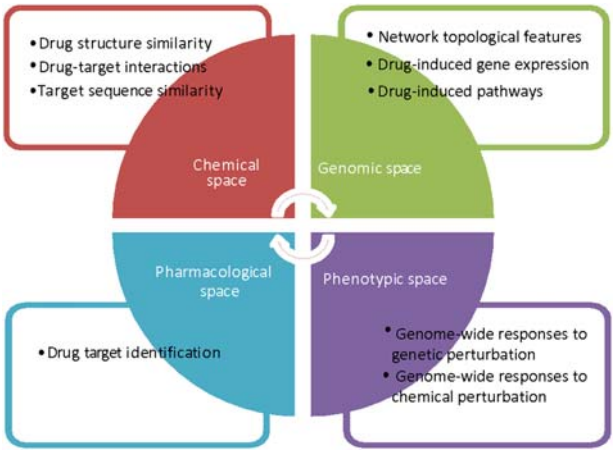

Fig. 2 Integration of heterogeneous data from different spaces for drug–target identification.

2.19.5 Drug Repositioning and Drug Combination

Pharmaceutical research and development (R&D) reports show that the number of approved new drugs has declined in the past two decades, although investment in pharmaceutical R&D has increased substantially.[76] Moreover, the average development time of drugs has increased significantly, urging researchers to seek more efficient solutions. Drug repositioning or drug repurposing, which aims to find new uses for known drugs, can narrow down drug candidates and, thus, shorten the development time, offering a promising alternative to *de novo* drug discovery. A variety of methods have been developed for drug repositioning. Computational strategies can predict new therapeutic indications for existing FDA-approved drugs that are subject to clinical trials. One of the great benefits of drug repositioning is that the pharmacokinetics and safety of known drugs do not need to be reassessed. Here, we focus on network-based drug repositioning methods relevant to systems chemical biology.

Core concepts that support drug repurposing using network strategies include drug–target interactions, target–disease associations, and drug–indication associations. As shown in **Fig. 3A**, a drug may have multiple targets, and identification of a new drug target that connects with causal genes for another disease may be helpful for drug repositioning. In addition, a new indication can be predicted by revealing new target–disease associations, that is, new associations of an existing drug target with another disease. For example, Sawada et al.[77] developed a target-based drug repositioning method to predict potential drug targets and new drug indications based on chemical structural similarity and phenotypic effect similarity derived from large-scale chemical–protein interaction data. A comprehensive drug–target–disease association network of over 8000 drugs and 1400 diseases has been constructed in this study, providing insights into the mechanisms of the predicted new drug indications. Zhao and Li presented a comodule approach to describing drug–gene–disease relationships. In this study, network-based gene closeness profiles are constructed to relate drugs to diseases, and a Bayesian partition method is then used to identify drug–gene–disease comodules.[78] Napolitano et al.[47] adopted a machine-learning approach integrating multiple layers of information including the similarity of chemical structures of drugs and the closeness of drug targets within the protein–protein interaction network for drug repositioning.

Drug-induced gene expression data have rich information for systematic drug repositioning, as illustrated in **Fig. 3B**. To discover the functional connections among diseases, genetic perturbation, and drug action, Lamb et al.[79] created a reference collection of gene expression profiles from cultured human cells treated with bioactive small molecules. This Connectivity Map (CMap) can be used to find connections among small molecules sharing a mechanism of action and is a useful resource for drug repositioning. One of the successful applications of CMap was conducted by Iorio et al.[80] In this study, the similarities in phenotypic effects and modes of action of drugs are calculated based on the similarity in gene expression profiles following drug treatment. A drug network displaying similarities of pairs of drugs was next constructed and partitioned into densely interconnected modules. A drug can be repositioned based on the drug modules to which it belongs. The mode of action for nine anticancer compounds was correctly predicted, and an unreported effect for a well-known drug, fasudil (a Rho-kinase inhibitor), was discovered using this network approach.[81] In the study conducted by Iskar et al.,[81] a large set of drug-induced transcriptional modules was identified using CMap data. Based on conserved and cell type-specific drug-induced modules, they further predicted gene functions of some regulators and revealed new mechanisms of action for existing drugs, providing a starting point for drug repositioning. Sirota et al.[82] integrated gene expression measurements from diseases with the CMap data and successfully predicted the new therapeutic effects of drugs based on the correlation scores between drugs and disease gene signatures. The assumption underlying this method is that a drug has the potential to have a therapeutic effect on a disease if exposure to this drug can reverse the disease state signified by a specific set of gene expression changes. More drug repositioning methods can be found in a recent comprehensive review.[83]

Drug combination strategies, which refer to the use of two or more drugs administered to a patient, can also be used as a rational therapeutic intervention. A drug combination therapy may have higher efficacy, fewer side effects, and less toxicity

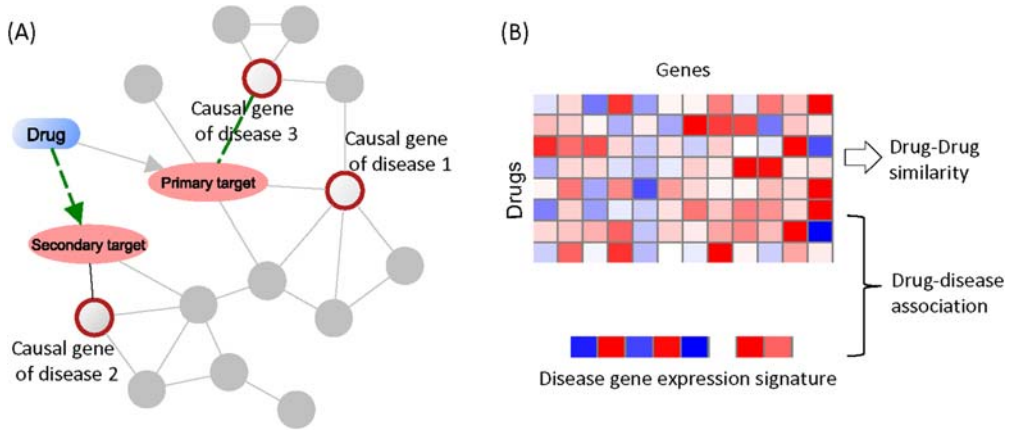

Fig. 3 Examples of network-based drug repositioning. (A) Drug repositioning based on new drug–target interactions and new target–disease associations. (B) Drug repositioning based on correlation of the drug-induced gene expression profiles.

compared to single-drug treatment due to additive or ideally synergistic effects among different drugs.[84,85] Some drug combinations have been used in treating complex diseases, such as cancer and cardiovascular diseases. For example, it has been demonstrated that the combination of aspirin and dipyridamole is more effective than aspirin alone in reducing the risk of stroke and other serious vascular events.[86] Experimental screening of drug combinations, however, is very costly and often only identifies a small number of synergistic combinations owing to the large search space and the difficulties in quantifying drug synergy.[87,88] With the exponential growth of molecular data available, systems chemical biology approaches can be used to filter this experimental search space and predict novel synergistic drug combinations with the aid of computational methods and mathematical models.[52] As in drug repositioning, drug-induced gene expression profiles can capture the complex dependencies of drugs and provide rich information for drug combination identification. A community computational challenge was launched to develop computational methods for ranking compound pairs based on gene expression profiles of human cells treated with individual compounds at multiple time points and concentrations.[89] Four of the 32 submitted methods performed significantly better than random guessing, indicating that computational prediction of optimal drug combinations is possible. In a recent study, Sun et al.[90] established a semisupervised learning model called the Ranking-system of Anti-Cancer Synergy to predict the synergistic potential of the available anticancer drugs by combining features of targeting networks and transcriptomic profiles. The model first does a preliminary ranking by calculating the synergistic potential for queried drug pairs and then refines the rankings based on gene expression correlations between individual drugs. In addition, a framework based on differential coexpression and Pareto optimization has been developed to mine drug-induced high-throughput transcriptomic data for predicting targeted drug combinations.[91] Drug combinations not only can achieve higher efficacy but also can reduce side effects. For example, rosiglitazone is an antidiabetic drug with cardiovascular side effects including myocardial infarction (MI). Zhao et al.[92] searched for the usage of a second drug in the FDA's Adverse Event Reporting System (FAERS) that could mitigate the risk of rosiglitazone-associated MI and found that the combination of rosiglitazone with exenatide significantly reduces rosiglitazone-associated MI.[92] Next-generation high-throughput technologies that enable the measurement of millions of cellular data points simultaneously also provide a great opportunity for systems chemical biology to identify more synergistic drug combinations.[85]

2.19.6 ADE Prediction

In Europe, nearly 200,000 people die every year from ADRs according to estimates from the European Commission. Taken together, about 328,000 patients in the United States and Europe die from prescription drugs each year. ADEs or ADRs have posed serious challenges to public health.[93,94] Therefore, early and accurate prediction of ADEs is critically important for reducing the event rates and has direct impact on drug safety and public health. Thus far, there has been a wide range of methods developed to detect or predict ADEs. Approaches from systems chemical biology integrating technologies from biological, chemical, and quantitative sciences can elucidate and predict adverse drug effects from cellular to whole-systems levels. These approaches, which integrate large-scale data related to drugs, proteins, and biological pathways, not only enhance our ability to assess the side effects of small molecules with higher accuracy than traditional toxicity studies but also provide mechanistic insights leading to ADRs.[95] In addition to data from genomics, chemistry, and systems biology, there are a few public data sources for drug safety and drug toxicity that can be utilized in early identification of ADRs through computational inference. **Table 3** summarizes some relevant data sources for this purpose.

Table 3 Select publicly available data sources for prediction of ADEs

Databases	*Descriptions*	*Web links*
FAERS	An information database designed to support the FDA postmarketing safety surveillance program for all approved drug and therapeutic biological products	http://www.fda.gov/Drugs/default.htm
SIDER	A side-effect database that contains information on 1430 marketed drugs and their recorded adverse reactions	http://sideeffects.embl.de/
CTD	A database that provides manually curated information about chemical–protein interactions, chemical–disease relationships, and gene–disease relationships	http://ctdbase.org/
DrugMatrix	A toxicology reference database that stores the results of thousands of highly controlled and standardized toxicological experiments	https://ntp.niehs.nih.gov/drugmatrix
Open TG-GATEs	A toxicogenomic database developed to store data on observed gene expression and toxicity in rats and humans after exposure to 150 compounds	http://toxico.nibiohn.go.jp/english/
ToxRefDB	A database capturing thousands of in vivo animal toxicity studies on hundreds of chemicals	http://www.epa.gov/comptox/toxrefdb/
DSSTox	A high-quality chemistry resource for supporting improved predictive toxicology	https://www.epa.gov/chemical-research/distributed-structure-searchable-toxicity-dsstox-database

As shown in Fig. 4, the datasets that provide relevant information for drug side-effect prediction are diverse, including similarity of drug or target structure, drug–ADR relationships, drug–target relationships, and drug–drug interactions. In addition, knowledge of the affected biological pathways of drugs and the gene ontology (GO) annotations of drug targets is useful in drug safety prediction. Xie et al.[96] generated protein–ligand binding profiles on a genome-wide scale by comparing ligand-binding sites with known protein structures and elucidated the molecular mechanisms associated with the adverse drug effects of CETP inhibitors for the treatment of cardiovascular diseases. The serious side effects of one CETP inhibitor, torcetrapib, were explained using this systems chemical biology approach by recognizing that torcetrapib, in addition to other members of the class of compounds, activates the renin–angiotensin system increasing blood pressure with its attendant cardiovascular risks. Based on chemical structure similarities between drugs and those molecules that lead to specific side effects, Lounkine et al.[97] used a molecular fingerprint strategy to screen computationally the 656 drugs against the 339-target panel and predict their activities on 73 unintended 'side-effect' targets. An association metric was then developed to prioritize those new off-targets and created a drug–target–ADR network. Cami et al.[56] constructed a bipartite network representation of existing drug–ADE associations called predictive pharmacosafety networks on the basis of a widely used drug safety database, defined nine network covariates and taxonomic covariates, and then used a logistic regression model to predict whether a given drug–ADE pair has a relationship or not. A recent study presented a new method to predict potential side effects of drugs from their drug–target relationships. This approach uses a canonical correlation analysis of the full drug–target and drug–ADE matrices and then calculates the probability that each drug has a given side effect using a Bayesian discriminant analysis technique.[98]

Other studies utilized complementary methods to predict the side effects of drugs. The data in spontaneous reporting systems may have many uncharacterized confounding factors, such as concomitant medications, patient demographics, and patient medical histories that interfere with statistical analysis. Tatonetti et al.[99] presented an adaptive data-driven approach for correcting some of these factors and created comprehensive database of drug effects (OFFSIDES) and a database of drug–drug interaction side effects (TWOSIDES). Brouwers et al.[100] mapped drug targets to protein–protein interaction networks and found that network neighbors of drug targets contribute to the similarity of drug side effects. Recently, a community-based DREAM challenge was launched to predict the toxicity of environmental compounds on human health.[3] The given data are the cytotoxicity of 156 compounds in human cell lines for which genotype and transcriptional data are available. The challenge participants were asked to develop algorithms to predict interindividual variability in toxic response based on genomic and transcriptional profiles and predict population-level cytotoxicity based on the structural attributes of the compounds.[3]

Cardiotoxicity is one of the major causes for drug withdrawals, and many drugs can induce irreversible cardiotoxicity.[101] Huang et al.[102] developed a network biology method integrating clinical observation data with drug–target data, protein–protein interaction networks, and GO annotations to predict drug side effects by using the combination of SVM and logistic regression. Using cardiotoxicity as a case study, they demonstrated that biomolecular networks and gene annotation information can significantly improve the predictive accuracy of ADRs of drugs. Incorporating drug chemical structures is also informative for drug safety prediction.[103] Ivanov et al.[104] developed a computational approach for identifying drug-induced MI-related proteins by predicting drug–target interactions based on the chemical structural similarity of the compounds. Drug-induced gene expression profiles can also provide insights into the similarity of drug side effects. Wang et al.[105] explored the prediction of ADRs based on the drug-induced gene expression profiles from CMap. They found that drugs inducing comparable ADRs tend to lead to similar CMap

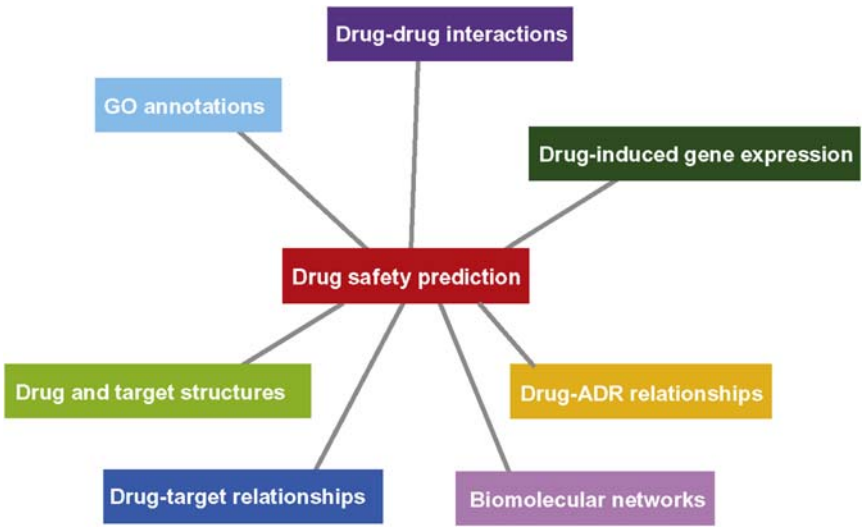

Fig. 4 Diverse datasets that can be used in drug safety prediction.

expression profiles. Based on such correlations, predictive models were constructed for various ADRs, including severe myocardial and infectious events. More systems biology approaches to understanding cardiotoxicity in cancer treatments can be found in a recent review.[101]

There is still a long way to go for reliable drug safety prediction, but systems chemical biology offers new avenues for investigating this critical area of drug development. Different from conventional drug design models, systems chemical biology combines the biological and chemical characteristics of drug targets and small molecules and considers system-wide side effects that cause the drug to fail. The approaches of systems chemical biology allow us to develop the hypotheses about drug side effects by understanding the signaling pathways underlying drug toxicity. We expect that systems chemical biology will have an increasing impact on drug safety prediction in the future.

2.19.7 Systems Chemical Biology for Personalized Medicine

Clearly, the high rate of ADRs is a major challenge in drug development. The one-size-fits-all drug model that ignores individual differences is often a primary cause of the ADRs. Personalized medicine puts aside the time-honored one-size-fits-all drug model and aims to provide an individual patient with tailored treatments based on his or her genetic profiles. The chemical biology community has successfully adapted high-throughput screening methodologies to facilitate the discovery of targeted therapeutics for personalized medicine. For example, chronic myeloid leukemia (CML) is characterized by a reciprocal translocation between chromosomes 9 and 22 that results in the constitutive activation of the tyrosine kinase enzyme BCR-ABL. A compound identified by *in vitro* screening for tyrosine kinase inhibitors, imatinib, was developed to act on cancers where BCR-ABL is stuck in the "ON" position.[106] This is one of the first cancer therapies that shows the potential for targeted treatment and has been widely used in the treatment of CML, gastrointestinal stromal tumors, and a number of other "unrelated" malignant tumors with this translocation. Since then, an increasing list of molecularly targeted therapeutics has been developed by similar approaches to drug discovery and target validation,[107–109] demonstrating the great potential of personalized medicine.

By contrast, systems biology has had many successes in utilizing high-throughput omics technologies to illuminate potential targets for disease intervention. With the increasing accumulation of next-generation sequencing and DNA variation array data, personalized medicine takes advantage of the great opportunity and is making promising progress. For example, The Cancer Genome Atlas (TCGA) is a publically funded project that aims to catalog and identify cancer-causing somatic variants in DNA, chromatin, and RNA of cancer genomes. Thus far, TCGA research team has analyzed large cohorts of over 30 human tumors through latest large-scale genome sequencing technologies and sophisticated multidimensional analytic methods.[110,111] The results are expected to provide rich information for personalized drug design. Chen et al.[112] combined different high-throughput technologies to present an integrative personal omics profile analysis that integrates genomic, transcriptomic, proteomic, metabolomic, and autoantibody profiles from a single individual over a 14-month period. This longitudinal analysis assessed disease risks and monitored disease states and trajectories for some complex diseases, such as type 2 diabetes, rhinovirus infection, and respiratory syncytial virus infection, demonstrating the possibility of personalized medicine enabled by systems chemical biology.

Personalized medicine focuses on personalized benefits, that is, improving a drug's potential to benefit a particular patient based on that patient's genetic makeup. A recent study demonstrated that it is possible for personalized medicine to predict a drug's downside risk as well, that is, a drug's side effects.[113] This study collected omics data from individuals and constructed data-driven personalized whole-cell kinetic models of metabolism to identify individuals at risk for a drug side effect. Although personalized medicine models have not yet been fully realized, the availability of large-scale genomic data and chemical data has revolutionized how biomedical scientists understand and explore biological systems. It has long been recognized that genetics may contribute to variability in drug action.[114] Exploration of available genomic sequencing data allows us to understand the variability of drug responses in different people. Systems chemical biology integrating genomics and other types of omics data with small molecule–target interaction profiles provides unprecedented opportunities for targeted therapeutic agents and new diagnostics. The contributions of system chemical biology to personalized medicine will become increasingly important and will urge new strategies not only for drug discovery but also for clinical trial design.[115,13]

2.19.8 Conclusions

Systems chemical biology is an emerging field that spans multiple disciplines including chemical biology, medicinal chemistry, systems biology, and computational science. By integrating heterogeneous chemical data and omics data using computational modeling, systems chemical biology could alter our way of thinking about biological systems and offers new avenues for understanding how small molecules perturb biological systems as a whole. A higher-level understanding of perturbation mechanisms of biological systems can guide researchers in the potential therapeutic impact of a small molecule on a signaling pathway and further affect the field of drug discovery. We anticipate more discoveries and applications in the field of systems chemical biology in the near future.

2.20.1 Introduction

The efficiency of drug development has seen a constant decline. For instance, during the past 65 years, the number of drugs approved per billion US dollar investment has halved every 9 years.[1] This observation is somewhat paradoxical since during the same time there have been huge advancements in drug discovery and development technologies that made it much cheaper, faster, and easier to identify new drug targets and new drug molecules. The number of drug-like molecules that can be synthesized by one chemist, for example, has increased from 1 per week by about three orders of magnitude since the early 1990s.

Translational Science or Translational Medicine (TM) has arisen as an important discipline in modern drug discovery and development. It was triggered by the recognition of the so-called valley of death[2,3] where despite the huge advances in drug discovery technologies that resulted in the discovery of large amounts of new drug targets as well as the development of promising biological and small molecule drugs modulating these targets, many of these drugs failed in clinical trials. The challenge was thus to enhance the predictivity of the preclinical models and to design exploratory clinical trial designs and methodologies to test promising molecules earlier and faster.

Despite some advances, the number of drugs that finally receive regulatory approval is still low, and those drugs that make it to the market are often improved versions of older drugs (me-better drugs such as new formulations or new chemical entities targeting

known modes of action). The main reason for this drug failure rate was a lack of efficacy observed in clinical trials of drug candidates that showed great promise in drug discovery.

There may be two main factors responsible for this:

1. The industrialization of drug discovery and development led to huge specialized departments that operate in isolation, often distributed over different countries, continents, and time zones. A lack of communication between the relevant disciplines within a company or academic institution but also with other key stakeholders, for example, patients, prescribers, regulators, and payers, is thus probably one of the key factors. While each discipline was probably able to produce highly sophisticated work, there was not sufficient interaction and alignment as well as limited integration of knowledge during the whole drug development process.
2. Tools for successful translational research have only been developed in the last one or two decades. Among those tools are biomarkers that can help (if used wisely) to achieve more efficient translation between in vitro findings, animal model results, and clinical trial endpoints. Another opportunity is represented by the increased bioinformatics capabilities and the greater predictive power of in silico methods enabling evaluation of likely benefit/risk profiles for future drug candidates.[4] Other tools that have become available or that have been greatly advanced during the last years are animal models, modeling and simulation as well as imaging technologies.

In this article, we will describe the tools used in translational research, that is, biomarkers, animal models, imaging, in silico modeling and simulations. Their use will be illustrated with examples and specific tips and tricks of how to implement those into daily project work. We believe, however, that TM is more than these tools and technologies—it is not yet another discipline or department, it is a way of thinking that should become part of every discipline involved in drug development. Thus, in addition to describing the tools and how best to use them, we will elaborate on how to design a translational research strategy and exemplify with some case studies as to how this has been successfully implemented in the past.

2.20.2 Biomarkers

2.20.2.1 Definition

"Biomarkers" or "biological markers" are biological measures of biological processes. In Dec. 1998, the National Institutes of Health Biomarkers Definitions Working group defined a biomarker as "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention."[5] Biomarkers can take many shapes or forms and in essence any biological marker that objectively quantifies a certain disease process or engagement of a drug to its target and has the potential to correlate statistically to clinical outcomes falls in this category. Depending on how a specific biomarker is measured, it will be subdivided into "wet biomarker" or "dry biomarker." Examples of wet biomarkers include soluble markers (in plasma, urine, or any other biological matrix) and genomics (gene expression patterns, genotyping), whereas examples of dry biomarkers include imaging (computed tomography (CT), positron emission tomography (PET), X-ray, magnetic resonance image (MRI)), scoring systems, questionnaires, etc.[6]

There is no well-established categorization system for biomarkers, but typically the following classes are frequently used based on the purpose for which they are destined: pharmacodynamic (PD) biomarkers, efficacy biomarkers, safety biomarkers, stratification and predictive biomarkers, competitive biomarkers, prognostic biomarkers, and pharmaco-economic biomarkers. It is important to bear in mind that for any classification system, classes are not discrete and/or mutually exclusive, that is, one biomarker can belong to either one or several classes based on the intended "purpose" of the biomarker. For instance, insulin sensitivity can serve as an efficacy biomarker in the context of type II diabetes[7] and a safety biomarker for the assessment of an antipsychotic drug.[8]

2.20.2.2 Types

2.20.2.2.1 Pharmacodynamic biomarkers

PD biomarkers are markers of a certain pharmacological response that is directly linked to engagement of the primary molecular target by the drug. As such, PD markers intervene upstream in the cascade of events that ultimately lead to the disease and are thus also referred to as proximal biomarkers as opposed to distal biomarkers (or efficacy biomarkers). Importantly, PD markers are modulated by drug treatment in a drug concentration-dependent manner and hence, correlate drug concentration to target occupancy when not at saturation. These biomarkers are crucial in gaining insight into disease mechanisms for first-in-class drugs with a novel nonvalidated mechanism of action. For example, if the PD biomarker indicates a strong target engagement but this relates to a lack of clinical effect, it is very likely that the biological process that is modulated does not play a prominent role in the pathophysiology leading to the disease, or that the patient population was inadequately selected. Ideally, a suitable PD biomarker should therefore be identified early on in the drug development process before or during proof-of-efficacy animal studies. The translatability of the PD biomarker from animal models to humans is critical such that any findings from preclinical studies can be appropriately bridged to the clinical setting. For example, the robustness and suitability of soluble IL-6 receptor levels as a PD biomarker for anti-IL-6 receptor biologics (ALX-0061 and tocilizumab) has been shown both nonclinically[9] and clinically.[10]

2.20.2.2.2 Efficacy biomarkers

Efficacy biomarkers (or distal biomarkers) typically are situated further downstream in the biological cascade that leads to the clinical disease in contrast to the PD biomarkers (or proximal biomarkers) that intervene more upstream. The separation between PD biomarkers and efficacy biomarkers can be very thin and in practice the term "efficacy biomarkers" is used for surrogate, predictive, and PD alike. In this section, efficacy biomarkers are seen as a specific class and are modulated by drug treatment in a dose-dependent manner, which correlates with a favorable efficacy, clinically meaningful response, or outcome and can range from more proximal PD biomarkers, to the most distal markers. As such, efficacy markers measure effects that are indirectly linked or are secondary to the drug binding to its target. A small proportion of efficacy biomarkers are validated and are accepted as surrogate endpoints for regulatory approval such as arterial blood pressure as a surrogate for heart failure, blood glucose levels as a surrogate for survival, and/or complications in diabetes mellitus, prostate-specific antigen response for survival in prostate cancer, forced expiratory volume (FEV1) in 1 second for lung function.

2.20.2.2.3 Stratification and predictive biomarkers

Stratification biomarkers are typically pretreatment markers (i.e., baseline markers) or signatures associated with a specific anticipated beneficial response (or safety concern) or lack of response to a particular therapy in that population. In other words, the stratification biomarkers are used in the context of a clinical trial and in daily clinical practice to select patients who are eligible to a certain treatment and whose response to that treatment is predictable, while patients who are unlikely to benefit or who are at risk of developing adverse reactions to the given treatment can be excluded. This stratification of patients upfront mainly serves two important purposes: firstly, because of the selection of more homogenous patient subpopulations, clinical effects will be augmented which will increase the success rate of drug approvals; secondly, the number of patients at risk of side effects who would likely only partially respond to treatment is minimized. More broadly, stratification biomarkers are also useful in routine clinical practice as they can assist physicians in making initial treatment decisions (e.g., selecting treatment options) for their patients or in identifying patients with different disease subtypes. Predictive biomarkers, although often used interchangeably with stratification biomarkers, are associated with a response or lack of response to a particular therapy. In contrast to stratification biomarkers that are typically pretreatment markers, predictive biomarkers can be measured throughout the treatment course and allow to adapt or adjust the treatment of a patient as early as possible and to predict long-term effects based on an early change in predictive biomarker signatures. For example, V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog (KRAS) and v-raf murine sarcoma viral oncogene homolog B1 (BRAF) are currently under focus as useful predictive biomarkers in patients with metastatic diseases treated with antiepidermal growth factor receptor monoclonal antibodies (mAbs), such as cetuximab and panitumumab.[11]

It is important to note the difference between "prognostic" and "predictive" biomarkers. A prognostic biomarker provides information on the clinical outcome of a disease in the absence of therapy, and is in essence a measure of its natural history. A predictive biomarker in contrast provides information on the likely outcome of treatment. For example, there is a weak but significant association between poor clinical outcome (i.e., poor prognosis) and overexpression of the oncogene Her2, as seen in approximately 15% of invasive breast cancers. In addition, Her2 overexpression predicts that those patients will likely not respond to cytotoxic chemotherapies (e.g., the combination of cytoxan methotrexate-5-fluoracil) but will likely respond to others (e.g., anthracyclines, taxanes, and trastuzumab). As such, Her2 expression status is both a prognostic and a predictive biomarker.[12] In contrast, the expression levels of both the estrogen receptor-α and the progesterone receptor have a relatively weak prognostic value but a very strong predictive value for response to hormonal therapies, such as tamoxifen.[12]

The use of stratification biomarkers or predictive biomarkers in clinical trials requires the development of a companion diagnostic in parallel to drug development. The Food and Drug Administration (FDA) has drafted in 2014 a guideline to facilitate companion diagnostic development.[13] It defines what a companion diagnostic is and various scenarios for use, and describes FDA policies for approval and labeling. Regulatory approvals of the device and drug should be contemporaneous. European Medicines Agency (EMA) published some reflection papers, still mostly focused on pharmacogenomics biomarkers to provide guidance.[14–18] Although companion diagnostics are a natural consequence of the flow toward a more personalized medicine, it comes with an extra burden during drug development.

2.20.2.2.4 Safety biomarkers

Safety biomarkers are markers that predict or diagnose clinically relevant adverse outcomes in response to a drug treatment or therapy. As this class of biomarkers is of prime importance to guarantee drug safety, the selection of safety biomarkers should be based on robust preclinical data, previous studies, or literature data. Ideally, these biomarkers should be specific and sensitive markers of early clinical injury and of high predictive value. This predictive value of a specific biomarker depends on the temporal relationship between the change in the biomarker and the occurrence of the adverse event. If the change in the biomarker occurs before the adverse event has occurred, the biomarker will be truly predictive and referred to as a "predictive safety biomarker." For example, QT wave interval prolongation on electrocardiograms is used as a surrogate marker for a particular type of cardiac arrhythmias, that is, torsades de pointes in drug development.[19] If the change in biomarker occurs concomitantly or after an adverse event (but before the appearance of the clinical manifestations), the biomarker will be referred to as a "diagnostic safety biomarker." The aim of safety biomarkers is primarily to identify and assess the risk for adverse effects and, as a result, increase drug safety but they are also used to increase drug development cost-effectiveness/success rate by identifying early those drugs that display acceptable safety profiles and by stopping early the development of those drugs that show an unacceptable safety profile. In addition safety

biomarkers help guide the selection of the starting dose for clinical studies or aid in the identification of patients that are at risk of developing adverse events to the drug (see also stratification biomarkers).

Several safety biomarkers have been developed and accepted over the years, such as alanine aminotransferase and aspartate aminotransferase that can detect toxicity in the liver. The predictive nature of these two biomarkers is rather weak as they are reflective of ongoing liver toxicity when tissue damage has already occurred but are not predictive of liver function. Several other biomarkers of liver toxicity that are being evaluated include glutamate dehydrogenase, malate dehydrogenase, paraoxonase/arylesterase 1, purine nucleoside phosphorylase, arginase, sorbitol dehydrogenase, and glutathione *S*-transferase.[20] Biomarkers for drug-induced renal damage and nephrotoxicity such as urinary protein biomarkers include Kim-1, albumin, total protein, β2-microglobulin, cystatin C, clusterin, and trefoil factor-3.[21,22]

2.20.2.2.5 Competitive biomarkers

Competitive biomarkers are used to assess whether or not a treatment has a competitive benefit versus a comparator (competitor, benchmark, standard of care therapy). This benefit can be on safety, efficacy, cost, etc. These competitive biomarkers aid in guiding strategic decisions and clinical trial designs, specifically when performing a head-to-head clinical trial with the benchmark or comparator drug. Go/no go decisions can be taken on the basis of the competitive biomarker data which provides an insight into the competitive edge of the investigational drug versus the benchmark. The use of such competitive biomarkers is especially important for a drug being developed in a "saturated indication" where a lack of competitive edge would allow early decision making and decrease drug attrition rates. For example, changes in HbA1c (glycated hemoglobin) levels were used to indirectly estimate the comparative efficacies of two dipeptidyl peptidase-4 inhibitors (sitagliptin and linagliptin) for the treatment of type II diabetes mellitus.[23] While often the competitiveness is either for efficacy or safety (i.e., the competitive biomarkers would overlap with those biomarkers) those could also include markers for speed of onset of action. When selecting a competitive biomarker, one should keep in mind that this biomarker does not need to be the best efficacy or safety biomarker, but should be selected to provide the best possible or most meaningful differentiation.

2.20.2.2.6 Pharmaco-economic biomarkers

One factor that drives increasing failure rates of approvals and reimbursement of drugs, besides a lack of efficacy or safety concerns, is the increasing awareness of many regulatory authorities and payers about the cost-effectiveness of a drug, specifically for "life-style drugs" that would a priori not obtain reimbursement (e.g., urinary incontinence, sexual dysfunction). Pharmaco-economic biomarkers are used to assess the pharmaco-economic value of a new drug and to compare the cost-effectiveness versus the standard of care. In essence, the assessment of pharmaco-economic biomarkers enables the analysis of the affordability of a drug. In the current healthcare system environment, which is becoming more and more cost sensitive, it is essential to include early measures to quantify patient benefits and potential cost savings in other areas (e.g., number of days in hospital). Even if a drug receives regulatory approval, the payers may decide not to reimburse the costs or to a level that would not be sufficient to compensate the costs of its development. Increased safety or efficacy by its own may not be sufficient for a premium price versus generic competitors but if there are quantifiable savings in other health care costs, for example, less surgeries or doctor visits this may support a higher than generic drug price.

2.20.2.3 Use of Biomarkers

Over recent years there has been a decline in drug approval and an increase in the attrition rate of compounds in late clinical development resulting in increased drug development costs.[24] As a consequence, the use of biomarkers as key components of translational strategies in drug development and clinical practice is encouraged by the US FDA.[25] Incorporating biomarkers into drug development at preclinical and clinical stages serves several objectives. Their use aids in appropriate decision making throughout the development process such as "go/no go" decisions, lead candidate selection, defining optimal dose regimens for efficacy and safety, and for guiding treatment decisions. They also provide valuable information on the disease mechanism and ultimately allow patient stratification which is core in a personalized medicine approach or to be used as a surrogate endpoint for clinical effect or clinical safety. Recommendations to improve the decisions about incorporation of biomarker studies in early investigational drug trials have been published.[26]

2.20.2.4 Assays/Methods

As mentioned previously, there is a clear incentive by regulatory bodies (FDA and EMA) to include biomarkers in translational strategies. As a consequence, the reliable and quantitative measurements of a large number of biomarkers are warranted. As biomarkers can take numerous and ever expanding forms, it is not the intent of this section to list all possible methods here but to focus on the methods currently most frequently used for quantitative biomarkers and their advantages and disadvantages. For the sake of this article, this will focus on peptide biomarkers. For the validation of other methods to assess biomarkers, there is less guidance available and this is thus on a fit-for-purpose approach. While it is impossible to give advice on the validation of all kinds of assays and measurements, the criteria given further below can serve as guidance for the validation of other assays.

Currently, there are two approaches for absolute quantification: antibody-based assays and mass spectrometry (MS)-based assays.[27] Although the current standard for biomarker quantification is the classical enzyme-linked immunosorbent assay (ELISA),

Table 1 Advantages and disadvantages of analytical methods

Assay type	*Advantages*	*Disadvantages*
Mass spectrometry MRM/SRM	● Eliminates analytical interferences (e.g., nonspecific antibody binding, matrix effects) ● Allows the analysis of a wide variety of compounds, even across different compound classes ● Antibody-free detection ● Linear response over a wide dynamic range ● Increased sensitivity for targeted methods	● Impeded by lack of sensitivity and its nonquantitative nature for untargeted methods ● Requires prior knowledge of protein mass/sequence ● SRM is currently limited to the targeted measurements of up to 100 proteins per run versus thousands for untargeted approach
Immunoassays		
Singleplex ELISA	● High selectivity, sensitivity, and assay versatility	● Requires relatively large sample volumes ● Requires the use of high-quality antibody pairs ● Narrow dynamic range ● Immobilization of antigen to the solid matrix can cause issues with accuracy and reproducibility
Multiplex assays	● Multiple analytes measured in the same run from the same sample (limits freeze/thaw cycles, reduces sample storage space, etc.) ● Reasonable sensitivity, reproducibility, and broad assay dynamic range (pg mL^{-1} to ng mL^{-1}) ● High-throughput nature ● Requirement for smaller sample volume ● Time/cost efficiency ● Reagent costs substantially reduced	● Requires the use of high-quality antibody pairs ● Resources needed to develop multiplex assays as frequently hampered by lack of adequate selectivity and specificity ● Extensive validation

alternative methods such as multiplex assays and MS-based quantification assays are gaining in importance. Singleplex assays, of which the ELISA is the best example, have one important shortcoming in that one single analyte is measured at a time. In view of the integration of biomarkers in translational strategies and the requirement for high-throughput screening, singleplex assays are ill-suited for the quantification of a large number of candidate biomarker proteins. In contrast, multiplex assays (such as Luminex, bead arrays, etc.) allow the quantification of multiple analytes at once but will require extensive development (Table 1).

2.20.2.4.1 Enzyme-linked immunosorbent assay

ELISA is a solid-phase enzyme immunoassay and is the most widely used method for biomarker detection and quantification. It offers high selectivity, sensitivity, and assay versatility; however, it presents certain limitations such as a narrow dynamic range, low throughput, modest reproducibility due to its numerous wash steps, and the requirement of antibodies with high-specificity against each targeted protein or peptide of interest. ELISA assays also have limited multiplexing capabilities which can render the quantification of multiple biomarkers costly and time-consuming. In addition, higher sample volumes would be required to allow sequential analysis of various biomarkers. This would particularly pose a problem during clinical studies in certain patient populations (e.g., infants) or with particular matrices (e.g., synovial fluid) where the collected amount of biological material will be limited.

2.20.2.4.2 Multiplex assays

Due to the shortcomings of the singleplex assays, multiplex assays have gained importance over the years as they allow the quantification of multiple analytes in a single step and are often used for high-throughput screening.[28] Antibody-based multiplex assays offer significant advantages with regards to time, cost, sample volume, and storage requirements, and the amount of data that can be generated in a short timeframe. Multiple platforms are available which rely either on microbeads for the in-solution format (such as Luminex) or microspot array for the planar format (such as Luminex, MesoScale Discovery, and Fast Quant).[27] The main hurdle of multiplex assays is the requirement for extensive development and validation in order to minimize assay imprecision and inaccuracy (see section "Validation").

2.20.2.4.3 Mass spectrometry

MS is a widely used analytical technique in the physical and chemical sciences to quantify low molecular weight compounds (~200 Da or less). Over the past 30 years, the use of MS technology in bio-specimen analysis has grown and its use is currently widespread in clinical reference and referral laboratories.[29] The advances in MS, bioinformatics tools, and related proteomic technology have made it possible to identify thousands of proteins from a single sample.[27] In these proteomic studies, the common approach used is generally what is referred to as the "shotgun" or untargeted approach, in which the sample proteins are enzymatically degraded to peptides, which are then analyzed by MS operated in data-dependent acquisition mode, in an attempt to cover as many proteins as possible in the hope of revealing promising biomarker candidates.[30] This shotgun approach is a powerful tool for

high-throughput screening of peptides and their relative quantification, but is unsuitable for absolute quantification or for the targeting of specific proteins because of the limited sensitivity and poor reproducibility of target selection. Selected reaction monitoring (SRM) or multiple reaction monitoring (MRM) measurement platforms allow multiplexed analysis using tandem MS for targeted proteomics and allows the reliable quantification of low abundance analytes in complex matrices. The high sensitivity of this technique complements the untargeted shotgun methods.[30–32]

2.20.2.5 Validation and Qualification

The terms "biomarker validation" and "biomarker qualification" are regularly used interchangeably in the literature despite the fact that both terms mean different things. Whereas validation is the assessment of the performance characteristics of the biomarker measurement, qualification, however, is the evidentiary process of providing a linkage between the biomarker and a clinical endpoint such that it can be used as a surrogate endpoint.[33]

2.20.2.5.1 Validation

As reliable and accurate data are crucial for sound decision making, biomarker assays must be validated in a manner that enables the generation of such data. Validation is the process of evaluating the biomarker and its measurement performance characteristics and determining the range of conditions under which the biomarker will give reproducible and accurate data.[34,35] It is a necessary component to deliver high-quality research data for effective use of biomarkers. Depending on the intended use of the biomarker and the nature of the technology utilized, the extent of validation can differ in a "fit-for-purpose" approach[36] (**Fig. 1**). During preclinical and clinical development, biomarkers can be used for decision-making purposes or can be rather supportive or exploratory. Validation of the assays needs to be tailored to their intended use. The further along the spectrum toward a surrogate endpoint or decision making diagnostic the biomarker is positioned, the greater the degree of thoroughness necessary to validate the biomarker assay is[36–38] (**Fig. 1**). A noncomprehensive list of definitions linked to bioanalytical method validation is represented in **Table 2**.

For supportive and exploratory biomarkers, a *limited validation* might suffice, while for decision-making biomarkers (e.g., for patient stratification) a *full validation* is required (**Table 3**). Both types of validation are dependent on acceptance criteria which are set up front. The most extensive set of parameters which can be evaluated are listed and briefly discussed here. This set is applicable in the setting of a quantitative ELISA or multiplex assay but by no means applies to all platforms and biomarker types. An example of "deviating platform" is flow cytometry where the accuracy of a certain biomarker is seldom being determined due to a lack of established standards to do so.[39] An example of a type of biomarker very different with respect to validation in comparison to an ELISA is a questionnaire or an index like the EULAR Sjogren's Syndrome Patient Reported Index. This index is based on three questionnaires designed to measure patients' symptoms in primary Sjogren's syndrome and for which a prospective international 6-month duration validation study was conducted in 15 countries to conclude that it had good construct validity and sensitivity.[40,41]

The validation of an assay follows the initial stage of method development, where the global purpose of the assay is being defined, where the selection of the assay setup and conditions occurs and during which the strategy for method validation is being designed (adapted from Ref. 36). After method development, exploratory validation and prevalidation follows. During this phase, the dynamic range is established and the selectivity and specificity of the candidate assay is tested. When this is successful, effective validation takes place during which the assay performance is characterized. This validation ultimately evaluates and concludes whether the assay is fit-for-purpose. Validation results are recorded in a method validation report and a working protocol, rendering the assay ready for in-study target population sample analysis. Further evaluation of the "fit-for-purposeness" occurs with the true study samples during "in-study validation." This entails parallelism testing on study samples, incurred sample reanalysis, and trending of low–medium–

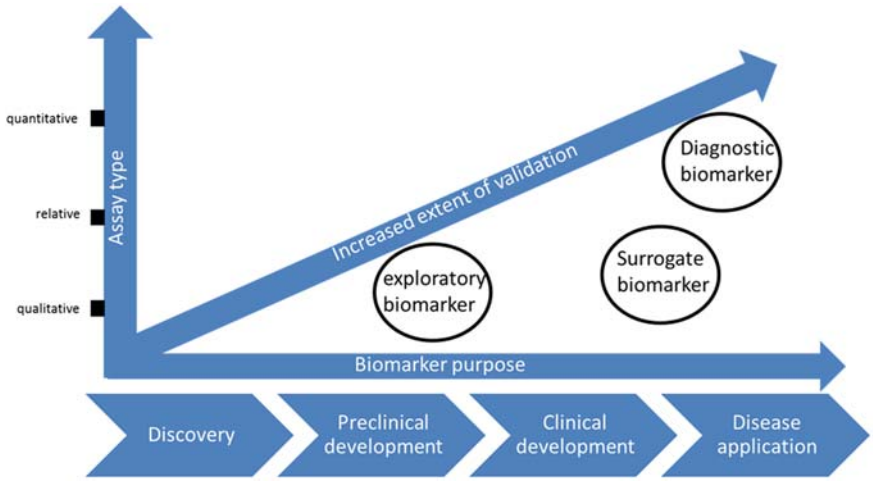

Fig. 1 Link between biomarker validation, assay type, and biomarker qualification.

Table 2 Noncomprehensive overview of definitions valid in the context of bioanalytical methods

Accuracy	The accuracy of an analytical method describes the closeness of mean test results (calculated concentration) obtained by the method to the theoretical value (nominal concentration in case of spiked samples) or target value (defined in target definition runs in case of endogenous samples) o f the analyte. This is also referred to as bias or relative error
Dilutional linearity	Dilutional linearity implies a test to demonstrate that the analyte of interest, when present in concentrations above the dynamic range, can be diluted to bring the analyte concentrations into the dynamic range for analysis by the method
Dynamic range	The interval between the upper and lower sample analyte concentration for which the assay has been demonstrated to have an acceptable level of precision and accuracy
HiQC/VS	High concentration quality control sample or validation sample
Incurred sample	Study sample
LoQC/VS	Low concentration quality control sample or validation sample
Matrix effect	Direct or indirect change in signal of the analyte by the presence of unwanted components or other interfering substances in the processed sample
MeQC/VS	Medium concentration quality control sample or validation sample
MRD	Minimum required dilution: the minimum dilution required to dilute out matrix interference in the sample
Parallelism	Parallelism documents that the concentration/response relationship of the endogenous analyte in the sample matrix from the study population is sufficiently similar and proportional to the reference material in the (substitute) matrix
Precision	Precision of an analytical method describes the closeness of individual measures of an analyte when the procedure is applied repeatedly to multiple aliquots of a single homogeneous volume of biological matrix. Precision is usually expressed as standard deviation (SD) and coefficient of variation (CV). This may be considered at the repeatability (=intra-assay precision) level
Quality controls (=QCs)	A set of sample, preferably endogenous analyte or alternatively recombinant analyte prepared in the intended biological matrix with concentrations that span the dynamic range. QCs are used in each sample analysis run to monitor assay performance for batch acceptance (in-study run acceptance). Three levels are used: LoQC, MeQC, and HiQC. These samples are the same as the validation samples and are called QCs once the precision and accuracy assessment is successfully finished. The target concentration of the QC samples will be calculated using the concentrations obtained in the three target definition runs and the six precision and accuracy runs
Selectivity	The ability of the method to measure the analyte unequivocally in the presence of other components in the assay matrix
Sensitivity	The lowest concentration of analyte that an analytical method can reliably differentiate from background
Specificity	The ability of the assay reagents to bind the antigen of interest without cross reactivity with variant forms of the analyte or other structurally related compounds that might be present in the sample
Target range	Range of analyte concentrations wherein the study samples are expected to fall
Validation	The confirmation via extensive laboratory investigations that the performance characteristics of an assay are suitable and reliable for the intended analytical use
Validation samples (VSs)	A set of sample, preferably endogenous analyte or alternatively spiked recombinant analyte prepared in the intended biological matrix with concentrations that span the dynamic range. Validation samples are used in each prevalidation and in the first validation runs to evaluate assay performance. The target concentration of the VSs will be calculated using the concentrations obtained in the three target definition runs. After the accuracy and precision runs of the validation, these samples can become the quality controls (QCs)

Table 3 Overview different steps of limited and full validation (based on Cummings et al.[36] and Lee et al.[35])

Exploratory validation	1. Theoretical establishment of target range, sensitivity, and acceptance criteria 2. Choice of calibrators and establishment of working range 3. Initial choice of appropriate working regression model 4. Choice of matrix for validation samples	
Prevalidation	1. Minimum required dilution 2. Establishment of limit of detection 3. Establishment of assay dynamic range and limits of quantification 4. Parallelism	
Validation	Limited validation 1. Intra- and interassay accuracy and precision calibrators based on three runs 2. Intra- and interassay accuracy and precision–validation samples based on three runs 3. In-study validation	Full validation 1. Intra- and interassay accuracy and precision calibrators based on six runs 2. Intra- and interassay accuracy and precision-validation samples based on six runs 3. Spike recovery 4. Stability 5. In-study validation

high-quality control (QC) samples. After successful "in-study validation," the assay may enter into routine use, while continuously monitoring the behavior of the assay QCs and evaluating the effect of reagent batch to batch differences.

For an *exploratory validation* (Table 3) the following parameters are being defined: (1) the theoretical potential target range, the required sensitivity, and acceptance criteria; (2) the selection of calibrators and the establishment of the working range; (3) the appropriate working regression model; and (4) the choice of validation samples. During *prevalidation* (Table 3) the following attributes are being defined: (1) the minimum required dilution (MRD) of the samples; (2) the limit of detection; (3) the assay dynamic range and limits of quantification; and (4) parallelism (which evaluates whether the concentration/response relationship of the endogenous analyte in the sample matrix from the study population is sufficiently similar and proportional to the reference material in the substitute matrix).

For a *limited validation* (Table 3), three runs are sufficient to determine intra- and interassay accuracy and precision of both calibrators and validation samples. For a *full validation* (Table 3), at least six runs are required to determine intra- and interassay accuracy and precision of both calibrators and validation samples, as well as the assessment of whole plate uniformity, spike recovery, and stability. Spike recovery is used to determine whether analyte detection is affected by the biological sample matrix. Stability testing evaluates to what extent the conditions under which study samples will be collected, stored, and processed (RT, freezing, long-term storage, etc.) could affect the stability of the biomarker.

However, if certain effects are expected (e.g., if the selected matrix affects biomarker stability), these parameters for limited validation should be extended to meet the fit-for-purpose quality evaluation.

2.20.2.5.2 Qualification

Biomarker qualification is an official evidence-based development process which provides a framework for scientific development and regulatory acceptance of biomarkers for use in drug development.[42] The biomarker qualification process consists of three major stages: initiation, consultation, and advice and review. The first stage consists in the submission, by the submitter, of a letter of intent (LOI) which contains a description of the potential biomarkers with their proposed context of use (COU) and a rationale to support qualification. In order to reduce the time taken by the applicant to prepare LOIs and to facilitate parallel submissions to the EMA and to the US FDA, the two agencies launched a joint LOI in Dec. 2014 which allows the two agencies to share scientific perspectives and advice.[43] This COU is the most important part of the qualification discussion as it identifies the boundaries of known reliability as shown by evidence and should clearly describe how a biomarker should be used such that the results enable decision making in drug development. For example, it defines how the biomarker should be sampled and analyzed and what decisions will be made based on the gathered data. The FDA then evaluates the potential and scientific merit of the proposal and decides whether the biomarker submission is accepted or not into the biomarker qualification program. If accepted, the consultation and advice stage begins with the assembly of an interdisciplinary working team (Biomarker Qualification Review Team—BQRT or QT) that will guide the submitter toward further biomarker development (e.g., additional studies to be conducted as needed) to support the proposed COU, and will review the complete evidence. The BQRT will provide the submitter with instructions for submission of the full qualification package when it determines that no critical gaps in knowledge remain and when the data are considered sufficient to initiate a review. Following the submission of the full data package by the submitter, the review stage, which consists of an evaluation of the full qualification package, can start. After complete review of the package, qualification recommendations are generated and, if positive, formal qualification is granted which indicates that the gathered data on the biomarker supports its use within a specified COU. The qualification statements are then made public on the FDA and EMA website first as a "draft guidance" and later finalized after a public comment period. The qualified biomarker can then be used by drug developers for the qualified context in regulatory submissions without the Center for Drug Evaluation and Research or the Committee for Medicinal Products for Human Use having to re-review or reconsider the suitability of the biomarker.[44–46]

2.20.3 Modeling and Simulations

2.20.3.1 Introduction

For a long time PKs (pharmacokinetics) and PDs have been considered as two independent disciplines of pharmacology, and in the past PK studies, evaluating the time course of drug levels, were mostly focused on meeting regulatory requirements. However, when considered separately from PDs, PKs are of limited information, and provide only summary drug characteristics for observed levels of systemic drug exposure.

Given the limited regulatory requirements, there has been little motivation for companies to invest in intensive efforts in linking PKs to PDs. In addition, drug development has usually relied on observed effects at a certain dose of the drug without understanding how systemic drug exposure is linked to the observed effects. This knowledge gap has been considered one of the factors impacting the attrition rate in drug development,[24] and companies are now encouraged by regulatory agencies to invest in quantitative methods to explain dose/exposure/response relationships allowing more informed/less risky decisions during drug development. It is proposed to use the advances in informatics technologies and the increased computational power[4,47] as tools for making, testing, and confirming hypotheses, which might be revisited in case of unexpected findings,[48] thus increasing the knowledge on the drug, eliminate less promising candidates, and focus on those with higher probability of success.

2.20.3.2 From Empirical to Mechanistic Pharmacokinetic/Pharmacodynamic Models

The activity of a drug depends on its concentration at the effect sites, but often these are of difficult access. Traditional PKs assume that changes in systemic exposure reflect changes in drug concentrations at the effect site(s), although this might not always hold true.

After administration, the drug undergoes several processes occurring concomitantly or in parallel at different rates. These processes are generally referred to as absorption, distribution, metabolism, and excretion (ADME). In vitro "ADME studies" can focus on each of these processes specifically, whereas in in vivo studies, mostly referred to as "PK studies," the resultant time-course drug concentration profiles result from the integration of the different ADME processes. These latter can be represented through mathematical functions including "PK parameters" characteristic of the drug under study. Mathematical models representing simplifications of body structures (*compartmental models*) can be used to describe the observed drug levels. These models are empirical because the observed data determine the type of model required to describe the data themselves. The compartments used to describe a drug's behavior do not represent real physiologic spaces, rather groups of organs/tissues in which the drug has similar distribution characteristics: the highly perfused or central compartment (blood, heart, liver, kidney, lung) and the peripheral compartment (including fat, muscle, cerebrospinal fluid, skin, etc.). A classical two-compartmental model is shown in Fig. 2.

If adequate for extrapolation of other dosing regimens under certain conditions, the value of empirical models is limited for translational purposes (across different species, populations, disease states, etc.). In these cases, mechanistic models with a more accurate representation of anatomic and physiological functions are needed.[49–53] Physiologically based pharmacokinetic (PBPK) models use several differential equations parametrized using not only physicochemical parameters, characteristic of the drug (size, solubility, effective permeability, etc.), but also known physiologic and anatomical parameters of the "system" to which the drug is administered (organ volumes, blood flows, etc.) (Fig. 3). If the drug characteristics remain identical across species, populations, and disease states, the system parameters can be scaled or adjusted, allowing a reliable extrapolation of the drug behavior in other animal species, disease states, or general conditions. PBPK models can also predict drug exposure in inaccessible tissues where the drug acts or exerts its desired or undesired effects. The shortcoming of the PBPK approach is that it relies heavily on systems of differential equations involving a large number of parameters from different research fields, and often from in vitro experiments and summarized literature data (for drug-related and system-specific parameters, respectively), always carrying a certain degree of error due to the uncertainty of in vitro results or in vivo reported parameters. Hence PBPK models have often to be confirmed with real data, so that a "data-driven" refinement of certain parameters can be done for further use of the model. The PBPK modeling has also been extensively used by regulatory agencies in the last decade for regulatory review or labeling claims[54–57] to evaluate the effect of intrinsic (age, gender, race, weight, height, disease, genetic polymorphism, pregnancy, and organ dysfunction) and extrinsic (drugs, herbal products, diet, smoking, and alcohol use) factors affecting the response (safety/efficacy) to the administered drug. An example is the dose-adjustment based on individual patient factors in the FDA labeling of rosuvastatin. The effects of the concomitant use of other drugs, ethnic factors, renal and hepatic impairment on the exposure to rosuvastatin have been investigated through a PBPK model, including the available information on the metabolism and transporter kinetics of the drug, and the label has been accepted after review of the results of these investigations in various clinical pharmacology documents.[31]

As previously mentioned, if not linked to the effects, PK models are of limited use. Linking PKs to PDs through mathematical Pharmacokinetic/Pharmacodynamic (PK/PD) models moves the focus on the driver of effects from the dose/administration site to the exposure at the site of effect. The use of integrated PK/PD models enables the prediction of desired and undesired effects, allowing the optimization of study designs to maximize efficacy while minimizing toxicity. These models are widely used for comparison and selection of lead drug candidates, starting doses for human studies, risk/benefit evaluations, and drug benchmarking.

As for PK models, a distinction between empirical and mechanistic models exists for PK/PD models. An assumption of descriptive PK compartmental models is that systemic drug levels reflect drug levels at the site of action. However, for numerous drugs the distribution into organs/tissues can represent a rate-limiting step for the onset of the effect. This delay has been accounted for in empirical PK/PD models with the addition of an "effect compartment"[58,59] into which the drug would distribute in minimal amount without perturbation of the overall PKs (Fig. 4). These empirical PK/PD effect-compartment models have been frequently used to predict steady-state timecourse of effects from non-steady-state data, but their predictability becomes less reliable when perturbations of the "system" occur, such as a change in the equilibration of the drug levels consequent to a reduced blood flow, or a change in permeability of a tissue in a diseased state, etc. For translational purposes, mechanistic PK/PD[60–62] models demonstrate much improved properties. As for their PK analogs, mechanistic PK/PD models include parameters describing drug-specific properties (e.g., target affinity, intrinsic efficacy) constant across species/individuals and biological system-specific properties (e.g., time-dependent transduction factors, homeostatic feedback mechanisms) with species-dependent intra- and inter-individual variability (Fig. 5).

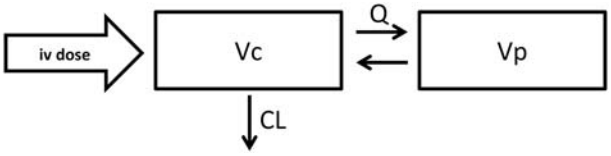

Fig. 2 Two-compartment model. V_c is the central compartment and V_p the peripheral compartment. The drug is cleared from the central compartment, the elimination being characterized by a clearance CL. The drug also distributes to peripheral organs/tissues, and the mass transfer is characterized by an intercompartmental clearance Q.

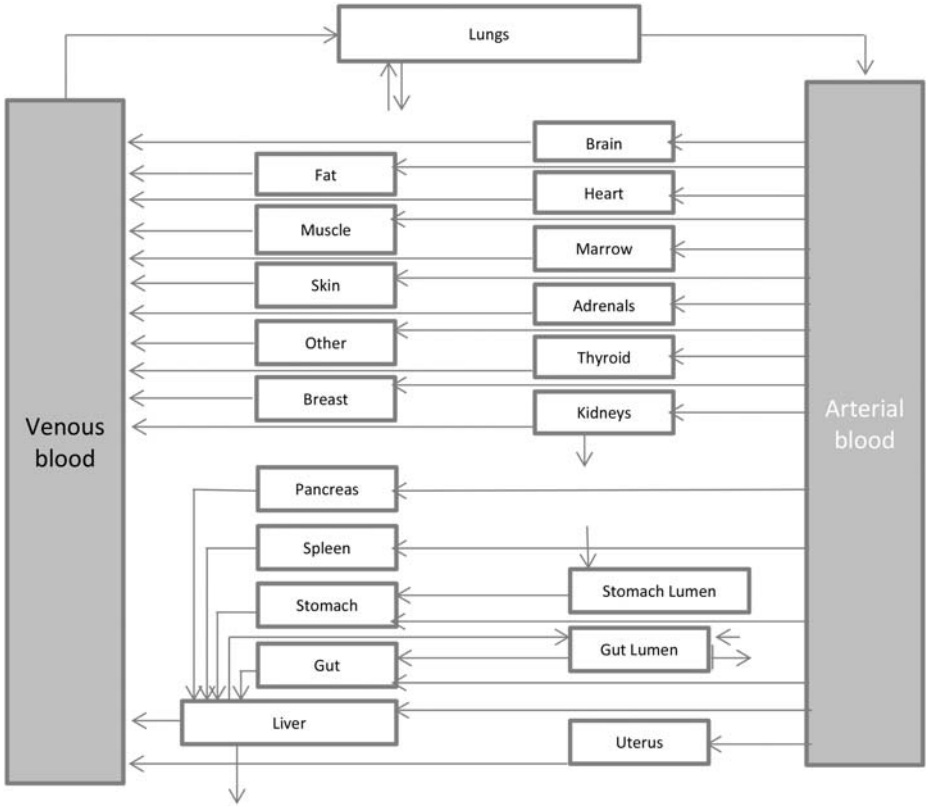

Fig. 3 A whole-body physiologically based pharmacokinetic model.

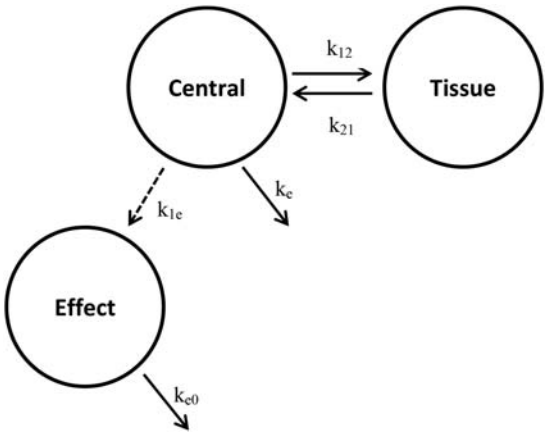

Fig. 4 Effect-compartment PK/PD model. Hypothetical effect compartment, connected to central through k_{1e}, very small relative to other rate constants of PK model. k_{e0}, the rate constant of drug removal from the effect compartment, characterizes the temporal aspects of equilibration between drug concentrations in the central compartment and the effect.

2.20.3.3 From Mechanistic Models to System Biology Models

If mechanistic models appear as more complex than simple empirical compartmental models, an even higher degree of complexity would be needed to address different important questions for selection of new drug candidates, such as "which target to hit" and "which would be the most relevant biomarkers to follow in preclinical/clinical studies for safety/efficacy evaluation" or "which drug candidate would have characteristics closer to the defined target product profile, TPP." In this case, mathematical models are built on hypothetical pathways and expression profile data linking the different components of the system of interest. This is what is known as "bottom-up modeling," in contrast to the "top-down modeling" based on the clinical data from an overall integrated system, as with compartmental models. A hypothetical example of a very small signaling cascade is the one indicated in Fig. 6.

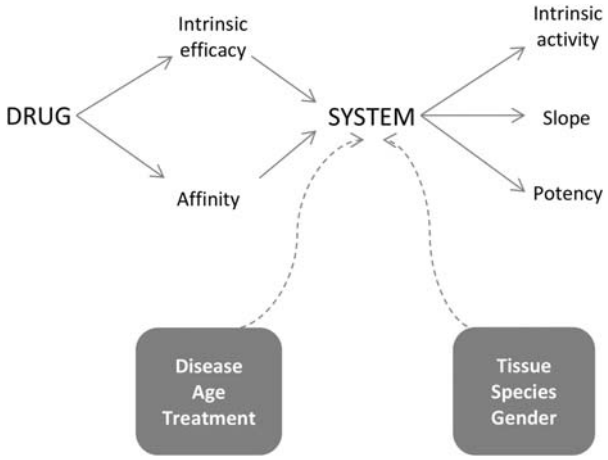

Fig. 5 Shape and location of in vivo drug concentration–effect relationships is determined by drug-specific (affinity, intrinsic efficacy) and biological system-specific (transducer function relating receptor activation to effect) properties. Adapted from Van der Graaf, P.H.; Danhof, M. Analysis of drug-receptor interactions in vivo: a new approach in pharmacokinetic-pharmacodynamic modelling. *Int. J. Clin. Pharmacol. Ther.* **1997**, *35*, 442–446.

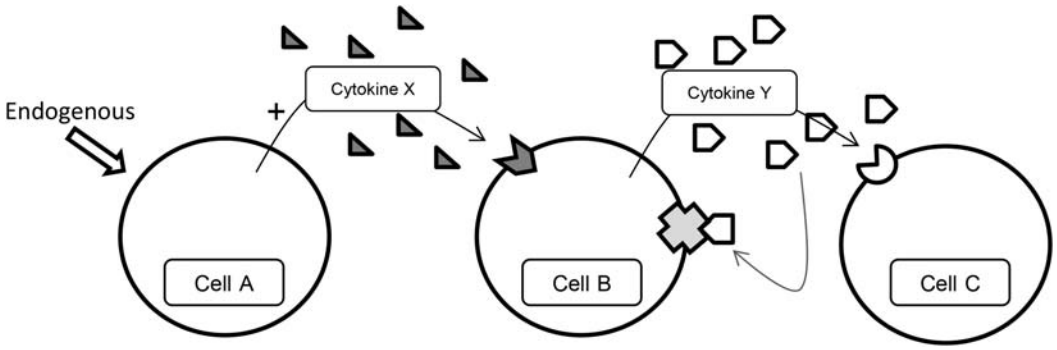

Fig. 6 Hypothetical signaling cascade. Cell A is inappropriately activated by an endogenous signal, which results in the upregulation (+) of the expression and secretion of cytokine X, which in turn stimulates cell B to upregulate the expression of cytokine Y and its autocrine receptor. Cytokine Y signals cell C to produce deleterious effect.

Here, a cell A is inappropriately activated by an endogenous signal to secrete cytokine X, which in turn stimulates the production of cytokine Y from cell B. Cytokine Y could stimulate the autocrine receptor on cell B as well as another receptor present on cell C initiating a deleterious effect. If the objective would be to interfere with this cascade of events to counter the deleterious effect, potential target processes to hit would be the activation of cell B by cytokine X, or of the stimulation of the autocrine receptor on cell B by cytokine Y, or the final activation of cell C. What is not known is which of these processes would be the most influential one on the deleterious effect. In silico models based in this case on in vitro data would allow through simulations to determine the relative importance of the different processes accounted for in the cascade of events and provide information on the most promising target to select. The previous simple example could be extended by integrating a wide variety of data, providing insight into how complex biological systems are regulated in both healthy and diseased conditions. These large-scale biosimulation models often involving disciplines like genomics, bioinformatics, and proteomics are referred to as *system biology models*, and can predict in a very early phase of development the overall clinical effect of modulating individual pathways or targets in terms of efficacy and side effects. Based on databases including literature, public and proprietary data and integrated information collected from experts in the medical areas of interest, clinical outcomes are related to biological mechanisms which in turn are dissected to unravel the underlying cellular and molecular processes that allow to quantify clinical and subclinical outcomes. If assumptions are not confirmed, gaps in the knowledge of the observed effects can be identified and further investigation steps to fill them can be planned. This provides new insights into complex mechanisms of action that determine the direction of program and study strategies. In silico simulations enabling a better understanding of protocol parameters contributing more to expected effects provide also an opportunity to explore different possible study designs, thus reducing the uncertainty on the outcomes, resulting in a faster and more efficient development of the drug. The complexity of these models, based on hundreds of equations and parameters, require extensive time and human resources for their building and testing.[63–66]

2.20.3.4 Examples of Applications of Empirical, Mechanistic, and System Biology Models

The models summarily described in the previous paragraph have a different degree of complexity and the choice of the model is dictated by the specific objective(s) of the modeling exercise. We give hereafter some examples of applications.

2.20.3.4.1 Empirical Pharmacokinetic/Pharmacodynamic models—effect-compartment model

Empirical models were first developed by anesthesiologists under the need to adjust doses of anesthetics using target controlled infusion (TCI) devices.[59,67] Most anesthetics have a narrow therapeutic index, and a precise control of the anesthetic effect requires a good understanding of the dose-effect relationship. As these drugs act in the brain, plasma concentrations do not reflect the extent of the effect, and a certain delay between maximal plasma concentration and maximal effect can be observed. "Effect compartment models" account for this delay through a parameter k_{e0} which can also be expressed as a half-time k_{e0}, directly corresponding to the time of equilibration between the central compartment and the effect site. The faster k_{e0} is, the faster the maximal effect will be attained (Fig. 7, left). In anesthesia, the dose to be given to achieve the target concentration will depend upon the PK characteristics of the drug (distribution properties to the site of action), and when using TCI it is usual to set a higher initial dose (infusion rate or concentration) to reach the desired effect more rapidly. The lower the k_{e0} value is, the higher will be the initial plasma overshoot (Fig. 7, right). At equilibrium, infusion conditions are maintained constant.

2.20.3.4.2 Mechanistic Pharmacokinetic/Pharmacodynamic models—selection of starting dose for first-in-human studies

The selection of the starting dose for human studies followed in the past the recommendations of an FDA guidance[68] on a maximal recommended starting dose selection. This guidance suggests how to determine the highest dose which can be considered safe, rather than the lowest dose which can be considered active. It is based on doses rather than exposures which are allometrically scaled from animals to humans. Unfortunately, the lack of integration of pharmacology, safety, and efficacy data of this approach revealed its limits when it was applied to the CD28 agonist antibody TGN1412.[69] In the volunteers, the selected starting dose was associated with life-threatening events related to the pharmacology of the mAb, not predicted from the toxicology studies performed in monkeys. The dose selection approach in the new EMA guidance[70] recommends to integrate all pharmacological, toxicological, and efficacy knowledge gathered in in vitro/in vivo preclinical studies to determine a minimum anticipated biological effect level (MABEL). The use of a simple formula to calculate the receptor occupancy (RO) has been suggested to determine a MABEL[71] (Fig. 8A), but a more accurate evaluation can be done through mechanistic PK/PD models,[72,73] accounting not only for the affinity of the drug to the target, but also for the turnover of the target (the balance of its formation and elimination rates) (Fig. 8B). Applied to the TGN1412 example, these equations predict a RO of $>90\%$ for the selected starting human dose. The model-predicted human

(A)

$$RO = \frac{[mAb]}{K_D + [mAb]}$$

for TGN1412 K_D: equilibrium dissociation constant, 1.88 nM; [mAb]: 0.1mg/kg of 150 kDa IgG in 2.5L plasma of a 70 kg human

(B)

$$complex = \frac{(K_D + TD + TT) - \sqrt{(K_D + TD + TT)^2 - 4 \cdot TD \cdot TT}}{2}$$

TD=[MAb]+[Cpx]

TT=[Ag]+[Cpx]

for TGN1412 TT: total target 150 000 receptors/T-lymphocyte and 1.3x109 T-lymphocytes/L blood; K_D: equilibrium dissociation constant, 1.88 nM; TD: total drug 0.1mg/kg of 150 kDa IgG in 2.5L plasma of a 70 kg human

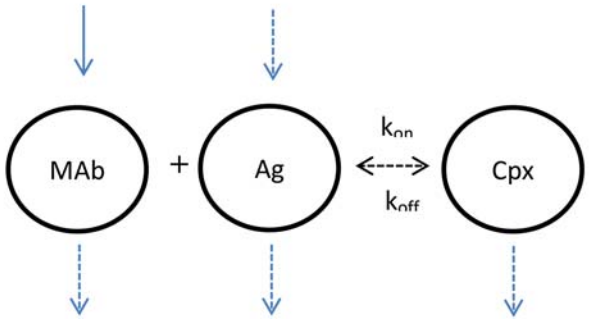

Fig. 8 Equations for calculating receptor occupancy: (A) when [mAb] ≫ [TT], (B) accounting for target expression.

dose corresponding to a minimal RO (10%) would be 100 times lower (i.e., 1.5 μg kg^{-1}) than the one selected based on the MSRD approach (i.e., 0.1 mg kg^{-1}).

2.20.3.4.3 PBPK models—drug–drug interactions consequent to drug-mediated cytokine elevations

Very often applied in the design of pediatric studies or to anticipate the impact of pharmacogenomics or race, physiological states (i.e., pregnancy, etc.)/diseases, and uncommon administration routes on drug exposure, PBPK modeling is widely used to study drug–drug interactions. Blinatumomab is a bispecific T cell engager antibody which, when binding to T cells, redirects them to B cell malignant cells.[74] Transient elevation of cytokines generally takes place on the first day of treatment, returning to normal by the second day. Proinflammatory cytokines are known to suppress cytochrome P450 (CYP) activities and consequently decrease the clearance of drugs metabolized through them. An effective antiinflammatory treatment would be expected to reestablish the normal CYP activity: this is critical for patients under chronic concomitant medications as the systemic exposure to these latter can be affected. PBPK modeling has therefore been used to prospectively predict the effect of the transient increase of IL-6 levels, consequent to blinatumomab treatment, on known drug-metabolizing enzymes (CYP3A4, CYP2C9, and CYP1A2), using simvastatin and midazolam, theophylline and caffeine, and (*S*)-warfarin as respective substrates in the simulations. The parameters and data used to predict the expected change in the substrate levels were IL-6 profiles from patients receiving blinatumomab, in vitro IL-6 parameters for enzyme suppression, such as E_{min} (minimum CYP enzyme activity, i.e., the maximum enzyme suppression) and EC_{50}, and the system parameters available for the degradation constant (k_{deg}) of CYP3A4, CYP1A2, and CYP2C9 in the liver and intestine. Simulations suggested that changes in exposure to substrates of the CYPs under study are expected to be less than twofold with the magnitude of the CYP suppression being highly dependent on the duration of the cytokine elevation. Drug monitoring is thus recommended in patients under concomitant treatments with narrow therapeutic index.[75]

2.20.3.4.4 System biology models—identification of optimal combinations of molecular targeted drugs in oncology

Targeted treatments in cancer research are very promising, but the inhibition/activation of specific pathways can be compensated by regulatory loops or bypass mechanisms. A system biology model, built to study the insulin-like growth factor (IGF) signaling network in the MDA-MB231 breast cancer cell line, demonstrated that the most straightforward strategy, consisting in the inhibition

of the input source for signal transduction (inhibition of insulin-like growth factor receptor (IGFR)), would not be the most successful for a selective reduction of tumor cell proliferation which is caused by p-mitogen-activated protein kinase activation through K-Ras and B-Raf mutations. A more effective inhibition of aberrant signaling would be accomplished through multiple combined inhibitions of targeted molecules such as mitogen-activated protein kinase (MPAK) and phosphoinositide-3-kinase/protein kinase B (PI3K/AKT).[76] The proposed computational approach is more and more used to identify and validate drug combinations that can inhibit aberrant networks in a panel of human cancer cell lines.

2.20.3.4.5 System biology models—a mathematical model for rheumatoid arthritis

A large-scale mathematical model of rheumatoid arthritis has been constructed with the Entelos® PhysioLab platform, mechanistically linking cellular and cytokine components of the pathophysiology across multiple compartments, including synovial lining, cartilage, and bone to patient-level measures. The scope of the biology represented in the Entelos RA PhysioLab platform is summarized in Fig. 9. This model has been used to explore new critical pathways and targets for intervention, to investigate and compare the potential of new drug candidates, and to test the expected outcomes for different virtual patient phenotypes and study designs.[77,78]

2.20.3.5 Conclusion

The scope of the basic PK science has broadened in the recent years from that of a descriptive science to an instrumental tool in support of drug discovery and development. No model is better than others, if its purpose and objective(s) are not clearly stated upfront. Hence the choice of the use of empirical, mechanistic, or system biology models, more and more complex and time-consuming, is dictated by the specific question to be answered. The concept of "quantitative pharmacology" relies on their use for making decisions on the future of the drug candidate, by increasing the understanding of its action, and the expected benefit/risk profile in the target patient population.

Hence, system biology models that provide better and more realistic insights into disease processes and drug mechanisms can help identify disease-specific molecules and drug-specific targets and biomarkers for safety/efficacy and patient stratification.

Once the target is selected, mechanistic models can hint to gaps in the knowledge of the PKs or PDs of the drug, so that its properties can be modulated to achieve the best possible ones described in the best possible wished product characteristics TPP.

Another important benefit of these models is that they may be scalable from preclinical species to humans, from healthy to diseased patients and support labeling claims on drug interactions and dose adjustments in special populations.

The early availability of PK/PD models also allows a more informed drug development strategy building and enables the evaluation of different scenarios for study designs, including the test of different doses, dose regimens, statistical tests, sampling/observation times, duration of treatment, study subpopulations, etc.

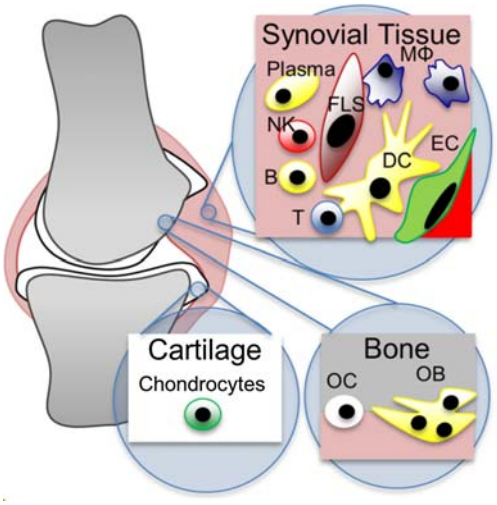

Fig. 9 Biology represented in the biosimulation platform (adapted from Schmidt, B. J., et al. Alternate Virtual Populations Elucidate the Type I Interferon Signature Predictive of the Response to Rituximab in Rheumatoid Arthritis. *BMC Bioinformatics* **2013**, *14*, 221). In the synovial tissue, the activity of fibroblast-like synoviocytes (FLS), B cells (B), plasma cells, natural killer cells (NK), macrophages (MΦ), and endothelial cells (EC) are modeled. T cells (T) are modeled with distinct CD4 and CD8 T cell subpopulations. CD4 T cells are further divided into Th1, Th2, Th17, and Treg subpopulations, as well as a CD28-subset that has lost the requirement for costimulation. Antigen presentation by dendritic cells (DCs) is also represented. Bone remodeling by osteoclasts (OC) and osteoblasts (OB) as well as cartilage remodeling by chondrocytes and MMPs is included.

2.20.4 Animal Model

2.20.4.1 Generalities

Animal models are a core tool for TM research, since they can be used to bridge in vitro research to clinical testing, for example, the generation of new potential therapeutic molecules or novel drug targets. More specifically, animal models can help to:

(i) Predict the efficacy of a potential novel therapy: new potential drug targets are often identified in screening efforts using omics technologies (e.g., genomics or proteomics) that can yield numerous targets in a short period of time. However, these potential targets often lack sufficient validation to be tested directly in pivotal clinical trials. Animal models can help in providing a certain level of validation or at least give a certain ranking of more or less promising targets. For this, several approaches are possible besides the direct testing of a drug candidate such as the use of transgenic animals with a changed expression of the target of interest or the use of siRNA or antisense.

(ii) Predict the safety of a potential new therapy: new targets come with largely unknown adverse event risks. Such adverse events might be specific or be more prominent in subjects suffering from the disease that is to be treated. Thus, in addition to classical safety pharmacology or toxicology studies that use healthy animals, animal models can also give important information as to the adverse event profile that can be expected under the disease condition and to the associated safety margin. For instance, patients suffering from type II diabetes have an increased risk for cardiovascular adverse drug reactions by sodium channel blockers.[79]

(iii) Dosing prediction for initial clinical trials: in order to be efficacious, drugs need to interact with a sufficient number of target molecules in the tissue of interest. For instance, in order to provide antipsychotic activity at least 50% of dopamine receptors need to be blocked by a drug.[80,81] Animal model studies can support predictions relating to the dose level and the administration scheme needed for a particular effect.

(iv) Competitive advantages: many new drugs are developed in areas for on which there is a standard therapy available (often as a generic drug). Thus, in order to provide a pharmaco-economic advantage, the new investigational drug must demonstrate a competitive advantage in order to be reimbursed. Animal models may provide early evidence for such competitive advantage (or the lack thereof) and thus reduce costly failures of drug development programs in late-stage clinical trials.

Despite their broad utility, the predictions of animal models often are not confirmed in large-scale clinical trials (see section "**Radiography**" and "**Stroke TM strategies**" for an example). This lack of predictivity can be multifactorial: (i) the design of the animal models was insufficient to support the prediction, (ii) the wrong prediction was drawn from the animal model results, or (iii) the animal model had no predictive validity.

There is numerous literature available on the correct design of animal model experiments such as: including sample size calculations (many experiments are underpowered), blinding, and randomization to reduce biases[82] and selection of the appropriate dosing and treatment schedule. Thus, instead of reiterating the importance of a correct experimental design, this section will focus on new developments to improve animal models and how to implement animal model testing into a translational strategy.

2.20.4.2 How to Improve Animal Models?

2.20.4.2.1 Multisite animal model trials

One major problem with the current use of animal models is the lack of reproducibility. This can be due to specific conductance or design of animal experiments in the laboratory that reports the results or even characteristics of the experimenter[83]: experimental conditions such as the lighting of the experimental room, the housing, and handling of the animals, the provider of the animals, or the gender of the experimenter. Such differences between laboratories influencing the outcome of an animal experiment can be overcome by multisite trials. The concept is well established in the clinical arena but has been recently introduced into animal research. A recent publication reports the outcome of a multisite randomized controlled animal model trial that investigated the efficacy of an anti-CD49d antibody in two models for stroke. This is a way to overcome the limitations of a single animal experiment in an isolated laboratory, that is, the small number of subjects and the lack of variability in experimental conditions that mirrors the variability that is present in clinical practice. Ideally, such multisite preclinical trials are conducted by consortia of academic centers under a central organization to ensure homogenous study design, central statistical analysis, definition of key primary and secondary endpoints. Another example is on the use of patient-derived xenograft models for the screening of potential oncology drug combinations for clinical efficacy. For this, researchers have used tumor material derived from patients and transplanted this to immunocompromised mice in a design whereby each mouse received material from a different patient. With that they mimicked the variability one would expect from a clinical trial in an animal model.

2.20.4.2.2 Enhance variability and reduce standardization

Standardization has been regarded key for the establishment of experimental methods in each laboratory. This standardization often includes the use of well-defined subjects (strain, breeder, gender, body weight), the housing conditions (light, temperature, food), their handling, and the exact experimental conditions. While this standardization certainly helps to reduce the variability within one experiment and therefore increases the power and allows for the detection of significant effects with lesser subjects, this may also cause problems. Richter and coworkers examined the reproducibility of behavioral parameters for experiments that were highly standardized and found that this was considerably lower than those for experiments where higher variability

was allowed.[84,85] A classical example for the application is in oncology animal studies. Originally one animal study was always performed with all mice receiving the same tumor cell line. More recently with the advent of patient-derived xenograft model each mouse in a given preclinical trial can receive the tumor material of different patients thereby reinstating the natural patient variability.[86] Perceivably, the number of animals needed to reach statistical significance in one experiment is larger. This may be seen in contrast to the 3R principle (reduce, refine, replace) of ethics in the use of experimental animals.[87,88] On the other hand, often several experiments are performed in order to support initiation of clinical trials and by increasing the meaningfulness of individual experiments this number could be reduced.

2.20.4.2.3 Design the animal model concurrent with the design recommended for a pivotal clinical trial

Where guidance is available with respect to the recommended design of a pivotal clinical trial in the same indication, the key recommendations should also be implemented in the animal model testing. A disease that has seen many discovery and early development programs fail during late-stage clinical trials is rheumatoid arthritis. One of the reasons might be that often the design and the endpoints of the animal models do not represent those of the pivotal clinical trials. Collagen-induced arthritis in rodents is used as an animal model to assess the efficacy of antirheumatic drugs. In the past the design has often involved the start of treatment early after induction of the disease and the evaluation of efficacy via the pain response toward evoked pain or the post-mortem joint histology. A more sophisticated approach has been taken by Bender et al.[89] who has enriched this classical mouse model for rheumatoid arthritis with clinically meaningful biomarkers and imaging to enhance its translational value. First of all they used radiographic analysis of joint morphology in their mouse experiment since this is the gold standard for the clinical assessment of disease progression. Secondly, they chose to initiate treatment in one group of mice late in the disease process since this normally is the point in time that patients would receive an experimental drug and would thus enter potential clinical trials. The aim of the work by Bender and colleagues[89] aimed at assessing the potential therapeutic utility of an EP4 receptor antagonist and predict its efficacy in a clinical trial. While this mode of action may be most relevant during the phases of the disease where inflammatory cells infiltrate the joint, the efficacy of the compound may strongly depend on whether or not an individual patient has a weaker or stronger ongoing local inflammatory response. Thus, this was monitored via bioluminescence imaging to provide a potential PD biomarker that could be directly translated to clinical trials with the potential to act as a stratification biomarker as well.

2.20.4.2.4 Humanize animal models

Although mammals share overall genetic similarity, there are important differences between, for example, mice and man, particularly in the immune system. Thus, for instance, many mAbs targeting immunological molecules in man are not cross-reactive to the mouse counterpart protein. In the simplest manner of mouse humanization, a mouse protein is replaced by its human homolog in order to allow for testing a human mAb targeting this protein in a mouse model. This has for instance been achieved for CD3, a protein that forms part of the T cell receptor complex and which is a potential target for drugs against type 1 diabetes. Human mAb targeting CD3 such as teplizumab or otelixizumab do not cross-react with mouse CD3 and could thus not be evaluated in mouse models of type 1 diabetes such as the nonobese diabetic (NOD) mouse. One approach would have been to create a mouse cross-reactive mAb against CD3 as a surrogate and to assess this in a mouse model. While this would allow for a general proof-of-principle for the target, it is virtually impossible to create a surrogate antibody that has exactly the same characteristics in mice than the parent antibody in man. Thus, the approach was to replace the mouse CD3 protein by its human homolog. This has allowed for a successful evaluation of a human anti-CD3 mAb in the NOD mouse model.[90] Importantly while the clinical trials already showed a potential therapeutic benefit of anti-CD3 antibodies against type 1 diabetes, the same trials showed the safety margin to be very small. Therefore, going back to an animal model allowed for an evaluation of different dosing strategies in order to improve the benefit risk ratio.

Humanization of animal models has a long history in oncology: anticancer compounds have for a long-time been assessed in xenograft models where mice receive subcutaneous implants of cell lines originally derived from human tumors. This requires mice deficient in their own immune response such as the nude or Severe combined immunodeficiency (SCID) mutant mice. While this approach has yielded some novel anticancer drugs, it remained largely unsuccessful mostly because the "human tumor" grows isolated from its mouse host, that is, creating a petri-dish on four paws and because the cell lines, originally isolated from human tumors, were used over decades and hundreds of generations, thereby loosing many of the original features. Thus, more sophisticated approaches use patient-derived tumor material that has undergone little manipulation in the laboratory setting thereby retaining its original heterogeneity. Such patient-derived tumor models allow for a phase 2 like preclinical testing of new anticancer drugs in mice.[91] Other attempts have been the creation of mice displaying some characteristics of the human immune system.[92]

While many organ systems show remarkable similarity between rodents and humans, the immune system is significantly different. Such differences make the assessment of immune-related phenomena in rodents difficult. That is why attempts have been made to reproduce a human immune system in mice by first ablating their own immune response and subsequently adding human immunocompetent cells.[92,93] Such models have helped to develop more representative cancer models that allow not only human cancer cells to form tumors in rodents but also for the established tumors to interact with the humanized immune system.[94,95] These models have enabled the development of the immune-oncological therapies that have great promise as novel anticancer therapies. One of the greatest debacles of modern drug development was the so-called Tegenero incident in which human volunteers treated with the experimental antibody TGN1412 experienced a severe cytokine storm. Such an effect has not been observed even at high doses when tested in nonhuman primates (NHPs). Recently a mouse model was created by reconstitution of human peripheral blood mononuclear cells in immunodeficient NRG (NOD-Rag1^{null} IL2rγ^{null}) double mutant mice in

which this effect could for the first time be replicated in an animal model.[96] Although these mice did not express all relevant human cytokines (IL-2, IL-4) and others to a much lesser extent, the mice responded to an injection of TGN1412 with a cytokine release storm including lymphopenia, release of interferon-gamma, tumor necrosis factor α, and several interleukins as well as behavioral signs indicative of severe illness.

Although humanization of animal models will always (by definition) remain imperfect, such models may certainly help to answer specific questions. The challenges with such humanized models are that on the one hand there is often an overlap between the original host species biology with the human biology that was introduced, for example, in the case of immunodeficient mice there is always part of the mouse immune system left. On the other hand, human receptors or signaling molecules expressed by the host species may not naturally interact with the respective host ligand or receptor systems. A profound knowledge of the target physiology is therefore essential for a proper interpretation of the results obtained with humanized animal models.

2.20.4.2.5 Introduce more relevant clinical endpoints

Animal models often use endpoints that are different than those used in clinical trials, especially the primary clinical endpoints. One of the prime examples for this is pain research. While many animal models naturally focus on an objective assessment of the pain response, the clinical endpoints accepted by regulatory agencies focus on subjective responses and more broadly on quality of life (QoL) rather than on pain itself. Analgesic drug development has has, as a consequence, seen many late-stage clinical failures due to lack of efficacy. Consequently, animal models have been enriched with more meaningful endpoints. Many of the simple pain measurements include reflex withdrawals in response to painful stimuli. This may be appropriate to assess a pain threshold under baseline conditions but ignores the potentially more important affective component. Moreover, for patients suffering from chronic pain, the nonevoked, that is, spontaneous pain is more debilitating than the evoked pain and thus potentially contributes more to the clinical assessment of pain, for example, via patient rating scales. Recently, an assessment of the facial expression in rodents revealed that the so-called grimace scale can provide a reliable and valid assessment of spontaneous pain in rats.[97]

Another example of a recent attempt to introduce more meaningful and sophisticated endpoints into animal models is the more detailed assessment of motor behavior. Many chronic diseases have a motor component, for example, arthritis pain, movement disorders such as Parkinson's disease or amyotrophic lateral sclerosis. Former methods to assess movement disability and its potential reversal included, for instance, wheel running which provides an easy quantitative assessment of gross motor but is confounded by motivational influences and provides little information on more subtle qualitative changes. A so-called CatWalk system has been developed for a detailed analysis of the rodent gait such as symmetry of foot prints, body weight distribution, or walking patterns.[98]

QoL is probably the single most important clinical endpoint for most, especially chronic, disorders. This is especially true in the light of an increased need for cost efficiency in the health care system and the request of the reimbursement agencies for pharmacoeconomic measures which often include QoL. While QoL assessment is nowadays regularly used in clinical assessments of new therapies, this endpoint is still rarely used in animal models. Such measures can include relatively simple parameters such as body weight development or food intake. More sophisticated QoL endpoints need to be assessed more continuously by observation in the home cage of the animals which is technically more challenging but such technologies have become available, (for example, video observation systems, telemetry, or implantable chips). With such new technologies at hand, circadian rhythms, quality of sleep, social behavior, or grooming can be assessed. Most often QoL of patients is assessed by questionnaires, a methodology that obviously cannot be used in experimental animals. However, there are recent attempts to model questionnaires which serve as primary outcome measures in clinical trials, for example, for pain in animals. For instance, the human brief pain inventory was successfully modeled in dogs suffering from cancer pain.[99]

2.20.4.2.6 Ensure proper validation of animal models

Validation of models is a complex process and classically involves the assessment of face-, construct-, and predictive validity.[100] Face validity refers to the similarity between the symptoms observed in the model with the clinical signs typical for the human disease. Construct validity has to do with the plausibility that links the design of the animal model with the human disease and is perceivably the most difficult of the three criteria. Most often applied, especially when animal models are to be used for drug discovery and development, is the criterion of predictive validity, which means that clinically used treatments should have comparable beneficial effects in the animal model. Although most often used, the latter criterion has an inherent problem and may be the cause of limited innovation: if existing drugs are used to optimize animal models, these models may not be well suited to discover completely novel drugs. Thus, the emphasis should be to apply the criteria of face and construct validity more stringently.

Models, by definition, do not claim to fully reproduce the human condition but rather represent certain aspects of it. The fit-for-purpose concept applies to validation of animal models as well, i.e. that the particular use of the model determines the required validation. For instance, if one is interested in either the manic or the depressive phase of bipolar disorder it might be sufficient to model either one of the endophenotypes. If however there is a need to assess the effects of a drug on the disease, it may be needed to reproduce the cyclic nature of the human disease in the animal model.[101]

2.20.4.3 How to Implement Animal Models Into a Translational Strategy?

2.20.4.3.1 Design an animal model strategy with a high translational value

A model is a simple representation of a complex system. Consequently, an animal model for a human disease is by no means attempting to reproduce the human disease with all its complexities in an animal but rather to model specific aspects of a disease.

Whenever using an animal model, it is of utmost importance to address a specific question and to ensure that the chosen model is appropriate to provide an answer to this specific question. Since the type of question changes during a drug discovery and development process there is, in many cases, not one model that has a high validity throughout. Consequently it may be appropriate to select different models along the development path.

While a model is not a perfect replication of the clinical condition, not all criteria can be met in a single model. However, a combination of different models can eventually come closer to the clinical situation as a single, even highly sophisticated model. But what is an optimal combination of models? Frank Sams-Dodd has proposed a model validity scoring system of which an extended version is shown in **Table 4**.[102]

This scoring system uses five different criteria:

Species: The closer a species is to human (from a genetic point of view), the more likely it is that the pathophysiology of the disease is similar to that of humans.

Complexity: Test systems on a molecular level, for example, comprise enzyme inhibition or radioligand binding assays. Cellular assays use whole cell systems and assess endpoints like apoptosis or Ca-influx. Tissue assays investigate drug effects on whole tissues such as cardiac contraction. At the highest level, in vivo tests look at drug effects in living individuals, for example, locomotion or cognitive performance.

Disease simulation: Current models use different principles to induce the disease of interest. The simplest models do not even attempt to induce a disease but simply look at a measure in healthy individuals that is disturbed in a disease. Antipsychotic drugs, for example, are assessed in auditory gating models in healthy animals and humans, as auditory gating is impaired in schizophrenic patients.[103] Somewhat more complex is the use of drugs to induce disease symptoms such as phencyclidine or amphetamine to elicit psychotic like symptoms. For most central nervous system (CNS) disorders the etiology has not been fully elucidated which means that a true disease simulation, as for instance in infectious diseases, is not possible. However, models are available that model in a complex manner the disease pathophysiology. For example, hippocampal deficits, which are most probably induced during early development are, known for schizophrenic patients. An animal model has been developed based on these findings, which induces an early hippocampal lesion in rats, mimics several symptoms and recapitulates the characteristic time course of schizophrenia (disease onset after puberty).[104]

Predictivity: A drug effect in an experimental model can, in principle, be observed in two different manners: a quantal (all or none) or a graded response. A quantal response does just indicate as to whether a drug is active or not. A graded response, however, allows to distinguish between drugs/doses with higher and lower activity. Such models allow the comparison of different drugs and may help to decide as to whether an experimental compound is similarly or even superior to the existing gold standard of therapy.

Face validity: This criterion can be further differentiated depending on whether just one symptom of a disease is modeled or a set of symptoms and whether this includes core symptoms or rather minor symptoms.

This scoring system can be of dual purpose. First it can help to compare different models regarding their validity. The apomorphine screening test for screening potential antipsychotics with antidopaminergic activity, for example, scores lower than the neonatal hippocampal lesion model for schizophrenia. But probably more importantly, the scoring system can help to assemble a screening cascade/combination of models which altogether has maximal validity. For example, the neonatal hippocampal lesion model for schizophrenia scores high for all criteria other than "species" and could thus be ideally complemented by a relatively simple human model.[105]

2.20.4.3.2 Back-translate clinical trial findings into animal models

Often clinical findings are at odds with the results of an animal model experiment and often, the conclusion is that the human clinical trial is right and the animal model wrong. An alternative view that may be more productive in the refinement of the translational drug development process is to consider both are right to some extent but the question is being viewed from different angles.

Table 4 Proposed validity scoring system

Criterion	*Value*	*Score*	*Criterion*	*Value*	*Score*
Species	Human	4	Complexity	In vivo	4
	Nonhuman primate	3		Tissue	3
	Nonhuman mammal	2		Cellular	2
	Nonmammal	1		Subcellular/molecular	1
Disease simulation	True	4	Predictivity	Graded for all pharmacological principles	4
	Complex	3		Graded for certain pharmacological principles	3
	Pharmacological	2		All or none for certain pharmacological principles	2
	No	1		No or not shown	1
Face validity	>1 core symptom	4			
	1 core symptom	3			
	1 symptom	2			
	No	1			

Translational research is often seen as a methodology to increase the probability that research findings generated at one level (e.g., animal model) can be reproduced at the next level (e.g., clinical trial). This forward translation is certainly the ultimate goal of translational research. However, this translation will never be perfect in that predictions generated at one level will not be verified at the next higher level of research. One could simply accept these failures, but in order to fully exploit the potential of the translational research spirit, a back translation of the discrepant findings at one level with the ones generated at an earlier level can be beneficial.

As mentioned earlier, the assessment of pain in experimental animals often involves the measurement of provoked pain responses. Many different pain responses have been established in animals such as the response to heat and cold but also different types of mechanical and chemical stimuli. In order to enhance the translatability of pain research in animals, attempts were made to establish the same measurements in clinical studies. This improved the translation from animal studies to clinical trials. However, when conventional and generally accepted pain assessments were run side-by-side with the evoked pain measures, the effects of (potential) analgesics were not always congruent on both sets of parameters. The failure of a number of initially very promising pain therapies in late-stage clinical trials has consequently led to the back translation of pain measures used in clinical trials into animal models (see the earlier text).

Another example of successful reverse translation of clinical findings into the improvement of preclinical models is in the field of multiple sclerosis research. Experimental autoimmune encephalitis is the gold standard model for screening drugs for potential therapeutic value for multiple sclerosis. While this model helped to identify and characterize some of the current treatment options for multiple sclerosis patients, the list of drugs that were found positive in the model but did not demonstrate therapeutic value in clinical trials is even longer.[106] This has led to controversies over the usefulness of this model in the research and development of therapies for multiple sclerosis and other demyelinating disorders.[107,108] Although many of the arguments put forward by the opponents of this model are well taken, there are virtually no alternatives for experimental multiple sclerosis research. Thus, a pragmatic approach forward is to back translate the findings of clinical trials into the model in order to improve the design and conduct of experiments and/or to understand the differences in the pathophysiology in the model versus the human disease.[109,110] Another interesting aspect of reverse translation comes from human genetic association studies, for example, in multiple sclerosis. Such studies often identify hundreds, if not thousands, of potential genes and it is virtually impossible to understand their relevance and function in human studies. For this purpose, the human findings can again be reverse translated in animal models to identify the genes and pathways with the potentially highest relevance for the human disease.[111]

2.20.5 Imaging

Most biomarkers, such as "wet biomarkers" which have biophysical properties allowing their quantification in biological samples such as urine, plasma, serum, cerebrospinal fluid, synovial fluids, etc. (e.g., cytokines), or in biopsies (e.g., gene expression profiles), are referred to as "molecular biomarkers" or "nonimaging biomarkers." In practice obtaining biological samples in which to quantify these molecular biomarkers can often prove to be difficult due to the frequency of sampling, volume needed, or to the relative invasiveness of the sampling techniques (specifically in the case of synovial fluid collection, for example, or blood collection in a neonate). In contrast, imaging biomarkers are measured using imaging techniques which quantify changes in anatomic, physiologic, biochemical, or molecular parameters[112] such as conventional radiography, CT, MRI, ultrasound, PET, single photon emission computed tomography, optical imaging, light microscopy, MR elastography, and spectroscopy.[112–114] These imaging-based biomarkers can provide objective measures in a reasonable time frame, potentially nonbiased by the act of taking a biopsy and usually in a noninvasive and painless manner. Although these imaging techniques tend to be expensive, they can be cost-effective when used in well-defined situations where subjective assessment has been the only approach available.[115]

2.20.5.1 Types and Technologies

2.20.5.1.1 Radiography

Radiography uses ionizing electromagnetic radiation (X-rays) to produce an image of an internal body structure. These X-rays are produced in a tube via an energy conversion that takes place when an electrical current accelerates electrons from a heated tungsten filament cathode to an anode. As it passes through the body of the patient, a fraction of the X-ray beam is absorbed by the different tissues and body structures, while the rest of the beam is captured by a detector which can be either a photographic film or a digital detector. The obtained image is therefore the sum of the various body densities that the beam has passed through.

2.20.5.1.2 Computed tomography

A major disadvantage of conventional radiography (X-ray) is that it reproduces a 3D structure into a 2D image. Although based on X-ray imaging, CT scan, also called X-ray computed tomography (X-ray CT) or computed axial tomography, provides a different type of imaging known as cross-sectional imaging. In the data acquisition phase, a fan-shaped beam of X-rays is emitted from a source that rotates around the inside of a circular opening and used to irradiate a section of the patient's body. Detectors on the opposite side of the emitting source measure the attenuation of the X-rays as they pass through the body at a given angle. Multiple 2D views or "snapshots" are collected and reconstructed by a computer into a cross-sectional image (or slice) during the image reconstruction phase allowing 3D imaging when the slices are assembled. "Multi-slice" or "multi-detector" technology allows up to 640 slices to be

taken at a time for the most recent scanners. Although the resolution of CT scans is lower than conventional radiography, it has extremely good low contrast resolution which enables the detection of very small changes in tissue type and gives accurate diagnostic information about the distribution of structures inside the body.

2.20.5.1.3 Magnetic resonance imaging

MRI scanners differ from X-ray and CT scanners in that they do not use ionizing radiation but instead use radio waves and a powerful magnetic field. The intense magnetic field forces the protons within hydrogen nuclei contained in water molecules to align with that field. When a pulse of radiofrequency wave is applied, the protons are stimulated and are knocked out of alignment, absorbing energy in the process. When the radiofrequency field is turned off, the MRI sensors are able to detect the energy released as the protons realign with the magnetic field. As each tissue has a different water content, the protons will realign with the magnetic field at different rates and release different amounts of energy which are used to create the image.[116]

2.20.5.1.4 Positron emission tomography

PET imaging relies on the detection of two simultaneously released gamma rays resulting from the annihilation of a positron (antiparticle to the electron) with an electron in tissue. This positron originates from a compound labeled with a positron-emitting radioisotope that was introduced into the body, usually by intravenous injection prior to the procedure, and that accumulates in regions with high metabolic activity for the most frequently used PET tracer—the glucose analog [^{18}F]2-fluoro-2-deoxy-D-glucose (^{18}FDG-PET). PET imaging provides a highly sensitive and accurate measure of the in vivo concentration of the radiotracer due to the physics of the emission, and the detection of the coincident gamma rays. In contrast to MRI and CT scans that show the structure of, and blood flow to and from organs, a PET scan measures important body functions, such as blood flow, oxygen use, and sugar (glucose) metabolism.[117,118]

2.20.5.1.5 Optical imaging

Optical imaging uses light to visualize cellular and molecular function or track molecules in the living body in a fast, sensitive, and cost-effective way. Images are generated by using photons of light in the wavelength range from ultraviolet to near infrared (NIR). Upon excitation of a target molecule with a light source such as a laser or by the use of a natural light-emitting protein such as luciferase, the photons that are emitted are captured by a detector. As the radiation used is nonionizing, optical imaging is appealing in many settings as it reduces costs and infrastructure requirements, such as shielded rooms. The technique exploits contrast that is derived through the use of either endogenous molecules with optical signatures (e.g., hemoglobin, collagen), exogenous agents that provide a signal (e.g., dyes or fluorescent probes) or reporter genes.

The intrinsic fluorescence of many substances such as keratin, elastin, collagen cross-links, phospholipids, tryptophan, retinol, lipofuscin, and metabolites nicotinamide adenine dinucleotide and flavin adenine dinucleotide as well as the differential absorption properties of oxy- and deoxy-hemoglobin, lipids, and water can provide information about both the structure and function of living tissue. In addition to this endogenous contrast present in many organisms, exogenous contrast can further add to the possibilities of optical in vivo imaging and consists in the in vivo injection of fluorescently labeled targeting agents (peptides or proteins), inorganic dyes, nanoparticles, and more complex constructs that exploit properties such as Förster resonance energy transfer (FRET).[119,120] NIR probes, in contrast to those that emit light at visible wavelengths, offers the advantage that biological tissues have a reduced absorption of NIR light. This feature allows NIR light to penetrate deeper into tissue than light at visible wavelengths. Another advantage of NIR probes is that it reduces the masking effect on the signal from the optical probe by intrinsic autofluorescence as less autofluorescence is present at the NIR, thus enabling higher signal-to-background ratios.[121]

2.20.5.2 Uses

2.20.5.2.1 Application of radiography in drug development

Radiography is currently used as the first choice imaging technique for the diagnosis and follow-up of rheumatoid arthritis[122] as it is cheap, easily reproducible, and provides a permanent record with which the disease can be serially evaluated. An additional advantage of radiographs is that they can be randomized and blinded for standardized scoring with radiographic scoring methods such as Kellgren, Sharp, Larsen, van der Heijde, etc. The main disadvantage, however, is the absence of hallmark radiographic findings of bony erosions and joint space narrowing relatively early in the disease course and these may only occur late in the pathophysiology of the disease. In contrast, MRI provides a more accurate assessment, as well as earlier detection of lesions. Radiography is also frequently used to assess the severity and progression of Rheumatoid arthritis (RA) during drug treatment, for example, in clinical studies evaluating anakinra, leflunomide, etanercept, and infliximab.[125]

2.20.5.2.2 Application of CT in drug development

CT scans are often used to evaluate metastatic liver disease and to assess the tumor response to therapy (e.g., cytotoxic chemotherapy,[126] trastuzumab[112]) with the efficacy endpoint being the reduction in tumor volume. CT imaging was also shown to be a useful technique for the in vivo evaluation of the PKs of platinated agents.[127]

2.20.5.2.3 Application of MRI in drug development

As MRI is being widely used in the clinical setting, it has also become an increasingly important tool for small animal imaging at multiple levels of preclinical research. Its applications cover the cardiovascular, neurovascular, and renal disease fields. For example, MRI enables in vivo assessments of renal perfusion or cardiac morphology and function; in vivo visualization of neuroinflammatory lesions in animal models of multiple sclerosis, of cerebrovascular dysfunction in animal models of cerebral amyloid angiopathies or angiogenesis and neovascularization in animal tumor models.[128] It can also play a pivotal role in the evaluation of neuroprotective agents in animal models of perinatal brain injury[129,130] or investigate multiple aspects of small animal vasculature and obtain hemodynamic and structural information in small animal peripheral artery disease models.[131]

2.20.5.2.4 Application of PET in drug development

PET has been widely used in the recent years by pharmaceutical companies, especially in the fields of oncology and neurosciences, to assess drug distribution to tissues of interest in microdosing studies,[132,133] to measure RO (as a surrogate biomarker of efficacy),[134–142] and to assess disease progression and pathological changes induced by the drug in the region of interest.[143,144]

2.20.5.2.4.1 Assessing drug distribution with PET in microdosing studies

PET has proven its effectiveness in assessing drug concentration–time profiles in body tissues targeted for treatment. Microdosing of carbon-11 or fluorine-18-labeled drugs allowed fast evaluation of PK properties of anticancer and CNS drugs. For example, brain exposure of ^{11}C-labeled CNS drugs has been compared in cynomolgus monkeys after PET microdosing, and the extent of P-glycoprotein mediated transport of ^{11}C-verapamil at the blood–brain barrier (BBB) has been characterized after administration of PET tracers at therapeutic doses and microdoses, demonstrating that the exchange of radioactivity between plasma and brain was not different after a microdose or a therapeutic dose, despite the differences in other PK parameters.[145] Microdosing data after ^{11}C-docetaxel PET can be used to predict tumor uptake of docetaxel to predict patients' responsiveness to chemotherapy.[146]

2.20.5.2.4.2 Measuring RO with PET

The assessment of RO has been widely used in TM for the dose selection in proof-of-concept (POCs) studies of drugs with relatively tight therapeutic margins, such as antipsychotics, anxiolytics, and antidepressants. Systemic kinetics can indeed not reflect the kinetics at the effect site, due to distribution delays and the dynamic interactions with the target. Furthermore, there can be significant differences between in vitro and in vivo results of RO assays, mainly due to the PK properties of the drug (distribution and metabolism). If in preclinical studies the target organ(s)/tissue(s) can be sampled at necropsy, this is not feasible in human, and PET provides an elegant noninvasive alternative for collecting useful information on the availability of the drug at the effect site. From PK/RO relationships established in preclinical species, human PK/RO profiles can be predicted after adjustments for cross-species differences in protein-binding and physiological parameters such as organ of interest blood flow and vascular/extravascular volume for different drug doses/regimens. A preliminary PET study in human allows the confirmation of the dose(s) to be selected for the POC study in patients. A prerequisite of these studies is the availability of a suitable radioligand[147–150] binding the receptor of interest. Often, regions devoid of the target receptor are taken as reference (to correct for a specific binding), and a ratio of radioactivity in the target/nontarget areas represents the signal. The assessment of RO is done in two steps:

1. the radioligand is administered by iv bolus or infusion at baseline (predose), PET scans are collected after an adequate lag-time, and the baseline target/not-target ratio(s) is(are) measured
2. the same radioligand is administered after treatment with the unlabeled drug, competing with the radioligand for the receptors of interest. The percent reduction in the target/nontarget ratio represents the fraction of total receptor occupied by the unlabeled drug.

2.20.5.2.4.3 Assessing pathological changes with PET

The use of PET scanning has a great potential for a more accurate and earlier diagnosis of degenerative disorders, such as Alzheimer's disease (AD). Currently, the definitive diagnosis of AD is possible histologically only by post-mortem observation of Aβ plaques and tau neurofibrillary tangles.[151] The use of PET neuroimaging together with radiotracers enabling the exploration/monitoring of specific mechanisms of dysregulation potentially causing AD (visualization of histone deacetylase (HDACs) activity, DNA methylation, Amyloid, tau protein) has revealed very promising for an improved prevention and treatment for AD.[143]

Functional imaging has been demonstrated invaluable in oncology, as metabolic changes in tissue usually precede structural changes detected via other imaging techniques such as CT and MRI, enabling detection of malignant disease at an earlier stage of development. For oncological PET studies, the most extensively used radiotracer is [^{18}F]-FDG-PET, with improved specificity and sensitivity versus structural imaging. However, coupling functional and structural imaging, as with PET/CT oncologic imaging, allows the accurate structure localization and intervention, as in the evaluation of mass lesions, staging and restaging of cancer, planning of radiotherapy treatments, and detection of cancer recurrence.[152]

In clinical practice, [^{18}F]-FDG-PET and integrated [^{18}F]-FDG-PET/CT are increasingly used to assess the therapeutic effect of drugs in tumor patients or to diagnose recurrence in curatively treated patients with head and neck cancer[153] and esophageal cancer.[154] These imaging techniques, however, have not yet been sufficiently validated to be accepted as a surrogate endpoint for clinical studies by regulatory agencies. Currently, a multicenter qualification study of [^{18}F]-FDG-PET/CT as a predictive marker of tumor response and patient outcome in patients with nonsmall cell lung cancer (NSCLC) has been initiated by the American College of Radiology Imaging Network.[155]

2.20.6 Strategy and Integration

2.20.6.1 Design of Translation Strategies

2.20.6.1.1 Introduction

The best translational tool is of limited value if not used as part of a translational strategy. Thus, at the beginning of each translational research project, a strategy should be designed that helps to select the best tools that are fit-for-purpose. This is best done by thinking backwards from the goal that is to be achieved. For a drug development project, this is normally the target package insert, the summary of product characteristics (SmPC), or the TPP. The most important features can then be back-translated, for example, if the key differentiating feature is an improved safety margin versus a competitor drug, one can think of the most appropriate endpoints in the various preclinical experiments and clinical trials and how those can best be translated from one step to the next. In reality, one rarely has a detailed SmPC at the beginning of a drug discovery project. Nevertheless, it is helpful to have a core of the TPP rather early on in the process and slowly develop this further during the discovery and development process. Alternatively one can work along a set of questions to identify the key focus points of the translational strategy:

1. What are the efficacy endpoints that the drug needs to meet? What are the primary endpoints that would be acceptable for the regulatory agencies and which endpoints would matter most for patients?
2. Which safety issues could arise based on the mode of action and based on the chemistry of the drug molecule?
3. Is there an important competitor drug? What is the competitive advantage of the drug in development over the competitor? Normally this is either efficacy or safety or a combination of both but it is not always the primary efficacy or safety endpoints that are key for differentiation.
4. What will be the pharmaco-economic case presented to the reimbursement bodies? While improved safety and efficacy is key for the regulatory agencies, the reimbursement bodies such as the British National Institute for Health and Care Excellence or the German Institut für Qualität und Wirtschaftlichkeit im Gesundheitswesen are keen to see a cost-benefit such as a reduction in other health care spending or an overall increase in the QoL.

It may be important to assign priorities to these various questions that need to be addressed during the course of drug development. For instance, for a life-threatening orphan disease with no marketed therapy, the competition and the pharmaco-economic case are less relevant than for a drug that is about to enter a market with strong generic competition. For the key arguments of highest priority it makes particular sense to back translate the criteria and desired results to allow for a project progress assessment throughout the life-time of the project. For this purpose, it is essential that the criteria and tools used are translatable from one step to the next.

2.20.6.1.2 Stroke TM strategies

Development of drugs for brain disorders has proven to be very challenging. More than 40 large clinical trials have failed to promote recovery from traumatic brain injury (TBI) and, similarly for stroke, over 1000 agents have been successfully tested preclinically but failed in clinical trials. In fact, only the thrombolytic agent tissue plasminogen activator (rtPA) and thrombectomy with a retriever stent have been approved so far for the treatment of ischemic stroke.[156,157]

Undoubtedly, stroke is a challenging and complex disorder as it is characterized by induction of a secondary neuronal injury by brain leukocyte infiltration after an acute brain lesion which might be categorized as an ischemic, hemorrhagic, or a transient ischemic attack. Only recently the involvement of the white matter (WM) has been acknowledged to play an important role in stroke.[158] It is the injury of the WM that is the major cause of paresis in all types of stroke and it is both the size of the infarct and, more importantly, the location that determines the functional outcome after stroke.[159] Hence in the field of neuropathology, a clear focus exists on the induction of WM lesions, the mechanisms involved in its pathophysiology, and the improvement of WM damage.[160]

As in all therapeutic domains, the success of translational research relies on target validation, use of predictive animal models, well-designed clinical trials, and inclusion of relevant biomarkers throughout the development of the drug. Improved translational research will let less drugs end in the drug graveyard and prevent more patients from receiving ineffective or even harmful drugs.

The pathophysiology and mechanisms of this injury in its different phases have not been fully elucidated, triggering the need for relevant animal models. Recently, WM has been recognized as playing a crucial role for functional recovery and post-stroke rehabilitation, based on clinical and preclinical data.[161,162] Clearly, differences in the architecture of the brain exist between rodents and humans, predominantly in the ratio of WM to gray matter, and the injury to WM can be induced by different agents and to different locations in the brain. All these parameters have a vast impact on the kind of induced lesion and hence caution is needed in translating results from preclinical models to a certain type of stroke or to a certain aspect of stroke amelioration. Obviously, current animal models do not reproduce all the clinical hallmarks of WM disease and support mostly the unraveling of the different mechanisms of damage induction and the potential interference of drugs in this process.

Improvement of the translation of animal models of stroke can be exerted at the level of the animal study (1) by selecting the right model to answer the particular question of interest, (2) by ensuring a sufficiently powered study, (3) by repeating the model in different centers, (4) by better mimicking a clinical trial in patients, (5) by a standardization of methods over the different centers involved, (6) by the implementation of relevant biomarkers in these studies, and (7) by the translation and interpretation of the results to the right patient population.

A good example of an improved preclinical strategy is the setup of a preclinical randomized controlled international multicenter trial (pRCT) to test anti-CD49d antibodies as stroke therapy.[163] Six independent European research centers investigated the efficacy

of anti-CD49d antibodies in two different mouse models of stroke in a centrally coordinated, randomized, and blinded approach, to better mimic the design of a randomized controlled clinical trial and avoid the confounding effects of bias. Maximum harmonization of the methods, used in the different centers, was pursued for the pRCT, as this is generally standard practice in a clinical trial. The multicenter approach facilitated achieving sufficient numbers to power the study and increase the sensitivity of outcome measures such as the infarct volume in the middle cerebral artery (MCA) occlusion model.

Before this cooperation, several smaller studies had been conducted by different laboratories, with conflicting results.[164,165] By performing the pRCT, the researchers could conclude that the benefit of anti-CD49d antibodies may depend on the severity and localization of the infarct as the reduction of lesion size was observed after the permanent distal occlusion of the MCA where a small cortical infarction was created, but not after transient proximal occlusion of the MCA, which induced larger lesions.

The power of a single study can be augmented as well by a meta-analysis of similar studies. Whereas the concept of meta-analyses is very common for clinical trials, it is very scarce for preclinical research in neurological disorders.[166,167] The major advantage of the pRCT, however, is the harmonization of protocols and the centralized analysis, which will substantially reduce intersite variation, while still capturing to some extent the intersite variation which might truthfully reflect variation in a multicenter clinical trial. In addition, prior to the actual pRCT, it might be optimal to run a pretrial to validate the methods which will be used, assess the level of harmonization in-between study centers, and possibly evaluate different drug doses. Confirmation of the predictive nature of a preclinical trial will ultimately require comparison of the results of the clinical trials with the results of their preceding pRCTs.

Several international research consortia have been established, including the European Union-funded Multicenter Preclinical Animal Research Team (Multi-PART) consortium for stroke research and the National Institutes of Health-funded Consortium for preclinical assESsment of cARdioprotective therapies (CAESAR) consortium for cardiovascular research to aid in the improvement of preclinical trial design, statistical analysis, and adequate reporting. Also the "Stroke Therapy Industry Roundtable" has proposed guidelines for the robust preclinical evaluation of neuroprotective drugs for ischemic stroke to improve the successful translation of neuroprotective agents.[168]

Improvement on the side of clinical trials depends on a better quality of trial design, well-selected outcome measures, adequate trial planning, homogeneous patient selection, and inclusion of reliable biomarkers that complement the clinical outcome measures.

Progesterone had consistently demonstrated a potentially neuroprotective effect in a vast number of experimental animal studies for brain disorders, including TBI and ischemic stroke[169,170] and the benefit was further supported by the findings in small phase 2 trials in TBI patients.[171,172] Two large, multicenter, randomized, and placebo-controlled phase 3 trials, named ProTECT III and SyNAPSE, however could not confirm its efficacy in TBI.[173,174] Critical comments about these trials included a different mode of administration than in the preclinical studies, a potentially suboptimal clinical dose setting and inadequate treatment duration, a presumed negative effect caused by abrupt discontinuation of treatment and inclusion of low sensitivity and low predictivity biomarkers like the Glasgow Coma Scale and Extended Glasgow Outcome Scale (GOS-E) for the evaluation of such a heterogeneous condition as TBI. Hence, a clear mismatch and failure in the translation of the preclinical knowledge to clinical studies of progesterone neuroprotection after TBI can be observed, of which some might have been caused by timing issues, preventing inclusion of the preclinical findings in the clinical trial design. As such, the failure of progesterone as neuroprotective agent after TBI represents another example of the exceptionally high attrition rate in drug development for CNS disorders.

Besides better design of preclinical and clinical studies and a thorough translational strategy that links, confirms, and improves the knowledge of both the disease and the drug throughout development, a higher success rate might be achieved by implementation of a pathoanatomically based classification system. The current thinking supports classification and treatment of TBI and stroke patients based on the pathoanatomic injury, that is, the abnormality to be targeted by the treatment; and less on the clinical symptoms the patients present.[175] Both in TBI and stroke, neurological assessments, brain imaging, and blood biomarkers may improve diagnosis, patient stratification, and clinical outcome evaluation.

As stroke is a very heterogeneous disorder in etiology, symptoms, severity, and recovery, there is a clear need for guidance in the selection of appropriate scales to assess recovery in stroke, both from a physical, psychometric, and a QoL perspective. Different clinical-rated and patient-reported outcome measures exist like the Stroke Rehabilitation Assessment of Movement, the Chedoke Arm and Hand Inventory, ABILHAND, Fugl-Meyer Assessment (FMA), and Action Research Arm Test (ARA).[176] Currently there is no general consensus on the scales that should be used, the required level of effect and the most appropriate timing both in clinical stroke trials and clinical practice. Attempts for the improvement of clinical measures in stroke have been reported and are being extended.[176–179]

Imaging helps unravel the role of WM in acute neurologic conditions and the mechanisms associated with WM injuries and hence the selection of a more homogeneous patient population.[180] Different modalities of MRI are being used to visualize brain lesions. Perfusion-weighted imaging and diffusion-weighted imaging identify the area of acute ischemia in acute stroke; diffusion tensor imaging measures the degree of diffusion anisotropy in the brain and enables a more thorough investigation of the WM.[181,182] The result is a visualization of the structural integrity of brain WM tracts, potentially serving as a predictive biomarker for motor recovery which can aid in a personalized and optimal rehabilitation regime.[183]

Overall, the arrival of such imaging techniques has significantly improved both the diagnostics of WM injury and the monitoring of structural changes in the brain. Lesion mapping has identified that the hemispheric WM is preferentially affected in patients with major MCA stroke as compared to patients with lesion regression[184] and that patients unresponsive to rtPA and without recanalization of the MCA showed larger brain lesions with greater hemispheric WM damage than those who experienced successful thrombolysis.[185]

Obviously, biomarkers complementary to imaging and neurological assessments, for example, metabolic, anatomical, immunological, and genetic characteristics can further improve diagnosis, stratification, and evaluation of clinical efficacy.[186]

It is critical for patients to be rapidly diagnosed and considered for acute therapy. The development of diagnostic blood biomarkers for stroke, which might help distinguish stroke from mimics, is being complicated by the heterogeneity of stroke, the complexity of brain injury involving excitotoxicity, oxidative stress, inflammation, BBB dysfunction, apoptosis, etc.[186] Overall, the biomarkers related to these processes might be applicable for the prediction, diagnosis, assessment, prognosis, or treatment of stroke. Whereas individual markers have lacked sufficient sensitivity and specificity for stroke diagnosis, panels of biomarkers (like a composite score of matrix metalloproteinase 9 (MMP-9), brain natriuretic factor, d-dimer, and S-100beta) may hold greater promise and are actively being evaluated.[187,188]

In addition to diagnosis, biomarkers might assist with the identification of stroke mechanism and aid in prevention and treatment strategies, once validated.[186]

In summary, approval of drugs for neurological disorders like stroke has proven to be very challenging. This is caused by the complexity and heterogeneity of these diseases, the incomplete understanding of the different pathophysiological processes leading to brain injury, and the lack of biomarkers to describe these pathways and diagnose and monitor the neuronal damage. In addition, preclinical studies of therapeutic agents have had some limitations and flaws, as was the case for the clinical trials in this domain. Better understanding of the pathophysiology will help improve current clinical diagnosis, assessment, prognosis, and therapy. Inclusion of biomarkers reflecting relevant events of the pathophysiological processes in clinical trials as well as implementation of optimized clinical scales to measure QoL, physical, and psychometric patient characteristics and new imaging techniques will hopefully further advance and multiply the treatment options for patients suffering from these complex neurological disorders.

2.20.6.1.3 ALX-0171 translational strategy

Human respiratory syncytial virus (RSV) is the most important viral pathogen causing acute lower respiratory tract infections in infants with clinical signs ranging from mild upper respiratory tract illness to severe lower respiratory tract infections, including pneumonia and bronchiolitis. ALX-0171 is a trivalent Nanobody which is designed to target the RSV F-protein for delivery via inhalation.[189] It is currently in clinical development for the treatment of RSV lower respiratory tract infections in infants.[190]

Based on project goals and the defined target population for which the drug is being developed, a TM strategy should be laid out and documented in a TM plan. Implementing such a TM strategy in drug discovery and clinical development is key, as it integrates all TM aspects for a particular project and provides clarity on the objectives and how those objectives are going to be reached. As a starting point in building such a TM strategy, critical points and/or issues of the project need to be identified.

In the case of ALX-0171, the following aspects were considered as key points.

2.20.6.1.3.1 Efficacy

Infants with RSV disease typically develop clinical manifestations such as bronchiolitis and pneumonia that both result in significant hypoxia. Hallmark symptoms of bronchiolitis include wheezing, rales, rhonchi, increased respiratory rates, and signs of air trapping with flaring of nasal passages and intercostal muscle retractions.[191,192] In fact most clinicians recognize bronchiolitis as a constellation of clinical symptoms and signs[193] with a high heterogeneity in disease severity likely due to a combination of host and viral factors.[194] As such, there is a high need for a valid and reliable scoring instrument that could be used as a measure to evaluate the efficacy of clinical interventions in randomized controlled trials.[195] Such lack of clinically validated scores makes translatability of any preclinical results to the clinical setting difficult. To overcome such a hurdle it was considered important to identify biomarkers which could support efficacy in addition to the clinical endpoints. A logical example for an antiviral drug would be to assess the effect of treatment on viral loads both preclinically and clinically. In this respect, it has been shown that viral load consistently correlated with increases in multiple different disease measurements (symptoms, physical examination, and amount of nasal mucus) in a human challenge study,[196] and predicts disease severity in previously healthy infants.[197,198] It is therefore possible that reducing the RSV burden of infected infants at the time of hospital admission results in clinical benefit.

Many animal models of RSV disease, including NHPs, calves, lambs, mice, guinea pigs, ferrets, hamsters, and cotton rats, have been described.[199,200] However, all these animal models have limitations and should be selected appropriately based on the study objectives. For example, mice are not natural hosts of RSV and therefore require high viral inocula for an effective infection but are easy to handle and many transgenic and knockout strains are available. Cotton rats are 100-fold more permissive to RSV infection and the viral kinetics are closer to that in humans than for mice but the disease still does not sufficiently parallel events in the infant disease.[201] As colostrum-deprived neonatal lambs are naturally susceptible to RSV disease, share anatomical, physiological, and developmental similarities to that of human infants[202–205] and develop mild clinical symptoms such as expiratory efforts, fever, tachypnea, wheeze, malaise, and listlessness when experimentally infected with RSV,[206–208] this model was selected to assess the PK/PD properties of ALX-0171.

2.20.6.1.3.2 Efficiency of administration and dose predictions

As RSV is an acute disease, it is expected that a rapid delivery of high concentrations of drug within the respiratory tract would allow rapid viral neutralization and consequently a shortened disease time course.[209] For these reasons, the inhalation route was selected for delivery of ALX-0171.

The first issue with this administration route is that the drug is submitted to high shear forces during the aerosol generation that could induce physicochemical degradation or protein fragmentation and could potentially result in loss of biological activity, toxicity, and/or immunogenicity.[209,210] The second issue is that drug deposition within the airways is highly dependent on particle size distribution, airway anatomy, respiratory parameters, and gas volume in the lungs[211] which can be quite different between not

only different animal species but also between human adults and infants. As a consequence, the translatability of dose predictions from the preclinical setting to the clinical setting needs to be multifaceted. One important consideration is that the target concentration in the epithelial lining fluid needs to be defined appropriately. As infants are not small adults with regards to the development of organ systems, ideally modeling approaches need to take the differences in anatomy/physiology into account as these parameters can possibly result in changes in drug disposition in infants as compared to the adult situation. A PBPK model as the one developed for ALX-0171[212] is a good example of such a model and is further described in section "**From Empirical to Mechanistic Pharmacokinetic/Pharmacodynamic Models**." This model, however, describes the PK behavior of the drug once it has reached the lower lung but does not provide insight in the dose that needs to be nebulized in order to reach the required lung deposited dose. Additional models such as the in vitro Sofia Anatomical Infant Nose and Throat model (SAINT)[213] or the Multiple-Path Particle Dosimetry (MPPD) computational model are useful to study aerosol deposition in the respiratory tract of infants and thus can further complement the PBPK model for dose selection.

2.20.6.1.4 Tocilizumab translation in Crohn's disease

System biology can be applied to scale across different indications. Dwivedi[214] published an elegant example of a multiscale systems model developed to describe IL-6-mediated immune modulation in Crohn's disease, to assess and compare the expected performance of intervention on different potential targets.

Crohn's disease is a chronic inflammatory disorder, caused by a combination of environmental, immune, and bacterial factors in genetically susceptible individuals, in which the body's immune system attacks the gastrointestinal tract possibly directed at microbial antigens.

Further to other cytokines, IL-6 is increased in the intestinal mucosa and in the peripheral blood of patients diagnosed with Crohn's disease. IL-6 signaling can occur through membrane-bound IL-6 receptor (mIL-6R) or soluble IL-6 receptor (sIL-6R). The complex IL-6/IL-6R can recruit a membrane-bound gp130 coreceptor, forming a trimer which subsequently dimerizes to form a hexameric complex, and triggers the phosphorylation of gp-130-bound Janus kinase proteins. IL-6 signaling results in an increased expression of acute-phase proteins such as C-reactive protein (CRP), as also reported in Crohn's disease. Hence, the development of a system biology model describing the IL-6-mediated immune signaling pathway at the cellular level, and target organs relevant in Crohn's disease can contribute to the evaluation of the most sensitive target to hit in Crohn's disease. The model was based in previous in vitro knowledge and in vivo information gathered in another patient population. CRP data from a previously published pilot clinical trial of the anti-IL-6R mAb Tocilizumab were used to qualify the model.

Based on the model, the effects of IL-6 or IL-6R inhibition and a fusion protein combining the extracellular portion of gp130 with the Fc region of human IgG1, sgp130Fc on PD serum and gastrointestinal tract (GI) tract biomarkers (CRP and pSTAT3 activity) have been compared. The predicted profiles of the PD biomarkers suggest that the best targets would be IL-6 and sIL-6R, whereas the sgp130 therapy will likely be less effective. The model also allowed the comparison of expected dose–response curves for IL6 or IL-6R inhibition, appearing different in shape: IL-6 inhibition is characterized by a smooth dose–response until saturation at high doses, whereas the interference with the IL-6R leads to an abrupt increase in the response. The different behavior is explained by the very different levels of free IL-6 and soluble (s)IL-6R. The different levels of IL-6 and sIL-6R confer different profiles to antibodies targeting them, and a greater dose-dependent modulation of the effects is predicted for anti-IL-6 than for anti-anti-IL-6R antibodies, so that targeting IL-6 would require lower and less frequent dosing compared to an anti-IL-6R, to achieve similar reduction of the effects of the IL-6 signaling. On the other hand, the very high baseline level of sgp130 compared to free IL-6 and complex makes it relatively insensitive to small changes in its concentrations. This hypothesis needs, however, further clinical validation.

2.20.6.2 Integrative Thinking

2.20.6.2.1 Introduction

The rapid evolutions in new technologies have opened up a lot of opportunities for basic and clinical research and diagnostics. In addition, elements from different sciences and technology branches are more frequently being combined. These developments are more and more being fed in clinical settings (TM from bench to bedside), while also the bedside to bench translation can be very informative and expedite finding of new or better therapies. Last but not least, integrative thinking in TM also refers to integration of knowledge within a particular field and over different fields, for example, the research that is concentrated in societies or other programs that integrate the experiences and requirements of researchers, clinicians, and health care providers.[215]

2.20.6.2.2 Bedside back to bench

Integrative thinking also entails learning from failed therapies, whether caused by safety or lack of efficacy reasons. By trying to elucidate failures and by reporting on failures, important knowledge is being captured that can in turn save a follow-up molecule from the clinical graveyard. One of the many drugs that was discontinued during phase I clinical trials due to safety concerns is the anti-CD40L mAb ruplizumab (h5C8, Biogen). Thromboembolic (TE) events occurred in several ruplizumab trials: in a lupus nephritis trial, two patients suffered a myocardial infarction[216] and in a transplant trial, one obese, bedridden woman died from pulmonary embolism.[217] In addition, during a Phase II study receiving another CD40L-targeting compound toralizumab (IDEC-131), a Crohn's disease patient developed a blood clot in the leg.[217] The mechanism of the safety findings was further investigated and reported and this facilitated the development of Dapirolizumab Pegol (CDP7657, UCB).[218,219]

CD40L is a costimulatory molecule expressed on activated T cells which signals to professional antigen-presenting cells,[220] but it is also expressed on platelets and monocytes, natural killer (NK) cells, mast cells, and basophils under inflammatory conditions. For almost two decades, CD40L was an inaccessible target due to the TE events that occurred in several clinical and preclinical trials with anti-CD40L compounds.[217,221] At the time, these adverse events could not readily be explained. As CD40L is also expressed on platelets, anti-CD40L drugs could have bound and activated platelets. This was extensively investigated and by now, evidence has been generated that immune complexes comprised of CD40L (a trimer) and antibodies are able to activate platelets and induce platelet aggregation in vitro, predominantly by cross-linking of FcgRIIs on the platelet membrane. Either CD40 or CD40L can act as docking station on the platelets for the immune complexes, resulting in FcgRII-mediated platelet activation.[222–225] This hypothesis was further strengthened by the results obtained in a hu FcgRIIa transgenic mouse model and the findings reported in NHP safety studies. The transgenic mouse model was developed to facilitate the binding of a human mAb-Fc to transgenic Fc receptors expressed on murine platelets.[223] Injection of preformed complexes of recombinant soluble CD40L and anti-CD40L antibody in these mice caused thrombocytopenia and intravascular microthrombi. In addition, two safety studies in NHP confirmed the dependence on the Fc part of the anti-CD40L mAbs to induce thrombo-embolism in these animals: TE were quantified in rhesus monkeys treated with either ruplizumab[221] or the follow-up molecule CDP7657,[218] a PEGylated anti-CD40L Fab fragment. Extensive immunohistochemical analysis of the lungs revealed a lower prevalence of microthrombi in the lungs of rhesus monkeys treated with CDP7657 as compared to ruplizumab and a similar number for the CDP7657-treated animals compared to the number in vehicle-treated animals and historical controls. Importantly, the same holds true for variants of ruplizumab without effector function such as the aglycosylated version of the mAb and its di-Fab fragment. Two trials have been completed in meanwhile with CDP7657: a Phase I study in both healthy individuals and patients with systemic lupus erythematosus (SLE)[219] (ClinicalTrials.gov Identifier: NCT01093911) and one in patients with SLE (ClinicalTrials.gov Identifier: NCT01764594). No TE events were reported in the report of the first trial.[219] In the latter, safety and tolerability was assessed and in addition, disease activity measures were explored using the British Isles Lupus Activity Group (BILAG)-based Composite Lupus Assessment and the Systemic Lupus Responder Index.[226] Preliminary and cautious enthusiasm exists as exploratory analyses show greater improvement in clinical measures of disease activity in the CDP7657 group versus placebo. More importantly, however, no serious treatment emergent adverse events and no deaths occurred.

As such, the CD40L story is a good illustration of how the failure of two drugs, when well investigated may aid the development of a third one and facilitate better patient care.

2.20.6.2.3 Integrative thinking in oncology

The field of Oncology is moving fast forward and this movement is being supported by strong integrative thinking in different areas: (1) treatment strategies focus both on the tumor and the immune system; (2) combination therapy is the future and requires excellent knowledge of the action of the different single therapies and the potential interactions thereof, and (3) a more profound characterization of the patient, both with respect to tumor and immune characteristics, will improve patient stratification and combination therapy (Fig. 10).

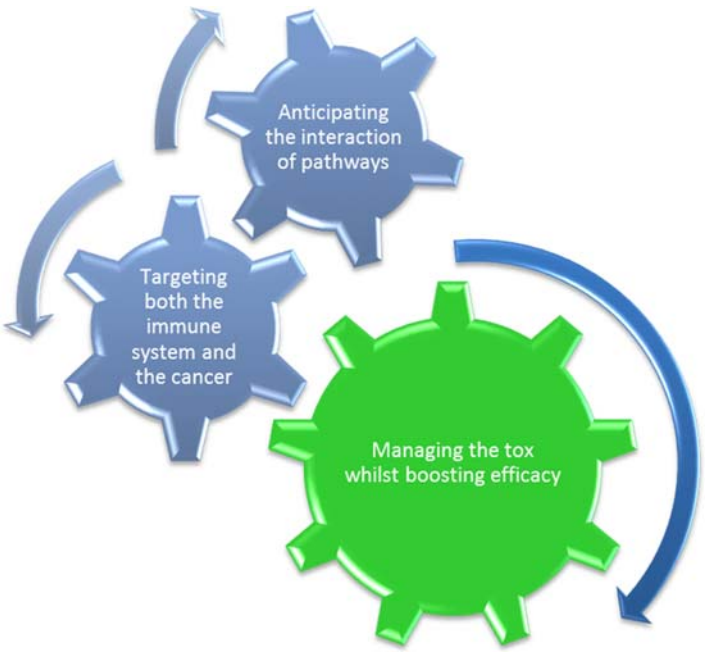

Fig. 10 The future of oncology is about combining.

2.20.6.2.3.1 Importance of both tumor and immune system (or immune contexture)

Before 2005, cancer therapy was focused on the tumor cells using antigen-targeted therapies, chemotherapy, radiotherapy, and kinase-targeted therapy. The treatment was mainly determined based on the characteristics of the tumor or the cancer (stage tumor lymph nodes metastasis (TNM), invasion status (L, V, Pn), grading (differentiated or not), mutations, histological subtype). This paradigm has changed by the rapidly advancing field of cancer immunology: now the focus is on the impact of the immune system and how this may be prompted to eradicate the cancer cells.[227] Insufficient immune-surveillance as well as the multiple immune suppressing mechanisms induced by the tumor might relate to the difficulty to recognize tumor as nonself and the subsequent elimination of tumor cells by the immune system. Many escape mechanisms are being exerted by cancer cells: (1) reduced expression of tumor/foreign antigens on their surface, (2) expression of immune suppressing proteins both on the tumor cell surface (e.g., Crry) and released in the tumor microenvironment (e.g., NO, IDO, and TGF-beta 1), and (3) the presence of multiple suppressing cell types like myeloid-derived suppressor cells (MDSCs), regulatory T cells (Tregs), etc. Hence, immunotherapy is focused on stimulating the immune system either by impairing the induction of tolerance (e.g., via PD-1, PD-L1, CTLA-4, LAG-3, TIM-3) or further strengthening the activating signals (e.g., via 4-1BB (CD-137), OX40 (CD134), and CD-27 agonists). As an example, tumors use checkpoint inhibitors,[228] which limit the strength and duration of normal immune responses to induce tolerance. Blocking the action of these checkpoint inhibitors has proven highly effective in multiple types of cancer and has led to the approval of ipilimumab (anti-CTLA4[229]), nivolumab and pembrolizumab (both anti-PD-1[230,231]), while many more are being evaluated and developed.[232,233] Durable tumor regression was most notable in melanoma and lung cancers, and favorable activity has been demonstrated in bladder cancer, head and neck cancer, renal cell carcinoma, ovarian cancer, and hematologic malignancies.[234–237] The importance of the immune system in cancer has been further highlighted by the predictive power of the immunoscore. This score, which is an assessment of infiltration of T cells in the tumor, has proven to be a strong prognostic marker and the most predictive parameter for overall and disease free survival (DFS) in colorectal cancer.[238,239] This immunoscore is in fact further complemented by the immunologic constant of rejection, which determines the functional orientation of the immune response (e.g., a predominantly Th1 driven cytotoxic response). Together they are referred to as the immune contexture. As a last example of the importance of the immune system in the control of cancer, it has been demonstrated in melanoma[240] and NSCLC[241] that more immunogenic tumors respond better to immunotherapy than cancers with a low mutational burden.

Although great leaps forward have been taken in cancer therapy, and more patients are experiencing durable long-term survival in certain cancer types, the majority of patients however remain unresponsive or relapse, warranting new drug combinations and further research both on tumor, tumor environment, and immune system.

2.20.6.2.3.2 Integration by combination of therapies: combination and sequencing

Tumors are in fact complex and heterogeneous tissues comprised of neoplastic cells interwoven with tumor-associated stroma cells. Targeted therapy, the former holy grail in the field of oncology, is susceptible to failure or relapse as the heterogeneity of the tumor warrants that a combination of targeted therapies will be necessary to achieve successful and sustained clinical benefit, as can be supported by the more favorable effect of the combination of a BRAF and (Mitogen-Activated Protein) Kinase/ERK (Extracellular Signal-Regulated Kinase) Kinase (MEK) inhibitor in BRAF mutation positive melanoma patients when compared to monotherapy.[242,243]

Further optimization of the potential of the immune system in cancer lies in (1) generation of sufficient numbers of antitumor T cells in the lymphoid compartment; (2) effective migration of T cells out to the lymphoid tissue into the tumor microenvironment; and (3) T cell effector function within the tumor microenvironment, characterized by the ability to bypass all aforementioned immune suppressing mechanisms.[244] Given the extensive toolbox that is currently available for cancer therapy, many combinations seem attractive from a theoretical point of view, to boost the immune response against the tumor cells. However, dose and dosing schedule, the optimal or even required order of the different treatments and even more importantly toxicity of a combination therapy render this approach a hazardous and difficult endeavor. Examples of potential combinations are a combination of an immune checkpoint inhibitor with a costimulatory receptor agonist[245]; or with radiation therapy,[246] chemotherapy,[247] or enhancement of innate immunity[248]; or with a second checkpoint inhibitor[249] or even with targeted therapy (NCT01454102, NCT0208812). Chemotherapy and radiotherapy form interesting combinations with checkpoint inhibitors as, in addition to the actual tumor cell killing, they both may indirectly release tumor-associated antigens, rendering the tumor more immunogenic for the immunotherapy as well as enhance costimulatory signals on antigen-presenting cells. Again, the sequence and the dose of this adjuvant therapy are crucial[250,251] and also here toxicity remains a concern.

2.20.6.2.3.3 Moving toward a multidisciplinary patient characterization will lead to more profound understanding of cancer progression and ultimately to better patient stratification

To identify the best treatment for a cancer patient, information from a multidisciplinary team should be assembled and interlinked[252]: the immune phenotype (e.g., expression of tolerance inducing signals; the T cell repertoire), the localization of the immune cells (infiltrating in the tumor or not), the genetic major histocompatibility complex (MHC) background, the tumor specific mutations and resistance mechanisms, and tumor staging and grading. These data may improve understanding of why a certain therapy is effective in some patients but not in others with the same type and even stage of cancer and more importantly if a patient is not responding, which therapy or combination of therapies would be more appropriate.

Comprehensive genomic characterization has identified molecular subgroups and consequently potentially actionable genomic alterations. Lung-MAP (SWOG S1400)[253] is a fine example of how state-of-the-art genomic profiling efficiently can be employed for drug development and does this in a very cost-efficient way: lung-MAP is a biomarker-driven squamous cell lung cancer clinical trial study design which is multidrug and multiarm. It uses a targeted screening approach, with state-of-the-art genomic profiling of neoplastic cells to match patients with substudies testing investigational new drugs and immunotherapies, based on their unique tumor profiles. Because a broad next-generation sequencing (NGS) platform is being used and tissue and blood is being banked, a lot of data will be generated that hopefully will lead to better understanding of responsive geno/phenotypes. A systematic tumor genomic profiling before treatment and after relapse is evidently very useful to identify acquired resistance mechanisms and to help predict the outcome with a similar therapy in other patients with the same tumor genotype.[242] Whole exome sequencing has deduced that a higher mutational load is correlated with better response to checkpoint inhibitors in melanoma and NSCLC[254,255] and immunohistochemistry has revealed that PD-L1 expression is being linked with improved clinical outcomes for anti-PD-1 or PD-L1 treatment.[256] However, the fact that the latter is not an exclusionary predictive biomarker as exemplified in NSCLC, metastatic renal cell carcinoma (mRCC), colorectal, and anal cancer still warrants better understanding of the host immune system as well as the tumor microenvironment.[239] Indeed, the presence and phenotype of immune cells both in the center of the tumor and the invasive margin is very informative. The immunoscore, as developed by Galon et al.,[257] depends on the number and localization of cytotoxic T cells in the tumor and is the strongest prognostic factor for DFS and overall survival in colorectal cancer (CRC). Although first described in CRC, the impact of the immunoscore has been demonstrated in many other human tumors and appears to be a general phenomenon.[258,259] Also the presence of Tregs,[260] tumor-associated macrophages,[261] and MDSC[262] might help clarify why a certain treatment is not efficacious, while indicating that the immune suppressive environment in the tumor is too strong.

During the last decade, biomedical technologies have undergone an explosive evolution. The widespread availability of next-generation genomic sequencing has opened the door to the development of precision oncology. Steadily, cellular and molecular mechanisms of tumorigenesis are being unraveled and the relevance of the microenvironment in the primary tumor is being acknowledged and understood leading to the clinical trial design with incorporation of more biomarkers, a more widespread use of NGS[263] and implementation of new (molecular) imaging technologies and immunohistochemistry (IHC) on tumor biopsies.[264]

2.20.6.3 Combination of Technologies

In the preceding sections we have highlighted important tools in translation research, for example, biomarkers, imaging, or animal models. While each of these tools helps to enhance translatability of findings from the preclinical to the clinical stage, it is the combination of these technologies that is really powerful.

Imaging has shown its power in translational research since it allows for visualization and quantification of (patho)physiological processes in vivo across species. However, the quality of the information obtained through imaging highly depends on the setting from which it was derived. For instance, many animal imaging studies are performed with anesthetized animals, well knowing that anesthesia by itself may have profound effects on general brain activity. An NHP study has demonstrated that the effects of buprenorphine in a nonanesthetized monkey were comparable to that seen clinically while in an anesthetized animal there was hardly any effect visible.[265] More importantly, the quality of imaging depends strongly on the validation of the imaging markers used. While a poorly validated marker may translate well from animals to human, the qualitative information may still be poor in both the animal and the clinical setting. Thus, it is the combination of a well-validated animal model and imaging that yields translatable and meaningful information.

Imaging and biomarkers are particularly useful especially when combined in an animal model to qualify markers for the discovery and development of new therapies.[266] Brain tumors are notoriously difficult to treat and few therapeutic approaches evaluated in animals have translated into successful therapies. One of the inherent problems of a brain disease is the difficulty to directly measure the pathophysiological processes and disease progression/attenuation in an organ that is probably the least accessible organ of the human body.

Parkinson's disease is one of the most common neurodegenerative disorders affecting up to 2% of the elderly population. A number of symptomatic therapies are available which have mostly been identified and developed with the help of the 6-OHDA model, one of the oldest animal models in neuroscience.[267–269] Since the model involves the destruction of dopaminergic neurons in the nigro-striatal system, all drugs developed so far are dopamine agonists that substitute for the loss of dopamine in the model. While these drugs show some symptomatic efficacy in the model, little progress has been made clinically since the initial introduction of the first of these drugs, L-DOPA, about half a century ago. Most importantly, no drug has yet been identified that affects the progression of the disease or could provide a cure. To overcome the vicious circle whereby validation of an animal model with existing drugs can lead to identification of drugs that are relatively similar thus providing little progress, new models have been developed that include additional markers beyond behavioral parameters.[270] Imaging and biomarkers have been established in animal models and in humans to assess disease severity and progression to higher precision and the hope is that with these combination of translational tools (animal models with imaging and biomarkers), disease modifying therapies can be identified.[271]

2.20.7 Conclusions

In the preceding sections, we have highlighted the various tools that are important for translational research and gave examples on how they have helped others to achieve drug development successes. Furthermore, we have highlighted that these tools need to be part of a strategy rather than to be used in isolation. The most important TM tool is integrative thinking. To summarize we have tried to formulate the key points into the 10 golden rules of TM.

1. Think through your translational research project from the end: what exactly do the results need to be in order to make it a success.
2. Back-translate your ultimate goals into intermediate objectives: what are the key results you need to achieve in order to be reassured that further investments are warranted. For instance, what results need to be achieved in the animal model to be convinced that the following clinical trial will be successful.
3. Select the tools carefully, making sure that they are qualified for the purpose. A biomarker, for instance, can be qualified as a general efficacy marker for a certain disease (e.g., amyloid beta for Alzheimer's disease) but still not be qualified for a specific purpose (e.g., cognitive function in Alzheimer's patients).
4. Assure sufficient qualification of the tool methodology: the best biomarker is useless if you cannot be assured that the way it is measured is reliable.
5. Keep consistency across the different steps: if progression-free survival is to be the main endpoint in a clinical trial, the assessment of tumor size in the animal model as primary endpoint may not be appropriate.
6. Use modeling and simulations in order to use the available results is redundant to create concrete hypothesis for the next stage.
7. Combine tools to evaluate a question based on different biomarkers, with different orthogonal methodologies.
8. Acquire knowledge in the pathophysiological interaction of key players and how one player influences the other, in the context of the expected outcome of a single treatment or the added value of combinations.
9. Get buy-in from all disciplines involved.
10. Learn from failures, that is, if something did not work out as foreseen, for example, a clinical trial endpoint did not show an effect while the animal model correlate did, it might be worthwhile to find out why. It might be that the disease pathophysiology is different or that the endpoint is not equivalent. The failure of one project may become the cornerstone of a successful one.

2.21.1 Introduction

Optimally, any drug-development project should rely on an in-depth understanding of the disease biology and the drug mechanism of action. However, we are not there yet, but within a disease area like oncology, the advances in molecular medicine have given us sufficient insight to allow us to practice a more rational drug-development process, which has led to the development of companion diagnostic (CDx) assays. These assays hold the promise of improving the predictability of the drug-development process and being an important tool for the clinical use of the drugs after their approval. For some drugs, the CDx assays have taken up a central role in the development process, and the success of this type of drugs largely depends on the performance of these assays. The CDx assays have the individual patient as a point of reference, and they will be decisive for the move toward a more precise and individualized pharmacotherapy.[1,2]

There is a crucial need for an improvement in the success rate of drug development. The likelihood of regulatory approval for a drug entering phase I seems to be no more than 10%, however, with some variability as regards to disease areas. For infectious diseases, the likelihood of approval has been estimated to 16.7% but is as low as 6.7% for oncology.[3] Such figures greatly influence the productivity of the research and development (R&D) activities in pharma and biotech companies. Based on the low productivity, the head of the European Medicines Agency (EMA), a few years ago, estimated that around 60 billion USD of the 85 billion USD spent on pharmaceutical R&D globally each year was more or less wasted due to the high drug failure rate.[4]

When it comes to the clinical use of drugs, we have recognized that the treatment outcome is subject to great inherent patient variability, which often seems to be of a significant magnitude. Over the last couple of decades, we have learned that drugs are not always as effective as they ought to be and that pharmacotherapy needs to be individualized in order to achieve an improved treatment outcome.[5,6] These considerations have led to an increased focus on "personalized medicine," and the US president Barack Obama's recent announcement of the national Precision Medicine Initiative should be seen in this context.[7]

A CDx is an assay linked to a specific drug, and it is often during the drug discovery phase that the biomarker candidates are identified, which will be tested for their predictive potential later on in the clinical drug-development phases. In this article, we will discuss the individual steps in the development of a CDx assay, from the discovery phase over assay development to analytic and clinical validation. In the last part of the article, we will also discuss the regulatory aspects of CDx and the impact they have had on the drug-development process. However, when it comes to the development of CDx assays, there is one disease area that has been in the forefront, and that is oncology. This will also be reflected in this article as most of the examples given will come from this disease area.

2.21.2 Companion Diagnostics

The term companion diagnostics appears for the first time in the literature in an article published in 2006.[8] This article discussed the state of immunohistochemistry (IHC) and devices available for a quantitative assessment of the human epidermal growth factor receptor 2 (HER2) expression. In this paragraph, we will discuss the different terms and definitions used in relation to CDx assays and briefly touch upon some few historical aspects.

2.21.2.1 Terminology and Definitions

A prerequisite for a CDx assay is the predictive biomarker, so let us start by defining what a biomarker is. In 2001, the Biomarkers Definitions Working Group came up with the following definition: "A characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacological responses to a therapeutic intervention."[9] It is especially the last part of this definition saying that a biomarker can be an objective measure for a pharmacological response to a therapeutic intervention, which is of interest when discussing CDx assays. The predictive property of a biomarker is the key to a CDx assay.

When it comes to the name that describes the predictive biomarker assay developed in parallel to a specific drug and used for preselection of likely responding patients, consensus seems to be lacking. In the literature and guidelines, different names are used, such as pharmacodiagnostics, theranostics, pharmacogenomic biomarkers, and companion diagnostics. However, within the last 5–6 years, the name companion diagnostics is being used more and more frequently. This term was first adapted by the US FDA and subsequently also by EMA and other regulatory agencies.[2,10,11]

In 2014, the US FDA issued a guidance document on *In Vitro Companion Diagnostics Devices* in which a CDx is defined.[12] According to this definition, a CDx assay is an in vitro diagnostic (IVD) device that provides information that is essential for the safe and effective use of a corresponding therapeutic product. Furthermore, the US FDA specifies four areas where a CDx assay could be essential: (1) to identify patients who are most likely to benefit from the therapeutic product; (2) to identify patients likely to be at increased risk of serious adverse reactions as a result of treatment with the therapeutic product; (3) to monitor response to treatment with the therapeutic product for the purpose of adjusting treatment (e.g., schedule, dose, and discontinuation) to achieve improved safety or effectiveness; and finally (4) to identify patients in the population for whom the therapeutic product has been adequately studied and found safe and effective, that is, there is insufficient information about the safety and effectiveness of the therapeutic product in any other population. Overall, these different areas in the US FDA's definition can be summarized as outcome prediction (efficacy and safety) and therapy monitoring. The fourth aspect mentioned in the definition can be regarded as a kind of disclaimer and is related to the type of study design most often used in the clinical validation of the CDx assays, the enrichment study design, which will be discussed later on in this article.

In the European Union (EU), the legal framework for IVD medical devices is under revision, and this also includes CDx assays. In the proposal issued in 2012, CDx is defined as a device specifically intended to select patients with a previously diagnosed condition or predisposition as eligible for a targeted therapy.[13] However, during a revision of the proposed legal framework by the Council of EU Ministers in 2015, this definition was changed, so it is now almost identical to the definition used by the US FDA.[14] If we look at how CDx assays have been used so far, especially the predictive role in relation to drug efficacy has dominated. A definition, proposed already in 2008, which has this focus and is making a link to "personalized medicine," reads as follows: "A pretreatment test performed in order to determine whether or not a patient is likely to respond to a given therapy. This type of test is classified as a predictive test and is a prerequisite for implementation of stratified and personalized medicine."[15]

2.21.2.2 Historical Aspects

Looking at the history of drug development, the first time we see molecular testing becoming an integrated part of the development process was in the 1970s. When the selective estrogen receptor modulator (SERM) tamoxifen (Nolvadex, AstraZeneca) was developed for the treatment of advanced breast cancer, data on estrogen receptor (ER) status were correlated with the treatment outcome. Based on data from a phase II study in patients with metastatic breast cancer, published in 1976, the investigators concluded "a high degree of correlation between response and positive estrogen receptor assay suggests the value of the diagnostic test as a means to select patients for tamoxifen treatment."[2,16] At that time, ER receptor status was measured by a biochemical assay and not as today with the simpler IHC test. With the development of the IHC test, determination of ER status became standard for all patients diagnosed with breast cancer, and today, it is a prerequisite for initiation of endocrine treatment with a SERM or an aromatase inhibitor. Although molecular testing in relation to the development of tamoxifen clearly identified a group of responders, that is, patients with a positive ER status, it was not until the 1990s that the drug–diagnostic codevelopment model really proved its value.

When Genentech developed the monoclonal antibody trastuzumab (Herceptin, Roche/Genentech) for treatment of women with advanced breast cancer who overexpressed HER2, they also developed an IHC assay that could determine the level of HER2 expression in the tumors. During the clinical development phases, this assay was used to preselect the patients for treatment with trastuzumab and, in fact, formed the basis for the enrichment study design as we know it today. The diagnostic company Dako further improved the IHC assay known as HercepTest. On the same day in Sep. 1998, the US FDA, in a new coordinated approval process, approved both the drug and the diagnostic assay simultaneously.[17] HercepTest became the first CDx assay linked to the use

of a specific drug, and the way that Genentech did the parallel development of drug and diagnostic has served as an inspiration to a number of other pharmaceutical and biotech companies and regulatory agencies. When the US FDA issued the concept paper on drug–diagnostic codevelopment in 2005, the inspiration was likewise clear.[18]

2.21.3 Biomarker Discovery

The prerequisite for the drug–diagnostic codevelopment model, as outlined in Fig. 1, is a thorough molecular knowledge of the disease mechanisms and of how the targeted drug in question interacts with these mechanisms. The drug discovery process is often sequential, starting with a characterization and understanding of the disease mechanisms, followed by target identification and then finally lead compound development. However, due to the large amount of data generated during this process, drug discovery has slowly become a nonlinear and iterative process, which can also involve preclinical and even different types of clinical data in a kind of "system pharmacological" approach. Both genetic and nongenetic data can be part of these integrated analyses. The genetic data will often originate from high-throughput technologies, such as next-generation sequencing (NGS), but also phenotypic data and other types of data are used. This type of dataset is often referred to as "big data." It is typically during this process that potential biomarker candidates will be identified, which have to be tested for their predictive potential later on during the preclinical and early clinical phases.[19]

Targeted drugs are designed to interact with or block specific molecular or intracellular pathways often driven by genetic changes of heritable or somatic nature, as we know it from cancer. The success of the drug–diagnostic codevelopment model very much depends on how well these mechanisms are understood and on the strength of the biomarker hypotheses that can be deduced from the knowledge generated mainly during the drug discovery and preclinical phases.[10] During the discovery phase, we often see several different parallel analysis methods applied; however, it is important to notice that the methods used during biomarker discovery are not always the same as the ones used later on in the clinic. Once the biomarkers are identified and characterized, often the simpler and more cost-effective methods will be applied to the samples in the clinic.[20] As stated earlier, it might be not only one hypothesis that is tested through a prototype assay but also sometimes several hypotheses. These hypotheses will then be investigated in parallel using different analytic platforms as described in the next paragraph.

2.21.4 Assay Development

In the former paragraph, we discussed biomarker discovery and underlined the importance of a strong biomarker hypothesis. However, a strong biomarker hypothesis is worthless if the CDx assay does not measure the biomarker in question correctly. In this paragraph, we will discuss assay development from choice of platform, development of prototype assays, and, finally, assay verification and validation. This is done to ensure that the CDx assay is robust and reliable before it undergoes clinical testing.

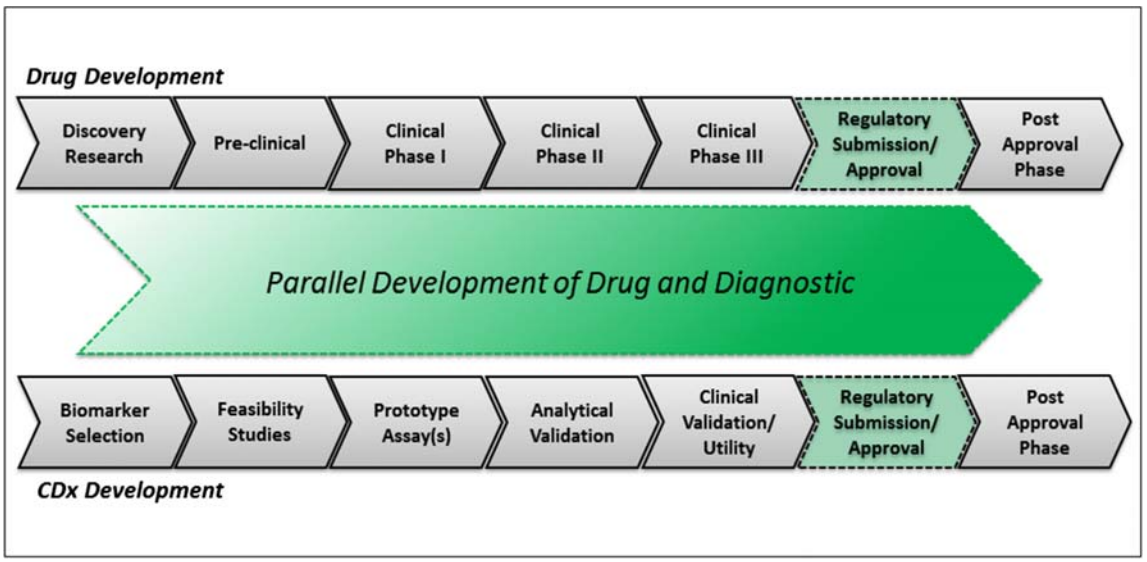

Fig. 1 The drug–diagnostic codevelopment model illustrating the parallel development of drug and CDx with an aligned regulatory submission and approval at the end of phase III.

2.21.4.1 Assay Methodology

The selection of the assay methodology is biomarker-dependent, and the method selected must be relevant for the predictive biomarker in question. The FDA-approved CDx assays analyze variations in the sequence, structure, or expression of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) or profiling protein expression. The first ER assay used to select a group of breast cancer patients for treatment with tamoxifen was a biochemical assay, as mentioned previously, but this has now been substituted by an IHC assay. The first FDA-approved CDx, HercepTest, was also an IHC assay, but since then, a few other technologies have been used as analytic method for CDx assays. So far, the methods that have been used as CDx assays to identify genetic or protein alterations/abnormalities in human diseases are polymerase chain reaction (PCR), fluorescence in situ hybridization (FISH), DNA sequencing, or IHC. Whereas the IHC assays identify protein expression, the remaining methods are used to analyze various nucleic acid compositions or alterations. The FISH and the IHC methods are semipreservative regarding the tissue morphology and make it possible to evaluate individual cells, whereas the other methods are disruptive to the tissue as some degree of nucleic acid extraction is needed to obtain a result. Both the IHC and FISH methods are single analyses with limited opportunities to multiplex in contrast to the methods based on nucleic acid extraction that can be run as multiplex analyses.

The antibodies used in the IHC assays must be specific and sensitive in recognizing the protein of interest. These antibodies can, for example, target a membrane protein such as HER2 or, more generally, identify the presence of a protein, as seen for other IHC assays.[17,21] The scoring criteria for these assays vary; in one instance, it can be identification of the percentage of positively stained cells and in other instances to identify the presence of a specific protein at a clinically relevant cut point. A pathologist normally performs the scoring of the IHC stained slides, and the method as such is considered to be quantitative or semiquantitative depending on the scoring method and reporting result.

FISH probes can be designed as a copy number evaluating assay such as *HER2* IQFISH pharmDx (Dako) where the gene of interest is targeted by a DNA-specific probe, or it can be used to identify changes on the gene or chromosome level as for the Vysis *ALK* Break Apart FISH probe kit (Abbott Molecular).[22,23] The *HER2* IQFISH pharmDx assay contains both a gene probe that targets the *HER2* gene and a centromeric probe that targets the centromeric region on chromosome 17. The cutoff for the assay is defined as the ratio between the gene copy number and the number of centromeric signals (*HER2*/CEN-17). For the *HER2* IQFISH pharmDx assay, cases with a ratio ≥ 2 are defined as being *HER2* amplified. The break-apart probe uses two probes labeled with different fluorophores (red and green); one probe is targeting the gene in question, whereas the other is targeting a sequence in close proximity to the gene. Under normal conditions, these signals will be close to each other and will appear yellow, but in case of rearrangement, the red and green signal will be identifiable as separate signals. In both types of assays, the specific gene and centromeric signals are enumerated, and the test can be considered quantitative. In case of the copy number enumeration, the ratio is translated into binary results as either positive (ratio greater or equal to the cutoff) or negative (below the cutoff). The *HER2* IQFISH pharmDx assay is linked to the use of the HER2-targeted drugs trastuzumab and in the United States also to the use of pertuzumab (Perjeta, Roche/Genentech) and ado-trastuzumab emtansine (Kadcyla, Roche/Genentech). The Vysis ALK Break Apart FISH probe kit is linked to the use of the ALK inhibitor crizotinib (Xalkori, Pfizer).

PCR is used for mutation analysis as in the case of the Cobas 4800 *BRAF V600* Mutation Test (Roche Molecular Diagnostics).[24] This test will identify if a *BRAF V600E* gene mutation is present or not. The Cobas 4800 *BRAF V600* Mutation Test is linked to the use of the BRAF inhibitor vemurafenib (Zelboraf, Roche/Genentech). The BRACAnalysis CDx (Myriad Genetic Laboratories) uses Sanger sequencing in combination with quantitative PCR to detect single-nucleotide variations and small deletions in the *BRCA1* and *BRCA2* genes.[25] The BRACAnalysis CDx assay is linked to the use of the PARP inhibitor olaparib (Lynparza, AstraZeneca).

The aforementioned methodologies include those that the US FDA have currently approved as CDx, but other methodologies such as immunoassays, enzyme-linked immunosorbent assay (ELISA), and fluorescence-activated cell sorting (FACS) are being tested in clinical settings in the attempt to generate a CDx.[26] Along with PCR, these techniques are becoming key in the process of generating CDx within circulating tumor cells (CTC) as exemplified by the immunoassay Kit CELLSEARCH Circulating Tumor Cell, which is currently the only cleared US FDA method for the clinical detection of CTC for patients with breast, colon, and prostate cancer.[27] The techniques are currently facing difficulties with the heterogeneity of the CTC within individuals, which is a big challenge in the process of analytic validation of the assays.[28]

WILEX has developed a HER-2/neu ELISA assay that has been US FDA-cleared as an IVD blood test for quantifying the serum HER-2/neu level in women with metastatic breast cancer as a criterion for a suitable therapy.[29,30]

2.21.4.2 Prototype Assays

When the assay methodology has been decided, feasibility of the selected CDx assay must be tested to document that the alterations in sequence, structure, or expression profile of the biomarker can be correctly identified. The first and foremost question to be answered is whether or not it is possible to develop a CDx assay for the selected biomarker.

This work includes selection of suitable antibodies, probes, primers, or sequences depending on selected assay methodology. Part of this is testing the assay's ability to identify the biomarker in a reliable way in all clinically relevant sample types. Also, the sampling and the potential method of fixation of tissue are being tested as these preanalytic processes can have large impact on the performance of the assay. Another important aspect of the initial phases of the CDx development is to establish the assay sensitivity and specificity for the detection of the relevant biomarker in patient specimens. The other part of the feasibility phase is to

demonstrate that the biomarker is relevant for predicting the efficacy of the drug in patients. This requires a thorough understanding of the biology of the disease and drug mechanism of action—as described in the previous paragraph. The design control is also established during the feasibility testing.

Once the characterization of the assay feasibility has been established, a prototype assay can be developed. The assay protocol should include all information on how to perform the test, including how to obtain and prepare the patient samples, test parameter setting, interpretation, and documentation of assay results. Additionally, the shelf lives and storage conditions must also be tested and documented for all kit components including both chemicals and biologicals. The acceptable ranges for pH, concentrations, temperatures, and reaction times also need to be established. If automation is being applied, the performance of the assay on the equipment must be described in detail, including operational specifications and calibration.

These activities are generated under design control to ensure that the documentation of the assay development process is captured and documented correctly. As a minimum, the assay design specifications should include the definitions of sensitivity and specificity, the disease in question, tissue type, and interpretation guidelines and/or scoring criteria. Furthermore, potential positive and negative controls should be tested and established. The purpose of these controls is to identify whether or not the assay performance is acceptable. The controls can be internal or external controls depending on the selected method. A data report form is established to ensure that the intended data is collected during the testing phases and when the prototype assay later on is applied to the patient samples in the clinical trials.

2.21.4.3 Assay Verification

The next phase of the prototype assay development is the analytic verification, which is performed to test the assay parameters that were identified during the feasibility phase. A number of assay robustness studies are conducted including assay stability (accelerated), reproducibility, and repeatability. The main parts of these studies are performed following development of the analytically validated assay. The outcome of the verification phase is a set of test parameters that are used to confirm or revise the assays' Instructions for Use.

During analytic verification, the prototype assay is tested, and the range for a positive test result is identified. The knowledge generated during the verification process serve as the basis for the transfer of the assay into the large-scale production environment. A prototype assay can be used in early clinical trials either retrospectively or prospectively depending on the amount of documentation available on its performance.

2.21.4.4 Assay Validation

According the US FDA, validation of a medical device means confirmation by examination and provision of objective evidence that the particular requirements for a specific intended use can be consistently fulfilled.[31] Before the analytic validation of a CDx assay can be initiated, there is an important task that needs to be clarified, which is the selection of the clinical cutoff. This is needed for the final configuration of the assay, which also includes potential positive and negative controls. The cutoff, or decision point for the identification of biomarker-positive or biomarker-negative patients, is based on outcome data obtained in earlier stage clinical trials and must be linked to the efficacy of the drug. The cutoff is also needed prior to entering the final clinical validation of the CDx assay as described in more details in the next paragraph. Furthermore, if a CDx assay is used prospectively for the selection of patients in a phase II or III pivotal trial, it is strongly recommended that it has been analytically validated.

The final configured assay must be produced under good manufacturing practice where the processes used to manufacture the assay have been through process validation.[31–33] This is to ensure that the assay produced in the new environment meets the predetermined product specifications. The analytic validation of the assay is performed in order to establish objective evidence that the specifications conform to the user needs and the intended use(s).[31] The final assay configuration and design are validated through generation of data on accuracy, technical sensitivity and specificity, robustness (tolerance), and precision/internal reproducibility (intra-assay, inter-assay, interlot variability, interreader variability, and interinstrumentation variability). Finally, an external analytic validation study is performed to document reproducibility (day-to-day, interreader, and interlaboratory) at clinical laboratories representing the end user sites.

The sensitivity and specificity testing of the assay is performed in order to confirm absence of cross-reactivity to closely related targets and its ability to identify the specified biomarker in both patient samples and samples from healthy subjects. If the assay is to be released as an IVD test, the shelf life of the assay/kit will be tested during real-time stability.[18] Furthermore, the individual kit components are tested for working stability along with the potential onboard instrument stability. The different analytic and process validation activities are critical to perform in order to ensure that the CDx assay meets its specification requirements; thus, it can be deployed in a safe and effective manner in the clinical setting.

An IVD test can also be developed for use within a single laboratory. This type of assay is called a laboratory-developed test (LDT), and supposing this is a CDx assay, often, it will not have undergone clinical validation, which could be critical in relation to its accuracy. Over the years, the US FDA has identified a number of problems with some high-risk LDTs, including situations where healthcare providers initiated unnecessary treatment or delayed treatment for serious health conditions. Based on this and on other problems identified by the US FDA, they have recently suggested a new framework for approval of high-risk LDTs such as those intended for assessment of treatment eligibility.[34]

2.21.5 Clinical Development

Seen from the CDx assays' point of view, the three most important elements in the drug–diagnostic codevelopment model are (1) the biomarker hypothesis, (2) the analytic validation, and (3) the clinical validity. In this paragraph, we will discuss the clinical development aspects, which will include cutoff selection and the strategies for clinical validation and the demonstration of clinical utility.

2.21.5.1 Cutoff Selection

In the former paragraph, we described how prototype assays were developed in order to test the biomarker hypotheses raised mainly during the discovery and research phases of the drug-development process. These assays will subsequently be tested in preclinical and/or early clinical phase studies in order to get an impression of the predictive potential. If one or more of these hypotheses appear promising, the next step will normally be to finalize the analytic validation of the CDx assay. However, before the analytic validation can start and the pivotal phase II/III studies can be initiated, the clinical cutoff must be selected. The assay cutoff will define what a positive test result and negative test result are and will transform the CDx assay into a clinical useful tool, which enables it to distinguish between likely responders and nonresponders to the drug under development.[10,18]

The selection of the assay cutoff is normally based on the test results and clinical outcome data generated in early phase I and II studies. To establish the cutoff for a CDx assay is often a challenging process due to the limited number of data available at this relatively early stage of the clinical development of the drug. One method often used to select an appropriate cutoff is the receiver operating characteristic (ROC) curves, where sensitivity (true positivity) is plotted against 1-specificity (false positivity) for a number of different preliminary selected cutoff points. Subsequently, the area under the curve (AUC) is calculated for the different cutoff points, and the one giving the largest AUC will normally be selected as the final clinical cutoff for the assay.[18] This method was used for selection of the cutoff for the PD-L1 IHC 22C3 pharmDx (Dako) assay, which is the CDx assay for the PD-1 checkpoint inhibitor pembrolizumab (Keytruda, Merck Sharp & Dohme).[35]

The dataset used for the selection of the cutoff for the PD-L1 IHC 22C3 pharmDx assay came from the KEYNOTE-001 study, which was the first larger data set to demonstrate a positive correlation between programmed death-ligand 1 (PD-L1) expression and the outcome following treatment with pembrolizumab in patients with advanced nonsmall cell lung cancer (NSCLC). The KEYNOTE-001 study was a large-scale phase I study aimed to evaluate the safety and efficacy of pembrolizumab in patients with NSCLC and to clinically validate the PD-L1 IHC 22C3 pharmDx assay. The study enrolled a little >500 patients of whom approximately one-third were assigned to a training group and two-thirds to a validation group. The data from the training group were used to define the clinical cutoff for the PD-L1 assay. Based on ROC analyses, a proportion score of $\geq 50\%$ was selected, which corresponds to a PD-L1 membrane expression in at least 50% of the tumor cells. When the treatment outcome data from the validation group were analyzed, applying the selected cutoff value, the results showed that patients with a proportion score $\geq 50\%$ had a higher objective response rate and also longer progression-free and overall survival than patients with a proportion score $<50\%$.[35,36]

The way that the selection of the clinical cutoff for the PD-L1 IHC 22C3 pharmDx assay was done, using data from the KEYNOTE-001 study, is an excellent example of how such an analysis should be performed. The initial relationship between PD-L1 expression and the objective repose rate following treatment with pembrolizumab was established using data from the training group, and based on these data, a cutoff was selected. In order to avoid overfitting, the selected cutoff was then applied on an independent patient dataset from the validation group.

2.21.5.2 Clinical Validation

The main aim of the clinical validation is to demonstrate that the CDx assay is able to detect the biomarkers of interest and to select the patient population of interest. Another aspect, very closely linked to the clinical validation, is the clinical utility, that is, the assay's ability to select a patient population that will experience an improved benefit/risk ratio of the drug in question.[18] In most situations, the clinical studies designed to evaluate the clinical validation of the CDx assay also support its clinical utility.

When the cutoff has been selected, the analytic validation of the CDx assay can be finalized, and subsequently, the pivotal clinical studies can be initiated. The reason why it is important to use the "final version" of the assay for the pivotal clinical studies is that the analytic validation is deemed to assure a correct performance of the assay. However, due to challenges with the alignment and timing of the development of the drug and the CDx assay, it is sometimes tempting to start the clinical study with a prototype assay and then replace it with the analytically validated version later on during the study. Unfortunately, such a strategy is not recommendable as it makes it difficult to interpret the results from the clinical study since it divides the patient into two subpopulations: one population selected with the prototype assay and another selected with the final analytically validated version of the assay. If different versions of the assay have been used in the clinical validation studies, a subsequent bridging study will be needed, which is both resource- and time-demanding. A kind of "golden rule" for the final clinical validation of a CDx assay is to use only *one* version of the assay, which must be the final analytically validated version, and, furthermore, only to use *one* testing site in order to reduce possible interlaboratory variability.[10,37,38]

In the drug–diagnostic codevelopment model, the pivotal phase II and III studies are aimed not only to demonstrate safety and efficacy of the drug but also to clinically validate the CDx assay. In these studies, it must be demonstrated that the assay, with

a relatively high probability, is able to select the responding patients. In this respect, the clinical diagnostic accuracy of the CDx assay is important, and in relation to the individual clinical study designs, the diagnostics metrics such as clinical sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) must be considered. For the drug–diagnostic codevelopment model, several study designs have been proposed; however, not all of them make it possible to calculate these diagnostic metrics.[10] The knowledge about these different metrics is important in order to assess the clinical value of a CDx assay. A low accuracy will lead to a suboptimal selection of the patient population that might benefit from the drug that is linked to the CDx assay. Assay accuracy has also been central in the recent discussion of the predictive value of PD-L1 expression in NSCLC for the selection of patients for treatment with PD-1 checkpoint inhibitors.[36,39]

2.21.5.2.1 The clinical study design

Looking at the list of CDx assays that have been approved through the US FDA premarket approval application (PMA) process, most of these have used the enrichment study design for the clinical validation.[40] Originally, this design is built on the traditional randomized controlled clinical study, however, with an extra step included in relation to the patient selection process. The enrichment design should only be applied if there is clear evidence of a strong relationship between a positive CDx status and the treatment outcome of the new drug under development, for example, from previous conducted preclinical and clinical studies. With this study design, all patients are tested with the CDx assay, but only the CDx-positive patients are enrolled in the study and subsequently randomized to the new drug or the "standard" treatment as outlined in **Fig. 2**.[10]

The advantage of the enrichment study design is that it generally requires a smaller number of patients compared with the traditional randomized study with an all-comers design. The reason for this is that only patients who have a CDx-positive status are enrolled in the trial, thus making the study population more homogeneous by reducing the variability that originate from the nonresponding patients. However, this design allows only the PPV to be calculated and not sensitivity, specificity and NPV, which is definitely a limitation of this design.[10,18] This study design was the one used for the approval of trastuzumab and its corresponding CDx assay. Here, 469 HER2-positive women with metastatic breast cancer where enrolled in a phase III study and then randomized to receive trastuzumab plus chemotherapy or chemotherapy alone.[41] The randomized enrichment study has subsequently been used for the approval of other targeted cancer drugs, such as vemurafenib (Zelboraf, Roche/Genentech) and pertuzumab (Perjeta, Roche/Genentech).

Within the last few years, an even simpler version of the enrichment design has been used in relation to the clinical development of drug–diagnostic combinations, which is the nonrandomized enrichment study as shown in **Fig. 3**.

When crizotinib (Xalkori, Pfizer) was under development for treatment of *ALK*-positive metastatic NSCLC, together with its corresponding CDx assay, the Vysis *ALK* Break Apart FISH probe kit (Abbott Molecular), this very simple clinical study design was used and proved to be successful. When the US FDA approved crizotinib in 2011, it was based on efficacy data from only 255 *ALK*-positive patients with metastatic NSCLC, who were enrolled in two nonrandomized phase I/II studies based on a preselection using the Abbott *ALK* FISH assay.[2,42] The approval of the drug was based on a quite impressive clinical efficacy of crizotinib in the selected *ALK*-positive patients. In the US FDA's medical review, the following was stated: "This new drug application is supported by two single-arm studies (Study A and Study B). Response rate of 50% in Study A and 61% in Study B is higher than any approved single and/or combined chemotherapeutic agent for the treatment of NSCLC along with a favorable safety profile compared to these chemotherapeutic agents is the basis for approval for this application."[43] Even when such a simple study design is used, as the nonrandomized enrichment study, it seems to be acceptable for the clinical evaluation of the CDx assay, if the drug that is linked to its use is sufficiently effective in the selected patient population. However, in cases where the number of patients in the clinical

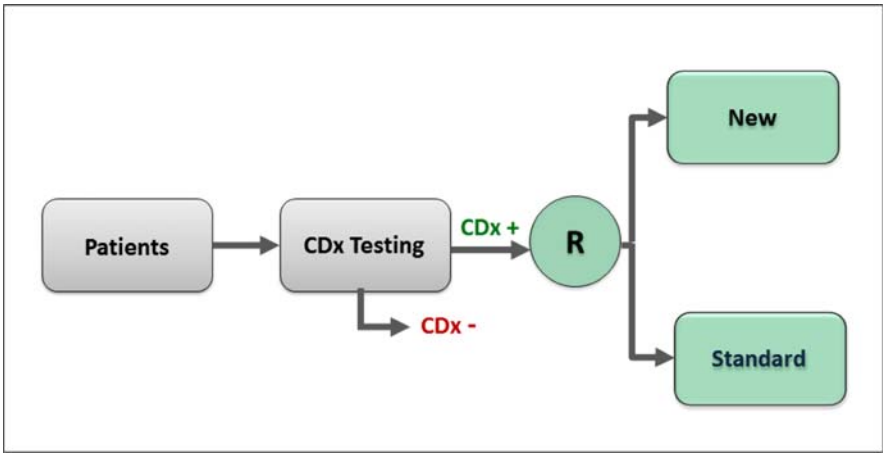

Fig. 2 The randomized enrichment study design. All patients tested positive (CDx+) are randomized (R) to one of the two treatment arms. CDx+ = test-positive patients; CDx− = test-negative patients.

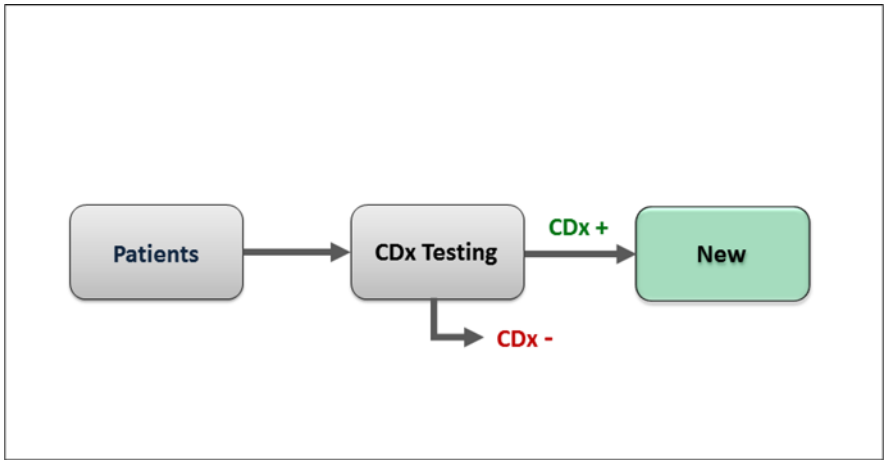

Fig. 3 The nonrandomized enrichment study design. All patients tested positive (CDx+) are treated with the new drug. CDx+=test-positive patients; CDx−=test-negative patients.

development program is as low as it was for crizotinib and the Abbott *ALK* FISH assay, it is reasonable that the regulators require data from the postapproval phase, which was also the case here.[2]

After the regulatory approval of crizotinib, a couple of other ALK inhibitors have achieved US FDA approval based on similar simple study designs in populations of *ALK*-positive patients with metastatic NSCLC. This is the ALK inhibitors ceritinib (Zykadia, Novartis) and alectinib (Alecensa, Roche/Genentech), which were both approved based on efficacy data from <250 patients. For ceritinib, the number of patients was 163, and for alectinib, it was 225.[44,45]

One of the drawbacks of the enrichment study design is that it provides no insight into the efficacy of the drug in the patients who are tested negative with the CDx assay. As previously mentioned, this is also the reason why this design should only be used if there are data available to support a strong relationship between a CDx-positive status and efficacy of the drug. If this type of evidence is weak or nonexisting, an all-comers or a stratified study design should be used.

The all-comers study design, as shown in Fig. 4, does not have positive CDx assay results as part of the inclusion criteria. Both test-positive and test-negative patients are allowed into the study and will be allocated to the two treatment arms as in the traditional randomized controlled study. Most often, this study design is used in phase I or early phase II where there is uncertainty about the link between drug efficacy and the biomarker status. There are both pros and cons in relation to the use of the all-comers study design. One of the positive aspects of this design is that it allows for calculation of the different diagnostic metrics, such as sensitivity, specificity, PPV, and NPV. However, there is also one significant drawback. If the prevalence of test-positive patients is low, it will require a large sample size to reach a conclusion about the predictive potential of the CDx assay.[46]

With the stratified study design, the patients are allocated into a CDx-positive or CDx-negative group based on the assay result and then subsequently randomized to either the new drug or the "standard" treatment as illustrated in Fig. 5. This design is more or less similar to conducting two independent randomized studies, one in the CDx-positive patients and one in the CDx-negative

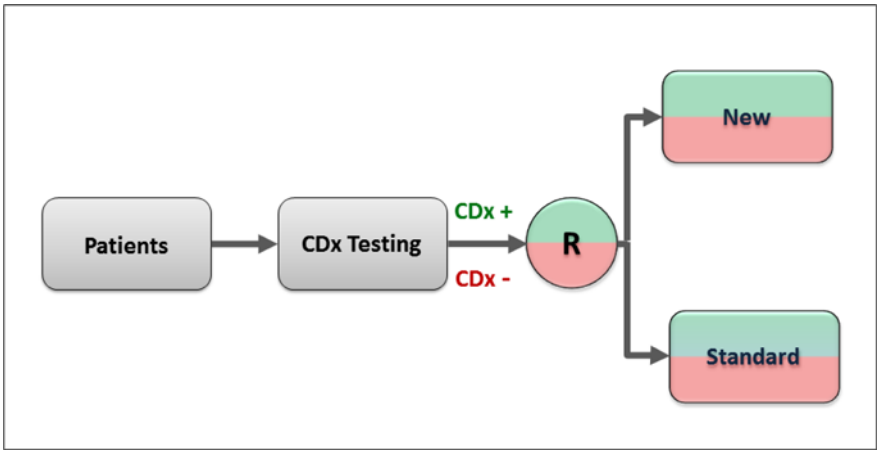

Fig. 4 The all-comers study design. All patients are enrolled in the study independent of a positive or negative CDx status and randomized (R) to one of the two treatment arms. CDx+=test-positive patients; CDx−=test-negative patients.

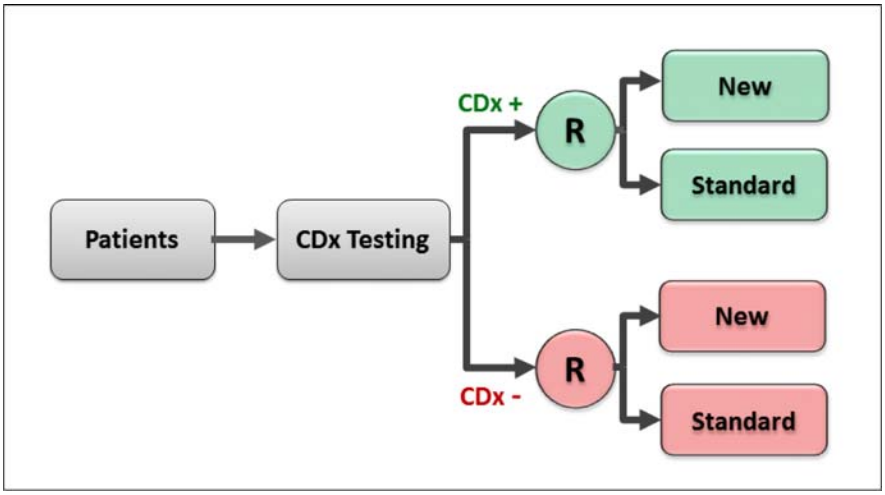

Fig. 5 The stratified study design. All patients are stratified based on the result of the CDx assay and subsequently randomized (R) to one of the two treatment arms. CDx+ = test-positive patients; CDx− = test-negative patients.

patients. However, these studies are conducted simultaneously as one logistic unit. Compared with the all-comers design, it is easier here to manage possible prevalence differences in the test-positive and test-negative patient groups, as they belong to different arms of the study. Furthermore, as for the all-comers study, it is possible to calculate the different diagnostic metrics for the CDx assay.[18,46]

2.21.5.2.2 Basket and umbrella studies

The advances in molecular medicine have provided an increased understanding of the molecular basis for a number of diseases, and especially within cancer, it has led to the development of new drug–diagnostic study designs. Traditionally, cancer diseases have mainly been classified according to the location in body and the histological characteristics; however, the progress within molecular diagnostic and tumor biology has taught us that the same targetable molecular aberration can be detected across different tumor types.[47] An example of this is HER2 overexpression and *BRAF* mutation, which is found in several cancer diseases.[48,49]

The basket study design should be seen as a direct consequence of the evolving new molecular understanding and disease classification within oncology. The assumption for using this study design is that the molecular characteristics prevail over tumor location and histology when it comes to the efficacy of the drug. In this basket study design, the purpose is to test the effect of a single drug related to a single biomarker, measured by a CDx assay, in multiple cancer types. This design allows a simultaneous evaluation of the effect of a specific drug in multiple cancer types with the same specific molecular characteristic, as it is shown in Fig. 6. Such

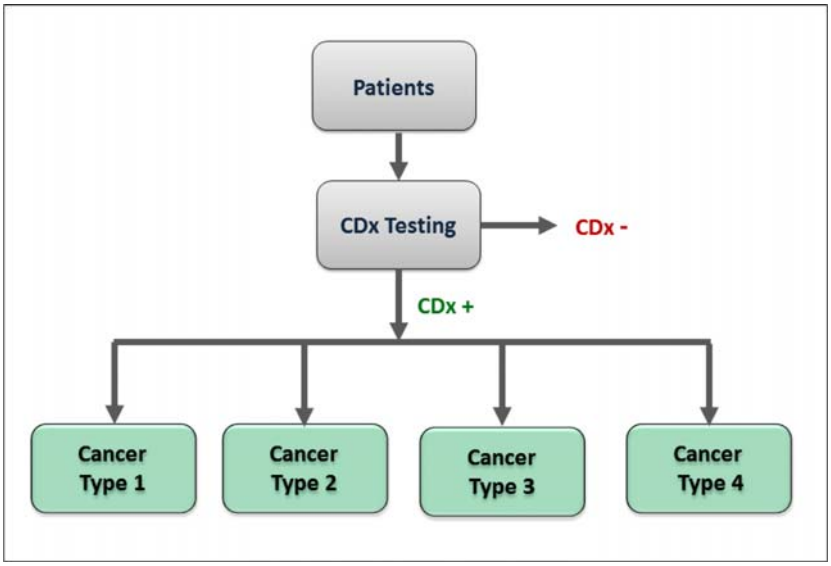

Fig. 6 The basket study design. Testing of one drug in multiple cancer types with one specific molecular characteristic measured by a CDx assay. CDx+ = test-positive patients; CDx− = test-negative patients.

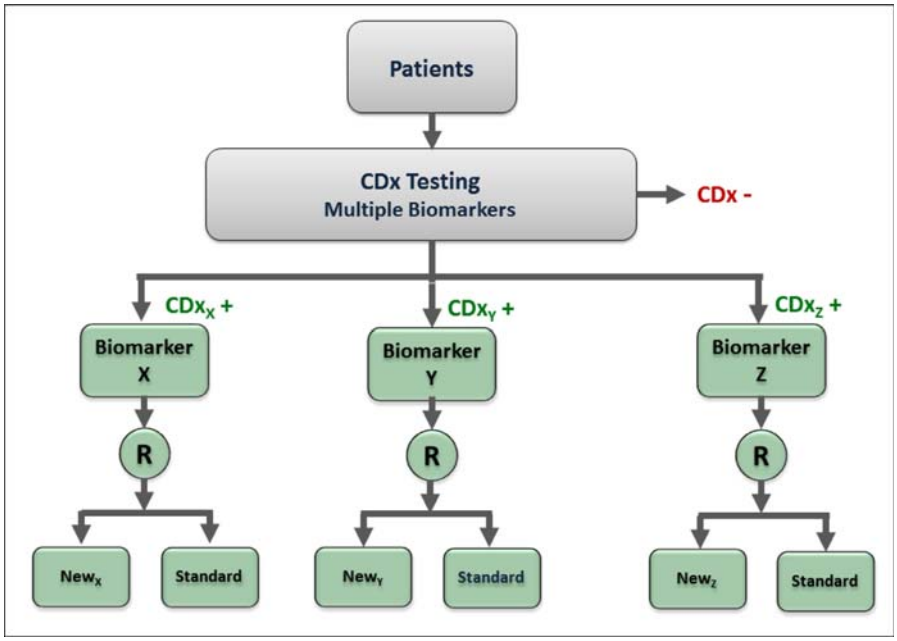

Fig. 7 The umbrella study design. Testing of multiple drugs in a single cancer type with different molecular characteristics measured by different CDx assays. CDx+=test-positive patients; CDx−=test-negative patients.

a study design would be useful in an early explorative phase of the clinical development of a new drug. An example of such study was recently published with the selective BRAF V600 kinase inhibitor, vemurafenib, which was originally developed for treatment of melanoma.[49] In this study, a number of nonmelanoma *BRAF V600* mutation-positive cancer patients were treated with vemurafenib, and the results showed that specifically patients with NSCLC and Erdheim–Chester disease responded to the drug with objective response rates above 40%.

Another new study design that will be described here is the umbrella study. Here, multiple drugs are tested in one cancer type, which is the opposite of the basket study where the effect of one drug is tested in multiple cancer types. To each of the drugs tested in an umbrella study, a specific CDx assay will be used to preselect the patients treated in the different arms of the study as illustrated in Fig. 7. An example of an umbrella study is the National Lung Matrix Trial, which is conducted by Cancer Research UK. In this study, a number of targeted drugs are tested in patients with NSCLC.[50]

2.21.6 Regulatory Aspects

The main purpose of developing a CDx assay in a drug research program is to have a test that can predict whether a patient is likely to benefit from the drug in question. For many of the new cancer drugs that have been developed within the last decade, the CDx assays have taken up a central role as an important stratification factor, both during development and subsequently also after approval when the drug is used routinely in the clinic. For the individual patient, this type of assays has become a kind of "gatekeeper" for the treatment decision.[2,10] However, if a CDx assay measures a specific biomarker but it turns out that it is insufficiently correlated with the clinical state or outcome, it will not provide meaningful results. Such an erroneous test result could lead to either a false-positive or false-negative result, which potentially may cause risk and harm to the patient. For example, a false-positive result could lead to treatment with a drug where the biological condition for a positive outcome is missing, and consequently, the patient will be put at risk due to potential toxic side effects from an ineffective treatment. Similarly, a false-negative test result could withhold a potentially beneficial treatment and thus also bring the patient at risk.[10,31] In oncology, an early and correct diagnosis and intervention are two elements of key importance when treating patients. In case of a wrong treatment decision, the cancer disease may become disseminated with no or very low chances of cure.[10]

With this central role of the CDx assay in mind, it has been argued that the regulatory requirements for these assays should be at the same level as for drugs.[2,51] This was also stressed recently in the interview with professor Daniel Hayes, University of Michigan Comprehensive Cancer Center, a biomarker pioneer, when he stated "a bad tumor biomarker test is as bad as a bad drug." In the same interview, he also expressed that people need to value biomarker tests as much as they value drugs and that researchers should do biomarker studies with the same amount of rigor as therapeutic trials.[52] The critical role of CDx assays in relation to both drug development and the clinical use after approval has also caught the attention of the regulatory authorities. Especially the US FDA has been at the forefront with respect to developing regulatory standards and guidelines for CDx assays and drug–diagnostic codevelopment.[10]

2.21.6.1 US Regulatory Requirements

In the United States, CDx assays are classified as IVD class III products, which according to the regulations are medical devices that usually support or sustain human life, are of substantial importance in preventing impairment of human health, or present a potential, unreasonable risk of illness or injury.[53] Furthermore, an IVD class III product normally requires a PMA application, in order to secure a high standard for both the analytic and clinical performance of the assays. Compared with other types of IVD submissions, the PMA requires the most comprehensive documentation level. The way that CDx assays are classified by the US FDA underlines their central and critical role with regard to the treatment decision for the individual patient.

Over the years, the US FDA has issued several important documents defining the requirements for development of CDx assays. One document, which has already been mentioned in this article, is the *Drug-Diagnostic Co-Development Concept Paper* that was issued already in 2005. This paper must be regarded as a landmark in relation to the drug–diagnostic codevelopment model, and it has served as guidance and inspiration for most CDx assays developed over the past decade.[18] This document was a kind of discussion paper, and on several occasions, the US FDA has announced that they would follow up with a real guideline, but in the beginning of 2016, such a guideline has still not been issued. While anticipating this guideline, the US FDA issued a guidance document on *In vitro Companion Diagnostics Devices* in 2014.[12] However, this guidance document should not be seen as a replacement for the concept paper that came in 2005, but rather an operational guide for pharma and diagnostic companies involved in codevelopment of drugs and diagnostics. This document defined what a CDx assay is and suggested possible regulatory pathways and labeling and other regulatory requirements.[10]

2.21.6.2 EU Regulatory Requirements

The regulatory framework for CDx assays in the EU is the IVD directive 98/79/EC issued in 1998.[54] However, this directive does not mention CDx assays in the definition of an IVD, and likewise, the classification system does not consider CDx assays at all, which, of course, has to do with the age of the directive. Currently, any CDx assay entering the EU market is classified as general IVD, which means low-risk devices, based on an assessment of conformity according to the IVD directive. The manufacturer itself, through the so-called self-certification procedure, performs this conformity assessment and subsequent CE marking. Compared with the PMA approval process in the United States, the EU self-certification procedure must be considered a very different regulatory pathway, which does not to the same extent take into consideration the critical role of the CDx assay in the treatment decision for the individual patient.[10]

In 2012, the European Commission proposed a new regulatory framework that will be more up-to-date with the current thinking when it comes to safety and effectiveness of medical devices, including CDx assays.[13,14] An important change in the proposed legislation is that CDx assays will no longer be considered as low-risk devices and likewise self-certification will no longer be a possibility. According to the new proposal, CDx assays will be classified as class C, which means a high individual risk or moderate public health risk, where an erroneous result would put the patient in an imminent life-threatening situation or would have major negative impact on outcome. It has also been proposed that evidence of the clinical utility of the device for the intended use should be required for CDx assays. Furthermore, it will also be required that the conformity assessment should be performed by an independent notified body and that this notified body also has to consult the EMA or one of the medical product national competent authorities.[11,13,14] Despite the fact that this proposal for a new legislation was put forward in 2012, it has still not been decided when it should be fully implemented, but it is likely to happen before 2020.

2.21.7 The Impact of the Drug–Diagnostic Codevelopment Model

Within oncology, the drug–diagnostic codevelopment model has produced a number of targeted drugs, which has demonstrated surprisingly high efficacy rates in the selected patient populations. In **Table 1** are listed some of these drugs that all have obtained approval within the past 15 years for different advanced or metastatic cancer indications. The objective response rates listed in the table are extracted from the prescribing information available to healthcare professionals in the United States.[55] The majority of the drugs listed in **Table 1** are not classified as chemotherapeutics but rather as targeted drugs, either monoclonal antibodies or small molecules, predominantly tyrosine kinase inhibitors. If these drugs are broken down according to whether they have a CDx assay linked to their use or not, there is a clear trend toward a somewhat higher response rate for the group of drugs with a CDx.[6] The response rates for this group range from 41.0% to 80.2%, while for the group of drugs that have no CDx assay linked to their use, the range is 6.8–45.0%.

It is clear that the drug–diagnostic codevelopment model has produced a number of effective drugs within several cancer diseases with great unmet medical needs, but there seem to be other benefits in relation to use a CDx assay in the drug-development process. When the drug–diagnostic codevelopment model was in its early implementation phase, 8–10 years ago, there was speculation that it could have a major impact on the different aspects of the drug-development process such as success rate, development time, and cost.[56]

One of the first to discuss the potential benefits of the drug–diagnostic codevelopment model and the clinical enrichment study design was Dr. Richard Simon at the US National Cancer Institute, Maryland. In an article published in 2004, he used the pivotal phase III study with trastuzumab, conducted in the late 1990s, to underline the power of the enrichment design.[34,57,58] In this

Table 1 Objective response rates for anticancer drugs with and without a CDx assay linked to their use[a]

Drug	*Indication and biomarker*	*CDx*	*Response rate (%)*
Pertuzumab (Perjeta)	Breast cancer (HER2+)	Yes	80.2
Crizotinib (Xalkori)	NSCLC (*ALK*+)	Yes	65.0
Erlotinib (Tarceva)	NSCLC (*EGFR*+)	Yes	65.0
Cetuximab (Erbitux)	Colorectal cancer (EGFR+/*KRAS*)	Yes	57.0
Imatinib mesylate (Gleevec)	GIST (CD117+)	Yes	53.9
Dabrafenib (Tafinlar)	Melanoma (*BRAF*+)	Yes	52.0
Vemurafenib (Zelboraf)	Melanoma (*BRAF*+)	Yes	48.4
Ado-trastuzumab emtansine (Kadcyla)	Breast cancer (HER2+)	Yes	43.6
Pembrolizumab (Keytruda)	NSCLC (PD-L1+)	Yes	41.0
Bevacizumab (Avastin)	Colorectal cancer	No	45.0
Ixabepilone (Ixempra)	Breast cancer	No	34.7
Paclitaxel protein-bound particles (Abraxane)	NSCLC	No	33.0
Pemetrexed (Alimta)	NSCLC	No	27.1
Pembrolizumab (Keytruda)	Melanoma	No	24.0
Ziv-aflibercept (Zaltrap)	Colorectal cancer	No	19.8
Eribulin mesylate (Halaven)	Breast cancer	No	11.0
Ipilimumab (Yervoy)	Melanoma	No	10.9
Sunitinib malate (Sutent)	GIST	No	6.8

[a]The indications mentioned in the table are for metastatic and/or advanced-stage disease. All drugs listed in the table have obtained FDA approval after 2000.[55]

article, the strength of preselecting patients by means of a CDx assay was illustrated by sample size calculations performed on two alternative clinical study designs—the enrichment and the traditional randomized design or all-comers design.[59] In the pivotal phase III study with trastuzumab, only HER2-positive breast cancer patients were randomized to receive chemotherapy with and without trastuzumab. A total of 469 patients were enrolled, and the result was statistically significant in favor of the trastuzumab arm with regard to 1-year survival.[41] Without the use of a CDx assay for preselection of the patients, a much larger study would have been needed in order to detect the same survival benefit as observed in the phase III study. Dr. Simon used two alternative scenarios of the traditional randomized study design to demonstrate this. In the first one, it was assumed that the effect of trastuzumab in the HER2-negative patients was half the effect observed in HER2-positive patients. The sample size calculation for this scenario showed that the number of patients needed in order to show a significant difference in 1-year survival was 1254 patients. A second scenario was calculated, and again, the traditional randomized study design was used with no preselection with a CDx assay, and the assumption here was that the assay-negative patients had no benefit from treatment with trastuzumab. The sample size needed for this scenario was 8050 patients, which were 17.2 times more patients than were enrolled in the original phase III study.[59] These sample size calculations clearly showed that the number of patients needed would have been dramatically higher, if Genentech had used the traditional randomized study design. It is obvious that the HER2 IHC assay played a critical role in the development of trastuzumab and, in fact, there was speculation that in absence of this assay, we would probably have been without this effective drug today.[59]

Drug development related to HER2-positive breast cancer has also been used to determine the success rate of new drug approvals.[58] A retrospective analysis has looked at industry-sponsored drug-development programs for HER2-positive patients and compared them with programs for patients that either had failed or had been exposed to an anthracycline or taxane. For the period from 1998 to 2012, a number of breast cancer drugs were identified; 29 for HER2-positive patients and 28 for anthracycline/taxane-exposed patients met the inclusion criteria for the analysis. The result of the analysis showed that the overall success rate of drug development in the anthracycline/taxane patients was 15%, while it was 23% in the HER2-positive patients. Furthermore, the analysis also showed that the use of a validated biomarker assay reduced the clinical trial risk by as much as 50%, which could be transformed to a cost saving of 27%.[60]

The impact of the drug–diagnostic codevelopment model on the success rate of drug development has also been demonstrated for other than the HER2-targeted drugs. Similar analyses have been performed on drugs for treatment of metastatic melanoma and NSCLC.[61,62] **Fig. 8** shows the cumulative success rates of the clinical development for melanoma and NSCLC, for drugs with or without a CDx assay linked to their use. The cumulative success rate represents the product of the probability for passing each of the prior phases, from phase I to III, and obtains regulatory approval. The data used in the analyses for melanoma were collected during the period from 1998 to 2013 and for NSCLC from 1998 to 2012.

As it appears from **Fig. 8**, the cumulative success rates for both advanced melanoma and NSCLC are many folds higher for drugs with a CDx compared with the drugs that have entered the clinical development without a CDx assay. The analysis performed in relation to NSCLC lung cancer also looked at the clinical development costs.[62] Here, it was estimated that the risk-adjusted costs for NSCLC clinical development were calculated to be 1.89 billion USD, but this was decreased substantially to 1.40 billion USD if conducted with a CDx assay. Furthermore, the researchers that performed the analysis put forward that the savings could be more significant if the combination of drug and diagnostics could decrease the number of clinical studies needed to obtain marketing approval. This was the situation when the ALK inhibitor crizotinib (Xalkori, Pfizer), which was discussed earlier, obtained

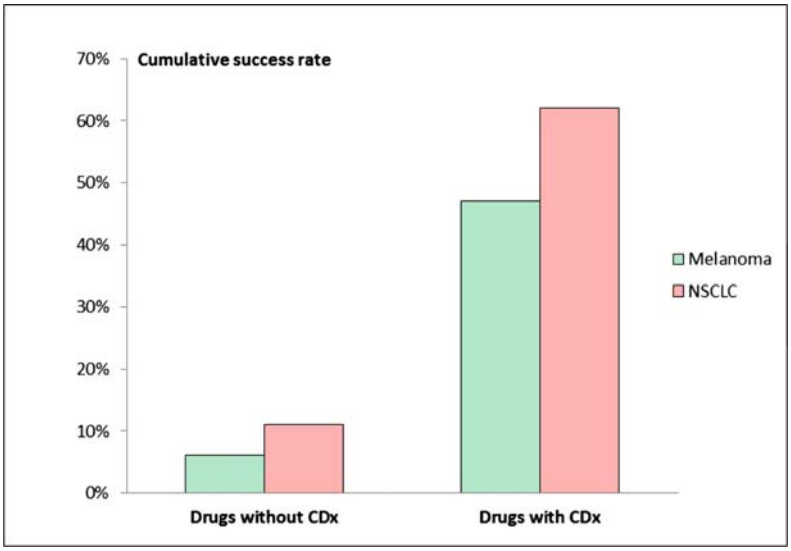

Fig. 8 The cumulative clinical development success rate in advanced melanoma and NSCLC for drugs with and without a CDx assay. The cumulative success rate represents the product of the probability for passing each of the clinical development phases (phases I–III).[60,61]

US FDA approval based on 255 patients from two phase I/II single-arm studies. Based on information from the clinical development program for crizotinib, it was estimated that the cost was between 500 and 600 million USD, which is less than a third of the estimated average cost for the clinical development of NSCLC drugs.[62] Furthermore, it should be added that the development time for crizotinib was extremely short, <4 years.[63] Subsequently, we have witnessed a couple of similar examples of drugs for treatment of advanced NSCLC. As also mentioned previously in this article, these are the ALK inhibitors ceritinib and alectinib, which have recently obtained US FDA approval based on efficacy data from nonrandomized studies with <250 patients. For ceritinib, the data originated from one early-phase study with only 163 patients and for alectinib from two studies with totally 225 patients.[44,45]

To some extent, it seems as if the drug–diagnostic codevelopment model has delivered on some of the expected promises, such as increased development success rates, shorter development times, and decreased costs. However, having said that, the number of drugs that have used the drug–diagnostic codevelopment model is still relatively small, so some reservation is needed in relation to the current data, but in spite of this, there seems to be basis for optimism in relation to the importance of using CDx assays in clinical drug development.

2.21.8 Future Trends and Conclusion

Based on the examples we have from oncology, CDx assays seem to hold the promise in relation to improving the predictability of the drug-development process and to become an important tool for the physician in relation to the choice of treatment for the individual patient as well. As described in this article, a number of drug–diagnostic codevelopment projects have already been completed successfully, and the prescription of a number of targeted cancer drugs is now guided by the result from a CDx assay. Many of the targeted drugs have shown significantly higher response rates and prolonged progression-free survival in selected groups of cancer patients. However, for all these drugs, resistance will develop at some point in time resulting in disease progression. For this reason, it is unlikely that the current approach of single biomarker detection and treatment with one specific drug will achieve long-lasting remission, and most likely, we will need to move away from the "one biomarker–one drug" scenario toward a more complex multimodal approach.[10] This new approach will need to integrate multiple biomarkers and multiple targeted cancer drugs used simultaneously or in sequence in order to block alternative signal pathways and thus prevent resistance to develop. For the CDx assays, this will mean development of specifically designed multiplex assays most likely based on technologies such as gene expression arrays or NGS.[10,64] Another area where the NGS technology will undoubtedly play a role is in relation to "liquid biopsies" and the analysis of freely circulating tumor DNA (ctDNA). Recent research has shown that ctDNA detected in plasma can indicate development of resistance to an ongoing treatment.[65] Similarly, measurement of ctDNA might also be used for monitoring of relapse, as was shown recently in breast cancer.[66]

To some extent, NGS has already moved in the direction toward being a CDx platform. By the end of 2013, the US FDA granted marketing authorization for the Illumina MiSeqDx platform for screening and diagnosis of cystic fibrosis. This platform can also be used to identify cystic fibrosis patients with specific mutations in the cystic fibrosis transmembrane conductance regulator gene that might be eligible for treatment with ivacaftor (Kalydeco, Vertex Pharmaceuticals).[67,68] NGS may also play a role for a group of drugs like antibiotics. Here, antimicrobial susceptibility testing based on detection of phenotypic resistance by measuring bacterial growth

has been used for decades. However, new knowledge with regard to the molecular determinants of antibiotic resistance has facilitated the development of a number of new methods, based on technologies like NGS, PCR, microarray, and mass spectrometry.[69] These new methods are likely to play a critical role in relation to cope with the increasing global problem with antibiotic resistance and in relation to the development of new antiinfectives. Another area outside oncology where we will probably see CDx assay development will be in relation to treatment of rheumatoid arthritis (RA) and other autoimmune diseases. For a disease like RA, early diagnosis and an effective and correct therapy are crucial in order to prevent joint destruction and functional disability. The use of biological targeted agents, such as anti-TNF-α drugs, has significantly improved the outcome for RA patients but approximately one-third of the patients do not respond adequately. A CDx assay that could stratify RA patients into likely responders or nonresponders to the different anti-TNF-α drugs is needed.[1] In the United Kingdom, such an assay is currently under development. It is based on a multiplex platform, and hopefully, it will be able to demonstrate clinical utility and be of benefit to the RA patients.[70]
